

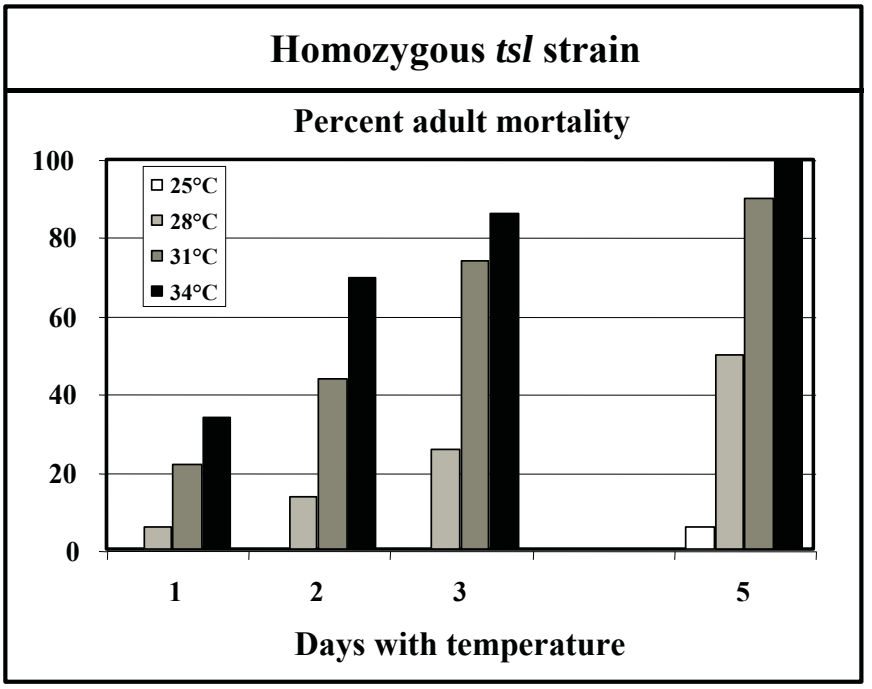

*Figure 3. Temperature treatment of adults homozygous for* tsl *mutation. After emergence, adults were maintained constantly at temperatures indicated.*

Tests of $F_1$ individuals from reciprocal crosses, between a wild-type strain and a homozygous *tsl* strain, demonstrated that the temperature sensitivity of the $F_1$ differed significantly, although in both cases the genetic constitution of the $F_1$ is identical (*tsl/tsl*$^+$). Fig. 4B shows that, in the first cross (wild type *tsl*$^+$ females and *tsl* males), the *tsl*$^+$ allele is completely dominant over the mutant allele, i.e. the same level of lethality is observed in $F_1$ offspring as in a wild-type strain (Fig. 4A). However, in the reciprocal cross where homozygous *tsl* females are used, a significant temperature sensitivity of the $F_1$ offspring is observed (Fig. 4C).

This difference is due to a maternal effect. During the early stages of development, the embryo's own genome is inactive, and apparently it utilizes a *tsl*-gene product that it receives in the egg from the mother. Consequently, during these early stages of development, the embryo is dependent on the genotype of the mother, and in a GSS the mother is homozygous for the *tsl*. Only after activating their own genetic material are the heterozygous *tsl/tsl*$^+$ males protected against elevated temperatures. Based on these findings, the temperature-treatment regime was modified, i.e. after collection, and before the treatment is applied, eggs are maintained at 25˚C for at least 24 hours. This led to a significantly improved recovery of males (Fisher 1998).

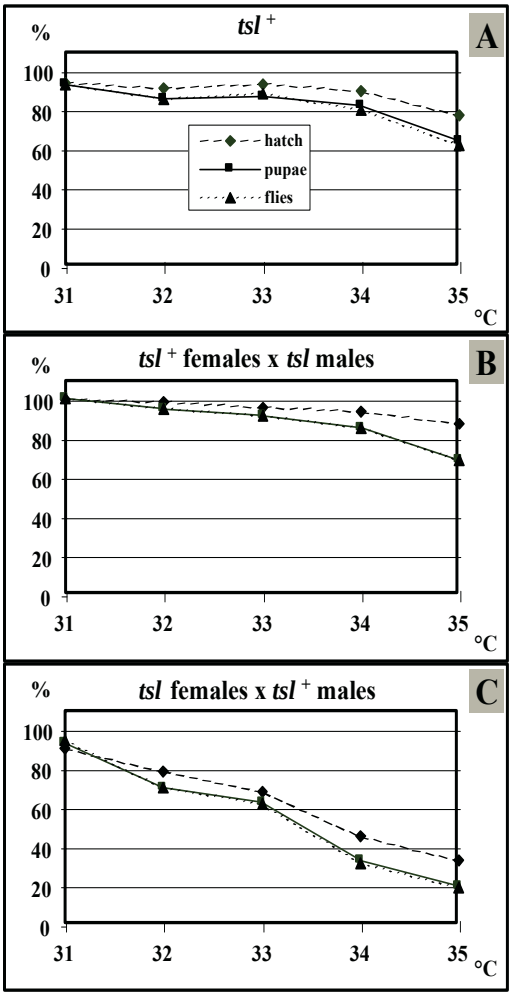

*Figure 4. Difference in temperature sensitivity of* tsl$^{+}$/tsl *genotypes depending on direction of parental cross (maternal effect). Values shown for hatch, pupae, and adults are given as percentage of values obtained at 25°C. Homozygous* tsl *strain shows no hatch starting at 34°C.*

*2.1.7. Delayed Development*

Individuals homozygous for the *tsl* mutation develop more slowly than those either heterozygous or homozygous for a wild-type allele. Already at 25˚C, homozygous *tsl* individuals pupate 1 day later than the wild type. If eggs and larvae are subjected to an extended incubation at elevated but sub-lethal temperatures, e.g. 29˚C, the speed of development is affected. As expected, the development of wild-type individuals is accelerated, i.e. pupation occurs 2 days earlier than at 25˚C. However, in the homozygous *tsl* strain, pupation occurs only 1 day earlier than at 25˚C, i.e. 2 days later than the $tsl^+$ individuals.

Differences in pupation time are a good indicator of the temperature increase during larval rearing. For example, poor rearing conditions, like excess heat in the larval diet, become apparent as increased differences in the pupation time of $tsl^+$ males and homozygous *tsl* females.

In principle, the delayed development of the homozygous *tsl* females could be used to separate the sexes at the larval or pupal stages, e.g. for mass-rearing of larval or pupal parasitoids. In mass-rearing a *ts*l-based GSS, the first day of pupal collection yields virtually only male pupae, but the collection on the 5$^{th}$ day contains mostly females (Fig. 5 in Caceres 2002). This permits loading production cages with an excess of females (to increase egg production) without using a mechanical pupal separator. The surplus of males can be added to the insects to be irradiated and released.

*2.1.8. Unwanted Recombinants and Filter Rearing System*

An additional improvement to maintain GSS stability or purity is the filter rearing system (FRS) (section 4.3.), i.e. the maintenance of a mother colony as a pure GSS where any exceptional flies are removed according to their pupal colour phenotype (Cáceres et al. 2000; Parker, Mamai et al., this volume). As described below, GSSs can generate unwanted recombinant individuals, some of which cannot be removed by inspection of the pupal colour (Table 2).

*Table 2. Recombinant types produced in T(Y;5)* $wp^+tsl^+$/wp tsl *males*

| Recombination type | $F_1$ genotype | $F_1$ phenotype | Accumulation in mass-rearing | Detection in filter rearing system |
|---|---|---|---|---|
| Type-1a | T(Y;5)*wp tsl*/*wp tsl* males | white pupae, *tsl*, 50% sterile | No | Yes |
| Type-1a | $wp^+$ $tsl^+$/*wp tsl* females | brown pupae, $tsl^+$ | Yes | Yes |
| Type-1b | T(Y;5)$wp^+$ *tsl*/*wp tsl* males | brown pupae, *tsl*, 50% sterile | No | No |
| Type-1b | *wp* $tsl^+$/*wp tsl* females | white pupae $tsl^+$ | Yes | No |
| Type-2 | Y/*wp tsl*/*wp tsl* males | white pupae, *tsl*, 100% fertile | Yes | Yes |

One type of recombinant female, *wp tsl*$^{+}$*/wp tsl,* emerges from white pupae, and therefore is not removed by the FRS, and will accumulate in the colony, where it becomes evident when an increasing number of white-pupae females survive the temperature treatment. However, such females can be distinguished from the non-recombinant females since the presence of the *tsl*$^{+}$ allele causes them to pupate early, together with the males. Consequently, it is recommended for the FRS that new adult cages be set up with only brown-pupae males that have pupated early, and with white-pupae females that have pupated late. It has been shown that this selection scheme significantly improves the accuracy of the FRS.

### *2.1.9. Large-Scale Temperature Treatment of Embryos*

In mass-rearing, eliminating female embryos requires only a simple and cheap water bath. The temperature treatment is applied during the "egg bubbling stage" when incubating eggs are oxygenated and maintained at a high density in water. The accuracy of the treatment is almost 100%, even in very large facilities where hundreds of millions of eggs are treated every day (Caceres 2002). Male quality and quantity is not affected significantly by the treatment. In rearing individuals for the colony, temperature must be carefully controlled; if not, female production is reduced, and, as described below, the stability of the sexing system is negatively affected (section 4).

## *2.2. Sex Linkage of Selectable Marker*

Selectable markers are generally not sex-specific. Therefore, the respective wild-type allele must be linked to the male-determining Y chromosome. In Mediterranean fruit fly, this linkage is achieved by irradiating wild-type pupae with 40–50 Gy, and backcrossing individual $F_1$ males with mutant females carrying the selectable markers. The $F_2$ is screened for lines where the mutation used in the screen is inherited in a sex-specific manner, i.e. males are wild type and the females mutant. The choice of the mutation determines which autosome is involved in the translocation.

Several independent experiments to induce Y-autosome translocations in the Mediterranean fruit fly have been performed (Robinson and Van Heemert 1982; Kerremans et al. 1992; Franz et al. 1994; Kerremans and Franz 1995; Delprat et al. 2002). On average, about 7% of $F_1$ crosses involve male-linked translocations. This frequency depends on the genome size and the size of the chromosomes involved. In total, more than 30 Y-autosome translocations involving chromosome 5 were generated. Chromosome 5 carries both the *wp* and *tsl* mutants. This diverse availability of translocations is a very important prerequisite for the successful development of sexing strains — it allows a choice of the most appropriate translocation (with reference to stability and productivity).

The productivity of a sexing strain is correlated primarily with the segregation behaviour of a Y-autosome translocation during male meiosis. There are two ways in which a Y-autosome translocation can segregate — alternate and adjacent-1 (Fig. 5).

In nearly all cases, these two types occur at equal frequencies (Franz 2000; G. Franz, unpublished data). Only alternate segregation leads to genetically balanced offspring, but adjacent-1 segregation results in severe deletions and triplications.

Deletions usually cause lethality already during embryogenesis, but triplications can survive, depending on the size and resulting sex, until the pupal or even adult stages. As a consequence of this segregation pattern, only 50% of the offspring produced by males carrying a simple translocation, involving only one autosome, are genetically balanced, i.e. males are 50% sterile. In males with a more complex translocation, where more than one autosome is involved, sperm sterility is increased accordingly (Franz 2000).

The structure of the translocation, in particular the structure of the Y chromosome and the location of the break point on the Y chromosome, affects the segregation behaviour and the viability of the resulting adjacent-1 offspring (Willhoeft and Franz 1996). If the break point is located between the Y-chromosomal centromere and the *Maleness* factor, the triplication-type adjacent-1 individuals will be female, e.g. strains VIENNA 7 and 8 (sections 4.1. and 4.2.; Robinson et al. 1999). It has been shown that females are about 100-fold more sensitive to triplications in most regions of chromosome 5 than males with triplications of similar size (G. Franz, unpublished data), and consequently they do not survive to the pupal stage. Additional rearrangements of the Y chromosome can lead to an increase in the alternate segregation frequency and, thereby, to an increase in the productivity of the strain.

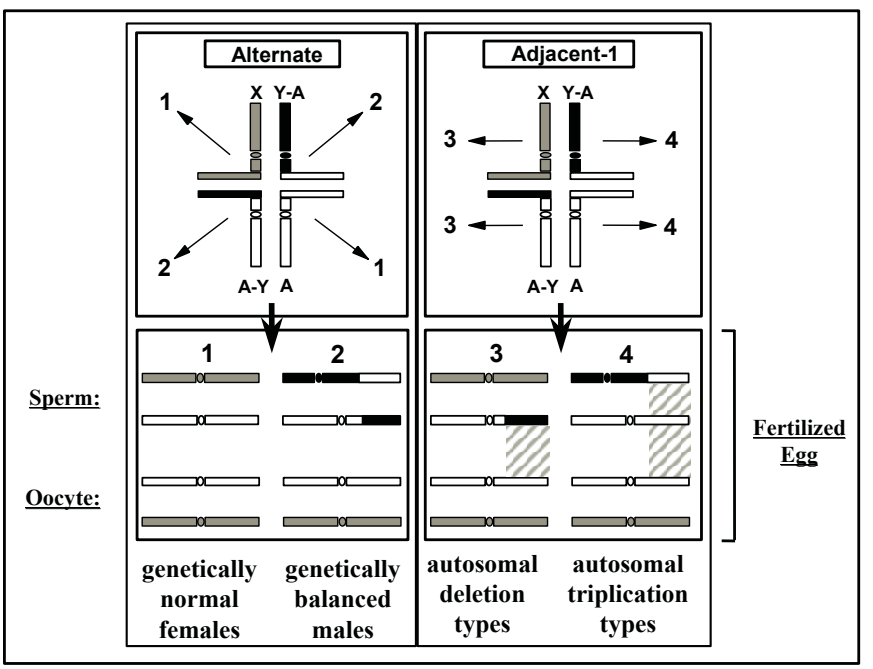

*Figure 5. Two different types of segregation of Y-autosome translocations during male meiosis. Y-A: translocation fragment carrying Y chromosomal centromere, A-Y: reciprocal translocation fragment carrying autosomal centromere, X: X chromosome, A: autosome. Adjacent-2 segregation represents a non-disjunction of homologous centromeres, and therefore is not considered here.*

## 3. INSTABILITY IN SEXING SYSTEM

The first Mediterranean fruit fly sexing strain was based on the *wp* mutation and the translocation T(Y;5)101 (Robinson and Van Heemert 1982). In laboratory-scale rearing, no obvious signs of instability were detected. In 1985, this strain was tested in mass-rearing. Although the scale of production was rather limited (about 1 million males per week), within a relatively short period the sexing system started to degrade (Hooper et al. 1987). The following actions were taken to remedy the situation:

- *Improving cytology, and developing chromosome maps.* During the development of polytene chromosome maps, it was discovered that there are two classes of tissues that contain polytene chromosomes with completely different banding patterns (Bedo 1986; Zacharopoulou 1987, 1990, 1991), and the Y chromosome is visible only in polytene chromosomes isolated from trichogen cells in male sub-orbital frontal bristles.
- *Induction, analysis, and mapping of new mutations.* Many new mutations were isolated and genetic maps constructed (Rössler et al. 1994). To date, seven phenotypic mutations are known for chromosome 5, several of which were mapped on polytene chromosomes by deletion mapping or *in situ* hybridization (Fig. 6).

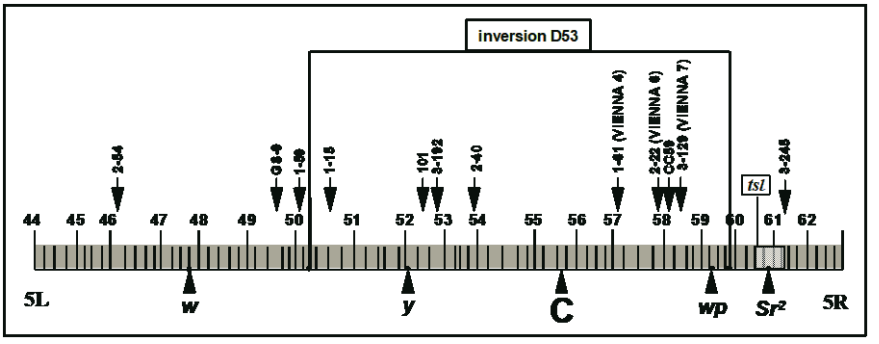

*Figure 6. Schematic polytene Mediterranean fruit fly chromosome map of autosome 5 from trichogen cells: map positions of mutations* white (w), yellow body (y) *and* Sergeant$^2$ (Sr$^2$) *are shown in addition to location of selectable markers* wp *and* tsl. *Arrows indicate break points of several Y-autosome translocations. Extent of chromosomal region inverted in D53 is shown. C: centromere. (VIENNA 8 includes translocation 101 combined with inversion D53.)*

### *3.1. Type-1 Male Recombination*

The most frequent cause of strain instability is autosomal recombination in males heterozygous for the selectable marker(s), i.e. recombination between the translocated wild-type chromosome and the free autosome carrying the mutant alleles (type-1 recombination, Franz 2002). In the GSSs being used in operational programmes that apply the SIT, where *wp* and *tsl* are used as selectable markers, genetic recombination

in two chromosomal regions is of relevance, i.e. in the region between the translocation break point and *wp* (type-1a), and the region between *wp* and *tsl* (type-1b, Fig. 7). Each sub-type produces two reciprocal recombinants; type-1a replaces the wild-type alleles of both markers on the translocation with the mutant alleles from the free autosome, while type-1b exchanges only the wild-type allele of the *tsl*. This results in the generation of several new combinations of these markers and sex (Table 2).

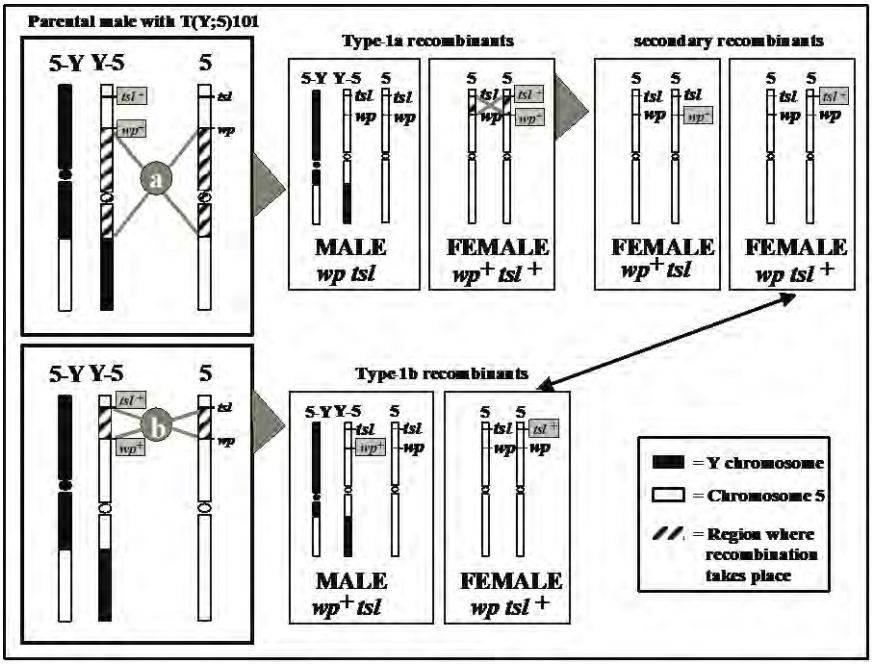

*Figure 7. Consequences of type-1 recombination in Y-autosome 5 translocation T(Y;5)101, either in chromosomal region between translocation break point and* wp *(type-1a) or between* wp *and* tsl *(type-1b). Also, the genotype resulting from secondary recombination in type-1a recombinant females is shown. 5-Y: translocation fragment carrying chromosome 5 centromere, Y-5: reciprocal translocation fragment carrying Y chromosomal centromere.*

In Mediterranean fruit fly males, the recombination frequency is very low, especially compared with recombination in females. For example, the recombination frequency between the relatively distant mutations *white* (*w*), on the left arm of chromosome 5, and *wp* on the right arm, is 0.176% in males (Franz 2002) but 48.4% in females (Rossler and Rosenthal 1992), i.e. these two markers behave as if they were unlinked in females. In spite of its rare occurrence, male recombination is nevertheless a threat to the integrity of the sexing system since some of the resulting recombinants have a selective advantage as compared with normal non-recombinant flies. In a continuous mass-rearing system, where exceptional individuals cannot be removed,

they will gradually replace the non-recombinant genotypes. To illustrate this, a GSS, based on the translocation T(Y5)101 (Robinson and Van Heemert 1982) and the markers *wp* and *tsl*, was reared in standard small-scale conditions for more than 3 years. In each generation, 34 ml of pupae were taken to initiate the next generation without removing any recombinants; in parallel, flies emerging from 40 ml of pupae were screened for recombinants (Fig. 8). A typical pattern of strain degradation due to type-1 recombination emerges from generation 20 onwards. During male meiosis the two reciprocal types of recombinants, $wp^+$ females and *wp* males, occur at equal frequencies. However, from generation 20 onwards, the $wp^+$ female recombinants accumulate rapidly, while the number of *wp* males remains insignificant. The accumulation of $wp^+$ females is even faster than expected based on a purely additive build-up of the recombinants occurring in each generation. This effect is caused by the selective pressure in favour of these wild-type females during the mass-rearing process.

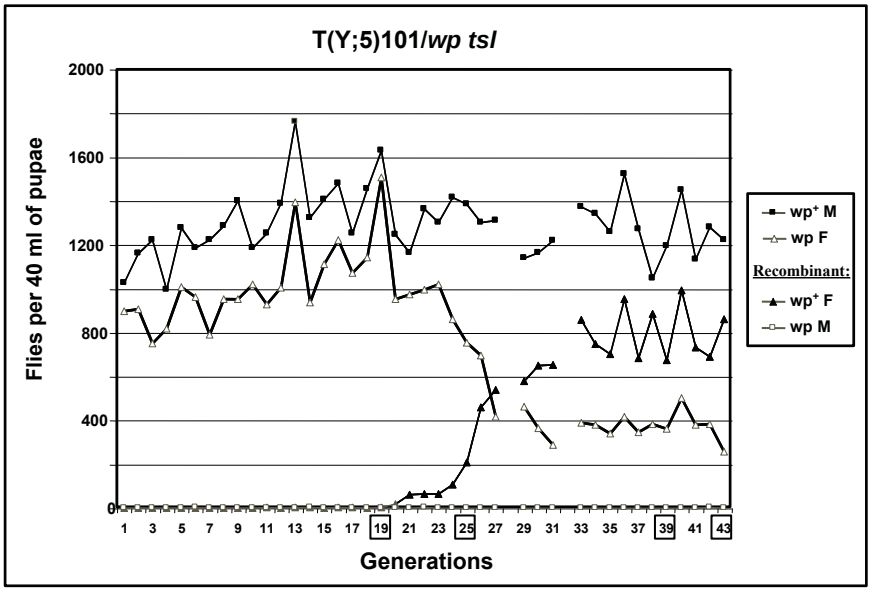

*Figure 8. Breakdown pattern of genetic sexing strain T(Y;5)101/*wp tsl. *In each generation, 34 ml of pupae were taken to initiate the next generation, without removing any recombinants, and a parallel sample of 40 ml of pupae was analysed. Temperature tests were conducted with females from highlighted generations (Fig. 9). F: females, M: males.*

The reverse argument applies to *wp* males; they have a selective disadvantage compared with normal non-recombinant males, and therefore do not accumulate. Furthermore, the accumulation of $wp^+$ females continues until, in about generation 33, a certain equilibrium is reached, where these wild-type females are about twice as abundant as the non-recombinant mutant females.

Temperature tests were needed to assess the exact nature of the recombinants, with respect to the *tsl* mutation. In generations 19, 25, 39, and 43, eggs from the colony were treated for 24 hours with temperatures between 31 and 35˚C, and the phenotype of the resulting adults was scored. Fig. 9A shows that the $wp^+$ females are also wild type for the *tsl* mutation (no reduction in numbers with increasing temperature), confirming that they are type-1a recombinants that resulted from recombination between the translocation break point and *wp*. As expected from the results shown in Fig. 8, such recombinants are not present in generation 19. However, in generation 25, $wp^+$ $tsl^+$ females are detected, and their frequency reaches a maximum in generations 39 and 43. Fig. 9B shows the survival of *wp* females following temperature treatment. In generation 19, all *wp* females are temperature sensitive, i.e. their genotype is therefore *wp tsl*. However, already in generation 25, about half of the *wp* females have lost the *tsl* (genotype *wp* $tsl^+$) (they survive even at 35˚C).

In generations 39 and 43, all *wp* females are $tsl^+$. As indicated in Fig. 7, there are two ways to explain the occurrence of these *wp* $tsl^+$ females, i.e. either by type-1b recombination in the males, or by a secondary recombination in the recombinant *wp* *tsl*/$wp^+$ $tsl^+$ females. The latter is the most likely explanation since recombination in females is much higher than in males. Furthermore, results with other strains show that type-1b recombination appears to be very rare (see below).

In conclusion, type-1 recombination, in combination with a secondary recombination in females, leads to a strain where the normal *wp tsl* females are completely replaced by a 2:1 ratio of $wp^+$ $tsl^+$ and *wp* $tsl^+$ females. The rate at which these recombinant females increase in number cannot be explained by simply adding the recombinants that occur in each generation. A very strong selection is acting on the colony, leading to the rapid accumulation of recombinants that display an advantageous phenotype. The primary increase in selective advantage is caused by the loss of temperature sensitivity and, consequently, no other types of recombinants accumulate. The presence of the *wp* mutation also causes a selective disadvantage (also noted in other combinations) (Fig. 7 in Franz 2002). The speed of accumulation will depend greatly on the rearing conditions, i.e. if they are sub-optimal, this effect will be accelerated.

An additional exceptional phenomenon can be observed only in large mass-rearing facilities. In the colony production line, pupal trays resulting from the first larval collection day, which normally consist of $wp^+$ $tsl^+$ male pupae, may also contain very few *wp* pupae. It is known that homozygous *tsl* individuals do not accelerate their development in response to elevated temperatures ("slow development") as a wild type strain (or a heterozygous $tsl^+$/*tsl* individual) would. So, the earlier pupal collections in a GSS are mostly $wp^+$ $tsl^+$ males, while later pupal collections primarily consist of *wp* *tsl* females. So, white pupae females detected in early pupal collections are expected to be due to recombination events between the *wp* and *tsl* loci. There has also been preliminary evidence that the "slow development" phenotype may not be directly associated with the *tsl* locus itself, suggesting that this is due to a different locus, namely slow larvae (*sl*), which should be close to the *tsl* locus on chromosome 5.

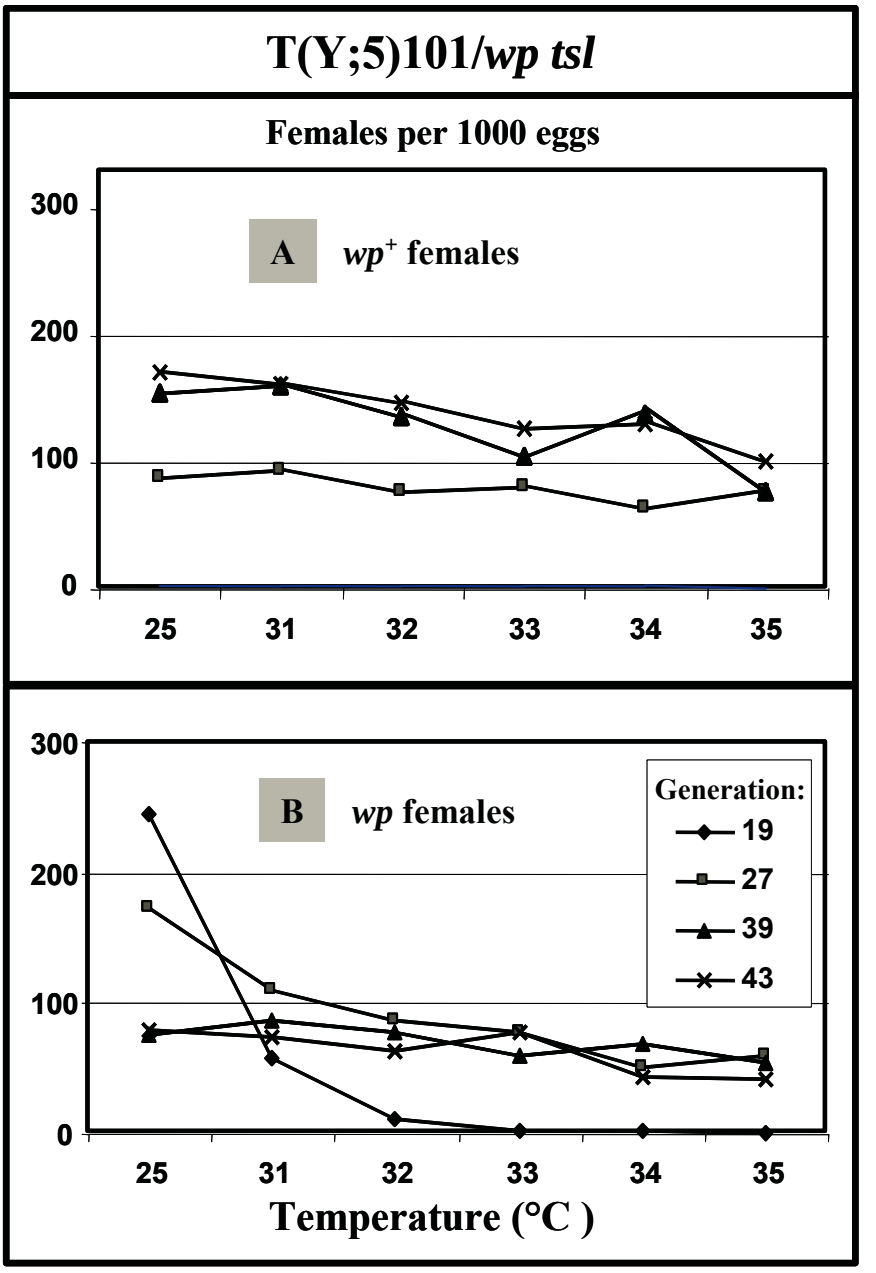

*Figure 9. Temperature tests with females of sexing strain T(Y;5)101/*wp tsl. *Temperature tests were done in generations 19, 27, 39, and 43.*

In an effort to confirm this hypothesis, early *wp* females were crossed with males from the balancer line 68b (Gourzi et al. 2000), the $F_1$ $wp^+$ progeny was inbred, and the $F_2$ *wp* individuals were screened for lines homozygous for *wp tsl* exhibiting an accelerated development. Temperature response tests confirmed that a few lines, which were homozygous for *wp* and *tsl*, exhibited faster development during the larval stage, confirming that this phenotype is due to its close association with *wp* and *tsl* loci in region 61 of the polytene chromosome map (Fig. 6). After the establishment of $sl^+$/$sl^+$ lines, crosses were performed as described in section 2.2., which resulted in lines with *wp tsl* female larvae that develop faster, almost like the $wp^+$ $tsl^+$ male larvae (M. Porras, personal communication). Rare recombination events, which can only be detected under mass-rearing conditions, may result in the loss of this phenotype (Type-1c male recombination).

The isolation of the *sl* locus is of major applied importance because a *wp tsl* line in which females develop almost as fast as males would significantly increase the rearing efficiency and reduce the overall costs. This is because males and females will have access to the same amount and quality of larval food, so facilities will reduce larval rearing time, and thus space and energy consumption required for colony maintenance. In any case, protocols still need to be developed and validated for this new strain at mass-rearing facilities prior to its incorporation in large-scale operational programmes (M. Porras, personal communication). Interestingly, a similar slow larval development phenotype was described recently in *A. ludens* (Meza et al. 2019).

### *3.2. Type-2 Male Recombination*

During mass-rearing, a second type of male recombination was detected (G. Franz, unpublished data). It is very rare (estimated frequency about $10^{-5}$ or less), and generates males with free untranslocated Y chromosomes that are homozygous for *wp* and *tsl* (Table 2). Such males accumulate rapidly in the mass-rearing colony (even though they are sensitive to temperature) because they are completely fertile. Their primary effect is on the productivity of the colony, and not on the accuracy of sexing, because together with females they are eliminated during the temperature treatment. The current hypothesis is that recombination occurs between the two translocated Y fragments. Choosing the appropriate Y-autosome translocation, e.g. where the Y-chromosomal break point is close to the centromere, can minimize this problem.

## 4. STRATEGIES TO IMPROVE STABILITY

Genetic tools are required to improve the stability of sexing strains, and two types of positional information are absolutely essential: (1) the position of the translocation break point, and (2) the position of the selectable marker(s). Also, at least one mutation per chromosome is needed to determine the structure (e.g. which autosomes are involved) and the genetic behaviour of the translocations.

There are two principal strategies to increase the stability of sexing strains. Firstly, by selecting translocations where the break point and the marker are close together, type-1 recombination can be reduced. Secondly, by incorporating inversions that cover

the critical region between the translocation break point and the selectable marker into the strain to eliminate, or at least reduce, type-1 recombination.

### *4.1. Improved Y-Autosome Translocations*

The *wp* mutation is at position 59B on the trichogen polytene map, and the *tsl* is located in the interval 60B–61B (Fig. 6) (Kerremans and Franz 1994; G. Franz, unpublished data). More than 30 translocations were analysed to determine: (1) the position of the break point on chromosome 5 (Kerremans et al. 1990; Franz et al. 1994; Kerremans and Franz 1995), (2) the position of the break point on the Y chromosome (Willhoeft and Franz 1996), and (3) the genetic behaviour (e.g. sterility and segregation behaviour). Based on this information, three strains were selected, i.e. T(Y;5)1-61 (VIENNA 4), T(Y;5)2-22 (VIENNA 6), and T(Y;5)3-129 (VIENNA 7). They were subjected to extensive stability tests, following the same protocol as described above for strain T(Y;5)101 (Franz 2002).

After small-scale rearing for up to 95 generations, no recombinants accumulated in the strains. The overall frequency of type-1a recombination was between 0.017 and 0.021%, and that of strain T(Y;5)101 was 0.084% (if only the generations before recombinants started accumulating were considered). Furthermore, no obvious decrease in sensitivity was shown by the temperature tests, indicating that here also type-1b recombination did not occur at any significant level. Since the distance between the *wp* and *tsl* in the three new strains is the same as in T(Y;5)101, the absence of *wp* $tsl^+$ individuals support the hypothesis that the occurrence of such genotypes during the rearing of T(Y;5)101 was caused by a secondary recombination event in the *wp tsl*/$wp^+tsl^+$ recombinant females.

### *4.2. Inversions*

The second strategy is to use the known recombination-reducing properties of chromosomal inversions. Chromosomal inversions render recombinants non-viable if the recombination has occurred within the inversion. Therefore, the aim was to induce an inversion in the *wp tsl* chromosome. Ideally, it should cover the interval between the translocation break point and the *tsl* mutation, and it must be viable in a homozygous condition. The genotype of the resulting strain would be T(Y;5) $wp^+tsl^+$/Inv *wp tsl* males x Inv *wp tsl*/Inv *wp tsl* females.

In a large screen for inversions, using reduced recombination in the interval between the mutation *yellow body* (*y*) and *wp* as indicator, one homozygous viable inversion, D53 (*wp tsl*), was detected (A. Zacharopoulou, C. Cáceres, and G. Franz, unpublished data). Unfortunately, it does not cover the *tsl*, i.e. it would not reduce type-1b recombination. However, recombination tests with *wp* and the mutation *Sergeant*$^2$ (*Sr*$^2$), located very close to *tsl* (Fig. 6) (Niyazi et al. 2005), showed that inversion D53 also has a strong recombination-reducing effect in neighbouring areas (G. Franz, unpublished data).

Based on this finding, D53 was combined experimentally with the translocation T(Y;5)101, and a new strain VIENNA 8 was constructed. This strain was reared for 5 years (60 generations), under the same conditions as T(Y;5)101, without inversion.

When the results in Fig. 10 are compared with those in Fig. 8, it is apparent that stability is improved significantly, i.e. no $wp^+$ females (type-1a) were detected. Temperature tests with *wp* females showed also that no *wp* $tsl^+$ female recombinants (type-1b) accumulated in the colony (Fig. 11), even though the inversion covers only a small proportion of the *wp-tsl* interval.

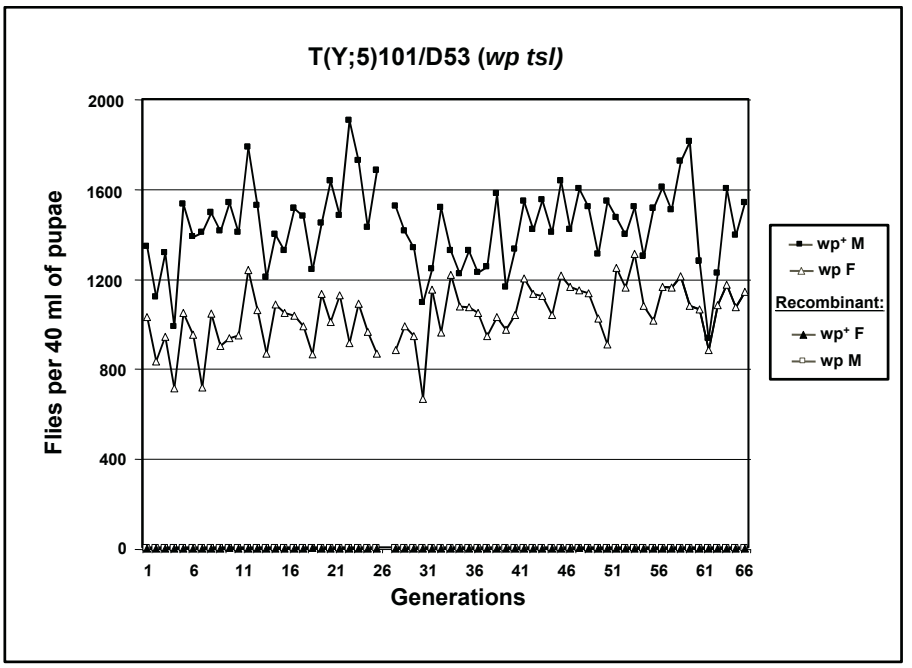

*Figure 10. Increased strain stability due to presence of inversion D53. Neither* wp$^+$ *females nor* wp *males are detected at significant levels. Rearing and analysis were identical to the experiment without inversion. In several generations,* wp *females were tested for temperature sensitivity (Fig. 11). F: females, M: males.*

Both genetic strategies to improve the stability of sexing strains have been successful. Using the appropriate translocation reduces the recombination frequency by 0.65, and if an inversion is added, the frequency is reduced by another 0.80. Inversions have the added potential that they permit translocations based on criteria other than stability to be used. For example, translocation T(Y;5)101 causes less sterility (10–30%, G. Franz, unpublished data) than other translocations, but is not very stable. However, in combination with inversion D53 in strain VIENNA 8, stability is very high. VIENNA 8 has now been provided to several operational AW-IPM programmes that integrate the SIT (Augustinos et al. 2017).

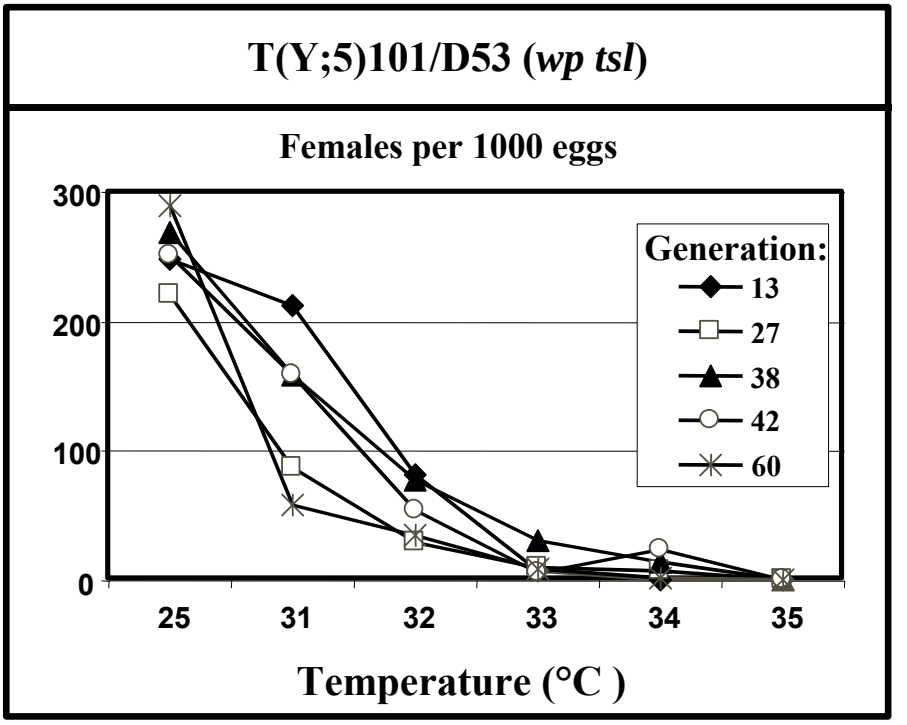

*Figure 11. Temperature tests with* wp *females from five different generations during rearing of sexing strain T(Y;5)101/D53.*

### *4.3. Filter Rearing System (FRS)*

Nevertheless, no GSS will be absolutely stable under conditions of large-scale mass-rearing. Experience with GSSs in different mass-rearing facilities has shown that rearing conditions and the scale of mass-rearing determine whether or not the stability of a strain can be maintained. Up to a certain level of mass-rearing, a facility with well-trained personnel, appropriate equipment, and adjusted operating procedures can maintain the stability. However, if the level of mass-rearing is very high, or any of the aforementioned requirements are not met, stability cannot be guaranteed, and additional measures are required (Caceres et al. 1993). It is for this purpose that the FRS was developed to help maintain the purity of the mother colony (Cáceres et al. 2000; Fisher and Caceres 2000; Parker, Mamai et al., this volume). In a systems approach, by avoiding the accumulation of recombinants, the FRS provides a second independent procedure to maintain strain integrity. Only with both strategies in place (genetically improved strains and improved mass-rearing procedures that also include a FRS) is it possible to produce more than 3500 million Mediterranean fruit fly males per week (Table 1). However, it must be emphasized that the FRS can be used only when a visible mutation is included in the GSS.

## 5. ADDITIONAL FEATURES: MARKERS

GSSs should carry markers (internal as well as external) that make them distinguishable from wild flies or other strains. Markers make it possible to: (1) detect the deliberate or accidental contamination of a strain with wild flies or flies from a different strain, (2) determine if non-irradiated flies (especially females) were released, and (3) reduce the biological and economic costs of, and ambiguities in, the currently used procedure for marking released flies (adults emerge from pupae coated with powdered fluorescent dye) (Dowell et al., this volume; Parker, Mamai et al., this volume; Vreysen, this volume).

To achieve this goal in the Mediterranean fruit fly, several strategies have been pursued. First, a particular type of mitochondrial DNA (mtDNA) haplotype was introduced into the GSS. This mtDNA haplotype was detected in a wild-type strain from Egypt, and it can be used to differentiate the GSS from most field populations where AW-IPM programmes integrating the SIT are being carried out. The mitochondrial genome of the Mediterranean fruit fly has been fully sequenced (Spanos et al. 2000). It was used for the development of a molecular approach to assess the mating success of sterile Mediterranean fruit fly VIENNA 8 males in SIT programmes (San Andrés et al. 2007; Juan-Blasco et al. 2013). In addition, microsatellite markers have been developed which have been used for genotyping purposes (Bonizzoni et al. 2000, 2001, 2004; Stratikopoulos et al. 2008; Karsten et al. 2013; Todd et al. 2017). The genome of the Mediterranean fruit fly has recently been sequenced, thus providing a wealth of information which can be exploited for the development of novel, faster, and more accurate genotyping (Papanicolaou et al. 2016). An alternative approach was based on the introduction of the dominant mutation $Sr^2$ (Niyazi et al. 2005) into GSSs, with males distinguishable from wild males because they show three instead of two white stripes on the abdomen.

## 6. FUTURE PERSPECTIVES

Currently, the *wp tsl*-based Mediterranean fruit fly and the *bp*-based Mexican fruit fly GSSs are used worldwide. The capacity to produce sterile males of the Mediterranean and Mexican fruit flies using these GSSs is expected to increase steadily. In many existing facilities, production will increase, and several new facilities are being constructed or expanded, e.g. Mexico, Morocco, and USA (Mission, Texas). Several countries want to use the technology for pest suppression to decrease the reliance on insecticides. The Mediterranean and Latin-American regions may eventually represent a market of 4000 million sterile Mediterranean fruit fly males per week.

Beyond the Mediterranean and Mexican fruit flies, there is an increasing need to develop GSSs for other insect species of agricultural or public health importance, particularly in the case of mosquitoes where the females are the disease vectors, and thus the removal of the females prior to the release of sterile males is mandatory (Marec et al. 2005; Bourtzis et al. 2016; Hendrichs and Robinson, this volume). Since the genetics of many pest species is not well known, using Mendelian genetics to develop a GSS takes some time. Part of the reason for this long lead time is that Mendelian genetics involves several unknowns. For example:

- Inducing desirable mutations, like the *tsl* mutation in the Mediterranean fruit fly, in other species is a very unpredictable process, with no guarantee that such selective markers will be identified. Genetic markers, potentially useful for sex separation at the pupal stage, are relatively easy to isolate. Therefore, they should be exploited until an efficient and robust embryonic female killing system is developed.
- Translocation induction is also a random process, and based on experiences with the Mediterranean fruit fly, there are at least two criteria that have to be used to select useful translocations: (1) only one autosome should be involved, and (2) the positions of the break points on the autosome and the Y chromosome have to be known.
- Inversions will be very important in any GSS based on classical genetics, but they can also be used to facilitate screening for mutations like the *tsl* and for outcrossing of GSSs. Screening for homozygous viable inversions is very time-consuming and labour-intensive, and requires appropriate mutations and a well-developed cytology.

In contrast to classical genetics, molecular strategies may offer the possibility of developing generic "sexing cassettes" in one species that can be transferred with only minor modifications to other closely related species (Robinson and Franz 2000; Robinson et al. 2004), using non-transgenic or transgenic approaches; this is discussed in more detail in another chapter (Häcker et al., this volume).

SUMMARY

Recent estimations from various studies suggest that the total number of insect species ranges between 2.8–30 x $10^6$; an estimate of 5.5 x $10^6$ is probably closer to reality (Stork et al. 2015; Stork 2018). Insect species have established sophisticated symbiotic associations with a plethora of diverse microorganisms including bacterial species. These symbiotic associations can drastically influence the biology, ecology, and evolution of insect hosts, including insect species of agricultural, veterinary, and human-health importance (Margulis and Fester 1991; Zilber-Rosenberg and Rosenberg 2008). Despite the widespread presence of symbiosis, only in the last decades have technological advances enabled us to take a first glance at the complexity of such interactions, at least at the genomic level. Although studies increasingly describe and assess different possible effects of insects' symbionts on their hosts, including in mosquitoes, tsetse flies, and other pest and disease-vector species, this chapter summarizes the knowledge, gained mainly in the last two decades, on the structure and importance of gut symbiotic communities of tephritid fruit flies of economic importance, focusing mainly on their beneficial impact and prospects for improvement in the sterile insect technique (SIT).

## 1. INTRODUCTION

Defining symbiosis and its types has been quite challenging. It was first defined as "the living together of unlike organisms" (De Bary 1879). However, the complexity underlying this term is extensive, and additional terms have been proposed to further elaborate this widely diverse phenomenon. For practical purposes, it is important to follow generally accepted criteria to define symbiotic relationships. Although not fully determined and quite dynamic, such criteria are necessary to categorize and study the different aspects of symbiosis.

A symbiotic relationship (and more specifically, a symbiont) may fall into more than one category, and categorization depends also on the perspective or the aim of the researcher studying the symbiont or the symbiotic relationship. Some of the prevailing terms and classifications of symbiosis are summarized in Table 1. Although the clear majority of insect symbiotic relationships can still be considered as unknown, there are some well-studied examples among different insects of economic, veterinary or human health importance. Their elucidation has been achieved due to numerous studies which have revealed the existence of specific bacteria that clearly are important in certain insect species; some of them are summarized below.

- *Buchnera aphidicola* in aphids: This gammaproteobacterium is a primary symbiont of aphids that provides a clear nutritional benefit to its host. It is an Enterobacteriaceae-like bacterium, but a long-standing symbiotic relationship, estimated to have started 160–260 x $10^6$ years ago, has led to the gradual loss of important genes from the *B. aphidicola* genome and the development of an obligatory symbiotic relationship with aphids (van Ham et al. 2003; Andersson 2006; Pérez-Brocal et al. 2006; Douglas 2009, 2013; Akman Gündüz and Douglas 2012).
- *Wigglesworthia glossinidia*: Like *B. aphidicola,* this bacterium is a primary obligatory symbiont of tsetse flies, offering primarily a nutritional benefit to its host. It has also lost many genes, resulting in a very small genome and dependency on the tsetse host (Aksoy 1995; Chen et al. 1999; Akman et al. 2002; Pais et al. 2008; Weiss and Aksoy 2011; Bing et al. 2017).

*Table 1. Different types and classifications of symbiosis*

| Term | Definition/examples |
|---|---|
| Mutualism *vs* commensalism *vs* parasitism | Mutualism is when both partners benefit from the relationship, commensalism when one benefits while the other partner is not affected, and parasitism is the relationship where one partner benefits at the expense of the other. |
| Obligatory *vs* facultative | In an obligatory symbiosis, partners cannot survive without each other. In a facultative symbiosis, the partners benefit from living with each other, but they can still live without each other. Alternatively, symbionts can be defined as primary (obligatory) or secondary (facultative). As an example, *Wigglesworthia glossinidia* is considered as a primary endosymbiont of tsetse flies. |
| Ectosymbiosis *vs* endosymbiosis | Depending on whether the symbiont lives on the outer surface or within the body of the host, symbiosis is defined as ecto- and endosymbiosis, respectively. In the case of endosymbiosis, if the symbiont lives either within the host's cells or outside them, it can be considered as intra- or extracellular symbiont, respectively. As examples, *Wolbachia* is considered as intracellular, while the different Enterobacteriaceae localized in the gut are primarily extracellular. |
| Tissue specificity | A symbiont may have a "universal" presence in the host or may be restricted to specific tissues. This may also indicate the specific role of the symbiont. In this respect, Enterobacteriaceae are considered mainly as "gut symbionts", while the alphaproteobacterium *Wolbachia* is considered as a "reproductive symbiont", although additional functions have been reported for it. |
| Type of benefit gained | Symbionts can be beneficial for their hosts in different ways. Among them, those delivering nutritional, reproductive, and immunity/defense advantages, are receiving much attention. |
| Autochthonous (or resident) *vs* allochthonous (or transient) symbiosis | One of the most difficult categories to define is whether we are dealing with "actual" symbiosis, which implies the establishment of long-standing symbiotic relationships, or the observed symbiotic communities are, at least partially, defined by chance (meaning by the random acquisition of symbionts from the environment that are not able to sustain themselves in the host without their continuous supply from the environment). Such relationships, although they may be beneficial for the host, will be eliminated after transfer to a different "ecological niche" (a laboratory can be considered as a different niche as well). In such observed changes, the question regarding symbionts that are no longer present is: are these microorganisms actual symbionts that were no longer beneficial in the new environment, or do they represent transient symbionts that disappeared since there was no longer an external continuous supply from the environment? |
| Type of partner | The usual assumption is that it is bacteria that have established relationships with their eukaryotic host. Although probably bacteria cover most of such symbiotic relationships, there are also symbiotic relationships involving archaea, viruses, and eukaryotic microorganisms (such as fungi and yeast). |

- *Candidatus* Erwinia dacicola: This bacterium is considered as a primary obligatory symbiont for the olive fruit fly *Bactrocera oleae* (Rossi). It is important for helping *B. oleae* larvae feed on a "challenging" environment, such as unripe olives. It is also a characteristic example of the confusing limits of obligatory and secondary symbionts, since it is no longer necessary for domesticated olive flies not reared on olives. Therefore, studying only laboratory populations would lead to the conclusion that this bacterium is not a symbiont of *B. oleae* (Capuzzo 2005; Estes et al. 2009, 2012; Kounatidis et al. 2009; Ben-Yosef et al. 2014) .

- *Wolbachia pipientis*: This group of Alphaproteobacteria is widespread in insects. It is found mainly in reproductive tissues, and is usually referred to as a "reproductive parasite" due to its ability to manipulate reproductive functions, leading to diverse phenotypes including parthenogenesis, feminization, male-killing, and cytoplasmic incompatibility (CI). It is a facultative intracellular symbiont that has developed preferential relationships with many insect species. Although referred to mainly as a reproductive parasite, there are studies indicating that *Wolbachia* also has a role in nutrition, metabolism, and immunity (Werren et al. 2008; Saridaki and Bourtzis 2010; LePage and Bordenstein 2013). Current knowledge on the status of *Wolbachia* in tephritids, regarding both presence and possible effects, has been summarized recently by Mateos and her colleagues (Mateos et al. 2020). In addition, it has been suggested that the SIT and *Wolbachia* symbiosis can be combined (SIT/IIT, Incompatible Insect Technique) into a safe and biosecure approach for the population suppression of *Aedes* mosquito species transmitting major human pathogenic diseases such as dengue, chikungunya, Zika, and yellow fever (Zheng et al. 2019; Lees et al., this volume).

## 2. MAPPING SYMBIOTIC DIVERSITY

An important step towards utilizing insect symbionts is mapping their diversity. This rather descriptive step is crucial, since we need to know the identities of the symbionts so that later on we can decide what roles symbionts have and which ones are important. Characterizing symbionts and symbiotic communities has been laborious, but recently technological advances in sequencing technology have enabled their quick identification, at least at the DNA level. However, the complete characterization of a symbiont requires a combination of approaches, and is still a labour-consuming task (Table 2).

Prior to DNA-based characterization, the classification of bacteria was based only on phenotypic characteristics. These include morphological, biochemical, and cultivation characteristics, including the ability to grow in selective media, production of characteristic substances that can be identified easily, and resistance/sensitivity to a variety of antimicrobials. As a prerequisite for classification, the bacteria had to be cultivable.

Systematic genotyping started with molecular methods that also required a cultivation-dependent step, especially in the time before the introduction of the Polymerase Chain Reaction (PCR). Sequencing of the 16S *rRNA* gene (or others), and related methods (such as the Denaturing Gradient Gel Electrophoresis (DGGE), Restriction Fragment Length Polymorphism (RFLP), and PCR-RFLP) based methodologies (Krafsur and Ouma, this volume), were utilized and are still being used. Reduction in the cost of Sanger sequencing, and advances in bioinformatic analysis during previous decades, enabled the development of Multi Locus Sequence Typing (MLST) and Multi Locus Sequence Analysis (MLSA) approaches, based on a combination of selected genes, universal for a species or closely related species. However, these methods are still time- and labour-consuming, as well as costly, permitting only a limited number of samples to be analysed and a rather restricted look into the genetic diversity of bacteria. A brief history on the transition from the

era of sole microscopy to the NGS-supported (Next Generation Sequencing) DNA genotyping is provided by Escobar-Zepeda et al. (2015).

*Table 2. Symbiont classification approaches*

| Criteria | | Approach | Outcome |
|---|---|---|---|
| Phenotypic | Morphological | Microscopic | Characterize the morphology of a selected bacterium |
| | | Macroscopic | Characterize the morphology of a selected bacterial colony |
| | Biochemical | Growth | Characterize the growth profile of a selected bacterium under different conditions (aerobic *vs* anaerobic *vs* microaerophilic, temperature, pH, selective growth media) |
| | | Antibiotic resistance | Characterize the resistance of a selected bacterium to different antimicrobials |
| | | Metabolic pathways | Characterize the presence/absence of specific enzymes through their effect on metabolism |
| Genotypic | Single gene (16S *rRNA* gene) | PCR-RFLP | Characterize genetic diversity based on differences in sequences that are recognized by restriction enzymes; mainly used for 16S *rRNA* gene |
| | | DGGE | Characterize genetic diversity based on differences in the DNA sequence of single genes that alter melting point and electrophoretic mobility |
| | | Sanger sequencing | Characterize genetic diversity of single gene; it can be effective without cultivation in the presence of species-specific primers and absence of multiple genetically close strains |
| | | NGS sequencing | Characterize the genetic diversity of mixed samples, based on a single gene; massive parallel sequencing that generates thousands or millions of short reads (amplicon sequencing) |
| | MLST | Sanger sequencing | Characterize genetic diversity of the DNA sequence of different genes; not suitable for mixed bacterial samples; it can be effective without cultivation in the presence of species-specific primers and absence of multiple genetically close strains |
| | Metagenomics | Genome sequencing | Characterize the genetic diversity based on the whole genome (complete or draft) in complex samples; more effective with cultivated material |
| | Single cell genomics | Genome sequencing | Characterize the genetic diversity based on the whole genome (complete or draft), derived from a single cell |

The recent advances in sequencing technologies, such as High Throughput Sequencing, have enabled quick and massive parallel sequencing at a reduced cost, thus allowing a better look into bacterial communities and not just isolated bacteria. These technologies have been widely used in the last decade for the simultaneous analysis of the 16S *rRNA* gene profile of environmental samples, producing thousands

to millions of reads per sample, based on the set-up and the needs of the researcher. Still, the major limitation of this approach was the reading length, which is restricted to a few hundred base pairs, thus compromising the robustness of 16S *rRNA* gene-based taxonomy.

These sequencing advances, along with advances in molecular biology and bioinformatic analysis, now enable a faster analysis of bacteria or bacterial communities of interest at a reduced cost. This is extremely important because single gene or MLST approaches cannot fully resolve the genetic diversity among bacteria of interest, especially considering that even strains of the same species can have quite diverse properties. Based on these advances, metagenomic approaches that can analyse almost the complete genomic content of communities of organisms, and single cell genomics (that is the ability to have the complete genome of a single cell), are offering opportunities for the analysis of symbiotic communities that did not seem realistic one or two decades ago.

## 3. EXPLOITING INSECT GUT SYMBIONTS TO ENHANCE THE SIT

There are several studies describing many different possible effects of insects' symbionts on their hosts, as well as their potential role to enhance SIT application. There are studies in mosquito species (for recent reviews see Guégan et al. (2018), Strand (2018), and Scolari et al. (2019) and references therein) and tsetse species (less) (for reviews see Snyder and Rio (2013) and Wang et al. (2013) and references therein), but most of the data derive from experiments on fruit flies in the family Tephritidae (Niyazi et al. 2004; Behar et al. 2008; Ben Ami et al. 2010; Gavriel et al. 2011; Hamden et al. 2013; Sacchetti et al. 2014; Augustinos et al. 2015; Kyritsis et al. 2017; Cai et al. 2018; Khaeso et al. 2018; Ventura et al. 2018; Akami et al. 2019; Augustinos et al. 2019).

### *3.1. Mapping Symbiotic Diversity in Fruit Flies of Economic Importance*

Numerous studies have been performed on different tephritids. Among them, most studies are on the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), which is a model for SIT application, and *B. oleae*. Recently, other species, mainly of the *Anastrepha, Bactrocera,* and *Zeugodacus* genera, have also been targeted. Studies that address the structure of symbiotic communities in tephritids are summarized in Table 3. As already stated, the first steps are descriptive; many studies deal with identifying which bacterial species are found in which hosts. The next step is to describe the relative abundances, and how bacterial symbiotic communities change under different conditions. Subsequently comes the question of functional roles; the mere analysis of presence and/or abundance of certain symbionts cannot answer such questions.

#### *3.1.1. Gut Symbiotic Communities in the Mediterranean Fruit Fly*

Starting with the Mediterranean fruit fly, many studies have been performed on the characterization of its gut symbiotic communities (Table 3). In more recent years,

beginning in 2005, gut symbiotic communities were described for this species under different conditions. *Klebsiella oxytoca*, an Enterobacteriaceae diazotroph common on plants and able to fix atmospheric nitrogen, was identified as a major symbiont of natural populations (Behar et al. 2005). Minor but persistent *Pseudomonas* communities were also identified using PCR-based assays (Behar et al. 2008).

The effect of irradiation on the structure of gut symbiotic communities was also documented (Ben Ami et al. 2010), and communities of reduced variability were identified in long-established laboratory populations and strains of SIT importance (Ben Ami et al. 2010; Augustinos et al. 2015). Although not strictly referring to gut communities, the reduced diversity of symbionts in a line of the Mediterranean fruit fly VIENNA 7 genetic sexing strain (GSS), reared in Australia (~99% *Enterobacter* sp.) (Morrow et al. 2015), is in accordance with these two studies. Utilization of NGS approaches enabled a more detailed look at the symbiotic communities of both wild and laboratory populations and at different developmental stages (Aharon et al. 2013; Malacrinò et al. 2018).

### *3.1.2. Gut Symbiotic Communities in the Olive Fruit Fly*

Among tephritids, the olive fruit fly is probably the species that most clearly demonstrates how advances in sequencing and bioinformatics have enlarged our ability to study and understand insect symbiotic communities (Table 3). More than a century ago, Petri described cultivable endosymbionts of *B. oleae* (Petri 1909). In 2005, *Candidatus* Erwinia dacicola was identified as the main symbiont of olive fruit fly's natural populations, while later other potential symbionts were identified in natural and laboratory populations of the species (Capuzzo 2005; Estes et al. 2009, 2012; Kounatidis et al. 2009; Ben-Yosef et al. 2014; Augustinos et al. 2019; Koskinioti et al. 2019).

Interestingly, it was also recognized that the primary symbiont of natural populations, *Candidatus* Erwinia dacicola, is almost absent from artificially reared populations ( Estes et al. 2009, 2012; Kounatidis et al. 2009). The presence of abundant and minor components of the communities could be better described, at least to the resolution of genus level (Ben-Yosef et al. 2014, 2015). Using single cell genomics and NGS sequencing, the draft genome of *Candidatus* Erwinia dacicola was obtained, starting from DNA of a single cell, which is important for bacterial species that cannot be cultivated (Blow et al. 2016).

### *3.1.3. Gut Symbiotic Communities in Some* Anastrepha, Bactrocera*, and* Zeugodacus *Species*

Except for the Mediterranean fruit fly and the olive fruit fly discussed above, there are only a few studies in other tephritids (Table 3). Using classical microbiological approaches, a small number of bacterial taxa has been characterized in *Anastrepha ludens* (Loew) (Kuzina et al. 2001), *Bactrocera dorsalis* (Hendel) (Pramanik et al. 2014; Gujjar et al. 2017; Khaeso et al. 2018; Khan et al. 2019), *Bactrocera zonata* (Saunders) (Naaz et al. 2016), *Zeugodacus cucurbitae* (Coquillett) (Hadapad et al. 2016; Gujjar et al. 2017), and *Zeugodacus tau* (Walker) (Prabhakar et al. 2013; Khan et al. 2014).

*Table 3. Efforts for mapping gut associated bacteria species in tephritids of economic importance*

| Species | Approach | Material used | Main outcome | Reference |
|---|---|---|---|---|
| *Bactrocera oleae* | Direct PCR and sequencing of the 16S *rRNA* gene of extracts | Wild material collected as pupae | *Candidatus* Erwinia dacicola is the main symbiont of wild populations | Capuzzo 2005 |
| | Microscopy, culture dependent, and culture independent approaches | Wild material kept on olives in the lab | *Candidatus* Erwinia dacicola is the main symbiont *Enterobacter* sp., *Citrobacter* sp., and *Raoultella* sp. also present | Estes et al. 2009 |
| | 16S *rRNA* gene libraries and sequencing | Wild material collected as pupae and laboratory colonies | *Acetobacter tropicalis* is present in laboratory colonies and wild sample; *Enterococcus* sp. and *Paenibacillus* sp. also detected; *Candidatus* Erwinia dacicola detected only in natural populations | Kounatidis et al. 2009 |
| | 16S *rRNA* gene PCR and *Candidatus* Erwinia dacicola specific assay | Wild material collected as pupae and laboratory colonies | *Candidatus* Erwinia dacicola spread in all wild populations *Candidatus* Erwinia dacicola present in laboratory colonies reared on olives; *Candidatus* Erwinia dacicola is rare in laboratory colonies reared on artificial diet; Presence of different Enterobacteriaceae in laboratory populations | Estes et al. 2012 |
| | 16S *rRNA* gene libraries and sequencing | Wild material collected as pupae (only oesophageal bulbs) | Two haplotypes of *Candidatus* Erwinia dacicola | Savio et al. 2012 |
| | High throughput sequencing -- 16S *rRNA* gene | Wild material of different developmental stages | High prevalence of *Candidatus* Erwinia dacicola; Low presence of *Pectobacterium*, *Pseudomonas*, and *Kluyvera* | Ben-Yosef et al. 2014 |
| | High throughput sequencing – 16S *rRNA* gene | Wild material kept on olives in the laboratory | High prevalence of *Candidatus* Erwinia dacicola in wild flies but not in mass-reared flies; Low presence of *Pantoea* and *Burkholderia* both in wild flies and mass-reared flies; High prevalence of *Providencia* in mass-reared flies but not in wild flies | Ben-Yosef et al. 2015 |

*Table 3. Continued*

| Species | Approach | Material used | Main outcome | Reference |
|---|---|---|---|---|
| *Bactrocera oleae* | Single cell genomics and metagenomics | Wild material | Draft genome of *Candidatus* Erwinia dacicola | Blow et al. 2016 |
| | High throughput sequencing – 16S *rRNA* gene | Wild material plus 1st generation in the laboratory | Detection of different OTUs including *Candidatus* Erwinia dacicola, *Providencia, Enterobacter,* and *Klebsiella,* Prevalence of *Candidatus* Erwinia dacicola | Koskinioti et al. 2019 |
| | 454 pyrosequencing | Laboratory population, different developmental stages, age, and sex | Mainly Enterobacteriaceae, *Morganella* prevailing, developmental stage and age influence structure of gut microbiota community | Augustinos et al. 2019 |
| *Bactrocera cacuminata* | 16S *rRNA* gene libraries and sequencing | Wild material | Dominant Gammaproteobacteria Mainly Enterobacteriaceae (*Enterobacter, Serratia, Klebsiella, Escherichia)* | Thaochan et al. 2015 |
| *Bactrocera carambolae* | Illumina sequencing | Wild material | Gammaproteobacteria dominant | Yong et al. 2017 |
| *Bactrocera dorsalis* | PCR of the 16S *rRNA* gene, DGGE, sequencing | Laboratory colonies and wild material | Dominant Gammaproteobacteria Diverse symbiotic community | Wang et al. 2011 |
| | Culture dependent, morphological and biochemical characterization | Laboratory colonies | 11 genera identified Dominant Enterobacteriaceae community (*Citrobacter, Enterobacter, Serratia, Klebsiella, Morganella*) | Pramanik et al. 2014 |
| | Pyrosequencing | Wild material | 172 OTUs identified Effect of developmental stage on symbiotic communities Firmicutes and Proteobacteria dominant | Andongma et al. 2015 |
| | Illumina sequencing | Wild material | Gammaproteobacteria dominant | Yong et al. 2017 |
| | Culture dependent, morphological, biochemical, 16S *rRNA* gene sequencing | Laboratory colonies | Mainly different Enterobacteriaceae genera (*Providencia, Klebsiella, Enterobacter, Citrobacter*) | Gujjar et al. 2017 |
| | Culture dependent, 16S *rRNA* gene sequencing | Labortory colonies | 13 bacterial species Firmicutes and Proteobacteria more abundant | Khaeso et al. 2018 |

*Table 3. Continued*

| Species | Approach | Material used | Main outcome | Reference |
|---|---|---|---|---|
| *Bactrocera dorsalis* | Illumina sequencing plus culture dependent 16S *rRNA* gene sequencing | Laboratory colonies | Dominance of Enterobacteriaceae, presence of other minor communities that increase their relative abundance after irradiation | Cai et al. 2018 |
| | Culture dependent 16S *rRNA* gene sequencing, morphological characterization | Laboratory colonies | Dominance of Enterobacteriaceae, reduced diversity | Khan et al. 2019 |
| | Illumina sequencing | Laboratory colonies and wild material | Differences due to developmental stage, age, and origin (wild versus laboratory) | Hadapad et al. 2019 |
| *Bactrocera minax* | 454 pyrosequencing | Wild material | Proteobacteria dominant<br>Genera of Enterobacteriaceae the most represented (*Enterobacter*, *Klebsiella*, *Serratia*, *Citrobacter*) | Wang A. et al. 2014 |
| | 454 pyrosequencing | Wild material | Proteobacteria dominant<br>Genera of Enterobacteriaceae the most abundant | Andongma et al. 2019 |
| *Bactrocera tryoni* | 16S *rRNA* gene libraries and sequencing | Wild material | Proteobacteria dominant, mainly Gammaproteobacteria | Thaochan et al. 2015 |

| | Illumina MiSeq sequencing, 16S *rRNA* gene | Wild material from different hosts | More than 3000 OTUs present, mainly Firmicutes and Proteobacteria<br>Significant differences among different developmental stages<br>Effect of the host fruit on the profile of the communities | Malacrinò et al. 2018 |
| *Anastrepha fraterculus* | 454 pyrosequencing | Laboratory populations of two morphospecies, different developmental stage, age, and sex | Mainly Enterobacteriaceae, *Morganella* prevailing, developmental stage and age influence structure of gut microbiota community | Augustinos et al. 2019 |
| *Anastrepha grandis* | 454 pyrosequencing | Laboratory population, different develop. stage, age, and sex | Mainly Enterobacteriaceae, *Morganella* prevailing, developmental stage and age influence structure of gut microbiota community | Augustinos et al. 2019 |

*Table 3. Continued*

| Species | Approach | Material used | Main outcome | Reference |
|---|---|---|---|---|
| *Anastrepha ludens* | Culture dependent, metabolic profile | Laboratory colonies | 18 species in 13 genera Enterobacteriaceae prevailing community (*Enterobacter*, *Providencia*, *Serratia*) | Kuzina et al. 2001 |
| | 454 pyrosequencing | Wild material | Mainly Enterobacteriaceae | Ventura et al. 2018 |
| | 454 pyrosequencing | Laboratory population, different developmental stages, age, and sex | Mainly Enterobacteriaceae, *Morganella* prevailing, developmental stage and age influence structure of gut microbiota community | Augustinos et al. 2019 |
| *Anastrepha obliqua* | 454 pyrosequencing | Wild material | Mainly Enterobacteriaceae | Ventura et al. 2018 |
| *Anastrepha serpentina* | 454 pyrosequencing | Wild material | Mainly Enterobacteriaceae | Ventura et al. 2018 |
| *Anastrepha striata* | 454 pyrosequencing | Wild material | Mainly Enterobacteriaceae | Ventura et al. 2018 |
| *Zeugodacus cucurbitae* | Culture dependent, morphological, biochemical, 16S *rRNA* gene sequencing | Wild material | Nine genera identified, mainly Enterobacteriaceae (*Enterobacter*, *Klebsiella*, *Citrobacter, Providencia*) | Hadapad et al. 2016 |
| | Culture dependent, 16S *rRNA* gene sequencing | Laboratory population | *Bacillus* and *Morganella* | Gujjar et al. 2017 |
| | Illumina sequencing | Laboratory colonies and wild material | Differences due to developmental stage, age, and origin (wild versus laboratory) | Hadapad et al. 2019 |
| *Zeugodacus tau* | Culture dependent, morphological, biochemical, 16S *rRNA* gene sequencing | Laboratory populations | Three species (*Klebsiella oxytoca*, *Pantoea agglomelans*, *Staphylococcus* sp.) | Prabhakar et al. 2013 |
| | Culture dependent, morphological, biochemical, 16S *rRNA* gene sequencing | Laboratory population | Mainly Enterobacteriaceae identified (*Proteus*, *Klebsiella*, *Erwinia*) but also others | Khan et al. 2014 |

Characterization based on construction of 16S rRNA gene libraries and/or Sanger sequencing has been performed in *Anastrepha fraterculus* (Wiedemann) (Juárez et al. 2019), *Bactrocera cacuminata* (Hering) (Thaochan et al. 2015), *B. dorsalis* (Wang et al. 2011; Khaeso et al. 2018), *Bactrocera minax* (Enderlein), (Andongma et al. 2019), and *Bactrocera tryoni* (Froggatt) (Thaochan et al. 2015).

Finally, using NGS approaches, the structure of gut symbiotic communities was resolved in higher resolution for some species, including both laboratory and natural populations. Among them are natural populations of *A. ludens* (Loew), *A. obliqua* (Macquart), *A. serpentina* (Wiedemann), *A. striata* Schiner (Ventura et al. 2018), *Bactrocera carambolae* Drew and Hancock (Yong et al. 2017), *B. dorsalis* (Andongma et al. 2015; Yong et al. 2017), *Bactrocera minax* (Enderlein) (Wang A. et al. 2014), *Z. cucurbitae* (Hadapad et al. 2019), as well as laboratory populations of two morphotypes of *A. fraterculus*, *A. grandis* (Macquart), and *A. ludens* (Augustinos et al. 2019), *B. dorsalis* (Hadapad et al. 2019), and *Z. cucurbitae* (Hadapad et al. 2019).

### *3.2. Gut Symbiotic Communities – Limitations*

Despite the advances in sequencing approaches that result in enormous data sets, we must keep in mind that such sequencing-based studies are descriptive in principle since a) the resolution provided does not easily go beyond genus level and, b) the "actual" bacteria are not isolated and cultivated, resulting in reduced usefulness regarding possible applications. Moreover, the differences in the methodological set-up (samples collection, DNA extraction, sequencing platform, number of sequences analysed, and algorithms applied for analysis of sequences) make comparisons among studies difficult.

Although the focus until now has been on bacteria, they are not the only symbiotic players in the insect microbiota. A few recent studies are investigating other symbionts that could be important. For example, there is a fungal survey of olive fruit fly wild populations, based on a metabarcoding analysis of ITS2 (Malacrinò et al. 2017), and the cultivation-based identification (coupled with sequencing of selected genes) of yeast in natural populations of *B. tryoni* (Deutscher et al. 2017).

## 4. GUT SYMBIONTS IN THE INSECT MICROBIOTA – ROLE ASSESMENT

It is rather difficult to document the role and importance of symbionts for their host, mainly because:

a. Symbionts may play a role in specific environments but may be redundant, unnecessary or outcompeted in others. *Candidatus* Erwinia dacicola plays a critical role in adult olive fruit flies by providing amino acids or converting inaccessible nitrogen. This symbiont is also important when olive fruit fly larvae feed on unripe olives. In such cases, poor sampling, or transfer of insects to a new environment for experiments, can compromise the results and interpretation.
b. Symbiotic communities probably function in a "redundant" way, meaning that some of the symbiotic bacteria may be important, but their absence can be compensated by others, based on availability and chance. Provided that we are

dealing with "actual" and not transient symbionts, this may explain why different bacterial species can be found in the same host under different circumstances.

c. There may be changes in preferential relationships during ontogeny. This is also difficult to prove and monitor, but may explain differences observed among developmental stages. During development, communities comprising different bacterial operational taxonomic units (OTUs) during development, or presenting quantitative differences, are commonly found. This means that the same OTUs are present but with significantly different relative abundances. This is what makes interpretation of data from natural populations difficult, where only a limited view of the life cycle is available.
d. Bacteria with the highest representation are not necessarily the most important symbiont. Sometimes, underrepresented members of the community may provide something crucial. Based on the methodological approaches used, such symbionts may remain cryptic and their role underestimated.
e. It is difficult to measure directly the effect of a symbiont. This is because it has to be isolated to test possible properties and functions or it must be studied as a part of the whole symbiotic association (but then it is not clear if a certain effect can be attributed to this specific symbiont).

To provide answers that are as robust as possible, different approaches are followed, and even better, a combination of them. However, all these approaches make certain compromises which must be considered both prior to planning and during the interpretation of results. Some of the main approaches used to estimate the importance of gut-related bacteria to their host are summarized below:

- *Characterization of the symbiotic communities of a species across its range:* As in all experiments, proper sampling is crucial. In this case, proper sampling means collecting material that represents different geographic origins, different seasons, and different hosts. In addition, different developmental stages, sex, and age are parameters that may shape the profile of symbiotic communities. Approaches that take into consideration the above could determine the "core microbiome" of an insect host. Obviously, ideal sampling targeting the symbiotic profile of a species can be a very laborious task.
- *Providing an excess amount of a cultivated symbiont under artificial-diet rearing:* Providing a symbiont through feeding can demonstrate its beneficial effects. However, this does not necessarily mean that these effects are present under standard conditions. Moreover, the positive effect may not have a linear correlation with the quantity; in such cases the effect will not be demonstrated by artificial accumulation of the symbiont.
- *Creation and test of aposymbiotic (symbiont-free) organisms:* This approach is useful because it provides evidence based on the negative (or positive) effects identified after the removal of symbionts. It can be done through antibiotic feeding, which results in the suppression or elimination of the symbiotic community. However, there are certain limitations. It is difficult to attribute an observed effect to a specific symbiont, since the whole community is influenced. Also, antibiotic treatment can influence non-symbiont mediated metabolic pathways (such as those of mitochondria), which makes the interpretation of results questionable. In such experiments, giving time for some generations to

develop without the effect of the antibiotic would reduce the possibility that the observed results are associated with anything but the removal of the symbionts.

- *Creation of aposymbiotic organisms and reintroduction of selected bacteria:* Although useful, this approach is partially compromised by the fact that an important effect may be identified, but this is in an artificial system and not in the framework of studying the host organism together with its symbionts as a single entity. That means that this effect could be substantially different in the presence of the other autochthonous symbionts.
- *Cultivation of symbionts and assessment of possible effects* in vitro*:* Cultivation in artificial growth media is necessary to find the metabolic pathway through which a symbiont affects its host. *In vitro* cultivation provides evidence about the potentially useful metabolites produced. However, it is not possible to assess *in vitro* whether the symbiont will produce the same effect under the complex *in vivo* interactions of its host and all associated symbionts.

## 5. SYMBIONTS AND THEIR POTENTIAL APPLICATION TO ENHANCE THE SIT

Symbionts can be useful in different ways to boost SIT application (Deutscher et al. 2019). The first application is what we refer to as "probiotic diets". A probiotic diet can be beneficial in different ways. Based on the experimental set-up and the aim of the researcher, a valid research goal is to determine how diets involving symbionts are beneficial. Symbionts can be provided as live material; they can be used as a source of nutrients or to establish their beneficial properties. Live or dead symbionts can also act as food sources for resident symbionts, thus offering an indirect positive effect. Another possible application is to explore the attractancy potential of symbionts, e.g. to make sterile males more attractive for mating with wild females or to include them as a lure in a "trap package" (Pereira et al., this volume). The focus of this chapter is mainly on probiotic applications of gut-associated bacteria.

### *5.1. Positive Effects of Symbiont-Enriched Diets*

Most of the studies have been performed on the Mediterranean fruit fly because it has been a model for the development of the SIT in tephritids (Table 4). This also means that there are universal protocols for rearing and handling, and laboratory rearing is quite easy and optimized. More importantly, the application of the SIT, involving the mass-production of the target species, makes these studies worthwhile. The potential positive effect of symbiont-enriched diets can be adopted easily in fly-rearing facilities, and may have a significantly favourable financial impact. However, the logistics aspect related to the large-scale production of probiotics still needs to be addressed.

*Table 4. Summary of probiotic studies in Tephritidae and the main findings*

| Species | Bacteria | Provision | Effect | Reference |
|---|---|---|---|---|
| *Ceratitis capitata* | Enterobacteriaceae mix (*Enterobacter agglomerans, Klebsiella pneumoniae*) | Adult diet | Positive on male mating competitiveness of irradiated males (diet-dependent)<br>Positive on male longevity of irradiated males (diet and age-dependent)<br>Positive on sexual calling of irradiated males (diet-dependent) | Niyazi et al. 2004 |
| | Enterobacteriaceae mix isolated from Mediterranean fruit fly (*Enterobacter* spp., *Klebsiella oxytoca, Citrobacter freundii, Pectobacterium cypripedi*, *Pantoea* spp.) | Adult diet | Positive on adult longevity (nutritionally restricted flies) | Behar et al. 2008 |
| | *Klebsiella oxytoca* (Mediterranean fruit fly gut isolated) | Adult diet | Positive on mating latency time (irradiated, nutritionally restricted males) | Ben Ami et al. 2010 |
| | *Klebsiella oxytoca* (Mediterranean fruit fly gut isolated) | Adult diet | Positive on mating competitiveness of irradiated males<br>Positive on mating receptivity of nutritionally restricted females<br>Positive on longevity in starvation of nutritionally restricted females | Gavriel et al. 2011 |
| | Enterobacteriaceae mix of unknown isolation source: *Enterobacter* spp., *Klebsiella pneumonia, Citrobacter freundii* | Larval diet | Positive on pupal weight<br>Positive on flight ability (irradiated males)<br>Positive on adult size<br>Positive on mating competitiveness of irradiated males<br>Positive on sperm transfer | Hamden et al. 2013 |
| | *Enterobacter* sp. AA26 | Larval diet | Replacement or partial replacement of yeast with dead *Enterobacter* can:<br>positively affect pupal and adult recovery<br>positively affect immature development duration (decrease)<br>positively affect female pupal weight<br>positively affect longevity under stress | Kyritsis et al. 2019 |

*Table 4. Continued*

| Species | Bacteria | Provision | Effect | Reference |
|---|---|---|---|---|
| *Ceratitis capitata* | *Enterobacter* sp. AA26 (Mediterranean fruit fly gut isolated) | Larval diet | Positive on immature developmental duration (decrease)<br>Positive on immature stages survival | Augustinos et al. 2015 |
| | *Enterobacter* sp. AA26, *Klebsiella oxytoca* | Larval and adult diet | *Klebsiella oxytoca* has a positive on immature developmental duration (decrease) as a larval diet probiotic<br>*Klebsiella oxytoca* has a positive on flight ability as a larval diet probiotic | Kyritsis et al. 2017 |
| *Bactrocera oleae* | *Pseudomonas putida* (olive fly gut isolated) | Adult diet | Positive on the fecundity of nutritionally restricted females | Sacchetti et al. 2014 |
| *Bactrocera dorsalis* | Various preparations of the identified bacteria | Larval diet | Effect on immature developmental duration (reduction or increase)<br>Positive effect on pupal weight | Khaeso et al. 2018 |
| | *Klebsiella oxytoca* and *Citrobacter coseri* separate live feeding | Larval diet | Feeding with live bacteria can restore ecological fitness of males that are sterilized through irradiation | Cai et al. 2018 |
| | *Proteus* sp. | Larval diet | Improved adult emergence, male ratio, and survival under stress | Khan et al. 2019 |
| *Bactrocera tryoni* | *Klebsiella* | Adult diet | No effect on fecundity | Meats et al. 2009 |
| | *Asaia* sp., *Enterobacter* sp., *Lactobacillus* sp., *Leuconostoc* sp. | Larval diet | *Enterobacter* sp. and *Asaia* sp. shortened immature development duration | Shuttleworth et al. 2019 |
| *Zeugodacus tau* | *Klebsiella* and *Proteus* | Adult diet | No effect on ovariole number or fecundity | Khan et al. 2014 |
| *Anastrepha obliqua* | Mix of endogenous gut symbionts | Adult diet | No effect on male longevity | Rull et al. 2015 |

### *5.1.1. Probiotic Supplements for the Adult Diet of the Mediterranean Fruit Fly*

Probiotics can be added to the larval or adult diets (or both). A positive effect of adult diets (enriched with an Enterobacteriaceae mix) on the mating competitiveness, longevity, and sexual calling of irradiated males was described by Niyazi et al. (2004). A different Enterobacteriaceae mix had positive effects on adult longevity

(Behar et al. 2008). Later, a positive impact (of the addition of *K. oxytoca* to the adult diet of the VIENNA 8 GSS) on the mating latency time of irradiated males was found by Ben Ami et al. (2010). By enriching the adult diet with the same isolate, and for the same Mediterranean fruit fly strain, positive effects on the mating competitiveness of irradiated males, and on the mating receptivity and longevity of females under starvation, were described (Gavriel et al. 2011) (see also Bakri et al., this volume; Barclay, this volume; Hendrichs and Robinson, this volume; Itô et al., this volume; Lance and McInnis, this volume; Marec et al., this volume; Parker, Mamai et al., this volume; Robinson, this volume; Vreysen, this volume; Whitten and Mahon, this volume). However, in an independent study a few years later, using the same bacterial isolate and the VIENNA $8^{D53+}$ strain, a positive effect on the mating competitiveness of irradiated males was not detected (Kyritsis et al. 2017).

#### *5.1.2. Probiotic Supplements for the Larval Diets of the Mediterranean Fruit Fly*

Regarding probiotic enrichment of larval diets, the addition of three Enterobacteriaceae strains, isolated from sources other than the Mediterranean fruit fly, showed positive effects on pupal weight, adult size, flight ability, and the mating competitiveness and sperm transfer of irradiated males (Hamden et al. 2013). The addition of an indigenous bacterial symbiont *Enterobacter* sp. AA26 decreased the duration of immature development and increased the survival of immature stages, leading to increased productivity in the fly strain. However, no positive effects on the mating competitiveness of irradiated males were observed (Augustinos et al. 2015).

The use of *K. oxytoca* as an additive to the larval diet led to a decrease in the duration of immature development, and also had positive effects on flight ability (Kyritsis et al. 2017). Finally, although not strictly probiotic, the partial or full replacement of yeast (the costliest diet ingredient) with dead *Enterobacter* sp. AA26, in the form of dry biomass, gave promising results regarding the reduction or elimination of yeast from the larval diet, which could lead to a decreased cost. More specifically, replacement had a positive effect on the survival of immature stages, on pupal weight, and on adult survival under starvation. At the same time, no effect was observed regarding the sex ratio, fecundity, flight ability, and male mating competitiveness, showing that it is an approach worthy of further investigation (Kyritsis et al. 2019; Stathopoulou et al. 2021).

#### *5.1.3. Probiotic Supplements for the Larval and Adult Diets of Tephritids Other than the Mediterranean Fruit Fly*

Several recent studies have described the effects of adding a bacterial inoculant to the larval diet of a fruit fly other than the Mediterranean fruit fly. In *B. dorsalis* and *B. tryoni*, adding various bacterial cultures either reduced or increased the immature developmental duration, and had a positive or no effect on pupal weight, emergence, sex ratio, flight ability or survival under stress (Khaeso et al. 2018; Khan et al. 2019; Shuttleworth et al. 2019). Also, studies were done on using probiotic-enriched adult diets. Adding *Pseudomonas putida* to an olive fruit fly adult diet had positive effects on female fecundity (Sacchetti et al. 2014), but adding *Klebsiella* sp. in a *B. tryoni* adult diet, and K*lebsiella* sp. combined with *Proteus* sp. in a *Z. tau* diet, had no effect

on fecundity (Meats et al. 2009; Khan et al. 2014). In a comprehensive analysis of virgin olive fruit fly females naturally infected with their symbionts, treated with antibiotics or treated with antibiotics and then provided with probiotic supplements of symbionts isolated from the olive fruit fly or Mediterranean fruit fly, it was shown that the first group with the natural microbiome (primarily consisting of *Candidatus* Erwinia dacicola) attempted oviposition significantly more times than the treated flies (Jose et al. 2019). Finally, adding a mix of endogenous symbionts in an *A. obliqua* diet had no effect on male longevity (Rull et al. 2015). In a recent report on *B. dorsalis* it was shown that a probiotic supplement of the gut-isolated symbiont *Klebsiella oxytoca* (BD177) can restore the biological quality of insects irradiated at the pupal stage (Cai et al. 2018).

### *5.2. Non-Probiotic Applications of Symbionts, and Alternative Documented Positive Effects*

Besides probiotic diets, there are other ways to exploit putative positive effects of symbionts (Table 5). Moreover, feeding in different stages is not the only starting point to assess a potentially beneficial effect. Comparisons between symbiotic and aposymbiotic olive fruit flies have shown that aposymbiotic flies have decreased fecundity, and their larvae cannot develop on unripe olives (Ben-Yosef et al. 2014, 2015). NGS characterization of symbiotic communities, along with the metabolic profile of *Citrobacter* sp., and accompanying insecticide resistance assays in *B. dorsalis*, demonstrated that this bacterium enhances its host insecticide resistance (Cheng et al. 2017). The use of aposymbiotic and reinfected *B. dorsalis* females revealed that symbionts influence mate selection (Damodaram et al. 2016), while aposymbiotic *B. dorsalis* flies exhibit a different foraging behaviour than symbiotic ones (Akami et al. 2019). Also, it is worth noting that commensal microbiota were shown recently to modulate larval foraging behaviour, development rate, and pupal production in *B. tryoni* (Morimoto et al. 2019). Finally, using bacterial cultures of different species in attractancy assays showed that *A. ludens*, *B. dorsalis*, *B. zonata*, *Rhagoletis mendax* Curran, and *Z. cucurbitae* adults can be attracted by various bacterial cultures (Maccollom et al. 1992; Reddy et al. 2014; Wang H. et al. 2014; Hadapad et al. 2016).

## 6. SYMBIONTS AS UNIVERSAL PROBIOTICS: REALITY OR ILLUSION?

Until now, results are encouraging but sometimes contradicted by other studies. Variations and inconsistencies among studies show that “universal probiotics” for the SIT-important species are feasible, at least for Tephritidae, but not yet applicable. The main origins of controversy are described below:

- *Obvious ones:* For several reasons it is not easy to compare directly the findings of different studies: the experiments are conducted with different insect species or strains, and use different bacterial species/isolates and feeding strategies (larval stages versus adults). Moreover, not all studies answer the same questions, e.g. they shed light on different parameters that are considered important in SIT application (such as rearing productivity or biological quality).

*Table 5. Summary of non-probiotic effects of symbiotic communities on Tephritidae*

| Species | Material | Methodology | Main effect | Reference |
|---|---|---|---|---|
| *Ceratitis capitata* | Laboratory colony | Symbiotic vs aposymbiotic flies | Aposymbiotic females showed an accelerated oviposition rate under restricted diets<br>Symbionts affect mating latency time | Ben-Yosef et al. 2008b |
| | Laboratory colony | Symbiotic vs aposymbiotic flies | Aposymbiotic adults have decreased longevity under restricted diets | Ben-Yosef et al. 2008a |
| *Bactrocera oleae* | Wild material | Symbiotic vs aposymbiotic flies | Aposymbiotic females have decreased fecundity under various restricted diets | Ben-Yosef et al. 2010 |
| | Wild material | Symbiotic vs aposymbiotic flies | Aposymbiotic females have decreased fecundity under various restricted diets | Ben-Yosef et al. 2014 |
| | Wild material | Symbiotic vs aposymbiotic flies | Gut microbiota are important for larvae when developing in unripe olives, but not in ripe olives | Ben-Yosef et al. 2015 |
| *Bactrocera dorsalis* | Wild material | Bacterial cultures as baits | Adults are attracted to bacterial isolates (autoclaved) | Wang H. et al. 2014 |
| | Laboratory colony | Aposymbiotic and reinfected females | Symbionts influence mate selection | Damodaram et al. 2016 |
| | Laboratory colony | NGS characterization of symbiotic communities, culture and metabolic profile of *Citrobacter* | *Citrobacter* sp. enhances insecticide resistance | Cheng et al. 2017 |
| | Laboratory colony | Symbiotic vs aposymbiotic flies | Suppression of the microbiome results in changes of foraging behaviour of males and females | Akami et al. 2019 |
| *Bactrocera tryoni* | Laboratory colony | Assessment of the effect of vertically and horizontally acquired bacteria to development | The presence of both vertically and horizontally acquired bacteria improves larval foraging behaviour, development rate, and pupal production | Morimoto et al. 2019 |
| *Bactrocera zonata* | Laboratory colony | Attractancy assays for bacterial cultures | *Enterobacter* sp. and *Klebsiella* sp. are highly attractive for adults | Reddy et al. 2014 |
| *Zeugodacus cucurbitae* | Laboratory colony | Cultivation of bacteria and attractancy assays | Adults are attracted to bacterial isolates | Hadapad et al. 2016 |
| *Rhagoletis mendax* | Wild material | Traps with *P. agglomerans* | Adults are more attracted to traps baited with *P. agglomerans* | Maccollom et al. 1992 |

Even in cases where the same questions are asked, the methodological set-up may be quite different, e.g. differences in rearing practices, and how male mating competitiveness is evaluated in laboratory, semi-field or field conditions. For all these reasons, results may vary or in some cases even be contradictory.

- *Differences in rearing practices:* Even in cases where the same insect strains (or strains sharing the same origin) and similar bacterial isolates have been used, results derived from different laboratories could be different. An important parameter influencing data interpretation is how each laboratory defines "standard (or control) rearing conditions". In the larval diet, different substrates that can influence the nutritional value of the control diet are being used. Diets such as wheat-bran, carrot-based or liquid diets are employed in various laboratories, and the percentage of yeast and other ingredients may vary as well. Diet has a strong effect on shaping the associated microbiota, as was shown recently in *B. tryoni, C capitata,* and *Z. cucurbitae* (Asimakis et al. 2019; Augustinos et al. 2019; Woruba et al. 2019). These aspects could strongly affect the results, and consequently the probiotic role assigned to the bacteria; some probiotic supplements could be beneficial only under specific conditions, e.g. in nutritionally poor diets.
- *Developmental stage specificity and dynamics:* Comparing the findings of related studies shows that the same (or similar) bacterial taxa do not consistently have the same effects. Bacterial taxa show great variations in the various developmental stages (Ben Ami et al. 2010; Aharon et al. 2013; Andongma et al. 2015; Augustinos et al. 2015). Over the last decade, many studies have tried to shed light on the characterization of gut symbiotic communities of tephritids, either conducted with long-time laboratory-adapted fly populations or with ones recently introduced into the laboratory. These studies suggest that gut symbiotic communities, although relatively simple in their structure, consisting of few bacterial taxa, show great variations in the different developmental stages at lower taxonomic levels (Ben Ami et al. 2010; Aharon et al. 2013; Andongma et al. 2015; Augustinos et al. 2015). These differences are usually evident at the taxonomic level of bacterial species or genus, may reflect the development of preferential relationships, and may explain why specific bacteria do not "retain" their beneficial effects when provided in different feeding stages (such as larval stages versus adults).

  From a different point of view, it is possible that different isolates belonging to the same bacterial species may not have the same effect. This can be related to either "real" differential properties of these strains, due to restricted but crucial genetic variability, or their "false" identification as being genetically close, due to the genotyping methodology used. Advances, that allow the complete metagenomic analysis at a relatively low cost, are expected to solve such potential misidentification issues.
- *Methodological and experimental set-up:* A major issue when trying to compare results regarding the effect of adult probiotic feeding on SIT-important parameters, such as male mating competitiveness and longevity under stress conditions, comes from experimental assumptions and limitations. The use of live instead of dead bacteria, the nutritional profile of the control diet, and the wild

populations used for mating competitiveness studies are important parameters that may affect both the results and their interpretation.

## 7. CONCLUSIONS

Insects have established coevolved complex and sophisticated symbiotic associations with diverse microorganisms, including bacterial species. Recent advances in molecular biology and microbiology, sequencing methods, and bioinformatics have enabled the characterization of these symbiotic interactions, indicating the importance of the symbionts in many aspects of insect host biology, ecology, and evolution (including nutrition, mating behaviour, reproduction, and immunity). These advances in insect symbiosis enable us to exploit these symbiotic associations to support improving SIT applications against insect pests of agricultural, veterinary, and human health importance. In particular, there appears to be considerable potential in harnessing insect gut-associated microbiota to improve mass-rearing cost-effectiveness, as well as the biological quality (including male mating competitiveness) of the resulting sterile insects for SIT operational programmes.

## SUMMARY

The sterile insect technique (SIT) is being applied against tephritid fruit fly pests in many areas of the world. Currently, fruit fly factories have the capacity to produce and sterilize several billion (thousand million) sterile insects per week, and to make them available for shipment to their final destinations. At sterile fly emergence and release facilities, the emerging flies are fed and held close to maturity, and then collected for area-wide release. While much research effort has been invested in improving mass-rearing and quality-control procedures at the fly-factory level, the post-factory handling of sterile flies has received much less attention. However, research (conducted mainly from 2000 onwards) has focussed on developing and validating ways of improving sterile male performance through better management during a critical period (starting with the arrival of pupae at the fly emergence and release facility and ending with the release of the sterile flies in the field). This chapter summarizes the progress made on this subject for fruit fly species (in the genera *Anastrepha, Bactrocera*, *Ceratitis* and *Zeugodacus*) against which the SIT is being applied. To increase the effectiveness of fruit fly SIT programmes, exposure of sterile males to nutritional, hormonal, and semiochemical treatments has been assessed for improvement in sterile male performance, and enhancement of post-factory handling and release methods. Incorporation of protein and juvenile hormone into pre-release *Anastrepha* spp. diets significantly accelerates sterile male maturation and improves sexual performance in several species. Improved or probiotic adult diets and semiochemical treatments using ginger root oil or citrus oils in *Ceratitis capitata*, and methyl eugenol and raspberry ketone in *Bactrocera* and *Zeugodacus* species, significantly increase sterile male mating competitiveness. Some of these treatments and improvements have been transferred to, and are being applied routinely in, operational programmes. However, these efforts need to be further strengthened to assess the interaction among different environmental and holding conditions, treatments and release systems, and to improve further the performance of mass-produced sterile males, a critical component of increasing the effectiveness of operational programmes.

## 1. INTRODUCTION

Application of the sterile insect technique (SIT), as part of an area-wide integrated pest management (AW-IPM) approach against fruit fly (Diptera: Tephritidae) pests, is gaining momentum, with active programmes targeting fruit fly pest species of economic importance in North, Central and South America, Europe, Middle East, Asia, Africa, and Australia (Enkerlin, this volume). There are now fruit fly factories with the capacity to mass-rear several billion (thousand million) sterile male insects per week (for detailed information, note the World-Wide Directory of SIT Facilities (DIR-SIT 2020)) (Parker, Mamai et al., this volume). After irradiation (Bakri et al., this volume), pupae are shipped to their destination, where they are processed in fly emergence and release facilities (FAO/IAEA 2017; Dowell et al., this volume). Several days after emergence, feeding, and sexual maturation, the sterile flies are released in the field, where the sterile males are expected to mate with, and transfer an effective ejaculate to, wild females. An industrial process, consisting of numerous complex steps, is required to achieve a biological goal (Pereira et al. 2013a).

Several quality-control and quality-assurance protocols have been developed to ensure that the released flies fulfil a series of minimum quality standards (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume), but exigencies of the industrial process often affect the biological qualities of the final product.

The mass-rearing of fruit flies up to the pupal stage, including sterilization, takes place in specially designed insect factories (where insects are adapted to indoor conditions) (FAO/IAEA 2018). As late-stage pupae, the mass-reared insects are irradiated and shipped to fly emergence and release facilities, where they are placed in containers/release bags, boxes or towers for adult emergence, feeding and holding

before they are released into target field areas (FAO/IAEA 2017; Dowell et al., this volume). During this critical period at these facilities, there is the potential to manipulate sterile males in a manner that will improve their mating success in the field (Pereira et al. 2013a). This includes optimizing the provision of nutritional supplements (Yuval et al. 2002), and hormonal (Teal et al. 2000) and semiochemical treatments (Shelly 2001), as well as the holding conditions and preparations for release (Tween and Rendón 2007; USDA/APHIS 2009; FAO/IAEA 2017).

An FAO/IAEA Coordinated Research Project (CRP) on "Improving Sterile Male Performance in Fruit Fly SIT Programmes" was conducted (2004 to 2009) with the objective of increasing the effectiveness of the SIT by improving the performance of sterile males after mass-rearing. The outcome of this research network, involving 31 research institutes in 17 countries, was summarized by Pereira et al. (2013a). Since then, the fields of applying nutritional, hormonal, and semiochemical treatments, as well as the work on optimizing pre-release conditions and operations that improve male quality, have continued to evolve. This chapter summarizes the current status in improving the performance of sterile males after mass-rearing.

## 2. NUTRITIONAL SUPPLEMENTS

In a majority of tephritid fruit flies, both males and females are anautogenous, emerging as adults with mostly undeveloped gonads. Both sexes rely on foraging during early adult life to ingest carbohydrates to fuel metabolic activities, as well as nitrogenous compounds for gonadal and accessory gland development and pheromone production (Epsky and Heath 1993; Hendrichs and Prokopy 1994). Thus, the survival and reproductive success of males in most tephritid species of economic importance is linked to the access to these nutrients. Nevertheless, several fly emergence and release facilities still do not include nitrogenous compounds in the pre-release diet of sterile males. The sterile males are generally offered a pre-release diet of only sugar or highly concentrated sucrose, presented in agar blocks, which are also a source of water (USDA/APHIS 2009; FAO/IAEA 2017).

The results on assessing nutritional supplements in the last 20 years are described thematically in more detail, together with relevant references, in Table 1. Studies on four genera of tephritids (*Anastrepha*, *Bactrocera*, *Ceratitis* and *Zeugodacus*) indicate that providing yeast hydrolysate to males, as part of the pre-release diet in the days following emergence, can enhance male sexual performance and reduce wild-female remating, although the optimal dosage and most practical form of presentation in an operational context still needs to be refined further (Kaspi and Yuval 2000; Aluja et al. 2001; Pérez-Staples et al. 2007; Haq et al. 2010a, 2014a). The implementation of such a strategy depends on a specific understanding of the nutritional needs of males (while feeding on nitrogenous sources in nature), trade-offs between sexual performance and survival, and operational costs and benefits. Another benefit of providing a protein-enriched pre-release diet is that sterile males will be much less attracted to nitrogenous baits in sprays or traps (such as Biolure or CeraTrap) that are increasingly being used for monitoring wild females when releasing only sterile males (Vargas et al. 2002; Maor et al. 2004; Vargas and Prokopy 2006; San Andrés et al. 2009).

*Table 1. Summary of results, by thematic subject, of research conducted on the incorporation of nutritional supplements into pre-release diets and male performance of tephritids of the genera* Anastrepha, Bactrocera, Ceratitis, *and* Zeugodacus *(modified after Pereira et al. 2013a, reproduced with permission)*

| Subject addressed | Summary of results |
|---|---|
| Natural food | • Males feeding on orange (*Citrus sinensis* (L.) Osbeck) or mango (*Mangifera indica* L.) exhibit modified pheromone composition and improved sexual performance in *Anastrepha ludens* (Loew) and *Anastrepha obliqua* (Macquart) (Liedo et al. 2013; Utgés et al. 2013).<br>• Male pheromone production is quantitatively affected by natural food in *A. ludens* and *A. obliqua* (Liedo et al. 2013).<br>• Wild *Bactrocera tryoni* (Froggatt) males feeding on natural sources of food mature much slower than wild males with access to yeast hydrolysate; effects of diet are far less pronounced in mass-reared males (Weldon and Taylor 2011). |
| Dietary supplements | • Adding yeast hydrolysate (protein) to the pre-release diet significantly improves male sexual performance in *Anastrepha fraterculus* (Wiedemann), *A. ludens, A. obliqua, Anastrepha serpentina* (Wiedemann), *Anastrepha striata* Schiner, *Anastrepha suspensa* (Loew), *Bactrocera correcta* (Bezzi), *Bactrocera dorsalis* (Hendel), *B. tryoni, Bactrocera zonata* (Saunders), *Ceratitis capitata* (Wiedemann), *Ceratitis quilicii* De Meyer, Mwatawala, and Virgilio, and *Zeugodacus cucurbitae* (Coquillett) (Taylor and Yuval 1999; Aluja et al. 2001; Shelly et al. 2005; Pérez-Staples et al. 2007, 2008b, 2009; Yuval et al. 2007; Pereira et al. 2009, 2010a, b, 2011; Haq et al. 2010a, b, 2013; Haq and Hendrichs 2013; Liedo et al. 2013; Liendo et al. 2013; Orankanok et al. 2013; Quilici et al. 2013; Ndzana et al. 2016; Shelly 2017a).<br>• Adding protein to the pre-release diet improves male weight and body protein content in *A. suspensa, B. dorsalis,* and *Z. cucurbitae* (Haq et al. 2010c; Pereira et al. 2011; Reyes-Hernández et al. 2019). It also enhances male sexual organ development in *B. dorsalis* (Reyes-Hernández et al. 2019) and *B. tryoni* (Pérez-Staples et al. 2011).<br>• Some studies in *C. capitata* found no difference between sugar-only fed males and yeast hydrolysate-fed males in terms of mating success (Shelly and McInnis 2003; Shelly et al. 2003, 2006a), survival rate (Shelly and McInnis 2003), and dispersal (Shelly and Edu 2008a). |
| Ratio of protein to carbohydrates | • Protein in dry diets early in adult life contributes to male sexual performance, but the ratio of protein to carbohydrates affects survival in a dose-dependent manner in *A. fraterculus, A. ludens*, *A. obliqua,* and *B. tryoni* (Prabhu et al. 2008; Gómez et al. 2013; Liedo et al. 2013; Liendo et al. 2013; Utgés et al. 2013).<br>• As little as 4–10% of protein content in the pre-release diet is sufficient to significantly enhance male sexual performance in *A. fraterculus*, *A. ludens*, *A. obliqua,* and *B. tryoni* (Pérez-Staples et al. 2008a; Pereira et al. 2011; Gómez et al. 2013; Liedo et al. 2013; Liendo et al. 2013). |
| Optimal formulation/ delivery system | • A formulation based on soy whey protein and incorporating methoprene has been developed and tested for *A. suspensa* (Teal et al. 2013).<br>• Concurrently, a commercial product "Mubarqui" containing protein has been introduced in a dry formulation into release programmes for *A. ludens* and *A. obliqua* (Gómez and Teal 2010; Gómez et al. 2013). |
| Dietary effects on remating inhibition | • Feeding on a nitrogen-rich food significantly improves sterile male ability to inhibit female remating in *A. fraterculus* (Abraham et al. 2011, 2012, but see Abraham et al. 2013), *Bactrocera carambolae* Drew and Hancock, *B. tryoni, C. capitata,* and *Z. cucurbitae* (Pérez-Staples et al. 2008a; Gavriel et al. 2009; Haq et al. 2014a). |

*Table 1. Continued*

| Subject addressed | Summary of results |
|---|---|
| Interaction between diet, dispersal, and survival | • Protein-rich diets are related to a lower resistance to starvation in *A. fraterculus, A. ludens*, *A. obliqua, C. capitata,* and *B. tryoni* (Levy et al. 2005; Utgés et al. 2013; Reynolds et al. 2014; Juárez et al. 2019).<br>• Adult diets that contain protein are related to lower recapture rates in protein-baited traps, and to reduced mobility and longevity in sterile *A. ludens*, *A. obliqua* (but not in *C. capitata*) males (Maor et al. 2004; San Andrés et al. 2009; Utgés et al. 2013).<br>• Protein-rich post-teneral diets do not adversely affect the survival and movement in the field of sterile *B. tryoni* and *C. capitata* males (Yuval et al. 2007; Gavriel et al. 2010; Taylor et al. 2013b).<br>• In the laboratory, protein-fed males live significantly longer than only sugar-fed males of *B. tryoni* and *Z. cucurbitae* (Haq et al. 2010b; Taylor et al. 2013b). The same was found for *A. ludens* and *A. obliqua* when the sugar:yeast ratio is 9:1 or 24:1, but not with a 3:1 ratio (Liedo et al. 2013).<br>• In the laboratory, *B. tryoni* fed a 3:1 ratio of sugar:yeast for two days following emergence are more vulnerable to starvation if food is unavailable in the following days than if the flies are fed only sugar (Taylor et al. 2013a). |
| Contribution of micro-organisms | • Supplementing post-teneral diets with symbiotic bacteria reduces mass-rearing costs and increases mating success in fruit fly pests in SIT application (Cáceres et al. 2019; Noman et al. 2020; Raza et al. 2020; Augustinos et al., this volume).<br>• The significant contribution of micro-organisms to the fitness of non-sterile *Bactrocera oleae* (Rossi) and *C. capitata* has been established (Behar et al. 2008a; Ben-Yosef et al. 2008a, b, 2010, 2014, 2015; Yuval et al. 2013; Stathopoulou et al. 2021). In *B. oleae,* the survival of males feeding on a probiotic diet is reduced compared with those fed on a sugar-only diet (Sacchetti et al. 2014).<br>• Presence of commensal bacteria affect mate-selection behaviour of *B. dorsalis* (Damodaram et al. 2016).<br>• Manipulating the microflora of sterile males by supplementing probiotic bacteria in adult diets can improve male sexual performance in *C. capitata* (Niyazi et al. 2004; Behar et al. 2005, 2008a, b, c; Ben-Ami et al. 2010; Gavriel et al. 2011; Hamden et al. 2013; Kyritsis et al. 2019), and in *A. obliqua*, *B. dorsalis,* and *Z. cucurbitae* (Rull et al. 2015; Yao et al. 2017; Cai et al. 2018; Stathopoulou et al. 2021). |
| Irradiation effects mitigated by dietary supplements | • Feeding with live bacteria can restore ecological fitness of males that were sterilized through irradiation in *B. dorsalis* (Cai et al. 2018).<br>• Diet and irradiation affect micro-organism diversity in *B. tryoni* (Woruba et al. 2019).<br>• Microflora diversity in laboratory-reared and irradiated males is low when compared with wild *C. capitata* males (Ben-Ami et al. 2010).<br>• Irradiation significantly diminishes the ability of *B. tryoni* flies to tolerate protein deprivation (Pérez-Staples et al. 2007; Taylor et al. 2013b). |

Studies on the nutritional requirements of males of several tephritid species and their effect on sexual success (involving various species targeted by the SIT) have reached different levels of understanding. For example, studies in nature on *C. capitata* provide evidence that wild males feed on sources of protein (Hendrichs and Hendrichs 1990; Hendrichs et al. 1991). However, while providing yeast hydrolysates or other sources of protein together with sugar to males generally improved mating success in *Anastrepha*, *Bactrocera,* and *Zeugodacus* (Table 1), in *Ceratitis* there is a variance in results reflecting the influence of other factors.

Different effects of protein-enriched diets have been found, in some cases reducing male survival and dispersal; the adverse effect was reduced when the protein ratio in the diet was lowered, but there are no clear procedural guidelines available currently for this and other target species (Blay and Yuval 1997; Shelly and Kennelly 2003; Shelly and McInnis 2003; Prabhu et al. 2008; FAO/IAEA 2017).

Moreover, there is evidence that the integrity of micro-organisms in the male gut contribute to fly health, foraging behaviour, and sexual performance (Yuval et al. 2013; Akami et al. 2019; Deutscher et al. 2019; Juárez et al. 2019; Augustinos et al., this volume). Adult diets enriched with different probiotic bacteria strains showed in irradiated *C. capitata* males a positive effect on the mating competitiveness, mating latency time, sexual calling or longevity (Niyazi et al. 2004; Behar et al. 2008b; Ben Ami et al. 2010; Gavriel et al. 2011).

Nevertheless, despite the increasing scientific evidence of the benefits of nutritional supplements, currently, possibly out of convenience, sterile males are often offered only a pre-release diet of highly concentrated sucrose, normally presented in an agar block, but without any protein addition. The formulation and testing of optimal pre-release diets, containing sugar, protein and probiotic bacteria (and possibly other ingredients) in proportions that will result in enhanced sterile male performance in the field, is still not fully understood and accepted by many operational programme managers, and remains to be implemented. However, the Moscamed programme in Mexico uses the Mubarqui adult diet for *C. capitata*, which contains proteins from diverse plant seeds (Gómez et al. 2013), and the Moscafrut programme in Mexico releases sterile *A. ludens* and *A. obliqua* flies fed with a 24:1 sugar:yeast adult diet. Managers should evaluate this matter in relation to their fruit fly species and decide on the most appropriate pre-release adult diet and feeding regime for sterile males.

## 3. HORMONAL TREATMENTS

Age is a significant factor affecting sexual signalling and reproduction in numerous tephritid species (Liedo et al. 2002; Pereira et al. 2013a). Being anautogenous, tephritid fruit fly pests in nature require a considerable period (over a week in *Ceratitis* spp.; 2–3 weeks in *Anastrepha* spp., *Bactrocera* spp., and *Zeugodacus* spp.) under adequate nutritional conditions to reach sexual maturation (Teal et al. 2013). Even though mass-rearing inadvertently selects for accelerated sexual maturation, the discrepancy between the standard holding periods at fly emergence and release facilities, and the time to reach sexual maturation, poses a significant problem for SIT programmes. After release but before reaching full sexual maturation, sterile males suffer significant losses due to predation and other causes, resulting in far fewer males surviving to maturity and copulation (Hendrichs and Hendrichs 1998; Rao et al. 2013; González-López et al. 2016).

Holding sterile males for more days also increases the management costs, and additional investment is required to expand the infrastructure at fly emergence and release facilities (USDA/APHIS 2009). In addition, in those programmes where sterile males are released together with sterile females, longer holding times are not advisable because males may start mating before release, thereby transferring their

limited sperm to sterile females. Clearly, the development of cost-effective methods to accelerate sexual maturity in released flies would have a significant positive impact on the efficacy of the SIT (Teal et al. 2000).

Research on several tropical *Anastrepha* species shows that juvenile hormone is a critical hormone, regulating sexual maturity and sexual signalling in these species (Table 2). Furthermore, application of juvenile hormone or the analogues, methoprene or fenoxycarb, can accelerate reproductive development and sexual signalling in sterile males of some species (Pereira et al. 2013a, b; Teal et al. 2013). Significant progress has been made in evaluating hormonal treatments using methoprene to accelerate reproductive development and, in some cases, improving further male sexual performance. It was found in many species (but not all) that sterile males become sexually mature significantly earlier when hormone exposure is included in pre-release holding protocols, but this optimum effect was only achieved when hormone treatment was coupled with a protein-enriched pre-release diet (Teal et al. 2013). Thus, irradiated males become sexually mature earlier and can be released earlier. This advantage is particularly important for SIT application against those species of *Anastrepha* spp., *Bactrocera* spp., and *Z. cucurbitae* that have long pre-copulatory periods. The improvement in male sexual performance by applying hormonal treatments was extensively studied in *Anastrepha* spp., *B. dorsalis*, *B. tryoni*, *Z. cucurbitae,* and *C. capitata*, although in these last two species no benefits were found. In addition, considerable progress was made in developing delivery systems to treat large numbers of flies with methoprene in operational programmes. The results on hormonal treatment assessments are described thematically in more detail, together with the relevant references, in Table 2.

*Table 2. Summary of results, by thematic subject, of research conducted on the effects of pre-release application of hormonal treatments on male performance of tephritids of the genera* Anastrepha, Bactrocera, Ceratitis, *and* Zeugodacus *(modified after Pereira et al. 2013a, reproduced with permission)*

| Subject addressed | Summary of results |
|---|---|
| Age of sexual maturation of males determined | • Age at which laboratory-reared and/or wild males of *A. fraterculus*, *A. ludens*, *A. obliqua*, *A. serpentina*, *A. striata*, *A. suspensa*, *B. correcta*, *B. dorsalis*, *B. tryoni*, *C. capitata, C. quilicii,* and *Z. cucurbitae* become sexually mature has been determined (Teal and Gómez-Simuta 2002; Aluja et al. 2009; Pereira et al. 2009; Gómez et al. 2013; Obra and Resilva 2013; Orankanok et al. 2013; Pereira et al. 2013b; Quilici et al. 2013; Segura et al. 2013; Sookar et al. 2013; Adnan 2019). |
| Improvement in reproductive maturation and sexual performance | • Hormonal treatment has positive effects on accelerating reproductive development and improving sexual performance in *A. fraterculus*, *A. ludens*, *A. obliqua*, *A. serpentina*, *A. striata*, *A. suspensa*, *B. tryoni,* and *Z. cucurbitae* (Aluja et al. 2009; Pereira et al. 2009; Segura et al. 2009; Haq et al. 2010a, 2013; Gómez et al. 2013; Collins et al. 2014; Gomez-Simuta et al. 2017; Bachmann et al. 2017; Adnan et al. 2020a).<br>• In *A. fraterculus,* the accessory glands of males treated with methoprene are less effective at inhibiting female remating than males not treated with methoprene (Abraham et al. 2012).<br>• There is no effect of hormonal treatment on either *B. dorsalis* or *C. capitata* (Faria et al. 2008; Shelly et al. 2009). |

*Table 2. Continued*

| Subject addressed | Summary of results |
|---|---|
| Interaction of protein and hormone treatments on sexual performance | • Males treated with hormone and feeding on a protein-rich diet effectively compete with mature wild males, but at significantly earlier ages for *A. fraterculus*, *A. ludens,* and *A. suspensa* (Gómez and Teal 2010; Liendo et al. 2013; Pereira et al. 2013b; Gómez et al. 2013).<br>• Males of *Z. cucurbitae* treated with methoprene and with access to a protein-rich diet have an accelerated maturation and improved mating performance (Haq et al. 2010a). |
| Interaction of irradiation and hormone treatments on sexual maturity | • Interaction of irradiation and hormone treatments has no negative effects on male acceleration of reproductive maturity in *A. fraterculus*, *A. ludens*, *A. obliqua*, *A. suspensa,* and *B. tryoni* (Teal et al. 2007; Segura et al. 2013; Adnan et al. 2019).<br>• Females mated with 6-day-old, methoprene-treated *A. fraterculus* males remated more and sooner than females mated with naturally matured males, either sterile or wild (Abraham et al. 2013). |
| Optimal dose to accelerate maturation | • Optimal hormone treatment dose has been determined using topical application for *A. fraterculus*, *A. ludens*, *A. obliqua*, *A. suspensa,* and *Z. cucurbitae* (Teal et al. 2007; Pereira et al. 2009; Segura et al. 2013; Haq et al. 2010a). |
| Response in males and females to hormone treatments | • A differential response in males and females to methoprene exposure is found in *A. fraterculus* and *B. tryoni;* it can act as a physiological sexing system, minimizing matings between sterile males and sterile females (Segura et al. 2009; Liendo et al. 2013; Adnan et al. 2019).<br>• No differential response to methoprene exposure has been found in *A. ludens* males and females (Pereira et al. 2013b). |
| Development of delivery systems other than topical application | • Agar-based diet with 5–10% protein along with 0.05% methoprene, tested with *A. ludens* and *A. suspensa*, produces large amounts of waste and is not cost-effective (Pereira et al. 2013b; Teal et al. 2013).<br>• Pupal dipping in an acetone bath containing 0.05% methoprene, tested with *A. fraterculus*, *A. ludens,* and *A. suspensa*, does not impact emergence or survival and accelerates reproductive development, although it can cause humidity problems when handling large volumes of pupae (Liendo et al. 2013; Pereira et al. 2013b; Segura et al 2013).<br>• Pupal dipping is impractical due to health risks, safety, and disposal issues associated with the use of acetone (Pereira et al. 2013a).<br>• A dry sugar–protein pre-release diet containing 0.0015% methoprene for *A. ludens* and *A. obliqua* is practical and effective in accelerating development when applied in operations of fly emergence and release facilities (Gómez et al. 2013).<br>• Dietary treatment with mosquito larvicide containing methoprene in a dry 3:1 mix of sugar to yeast is effective in *B. tryoni* (Adnan 2019; Adnan et al. 2019, 2020a). |
| Efficient large-scale methods for incorporation of JH analogues | • The dry sugar–protein–methoprene diet method was assessed in a 3500-ha pilot area for *A. ludens* in Mexico (Gómez et al. 2013).<br>• The hormone and protein delivery system has tested positive in the "Moscafrut" action programme to control *A. ludens* fruit flies in Mexico (Gómez et al. 2013). |

## 4. SEMIOCHEMICAL TREATMENTS

Males of most *Anastrepha* spp., *Bactrocera* spp., *Ceratitis* spp., and *Zeugodacus* spp. are attracted to natural compounds known as semiochemicals (Cunningham 1989; Kumaran et al. 2013; Segura et al. 2018). Some species are known to sequester these chemicals from plants for use in pheromone synthesis; for example, ingestion of methyl eugenol (ME) from natural sources by males of *B. dorsalis* and *B. carambolae* results in the storage of metabolites in the rectal gland and their subsequent release as part of the pheromone during fanning performed in courtship (Tan and Nishida 1996). Providing sterile *B. dorsalis* males with a source of ME to feed on before release could increase their mating competitiveness (Shelly et al. 2005). ME feeding may also confer a survival advantage because metabolites appear to act as a very potent allomone to deter vertebrate predators (Wee and Tan 2001).

In the case of *C. capitata*, exposure to ginger (*Zingiber officinale* Roscoe) root oil (GRO) or citrus oils (by contact or vapour) enhances considerably the mating competitiveness of wild or mass-reared males (Katsoyannos et al. 1997; Papadopoulos et al. 2001; Shelly 2001).

Exposure to guava (*Psidium guajava* L.) fruit volatiles increased the mating success of both wild and laboratory *A. fraterculus* males relative to non-exposed males (Vera et al. 2013). Also, citrus and grapefruit volatiles have potential to enhance the mating performance of male *A. ludens* and *A. fraterculus* (Bachmann et al. 2015; Morató et al. 2015). However, the attraction and mating enhancing effects of the semiochemicals so far found for *Anastrepha* effects are not as dramatic as seen with *Bactrocera*, *Ceratitis* and *Zeugodacus,* and suggest that similar compounds may exist in the *Anastrepha* ecological sphere and await discovery (Segura et al. 2018).

The research carried out in this area has helped to understand these phenomena, to extend them to other species, and to transfer and validate them under the large-scale conditions of action SIT programmes. Results obtained recently confirmed the compounds that have the potential to improve sterile male performance of target fruit flies in the field, and some additional ones have been identified. These chemicals are the following:

- Methyl eugenol (ME) is found in more than 450 plant species (Tan and Nishida 2012); exposure to holy basil (*Ocimum tenuiflorum* L.) and sweet basil (*Ocimum basilicum* L.) oils, as well as ripe fruits of tropical almond (*Terminalia catappa* L.), improve the mating competitiveness of several *Bactrocera* species, including *B. correcta, B. dorsalis*, and *B. zonata* males (Cunningham 1989; Tan and Nishida 1996; Quilici et al. 2004; Shelly et al. 2005; Shelly and Edu 2007; Obra and Resilva 2013; Orankanok et al. 2013).
- Cuelure (CUE) has potential to enhance the performance of *B. tryoni* and *Z. cucurbitae* males (Weldon et al. 2008; Shelly 2019).
- Raspberry ketone (RK) and/or zingerone (ZG) have potential to enhance attraction, maturation, and sexual performance of *B. tryoni* and *Z. cucurbitae* males (Khoo and Tan 2000; Akter et al. 2017b; Akter and Taylor 2018; Shelly 2019); however, Fezza and Shelly (2018) did not find that access to a RK-supplemented diet at an early age accelerated sexual maturation.

- Ginger root oil (GRO) and α-copaene enhance male performance of *C. capitata* and *C. quilicii* (Shelly 2001; Shelly et al. 2007a; Quilici et al. 2013).
- Manuka oil (rich in α-copaene) from the manuka tree (*Leptospermum scoparium* Forst and Forst) of New Zealand improves *C. capitata* male mating (Shelly et al. 2008c).
- Orange oils (OO) and other citrus oils enhance male performance of *C. capitata* and *C. quilicii*, and potentially *A. fraterculus* (Shelly 2001; Shelly et al. 2007a; Quilici et al. 2013; Vera et al. 2013).
- Citrus, grapefruit, and guava fruit volatiles have potential to enhance the mating performance of male *A. ludens* and *A. fraterculus* (Vera et al. 2013; Bachmann et al. 2015; Morató et al. 2015).

The results of assessing semiochemical treatments, together with the relevant references, are described in more detail in Table 3.

Methodologies for exposing large numbers of *C. capitata* males through GRO or citrus-oil aromatherapy on a large scale in adult-holding rooms at fly emergence and release facilities have been developed (Shelly et al. 2007c, 2008a). They are now applied routinely in a very cost-effective manner in on-going SIT programmes in Australia, Croatia, Guatemala, Israel, Mexico, Spain, and the USA, resulting in a significant improvement in mating performance of the released sterile males.

It is envisaged that providing sterile *Bactrocera* spp. males with a source of ME to feed on before release will place them on at least an even "playing field" against wild males, thereby potentially reducing the number or frequency of sterile males released (Barclay et al. 2014; Vargas et al. 2014). However, the common methods for holding sterile males in fly emergence and release facilities do not enable the feeding of ME to millions of adult flies after their emergence. Additionally, exposure to ME must be brief in view of ME toxicity when access is unlimited. In response, Tan and Tan (2013) designed an automated ME machine prototype for briefly feeding ME to sterile males on a belt impregnated with ME after which they are brushed off and collected. However, this approach is not really suitable for industrial processing of millions of sterile males. Considering this scenario at fly emergence and release facilities, Haq et al. (2014b, 2015, 2018) demonstrated that ME application by aromatherapy also enhanced the mating success of males of *B. carambolae* and *B. dorsalis*, finding that ME aromatherapy produced a mating boost as early as one day after exposure. This alternative method appears to have merit for adoption but needs to be evaluated at larger scales in fly emergence and release facilities.

Another advantage of exposure to ME is that it reduces significantly the response of sterile males to ME in male annihilation treatments, thus potentially enabling the simultaneous application of the SIT and male annihilation (Barclay et al. 2014; Vargas et al. 2014). Similarly, pre-release exposure to RK has been found to diminish the subsequent response of *B. tryoni* to CUE sources (Akter et al. 2017a).

*Table 3. Summary of results, by thematic subject, of research conducted on the effects of pre-release application of semiochemical treatments on male performance of tephritids of the genera* Anastrepha, Bactrocera, Ceratitis, *and* Zeugodacus. *Abbreviations explained in the text (modified after Pereira et al. 2013a, reproduced with permission)*

| Subject addressed | Summary of results |
|---|---|
| Search for semiochemical compounds that affect *Anastrepha* spp. male sexual performance | • Grapefruit volatiles increase male mating competitiveness in *A. ludens* (Morató et al. 2015).<br>• Male mating performance of *A. fraterculus* is positively affected by exposure to guava volatiles (Vera et al. 2013; Bachmann et al. 2015).<br>• Exposure to lemon fruit volatiles enhances male mating performance in *A. fraterculus,* but there are also some detrimental effects (Vera et al. 2013). GRO exposure also increases male mating success in *A. serpentina* (Flores et al. 2011). |
| Assessment of various semiochemicals in enhancing *Bactrocera* spp. male performance | • Exposure to basil oil (containing ME) has a positive effect on sterile male mating performance of *B. dorsalis* (Obra and Resilva 2013).<br>• Exposure to ripened tropical almond fruit (containing ME) enhances *B. dorsalis* male mating success (Shelly and Edu 2007).<br>• Exposure to ME significantly improves sterile male mating performance of *B. correcta* and *B. dorsalis* (Shelly et al. 1996, 2005, 2008b, 2009, 2010a; Hee and Tan 1998; Shelly and Edu 2008b; Ji et al. 2013; Orankanok et al. 2013).<br>• Some negative effects on the male ejaculate have been found in *B. dorsalis* (Reyes-Hernández et al. 2019).<br>• ME-mediated male mating enhancement also found in *Bactrocera cacuminata* (Hering) (Raghu and Clarke 2003), *B. carambolae* (Wee et al. 2007), and *Bactrocera umbrosa* (F.) (Wee et al. 2018).<br>• Exposure to commercial ME, and interaction with post-teneral adult diet, increases male mating performance of *B. correcta* and *B. dorsalis.* For both species, ME-treated sterile males are being released in operational SIT programmes in Thailand (Orankanok et al. 2013).<br>• Sterile males, feeding on commercial ME prior to release, induce higher egg sterility in wild populations than control sterile males denied ME (McInnis et al. 2011).<br>• Exposure to ME does not affect dispersal or survival of sterile flies of *B. correcta* and *B. dorsalis* (Orankanok et al. 2013). |
| Assessment of various semiochemicals in enhancing male performance of other *Bactrocera* spp. | • Feeding on CUE increases *Z. cucurbitae* mating success (Shelly and Nishimoto 2017). Feeding on RK enhances male mating performance of *Z. cucurbitae,* but only for one day post-feeding (Shelly 2000, 2019). However, exposure to zingerone has no effect on *Z. cucurbitae* male mating competitiveness (Shelly 2017b) or a positive effect only one day after exposure (Inskeep et al. 2019).<br>• Exposure to CUE and RK increases the mating competitiveness of *B. tryoni*, but young males fail to respond to CUE, OO, and GRO (Weldon et al. 2008; Kumaran et al. 2014a; Akter et al. 2017b).<br>• *B. tryoni* feeding on yeast hydrolysate enhances attraction to CUE (Weldon et al. 2008), and on CUE increases male signalling, female attraction, and male mating success (Kumaran et al. 2013, 2014b).<br>• *B. tryoni* feeding on RK (or caffeine supplements) promotes male early sexual maturation, greater mating success and increased multiple mating, without affecting remating receptivity in females (Akter et al. 2017b; Akter and Taylor 2018; Khan et al. 2019; Adnan et al. 2020b; GFV 2020).<br>• Exposing sexually mature adult *B. oleae* to the aroma of α-pinene significantly increases the mating performance over non-exposed males and females (Gerofotis et al. 2013; Kokkari et al. 2017). |

*Table 3. Continued*

| Subject addressed | Summary of results |
|---|---|
| Optimal age and feeding dose for *Bactrocera* spp. male flies | • For *B. dorsalis,* Obra and Resilva (2013) determined the optimal age and duration of ME exposure, and the diurnal pattern of ME feeding.<br>• Optimal age of ME exposure, in combination with nutritional supplements, has been determined for sterile *B. correcta* and *B. dorsalis* males (Orankanok et al. 2013). |
| Effect of semiochemical treatments on *C. capitata* sexual signalling (pheromone calling) | • GRO-exposed males exhibit higher rates of sexual signalling compared with unexposed *C. capitata* males (Shelly 2001, 2007a, 2008, 2010b; Papadopoulos et al. 2006), although the effect found by Briceño et al. (2007) was lower.<br>• During sexual courtship GRO-exposed sterile males exhibit the same wing-beat duration as wild males, and this is shorter than for unexposed sterile males (Morelli et al. 2013).<br>• Exposure to OO and their components increases sexual signalling and mating success of *C. capitata* males (Shelly et al. 2004, 2006b; Kouloussis et al. 2013); this effect is more pronounced in protein-fed males, independent of age (Katsoyannos et al. 2004; Papadopoulos et al. 2006; Kouloussis et al. 2013, 2017).<br>• Exposure to volatiles of leaves of the tea tree increases mating competitiveness of sterile *C. capitata* males (Shelly and Epsky 2015). |
| Identification of active compounds other than GRO, and their effects on sexual performance of *C. capitata* | • Exposure to oranges and grapefruits (*Citrus paradisi* Macfad) improves mating success of male *C. capitata* (Papadopoulos et al. 2001; Shelly 2009).<br>• Exposure to fruits of five citrus species shows that sweet oranges confer the highest increase in male mating performance of *C. capitata*. Exposure to commercial citrus oils is similarly effective (Kouloussis et al. 2013).<br>• There is a positive effect of OO components (limonene, β-myrcene, and linalool) on protein/sugar-feeding males, but not on sugar-only-feeding males (Kouloussis et al. 2013).<br>• A mixture of limonene, β-myrcene, linalool, α-pinene, and geraniol (1:1:1:1:1) is very effective for both wild and sterile *C. capitata* male sexual performance (Kouloussis et al. 2013). |
| Effects of GRO and OO exposure to *C. quilicii* | • Exposure of sugar-only-fed *C. quilicii* males to GRO and OO increases their mating performance, but only GRO increases the mating performance of protein/sugar-fed males (Quilici et al. 2013). |
| Effect of semiochemical treatments on *C. capitata* female remating frequency | • The remating frequency of *C. capitata* females mated with sterile males treated with 0.1 ml/$m^3$ GRO is similar to that of females mated with wild males and lower than that of females mated with sterile unexposed males (Morelli et al. 2013). |
| Effect of semiochemical treatments on *C. capitata* dispersal and survival | • Field dispersal and survival rates of GRO-exposed sterile males are similar to those of unexposed *C. capitata* males (San Andrés et al. 2009; Paranhos et al. 2010; Juan-Blasco et al. 2013). |
| Determining the dose of semiochemical exposure for *C. capitata* | • OO compounds show positive effects in increasing *C. capitata* male performance (Kouloussis et al. 2013). The optimal dose of OO exposure was determined for both protein-sugar and sugar-only *C. capitata* adult diets. There are positive effects of OO for a protein-sugar diet, but no effects for a sugar-only diet (Kouloussis et al. 2013). |
| Optimal delivery system for large-scale semiochemical application in *Ceratitis* spp. SIT programmes | • The cost-effective GRO exposure to sterile males has been established, and is in operation in several *C. capitata* SIT programmes (Shelly et al. 2007b, c, 2008a; Paranhos et al. 2008, 2013; Juan-Blasco et al. 2013; Silva et al. 2013; Steiner et al. 2013). |

## 5. CONCLUSIONS

Extensive laboratory and semi-field tests indicate that pre-release diets nutritionally enriched with some yeast hydrolysate improve sterile male performance; they can result in increased SIT efficiency for a majority of fruit fly species tested, and thus can be adopted by programme managers, although some confounding factors still need to be better understood for some target species, as well as the optimal protein to carbohydrate ratios and physical form of diet provision. Also, a better understanding of the effect of nutrition during the larval stage on the nutritional requirements of the adults is needed (Aluja et al. 2009).

In addition, hormone therapy coupled with feeding protein to adults generally accelerates male maturation and sexual performance among *Anastrepha* species and some *Bactrocera* species, with no negative side effects on survival. Furthermore, in some species, methoprene treatment has increased male mating and competitiveness. However, negative effects have been recorded on female remating in *A. fraterculus*, and on sperm storage and male ejaculate in *B. dorsalis*.

Accelerated male maturation and improved sexual performance can represent significant cost savings associated with infrastructure investment, reduced holding periods for sterile males prior to release, and fewer males dying in the field before reaching sexual maturity. Validation in a few fruit fly species has resulted in some of these major breakthroughs being incorporated into several action programmes, although others, for technical or practical reasons, have been reluctant to incorporate these innovations into their operations.

The development of cost-effective semiochemical treatments that improve sterile male sexual signalling and attractiveness to wild females, and thus overall mating performance, is highly desirable. Implementation of aromatherapy has significantly increased the effectiveness of on-going programmes integrating the SIT against C. *capitata*. On the other hand, while the incorporation of semiochemical treatments for *Bactrocera* species appears to be feasible, it still remains to be implemented operationally; major benefits result from the simultaneous field application of male annihilation to eliminate wild males. Thus, incorporating an ME pre-release treatment has considerable potential to significantly increase sterile to wild male overflooding ratios (Barclay et al. 2014; Vargas et al. 2014; Hendrichs and Robinson, this volume). For some *Anastrepha* species and other species such as *B. oleae* and *C. quilicii,* potentially similar semiochemicals and fruit volatiles probably exist, and more research funding should be allocated to find and investigate them (Segura et al. 2018).

Also critical for sterile male performance are the processes to which sterile males are subjected at fly emergence and release facilities (USDA/APHIS 2009; FAO/IAEA 2017; Dowell et al., this volume), the environmental conditions in which they are held, and their interaction with exposure to hormonal, nutritional and/or semiochemical treatments (Pereira et al. 2013a). In addition, holding densities (Díaz-Fleischer et al. 2009; Andress et al. 2015), the timing of providing treatments in relation to fly age and sexual maturation, and holding periods are also very relevant. For example, results indicate that in *C. capitata* sexing strains, the release of older males, closer to sexual maturity, is preferable; this results in more flies reaching mating age in the field (McInnis et al. 2013). Species with longer pre-copulatory

maturation periods, such as *Anastrepha* spp. and *Bactrocera* spp., benefit more from combined nutritional and hormonal treatments to reduce long pre-release holding periods (Gómez et al. 2013; Pereira et al. 2013a).

Assessing the interaction of different environmental and holding conditions, combined with hormonal, nutritional, and/or semiochemical treatments, on sterile fly performance has resulted in the routine application of GRO under large-scale holding conditions in operational *C. capitata* SIT programmes (USDA/APHIS 2009; FAO/IAEA 2017). Also, a hormone-and-protein-delivery system has been developed for the SIT programmes suppressing *A. ludens* fruit fly populations in Mexico (Gómez et al. 2013). Furthermore, the effects on fly performance (in terms of dispersal and recapture) of different sterile fly shipping and release systems, and their interaction with hormonal, nutritional, and/or semiochemical treatments, have been assessed for some aerial- and ground-release systems for *C. capitata* (Paranhos et al. 2010, 2013; Silva et al. 2013). Finally, parameters of sterile-fly quality, treatments, space, labour, and economics were assessed and compared at eight fly emergence and release facilities in Guatemala, Mexico, and the USA (USDA/APHIS 2009); there is a good baseline on which to improve.

Knowledge gained so far, and the practical procedures developed, are transferable, at least in part, to other insect pest species with management programmes that include an SIT component. Nevertheless, much remains unknown about the effects of manipulating the environmental holding conditions, either separately or in combination with nutritional, hormonal, and semiochemical treatments, on subsequent male quality in the field. Release methods, while operationally convenient, are not always optimal in terms of sterile male performance (Dowell et al., this volume). For example, the effect of chilling (to immobilize) collected flies for aerial release can at least temporarily affect sterile male flight ability and mating competitiveness, including pheromone quantity or quality (Andress et al. 2012, 2013; Shelly et al. 2013; Arredondo et al. 2016). Therefore, the effects and interactions of the different processes, treatments, and systems need to be further assessed and refined, tailoring them to the biology of each target fruit fly species.

## SUMMARY

The accelerating development of modern biotechnology, resulting continuously in new molecular techniques, has significantly increased the potential of understanding and modifying the genetic information in various organisms, from mammals to many insect species. Key molecular techniques developed over the past three decades include classical transformation technologies via transposable elements, and site-specific genome modification techniques using recombinases, both permitting the introduction of new genes or regulatory elements into the genome and their subsequent modification or (partial) removal. Tools like TALEN or CRISPR permit the precise editing of genomes at pre-defined positions, ranging from single-base changes to the knockout of complete genes, or the introduction of exogenous genetic material. On the other hand, RNA interference (RNAi) does not change genomic information but instead influences gene expression levels to various degrees, including complete suppression of expression. All of these tools can be used to develop or refine insect strains to improve the efficiency of existing pest control programmes, or to develop new SIT-based control systems. Modern biotechnology tools are being exploited to develop self-limiting as well as self-sustaining approaches. While the latter aim at population replacement strategies using gene drive or *Wolbachia*-based approaches and are mostly developed for vector and disease control, SIT-based control systems are self-limiting strategies that are supposed to leave no ecological footprint. Molecular technologies have already been applied to create sterility and sexing strains, and to introduce stable markers for monitoring in several insect species including the Mediterranean fruit fly, Mexican fruit fly, Australian sheep blow fly, New World screwworm, pink bollworm, and various mosquito species. Moreover, several of these strains have undergone an initial evaluation under mass-rearing scenarios or in open-field trials, although their wider adoption has so far been slow in view of low public acceptance of transgenic approaches, and the regulatory requirements and approvals that are required in most countries for their application.

## 1. INTRODUCTION

Successful implementation of the sterile insect technique (SIT) for insect pest control depends on several key factors, e.g. mass-rearing and irradiating the target pest insect. Both procedures can result in reduced biological quality and/or mating competitiveness of the produced sterile insects (Hooper 1972; Bloem et al. 2004; Andreasen and Curtis 2005; Parker and Mehta 2007; Guerfali et al. 2011). Besides sterilization by irradiation, it has been shown that sometimes other sterilization strategies, such as transgenic or symbiont-based approaches, also come at a cost to the mating competitiveness of the sterilized males (Catteruccia et al. 2003; Irvin et al. 2004; Bourtzis et al. 2014; Häcker et al. 2017; Kyritsis et al. 2019). This reduction in biological quality and mating competitiveness of the produced sterile insects influences the efficacy of SIT projects, and thereby their cost and feasibility. However, it should be noted that recent developments on insect symbiosis have shown that probiotic bacterial applications may significantly improve the biological quality (including male mating competitiveness) of the sterile insects (Ben Ami et al. 2010; Hamden et al. 2013; Ras et al. 2017; Augustinos et al., this volume).

Another important and challenging factor is the efficient and robust sex separation (sexing) for male-only releases. In the case of agricultural pests, this may affect the efficiency in action as well as the economy in production (Hendrichs et al. 1995; Cáceres et al. 2004). However, in the case of vector species such as mosquitoes, male-only releases are a prerequisite for SIT applications since females bite, blood-feed, and transmit major human pathogens. Therefore, efficient sexing on a large scale is needed (Gilles et al. 2014; Parker, Mamai et al., this volume).

For some insect pest species, morphological traits or markers have been developed in the last decades that help to discriminate between sterile and wild

insects in the target area, and in particular to separate sexes. This is the case for the naturally occurring pupal size difference between males and females in some *Aedes* mosquitoes, which is being exploited for mechanical sexing (Bellini et al. 2018; Zacarés et al. 2018), although it is difficult to achieve a 100% pure separation and is very labour-intensive when applied at larger scales. Genetic sexing strains (GSS) (Franz et al., this volume) offer the possibility of efficient and large-scale sexing. This has been achieved for several species including *Anastrepha ludens* (Loew) (Orozco et al. 2013), *Bactrocera carambolae* Drew and Hancock (Isasawin et al. 2014), *Bactrocera dorsalis* (Hendel) (Isasawin et al. 2012), *Ceratitis capitata* (Wiedemann) (Franz 1995), *Anopheles albimanus* Wiedemann (Kaiser et al. 1978), *Anopheles arabiensis* Patton (Yamada et al. 2012), *Aedes albopictus* (Skuse) (Lebon et al. 2018), and *Zeugodacus cucurbitae* (Coquillett) (McInnis et al. 2004), and for some species is successfully being used for sexing under mass-rearing conditions in current SIT programmes, while being further developed for others.

These genetic GSS were created by mutagenesis and classical genetics, and are based on two components: a mutation that can be used as a selectable recessive marker, and the placement of the dominant wild-type allele of this marker on the Y-chromosome that links it to the male sex. Thus, the males are heterozygous for the recessive mutation and therefore are phenotypically wild type, while in homozygous females, the mutation can be used for sorting or killing the females. However, genetic sexing systems produced by mutagenesis and classical genetics in one species might not be transferable to another species, as the underlying mutation is often a random product. Molecular technologies offer new perspectives and strategies to create insect strains possessing the traits needed for an effective pest control programme (Häcker and Schetelig 2018). These modern biotechnologies involve transgenic as well as non-transgenic approaches, and can be applied to optimize existing, or develop new, strategies and strains, thereby complementing classical approaches. Molecular technologies can be used either as stand-alone techniques, e.g. sexing systems for population suppression (Häcker and Schetelig 2018), or could be combined with the SIT and/or the incompatible insect technique (IIT) (Bourtzis et al. 2016; Lees et al., this volume), to improve efficiency and to increase the range of pest insects targeted by pest control strategies that are environment-friendly. Moreover, once the mechanism of a classical GSS is uncovered, molecular technologies could help build similar non-transgenic sexing strains in other species.

In support of and as an alternative to classical genetic approaches, molecular technologies and IIT approaches are being exploited to create population suppression, sexing, or marking systems in several insect pest species. The current key molecular technologies that can be used to support the SIT, including site-specific recombination technologies, genome editing tools, and RNA interference (RNAi), are described below. Insect transformation via transposable elements is also included; it is still a major tool to produce transgenic insects in spite of the fast development and adaptation of new biotechnologies, which may help address the needs of population suppression programmes against major insect pest species effectively and in a relatively short period of time. Progress made in developing such molecular technologies for use in the SIT is described, including their

preliminary applications in the first field trials, as well as the regulations and public acceptance issues that must be considered when transgenic insects are involved.

To assist in understanding the terminology used in this chapter, some definitions are given in Box 1.

*Box 1. Definition of Terms*

*Biotechnology*
Any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use (Cartagena Protocol on Biosafety to the Convention on Biological Diversity - CBD 2000, 2007).

*Cytoplasmic Incompatibility (CI)*
In diplo-diploid organisms, a phenomenon that is expressed as embryonic lethality in matings between *Wolbachia*-infected males and females that are either uninfected or infected with a different *Wolbachia* strain. CI is induced by symbiotic bacteria such as *Wolbachia* (Bourtzis et al. 2003).

*Endogenous vs Exogenous*
Endogenous substances, processes or genes originate from within an organism; correspondingly, exogenous substances, processes or genes originate externally.

*Gene Drive*
A phenomenon in genetics, where the inheritance of a gene does not follow the Mendelian rules of being inherited to 50% of the offspring of heterozygous parents. Instead, inheritance of this gene is favourably biased, resulting in more than 50% of the offspring carrying the respective gene. Thus, the gene spreads into a population even if it has no benefit for the organism. Natural forms of gene drives exist and can function by copying themselves onto homologous chromosomes during meiosis. Thus, every gamete carries the gene instead of only 50%. Gene drives can be used to replace a wild population with a genetically altered one that has desired traits (like pathogen refractoriness in insect vectors). Gene drives could be designed in different ways making them self-limiting or self-sustaining.

*Genetically Modified (GM)*
Any organism whose genetic material has been altered in a way that cannot be the product of natural mutation or recombination, using molecular biology/genetic engineering techniques.

*Incompatible Insect Technique (IIT)*
A method to suppress insect pest populations analogous to the SIT; it is based on the mechanism of cytoplasmic incompatibility (CI) (see above).

*Living Modified Organism (LMO)*
Any living organism that possesses a novel combination of genetic material obtained through the use of modern biotechnology (CBD 2000; FAO/IPPC 2017).

*Modern Biotechnology*
The application of: (a) *in vitro* nucleic acid techniques, including recombinant deoxyribonucleic acid (DNA) and direct injection of nucleic acid into cells or organelles; or (b) fusion of cells beyond the taxonomic family, that overcome natural physiological reproductive or recombination barriers and that are not techniques used in traditional breeding and selection (CBD 2000; FAO/IPPC 2017).

*Non-GM*
An organism, in which the genetic material has been altered in a way that could occur also naturally by mating and/or by natural recombination (Article 2(2) of the Directive 2001/18/EC of the European Parliament and of the Council of 12 March 2001 on the deliberate release into the environment of genetically modified organisms and repealing Council Directive 90/220/EEC).

*Non-Transgenic Approaches*
Pest control strategies not involving transgenic insects.

*Population Replacement*
A target population of pest insects is replaced by another population of the same species that has been specifically altered to bear new traits or remove old ones. For example, a genetically modified mosquito species that is refractory to pathogen infections could be generated and used to replace a natural population. This could be achieved by using a gene drive mechanism (see above).

*Box 1. Definition of Terms -- Continued*

*RNA Interference*
A conserved biological process to suppress gene expression or translation by neutralizing the corresponding messenger RNA (mRNA) molecules. Two types of small RNA molecules, microRNAs (miRNAs) and small interfering RNAs (siRNAs) in combination with several protein factors play a major role in identifying and cleaving the target mRNA. RNAi functions as an important defence mechanism against parasitic nucleotide sequences, but has also an important role in the regulation of gene expression. While transient RNAi is limited to a certain time-window in the development of one generation of an insect, systemic RNAi is inherited to the next generation(s).

*Self-Limiting vs Self-Sustaining*
In self-limiting control strategies like the SIT, the released insects do not persist in the environment. Therefore, repeated releases are necessary to control a population. In contrast, in a self-sustaining approach, the released insects are able to persist in the wild and spread into the wild populations. Therefore, a one-time release may be sufficient, depending on several factors including the fitness and spreading capacity of the released insects, so that the replacement of the target population happens in a reasonable amount of time.

*Sex Ratio Alteration*
Manipulation of the natural sex ratio of 50% male and 50% female offspring in favour of one of the sexes. This can be a means to produce male-only strains of a transgenic insect, and can be achieved by manipulating the sex determination pathways in embryonic development, for example by using RNAi or by influencing sex-specific splicing.

*Transgenic Insect*
Relating to an insect, whose genome has been altered by the transfer of an exogenous gene. Transgenesis can occur naturally or by genetic engineering techniques. A transgenic insect created by genetic engineering falls in the category of GM insects.

*Transgenic Population Suppression*
Molecular technologies, that use foreign DNA transferred into an organism, resulting in the death of its progeny, fall under the term transgenic population suppression. While the effects of the SIT and transgenic population suppression are similar, i.e. population size reduction, the modes of action are different. In the SIT, population reduction is achieved through sterile matings by the released males due to irradiation-induced damaged sperm, but in transgenic approaches the population reduction is often achieved by overexpression of lethal genes at certain stages of development in the offspring of the released males (Robinson, this volume).

## 2. KEY MOLECULAR TECHNOLOGIES FOR POPULATION CONTROL

### *2.1. Transposable Elements*

A frequently applied method to produce transgenic insects is using highly efficient class II transposable elements like *piggyBac* (Cary et al. 1989; Elick et al. 1996; Handler et al. 1998; Handler and Harrell 1999), *Minos* (Franz and Savakis 1991; Loukeris et al. 1995), *Mariner* (*Mos1*) (Jacobson et al. 1986; Lidholm et al. 1993) or *Hermes* (Warren et al. 1994; O'Brochta et al. 1996). These DNA transposons consist naturally of a transposase-encoding gene flanked by inverted repeat sequences. These elements integrate into short, defined, and randomly distributed recognition sequences in the insect genome (Handler 2002). For all transposons used commonly as molecular tools, the transposase gene has been separated from its flanking inverted repeats to create a bipartite system -- the transposase source in one vector (helper element) and a second transformation vector containing the inverted repeats flanking the transgene construct to permit its genomic integration (Handler and

Harrell 1999, 2001a). To increase the germline transformation frequency, mutagenesis approaches have resulted in hyperactive transposases with the *piggyBac* variant hyPBase being highly active in diverse insects (Eckermann et al. 2018). Due to their broad applicability to many different insect species, bipartite transposable systems have become a key tool for insect transgenesis (Wimmer 2003); nevertheless, they have some drawbacks. Although the rapid loss of the non-integrated helper element separates the integrated transgenes from a source of transposase, the possibility of unwanted transgene remobilization in the presence of an endogenous transposase remains. In addition, the essentially random integration of the transposable elements into the genome can lead to insertional mutagenesis that can be deleterious or lead to reduced fitness of the transgenic strains (Woodruff 1992; Spradling et al. 1995; Catteruccia et al. 2003; Scolari et al. 2008; Häcker et al. 2017). Moreover, the inserted transgene is subject to genomic position effects, where the presence of nearby enhancers or silencers influences transgene expression levels (Schetelig et al. 2009b). Transgenes inserted close to heterochromatic regions may also be subject to silencing due to position effect variegation, i.e. the inactivation of a gene in some cells through its abnormal juxtaposition with heterochromatin. Some of these effects can be avoided by using chromatin insulator elements (Horn and Wimmer 2003; Sarkar et al. 2006; Scolari et al. 2008) or site-specific genome modification tools.

### *2.2. Site-Specific Recombination Systems*

Site-specific recombination (SSR) systems have become important and universal molecular tools for targeted genome modification (Bode et al. 2000; Kolb 2004; Coates et al. 2005). These systems depend on a recombinase enzyme that recognizes and binds short recombination sequences, induces double-strand breaks in the central crossover region of the recombination sequence, and catalyses strand exchange. The Cre recombinase was the first enzyme to be established as a molecular tool, and it paved the way for genomic modification and conditional gene targeting in mammalian cell lines and mouse models (Sauer and Henderson 1988; Orban et al. 1992; Tsien 2016). SSR systems commonly used in mammals and insects include Cre/*lox* from the *Escherichia coli* phage P1 (Siegal and Hartl 1996, 2000), Flp/*FRT* from the two-micron plasmid of *Saccharomyces cerevisiae* (Andrews et al. 1986), as well as the phiC31/*att* derived from the *Streptomyces* phage phiC31 (Thorpe and Smith 1998). Recombination sequences of the tyrosine recombinases Cre and Flp (*lox* and *FRT*, respectively) range from 34 to 48 nucleotides, and consist of two nearly identical motifs with an inverted-repeat symmetry flanking an eight base pair (bp) central crossover sequence where the recombination takes place (Fig. 1A). Site-specific genomic integration occurs by recombination between a single sequence integrated in the genome (acceptor site) and a second sequence (donor site) in a vector containing the transgene of interest. Recombinase protomers bind to each inverted-repeat motif at both recombination sites to catalyse the strand exchange, leading to donor vector integration. The donor and acceptor sequences are identical in case of the *lox* and *FRT* sites. Thus, they remain unchanged upon completion of the recombination and are available for

successive reactions (Fig. 1B). Site preservation, however, also has a disadvantage: donor vector integration results in duplication of the recombination sites in the genome, flanking the transgene construct (Turan et al. 2013; Häcker et al. 2017). As the reaction between cis elements is thermodynamically and kinetically favoured over the reaction in trans, the excision reaction is much faster than the integration, leading to a very low frequency of stable integration events (Baer and Bode 2001; Wimmer 2005; Häcker et al. 2017). Adding the donor plasmid in excess can help to push the reaction towards the product (Turan and Bode 2011; Turan et al. 2013).

The recombination mechanism of serine recombinases, such as the phiC31 system, follows the same basic rules as Cre and Flp. However, it strongly differs on the sequence level and the architecture of the recombination sites. The recombination sequences recognized by the phiC31 integrase are termed *attP* and *attB*, and are much longer (about 200 bp) than the *lox* or *FRT* sites. The two arms of the *att* sites flank a 3-base-pair crossover region, and in contrast to *lox* and *FRT* sites they share only limited inverted repeat symmetry (Fig. 2A). Moreover, the *attP* and *attB* sites share no sequence identity besides the central crossover region. Therefore, recombination between *attP* and *attB* results in different and incompatible products, *attL* and *attR*, making it a one-time unidirectional reaction (Fig. 2B). In principle, however, the reverse reaction should be possible in combination with additional factors/enzymes that are naturally used by the phage to excise its DNA from the host genome.

Site-specific integration into insect genomes has been established with the integrase phiC31 for several species besides drosophilids, including two *Aedes* species (Nimmo et al. 2006; Labbé et al. 2010; Franz et al. 2011), *Anopheles gambiae* Giles (Meredith et al. 2011, 2013; Isaacs et al. 2012), and the Mediterranean fruit fly (Schetelig et al. 2009b). The drawback of site-specific integration via a single recombination site is the integration of the complete donor vector at the genomic target site, including bacterial resistance genes and regulatory elements within the vector backbone that may be unnecessary or even interfere with transgene expression.

The discovery that the mutation of certain bases in the central crossover region of *lox* or *FRT* sites does not abolish cleavage by the recombinase, but renders the sites incompatible with the wild-type sites (Hoess et al. 1986; Lee and Saito 1998; Missirlis et al. 2006), opened up new possibilities (Fig. 1A). These mutant sites recombine with an identical (homospecific) mutant site with equal efficiency as two wild-type sites, while the interaction between sites with non-identical core sequences (heterospecific sites) is usually prevented. This was the basis for a more sophisticated targeting strategy, the recombinase-mediated cassette exchange (RMCE). Cre- or Flp-RMCE is based on the double-recombination between two pairs of heterospecific recombination sites, flanking DNA cassettes in the donor vector and the genomic target site (Schlake and Bode 1994; Turan and Bode 2011), which leads to a cassette exchange instead of complete donor plasmid integration (Fig. 1C). Both, Flp/*FRT* and Cre/*lox*-based RMCE, were first demonstrated in *Drosophila melanogaster* Meigen (Horn and Handler 2005; Oberstein et al. 2005; Wimmer 2005).

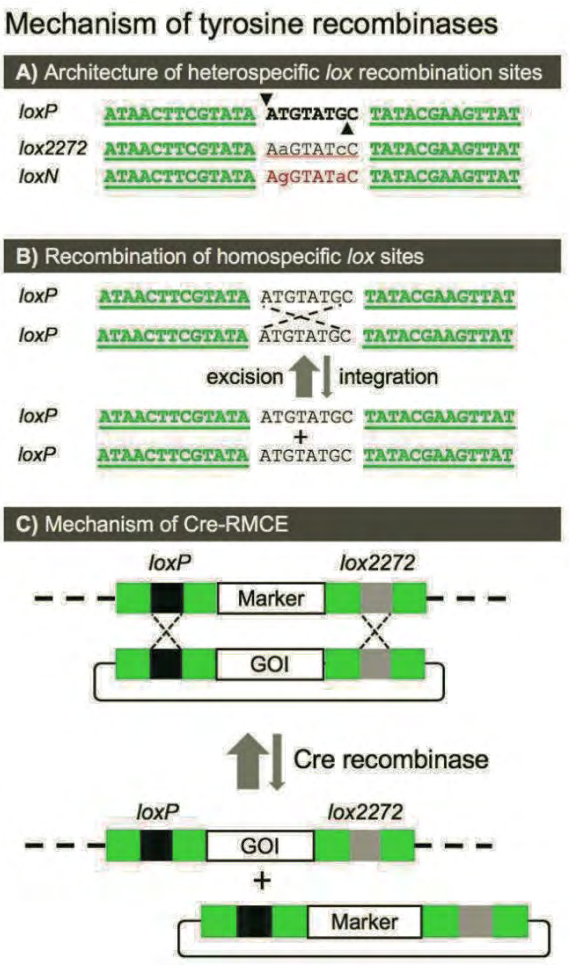

*Figure 1. Comparison of site-specific recombination mechanisms catalysed by tyrosine recombinases. A) General architecture of heterospecific recombination sequences recognized by the tyrosine recombinases shown exemplarily for the Cre/lox system. Note that the FRT sites of the Flp/FRT system show the same architecture and differ only in the recognition sequence. Inverted repeat sequences flanking the 8-bp core are underlined. The heterospecific lox sites differ from the wildtype loxP site in the core sequence (mutations shown in lowercase). Only two of the existing heterospecific lox sites are shown here, B) Due to the inverted repeat architecture of the lox sites, their sequence is preserved upon recombination between identical (homospecific) sites and the reaction is reversible by the Cre recombinase. Due to the thermodynamically and kinetically favoured reaction between recombination sites in cis, the excision reaction is much faster than the integration, resulting in a very low integration efficiency. C) The genomic landing site for Cre-RMCE consists of a marker cassette flanked by heterospecific lox sites. Recombination with the corresponding homospecific sites, that flank the gene of interest (GOI) cassette on the donor plasmid, leads to a cassette exchange. Recombination sites are preserved, the reaction is reversible.*

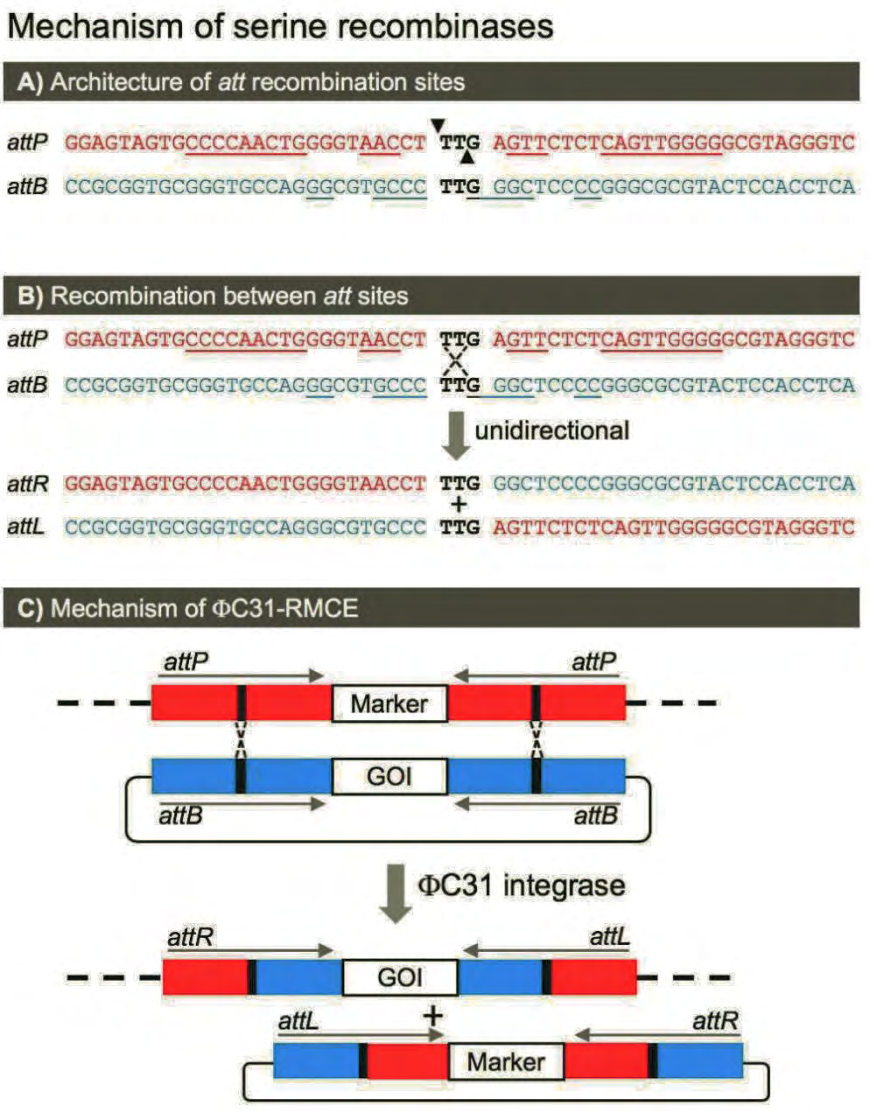

*Figure 2. Comparison of site-specific recombination mechanisms catalysed by serine recombinases. A) Serine recombinase recognition sequences show very limited repeat symmetry (underlined bases). Moreover, the attP and attB recombination sites recognized by the phiC31 recombinase share almost no sequence identity besides the 3 bp central crossover region (TTG). B) In contrast to lox sites (and tyrosine recombinases in general), the recombination between attP and attB results in incompatible attL and attR sites that can't recombine anymore. The absence of the reverse reaction enhances the integration efficiency via att sites in contrast to lox of FRT sites. C) For phiC31-RMCE, the genomic marker cassette is flanked by inverted attP sites, while the donor cassette is flanked by inverted attB sites. Recombination leads to cassette exchange but is irreversible due to the resulting incompatible attR and attL sites that are not recognized by the phiC31 integrase enzyme.*

Until now, Cre/*lox*-RMCE was applied to only two non-drosophilid species, the tephritid *Anastrepha suspensa* (Loew) (Schetelig and Handler 2013a) and the mosquito *Aedes aegypti* (L.) (Häcker et al. 2017). Very recently, it was also achieved in the highly invasive pest *Drosophila suzukii* (Matsumura) (Schetelig et al. 2019). The functionality of Flp-RMCE was also demonstrated in the silkworm *Bombyx mori* (L.) (Long et al. 2012). In both systems, Cre- and Flp-RMCE, the heterospecific sites are restored after recombination. Therefore, both approaches allow for the repeated manipulation of the same target site including the reversion of the reaction.

The difference in the sequence of *attP* and *attB* sites, and the resulting directionality of the reaction, abolishes the need for heterospecific sites for RMCE using the phiC31 system. For phiC31-RMCE, the genomic acceptor cassette is flanked by *attP* sites in inverted orientation, while the donor cassette is flanked by inverted *attB* sites (Fig. 2C). This advantage, however, comes with certain shortcomings, such as the lack of control over the directionality of the cassette integration. Moreover, as for the donor plasmid integration via *att*-sites, the phiC31-RMCE is a one-time, unidirectional reaction due to the resulting incompatible *attR* and *attL* sites. PhiC31-RMCE has been successfully demonstrated for *D. melanogaster* (Bateman et al. 2006), *B. mori* (Long et al. 2013), and *Ae. aegypti* (Haghighat-Khah et al. 2015). A different approach combines phiC31 and Flp- or Cre-recombination to achieve cassette exchange in a two-step process via a donor plasmid integration intermediate (iRMCE) (Haghighat-Khah et al. 2015).

### *2.3. Genome Editing Methods*

Genome editing methods use engineered nucleases, "molecular scissors", to site-specifically modify the genome, making use of two naturally occurring and conserved DNA repair mechanisms in the cell. The nucleases create double-strand breaks (DSBs) at desired locations in the genome. These are then repaired, either by the cell's homology directed repair (HDR) or the non-homologous end-joining (NHEJ) pathway, which results in targeted mutations. Molecular biologists have engineered four families of nucleases as genome editing tools: meganucleases, zinc finger nucleases (ZFNs), transcription activator-like effector-based nucleases (TALEN), and the clustered regularly interspaced short palindromic repeats (CRISPR)/Cas system.

Meganucleases have long recognition sequences (>14 bp) which makes them very specific. By modifying their recognition sequence through protein engineering, their rather limited choice of target sequences can be expanded (Sussman et al. 2004; Arnould et al. 2006; Rosen et al. 2006). Protein engineering, however, can be time-consuming and costly.

The concept behind ZFNs and TALENs is based on a fusion protein consisting of a non-specific DNA cutting enzyme linked to peptides that recognize specific DNA sequences, such as zinc fingers and transcription activator-like effectors (TALEs). The DNA cleavage domain used for both systems is the restriction endonuclease *Fok*I (Kim et al. 1996; Li et al. 2011) that is active in yeast, plant and animal cells (Wood et al. 2011). The DNA binding domain (ZNF or TALE) can be

engineered to bind nearly any desired DNA sequence. Both methods have been applied successfully to edit a variety of insect genomes (Bozas et al. 2009; Takasu et al. 2010, 2013; Liu et al. 2012; Aryan et al. 2013; Smidler et al. 2013), and they have been shown to work with satisfying efficiency and precision. However, as for meganucleases, the number of naturally occurring target sites is limited, and the engineering of the proteins to target new sites is cumbersome and costly, preventing the widespread use of these systems.

The CRISPR/Cas9 system has recently emerged as a very powerful tool for targeted genome editing in a variety of organisms. CRISPR/Cas is the prokaryotic equivalent of acquired immunity. CRISPR are repeat-spacer sequences found to date in approximately 40% and 90% of the sequenced bacterial and archaea genomes, respectively. The short spacer DNA originates from foreign DNA, e.g. virus or plasmid, and has been acquired by the bacteria and archaea as part of the immune response to a previous infection. These spacer DNAs are separated by short repeat sequences. Small clusters of Cas (CRISPR associated) genes are located next to the repeat-spacer array (for comprehensive explanations and illustrations, see Horvath and Barrangou 2010, Marraffini and Sontheimer 2010 or Bhaya et al. 2011). These repeat-spacer arrays are transcribed and processed into short CRISPR RNAs (crRNA) by nucleases of the Cas family of proteins. The crRNAs associate with other Cas proteins into ribonucleoprotein complexes that recognize foreign DNA by sequence complementarity with the crRNA. The foreign DNA is then cut by a Cas nuclease activity in a way similar to RNA interference in eukaryotic organisms (Marraffini and Sontheimer 2010), thus conferring immunity against infection with previously encountered infective agents.

Three different CRISPR/Cas systems are known so far, consisting of Cas proteins with different functions. The most used nuclease for genome editing is the multifunctional Cas9 protein from the type II system. Cas9 requires both the crRNA and a transactivating CRISPR RNA (tracrRNA) to function. For more convenient use, scientists engineered the crRNA and tracrRNA into one single-guide RNA (sgRNA) (Jinek et al. 2012). By adjusting the sequence of the sgRNA, the CRISPR/Cas9 system can be programmed easily to target any desired genomic location that is in the vicinity of a so-called PAM (protospacer adjacent motif) sequence (Jinek et al. 2012). The system can be used to knock out existing genes or add new DNA sequences, and has been adapted to different species. One drawback of CRISPR/Cas is the potential off-target effects, requiring very careful sgRNA design. However, the system is under constant adjustment and improvement, e.g. engineering the Cas protein (Kleinstiver et al. 2016), characterizing and adapting new Cas proteins, and engineering sgRNAs (Fu et al. 2014; Nowak et al. 2016). For insects, CRISPR/Cas was first developed in *D. melanogaster* in 2013 (Ren et al. 2013; Yu et al. 2013; Bassett et al. 2014), and by now has been adapted for several other species including *Ae. aegypti* (Kistler et al. 2015), *An. gambiae* (Hammond et al. 2016), *B. mori* (Wang et al. 2013; Ma et al. 2014), *Gryllus bimaculatus* De Geer (Awata et al. 2015), *Danaus plexippus* (L.) (Markert et al. 2016), and *Spodoptera litura* (F.) (Bi et al. 2016), and was recently transferred to the highly invasive agricultural pests *C. capitata* (Meccariello et al. 2017; Aumann et. al. 2018) and *D. suzukii* (Li and Scott 2016; Kalajdzic and Schetelig 2017; Li and Handler 2017).

This rapid adaptation of CRISPR/Cas to a variety of insects within just 4 years demonstrates the versatility of this method and its potential for future applications.

### *2.4. Binary/Conditional Expression Systems*

Genetic sexing or sterility systems are useful only if the trait conferring sexing or sterility can be switched off for strain rearing. Therefore, binary or conditional expression systems are required. The GAL4-UAS system is a binary expression system first established in *D. melanogaster* (Brand and Perrimon 1993). It consists of a driver line containing the budding yeast GAL4 transcriptional activator under the control of a promoter of interest, and an effector line containing the upstream activating sequence (UAS) to which GAL4 binds to activate a gene of interest. The system becomes activated only when both parts of the system are present in an insect, i.e. by crossing the two lines. Additional control of the system is possible by the repressor GAL80 (Lee and Luo 1999) or by temperature-sensitive GAL4 versions (Mondal et al. 2007). The GAL4-UAS system has become a milestone tool for functional genomics studies in *D. melanogaster*, with thousands of driver and effector lines (Rorth 1998; Hayashi et al. 2002; Pfeiffer et al. 2008). The system has also been applied to several other insect species (*B. mori* (Imamura et al. 2003), *Tribolium castaneum* (Herbst) (Schinko et al. 2010), *Ae. aegypti* (Kokoza and Raikhel 2011), and *An. gambiae* (Lynd and Lycett 2012)), and could be exploited to create genetic sexing or sterility systems. However, the necessity of constantly keeping two strains to be crossed only for the release generation hinders its potential and practical application, because it increases mass-rearing complexity and costs.

The recently established bipartite Q system utilizes regulatory genes of the *qa* gene cluster from the fungus *Neurospora crassa* Shear and B. O. Dodge (Potter et al. 2010), and resembles the GAL4-UAS system in that it consists of an activator QF and an upstream activating sequence QUAS. The system shows low basal expression in the absence of QF, and high expression in the presence of QF. Expression can be efficiently suppressed by the repressor QS. The advantage of the Q system over GAL4-UAS is the additional level of control via quinic acid. Feeding quinic acid to flies temporarily relieves QS suppression, thus permitting the creation of a conditional expression system. The Q system, which was established in *D. melanogaster* and recently transferred to *An. gambiae* (Riabinina et al. 2016), might advance to become another conditional tool in insect genetics, biotechnology, and pest control. This would allow developing insect strains with an additional and completely independent lethality or sterility system to counter the possibility of resistance development against the first system (Eckermann et. al 2014).

Food supplement-controlled conditional expression systems like the “Tet-on” and “Tet-off” systems were developed by Bujard and Gossen (Gossen and Bujard 1992; Gossen et al. 1995) as mechanisms for inducible and reversible gene expression in eukaryotic cells. They are controlled by the antibiotic tetracycline (Tet) or one of its derivatives, e.g. doxycycline. The Tet-system is based on a naturally occurring bacterial defence system against antibiotics. It consists of the tetracycline-controlled transactivator protein (tTA) and the TetO operator sequence. tTA represents a fusion of the DNA-binding domain from the bacterial tetracycline

repressor (TetR), and the transcriptional activation domain of the HSV1 protein VP16. For most Tet-on/Tet-off systems, several repeats of the TetO (mostly 7) are fused together with a minimal promoter, forming the Tet response element (TRE). tTA binds to the TRE and thereby triggers the expression of a downstream gene. In the Tet-off system, the binding of Tet to tTA inactivates tTA binding to TRE, therefore the downstream gene is not expressed, and the effect is "off". For Tet-on, binding of Tet to the reverse tetracycline-controlled transactivator protein (rtTA) enables binding to the TRE site and activates downstream gene expression – the system is "on". In contrast to other binary expression systems, like the GAL4-UAS system, the Tet-systems are controllable via the external addition of tetracycline. Moreover, the expression control is tighter, i.e. less leaky, than for example the estrogen receptor-based conditional expression systems (Sohal et al. 2001).

In insects, the Tet system was first tested in *D. melanogaster* (Bello et al. 1998), and has been applied to create conditional sterility or gender-specific lethality systems. Heinrich and Scott reported the first conditional female-specific lethality system in *D. melanogaster*, causing death in late pupal or early adult stages by expressing the pro-apoptotic gene *head involution defective* (*hid)* in the adult female fat body (Heinrich and Scott 2000). Such conditional lethality systems could, in general, also be constructed as a unisex lethality system that could be used in population control programmes instead of using radiation for sterilization. Since the released insects are not sterile in the strict sense, but carry a dominant lethal that would kill their offspring, Thomas et al. (2000) introduced the term RIDL – "Release of Insects carrying a Dominant Lethal" as an alternative to the SIT. Gong and colleagues created a one-component Tet-suppressible RIDL system in the Mediterranean fruit fly *C. capitata* (Gong et al. 2005). Instead of a specific promoter driving tTA, which then activates a lethal gene, they created an autoloop where tTA activates its own expression. This leads to the accumulation of toxic levels of tTA in the late larval or pupal stages in the absence of Tet. Fu et al. (2007) then combined this system with the sex-specifically spliced *Cctra*-intron (section 3.1.) to conditionally kill females, and named the system female-specific RIDL (fsRIDL). The fsRIDL system was subsequently transferred to a number of insect species using either exactly the same system as in *C. capitata* or by adjusting for species-specific regulatory elements (section 3.1.).

The first conditional transgenic embryonic sexing system (TESS) based on Tet-off was developed in *A. suspensa,* using a combination of an early promoter, acting at the egg stage, driving the tTA expression, and *hid* as a lethal effector gene to cause embryo-specific lethality in the progeny. Sex-specificity is achieved again by including the *Cctra*-intron into the *hid* gene (Schetelig and Handler 2012a). Like RIDL, also the early-acting Tet-off system can be designed as a unisex lethality system based on embryonic promoters and lethal effectors (Horn and Wimmer 2003; Schetelig et al. 2009a; Schetelig and Handler 2012a, b). The use of female-specific lethality systems for sexing is described in detail in section 3.1.; for the application of unisex lethality to create sterility systems, see section 3.3.

### *2.5. RNAi*

RNA interference (RNAi) is a conserved eukaryotic mechanism of defence against viruses and foreign double-stranded RNA (dsRNA). Long dsRNA molecules are recognized and cleaved by the Dicer protein. The resulting small interfering RNA (siRNA) molecules are incorporated into the RNA induced silencing complex (RISC), and guide it to the complementary target messenger RNA (mRNA) that is cleaved by RISC and thereby silenced. RNAi has become an important tool to study gene functions, also in insects (Bucher et al. 2002). Many studies were performed by microinjection of dsRNA into eggs, larvae or adults, but this procedure is not applicable for mass-producing insects. Therefore, the finding that oral ingestion of dsRNA can trigger RNAi opened the door for its use in pest control. Oral delivery of dsRNA in insects was first described in the triatomine bug *Rhodnius prolixus* Stål and the light brown apple moth *Epiphyas postvittana* (Walker) (Araujo et al. 2006; Turner et al. 2006).

The first topical application of dsRNA that also induced systemic RNAi (when the signal spreads throughout the insect's body) was shown in the Asian corn borer *Ostrinia furnacalis* (Guenée) (Wang et al. 2011). Systemic RNAi by topical application of IAP1 dsRNA in *Ae. aegypti* could not be confirmed despite a first positive report (Pridgeon et al. 2008, 2016). In contrast, it was shown that topical application of the *Aae* IAP1 dsRNA did not to have a significant knock-down effect on the mRNA level, and even microinjection of IAP1 and other IAPs into adult *Ae. aegypti* females did not cause significant mortality (Puglise et al. 2016). Therefore, it cannot be determined if failure of the topical application in *Ae. aegypti* was due to the method or the target selection.

Both methods, oral ingestion and topical application, require *in vitro* RNA synthesis, which on a large scale can become costly. Another option is the *in vivo* delivery via bacteria (Tian et al. 2009; Zhu et al. 2011), host plants (Baum et al. 2007; Mao et al. 2007; Pitino et al. 2011; Zha et al. 2011), or host-plant viruses (Kumar et al. 2012) expressing the dsRNA. All three strategies have been shown to induce systemic RNAi in the investigated species: western corn rootworm *Diabrotica virgifera virgifera* LeConte (Baum et al. 2007), cotton bollworm *Helicoverpa armigera* (Hübner) (Mao et al. 2007), tobacco hornworm *Manduca sexta* (L.) (Kumar et al. 2012), brown planthopper *Nilaparvata lugens* Stål (Zha et al. 2011), and green peach aphid *Myzus persicae* (Sulzer) (Pitino et al. 2011). The bacteria-based system had a stronger effect than delivering the dsRNA via host plants. A possible reason for the reduced effect via host plant delivery might be the processing of the produced dsRNA by the plant's own RNAi machinery and Dicer enzymes into siRNA molecules, which might be less effective in the insect than the dsRNA (Mao et al. 2007; Kumar et al. 2012). This hypothesis is in line with an observation in the western corn rootworm where dsRNAs (but not siRNAs) are internalized into the midgut tissue (Ivashuta et al. 2015).

Given careful target design (which includes target selection and design of dsRNA taking into account polymorphisms and paralogous genes), RNAi can be a very specific approach. This has been demonstrated by Whyard et al. (2009) who showed that, by targeting the same enzyme in four different species, one can selectively kill only the species for which the dsRNA was designed. However,

biological barriers, and not the proper target gene selection, are the most important limiting factors in insect RNAi. First, an efficient uptake by the midgut epithelial cells is required. Second, the alkaline environment in the insect midgut, as in lepidopterans (Dow 1992), could present a problem due to lysis of the dsRNA. Third, another significant barrier is the presence of nucleases in the midgut and salivary glands of insects. These nucleases might also be the reason for the lack of systemic RNAi in some insects. This is supported by a comparative study which showed that, in the RNAi-insensitive lepidopteran *M. sexta*, the dsRNA is rapidly degraded in the hemolymph, but in the hemolymph of the RNAi-sensitive cockroach *Blattella germanica* (L.) the dsRNA is stable (Garbutt et al. 2013). Along the same line, the desert locust *Schistocerca gregaria* (Forskal) shows a potent systemic RNAi response to injected dsRNA, but is insensitive to ingested dsRNA (Wynant et al. 2012). This phenomenon was explained when four different midgut RNAses were identified in *S. gregaria* (Wynant et al. 2014). Nevertheless, it might still be possible to target insects not susceptible to systemic RNAi by targeting midgut-specific genes, e.g. genes involved in detoxification pathways that are accessible for ingested dsRNA, provided that there are no midgut RNAses present.

In contrast to transgenic insects, the effect of RNAi is mostly transient (except for some cases of systemic or transgenerational RNAi). Therefore, the dsRNA must be supplied constantly during relevant developmental stages to guarantee the silencing effect. Depending on the production costs for the dsRNA and the required amounts (which depends on the production scale of the insects and the effectiveness of the dsRNA to silence the target gene), RNAi might be a costly method for pest control. An alternative to the synthetic production of dsRNA is the use of dsRNA-producing transgenic plants for agricultural pests or feeding the insects during mass-rearing with bacteria expressing the dsRNA. While this decreases the costs of dsRNA production, it involves using transgenic organisms, and with them come regulatory constraints in most countries, thus eliminating the advantage of RNAi (which by itself is a non-transgenic approach). Moreover, as the bacterial strain commonly used to express the dsRNA does not colonize the insect gut, this delivery method also has only transient effects. Recently, Whitten et al. (2016) succeeded in modifying symbiotic gut bacteria to express the dsRNA; these bacteria recolonized the gut of the target species and thereby induced a long-term silencing effect. Another option to circumvent the only transient effect of RNAi is by using transgenic insects expressing the dsRNA themselves. However, this would require again a conditional expression system (section 2.4.) to suppress dsRNA production for rearing the strains.

Several comprehensive reviews summarize the current insights and achievements in insect RNAi, and describe the challenges that are faced when developing this method as a tool for use in pest control (Baum and Roberts 2014; Joga et al. 2016; Darrington et al. 2017; Cooper et al. 2019).

## 3. APPLYING MOLECULAR TECHNOLOGIES TO IMPROVE THE SIT

Modern molecular technologies can be used potentially to address and improve key aspects of programmes integrating the SIT such as sexing, sterilization, and marking of the insects destined for release. Combining available knowledge on insect biology, e.g. sex determination pathways, with specific and targeted genome modifications, could pave the way for new pest control systems. The following sections describe the current knowledge on sexing, sex determination and distortion, sterilization, monitoring, and transgene stabilization, as well as existing genetic (transgenic) systems with potential application for the SIT.

### *3.1. Sexing*

The release of only male insects can enhance the efficacy of SIT applications because the presence of sterilized females appears to prevent some sterilized males from competing with wild males for matings with wild females. Large-scale field studies comparing mixed sex versus male-only releases of the Mediterranean fruit fly in Guatemala showed a three- to five-fold increase in efficacy (Rendón et al. 2004). Moreover, male-only releases are a prerequisite in the case of vector control programmes because, for example, released female mosquitoes (even if sterile) would increase the number of biting and potentially disease-transmitting insects. For agricultural control programmes, it may also be beneficial not to release females, because the sterilized females could still cause damage by laying their eggs into fruits. Another important factor of male-only rearing is the reduction in costs, space, and logistics required at all levels of pest control programmes that apply the SIT, i.e. mass-rearing, quality control, distribution, and release as well as monitoring (Cáceres et al. 2004).

Significant savings can be gained if females are eliminated early in the rearing process (Franz et al., this volume). The role model for sexing is the Mediterranean fruit fly *temperature-sensitive lethal* (*tsl*) strain developed by classical genetic approaches, where the *tsl* mutation specifically and effectively kills all female embryos upon heat shock (Franz and McInnis 1995; Franz et al., this volume). Recently, another *tsl* mutation was created successfully by chemical mutagenesis in the mosquito *An. arabiensis* (Ndo et al. 2018). However, at the present time, the *tsl* mutations are not identified molecularly, and the creation of such a mutation using classical mutagenesis often takes a long time. Nevertheless, once the molecular basis of such a mutation is identified, modern molecular tools, as described above, could be used to build this highly efficient system in other species to create new conditional sexing strains based on heat shock, thus avoiding chemicals and antibiotics. These new strains might be classified as non-transgenic since no foreign DNA is transferred to the insect of interest, and potentially even as non-GM since the modification is based on a naturally occurring mutation. Thereby these sexing strains would evade the regulatory restrictions that apply to the release of GM organisms.

Other strategies could rely on the use of sex-determining factors to produce male-only strains. Sex-determination pathways in insects are very diverse, but all

appear to be centred around a highly conserved sex-determining factor in Diptera, Lepidoptera, and Hymenoptera, *doublesex (dsx),* at the end of a sex-determination cascade (Funaguma et al. 2005; Verhulst et al. 2010; Geuverink and Beukeboom 2014). *Dsx* is sex-specifically spliced into a male and female isoform. In many tephritids this is controlled by *transformer* (*tra*) (Saccone et al. 2011) as a master epigenetic switch. A functional *tra* protein seems to be produced only in females (XX), while the male pre-mRNA is not spliced, and therefore contains an early stop codon leading to a non-functional protein (Verhulst et al. 2010). The female *tra* protein functions as splicing enhancer, leading to the female-specific splicing of *dsx*. In contrast, the absence of functional *tra* protein in males results in male-specific splicing of *dsx*. Female-specific *tra* expression is maintained through a positive feedback loop. When zygotic activation of this loop is prevented, male development follows. Although the function of *tra* appears to be conserved across many species, its sequence is not (Pane et al. 2005; Verhulst et al. 2010). This not only makes the identification of species homologues difficult, but also allows diversity of upstream-acting factors in different species. Therefore, deciphering the sex-determination pathways and other factors involved in different insects can be challenging.

Recently, breakthroughs were achieved in several insect species. Scientists identified the long-sought M-factor *Nix* in *Ae. aegypti* and *Ae. albopictus* (Hall et al. 2014, 2015; Liu et al. 2020), the maleness gene *Yob* in *An. gambiae* (Krzywinska et al. 2016), *GUY1* in *Anopheles stephensi* Liston (Criscione et al. 2013, 2016), *Mdmd* in *Musca domestica* L. (Sharma et al. 2017), and the *Maleness-on-the-Y* (*MoY*) gene in *C. capitata* (Meccariello et. al. 2019). *Nix, Yob, GUY1*, and *Mdmd* are located upstream of *dsx* in the cascade, and are needed for male development by directly or indirectly inducing male-specific *dsx* splicing. In the Mediterranean fruit fly, where *tra* is maternally deposited in the embryo to induce its auto-regulatory female-specific splicing, *MoY* is necessary and sufficient to suppress this female-specific *Cc-tra* splicing, resulting in male development. However, the mechanism of suppression has not yet been solved. Interestingly, *MoY* is functionally conserved in two other tephritids, *Bactrocera oleae* (Rossi) and *B. dorsalis*, providing a candidate gene for genetic-control strategies. Another mechanism of female-specific splicing of *dsx* was discovered in the WZ sex-determination system of the lepidopteran *B. mori*, where it is induced by a female-specific piRNA (piwi-interacting RNA) (Kiuchi et al. 2014).

The sex-determining factors could be promising tools to eliminate females or convert them to males for SIT projects (Schliekelman et al. 2005). The sex-specifically spliced *C. capitata tra*-intron is already successfully being used to robustly eliminate females. The female-specific splicing of the *tra*-intron leads to a functional protein, whereas the male isoforms result in truncated, non-functional versions. This has been exploited to develop a Mediterranean fruit fly sexing system using the *Cctra*-intron to female-specifically express a toxic gene in the fsRIDL system (Fu et al. 2007), which was also directly applied to the olive fruit fly *B. oleae* (Ant et al. 2012). Recently, the system was adapted to the Australian sheep blow fly *Lucilia cuprina* (Wiedemann) and the New World screwworm *Cochliomyia hominivorax* (Coquerel) using the sex-specific first intron of the screwworm *tra* gene for both species to female-specifically overexpress tTA to toxic levels (Li et al.

2014; Concha et al. 2016). The successful characterization of the lepidopteran *doublesex* (*dsx*) gene was the basis for transferring the fsRIDL to the pink bollworm *Pectinophora gossypiella* (Saunders) and the diamondback moth *Plutella xylostella* (L.) using sex-specific splicing of *dsx* to accumulate tTA in females (Jin et al. 2013). fsRIDL kills females in the late larval or pupal stage (Fu et al. 2007). In contrast, in the TESS, the early embryonic and female-specific expression of the pro-apoptotic gene *hid* using the *sry-alpha* promoter kills females early in embryonic development in *A. suspensa, A. ludens,* and *C. capitata* (Schetelig and Handler 2012a; Ogaugwu et al. 2013; Schetelig et al. 2016), which in a large-scale production would reduce the cost of rearing. Similar systems have recently been developed for *Lucilia cuprina* (Yan and Scott 2015) and *C. hominivorax* (Concha et al. 2016; Scott et al. 2017). Following this approach, the *An. gambiae Yob* might be a promising new candidate gene to create a mosquito sexing strain, because overexpression results in female lethality, potentially due to a role in dosage compensation (Krzywinska et al. 2016; Krzywinska and Krzywinski 2018).

Instead of eliminating females, male-only populations could be created by reversing females into males. This would have the advantage of doubling the male output. Sex reversion via a transient RNAi effect has been successfully performed in several species by targeting *transformer* genes, whose function is required only for female development. In *A. suspensa*, injection of dsRNA against *Astra* and *Astra-2* into fertilized embryos led to at least 97% male progeny, of which half were XX males. These XX phenotypic males mate successfully but are infertile due to hypertrophic testes and reduced sperm motility (Schetelig et al. 2012). In contrast, transient RNAi against *tra* in *C. capitata*, *B. oleae*, and *L. cuprina* (Pane et al. 2002; Lagos et al. 2007; Concha and Scott 2009) resulted in fully transformed XX males, which were also fertile. Sex conversion could also be achieved by overexpressing suitable sex-determination genes or maleness factors, like *Nix* in *Ae. aegypti* (Hall et al. 2015; Aryan et al. 2019).

A different approach to sex distortion is the so-called X shredder. The endonuclease I-*Ppo*I specifically cuts X-chromosomal ribosomal rDNA sequences in *An. gambiae*. Tissue-specific expression of I-*Ppo*I in the testes using *beta2-tubulin (β2-tub)* 5' and 3' regulatory sequences leads to shredding of X chromosomes during gametogenesis, resulting in a strong bias for Y gametes, but also male sterility in crosses of heterozygous males with wild-type females. This is due to the long half-life of the I-*Ppo*I protein, which is transferred via sperm into the zygote where it shreds the X chromosome of the oocyte upon fertilization (Windbichler et al. 2008). The system was optimized to create a pure sex-distortion system without male sterility by reducing the half-life of the I-*Ppo*I protein through protein engineering (Galizi et al. 2014). Recently, the same group successfully rebuilt the X shredder in *An. gambiae* based on CRISPR/Cas. The guideRNAs were designed to recognize a conserved rDNA target sequence of the *An. gambiae* complex. By expressing the Cas9 protein specifically during spermatogenesis, the X chromosome in sperm is shredded. The selected guideRNA target sequence is conserved among *An. arabiensis*, *An. gambiae*, *An. bwambae* White, *An. melas* Theobald, and *An. merus* Dönitz. Therefore, this CRISPR/Cas-based X shredder should be applicable to the complete *An. gambiae* complex (Galizi et al. 2016).

### *3.2. Marking/Monitoring/Sex Sorting*

To be able to monitor the effect of SIT releases, sterile insects have to be distinguished from wild insects in the field (Dowell et al., this volume; Franz et al., this volume; Parker, Mamai et al., this volume; Vreysen, this volume). Traditionally, colourful adhesive powders are used to mark the sterile insects before release (Schroeder and Mitchell 1981). However, the colourful powders are error-prone in some species because of a possible transfer of the marker during contact with wild insects, or removal of the powder by grooming. Moreover, some of the dusts can be harmful to workers handling the dye. An alternative would be replacement with genetic markers coding for fluorescent proteins stably integrated into the genome of insects (Hagler and Jackson 2001; Hendrichs and Robinson, this volume). Such genetic fluorescent markers are available in a variety of colours, and can be selectively expressed by using specific promoters. Transgenic strains carrying fluorescent markers have been developed in a wide variety of insect pests, including the mosquitoes *Ae. aegypti* and *An. gambiae* (Catteruccia et al. 2005; Smith et al. 2007) as well as fruit flies like *A. suspensa* and *C. capitata* (Handler and Harrell 2001a, b; Scolari et al. 2008; Zimowska et al. 2009). Important for the use of fluorescent markers in field monitoring is the stability of the fluorescent proteins over a long time under trapping conditions. This has been shown for the pink bollworm, where DsRed proteins were stable for at least 2 wk after trapping of specimens as confirmed by fluorescence microscopy and PCR (Simmons et al. 2011). A similar study with a transgenic strain of *A. suspensa* proved the stability of DsRed fluorescent marker protein over a period of 3 wk in field traps, monitored by visual inspection and PCR (Nirmala et al. 2011). Studies in *A. ludens* confirmed the marker stability under dry conditions over several months (Meza et al. 2011). As the fluorescent protein degrades over time, PCR assays have been developed to verify the DsRed marker molecularly (Zimowska et al. 2009).

Besides monitoring released insects in the field, fluorescent markers could serve multiple purposes. By using the *β2-tub* promoter, the marker is expressed in the male sperm (Catteruccia et al. 2005; Scolari et al. 2008). Thus, via marker expression in the gonads, such strains can be used to monitor the mating success of the released males by screening for the fluorescent sperm in the spermathecae of wild females (Juan-Blasco et al. 2013). Moreover, the male- (or sex-) specific expression of fluorescent markers allows (automated) sexing, as shown for *Aedes* and *Anopheles* species. A transgenic *Ae. aegypti* strain has been constructed in which DsRed expression is driven by the *β2-tub* promoter, allowing reliable sorting of DsRed males from non-marked females using the Complex Object Parametric Analyser and Sorter (COPAS) (Smith et al. 2007). In a transgenic strain of *An. stephensi*, *β2-tub* drives the expression of an enhanced green fluorescent protein (EGFP) permitting late larval automated sorting (Catteruccia et al. 2005). Marois and colleagues used the *dsx* promoter to drive EGFP in *An. gambiae*, which permits early larval separation by COPAS (due to the higher expression of EGFP in the midgut in male L1 larvae compared with females) (Marois et al. 2012). Importantly, the COPAS sorting does not significantly affect the viability and competitiveness of sorted males (Catteruccia et al. 2005; Smith et al. 2007).

Instead of using suitable promoters to express the markers sex-specifically, transgenic lines with insertions of the marker on the Y chromosome can be used, as available for *A. suspensa*: four Y-linked *Dmel*-PUb-DsRed lines have been created, of which one expresses the marker already in early embryogenesis (Schetelig and Handler 2013b). Ideally, a Y-chromosome insertion should also contain a landing site, e.g. *attP*, *lox*, or *FRT,* for site-specific integration, such that any construct of interest can be inserted into the Y chromosome. Such lines are available for *An. gambiae* (Bernardini et al. 2014) and *A. suspensa* (Schetelig and Handler 2013b) having a Y-linked *attP* site.

### *3.3. Sterilization*

Genetic sterilization approaches can also contribute to the population control of insect pests and disease vectors. One of the first genetic sterilization systems causes reproductive sterility by the transfer of embryonically lethal transgenes. It was developed in *D. melanogaster* (Horn and Wimmer 2003), and was later successfully adapted and transferred to important pest insects like *C. capitata, Anastrepha ludens*, and *A. suspensa* (Schetelig et al. 2009a, 2016; Schetelig and Handler 2012b). It is based on the conditional expression of a lethal effector molecule, *hid*, controlled by an early embryonic promoter, to cause embryo-specific lethality in the progeny. During mass-rearing the conditional systems can be switched off by a food supplement, or the antibiotics tetracycline or doxycycline. Such strains, if released into the field where no antibiotics are present, will lead to biologically fertile matings, but their progeny will die due to the embryonically active lethal system. This results in the reduction of the wild-type population.

In contrast, RIDL was designed as a late-acting conditional lethality system that kills progeny in late larval or pupal stages by accumulation of toxic levels of tTA. RIDL systems that confer unisex lethality in the next generation, and can be used as sterility systems, were designed for *C. capitata* and *Ae. aegypti* (Gong et al. 2005; Phuc et al. 2007; Harris et al. 2011). More details about the design and function of the RIDL and conditional expression systems (Tet-on/Tet-off) and their applications are given in section 2.4.

### *3.4. Transgene Stabilization*

Most transgenic insects have been routinely generated using germline transformation procedures and transposable elements as tools to randomly integrate DNA into genomes. To prevent instability or a horizontal gene transfer through the transposon system to other insect species, all commonly used transposons have been split into two non-autonomous parts, one vector encoding the transposase gene (helper), and a second vector containing the inverted repeats flanking the transgene construct to be integrated into the genome. After injection into the germline, the transposase is only transiently expressed from the plasmid that quickly gets lost during cell divisions, while the transgene should be stably integrated into the genome. However, as long as the intact inverted terminal repeats (ITRs) of the transposons flank the transgene

construct in the genome, it can be remobilized in the presence of a suitable transposase enzyme, which could lead to a loss of function. Thus, endogenous, related cross-mobilizing transposases, could potentially remobilize the construct.

An additional concern has to do with the risk of horizontal gene transfer through the uptake of foreign DNA by other organisms in the field and the subsequent remobilization of transposons contained therein by various means. Although this risk is minimal, the possibility exists. For the use of transgenic insects in SIT projects, this possibility could be investigated by feeding the transgenic organism to other organisms in question and assess potential horizontal transfer events by molecular techniques.

Regarding remobilization, such events could be prevented by removing one or both inverted repeats. Mechanisms described for *D. melanogaster* and *C. capitata* introduce additional ITRs such that additional ITR-flanked cassettes are created at the genomic integration site. A subsequent remobilization experiment either remobilizes the two outermost ITRs, which removes the whole transgene construct (the unwanted side product), or one of the outer ITRs remobilizes with the internal ITR, thus leaving the organism with the third ITR and part of the transgene construct (the desired product). Studies verified that one ITR is not sufficient anymore to remobilize the transgene, which is therefore considered as "stabilized" (Handler 2004; Dafa'alla et al. 2006; Schetelig et al. 2009b; Long et al. 2015).

### *3.5. Quality Control of Transgenic Lines*

The success of large-scale operational programmes with an SIT component depends on the regular monitoring and evaluation of the quality of the strain used (Franz et al., this volume; Parker, Vreysen et al., this volume; Vreysen, this volume). After several decades of successful development and implementation of the SIT, the FAO, IAEA, and USDA have developed standard operating procedures for the evaluation of the biological quality of strains used in mass-rearing and SIT applications (FAO/IAEA/USDA 2019). The most important parameters are rearing efficiency and sterile male performance, including mating competitiveness.

The VIENNA 8 strain is the non-transgenic genetic sexing strain, produced through classical genetics, currently used in large-scale operational Mediterranean fruit fly SIT programmes worldwide (Augustinos et al. 2017; Franz et al., this volume). VIENNA 8 exists in two versions, with and without the inversion D53, which is used to suppress recombination and ensure the genetic stability of the strain under large scale production: VIENNA $8^{D53+}$ and VIENNA $8^{D53-}$ (Augustinos et al. 2017). Its sexing properties are based on two selectable markers, the *white pupae* (*wp*) and the *temperature-sensitive lethal* (*tsl*) genes. A transgenic version of this strain was developed, VIENNA 8-1260, which carries two fluorescent markers, the DsRed in the body and the GFP in the testes (Scolari et al. 2008). In a recent study, the Mediterranean fruit fly VIENNA $8^{D53+}$ strain was compared with the transgenic strain VIENNA 8-1260 with respect to the parameters egg production, egg hatch, and egg sterility under semi-mass-rearing conditions, and male mating competitiveness in field cages (Rempoulakis et al. 2016). VIENNA 8-1260 produced significantly fewer eggs as compared with the classical genetic sexing

VIENNA $8^{D53+}$ strain, while egg hatch and egg sterility were similar. However, after ten generations under continuous semi-mass-rearing conditions, the male mating competitiveness of the VIENNA 8-1260 strain, when compared with wild-type males, was statistically significantly lower than that of the classical genetic sexing VIENNA 8 strain (Rempoulakis et al. 2016). The VIENNA $8^{D53+}$, VIENNA $8^{D53-}$, and VIENNA 8-1260 strains were also tested on a mass-rearing scale. The analysis showed that the transgenic VIENNA 8-1260 strain had significantly lower yield than both VIENNA $8^{D53+}$ and VIENNA $8^{D53-}$ strains. In addition, the relative sterility index and male mating performance of the VIENNA 8-1260 was significantly lower than those of VIENNA $8^{D53-}$, which is a major disadvantage for its use in large-scale operational SIT programmes (Ramírez-Santos et al. 2017a). Another limitation of this transgenic strain is that it requires higher irradiation doses to eliminate the possibility of the vertical transfer of the fluorescent gene into wild flies and the environment (Ramírez-Santos et al. 2017b). However, the required higher irradiation doses compared with the classical genetic sexing strain VIENNA 8 may further reduce the mating competitiveness of the transgenic strain VIENNA 8-1260 (Ramírez-Santos et al. 2017b; Bakri et al., this volume).

Until now, only a few transgenic strains (and of only two species, *C. capitata* and *Ae. aegypti*) have been evaluated with regard to their potential suitability for use in large-scale open-field releases. In a recent study, a *C. capitata* fsRIDL strain, OX3864A, was assessed under field-cage conditions in comparison with the VIENNA $8^{D53+}$ strain and wild-type males for its male sexual competitiveness (Virginio et al. 2017). For both strains, the mean duration of mating events was significantly lower than for the wild type. Moreover, the latency period, i.e. the time elapsed until mating starts, for transgenic males was significantly longer than for VIENNA $8^{D53+}$. In contrast, there were no differences observed in the proportion of females mated, and in the relative sterility index.

Transgenic RIDL strains of *Ae. aegypti* have been developed and tested for their rearing efficiency and male mating competitiveness. A female-specific RIDL version of an *Ae. aegypti* strain (fsRIDL) was tested in outdoor field cages; it failed to eliminate a target population because of its low mating competitiveness (Facchinelli et al. 2013). The bisexual *Ae. aegypti* OX513A RIDL strain has, in several places, successfully suppressed the population of this major mosquito vector species (see below). It is the only transgenic mosquito line which has been semi-mass-reared for releases of up to 1–1.5 million male mosquitoes per week (Carvalho et al. 2014). However, in addition to its low male mating competitiveness (thus releases were done with very high transgenic to wild male ratios), this RIDL strain also presents additional disadvantages. It is not a sexing strain, meaning that sex separation based on pupal size is very labour intensive and inefficient, thus some fertile females are released into nature; this raises concerns about their role in disease transmission as well as in spreading the transgene and leaving OX513A‘s genetic footprint in the environment (Bourtzis et al. 2016). Moreover, a recent study showed introgression of OX513A’s genetic background into the local population, resulting in hybrids of originally genetically quite distinct populations with potentially increased robustness, and an unclear vectorial capacity (Evans et al. 2019). The rearing of this transgenic *Ae. aegypti* OX513A RIDL strain also depends

on the use of tetracycline in mass-rearing. The use of this antibiotic may have a negative impact on the mosquitoes' endogenous microbiota -- known to be important in the biology, physiology, and ecology of the host, potentially affecting the rearing efficiency and mating competitiveness of the strain (Bourtzis et al. 2016).

During the past 15 years, numerous so-called landing-site lines for site-specific genome modification have been created in many insects. These lines carry transgene constructs with recombination sites for site-specific recombination systems like Cre/*lox*, Flp/*FRT* or PhiC31/*att* (section 2.2.), and could be used to build transgenic strains for population control programmes. Since all of these lines were created by transposon-mediated transformation resulting in the random transgene integration into the genome, the integration site could have a negative effect on the biological quality of these lines, and thereby on their suitability for large-scale pest control programmes. Therefore, it is crucial to assess the fitness of such lines.

Such assessments have been performed recently for several landing-site lines of the vector *Ae. aegypti* in a comprehensive set of laboratory-scale tests (Häcker et al. 2017). The lines carry a construct for site-specific genome modification via Cre-RMCE. The tests included parameters important for successful and economical mass-rearing, e.g. female fecundity and fertility, and time for larval development. In addition, they included parameters important for releases such as male mating competitiveness and adult male longevity. They were based on a statistical sample size estimation to ensure the detection of differences in quality of up to five percentage points compared with the parental strain Higgs White Eye (HWE). The tests showed that one of the lines, AH0212-F1, with an intergenic integration site of the transgene construct, performed closest to the parental HWE, and thus is the most suitable line for downstream site-specific modifications.

However, the tests also showed that transgene integration at sites annotated as intergenic (DNA sequences located between genes) does not necessarily indicate a "good" integration site regarding fitness costs, as observed for the line AH0212-M1 (Häcker et al. 2017). This line showed strong deficits in several parameters including female fecundity and longevity, and pupation time. This effect is purely due to the integration site since the transgene construct is identical in all lines. None of the lines, however, performed "good" or "bad" in all of the quality parameters, because different integration sites will influence different sets of genes or gene-expression pathways, thus influencing various life traits. Moreover, experiments analysing the larval hatch rate under different food conditions (baker's yeast as minimal *Ae. aegypti* food source in the hatching water versus TabiMin fish food as optimal food source) revealed a strong influence of the chosen experimental conditions on the results of the fitness tests. When using an optimal food source, no significant differences in larval hatch rates between the transgenic lines and the HWE reference strain were observed. However, significantly decreased hatch rates for some lines were revealed when the lines were put under "stress" by hatching them using minimal food (Häcker et al. 2017). All of the above-mentioned assessments were performed under small-scale laboratory conditions. The next step is to evaluate these lines under semi-mass-rearing conditions, and finally the best line will be assessed in a large-scale mass-rearing setting.

## 4. SUCCESSFULLY APPLYING MOLECULAR TOOLS – FIRST RELEASES OF TRANSGENIC INSECTS

The first open-field tests with transgenic insects were performed in 2007/2008 with the pink bollworm strain OX1138B; this strain carried a transgenic marker for field monitoring. After the first field trials in 2007, when 1.1 million moths were released in Yuma County, Arizona, in 2008 this was increased to over 15 million moths released within the framework of an operational demonstration trial. The performance of the moths was equal to that of the traditional non-transgenic APHIS strain established for the ongoing SIT programme against the pink bollworm, i.e. in terms of mating success, dispersal, and persistence in the release area (Simmons et al. 2011).

The first open-field trials with transgenic *Ae. aegypti* mosquitoes were started in 2009 and 2010 in Grand Cayman (Harris et al. 2011), followed in 2010 by a larger scale release; over a 23-week period, 3.3 million engineered OX513A males were released in three adjacent areas. This trial showed the potential of the transgenic control strategies for mosquitoes in general, and of the OX513A in particular, as it achieved 80% population suppression at an overflooding ratio of 5:1 (Harris et al. 2012). If there is a link between the disease-carrying insects and the epidemiological burden (which should be further evaluated in the future), this reduction in the insect population is most important and valuable. Subsequent to the success of the Grand Cayman study with OX513A, a sustained release of this strain, for a period of more than one year, was done in 2015 in a suburb of Juazeiro, Bahia, Brazil, reducing the local population by 81% (Carvalho et al. 2015). The most recently published study on OX513A additionally addresses the important question of recurrence of mosquito populations following post-release interruption in two distinct release areas in Brazil (Garziera et al. 2017). The study showed that mosquito populations recovered within 17–32 weeks after the end of the releases, demonstrating the necessity of continuous releases for permanent population suppression. Field trials with OX513A are also scheduled for the Florida Keys after the 2016 final decision by the FDA that no significant impacts on the environment are expected, although these have until now not been initiated in view of public opposition.

Field trials with *Wolbachia*-infected *Ae. aegypti* have been successfully performed in Australia, starting in 2011, with a self-sustaining (population replacement) objective (Hoffmann et al. 2011). More releases of *Wolbachia*-infected *Aedes* males are ongoing or planned in Brazil, China, Singapore, and the USA, although mainly as part of self-limiting (IIT) approaches (Callaway 2016; Waltz 2017).

A large-scale performance evaluation is also planned for a transgenic sexing strain of the New World screwworm; it will be tested for its performance in mass-rearing by the *Comisión Panamá - Estados Unidos para la Erradicación y Prevención del Gusano Barrenador del Ganado* (COPEG). An application to conduct open-field trials has been submitted to the government of Panama (Concha et al. 2016).

## 5. CONCLUSIONS AND FUTURE CONSIDERATIONS

Modern molecular technologies offer many possibilities to address issues and bottlenecks in current insect pest and disease-vector population suppression programmes, e.g. the sexing of insects for male-only releases; for many species this is a critical tool in establishing an efficient large-scale operational programme. In addition, sterilization and marking techniques can be developed and combined to create sterile-male insect strains of good biological quality for population control. These modern biotechnologies permit strains to be tailored to meet the requirements of control programmes, and have the potential to facilitate greatly the transfer of successful strategies to new pest species in just a few years. However, for a species to be effectively targeted with these technologies, the availability of genome sequence data is beneficial, and molecular tools for insect transformation have to be available in the species of interest. For the Mediterranean fruit fly, such a resource has been built up (Papanicolaou et al. 2016), and in combination with a strong understanding of the chromosomal organization resulting from research and development of the SIT for this species, this database and knowledge will help to further identify crucial markers, genes, and targets for related tephritid and other pest species. However, high-quality genomes with mostly manual annotations are still limited, and, although the i5k insect genome project (Robinson et al. 2011) is sequencing multiple insect species, it will take many years before high-quality genomes will be available.

The CRISPR/Cas technology will also benefit from available sequence information, and promises to be a key method for editing genomes in the coming years. Current drawbacks of the method, because of off-target effects, are continuously being addressed, and the system is being improved and refined. CRISPR/Cas is only one of the techniques that can be used for creating strains useful for the suppression of populations of insect pests and disease vectors. There are several other techniques available, with distinct advantages, which can complement those of CRISPR/Cas. Thus, while CRISPR/Cas is highly flexible regarding the choice of the target site, Cre- or FLP-RMCE offer the possibility of successively targeting the same site, permitting the modification and adjustment of existing systems to changing requirements.

Until now, the described population suppression strategies for SIT applications are based on self-limiting genetic systems; they are suitable for both disease vectors and agricultural pests. In contrast, population replacement strategies make most sense in species that are transmitting a disease but are not pests by themselves, e.g. mosquitoes or vectors of plant diseases. In such insects, replacing the natural population with insects refractory to infection with the pathogen could be a viable option for disease control. However, such approaches have the disadvantage that they leave an "ecological footprint", and unexpected complications would have to be controlled by yet another self-sustaining genetic system controlling the problematic first one.

Research on such refractory strains has been performed mostly with regard to dengue and Zika infections in *Ae. aegypti,* using a *Wolbachia*-based replacement approach (Moreira et al. 2009; Hoffmann et al. 2011; Walker et al. 2011; Dutra et al. 2016; Lees et al., this volume). Moreover, trypanosome refractoriness in *Glossina*

*morsitans morsitans* Westwood was achieved using a paratransgenesis approach (De Vooght et al. 2018). Another strategy uses transgenic approaches to make *Anopheles* mosquitoes refractory to *Plasmodium* infection (Ito et al. 2002; Moreira et al. 2004; Meredith et al. 2011; Isaacs et al. 2012; Smith et al. 2013; Sumitani et al. 2013; McArthur et al. 2014; Gantz et al. 2015). For population replacement approaches, the plan is to use gene drives to spread and establish such a transgenic refractory system in a wild population. Synthetic gene drives, based on naturally occurring selfish genes (the so-called homing endonuclease genes (HEG)), were first proposed in 2003 (Burt 2003). HEGs can be reprogrammed to target other than their natural target sites in the genome, e.g. in the human malaria vector *An. gambiae* (Windbichler et al. 2011). However, reprogramming HEGs is a challenging process, and limits their application in developing new gene drives (Champer et al. 2016).

The discovery of CRISPR/Cas not only provided a universal genome editing tool but also opened the door for the fast development of gene-drive systems. Due to the easy reprogramming of the CRISPR/Cas target site via the sgRNA sequence, the CRISPR-derived gene drives could theoretically be used to engineer almost any trait. In fact, a CRISPR/Cas gene drive with dual anti-*Plasmodium* effector genes has already been created for the malaria mosquito *An. stephensi* (Gantz et al. 2015). In case population replacement is not the desired strategy, gene drives could also be used to temporarily or locally suppress a population, e.g. by targeting female reproduction as shown for *An. gambiae* (Hammond et al. 2016) or by female to male conversion as modelled for *C. capitata* (KaramiNejadRanjbar et al. 2018). The difference to other population suppression strategies, such as the SIT or the RIDL system, is that theoretically the gene drive requires only a single seed release of a small number of individuals spreading into the population in contrast to the necessity of repeated mass-releases of sterile or transgenic males.

### *5.1. Mutations and Resistance Development to Genetic Modifications*

All genetically-based technologies have the risk that mutations and recombinations could alter or inactivate the transgene function. An important quality parameter for strains used in operational programmes is their genetic stability under large-scale rearing conditions. Mass-rearing facilities can produce hundreds or even thousands of millions of insects per week, which significantly increases the probability of the occurrence of these chance events (Dowell et al., this volume; Franz et al., this volume; Parker, Mamai et al., this volume;). Depending on where the mutations occur, they can have a variety of impacts on the transgene. Single-point mutations (which are the most likely mutations to occur) in the promoter or regulatory elements might not abolish the function of the element, but the accumulation of multiple mutations might do so. In contrast, a point mutation in a coding gene, leading to a missense or nonsense mutation, could cause a knockdown or knockout effect. The potential rate of a knockout mutation in a regulatory sequence can be estimated at the rate of $10^{-7}$ per bp or similar to a point-mutation reversion rate in a ~1 kb coding region (Handler 2016), while a knockout mutation in a 1 kb coding region is estimated at a frequency of about 1–5 x $10^{-6}$ (Tobari and Kojima 1972; Neel 1983; Woodruff et al. 1983). Therefore, under mass-rearing conditions (up to

2 x $10^9$ insects per week), the occurrence of one or more revertant mutations can be expected. Upon release, these mutations might allow survival under restrictive conditions, and might even lead to population replacement or result in the breakdown of the mass-reared strain. Therefore, backup systems will be needed. Moreover, large-scale tests will be required to test for the actual occurrence of revertant mutations, and revertants to be analysed to identify the resistance mechanism. If a transgenic strain is mass-produced on a large scale, and taking into consideration natural mutation rates, a mutation inactivating the transgene resulting in genetic instability, and the breakdown of the transgenic strain, is possible (Handler 2016). This is a significant concern which has urged researchers in the field to consider strategies which can minimize or eliminate the likelihood of resistance development by incorporating, for example, a second selectable marker or effector gene (Eckermann et al. 2014; Handler 2016). However, such transgenic strains have not yet been developed and validated. Currently, filter rearing systems are used in mass-rearing to prevent spontaneous mutations from spreading in the mother colony and being released; each batch of insects is started from a checked population and then mass-reared for the release population (Parker, Mamai et al., this volume).

In the case of gene drives for population suppression or population replacement, it is expected that drive-resistant alleles will emerge for virtually any gene drive described so far (Champer et al. 2017; Noble et al. 2017; Unckless et al. 2017; KaramiNejadRanjbar et al. 2018). Resistance can arise from a variety of mechanisms. The most frequent reason will probably be by the action of the drive itself, when the Cas-induced double-strand break is not repaired by homology-directed repair as intended, but instead by the cell's non-homologous end-joining (NHEJ) repair mechanism, that often introduces small insertions or deletions at the repair site. These base changes will then not be recognized by the drive anymore, thus preventing the construct from spreading to the entire population. This is more likely to happen if the drive cuts only at one site. Other mechanisms of resistance are possible as well but will likely be a less frequent cause, such as standing genetic variation between populations as found for *An. gambiae* mosquitoes in Africa (Miles et al. 2016) or *de novo* mutations in the targeted gene(s), particularly if the target locus is not highly conserved.

Several solutions have been suggested to prevent resistance development against gene drives, e.g. targeting multiple sequences within a gene or targeting different genes at once, so that resistance would have to evolve independently for each site (Esvelt et al. 2014; Champer et al. 2016; Noble et al. 2017; KaramiNejadRanjbar et al. 2018). Moreover, it should be possible to prevent, or at least delay, the emergence of resistance by targeting highly conserved genes for which resistance due to mutation is expected to have a severe fitness cost, or to target a haplolethal gene whose function is only preserved under successful conversion (Esvelt et al. 2014; Champer et al. 2016; Noble et al. 2017). The concomitant expression of a short-hairpin RNA (shRNA) gene to suppress NHEJ repair could also help to prevent resistance development (Chu et al. 2015).

### *5.2. Regulatory Considerations for the Application of Transgenic Insects*

Most modern molecular techniques applied to insect genomes create transgenic insects. The use of transgenic strains in open-field conditions, and potentially in operational programmes, requires them to be of adequate biological quality, but they also need to have all of the necessary regulatory approvals (Reeves et al. 2012). It is worth noting that the regulatory framework for transgenic insects, developed by the various technologies, is not harmonized within and between different countries and continents, and this is not expected to change in the near future. In addition, scientists and managers planning to use transgenic insects in the field must, in advance, address questions and concerns raised by the general public and stakeholders. In that respect, a decision-making process based on scientific evidence, evaluations, risk assessment studies, and large-scale experiments (in the laboratory, but also in contained and open-field release trials) would be necessary (FAO/IPPC 2004; FAO/IAEA 2006). Thanks to the novel technologies, and because of the extremely different control scenarios unfolding, a clear case-by-case evaluation is needed. A generalized treatment of the different systems and/or insect strains should be avoided. Several efforts have been initiated to include transgenic insects in regulatory frameworks, e.g. by the North American Plant Protection Organization (NAPPO 2007), the European Food Safety Authority (EFSA 2013), and recently by the National Academy of Sciences, Engineering, and Medicine (NASEM 2016). These documents inform in a detailed and scientific way, and hopefully will foster a balanced discussion to improve the decision-making in this exciting but complicated modern biotechnological field.

As an alternative, non-transgenic approaches could be pursued. In addition to classical genetic approaches, CRISPR/Cas and RNAi strategies offer different possibilities. Although organisms created by CRISPR/Cas genome editing will be treated under the GMO directive in the EU, based on a very recent decision of the European Court of Justice, CRISPR mutations that could also have been developed through traditional breeding methods, such as point mutations or small insertions or deletions, are classified as non-GM by the US Department of Agriculture and the Government of Japan (Nature 2018). As the evaluation of the CRISPR technology by governments and authorities is just starting, in future CRISPR mutations have the potential to be classified as non-GM in more countries. Thus, in these countries, strains created by CRISPR mutagenesis would not be affected by the regulations for transgenic organisms. Such mutations could be used, for example, to knock out genes required for sex determination to create non-transgenic sexing strains. RNAi methods also offer a way to work without transgenic organisms, i.e. if the dsRNA is not conditionally or constitutively expressed in the insect, and if it does not persist in the environment.

### *5.3. Novel Developments in Insect Pest Control: Impaired Male Fertility*

Very recently, a completely new path to population suppression via impaired male fertility has been studied; the idea is based on the fact that mitochondria are inherited maternally. Therefore, mutations on the mitochondrial DNA (mtDNA) that are deleterious to males escape evolutionary selection to a high degree; the mutations don't have negative effects on the females which pass them on across generations (Frank and Hurst 1996; Gemmell et al. 2004; Beekman et al. 2014). By releasing females carrying such mutations into wild populations, these females and their female descendants would continuously produce males with impaired fertility, which should cause perpetual suppression of the target population. This idea was termed the Trojan Female Technique (TFT) (Gemmell et al. 2013). The initial data from different organisms, including *Drosophila* (Yee et al. 2013; Dowling et al. 2015; Patel et al. 2016; Wolff et al. 2016) and the cowpea weevil *Callosobruchus maculatus* (F.) (Dowling et al. 2007), show that such mtDNA mutations indeed can affect male fertility without affecting female fertility, supporting the possibility of using TFT for population suppression. However, there are many factors that could influence the effectiveness of the TFT (Wolff et al. 2016); for example, females could still get enough viable sperm to fertilize the eggs if males are not completely infertile or by remating with another partially fertile male. Moreover, the selective pressure on the males could lead to compensatory mutations, and genetic drift and population dynamics among other factors could lead to the disappearance of male fertility-impairing mutations even if they are not selected against (Rand et al. 2001; White et al. 2008).

An initial study with *Drosophila melanogaster* showed that a male-harming mitochondrial haplotype can indeed decrease the population size under density-controlled conditions over 10 generations by an average of 8% at a 75% haplotype frequency at the start of the treatment (Wolff et al. 2016). However, when the population size fluctuated, no effect was observed, although the TFT haplotype was stably persistent in most cases. Many more studies with different candidate mutations will be necessary to test if such Trojan females can indeed decrease the population size to meaningful levels under natural population conditions and across generations. If a naturally occurring mtDNA mutation was used, TFT would also be considered a non-transgenic approach.

Nevertheless, independent of the technology and strategy used, each product resulting from the application of modern biotechnology should be thoroughly tested and evaluated for functionality, efficacy, safety, and stability of the applied system. The ultimate goal is to select a safe, economical, and ethical strategy to perform environment-friendly and thus sustainable pest control for most of the important insect pest and vector species.

## SUMMARY

Geographic information systems (GIS) and spatial modelling are crucial for designing, implementing, and optimizing area-wide programmes of insect and/or disease control. This chapter provides a basic introduction to the science of GIS, Global Positioning System (GPS), satellite remote sensing (RS), and spatial modelling, and reviews the principal ways in which these technologies can be used to assist various stages of development of the sterile insect technique (SIT) as part of area-wide integrated pest management (AW-IPM) programmes — from the selection of project sites, and feasibility assessments and planning of pre-intervention surveys, to the monitoring and analysis of insect suppression programmes, and the release of sterile insects. Potential barriers to the successful deployment of GIS tools are also discussed.

## 1. INTRODUCTION

The success of the sterile insect technique (SIT) and other area-wide interventions, aimed at controlling populations of insect pests, depends to a large degree on appropriate project planning and implementation. More specifically, successful programmes depend on an accurate knowledge of pre-existing distributions of insects in time and space, on the appropriate design of insect suppression strategies and sterile insect release projects, and on the development of suitable frameworks for monitoring and evaluation. Methods and tools have become available that enable the development of models simulating the demography of a metapopulation of insects, thus making the *ex-ante* assessment of various control strategies possible (Peck 2012; Peck and Bouyer 2012).

Geographic Information Systems (GIS), the Global Positioning System (GPS), remote sensing (RS), and spatial modelling are allied technologies that together provide a means of gathering, integrating, and analysing spatial data. These tools are already being used extensively in other areas of agroecological management and epidemiological research (Barnes et al. 1999; Nutter et al. 2002; Moiroux et al. 2013; Tsafack et al. 2013; Dicko et al. 2015), and their use within area-wide integrated pest management (AW-IPM) programmes (Adam et al. 2013; Percoma et al. 2016) including those with an SIT component is growing quickly (Bouyer et al. 2010; Dicko et al. 2014). The tools are becoming increasingly accessible to non-specialists thanks to a wide range of freeware (FAO/IAEA 2006).

The principal aim of this chapter is to present applications of GIS and associated spatial tools within AW-IPM programmes. The first part of the chapter constitutes a short primer on GIS, GPS, and RS technologies. Subsequent sections illustrate the use of these tools in ecological and epidemiological studies, and address issues specific to

area-wide programmes integrating the SIT, particularly with respect to the use of spatial tools in feasibility assessments, planning and implementing pre-intervention surveys, and guiding the subsequent operational programmes of insect suppression and sterile insect release.

## 2. SPATIAL TOOLS: STATE OF THE ART

### *2.1. Geographic Information Systems (GIS)*

GIS can be defined as computer-based systems capable of capturing, cleaning (checking for errors and gaps), integrating, storing, retrieving, analysing, and displaying spatial data. GIS incorporate spatial data (geographical features) in the form of geographical coverages (maps), and descriptive data (attributes) in the form of relational databases linked to the mapped features (Kitron 1998).

GIS coverages can be developed using information from a variety of sources, including digitized paper maps, field surveys using hand-held GPS receivers, and thematic layers derived from remote sensing. Much of the utility of GIS stems from their ability to combine datasets of different provenances, spatial scales, and data types. Most, if not all, of these applications have become freely available in general-purpose computing environments such as R (Bivand et al. 2008).

In most GIS packages, geographic data are represented by vector and raster data models. In the vector model, geographical features are represented by points, or as lines and polygons made up of points joined by lines (arcs). In the raster model, spatial data comprise a regular grid of cells in which points are represented as single cells, and lines as strings of connected cells. Raster data are better suited to storing and modelling variables that vary continuously in space (Bonham-Carter 1994). Topographic data, for example, are commonly stored as raster grids (digital elevation models). Climate data, which vary continuously in space and time, are also commonly stored as rasterized climate "surfaces" (Hutchinson et al. 1995) or raster stacks combining hundreds or thousands of elementary rasters (Anyamba et al. 2014). Most GIS software packages can handle both vector and raster data, which are complementary and frequently used jointly.

GIS can be used for their mapping and visualization capabilities, or for much more sophisticated forms of spatial and statistical analysis. In this context, spatial analysis refers to the manipulation and transformation of GIS data to extract additional meaning from them. Common examples of spatial analysis include buffering map features (e.g. to define areas of exposure (potential infestation) around insect-breeding sites), interpolating between points (e.g. to produce climate "surfaces" from a network of weather stations), overlaying a number of individual geographical coverages to produce derivative maps, or even spatial modelling of suitable landscapes for target insect species, insect distribution or density. The latter approach can often take the form of "suitability analysis", in which spatial coverages are weighted and combined to identify and display locations that meet specific criteria (Clarke et al. 1996). Later in this chapter, an example is described in which suitability analysis has been used for decision support in trypanosomosis control. Several introductory texts provide more detail on the range of spatial analytical techniques

available in most GIS packages (Bonham-Carter 1994; Burrough and McDonnell 1998).

GIS software and general-purpose computing environments now commonly include a range of geostatistical commands and specialized add-on packages allowing basic as well as sophisticated spatial analyses, including testing for space-time clustering among point and polygon data (Pfeiffer and Hugh-Jones 2002; Bivand et al. 2008). This type of exploratory data analysis is particularly appropriate for identifying unusual spatial patterns within large datasets, and is often used as a means of hypothesis generation.

The accuracy of the final output from a GIS-based analysis is, to a significant degree, determined by the quality of the data in the GIS. The spatial and temporal resolutions of the data used in GIS need to be appropriate for the application in question. For example, topographic maps at a scale of 1:250 000 would be of little use in a village-scale study. Similarly, a series of annual climate surfaces would be ill-suited to attempts to determine the seasonality of insect populations. Hand-held GPS receivers for ground assessment and validation, and satellite remote sensing for updated information on changes in surface conditions, have become easily accessible for pest control programmes.

### *2.2. Global Positioning System (GPS)*

Hand-held GPS receivers are ideally suited to mapping spatial features where conventional maps are unavailable or inadequate (Thomson and Connor 2000). The basis of the GPS is a constellation of 24 NAVSTAR satellites developed and maintained by the US Department of Defense. These satellites act as reference points, with each satellite transmitting a radio signal in the form of pseudo-random code. On the ground, GPS receivers use this code to determine distances to each satellite ("ranging"), and calculate their position and altitude by "trilaterating" signals from a number of satellites. A European alternative named "Galileo" was launched in May 2016 with two new satellites, and will allow much more accurate positioning, but it will not be available before 2020.

GPS receivers typically achieve a horizontal accuracy in the 5–15 m range. Positional errors arise mainly from atmospheric effects on the GPS signals, from clock errors, and as a result of multipath reflection of signals at ground level. Much of the error due to atmospheric effects can be removed using "differential" GPS techniques, in which positions obtained from a roving GPS are corrected using signals received by a static GPS located at an accurately surveyed position. Horizontal accuracy using differential GPS techniques is usually in the 1–5 m range, although sub-metre accuracy can also be achieved depending on the hardware used. However, in most ecological or entomological survey situations, a positional error of 5–15 m is probably acceptable.

GPS receivers are often used simply to collect spatial data (coordinates) for geographical features, with associated attribute data recorded separately and manually on survey forms. However, in many cases, GPS-receiver software now includes programmable "data dictionaries" which can be used to capture attribute information directly. Alternatively, some GPS receivers can be linked up to other devices such as

a tablet or a notebook computer. Both approaches greatly increase the speed and efficiency with which GPS data can subsequently be incorporated into existing GIS.

It is also possible to upload the results of spatial modelling, like suitable habitats for insects (see below), using a GPS to guide operational teams toward specific sites used for monitoring (Bouyer et al. 2010) or control (Dicko et al. 2014).

### *2.3. Satellite Remote Sensing (RS)*

Satellite RS is the process of gathering information about the earth's surface using electromagnetic sensors on board satellites. Sensors can be "passive", e.g. Spot, Landsat, and Meteosat satellites, in the sense that they detect solar radiation reflected from the earth's surface, or "active", e.g. radar, which provide their own energy source for illumination, and the reflected radiation is measured by the sensor. The latter have rarely been applied in ecological and epidemiological studies. Data from passive sensors can be used in a relatively raw form, e.g. to derive land-cover classification maps, or can be transformed into indices that constitute direct proxies (substitutes) for environmental variables, such as rainfall, land-surface temperature, and vegetation status (Hay et al. 1996).

The value of satellite RS for ecological research has long been recognized, particularly in terms of its ability to offer objective, up-to-date assessments of surface conditions over large, sometimes inaccessible, areas. Moreover, the repeatability of satellite measurements makes RS particularly suitable for monitoring environmental conditions over time. The applicability of remote sensing to different types of ecological study will, however, depend on both the nature of the study and the spatial, temporal, and spectral characteristics of available image data (Box 1).

Images from different sensors vary greatly in terms of spatial resolution, e.g. with pixel sizes for commonly available products currently ranging from under a square metre to several square kilometres. Similarly, the temporal resolution (or revisit time) of individual sensors can be as little as 30 minutes in the case of geostationary meteorological satellites, or as much as 30 days in the case of some polar-orbiting satellites. Near-polar orbit satellites such as Landsat, Spot, or Moderate-resolution Imaging Spectroradiometer (MODIS) offer intermediary temporal resolutions, and are the most frequently used. In a project that requires local, detailed assessments of land cover, spatial resolution will be the prime consideration when selecting satellite data. If the project is more concerned with changing meteorological and vegetation patterns over time, temporal resolution will be of greater concern.

Species distribution modelling is increasingly based on the combination of high spatial and temporal resolution data, particularly MODIS data (Hartemink et al. 2011; Dicko et al. 2014).

In the context of ecological and epidemiological studies, satellite data have been extensively used to model and predict the distributions of insects and/or associated diseases in time and space (Rogers and Randolph 1986; Rogers et al. 1996; Linthicum et al. 1999; Moiroux et al. 2013; Dicko et al. 2015). Modelling on a large scale has commonly involved using satellite data to delimit specific insect-breeding sites or habitats (Linthicum et al. 1987; Pope et al. 1994; Rejmankova et al. 1995). On a national or regional scale, these distributions are more commonly modelled on the

basis of proxies for meteorological variables and/or vegetation status (Linthicum et al. 1987, 1990; Rogers et al. 1996; Hay et al. 1998; Brooker and Michael 2000; Randolph 2000). Several general reviews, covering these and other studies, are available (Thomson and Connor 2000; Hay et al. 2006).

*Box 1. Resolution in Satellite Remote Sensing*

*Spatial Resolution (Fig. 1)*

The spatial resolution (pixel size) of various sensors varies enormously: 0.61–2.4 m for QuickBird, 5–10 m for SPOT 5, 15–90 m for ASTER, 15–60 m for Landsat, 250–2000 m for MODIS. The width (swath) of images varies accordingly, e.g. about 25 km for QuickBird, 185 km for Landsat. Polar-orbiting meteorological satellites have relatively low spatial resolutions and large swath widths (1.1 km and about 2400 km, respectively, for AVHRR), while images from Meteosat and other geostationary meteorological satellites have 1–8 km pixels, but comprise an entire earth half-disk.

*Temporal Resolution*

Temporal resolution is defined by the time taken for a satellite to revisit the same point in its orbit (repeat time). Sensors with high spatial resolutions tend to have low orbits and long repeat times, e.g. 16 and 26 days in the case of Landsat and SPOT satellites, respectively. Since over a year's period some satellites sense only a few images for a given locality, obtaining cloud-free data can be problematic. At the other extreme, meteorological satellites have very short repeat times (12 hours for AVHRR, 30 minutes for Meteosat), and obtaining cloud-free data is rarely a problem.

*Spectral Resolution*

Passive sensors detect radiation from the sun that has been reflected by the earth's surface (as well as, in some cases, radiation emitted directly from earth). The amount of reflected radiation depends on the nature of the surface and on the wavelength of the radiation concerned. For example, vegetation reflects most of the radiation it receives in the green (visible) part of the electromagnetic spectrum, but absorbs much of infrared energy. Dry soil, on the other hand, absorbs large amounts of visible light, but reflects a large proportion of near infrared. The ability to use these "spatial signatures" to infer surface properties depends on the spectral resolution of the remote-sensing data being used. Spectral resolution refers to the number, width and spacing of the spectral "bands" used by the sensor. Traditionally, most sensors have included three to seven bands in the visible and near-to-thermal infrared part of the electromagnetic spectrum (0.3–14-mm wavelengths). However some new sensors, e.g. MODIS and ASTER, have many more, and this improved spectral resolution should increase the ability to distinguish between different land-cover types.

Long-standing sensors, such as the National Oceanographic and Atmospheric Administration's Advanced Very-High-Resolution Radiometer (AVHRR), or the MODIS on NASA's Terra satellite, are helping to bridge existing gaps in data availability by providing data at both moderate spatial and temporal resolutions (250–2000 m, and daily, respectively, in the case of MODIS). Another Terra sensor, ASTER, provides imagery with a spatial resolution similar to Landsat and SPOT data (15–30 m in visible and near-infrared bands), but with a vastly superior spectral resolution. Commercial satellites now also provide relatively low-cost data at very high spatial resolutions. For example, data from Digital Globe's QuickBird sensor has a spatial resolution of 0.61 m in panchromatic mode and 2.4 m in multispectral mode. SPOT images offer a good compromise between spatial resolution and coverage. Pléiades 1A (launched in 2011), Pléiades 1B (launched in 2012), and SPOT 7 satellites (launched in 2014) deliver images at very high spatial resolution (0.5 cm and 1.5 m).

*Figure 1. The significance of spatial resolution in remote sensing. These images represent false-colour composites of data from three satellite-borne sensors: (Left) ASTER (bands 2, 3, 1) with a 15-m spatial resolution (pixel size); (Centre) Landsat ETM+ (bands 2, 4, 3) with a 30-m spatial resolution; and (Right) MODIS (MOD09A1 8-day surface reflectance composite, bands 1, 4, 3) with a 500-m spatial resolution. The images represent an area of approximately 7 x 8.25 km, and cover a portion of the Nile Valley in the vicinity of Merowe, northern Sudan. Field boundaries and roads are clearly visible in the ASTER data, but are less apparent in the Landsat data. At a resolution of 500 m, the spectral properties of the Nile channel and surrounding vegetation are not visually distinct. (Note that data from meteorological satellites (AVHRR and Meteosat) are commonly available at a resolution of 8 km.)*

By improving the accuracy and coverage, taking into consideration temporal and geographic requirements, current satellite imagery is ideally suited for disease/vector control programmes at regional, national or smaller scale. Thematic layers like hydrographic networks, human or animal densities, tree cover, and vegetation classification are available on the web and can be used for operational programmes (Cecchi and Mattioli 2009; Stevens et al. 2015; Nicolas et al. 2016). However, it is crucial to validate the various layers in the field depending on its intended specific use, particularly in the case of vegetation layers that should be validated depending on the ecology of the target insect species (Guerrini et al. 2008, 2009).

## 3. APPLICATION AREAS FOR GIS, GPS, AND RS IN OPERATIONAL PROGRAMMES

There is enormous potential to use powerful analytical frameworks in spatial decision-support systems in AW-IPM programmes, which can take decision-makers beyond the point of simply possessing data, information, and knowledge.

Individually, GIS, GPS, and RS potentially have several important roles to play at various stages of project planning and implementation. The following sections illustrate how these technologies can be used to prioritize areas for control operations or to optimize these operations. Several key individual stages of project planning and implementation are addressed, from the design of pre-intervention surveys to monitoring and analysing data from insect release programmes.

### *3.1. Planning and Implementing Pre-Intervention (Insect, Disease, Host) Surveys — GIS-Based Modelling of Spatial Distribution of Target Insects*

Insect pest control programmes, integrating a combination of suppression techniques, require accurate, up-to-date information on the spatial and temporal distribution of the target insect population. A spatially-explicit analysis can bring together a wide range of information sources — e.g. climate data, remote-sensing data, land-use and topographic data, historical data on insect distribution and abundance, disease prevalence, etc. — that together can be used to develop modelled or empirical estimates of the temporal and spatial distributions of the pest or disease. The nature of this spatial analysis, and the data sources used for it, will reflect the stage to which pre-intervention planning has developed. At the very early stages of feasibility assessment and planning, for example, spatial modelling will focus on identifying areas of relatively high pest density or areas where intervention programmes have potentially high benefit-cost ratios (Mumford, this volume) at the national or regional level, using low spatial resolution data for climate and medium or high spatial resolution data for land cover in combination with available historical information on the insects and/or diseases. These maps may be adequate for planning purposes in cases where insect intervention programmes are implemented at the national or regional scale. In other cases, it may be more appropriate to use these broad assessments for directing more detailed modelling efforts, using higher-resolution geographic datasets to focus sampling of insects to specific areas of interest.

*3.1.1. Mapping Pest Distribution on a Regional Scale*

Many published research studies have used GIS and RS to predict the distribution of insects on national to global scales (Hay et al. 2006; Rogers 2006). The discussion here is limited to work most pertinent to using the SIT in the context of AW-IPM programmes, most of which has focused on the spatial prediction of tsetse flies *Glossina* spp.

The use of low-spatial-resolution satellite data to predict insect distributions dates back to attempts in the early 1990s to correlate the distribution of tsetse and the incidence of trypanosomosis to spatial variations in climate and the normalized difference vegetation index (NDVI) (Rogers 1991; Rogers and Randolph 1991; Rogers and Williams 1993). Later models also incorporated surrogates of land-surface temperature from AVHRR satellite data, and a proxy variable for rainfall (cold-cloud duration) from Meteosat data. Rogers et al. (1996), for example, used Fourier-processed satellite data for climate and NDVI in combination with digital elevation data to predict the presence/absence of eight tsetse species in Côte d'Ivoire and Burkina Faso, with an accuracy of 67–100%.

A similar approach, using logistic regression, has also been used to model ranges of tsetse species in East Africa. The modelling process relies on the logistic regression of fly presence against a wide range of predictor variables for a large number of regularly spaced sample points for each area. The predictor variables include remotely sensed (satellite image) surrogates of climate — vegetation, temperature, and moisture, which have been subjected to Fourier processing to provide an additional set of season- and timing-related measures for each parameter. Demographic, topographic, and agro-ecological predictors are also used. These models are then applied to the predictor imagery to produce predicted probabilities of fly distributions at 1-km resolution.

In southern Africa, Robinson et al. (1997) used climate surfaces, together with NDVI and elevation, to model the distributions of three tsetse species in the common fly belt. Maximum-likelihood classification techniques yielded overall correct predictions of 92.8 and 85.1% for *Glossina morsitans centralis* Machado and *Glossina morsitans morsitans* Westwood, respectively. In Togo, Hendrickx et al. (2001) found that discriminant models, based on satellite data, were generally less successful at predicting disease outcomes in cattle (trypanosomosis prevalence or packed-cell volume) than tsetse abundance.

More recently, MaxEnt models have been used extensively to predict tsetse suitable habitats in southern (Matawa et al. 2013) and western Africa (Bouyer et al. 2015; Dicko et al. 2015). MaxEnt, one of the most widely used species distribution models, is a machine-learning method based on the information theory concept of maximum entropy (Elith et al. 2011). MaxEnt fits a species distribution by contrasting the environmental conditions where the species is present to the global environment characterized by some generated pseudo-absence data, also called the background. The logistic output gives us a quantitative indicator of the habitat preferences of the species in the study area (Fig. 2). In West Africa it was used, together with a friction model to predict the resistance of landscape to tsetse dispersal (Krafsur and Ouma, this volume), to identify isolated populations of *Glossina palpalis gambiensis* Vanderplank that could be potential targets for eradication.

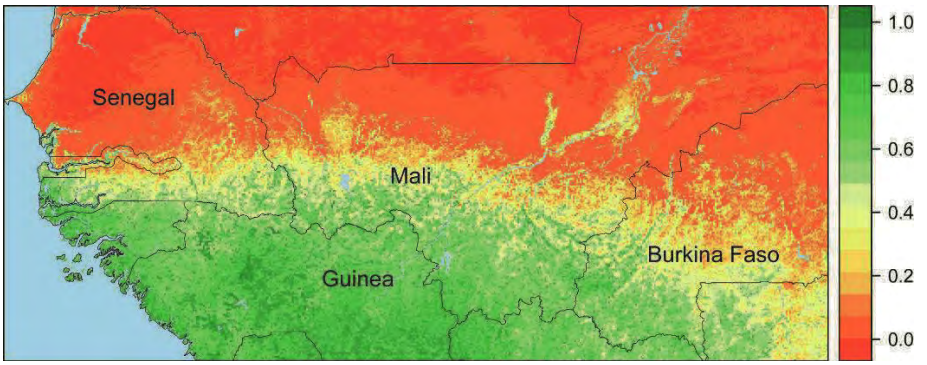

*Figure 2. Distribution of* G. p. gambiensis *in West Africa. Mean habitat suitability index predicted by a MaxEnt model. The index varies between 0 (less suitable, red scale) and 1 (highly suitable, green scale). (Modified from Bouyer et al. 2015, reproduced with permission.)*

High predictive accuracy in prediction models requires recent and well-distributed insect data to train and validate the prediction process, and assess the accuracy of the model output. Models based on entomological data that were collected several decades ago may be used for regional prioritization of tsetse and trypanosomosis interventions but, because of their poor sensitivity and specificity, should be avoided for guiding control programmes (Guerrini et al. 2009).

Data on insect abundance is even more sensitive because the efficiency of traps depends largely on environmental conditions, period of the year, experience of the entomological team, etc. At the continental or regional scale, it could be argued that the relative risk of insect presence is an adequate indicator of abundance. However, this assumption is not valid for smaller areas, where models require up-to-date data from abundance surveys. It is probable that, in these situations, the principal role of RS and GIS is to make prospective surveys more cost-effective (Hendrickx et al. 1999). In Burkina Faso a large grid-based baseline data survey, implemented in preparation for a control programme (L. Percoma, personal communication), deployed 3189 traps in an area of 40 000 km$^2$, and the data were used to develop a spatio-temporal model of African Animal Trypanosomosis (AAT) risk that was validated using parasitological data on cattle (Dicko et al. 2015; Feldmann et al., this volume). The model included the prediction of tsetse densities and their infection rate, and hence such predictions can be very useful to focus the control effort on disease transmission "hot spots".

### *3.1.2. GIS for Decision Support*

Mapping pest distribution on a regional or national scale is an important first step in assessing the feasibility and spatial targeting of the SIT and other area-wide control actions. However, technical and resource constraints may make large-scale operations, over the whole of the identified area of potential pest distribution, to be impractical or uneconomic. Therefore, specific environmental information is required,

either to identify parameters that are linked to pest presence, or to guide future sampling efforts to address specific questions including levels of genetic variability, similarity, and diversity among target insects.

Recently, the economic benefits to livestock keepers from intervening against AAT were mapped in eastern Africa (Shaw et al. 2014). The study was conducted for six tsetse-infested countries in eastern Africa: Ethiopia, Kenya, Somalia, South Sudan, Sudan, and Uganda. Cattle production systems were mapped, and herd models for each production system were developed, in the presence or absence of AAT. The differences in income between these two scenarios enabled the mapping of the maximum potential benefits that could be obtained from tsetse and trypanosomosis control. The potential benefits ranged from USD 500 per square kilometre to more than USD 10 000. Such models could be used to prioritize tsetse and trypanosomosis interventions on a regional scale when used in combination with other data layers, e.g. tsetse distribution and density. The models also accounted for possible restocking of livestock in neighbouring areas when maximum stocking rates were exceeded.

### *3.1.3. Mapping Pest Density with a Large Spatial Resolution*

The spatial distribution of most insect pests is not uniform but patchy, and there can be localized pockets of high insect density, in spite of a potentially misleading low-overall population density. It is of prime importance, for the development and implementation of an insect control programme, that these pockets or "hot spots" be located (Shiga 1991).

Depending on the spatial scale of the heterogeneity of insect density, the climate and remote-sensing datasets used to predict insect distribution over wide areas may not be appropriate for work on larger scales. AVHRR data, for example, have a native resolution of 1.1 km, but are commonly resampled to derive images with 4×4 or 8×8 km pixels. However, several studies have successfully used high-resolution spatial data from Landsat and SPOT satellites to identify habitats associated with high insect density (Rejmankova et al. 1995; Roberts et al. 1996). For tsetse flies, fine-tuned studies of their habitat (type of vegetation and fragmentation level) at a high resolution (Landsat ETM+ data with a 30-m resolution) successfully predicted their densities at a local scale in Zambia and Burkina Faso (Guerrini et al. 2008; Ducheyne et al. 2009). More recently, MODIS data (1-km resolution) were used to upscale these studies to a national level in Burkina Faso (Dicko et al. 2015).

Since the spatial distributions of insect populations are not constant, but tend to change over time, it is important that, where possible, risk maps be dynamic rather than static. For example, populations of riverine tsetse flies in West Africa commonly expand and contract seasonally along the river vegetation and perpendicular to the tributaries. The use of spatial analysis incorporating multi-temporal remote-sensing data enabled generating a "dynamic population distribution model" to predict these temporal and spatial population dynamics, and to link spatial patterns with heterogeneity of habitat (Dicko et al. 2015). This allows a more efficient and guided (rather than ad hoc) deployment of sampling devices during subsequent surveys, i.e. the sampling devices can be deployed in those areas where there is a high probability of trapping or, alternatively, in areas of low probability to confirm the model). The implication is that, assuming an adequate geo-spatial model exists, an efficient survey

strategy can be developed largely from the office, and detailed implementation guidelines, regarding where, how, and when to deploy the sampling devices, can be elaborated for the field teams. This would not only ensure adequate sampling coverage in all ecosystems, but also prevent the deployment of too many sampling devices in unproductive or unrepresentative sites, unnecessarily increasing project costs (Bouyer et al. 2010).

The availability of temporal and spatial distribution models of the target insect populations on a large spatial scale has implications beyond the design of efficient sampling frames. In particular, such models can facilitate a more-efficient deployment of suppression tools and also a better-targeted release of sterile insects (Dicko et al. 2014). This would also enable simulating combinations of strategies like successive or simultaneous use of insecticide targets and the SIT to identify the most effective strategy (S. L. Peck, personal communication). This increased efficiency should also translate into considerable economic savings in terms of logistics, personnel and sterile insects.

### *3.2. Development and Implementation of Appropriate Insect Suppression and Sterile Male Release Programmes*

#### *3.2.1. Selection of Appropriate Suppression Methods*

Since the release of sterile insects is only efficient when they sufficiently outnumber the native insects, the SIT is more cost-efficient with a reduced density of the target population (Dame 1971). The density of untreated insect populations is usually too high, and needs to be reduced prior to the mass-release of sterile insects. Depending on the target insect, a variety of pre-release population suppression methods are usually available (Mangan and Bouyer, this volume), but their usefulness, appropriateness, and effectiveness will be determined by the characteristics of each target area or local situation. Pending the availability of suitable data layers (demography, land use/land cover, vegetation classification, distribution of target insect, etc.), spatial analysis can assist with the decision to select the most appropriate suppression method for a given target zone. This is demonstrated by the following examples for the suppression of tsetse fly populations in AW-IPM programmes:

- *Sequential Aerosol Technique (SAT).* The SAT involves the application of non-residual ultra-low-volume insecticides by fixed-wing aircraft or helicopter (or from vehicles using hot and cold fogging). The goal is to kill adult tsetse flies in the first spraying cycle by direct contact with insecticide droplets, and then kill emerging flies in five subsequent application cycles before the emerged flies can deposit larvae (Allsopp 1984). In view of the sensitivity and susceptibility of the SAT technique to topography, wind velocity and direction, temperature inversion, etc., a spatial analysis can provide information on the suitability of the target zone in terms of: (1) topography (the application of the SAT becomes problematic when the terrain becomes mountainous), (2) habitat and vegetation cover (correlation analysis between the vegetation density and the propensity of insecticide droplets to penetrate the tree canopy, to make predictions on the vertical dispersal rate of insecticide droplets in various vegetation types), and (3)

wind velocity (using climatic models to predict the dispersal and distribution patterns of insecticide droplets in each particular situation). In the eradication programme against *Glossina morsitans centralis* in Botswana (Kgori et al. 2006), GIS not only enabled the close alignment of flight swaths to assure full coverage of the target population in the spraying areas, but were also used to develop the monitoring system that demonstrated the successful outcome of the project.

- *Live-Bait Technology.* In this technique, residual insecticides are applied to host animals that attract tsetse flies, which are killed on contact with the insecticide (Bauer et al. 1992). The technique is efficient and cost-effective, provided the density of the livestock population in the target area (if livestock is the main host) is sufficiently high. The distribution of animal herds is generally heterogeneous in space, and GIS can help identify areas where additional control tactics such as targets and traps are necessary to control the target population (Kagbadouno et al. 2011; Adam et al. 2013).
- *Stationary-Bait Technology (insecticide-impregnated targets and traps).* Tsetse populations can also be suppressed by deploying artificial stationary devices, which attract tsetse flies (Green 1994). The flies will be killed either upon making contact with the surface area of the target/trap (which is impregnated with a residual insecticide) (Laveissière et al. 1980) or when retained in a no-escape device (Dransfield et al. 1990). A spatial correlation analysis, using demographic data layers and tsetse population distribution models, can indicate how efficient or suitable this technology is in specific areas.

### *3.2.2. Models to Predict Outcome of Different Suppression Scenarios*

Each area targeted for control will in most cases be heterogeneous, in terms of composition of the habitat (land use and land cover), vegetation cover and species composition, host (e.g. livestock and agricultural crops) distribution, demography, topography, etc., which will demand an integration of different suppression methods (Vreysen 2001; Mangan and Bouyer, this volume). Spatial analysis can be used to model the effect of various combinations of methods on the insect population, and assist in the decision to select the best combination (Kagbadouno et al. 2011; Adam et al. 2013).

### *3.2.3. Implementation of Suppression and Sterile Male Release Programmes*

Aside from providing decision-support in the development and implementation of surveys, optimizing the suppression phase, and modelling the outcome of various suppression scenarios, GIS tools can assist in the actual implementation of suppression programmes, including sterile insect releases. A geo-spatial model, e.g. developed in the programme against *G. p. gambiensis* in Senegal to guide the distribution and density surveys, can be exploited to inform decisions on how a suppression strategy can be implemented. For example, spatial analysis can provide decision-support to select appropriate sites to deploy insecticide-impregnated traps and targets in tsetse suppression programmes, and ensure that the required target/trap density per surface unit is achieved with respect to vegetation type, topography, insect distribution, and other relevant factors (Fig. 3 and Box 2).

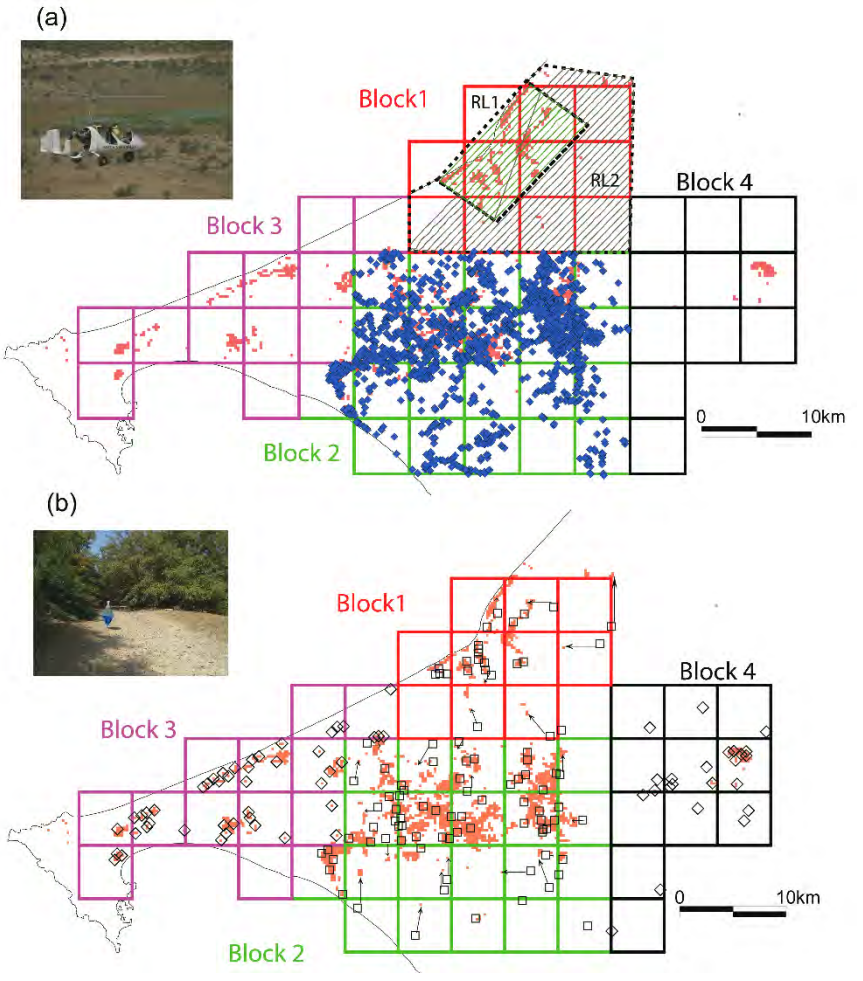

*Figure 3. GIS and spatial modelling to optimize the tsetse eradication project in the Niayes region of Senegal. (a) Optimization of the integrated control strategy using model predictions. A MaxEnt model predicted suitable habitats for G. p. gambiensis (sensitivity 0.96, specificity 0.57). Block 1 - suitable habitats delimited two polygons for aerial releases (RL1 and RL2) where the minimum numbers of sterile males released per km$^2$ were 24 and 11, respectively. Chilled adult tsetse flies were released with a Mubarqui smart release machine in a gyrocopter (upper left) from the Kalahari aerodrome. Block 1 - green and grey lines show the track flying records on 14.04.2014 in RL1 and 11.04.2014 in RL2, respectively. Block 2 – for population suppression 1347 insecticide-impregnated traps were set from December 2012 to February 2013 in the predicted suitable sites (blue lozenges). (b) Optimization of the monitoring system (biconical traps, upper left) using MaxEnt model predictions. Blocks 1 and 2 - 23% of the traps (black squares) deployed in the closest suitable patch. Blocks 3 and 4 (monitoring not yet started) - theoretical positions of the traps (black lozenges) suited to model predictions. Black arrows show displacements of traps following model predictions. (Modified from Dicko et al. 2014, reproduced with permission.)*

*Box 2. Past and Current Applications of GIS in Area-Wide Integrated Pest Management Programmes that Include the SIT*

The GIS/RS, as a decision-support tool in AW-IPM programmes integrating the release of sterile insects, has been used to spatially display data, and to plan, implement and evaluate programmes. AW-IPM programmes using the SIT against fruit flies are among the most successful programmes against major insect pests, and these programmes rely on the advanced use of GIS. In programmes against the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), such as the programme in Argentina, the "Moscamed" programme in Guatemala/Mexico, and the prevention programmes in California and Florida (Enkerlin, this volume), GIS/GPS/RS are mainly used to:

- Provide navigational guidance in the release of the sterile insects, and to provide "real-time tracking" using commercially available satellite navigation/flight recorders.
- Map and visually display the various trapping sites and monitoring routes.
- Select trapping sites, using a grid layer over topographical maps or satellite imagery, and associating the trapping site with host and topographical features and their attributes.

In addition, the "Moscamed" programme in Guatemala/Mexico is using GIS as a major component of various studies on: (1) fly performance in relation to altitude, wind velocity, habitat, etc., (2) "hot-spot" areas (where the pest persists over time despite intense efforts to suppress it), (3) insect behaviour in relation to the timing of release (afternoon, night, or morning), and (4) changes in the dispersal behaviour of sterile insects over time (P. Gomes, personal communication).

GIS/RS were also used in AW-IPM programmes against the New World screwworm *Cochliomyia hominivorax* (Coquerel). In Panama, GIS/RS were used to identify different vegetation types, and correlate the spatial and temporal distribution of screwworms with the various vegetation covers in a tropical environment. After classifying the forests based on tree height, structure, and species composition, the highest screwworm population density was found during the transition period from the wet to the dry season, and in forest habitats as opposed to open areas (Phillips et al. 2004). These data were used to more efficiently deploy monitoring tools in habitats favoured by screwworms, which could lead to earlier detection of low densities of screwworm populations, or possibly earlier control of outbreaks. The study clearly showed that GIS/RS can be used to improve trap placement by identifying areas of high screwworm activity. The method was applied in early 2003 to develop a trapping strategy after the accidental outbreak of the screwworm at the screwworm facility in Chiapas, Mexico (Phillips et al. 2004). Using GIS/RS techniques, optimal trapping sites were selected, which represented a reduction of 79% of the original trapping sites, i.e. considerable savings in terms of personnel and logistics.

A recent example of using GIS and spatial modelling for planning, implementing and evaluating an AW-IPM program with an SIT component is the tsetse eradication programme in Senegal. In this programme suitable tsetse habitat was identified using a supervised classification during the feasibility phase, which reduced by 94% the required sample area to identify the distribution limits of target populations (Bouyer et al. 2010). Thereafter, these technologies were used during the pre-operational phase to assess the survival, mortality, and competitiveness of sterile males during pilot release trials. Finally, the method to identify suitable habitats for *G. p. gambiensis* was optimized and improved by RS techniques that were based on a MaxEnt population distribution model (Dicko et al. 2014). Using this model the number of traps per km² needed to suppress tsetse populations was reduced by >95%. The model was also used to determine the densities of sterile males to be released in the target area, i.e. 10 sterile males per km² if the habitat was unsuitable, 100 sterile males per km² if it was suitable. The releases were done using an automatic chilled-adult release device that was parameterized with the GIS during the flights. Finally, it improved the sensibility of the permanent monitoring system by locating the fixed monitoring sites in the most suitable places (Fig. 3).

The uniform application of certain suppression measures (e.g. bait sprays for fruit flies, SAT for tsetse flies) over a heterogeneous pest distribution target area can have negative implications, both in terms of cost and environmental impact, since habitats may be contaminated by unnecessary applications of insecticide (Papadopoulos et al. 2003). Navigation/recording systems (such as Trimble's TrimFlight 3 Ag-GPS system or SATLOCK's AirStar system), which guarantee the correct application of the insecticides during aerial application, and ensure that fuel and materials are used efficiently, have been used for years in several fruit fly AW-IPM programmes that release sterile flies. Using these systems facilitates precise guidance, automated recording of covered areas (maximum efficiency, minimum overlap, and skips (omission of areas), identification and remedy of skips before leaving the operational area (avoiding costly call-backs), waypoint navigation, mapping capabilities, and control of insecticide-flow and sterile insect release rates (depending on pest distribution and density) based on ground speed. This eliminates the need for time-consuming and costly ground markers, such as beacons or flaggers. The system is compatible with a wide range of GIS software packages, and enables applications to have better than 1-m accuracy.

In many programmes that include the release of sterile insects, these are released at a constant dispersal rate (i.e. a uniform density per surface unit). As a consequence, insufficient overflooding ratios might result in areas of high native-insect population density, whereas more sterile insects than necessary might be released in areas of low native-insect population density (Vreysen, this volume). GIS and spatial analysis can provide guidance on spatial sterile insect requirements and dispersal patterns, in relation to wild insect population densities, habitat, elevation, etc. in a dynamic way (i.e. data layers on the target insect distribution are updated regularly or spatio-temporal models of insect densities are used (Dicko et al. 2015)). This will result in a much more efficient use of sterile insects. In addition, commercially available satellite navigation/flight recorder systems, e.g. Ag-Nav, provide real-time tracking, and can visually display the areas that were treated with sterile insects (or have been left out), and at which altitude insects were released (to ensure a proper spread). This permits proper feedback to programme managers (Dowell et al., this volume).

An example of a new automatic release system is the Macx System (Mubarqui group); it has been used routinely in fruit fly control programmes. It is linked to GIS software installed on tablets on board the aircraft. These systems ensure an efficient use of the sterile insects available as they automatically start and stop the releases of sterile males when entering or leaving the release areas (Fig. 4a), but also because they can adapt the sterile male release density to that of certain vegetation types, topography or density of the wild populations (Mubarqui et al. 2014). (For example, in Valencia, Spain, the rate of releasing sterile Mediterranean fruit flies is automatically adjusted according to the ripening period of citrus varieties in the target area (R. Argilés Herrero, personal communication)). The software provides automatic reports of the flights by uploading the data to an online relational database once the aircraft is back at the airport, or even in real time using a Global System for Mobile Communications (GSM) connection.

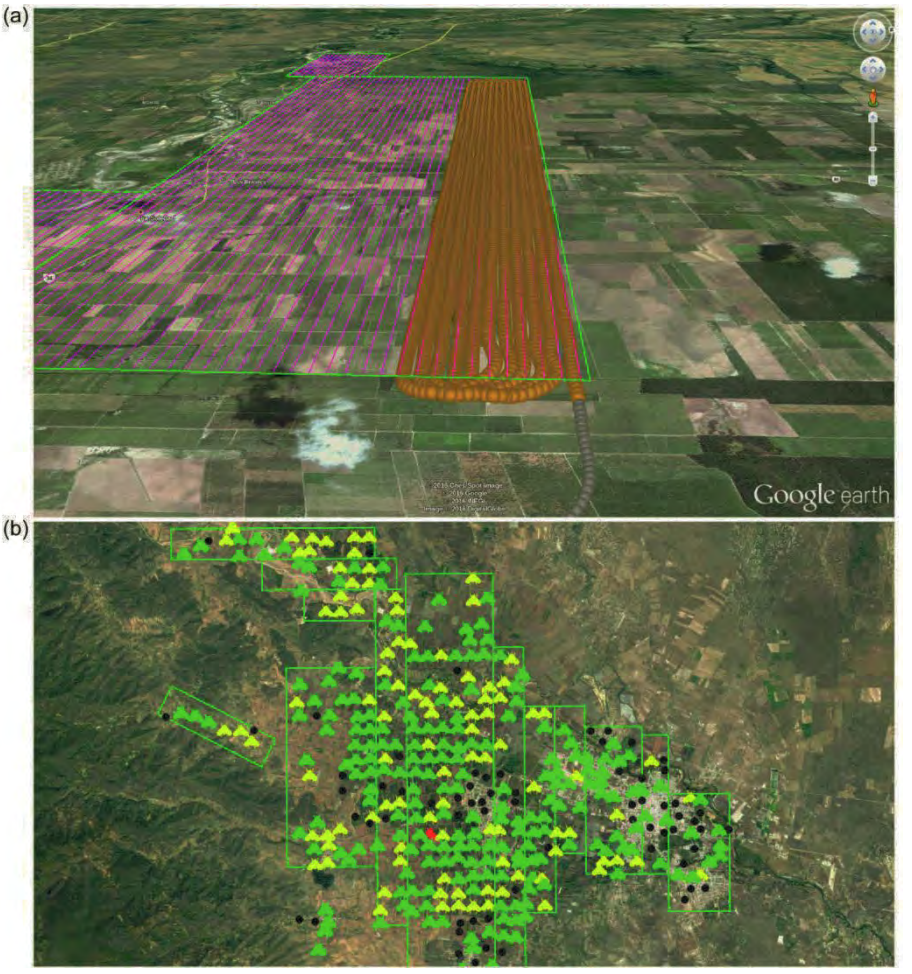

*Figure 4. Optimization of area-wide fruit fly control in Mexico using the Macx System. (a) Parametrization of the sterile male releases of Anastrepha ludens (Loew) near Padilla, Tamps, on 10 July 2016. Release polygons are shown as green rectangles, theoretical release lines as pink lines, and tracks of the actual flying/release lines as orange-coloured spheres. (b) Monitoring results of A. ludens on week 28 of 2016 near Rio Verde, San Luis Potosí. Release polygons are shown as green rectangles, traps with catches of only sterile males as symbolic green flies, traps with catches of mixed sterile and wild males as yellow flies, traps with catches of only wild males as red flies, and traps without captures as black circles. (Reproduced with the permission of the Mubarqui group.)*

### *3.3. Monitoring Suppression or Release Programmes*

Monitoring is an essential component of any AW-IPM programme (Vreysen, this volume). However, monitoring is time-consuming, and requires considerable funds for materials, logistics, and personnel. A careful balance must be found between "cost-efficiency" and collecting "reliable data". In most AW-IPM programmes, in view of the size of the target areas, monitoring (direct and indirect) must be restricted to carefully selected representative sites. Spatial analysis can assist in identifying and selecting appropriate reference or fixed monitoring sites (FMS). The concept of FMS was developed and used during the monitoring activities of the AW-IPM programme in Zanzibar, Tanzania, against the tsetse fly *Glossina austeni* Newstead, albeit without any GIS support (Vreysen et al. 2000; Vreysen, this volume), and was also used in the eradication programme of *G. p. gambiensis* in Senegal (Box 2).

From a pragmatic standpoint, it is important that all avenues of increasing the efficiency of trap-based monitoring systems are explored. Technologies that assist in the rapid transfer of data from the field to GIS are a key element of such systems. For example, in the codling moth AW-IPM programme in British Columbia, Canada, a GIS-based system is used to monitor a network of georeferenced traps. A bar-coding system is employed, in which the time and date that traps are monitored is automatically recorded, along with data on trap catch entered manually during a trap check (Dyck et al. 1993). These data can then be uploaded to the main project database via modem, facilitating the rapid output of electronic maps showing trap data.

Area-wide pest control activities can also use geostatistical analysis routines to get "better value" out of available trap data. A range of spatial analysis techniques, employing both geostatistics and GIS, may be valuable for analysing insect population processes at a landscape scale (Liebhold et al. 1993). Of these, one possible analytical technique is "kriging" — an interpolation procedure that relies on an autocorrelation function (the variogram) to provide weighting of nearby points used in the estimates. Kriging is ideally suited to the analysis of trap data, with interpolated output taking the form of contour maps or density surfaces of insect densities.

Such an approach has been used to monitor and predict populations of the spruce budworm *Choristoneura fumiferana* (Clemens), an important defoliator of trees in boreal forests in North America. Using kriging as a basis, Lyons et al. (2002) developed a set of software tools to produce interpolated estimates, using data from a pheromone-trapping network covering much of Canada and north-eastern USA. Output from the software system can be reclassified in a variety of ways, using GIS to provide maps that address particular management concerns. For example, maps are routinely produced that display areas where moth densities exceed a critical threshold, and hence where conventional larval sampling activities need to be initiated. Change-analysis approaches are also used to create difference maps for consecutive years which, when reclassified, highlight areas of increasing, decreasing and stable moth populations. Kriged map surfaces have also been used as variables which, when combined with historical data on defoliation and defoliation frequency, have been used to successfully predict levels of defoliation in the following year.

In the wider context of commercial crop decision-making, this type of approach has been taken a step further. In several states in the USA, integrated systems of insect and weather monitoring have been developed, providing estimates of insect and disease risk in near real-time. These systems, described by Thomas et al. (2002), use a network of georeferenced automated weather stations, which utilize radio telemetry to send data — on temperature, relative humidity, precipitation, and other meteorological parameters — every 15 minutes to a central processing centre. These data form the basis of Internet-based, daily estimates of weather and disease-risk related parameters (including insect degree-day maps), in addition to risk maps for specific diseases such as powdery mildew and *Botrytis* spp.

Another example of the use of GIS for monitoring is the Moscamed Programme in Mexico. This successful containment programme includes a trapping network of 24 760 georeferenced traps (14 710 in Chiapas and 10 050 in the rest of the Mexican States) (Enkerlin et al. 2015). Data of adult captures, including sterile and wild flies, enable the assessment of relative population density and ratio of sterile to wild males in space and time (Fig. 4b). A new system called "sabueso" has recently been developed by the Mubarqui group in Mexico, which represents a relevant advance in technology for capturing the information from the field in real-time from the trapping network. The system is installed in low-cost smartphones, and allows the monitoring teams who are seeking the larvae and outbreaks to report their observations in real-time to the team in charge of mechanical control. The same information is available in maps similar to Fig. 4b, enabling easy queries and analyses by management teams while optimizing economical and human resources.

### *3.4. Data Analysis*

Area-wide insect pest control programmes generate a large amount of entomological and other related data, not only during baseline data collection and feasibility surveys but also during the monitoring of suppression and release activities (Dyck, Reyes Flores et al., this volume; Vreysen, this volume). It is a real challenge to manage data efficiently, analyse and interpret the results in a timely manner, and provide programme managers with consolidated data in a suitable format. The GIS unit of any pest control programme, if linked to a relational database, provides an ideal medium for the storage and analysis of data, and it can greatly facilitate their interpretation. Adequate feedback to programme managers is a prerequisite for sound decision-making. The complexity and diversity of data accumulated during a control programme, requiring proper spatial analysis, are typified in the following examples:

- *Data derived from initial surveys.*
  Temporal and spatial fluctuations in:
  - Population distribution (immature and adult stages)
  - Population density
  - Population structure (composition -- immature and adult stages)
  - Disease prevalence or infestation level in hosts.
- *Data derived from monitoring suppression activities.*
  - Temporal and spatial changes in population distribution due to the application of the suppression methods

- Temporal decline in the density of the target pest population in relation to different ecosystems
- Temporal changes in population structure (due to increase in mortality rates) in relation to different ecosystems.

- *Data derived from monitoring sterile insect releases.*
  - Spatial and temporal fluctuations in the ratio of sterile to wild insects
  - Spatial and temporal fluctuations in the rate of induced sterility in the native insect population.

  Spatial correlation analysis using these variables will contribute to modelling the competitiveness of released insects in relation to habitat, host abundance/distribution, climatic variables, etc. Obtaining spatial and temporal data on sterile insect competitiveness is one of the most important features of any AW-IPM programme that releases sterile insects.
  - Spatial and temporal fluctuations in the recapture rate of insects in traps, damage to hosts, disease patterns, etc.

  These data can be correlated with the release rate of sterile insects over the release grids, and then models developed on the mobility, dispersal characteristics (Vreysen et al. 2013), and spatial occupation of the sterile insects in different vegetation types, etc. It can also be used to assess whether sterile males are aggregating in the same ecological niches as wild males -- to ensure appropriate sterile to wild male ratios throughout the control area (Vreysen et al. 2011).

The results of a spatial analysis of a suppression and release programme can provide answers on issues such as the adequacy of deployment of suppression devices (sufficient number, adequacy of spread, efficiency, level of damage, timeliness of replacement of the suppression methods, etc.), and the appropriateness of sterile insect release operations (e.g. coverage of the proper block, flight at the proper altitude, possibility that insects were blown into nearby bodies of water, influence of wind, delivery of sterile insects so that they find and concentrate at the same locations as wild insects, etc.). They can also be used to implement spatio-temporal models that enable the testing of various control scenarios and then using the most appropriate one (S. L. Peck, personal communication).

### *3.5. Support for Sterile Insect Quality Control*

Frequent monitoring of the performance of sterile insects (i.e. insect quality) in the field is an important, although often neglected, component of AW-IPM programmes that integrate the SIT (FAO/IAEA/USDA 2019). Parameters such as survival, mobility, dispersal characteristics, and spatial occupation of the habitat significantly influence the field performance or the competitiveness of released insects (Lance and McInnis, this volume; Parker, Vreysen et al., this volume; Vreysen, this volume). The values of these parameters may change over time, and are affected by host availability, vegetation cover, vegetation species, altitude, etc. GIS and spatial modelling can be used to predict these temporal and spatial changes in insect quality, and thus assist in developing remedies and timely adjustments in an intervention programme. As an example, swaths of flight release lanes are inherently linked to the dispersal capacity and mobility of the released insects, whereas their average survival

determines the release frequency (Hendrichs, Vreysen et al., this volume). Models can be developed to correlate sterile insect survival with host availability, vegetation cover, etc. to assist in regularly adjusting the dispersal rate of insects in relation to space (e.g. more frequent releases in those areas where survival is low). In addition, a spatial and temporal analysis of the dispersal characteristics offers opportunities to assess whether this parameter is changing with the length of time that the insects have been colonized in the rearing facility (Parker, Mamai et al., this volume).

There is great potential for GIS to support the assessment of the quality control of released insects, particularly with regard to: (1) comparing the performance (competitiveness, mobility, dispersal, survival) of sterile insects derived from different strains, (2) studying the effects of releasing flies using different release systems, or at different altitudes, over different topographies (e.g. canyons), at different wind velocities, etc., and (3) analysing hot spots or reservoir areas where the pest persists in spite of intense actions to suppress the population.

### *3.6. Barriers to Using GIS*

After the 1990's GIS became more available and accessible to the general public, and the further development and diffusion of GIS have made available a large amount of information from different sources. The cost of acquiring primary data (such as satellite remote-sensing data) has decreased considerably, and many satellite data are now freely available on the Internet. RS images and derivative products (vegetation indices, rainfall indices, etc.) are now available at different levels of geometric pre-processing, thus facilitating their use by non-experts.

Today, the barriers to successful GIS development are significantly lower than they were in the past. The costs of hardware are now relatively low, while most software and data are free. Perhaps most significantly, GIS software is becoming increasingly accessible to non-specialists; non-geographers, after receiving appropriate training, can now carry out many GIS procedures without specialist support (although this does not completely eliminate the need for expert input; note comments below under "GIS expertise").

These advances, however, do not mean that potential barriers or pitfalls no longer exist. Several considerations need special attention, particularly when working in the context of a developing country, if a GIS endeavour is to be successful (BESR 2002). These considerations include:

- *Technical limitations.* Limits in the accessibility of spatial data, such as inadequate telecommunications infrastructure, limited bandwidth or data storage capacities, and low Internet connectivity in certain countries, may hamper efforts to rapidly process and output GIS data.
- *GIS expertise.* Trained and experienced experts in GIS are often in rather short supply, particularly in developing countries. The increasing accessibility of GIS software does not obviate the need for input from appropriately trained operators. Technical issues around data capture and integration can be non-trivial, as are procedures for image processing. Decisions regarding accuracy and permissible levels of data generalization also require relevant experience on the part of the GIS operator.

- *Maintaining consistency.* In many instances, AW-IPM programmes are implemented over large geographical areas, i.e. on a national or regional scale, employing various field teams in a series of sub-programmes, each attached to a particular country, zone or region. Agreements must be reached on compatible GIS formats, standardized methods of data collection, and data resources. These need to be kept consistent throughout the life of a project.
- *Administrative challenges.* It can be a real challenge to easily gain access to available data because of unawareness about data request procedures on the part of government officials, complicated protocols for requesting government data, a variety of data standards making the sharing of data difficult, and complications due to copyright and distribution issues.
- *Pre-processing GIS and RS data.* This step is often the most time-consuming task in any project involving such data. Based on the data considered in the analysis and particularly for RS data, some pre-processing steps must be applied to make the data usable for further analysis. The most common pre-processing methods for RS data are corrections (radiometric and geometric corrections) that seek to minimize distortion caused by satellite sensors. Furthermore, image enhancement methods such as noise removal or filtering may also be applied to RS data prior to the analysis. Finally, other operations such as georeferencing and mosaicking (combining multiple images) can also be used before analysis.

It is important that, at all stages of GIS development, a dialogue between those responsible for designing and maintaining a GIS system, and those whose principal interest is the output of the system, begins at the start of the planning process, and continues throughout the life of a project. GIS operators need to realize that many decision-makers, in developed and developing countries, have no experience with GIS and other spatial decision-support tools, and thus do not appreciate the potential in using geographic information, or the technical issues involved in setting up and maintaining GIS.

In this context, one essential message must be conveyed — the development of GIS requires careful planning, and often a substantial time-commitment. In a previous section (2.1.) of this chapter, GIS were defined as systems for capturing, cleaning, integrating, storing, retrieving, analysing, and displaying mapped information and data. These functions can be broadly seen as a series of operations that describes the data stream from the original source to a final map or output. The initial stages of this process (up to the point of storing the data) can be extremely time-consuming, and therefore it is important that GIS are designed to meet the needs of the various end users, and to include as little redundant information as possible. Once data have been integrated into GIS, it is possible to perform a wide range of spatial analyses on them at very little cost.

## 4. CONCLUSIONS

In ecology and epidemiology, GIS, GPS, RS, and spatial modelling are increasingly used as a complementary set of spatial tools for project planning, implementation, and evaluation. A GIS-centred approach offers many potential advantages to the area-wide application of the SIT and other control methods, as a decision-support tool in

the day-to-day management of AW-IPM programmes. In the past, GIS have been applied mainly by academics as an end in itself, or at best as a research tool analysing correlations between different parameters to select priority areas where pest elimination would result in the highest socio-economic impact. More recently, GIS have been used as a tool for planning, implementing, optimizing, and evaluating SIT-based operations.

GIS also facilitate the overlaying of a variety of data coverages, e.g. climate, land use, drainage, etc., to identify factors that may explain the spatial and temporal patterns of insects and/or diseases. Using appropriate spatial analytical approaches, GIS can be used to identify and map the habitat of insect species and their relationship to cropping areas or human and animal populations. In this way, it is possible to generate maps indicating the risk of pests or diseases on a variety of spatial scales, and to monitor, in space and time, integrated information on insect population dynamics, ecological and meteorological conditions, and the incidence of disease or crop damage.

AW-IPM programmes that include the release of sterile insects are, because of the interdependence of their many linked components, inherently complex; the collapse of one component might jeopardize the successful outcome of the entire programme. The success of such a programme depends mainly on aspects related to: (1) the quality of the sterile insect (e.g. sexual competitiveness of the irradiated and released insects, survival, mobility, dispersal characteristics, etc.), (2) the management of the release programme (e.g. timely delivery of insects, appropriate placement of the insects in the natural habitat, uninterrupted supply of sufficient sterile insects, etc.) (Dowell et al., this volume), and (3) the implementation of related programme components (e.g. adequate suppression of the native-insect population, relevant public relation campaigns, ample collaboration with the livestock/crop industry and other stakeholders, etc.) (Dyck, Regidor Fernández et al., this volume; Mangan and Bouyer, this volume). Programme managers need to keep a comprehensive overview of all these essential programme components and their outcomes, almost on a daily basis, and GIS provide an ideal tool to analyse and display data from these multifaceted programmes. Close collaboration between programme entomologists, and SIT and GIS experts and modellers, will be a prerequisite to fully exploit the potential of GIS and spatial modelling as decision-support tools, and to render AW-IPM programmes using the SIT much more efficient and cost-effective.

To make GIS/RS more applicable, programme managers must get access to all available data layers (administrative boundaries, soil types, crops, meteorological data, satellite imagery, vegetation cover, etc.). GIS technicians and modellers can, in many instances, produce data layers that are not available or are missing, e.g. by digitizing topographical maps and implementing supervised classification to map the landscape cover or even insect distribution models. Also, the establishment of global networks to enhance research collaboration, data sharing, and the pooling of common resources, e.g. via the development of special websites, can greatly facilitate the development potential of GIS. Regarding the day-to-day implementation of the various programme components, all data sets on the target insect (survey data, monitoring data, etc.) and related aspects (crop damage, disease incidence, etc.) must be georeferenced and entered into relational databases that are compatible with, and

can easily be linked to, GIS software (e.g. using ACCESS-based databases rather than EXCEL spreadsheets), allowing straightforward summaries and queries. Finally, standardized data collection, continuous flow of data files to a central location, and increased understanding of the basics of GIS by programme managers, are additional prerequisites to exploit GIS to their full potential in AW-IPM programmes.

*V. A. Dyck, J. Hendrichs and A. S. Robinson (eds.), Sterile Insect Technique. Principles and Practice in Area-Wide Integrated Pest Management. Second Edition.*

SUMMARY

Area-wide integrated pest management is designed for specific purposes, and an economic evaluation should determine its performance against those purposes. The sterile insect technique is used for eradication, suppression, containment and prevention, each of which has different performance measures. Eradication or suppression of insect pest populations using the sterile insect technique (SIT), together with other area-wide control measures, may require significant initial capital investments to achieve long-term returns in subsequent periods. It may also raise questions about the distribution of benefits or the justification of public or private pest control efforts, given long-term uncertainties about the pest challenge and the potential of new control options. A consistent and transparent evaluation is needed to analyse the benefits and costs of such projects and to demonstrate their value, or in some cases to assess appropriate contributions to the costs by the various stakeholders who gain the benefits. Suppression must be compared with expected losses and costs in alternative conditions without SIT application, either from recent experience prior to implementation of the SIT or with similar areas without SIT treatment. Preventive SIT should reduce the frequency of outbreaks compared with experience prior to the application of the SIT or in similar areas elsewhere without SIT use. This chapter outlines the process of benefit/cost analysis, in which itemized future costs and benefits are compared in terms of present values. It also provides a review and examples of the application of benefit/cost analysis to the SIT. A checklist of benefit/cost analysis inputs and some example benefit/cost outputs are also presented.

## 1. INTRODUCTION

The sterile insect technique (SIT) has been used under different circumstances for four purposes: eradication, suppression, containment and prevention (Hendrichs, Vreysen et al., this volume). Eradication has been effective particularly in eliminating new outbreaks in areas with a low probability of reinvasion, or on established populations in isolated areas such as islands (Feldmann et al., this volume). Suppression has been effective for established populations in endemic areas, with buffer zones to limit immigration of mated wild females (Mangan and Bouyer, this volume). Containment has been achieved to avoid the spread of a pest into a free area (Enkerlin, this volume; Vargas-Terán et al., this volume). Prevention has been successful to prevent the establishment of an invasive pest incursion in areas of relatively frequent invasion (Enkerlin, this volume). Economic evaluation of programmes for each of these purposes should focus on indicators of performance relevant to the intended design, and the temporal and spatial scales involved. In each case a form of benefit/cost analysis (BCA) may be appropriate, usually involving probabilistic simulations of scenarios reflecting the pest challenge and control efficacy.

### *1.1. Benefit/Cost Analysis*

The principle of a benefit/cost analysis is to provide a model framework in which all costs and benefits applicable to a programme (targeting eradication, suppression, containment or prevention) can be compared with alternative management options over a specified period of time (Kehlenbeck et al. 2012). This is important for comparing area-wide projects integrating the SIT (which generally have substantial initial costs, but which provide long-term benefits, including in some cases eradication) with individual and short-term localized control (such as by conventional pesticide application). The analysis informs decision-making by

structuring the estimates of all costs and benefits, including externalities such as environmental and social impacts, but it does not prescribe choices. Ultimately, decisions depend on social, political and commercial judgements, and a BCA is a tool for making that decision process more transparent for governments, investors and beneficiaries.

In a BCA the monetary values of all identifiable benefits and costs are estimated as objectively as possible over the expected period during which the project will operate and be effective. Establishing a reasonable estimate of the relevant time horizon in which to judge a programme is a critical step in such an analysis. Because the benefits and costs are in the future, inevitably there is uncertainty in these estimates. A BCA model needs to be flexible so that the various management options and expected scenarios can be tested, taking into account these uncertainties and demonstrating the sources and influence of the uncertainty. For example, Vo (2000) presented two scenarios for an assessment of the New World screwworm *Cochliomyia hominivorax* (Coquerel) in Jamaica, in which the major uncertainty was programme cost. For some species, e.g. the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann), rearing costs are well known (IAEA 2008) but there may be considerable uncertainty about other variables, such as reinvasion frequency, which may change with trade patterns or short-term climate variability. For other species that are less commonly mass-reared, such as the codling moth *Cydia pomonella* (L.), technological improvements can quickly change the costs and effectiveness of reared irradiated insects (Vreysen et al. (2010); Chidawanyika and Terblanche (2011); Parker, Mamai et al., this volume; Simmons et al., this volume). Current small-scale releases of sterile or genetically modified sterile mosquitoes for dengue and Zika management in Brazil (Carvalho et al. 2015) are likely to become much less expensive and more efficient as experience and development continues (Lees et al., this volume). The combination of technological, trade, development and climate change suggests keeping time horizons for a BCA relatively short to avoid levels of uncertainty that could make sound predictions not feasible.

Sensitivity analysis, the process of testing the model with a realistic range of values, is important in benefit/cost analysis to indicate how risks associated with the project could affect decisions. Ideally, the economic framework should be prepared in parallel with the design of technical plans for the project so that each can inform the other. In this way, the final analyses can be efficiently directed to the most effective technical and economically viable plans.

### *1.2. Project Phases*

The initial steps in a BCA include defining the timescale and the likely geographic scope of the project. The time period may include: preparatory phases (research, host surveys, baseline data collection, construction of SIT production facilities, etc.), a control phase (which could include a series of zones through which treatments are applied in succession as eradication, suppression, containment or prevention is achieved), and a reasonable period beyond the control stage (long enough for benefits to establish before there is the inevitable time-related increase in uncertainty about reinvasion, new pest entry or other circumstances that could affect the

expected benefits or costs). The first two phases can be limited by technical constraints, although there may be opportunities to reduce such constraints by spending more money, whereas managerial and political constraints are more difficult but can be overcome by improving managerial capacities, facilitating the organization of grower associations, and establishing public-private partnerships. The geographic scale may also be determined by technical considerations (islands, topography and limit of host range) or by economic factors (too little return in areas of marginal productivity or lower pest attack).

A cost function is likely to be composed of three parts: variable costs per area to be treated for control and variable costs for all other related management activities (surveillance, follow-up treatment, etc.), along with fixed costs associated with operating the project. The benefits would include a function based on replacing current costs and losses in the area to be controlled, plus any additional market opportunities that may arise through low pest prevalence, pest eradication and/or elimination of pesticide residues. Costs and benefits may need to be attributed to particular production sectors or uses, e.g. production of meat, milk and draught power for tsetse fly control (Feldmann et al., this volume), or to geographic areas, e.g. in selection of individual regions where benefits might be greatest. Environmental costs and benefits, discussed later in this chapter, should be included along with direct monetary values from improved production and cost savings. An increasingly important issue in pest management BCAs is how much of the cost can be recovered from stakeholders (in cash or kind), and how this can be achieved (Waage et al. 2007; Dyck, Reyes Flores et al., this volume).

### *1.3. Project Implementation*

A BCA may be needed both before and after project implementation, first as a design tool to plan the project, and later to evaluate performance and suggest operational improvements (Pereira et al. 2013). Many eradication and suppression projects have been undertaken or proposed, of which most have had either formal or informal benefit-cost analyses. Enkerlin (this volume) summarizes benefits from a wide range of fruit fly programmes. SIT projects and plans have included: Mediterranean fruit fly (California (Dowell et al. 2000; CDFA 2014; USDA 2014), Florida (USDA 2014), Maghreb (Mumford et al. 1995), Eastern Mediterranean (Enkerlin and Mumford 1997), South Africa (Mumford 1997; Barnes 2007), Portugal (Mumford and Larcher Carvalho 2001), Western Australia (Mumford et al. 2001), Chile (UN 1997), Tunisia (Knight 2001), Argentina (De Longo et al. 2000)), tsetse fly (Kabayo and Feldmann 2000; Msangi et al. 2000; Vreysen et al. 2014; Feldmann et al., this volume), New World screwworms and Old World screwworms *Chrysomya bezziana* (Villeneuve) (Tweddle and Mahon 2000; Vo 2000; Wyss 2000; Vargas-Terán et al., this volume), codling moth (Canada (Bloem et al. 2000; Simmons et al., this volume), Syria (Mumford and Knight 1996), South Africa (Mumford 1997)), and *Aedes* mosquitoes (Carvalho et al. 2015; Lees et al., this volume). Cost and general loss estimates for some other fruit fly programmes without an SIT component exist for Egypt (Joomaye et al. 2000), the Indian Ocean

islands (Price and Seeworoothun 2000) and Pakistan (Stonehouse et al. 1998) for comparison with programmes that integrate SIT management.

The economic conditions that favour an area-wide approach include the integration of efficient and effective techniques such as the SIT, clearly articulated demand by stakeholders, good management capacity (Dyck, Reyes Flores et al., this volume), stakeholder participation, risks that are similar across a broad range of beneficiaries so that economic returns are fairly evenly distributed, a mechanism to capture benefits and recover costs, and, because the SIT is species-specific, it also relies on there being preferably a single dominant pest species (Klassen 2000; Lindquist 2000; Mumford 2000).

## 2. PREVENTION

Prevention of pest establishment using the SIT in pest free areas with a high invasion risk reduces the frequency and cost of outbreaks. It replaces occasional and unpredictable costs with a lower, relatively stable cost of preventive control. It can also reduce the externalities associated with emergency control in a crisis, if widespread pesticide spraying is needed in such a crisis.

The preventive SIT programme against the Mediterranean fruit fly in California is a partnership between the California Food and Agriculture Department and the United States Department of Agriculture. It operates in an area around the Los Angeles basin at a cost of about USD 16 million per year, and has reduced outbreaks from an average of 7.5 per year to less than 1 per year within this area (CDFA 2014). Similar programmes have been run in Florida, with both states using preventive SIT since the mid-1990s. These long-term predictable costs are preferable to relatively frequent and unexpected emergency eradication costs which, together with the temporary loss of exports, can run in extreme cases to over USD 100 million for a single eradication campaign (Box 1)

*Box 1. Preventive Release*

This is an example of a comparison of scenarios for preventive SIT release with an alternative form of periodic pest outbreak control. In this example, preventive SIT reduces the annual probability of a pest introduction becoming established to create an outbreak from 0.3 to 0.1, and the cost of controlling such an outbreak when it does occur from a mean and standard deviation of (USD 50 million, USD 10 million) to a much smaller distribution of costs (mean USD 10 million, standard deviation USD 2 million). In this example preventive SIT has an annual cost of USD 5 million, which would include rearing and release of the sterile insects, monitoring and surveillance, and publicity. The two options can be compared in a series of simulation runs sampled from the probability distributions of outbreaks and costs and a net present value (NPV) cost for each option can be calculated, in this case with a discount rate of 0.03. Multiple runs would provide a distribution of potential outcomes (based on total costs over ten years) so that a comparison of the two distributions could be made. Fig. 1 illustrates one such run. Because the number and cost of outbreaks are probabilistic, the number and timing of outbreaks would be different in each run.

| | | | Year | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | |

## 3. CONTAINMENT

Releases to establish a sterile-insect barrier across the edge of a potentially advancing pest population can have a containment effect, where they are used to avoid the spread of the pest population into an area free of that pest (Enkerlin, this volume; Vargas-Terán et al., this volume). This is in principle similar to a preventive release programme, but one in which the threat comes mainly from natural spread from an immediately adjacent infested area rather than from introductions through trade or travel from a distant source. The economic value of containment is the trade value retained by being able to demonstrate continued pest free status in the uninfested area and the further value of not needing to apply regular pest control measures for the excluded pest. In several respects the conditions for a containment barrier are different from a preventive release programme. In containment the source, population density, movement and destination of the pest are likely to be well known and occur at relatively high pressure along the boundary between the infested and uninfested areas. For preventive programmes, intermittent unpredictable introductions from a range of sources can occur that are likely to result in dispersed isolated outbreaks over large areas of vulnerable territory, depending on where infested material is taken through human-assisted transport. Containment programmes, therefore, are likely to face greater and more sustained pest pressure, but in relatively well-defined areas.

Containment, by some means, would be a form of official control needed to establish and maintain the status of a pest free area. The containment activities would need to be compatible with the surveillance used to demonstrate pest free status. The width and intensity of the containment zone would be the major determinants of the cost of containment, and the extent to which the containment zone extended into areas which otherwise might enjoy pest free status would limit the benefits.

Successful containment may also have an economic option value, keeping open the potential for a future eradication campaign in the infested area.

## 4. ERADICATION

The benefits of SIT-based eradication have been widely described, and vary enormously with the species concerned and the scale and objective of the project. For example, the potential eradication of tsetse species of economic importance throughout Africa anticipated an overall benefit of USD 4500 million/year (of which USD 1200 million/year is in direct losses from trypanosomiasis affected cattle and associated current control costs (OAU 2000)). Vreysen et al. (2014) indicated higher development potential in areas with effective tsetse control, with the proportion of small-scale farmers keeping indigenous cattle increasing three fold to 94% after the elimination of tsetse pressure in Zanzibar. Subsequent to eliminating tsetse, the largest benefit to agriculture in the long-term is the opportunity to introduce more productive cattle breeds (Feldmann et al., this volume). On the other hand, in areas with multiple tsetse species, eradication would entail much higher costs and therefore be less economically feasible (Hargrove 2003). Such analyses could also

be used to set target cost levels for more efficient sterile insect production (Parker, Mamai et al., this volume) and release (Dowell et al., this volume) to achieve returns comparable with conventional control that also has the capacity to achieve eradication.

Very large-scale eradication projections should take into account uncertainties about the continued political will or institutional capability to see a programme through to its final stages to ensure full realization of the benefits, and prevent reinvasion from the remaining uncontrolled areas. Continental-scale eradication integrating the SIT for the New World screwworm in North and Central America has been possible because of the long-term commitment to maintain and extend the SIT control effort.

Mediterranean fruit fly outbreaks in California threaten losses estimated from USD 1000 million/year (IAEA 1999) to USD 1800 million/year (CDFA 2008). The successful eradication of the Mediterranean fruit fly in Chile in 1995 opened up approximately USD 100 million/year in additional fruit markets (IAEA 1999). Enkerlin (this volume) reviews other examples of significant economic benefits from SIT eradication projects (Box 2).

*Box 2. Eradication*

The Mediterranean fruit fly has been a pest of commercial and backyard fruit throughout much of Western Australia since it was introduced to the state around 1900. It imposes costs on fruit growers who use pesticides for control and through both the presence of the insects themselves and the residues from insecticide. Backyard growers also suffer and get less enjoyment from their fruit trees. It also causes problems for the export of Western Australian fruit internationally and to other Australian states. South Australia, in particular, is faced with costs of quarantine and eradication of frequent incursions or outbreaks due to the Mediterranean fruit fly originating from Western Australia.

A pilot project applying the SIT was conducted at Broom, Western Australia, and showed that SIT-based eradication of the Mediterranean fruit fly was technically achievable in Australia (Jessup et al., 2007). In an analysis of the feasibility of eradicating this pest in Western Australia (Mumford et al. 2001), it was clear that eradication would take several years in a series of geographical zones. The model was based on a concept of summing the individual costs and benefits across each zone, allowing for a phased extension of the eradication across the state with a rolling quarantine to protect the eradication frontier as it progressed. The principal inputs within each zone affecting costs and benefits were the total areas to be treated and the values of losses that would be prevented with eradication. The zone boundaries were selected based on:

- climate (related to the threat from the Mediterranean fruit fly, mainly the effect of winter temperature)
- a phased increase in the treated area to build up expertise and capacity
- treatment areas were determined by satellite imagery of likely host presence and agricultural census data
- a maximum annual area to treat of 1000 $km^2$ (reflecting managerial capacity)
- a phased decrease in treated area as the programme winds down through lower risk areas to maintain capacity in the event of renewed outbreaks in any fly-free areas
- existing local government administrative districts to be used as the basis of both statistics and management.

## 5. SUPPRESSION

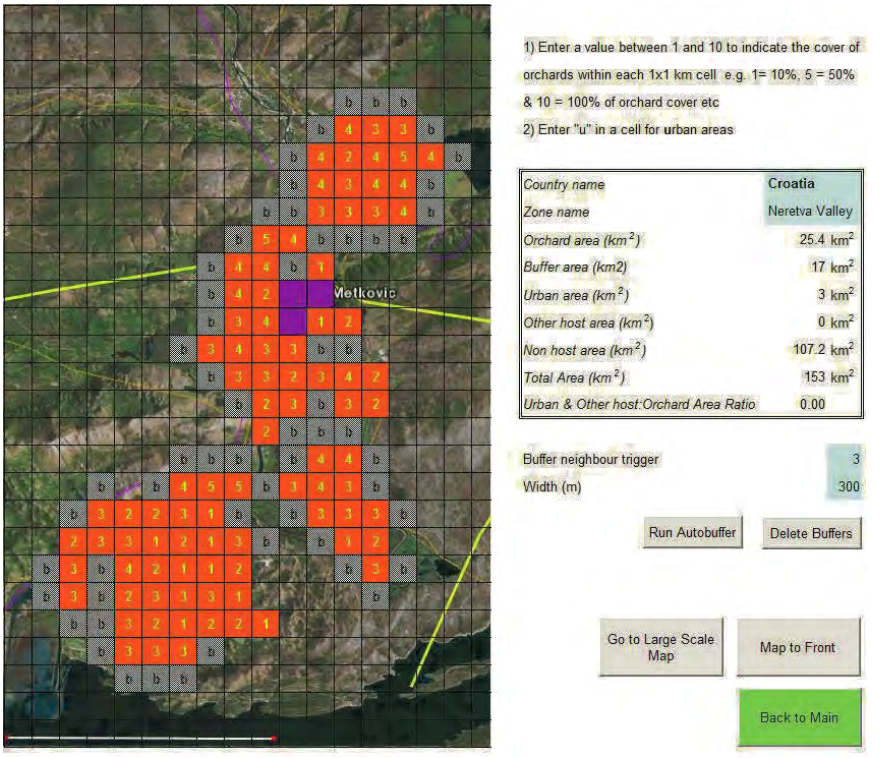
On a much smaller scale, in South Africa grape growers on 4000 hectares in the Hex River Valley were predicted to save over USD 150 per hectare per year in conventional insecticide costs, plus the added value of entering low-residue markets, through using the SIT for Mediterranean fruit fly suppression (Mumford 1997). Subsequent results showed control costs falling from USD 350 000 to USD 130 000 as the SIT replaced most chemical control, and market rejections due to fruit flies were reduced by half (Enkerlin, this volume). While pesticide reduction was not as great as expected, it was still substantial, and illustrates the uncertainties involved in making estimates. Permanent suppression integrating the SIT, rather than targeting eradication, offers advantages for Mediterranean fruit fly control in countries around the Mediterranean where nearby endemic pest populations would result in continual reinfestation and the cost of effective quarantine would be prohibitively high. While suppression does not have the finality that gives eradication such political appeal, it does not have such high costs of certification and quarantine (Mangan and Bouyer, this volume). Furthermore, because there would be an ongoing need for sterile insects, there may be greater potential interest for private investment in sterile insect production facilities and delivery services (Mumford 2000; IAEA 2008). Continued benefit from reduced pesticide use can offer a steady and attractive market for efficient SIT suppression.

The integration of sterile or genetically modified mosquitoes for suppression of vectors is a new development for the SIT, aimed at more effective control than can be achieved by only applying insecticides or removing breeding sites. Outbreaks of dengue can occur at very low densities of *Aedes* mosquitoes, and control methods with inverse density-dependent performance such as the SIT are more economically efficient in such low-density populations, or after other vector populations have been suppressed by conventional means (Pereira et al. 2013; Häcker et al., this volume; Lees et al., this volume; Mangan and Bouyer, this volume). Effective suppression of vectors may in some cases be sufficient to eliminate a disease in an area, if the vector population can be reduced to a density that does not sustain transmission (Smith et al. 2012).

For a practical decision on the merits of SIT eradication or suppression, the benefits must be set against expected costs, which for many projects integrating the SIT are now well-documented in a range of national circumstances. Issues remain, however, around how to capture the benefits within the various economic sectors that gain from control, and to transfer some of this to the public or cooperative sectors that provide the service. SIT projects have traditionally been public projects, but may increasingly be partly or wholly funded directly by beneficiaries. Payment for the SIT as a service by direct beneficiaries is more likely where ongoing inputs are involved (suppression and prevention) to give relatively immediate returns to those paying for the service (Dyck, Reyes Flores et al., this volume). Because eradication gives benefits in the future, and requires external efforts to prevent reinvasion, it is likely to be less attractive to private subscribers (Box 3).

*Box 3. Suppression*

Scenarios for suppression can be designed on a spatial grid that considers the costs and benefits per cell each year. The example below, from the CLEANFRUIT project funded by the European Commission (J. D. Mumford and A. W. Leach, unpublished; CLEANFRUIT 2017), illustrates an example of a scenario for a Mediterranean fruit fly suppression programme in Croatia. Each 1-km$^2$ cell on the map has a number indicating the density of citrus production in the cell, which is an indicator of the potential benefit from SIT suppression. Buffer zones are indicated near any cell with a sufficient density of citrus to trigger the need for a buffer. All citrus, urban and buffer cells have a standard cost function for the SIT inputs needed for a cell area of that size. Annual costs and benefits can then be estimated for any scenario in a potential programme design, supporting decisions on where to draw programme boundaries and how to allocate public or subscription costs. For example, private subscriptions may be based on specific cell benefits and public subsidy based on average cell costs.



## 6. BENEFIT/COST ANALYSIS FORMAT

The output of a BCA is likely to appear as a time profile indicating inputs and outputs by year, location and sector (which could be crop/livestock/human health type, urban/rural, public/private, etc.) depending on the needs of the commissioning agency. A scenario for a programme outlines the conditions for the modelled flows of inputs and benefits as each area reaches the stage assigned for particular management actions. An example of output flow of benefits minus costs appears in Fig. 2, illustrating the time flow of outcomes in an eradication plan.

The model structure has a set of cost and benefit components, specified as a probability distribution for each area and each year. Each of these refers to a standard set of cost, price and production parameters (with associated uncertainties) per area to give the model consistency while allowing the flexibility to analyse different SIT management plans. Different plans could, for instance, include changing the sequence of zones to be controlled, or the number or size of zones eradicated in each year. Values would be expressed with specified levels of uncertainty associated with them. For example, the cost of sterile flies may not be known before a factory is built, but costs from similar factories give a good approximation. Sensitivity analysis would demonstrate the range of outcomes using input values with some variation around the most likely expected values.

Many of the BCA models referred to in this chapter are related to the general format of a generic Mediterranean fruit fly BCA model developed for the IAEA (FAO/IAEA 2007). While each case has specific elements of geography, ecology or market conditions, there are many common principles and a growing globalization of SIT infrastructure. For example, large and efficient production facilities (IAEA 2008) can ship sterile insects to an international market at competitive prices: New World screwworms from Mexico to Libya, and Mediterranean fruit flies from Guatemala to the USA, Israel and South Africa, Spain to Morocco, and Israel to Croatia. Many items of equipment used in rearing and aerial release are now common across many projects. Many components of costs for sterile insects and their application are therefore fairly standard throughout the world, and common tables of such costs and standard application procedures help in planning both publicly and privately financed SIT efforts. However, as noted earlier, costs are not so stable for many species other than the Mediterranean fruit fly. Labour costs vary from country to country, but automated systems can reduce some of these costs.

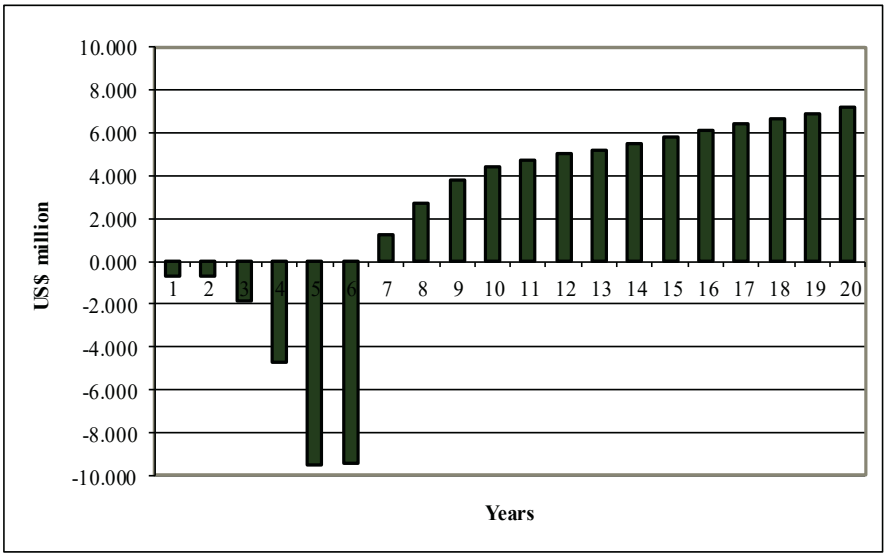


*Figure 2. Annual net projected benefit-cost for one scenario of the Western Australia Mediterranean fruit fly eradication plan before any discount rate was applied (Mumford et al. 2001).*

### *6.1. Time Dimension*

The time dimension for BCA predictions is very important, since there is a trade-off between adding the extra benefits over a longer term after most of the cost has been completed and adding greater uncertainty of further pest invasion, market changes, etc. While eradication may be seen by many as a once and for all achievement with an indefinite stream of benefits, experience shows that reinvasion may occur frequently in some areas of high risk of incursions (for example, the Mediterranean fruit fly has recurred in California and Florida following eradications, although the benefits of even short-term eradication exceeded the costs in such major exporting areas). So, while longer time frames would give a greater apparent return to an eradication programme, assuming the costs of maintaining quarantine or preventive control are not prohibitive, the probability of losing the benefits through a new outbreak increases as more years are added to the anticipated flow. In any event, future discounting reduces the impact of extending the time horizon.

### *6.2. Discount Rate*

Benefits and costs that arise in future years should be compared in terms of their equivalent present values so that all the values are directly comparable, since the same nominal value further in the future is worth less in present terms. The net benefit (benefit minus cost) over the whole project period being considered would

be expressed as a net present value. The discount rate is used to calculate these present values. The discount rate is a measure of the value that people place on having money now rather than later. It is generally considered to be equal to the interest rate on savings minus the inflation rate, both of which are currently at very low levels in developed economies. At present, in relatively stable economies, the discount rate ranges from about 1–4%, with the US government guideline on discount rate suggesting a central value of 2.9% for public benefit projects with a time period of 10 years (OMB 2015). However, it is likely to be higher in less stable economies (Mumford 2000). While a common discount rate, such as 5%, could be used in all analyses, this would not demonstrate the differences in future values that actually occur in different economies. To calculate present value, the following formula is used:

$$\text{Present value} = \text{Future value}/((1+\text{Discount rate})^{\text{Years}})$$

At a discount rate of 0.05 (5%) this formula indicates that a value of USD 100 in 10 years has a present value of only USD 61, and USD 100 in 20 years is worth only USD 38 in present terms. Therefore, long time frames do not add as much benefit as may be imagined, particularly where discount rates are high, while they add greatly to the uncertainty of the estimates. Because discount rates now used by many governments are much lower than they were in the past, the net present value of area-wide insect control over ten-year periods will be much greater than it would have been in previous decades, when much higher discount rates prevailed.

## 7. MODEL INPUTS

### *7.1. Costs*

The following cost items need to be predicted:

- Pest management treatments (the combination of the SIT and related technologies to be applied based on technical selection and specification of control activities and locations; variable costs to be determined per unit area, plus initial and subsequent annual fixed costs)
- Management area (this is the main driver for costs because most costs are variables based on treatment application per unit area; also consider if particular areas have additional needs that affect costs, due to terrain, remoteness, etc.)
- Cost categories (examples are given for some of the important cost categories, mainly based on values for the Mediterranean fruit fly, one of the most commonly controlled pests using the SIT, but some of the categories are too site-specific to give meaningful examples)
- Pre-treatment preparation (baseline data collection, demonstrations, trials to prove the effectiveness of techniques, and to build technical capacity and public confidence)
- Surveys (pest population, host areas, current control practices and losses)

- Population reduction needed prior to the SIT (by bait or other treatment) to bring populations to a low enough density for effective SIT control (Mangan and Bouyer, this volume)
  - For the Mediterranean fruit fly, approximately USD 6000 per $km^2$ (Mumford et al. 2001)
- Environmental costs (mainly pesticides used for pre-SIT population reduction):
  - Leach and Mumford (2008) proposed a Pesticide Environmental Accounting value for pesticides which gives an economic value for the environmental damage for many individual pesticides, particularly those used in horticulture. The environmental values are very variable depending on the particular pesticide properties.
  - Environmental and health impacts can also be quantified in monetary units using willingness-to-pay methods or by establishing aspiration levels (Farnsworth 1986; Nagel and Peveling, this volume).
- SIT costs:
  - Production, for the Mediterranean fruit fly, approximately USD 250–500 per million irradiated male pupae at the factory (rate of release would be 100 000–150 000 per $km^2$ per week, numbers may depend on host density) (IAEA 2008)
  - Delivery, reception and release actions are described in detail in FAO/IAEA (2017) (Dowell et al., this volume)
    - Costs are highly dependent on the proximity of the production facility to release points.
    - Aerial release costs depend on the type of aircraft and the numbers released; ground release is only practical for small areas.
- Quarantine (prevention of re-entry and management of outbreaks post-eradication)
- Monitoring (during and post-eradication) and certification (intensive monitoring post-eradication to prove pest free status) (Barclay et al., this volume; Vreysen, this volume)
  - For the Mediterranean fruit fly, a certification trap grid of 10 per $km^2$ inspected fortnightly at USD 2–3 per inspection (Mumford et al. 2001); monitoring during control may be less, e.g. 4 traps per $km^2$ in the preventive release programme in California (Dowell et al. 2000).
- Miscellaneous costs (administration, public awareness, marketing the improved pest free quality of produce from the area)
- Additional management and infrastructure costs to cope with possible increased pressure on land use after pests are eliminated.

Also needed - a time profile of the inputs, with changes over time, a time limit for analysis and an agreed discount rate.

### *7.2. Management Operations*

The management operations are specified according to the technical needs of the project, for example pre-SIT bait applications. The economic analysis can be used to choose between different technical options, e.g. the order in which zones are treated in a phased eradication may have significant economic implications. There may be technical or managerial limits on the size of treatment zones, which affects the pace of eradication. The release rate of sterile insects, pre-SIT control regimes and standards for monitoring are all based on previous experience in successful eradication projects and the ecological circumstances in the area, or for new SIT species on field research in pilot projects.

The treatment area in each year consists of all of the pest-host area within a zone, along with some additional areas along the edges of host areas, which may result in the infilling of heterogeneous areas depending on the distribution of hosts. The areas may be predicted by land-use images from satellite or aerial photos, and/or from ground surveys. Crop areas, livestock densities and production levels are often available from agricultural statistics, and households can be obtained from census records. Local surveys of vegetation, animals and households may be needed where information is scarce.

Prior to applying SIT treatments there may be a need for trial runs to practise procedures, or to provide some stakeholders with demonstrations of operations and impacts. All subsequent operations can be treated as either direct area functions in a BCA spreadsheet, or as indirect area functions (for instance, environmental costs are likely to be determined by the volume or value of pesticide used, which will itself be area-related).

The timescale for the analysis should include the preparatory phase, the operational phase, and the ongoing period during which benefits and any further costs can be confidently expected to accrue. The endpoint for the analysis should be chosen after consideration of ecological, market and quarantine uncertainties, which increase over time, and the effect of future discounting, which makes long-term future values relatively less significant in present terms.

### *7.3. Benefits*

The following groups of benefits are likely to accrue:

- Reduced direct and indirect costs of current control (this requires technical specification and information on the proportion of users for each current practice, obtained by survey)
- Reduced residual losses to crops or livestock, and reduced disease transmission, due to target pests which an SIT treatment would eliminate (such losses may exist despite current control efforts, either because little or no control is applied in many low-input farms, or because control is often not completely effective even when fully applied). The lack of fully effective controls is often a substantial motivation for an SIT treatment, whether targeting suppression or eradication.

- For livestock, reduced veterinary, surveillance and treatment costs, and faster time for animals to reach sale weight
- Pest control reduces losses because pest attack lowers resistance and increases susceptibility to further insect and disease attack
- Reduced environmental impact from pests that affect natural vegetation or wildlife, which control would prevent. Mumford (2001) describes the ways in which economic values can be put on non-crop losses in natural environments.
- New market opportunities or improved retention of existing markets, e.g. due to reduced pesticide residues on produce or certified disease or insect free status
- Additional development potential in areas under effective pest management, e.g. see Vreysen et al. (2014)
- Greater impetus to invest in agriculture in areas in which pests have been controlled.

A time profile of benefits and their distribution (geographical, sectors, etc.) would be needed, along the same lines as for costs.

### *7.4. Input Format*

A typical spreadsheet for a BCA would consist of the following example data pages: a delineation of areas; a catalogue of data on $km^2$ per district (total area and area for particular pest hosts, or density of hosts); SIT treatment areas by zone (excluding areas the target pest would not inhabit due to a lack of hosts or to climatic conditions); potential and residual losses due to the pest (affected by productivity in the area, climate and susceptibility of hosts to pest); current control costs, including social and environmental costs of current control practices, lost market opportunities (due to residues, residual pest damage or quarantine exclusion), SIT treatment costs, including additional monitoring and quarantine costs and pre-treatment preparation, and a discount rate for the country; and the input summaries for each of the scenarios being compared.

## 8. MODEL OUTPUTS

Model outputs should indicate: summaries of costs and benefits over a time line agreed for the analysis of the scenario, and economic indicators (such as net present value, payback period, and internal rate of return) for each proposed scenario. The net present value is the sum of the present values of future net returns, using the discount rate to calculate back to the present from the expected future nominal values. The payback period is the number of years before the cumulative benefits exceed the cumulative costs, which is a measure of the riskiness of a project. The internal rate of return is the discount rate that would give a net present value of zero to the stream of net benefits from the project. The project would exceed the break-even point if actual discount rates are expected to be below this value.

### *8.1. Interpretation*

The output of the BCA provides a comparison of the stream of net benefits, expressed in present values. Scenarios with higher net present values are preferred, although sensitivity analysis may indicate that some high returns are associated with greater risk. Eradication requires a long-term commitment to ensure the investment in eradication is protected, and this can add considerable cost. The net present value displayed is calculated using the average of each input value, but each of these inputs may be uncertain. Where probability ranges have been estimated for various input values it is possible to use simulation software such as @Risk™ to calculate the range and frequencies of output values.

The distribution of benefits can be apportioned by sector (e.g. commercial versus backyard), by geographical zone, by public/private finance, etc. This has important implications for the political desirability of a project, the relative role of various stakeholders and the potential for cost recovery. The initial benefits are likely to go to commercial producers for projects involving fruit flies, codling moths or other agricultural pests. Consumers may subsequently benefit from lower prices if production becomes more efficient later. Also, inhabitants in an area with lower insecticide use will benefit, justifying their financial support to an SIT project (Cartier 2014; Dyck, Reyes-Flores et al., this volume; Simmons et al., this volume).

### *8.2. Cost Recovery*

Many countries now have policies that require government to seek to recover costs, wherever possible, from public projects such as insect eradication (Waage et al. 2007). A BCA could form the basis for determining not only what expenditure will be needed for a successful project but, through the assessment of the benefits, how that expenditure should be shared. However, identifying benefits does not directly indicate who should pay. Some costs, for instance non-monetary environmental costs, are difficult to recover, and may only be practical for society as a whole to bear or to claim compensation from government (Mumford 2001). In other cases, many beneficiaries may be involved, making it difficult to collect voluntary payments for area-wide control individually, e.g. when urban householders benefit. In such cases collective payments are more efficiently made, as in the Sterile Insect Release Program in Canada, which has been supported partially by urban residents (through property taxes) for more than 20 years (Cartier 2014; OKSIR 2020; Dyck, Reyes-Flores et al., this volume; Simmons at al., this volume). Such support may need the mandate of a local referendum, or election, for it to be imposed on all those required to pay.

Any area-wide integrated pest management programme (AW-IPM) will encounter the issue of free-riders who do not contribute directly (Lindquist 2000). Where these benefits contribute to the broader public good it may be more efficient to fund projects centrally from government and spread the cost through general taxation. Where the benefits are geographically isolated and beneficiaries are few in number and well-organized, such as in the Hex River Valley Mediterranean fruit fly control project in the South African table grape industry (Barnes 2007), a levy on

growers or a cooperative subscription system is a practical and fair way to pay for part of the costs. In Brazil, the city of Piracicaba has contracted a commercial supplier to rear and release sterile *Aedes* mosquitoes in a municipal vector control programme (Le Page 2016), along with enforcement efforts to reduce mosquito breeding sites.

## 9. BENEFIT/COST ANALYSIS CHECKLIST

The following bullet points provide a checklist for decisions on benefits and costs; further examples related to control by more general means can be seen in Kehlenbeck et al. (2012):

- Planning and feasibility studies (technical and economic) that provide initial descriptions of inputs, and estimates of costs and effectiveness
- Current losses due to pests (without control and even with control, for crops or livestock over several seasons) or disease transmission by insect vectors
- Market exclusion due to pest presence, damage or pesticide residues
- Current control practices (area treated, effectiveness, cost, environmental impact)
- Area to be treated overall, including necessary buffer areas beyond infested host areas to prevent reinvasion
- Area within the overall treatment area that contains non-productive land
- Pre-project baseline data collection and monitoring for hosts and populations
- Publicity to make the public aware of an area-wide programme (Dyck, Regidor Fernández et al., this volume)
- Regulatory controls (such as hygiene, local quarantine inspections, reporting of pest occurrence)
- SIT costs:
  - Pre-release insecticide baiting (or alternative population reduction practices)
  - Sterile insect production (Parker, Mamai et al., this volume)
  - Sterile insect storage and transport
  - Sterile insect release (Dowell et al., this volume)
  - Field monitoring (for operational management) (Vreysen, this volume)
- Field monitoring for pest free certification (Barclay et al., this volume; Vreysen, this volume)
- Post-control area quarantine
- Marketing to capture benefits of pest and pesticide reduction/elimination
- Additional development potential in controlled areas with effective pest management
- Agreed project timescale and applicable discount rates.

This checklist provides guidelines on the basic information that would ideally be used in a BCA. More precise information will give more confidence in the analysis, but may be expensive to obtain. Therefore, some compromises between uncertainty and cost may be required. The goal is to provide transparent comparisons of specified scenarios with as much objectively agreed information as possible, with any uncertainties explicitly identified and included.

SUMMARY

The sterile insect technique (SIT) is an exceptionally promising pest control method in terms of efficacy and environmental compatibility. Assessments of environmental risks vary according to the status and origin of the target pests. The suppression or eradication of non-native pest populations with the sit raises few environmental concerns, and these are related mainly to some pre-release suppression techniques. However, the elimination of native species, or at least populations of native species, requires more detailed and complex assessments of ecological effects and consequences for biodiversity conservation. Eradication programmes provide opportunities to study these topics within the scope of both environmental impact assessments and operational monitoring programmes.

## 1. INTRODUCTION

The sterile insect technique (SIT) is a species-specific control method that may be applied in the area-wide integrated pest management (AW-IPM) of insect pests of medical, veterinary, and agricultural importance. Contrary to chemical or other products that are intrusive, toxic, pathogenic or otherwise destructive entities, or to most other biological agents whose establishment is irreversible once they are released, sterile insects are non-invasive agents that leave no "ecological footprint" because they cannot become established due to their sterility. Consequently, sterile insects have been recognized among *beneficial organisms* by the International Plant Protection Convention to which most countries are parties (IPPC 2017). Therefore, the SIT alone poses *a priori* an exceptionally low risk to the environment (Müller and Nagel 1994). Ecologically, the release of sterile insects represents an input into ecosystems of allochthonous, living yet non-reproductive biomass readily integrated into and processed within food webs. Thus, if there are any direct adverse impacts of sterile insects on non-target biota, they are most likely related to changes in interactions among species.

The SIT is not a stand-alone technique, however, and in most situations, to be effective and economically viable, the SIT requires pre-release suppression of the pest population with conventional control techniques. These encompass simple devices such as sticky traps, as well as large-scale aerial treatments with insecticides. Therefore, environmental hazards range from negligible to high, depending on the actual type and combination of suppression agents and tactics. When target population densities are low, less hazardous control techniques can be employed to reduce target populations. For example, the initial population densities of the tsetse fly *Glossina austeni* Newstead in Unguja Island, Zanzibar, were already low due to previous habitat destruction by farmers. Thus, suppression was achieved with pour-on pyrethroids sprayed on cattle (living targets) in pastoral areas, and with insecticide-impregnated blue cotton screens (targets) deployed in areas where cattle were scarce (Vreysen et al. 2000), posing a low risk to the environment (Nagel 1995). An even lower risk is estimated from the use of chemical larvicides to control the New World screwworm *Cochliomyia hominivorax* (Coquerel); they are applied directly to the wounds of infested livestock, posing no hazard to treated animals or components of the environment (USDA 2001a).

Area-wide control targets the entire population of a specific pest in a particular area (Lindquist 2000; Hendrichs et al. 2007; Klassen and Vreysen, this volume). Therefore, it is more cost-effective than local control which only targets a portion of

the pest population and permits continuous pest movement from non-treated neighbouring areas into the treated areas (Klassen 2000; Hendrichs et al. 2007).

Most suppression or eradication programmes with an SIT component were directed against populations of introduced (non-indigenous) species, and did not aim explicitly at eradicating a pest species from its entire natural range. The risk assessment of full eradication strategies requires in-depth investigation of the ecological role of target indigenous pests in ecosystems and food webs, and the possible consequences of their disappearance.

This chapter discusses environmental issues related to different steps in the SIT strategy and process, from sterile insect production to release, and from direct to indirect ecological effects. Given that suppression and/or eradication programmes may eventually extend from area-wide to range-wide, in other words from population eradication to species extinction in the wild, trophic and other ecological interactions among target insects and non-target fauna and flora will also be addressed. While evaluating environmental risks associated with the SIT in a more general sense, particular emphasis is placed on the environmental effects of tsetse fly *Glossina* spp. control in Africa.

## 2. MASS-REARING AND STERILIZATION

### *2.1. Mass-Rearing*

Insect-rearing facilities pose a low environmental risk if designed using current biosafety principles, and if managed according to best practices and standard operating procedures (FAO/IAEA 2008; Parker, Mamai et al., this volume). However, given that large numbers of insects are reared at a single site, they are a potential source of unintentional release of fertile insects into the environment. This might cause limited damage if facilities are located within the natural range of the native pest species, but potentially more serious hazard if environmental conditions are suitable for the establishment of an invasive species, although such a situation could immediately be mitigated by releases of sterile insects of that same species. Therefore, setting up facilities within the potential habitats of the target insect requires adherence to strict quarantine and security guidelines during all steps of insect production and shipping. To reduce this risk, sterile fruit fly production in the United States is only allowed in areas where the respective species is established or where environmental conditions are not suitable for establishment (USDA 2001b). Thus, production facilities may be located far away from the release area, but in many programmes that release sterile insects, mass-production takes place in their vicinity to minimize shipping costs.

Insect mass-rearing facilities can pose occupational health risks. Exposure to frass, hair, and scales may induce allergenic responses in humans (Parker, Mamai et al., this volume). Another risk arises from exposure to microbials (fungi, bacteria). Therefore, rearing facilities must be equipped with effective air filtration systems to minimize the aerial concentration of allergenic particles and potential pathogens, and staff frequently exposed to these agents should wear protective clothing and masks.

This may be problematic in countries with insufficient occupational health standards and capacities for industrial processes in general.

Another problem is the disposal of large quantities of liquid and solid organic wastes (Parker, Mamai et al., this volume), which can carry immature stages of the insect as well as various microbial species, e.g. *Escherichia coli* (Migula). Effective waste-treatment facilities are needed to prevent the release of insects and pathogens into the environment, and to prevent the direct infection of livestock if solid waste is processed further into animal feed.

RIDL (release of insects carrying a dominant lethal), a genetic control method based on modern biotechnology, is being applied using transgenic strains that require tetracycline in their larval diet to suppress lethality during mass-rearing (Alphey 2014). The disposal of such diet will require special procedures to prevent this broad-spectrum antibiotic from ending up in animal feed or the environment. Also, the potential effects of continuous exposure of mass-rearing staff to such antibiotics in the production facility needs to be assessed. Moreover, according to Leftwich et al. (2016), the permanent exposure of mass-reared colonies of RIDL strains to antibiotics is likely to (1) alter the composition of gut bacterial communities through a reduction in gut bacterial diversity, and (2) select for tetracycline-resistant gut bacteria. The effects on sterile insect fitness of gut bacterial communities that are altered in these ways, or their environmental impact, are not yet known (Augustinos et al., this volume).

Insects mass-produced for the SIT are reared on natural or artificial diets. For most species, no problems arise from using these techniques and diet ingredients. However, in the early days of tsetse mass-rearing, living mammals were used as hosts to feed the flies. This procedure was neither practical nor compatible with animal welfare. It was eventually replaced with a silicone-membrane feeding system simulating the skin of a host, and using warmed blood collected from abattoirs (Bauer and Wetzel 1976).

### *2.2. Irradiation*

The radioactive isotope Co-60 is the most commonly used isotope for the sterilization of pupae or adults of target insects (Bakri et al., this volume). In the past, some radiation sources used Cs-137; this is problematic because Cs-137 in nature can move easily due to the high water-solubility of caesium's most common chemical compounds. Therefore, its use has been discouraged for insect sterilization. Nevertheless, also facilities containing Co-60 sources have to be earthquake-safe and operated according to nuclear safety standards. These are part of the standard operating procedures for sterile insect production (FAO/IAEA 2008). Further guidance is given by the International Atomic Energy Agency (IAEA), which supports many AW-IPM programmes that use the SIT. Thus, in countries with a proven record of the safe use and correct disposal of hazardous substances, a risk associated with the regular use of irradiation sources is not anticipated. According to IAEA norms, irradiation facilities cannot be set up in countries with insufficient nuclear safety legislation and infrastructure. In situations of political instability,

contingency plans must foresee that irradiators and associated technology are secured.

Recently, the development of X-ray machines for insect sterilization is being encouraged because they have the advantage of requiring access only to electricity, and do not involve the complex and costly shipment of radioactive sources across international borders, as well as their eventual problematic disposal (IAEA 2012, 2017).

### *2.3. Autosterilization*

Autosterilization in the field has been proposed as a complement to the release of reared sterile insects. This technique relies on attracting target insects to baits or trapping devices and exposing them to chemosterilants which they then spread to other individuals of the target population. Various chemosterilants have been tested for tsetse control, including metepa, bisazir and insect growth regulators (IGRs) such as triflumuron, a chitin synthesis inhibitor, and pyriproxyfen, a juvenile hormone mimic. They aim at female flies, leading to the sterilization of females and a gradual suppression of the tsetse population (Knipling 1999; Oloo et al. 2000). Metepa and bisazir are carcinogenic, and may pose a risk to operators and trespassers. Therefore, these chemosterilants have never been used in operational control programmes. The other agents are less harmful, but lack clear evidence of efficacy. The environmental risk of chemosterilants such as IGRs is similar to the risk associated with stationary attractive devices (section 3.3.). Field work in Spain has indicated some potential for this technique (Navarro-Llopis et al. 2004).

## 3. SUPPRESSION OF TARGET POPULATION

### *3.1. Overview*

Although large numbers of sterile insects can be produced in modern rearing facilities, achieving adequate overflooding ratios with competitive sterile insects is essential for effective SIT application. Depending on the target species, minimum ratios of sterile to wild fertile insects during the first release cycle vary from 2:1 to 15:1 (Feldmann and Hendrichs 2001), but may reach 100:1 (Drew et al. 1982). Therefore, applying additional suppression measures against the wild population remains a prerequisite for many AW-IPM programmes that release sterile insects. However, not all such programmes need to be preceded by sprays of synthetic insecticides to suppress the target population. Integrating pest management strategies by combining different techniques, both before and during sterile insect releases, can optimize control efficacy and minimize adverse environmental effects (Mangan and Bouyer, this volume).

One approach is to make releases when the target wild population is naturally low, as generally occurs in winter or dry seasons in sub-tropical and temperate climates, or during periods of low natural host availability. Such strategies often include using non-insecticidal suppression methods such as those based on cultural and mechanical controls, but can also include mating disruption, augmentative

release of natural enemies and pathogens, baits and biopesticides, or even genetically modified crop plants that express a toxin (Suckling et al. 2012).

Sometimes, insecticide-based methods are applied to suppress target populations before SIT application; they fall into two broad categories: insecticide spraying and artificial attractive devices. Other methods are employed against particular insects, e.g. insecticide treatment of livestock (pour-ons) against tsetse flies, wound treatment against screwworms, and soil-drench treatment against fruit flies.

### *3.2. Insecticide Spraying*

Insecticides are applied with ground sprayers or aircraft, depending on the type, accessibility, and size of the target area. Aircraft are often used to apply larvicides to bodies of water to control mosquitoes and black flies. Ground applications include spot as well as small-scale, full-cover treatments, and are more focused than aerial applications. Many AW-IPM programmes, however, extend over large areas where ground access is very limited or even impossible, and reliance has then to be placed on aerial spraying as the main tool to reduce a population. Chemical pesticides are selected mainly based of their efficacy and friendliness to the environment. Furthermore, spraying techniques and cycles are adapted to specific behavioural and life-history traits of the target. Thus, environmental effects depend not only on the type of insecticide but also on the actual use pattern. Two examples of the environmental impact of aerial spraying for population suppression are given below.

#### *3.2.1. Fruit Flies*

Aerial bait-spray applications have been an effective tool as part of eradication campaigns against large outbreaks of non-native fruit flies (USDA 1993, 2001b), although their use is increasingly avoided in view of growing public opposition. The spray is used alone, or in advance of SIT application, to suppress or eradicate fruit flies. In the past, the sprays consisted mainly of the organophosphorous insecticide malathion mixed with a protein hydrolysate acting as an attractant and feeding stimulant. The bait, applied in larger droplets, improves efficacy because the insecticide uptake by attracted flies is then higher (via ingestion and the integument). Therefore, aerial sprays can be applied at ultra-low volume dose rates, lower than necessary for contact applications. Malathion is highly toxic to terrestrial and aquatic non-target invertebrates. Aquatic fauna are exposed via direct over-spray of water bodies or via run-off. Terrestrial insects, which are also attracted to the bait, are particularly at risk, including ground beetles (Carabidae) and many other beneficial organisms. In fact, a malathion bait spray may disrupt a substantial portion of natural biological control agents (USDA 1993, 2001b). Native fruit flies may also be adversely affected, resulting in shifts in community structure and perturbations of ecological services (section 5.5.). Possible hazards further up the food chain include secondary poisoning or food deprivation of insectivorous vertebrates.

Fortunately, malathion has been largely replaced by new and more environment-friendly insecticides in the bait, in particular spinosad (naturally produced bacterial (actinomycete) compounds) and SureDye® (xanthene dye) (Vargas et al. 2002; Mangan 2014; Mangan and Bouyer, this volume). The toxicity of these agents to non-target biota is much lower than that of malathion, and fewer adverse effects have been recorded (USDA/APHIS 2003). Acceptable spinosad formulations, certified as organic, have been developed and are being used extensively, e.g. in pest hot spots in the Mediterranean fruit fly programme in Guatemala and Mexico, before sterile male releases (USDA/APHIS/PPQ 2000; Enkerlin et al. 2017).

### *3.2.2. Tsetse Flies*

The second example is from tsetse fly control. The pre-release suppression of tsetse, in some cases, has involved sophisticated aerial spraying techniques. Sequential aerosol drift application with fixed-wing aircraft, which previously relied on endosulfan with sometimes negative ecological impact especially on fish in shallow water, is now based on pyrethroids, in particular deltamethrin. This insecticide is one or two orders of magnitude more toxic to tsetse than to house flies and honey bees, respectively (SWRC 2001). Therefore, field rates are exceptionally low, posing a low risk to terrestrial non-target invertebrates. Furthermore, application parameters such as height, time and sequence of spraying are adapted specifically to behavioural and life-history traits of tsetse flies, reducing the risk to terrestrial organisms even further. Finally, as deltamethrin has low persistence, it does not accumulate in food chains. Nevertheless, adverse effects may occur temporarily in terrestrial environments, e.g. effects on certain spiders, and in particular in aquatic environments (Peveling and Nagel 2001). For example, diving beetles and decapod crustaceans are highly susceptible to pyrethroids. A reduction of aquatic and semi-aquatic macroinvertebrates may translate into food shortages for fish and reduce the survival of fry, which in turn may adversely affect local fisheries.

Another possible risk arising from broad-scale sequential applications of low-dose pyrethroids is that the selection for resistance in other insect pests may be enhanced. For example, bednets impregnated with pyrethroids are widely used for mosquito control to prevent malaria in tropical areas. Selection for resistance in malaria vectors, enhanced through insecticide use in AW-IPM programmes that release sterile insects against agricultural pests, would reduce the efficacy of this important control method. This externalized consequence of population suppression for the SIT would be expected mainly in rural areas with a high human population density, where pesticides are used for domestic and/or agricultural purposes.

Treatments with deltamethrin, using the sequential aerosol technique (SAT), have been used mainly in combination with trapping and baiting devices for tsetse suppression (section 3.3.). In a tsetse eradication programme in the Okavango Delta, Botswana, the technique was successfully applied for eradication (Allsopp and Phillemon-Motsu 2002; Feldmann et al., this volume). Preliminary assessments showed that adverse effects on terrestrial invertebrates were minimal (Biotrack 2003). Another insecticide widely used for sequential aerosol applications in the past is endosulfan, a chlorinated hydrocarbon. Tsetse flies are three orders of magnitude more sensitive to this chemical than honey bees (SWRC 2001). However,

endosulfan is highly toxic to fish and other non-targets, including the Salvinia weevil *Cyrtobagous salviniae* Calder and Sands, a classical biological control agent introduced successfully to contain the invasive aquatic fern *Salvinia molesta* Mitchell (SWRC 2001). In view of these risks, the endosulfan option for Okavango was discarded in favour of deltamethrin.

All available evidence suggests that the effects of the SAT with deltamethrin on most terrestrial non-target arthropods are of short duration. Nevertheless, environmental monitoring in Zimbabwe revealed long-term adverse effects on populations of certain lycosid spiders, *Hippasa* sp. (SEMG 1993). Given that little is known about the resilience of affected populations in natural or semi-natural ecosystems, the SAT should be used only temporarily for pre-release suppression. More selective techniques, such as stationary targets (section 3.3.), should be given priority unless they are logistically too demanding for large-scale operations or do not yield sufficient pest population suppression. Using a four-scale risk classification scheme (negligible, minor, serious, severe), Grant (2001) classified the environmental impact of sequential aerosol spraying as "minor". In principle, this classification is acceptable, but should be taken with caution. The resilience of small and often highly fragmented non-target populations, to tolerate incremental insecticide stress in a multiple stressor environment, declines (Peveling 2001). Therefore, environmental impact assessments should be conducted with respect to site-specific features, such as the prevailing land-use patterns or the presence of vulnerable species. As one measure to mitigate adverse effects, Nagel (1995) proposed patchwork applications of different insecticides. This tactic would also reduce the above-mentioned risk of resistance development in other pests (Hoy 1998).

Low-flying spray aircraft may disturb domestic animals and wildlife, visually and by noise. Nesting birds are particularly vulnerable to this combination of disturbances. Although adverse effects such as increased susceptibility to predation should be temporary, nest abandonment may occur in the more sensitive species (USDA 2001b). A critical situation may arise in tsetse spraying, which relies on nocturnal treatments for optimal efficacy, using low-flying aircraft equipped with bright spotlights. Scared birds are unlikely to recover their nests during the night, leading to increased egg or nestling mortality. In Botswana, for example, there was concern that the wattled crane *Grus carunculatus* (Gmelin), an endangered species breeding in seasonally flooded marshes in the Okavango Delta, might experience reduced breeding success following perturbations by spray aircraft and insecticide-induced food shortages. A pilot study found high levels of nest attrition due to predation and other factors in both sprayed and unsprayed areas, but no indication of breeding failure due to tsetse spraying (Allsopp and Phillemon-Motsu 2002; BBCWG 2002). However, pre-spray observations were lacking, and follow-up studies are necessary before final conclusions can be drawn.

### *3.3. Artificial Attractive Devices*

A variety of traps and targets (devices attracting insects without necessarily trapping them) have been developed for the detection, monitoring or control of insects. Tsetse

flies are attracted by odours (ketones, octenols, phenols, acetone, carbon dioxide) and by visual cues (colour, shape). Some odours induce host searching behaviour while others promote landing on the device or entering the trap (Vale 1993). Fruit flies and screwworms respond to olfactory cues, such as pheromones, parapheromones, host odours or food baits. Devices such as odour-baited targets for tsetse flies, and coloured baited traps or bait stations for fruit flies, combine visual and olfactory stimuli to enhance trapping efficacy (Piñero et al. 2014; FAO/IAEA 2018). Insects lured to traps or targets become stuck to glue (sticky traps), or are exposed to insecticides applied to the material. Traps or sticky panels for fruit fly suppression use synthetic lures (trimedlure, ceralure, cuelure) applied directly to the panels or to wicks attached to the traps or panels (USDA 2001b). These devices are deployed from the ground by placing on host trees, or nailing to posts. Alternatively, insecticide-treated baited blocks (wood chips) or wicks (so-called cordelitos) are released from aircraft for population suppression. The parapheromone methyl eugenol is particularly attractive to males of some species of *Bactrocera* fruit flies (Shelly et al. 2014), and is used in male-annihilation technique (MAT) programmes, either alone, or prior to or simultaneous with the release of sterile males (Barclay et al. 2014; Vargas et al. 2014). Baited traps for screwworm flies are employed only for detection and monitoring purposes (USDA 2001a); population suppression is achieved effectively by treating livestock.

The densities of traps or targets deployed for suppression vary depending on the insect species and its potential growth rate (Weidhaas and Haile 1978), the type of device, and features of the landscape. In the case of fruit fly suppression, trap densities must be very high to be effective, and mass-trapping is, therefore, not practicable over larger areas (USDA 2001b; Navarro-Llopis and Vacas 2014). For example, more than 1000 traps per square kilometre were deployed in an oriental fruit fly *Bactrocera dorsalis* (Hendel) eradication programme in Mauritius (Seewooruthan et al. 1997). In contrast, suppression of certain tsetse fly populations can be achieved with as few as 2–4 targets per square kilometre (Dransfield and Brightwell 1992).

The deployment and maintenance of trapping devices requires a network of tracks and roads. Servicing activities may disturb wildlife, especially in wilderness and/or sensitive areas. Thus, two issues have to be addressed with respect to the risk assessment of insect trapping techniques, particularly when deployed at higher densities for population suppression: (1) direct effects on non-target animals, and (2) indirect effects related to trap placement and servicing.

### *3.3.1. Direct Effects on Non-Target Animals*

Traps using species-specific pheromones pose a low risk to non-target organisms. Certain species may be attracted coincidentally, especially potential predators and scavengers of target insects. However, local populations are unlikely to be affected. Ecologically relevant adverse effects are most likely to occur with non-target animals from the same genus or family as the target insects, even though other non-target species may sometimes be collected in high numbers. For example, mass-trapping of fruit flies, using parapheromones as attractants, may also have an effect on non-pest fruit flies. Some species are pollinators, thus, there may be a risk of

reduced pollination and hence fruit-set of certain plants at high trap densities (Tan 2000) (section 5.5.). Obviously, the risk to non-target organisms rises with increasing trap density, yet the risk is expected to be lower than that associated with aerial bait spray or with the application of insecticide-treated cordelitos dispensed in high numbers from aircraft (USDA 2001b). Suda and Cunningham (1970) reported that lacewings (beneficial predators) were caught unintentionally in methyl eugenol-baited traps or sources (fibreboard blocks, cotton strings or viscous slow-release paste) applied by ground or air in some MAT programmes against *Bactrocera* spp. fruit flies (Koyama et al. 1984; Vargas et al. 2014). However, Vayssières et al. (2007) provided evidence that the area-wide release of methyl eugenol-impregnated blocks had no greater impact on non-target insect populations than the non-impregnated blocks.

Contrary to fruit flies, tsetse fly trap densities are much lower, and the chances of incidental encounters of non-target organisms with stationary targets deployed for tsetse suppression are scarce. The degree of species-specificity depends on the combination of visual traits (shape, colour) and odours (octenols, phenols), as well as on the mode of placement. Blue and white targets attract more insects, including pollinators, than odour-baited black screens, which attract mainly stable flies (Stomoxyinae), non-biting Muscidae, and horse flies (Tabanidae). Some of these flies are possible vectors of livestock and human diseases, including trypanosomosis (Sumba et al. 1998), and can be considered as pests, but others such as male tabanids are beneficial flower-visitors and pollinators. Even though the number of studies is limited, there is as yet no clear indication that these taxa are adversely affected at the population level (SEMG 1993; SWRC 2001; Ciss et al. 2019). Likewise, insecticides such as deltamethrin and α-cypermethrin, used to impregnate the fabric of targets, pose a low risk. During the rainy season, some active ingredient may be washed off, but the contamination is negligible compared with full-cover spraying in agriculture and vector control, and the effects are restricted locally (Cuisance et al. 1984; Müller et al. 1984).

### *3.3.2. Indirect Effects on Non-Target Animals*

The deployment and servicing of large numbers of traps and targets are logistically feasible and environmentally sound in agricultural areas with existing road networks. These conditions prevail in some areas subjected to fruit fly suppression or eradication. Therefore, disturbances of wildlife through the placement and maintenance of traps are expected to be minimal when compared with those induced by other agricultural activities such as planting, irrigation, and harvesting. However, disturbances may become more critical in landscapes composed of mosaics of agricultural and natural land.

This is particularly true for tsetse control, which is often conducted in protected and/or wilderness areas. Opening vehicle tracks for the deployment and maintenance of stationary targets can cause erosion, and provide access, not only to control operators and park rangers, but also to poachers (Grant 2001). It also facilitates unauthorized logging activities and firewood collection. Such illegal activities may disturb wildlife. A study in Kasungu National Park, Malawi, found significantly reduced numbers of small antelopes and certain birds on transects with odour-baited targets (Cheke et al. 1997; De Garine-Witchatitsky et al. 2001). For birds, the effect

was linked to the possible decline in the number of horse flies, affecting the insectivorous little bee-eater *Merops pusillus* Muller, and, as a consequence, reduced pollination and fruit-set of flowering plants, affecting nectarivorous sunbirds and the frugivorous bulbul *Pycnonotus barbatus* (Desfontaines). However, as no pre-treatment observations were made, follow-up studies are needed to validate these results. In West African gallery forests, insecticide-impregnated blue screens along river courses are sometimes deployed at distances of only 100 m. Studies in West Africa on invertebrates and insecticide residues in soil and wildlife showed at most negligible ecological effects (P. Müller et al., unpublished data). It is not known if there are further studies on indirect ecological effects resulting from such high screen densities, but assumedly the effects are of minor importance compared with other anthropogenic disturbances encountered in West African river systems.

### *3.4. Other Methods*

A range of alternative methods to suppress fruit fly populations in AW-IPM programmes has been reviewed in environmental impact assessments, including mechanical, cultural, biological and biotechnological methods (USDA 2001b). A detailed discussion of these methods is beyond the scope of this chapter, but one method, soil treatment with organophosphorous insecticide, deserves mention because it may cause serious hazards. It consists of drench treatments within the dripline of infested host plants to control larvae entering the soil and adults emerging from the soil. Soil drenches with organophosphates, such as chlorpyrifos, fenthion and diazinon, are highly toxic to soil fauna, and may adversely affect key ecological processes, such as the breakdown of organic matter and nutrient cycling. Individual vertebrates are also at risk, even though the limited use of soil drenches (usually less than 1% of the total surface), as a whole, provides protection of populations.

Pour-on treatments of livestock (living targets) with insecticide, for population suppression of tsetse flies and other parasites, are widely used in Africa. Livestock are treated in dip tanks or by applying pour-on formulations. Pyrethroids, such as deltamethrin, α-cypermethrin and flumethrin, are used for this purpose. Originally, pyrethroids were applied mainly to control ticks, but it was found that they were equally effective against tsetse flies.

Dip and pour-on techniques may have adverse effects on non-target insects, including blood- and dung-feeders, as well as on livestock-associated insect-eating birds. Insect species attracted to livestock are often the same as those attracted to stationary targets, but there is an elevated risk since livestock densities are often much higher than stationary target densities. Adverse effects to other dipteran pests are highly desirable, from an animal health perspective. However, a risk to birds cannot be dismissed. For example, the decline or local extinction of the oxpecker *Buphagus africanus* L. in South African rangelands has been associated with the use of arsenic pesticides and organophosphates in cattle dips for tick control (Mundy 1991). These compounds were eventually replaced with insecticides posing a low risk of acute poisoning in birds. Nonetheless, little is known about sub-lethal effects or indirect effects due to food deprivation.

Dung beetles (Scarabaeidae) are important decomposers of animal dung, and benefit soils and plants by improving soil fertility. They are also important food items for a wide range of invertebrate and vertebrate predators. Similar to parasiticides such as avermectin (Petney 1997; Steel and Wardhaugh 2002), faecal residues of pyrethroids are toxic to dung beetles and other dung fauna such as muscoid larvae (Krüger et al. 1999; Grant 2001; Vale 2002), thereby impeding the decomposition of pats and depriving predators of their prey.

Inappropriate disposal of used pesticides is another serious risk of the insecticide-dipping technique. Dips are often disposed of on open ground, resulting in soil contamination. In other cases, dips are dumped in pits and covered with soil; this may lead to the contamination of groundwater.

### *3.5. Environmental Effects of Some Suppression Techniques — Conclusion*

Each population suppression technique incorporated into AW-IPM programmes is associated with particular environmental risks. The optimum combinations of control methods, that result in the lowest cumulative risk but achieve the highest possible effect on target populations, vary among species, regions and ecosystems. Therefore, environmental assessments may come to different conclusions in different environmental settings. Nevertheless, some general conclusions can be drawn. Aerial spraying, depending on the form of application, is usually more harmful to non-target biota than ground spraying (which is often more focused and limited in scale) or attraction techniques using traps, bait stations or targets. One exception is residual ground application against tsetse flies; due to relatively high insecticide doses and persistence, it may be more harmful than aerial sequential aerosol applications as shown by the environmental recovery monitoring in Botswana, which indicated that most non-target species recovered to pre-spraying levels (Perkins and Ramberg 2004). Stationary attractive devices are normally the least harmful method (Nagel 1995, 1996), but the direct and indirect impact of generating and maintaining access (tracks or transects) to service them over large areas is usually underestimated.

In general, treatments in protected and/or wilderness areas require more careful approaches and risk mitigation measures than those conducted in croplands. This is because protected/wilderness areas are more complex in terms of biodiversity and interactions among biota, and hence less predictable in their responses to disturbances. Also, natural systems lack the adaptation of agroecosystems to human impact manifested in the dominance of ubiquitous or euryoecious species.

## 4. STERILE INSECT RELEASE

In AW-IPM programmes integrating the SIT, sterile insects are released from vehicles or aircraft (Dowell et al., this volume). Ground release requires appropriate road networks. This may be critical in sensitive areas, posing similar risks to non-target organisms as trap or target deployment and maintenance (section 3.3.2.) (Vreysen, this volume). Likewise, sensitive species, or life stages such as nesting birds, may be disturbed by the sight of, and noise from, aircraft dispensing sterile

insects (USDA 2000b; SWRC 2001). However, such disturbances are expected to be lower than those caused by low-flying spray aircraft because sterile insects are released at higher altitudes, e.g. greater than 200 m for tsetse flies (Vreysen et al. 2000) and about 600 m for Mexican fruit flies *Anastrepha ludens* (Loew) (SIRF 2001; FAO/IAEA 2017).

Aerially applied sterile insects are released directly into the air from temperature-controlled containers (chilled flies) or indirectly from cardboard boxes or paper bags that open once thrown out of the aircraft (FAO/IAEA 2017). In the latter cases, debris from the releases may be a visual disturbance, but such disturbance is transient since the materials used are biodegradable.

Sterile insects released in large numbers may become a nuisance to potential host animals, or may damage plants or fruit. Moreover, natural trophic interactions within communities, such as host or prey detection, may be disturbed by the sheer abundance of sterile insects. However, this is unrealistic, as in the case of the Mediterranean fruit fly, the insect with the highest release rates, approximately only one sterile male is released per 10 $m^2$. Nevertheless, little research has been done on this subject. In the case of tsetse control, sterile males are released at the lowest rates (approximately 20–100 sterile insects per $km^2$). Since this may increase the vector load in the target area, leading to a temporary increased risk of trypanosomosis transmission, only sterile males that have been pre-fed with a trypanocide-treated blood meal are released (Dyck et al. 2000).

Biosecurity concerns may arise in the case of releases of sterile insects of species outside their natural range (section 2.1.). Nevertheless, unlike classic biological control, where released non-native agents are fertile and become established with sometimes irreversible negative consequences (Simberloff and Stiling 1996; Follett and Duan 2000), any adverse effects of released sterile insects are short-lived because of their high natural mortality, and because they cannot reproduce. No such concerns exist if AW-IPM programmes using the SIT are directed against native species. In this case, the SIT can be compared with augmentative biological control, in which native species are mass-produced and released in their natural range.

## 5. ECOLOGICAL CONSEQUENCES OF ERADICATION

Many area-wide SIT applications aim at suppression, containment or prevention, not eradication (Simmons et al., this volume; Enkerlin, this volume; Hendrichs, Vreysen et al., this volume; Klassen et al., this volume). However, if eradication is the goal (Feldmann et al., this volume; Vargas-Terán et al., this volume), the following issues are relevant.

### *5.1. Risks and Benefits*

Populations living on remote islands are more vulnerable to extinction than those living on continents. This also holds for pest species targeted by area-wide control programmes. For example, the coconut moth *Levuana iridescens* Bethune-Baker, a widespread local pest in Fiji, is thought to have been eradicated by the tachinid fly *Bessa remota* (Aldrich) during a classical biological control programme in the 1920s

(Howarth 1991). However, in the history of economic entomology, there is only one known case of a continental agricultural insect pest becoming extinct. The Rocky Mountain grasshopper *Melanoplus spretus* (Walsh) was a major pest of crops in North America in the nineteenth century. The demise of this species was the result of the anthropogenic destruction of breeding habitats in river valleys (Lockwood and Debrey 1990). This shows that numerical abundance alone does not assure survival (Lockwood 2002). On the other hand, even the most intensive use of chemical insecticides has not threatened the survival of any major insect pest. Only area-wide control strategies incorporating the SIT or modern biotechnologies offer the opportunity to eradicate entire pest populations from selected areas. Eradication is most effective when directed against isolated populations on islands and in isolated habitats separated by natural barriers from the main range. However, the eradication of the New World screwworm populations in North and Central America shows that a pest can be eliminated even from continuous continental areas (Vargas-Terán et al., this volume).

Thus, the extinction of whole pest species from the wild seems possible in the longer term. It follows that ecological consequences must be evaluated thoroughly and impartially. What are the benefits and risks associated with the area-wide elimination of major pests? As for the benefits, these are beyond dispute. An immediate economic as well as environmental benefit is the enormous reduction in pesticide use (Kinley 1998; CDFA 2001). For example, to contain and mitigate permanent Mediterranean fruit fly establishment in California with conventional methods, more than 2 million kg of active ingredient would be needed annually (CDFA 2001; Enkerlin, this volume). The benefits arising from the eradication in 1991 of the New World screwworm in Libya are immeasurable (Reichard 2002; Vargas-Terán et al., this volume). Its spread over the entire African continent and Mediterranean region would have been an environmental, social and economic disaster, possibly comparable with the impact of rinderpest in the 19$^{th}$ century.

The environmental risks of eradicating indigenous populations are much more controversial (Allsopp 2001; Feldmann and Hendrichs 2001; Grant 2001; Vargas-Terán et al., this volume). In view of the devastating economic and/or medical impacts of the prime targets of the SIT, most notably the huge economic losses caused by fruit flies, mosquitoes, moths, screwworms and tsetse flies (Mumford 2000; Enkerlin, this volume; Vargas-Terán et al., this volume), the suffering of people and livestock from tsetse-transmitted trypanosomosis in Africa (Grant 2001), and the threat to the biodiversity of island faunas by non-indigenous invasive species which could be effectively controlled with the SIT (Suckling 2003), one might even question the justification for raising the risk issue at all. Nonetheless, it is important that possible risks, however low, be brought into perspective too, irrespective of the overwhelming environmental, economic and health benefits; only then can risks be managed adequately. The specific goal of this section is to elucidate ecological roles of certain target insects in their respective ecosystems, and to identify research themes and topics that should be addressed when embarking on future eradication programmes.

### *5.2. Loss in Genetic Diversity of Target Species*

An area-wide programme that targets the eradication of populations of the pest insect leads inevitably to a decline in the genetic diversity of that pest species. For various reasons (section 5.3.) this may not be generally acceptable. Therefore, in the unlikely case of eradication from the whole range, a certain level of genetic diversity of the target insect can be maintained in laboratory colonies. These could be used, and their genomes explored, for future research in the biological and life sciences. It would be impractical, of course, to rear strains from all populations representing discrete demes within metapopulations. Yet, as a minimum requirement, voucher specimens from all target populations must be deposited in scientific collections, including all development stages and both sexes. One part should be mounted, and others preserved deep-frozen and in alcohol (various concentrations between 60–100%). The preservation of insects will be greatly facilitated by using the cryopreservation techniques for embryos (long-term storage at liquid-nitrogen temperatures), which are already available for a number of insects (Leopold 2000; Parker, Mamai et al., this volume).

### *5.3. Eradication versus Conservation*

The prospect of the eradication of native species from their complete natural range is largely theoretical at this point. Nevertheless, it raises some general questions with respect to conservation. On the one hand, the planned extinction of a limited number of pests appears to be a negligible issue in view of the scale and dynamics of the speciation and extinction processes in the evolutionary history of the earth. However, in modern times, human activities have become the major cause of extinction, leading to a strong imbalance of speciation/extinction rates towards extinction. Given the dramatic decline of species worldwide, biodiversity conservation — as outlined in the Convention on Biological Diversity (CBD) — has become a global priority. This was motivated partly by the prospect that biodiversity will provide enormous resources for future uses, as well as by fears that ecosystems might be destabilized if extinction continues unabatedly. The latter notion leads to the introduction of the *precautionary principle* into decision-making (Cartagena Protocol on Biosafety (CBD 2018). Precautions must be taken whenever we are uncertain about the ecological consequences of our activities. This principle, however tentatively, also applies to pathogens and pests. Only if ecological consequences could be assessed and predicted conclusively would we dare to signal the deliberate elimination of a species. Such safety of judgement did not even exist for the smallpox virus, which is still being preserved for possible future medical research, including drug development (Joklik et al. 1993).

In view of our limited knowledge about the consequences of eradication, strategies that suppress populations of native pests, without necessarily eradicating them from their entire natural range, are preferred. Suppressing a key insect pest population by the integration of the SIT with other environment-friendly methods often also leads to decreases in secondary pest populations once overall insecticide treatments are minimized, which in turn allows even further reductions in insecticide

use. For example, as a result of the codling moth sterile insect release (SIR) programme in Canada, leafroller populations (*Spilonata ocellana* (Denis and Schiffermüller), *Choristoneura rosaceana* (Harris) and others) appear to be on the decline (Nelson et al. 2021). This is similar to what organic growers have experienced when natural enemy populations are allowed to increase once insecticide use is reduced (Leach and Mumford 2008). Furthermore, alternative approaches, such as transgenic technologies introducing and expressing foreign genes with antipathogenic properties that interfere with pathogen viability, development or transmission, rather than vector population elimination, should not be ignored (Hao et al. 2001; Van Den Abbeele et al. 2013; Gilbert et al. 2016). These options obviously require that genetic resources be preserved in a viable state.

The precautionary approach does not apply, in the same way, to the elimination of populations of invasive species that have invaded areas outside their native range (Hendrichs, Enkerlin et al., this volume). Application here of the precautionary principle implies the imperative that outbreaks of non-indigenous pests be eliminated to prevent adverse effects on native communities (CBD 2000, 2001). Even then, care should be taken to minimize destabilizing impacts on other species as the non-native one is progressively removed.

It is beyond the scope of this chapter to discuss these hypothetical possibilities in more detail; doing so would involve ethical, philosophical, biological, and ecological discourses. Nevertheless, it is important to point out that these aspects should be considered when designing strategies that attempt the eradication of native species throughout their whole range.

### *5.4. Release of Wildlife from Disease*

Diseases induced by tsetse flies, screwworms, and other insect vectors can adversely affect the health of wildlife, and reduce their survival rates. Conversely, free-ranging wild animals may benefit from the eradication of disease vectors and/or parasites, and increase the size of their populations.

If tsetse flies were eliminated, the immediate benefit to wild mammals would be only moderate, since African wildlife is trypanotolerant to at least those trypanosomes to which they are continuously exposed (Reichard 2002). Yet wildlife could benefit indirectly by spending more time in habitats previously avoided when fly densities were high. For example, the presence of tsetse can deter elephants from riverine forests (Bond 1993). These habitats would become fully available after tsetse eradication, but to the possible detriment of the woody vegetation. Nevertheless, experience has shown that forests are exploited and devastated whenever elephant populations exceed the carrying capacity, irrespective of the presence or absence of tsetse flies (Nagel 1995).

The impact of screwworms on wildlife can be much more pronounced. Prior to the eradication of the New World screwworm from the southern United States, a wide range of mammals was attacked by this parasite. White-tailed deer *Odocoileus virginianus* (Boddaert) populations were highly susceptible to myiasis, with fawn mortality reaching 80% (Reichard 2002; USDA/APHIS 2017). White-tailed deer are hosts to more than 100 disease agents (Schaefer and Main 2001). While these agents

are seldom, by themselves, fatal to deer, interactive effects may, in periods of stress and malnutrition, weaken animals and cause substantial mortality. After the eradication of the screwworm, a dramatic surge in deer numbers was observed, and this was welcomed by hunters and the game-ranching industry (Reichard 2002). However, it caused a new problem for cattle — they became heavily infested with the deer-parasitizing Gulf Coast tick *Amblyomma maculatum* Koch (Kettle 1993). Moreover, in marginal production areas, increased numbers of deer increased competition for pasture. Overall, however, both domestic and wild animals benefited tremendously from screwworm eradication. This includes the endangered Florida or dwarf key deer subspecies *Odocoileus virginianus clavium* Barbour and G. M. Allen. Its population has stabilized to several hundred animals from a low of fifty in the 1930s (Schaefer and Main 2001). Likewise, the endangered Florida panther *Puma concolor coryi* (Bangs), the bobcat *Lynx rufus* (Schreber), and other predators profited from the increase in the numbers of deer and wild boar *Sus scrofa* L.

Similar effects may occur in other areas subjected to screwworm eradication, yet with different ecological consequences and management implications. The endemic Jamaican hutia or cony *Geocapromys brownii* (J. Fischer) is highly endangered due to predation by the invasive small Indian mongoose *Herpestes javanicus* (E. Geoffroy Saint-Hilaire), as well as stray domestic cats and dogs. Stray dogs, with a screwworm infestation rate of 40% (Hoelscher 1999), are to some extent kept in check by this pest. Releasing cats and dogs (mongoose seems to be less susceptible) from the disease may translate into increased predation on conies, and, unless predator control measures are intensified, upset conservation efforts. Likewise, free-ranging introduced deer, pigs, and goats can be expected to increase in numbers in the absence of myiasis, threatening crops and remnants of natural vegetation. These examples show that the risk of area-wide control differs among ecosystems. Island ecosystems are highly susceptible to the addition or elimination of elements of native food webs. Pest management solutions must, therefore, be adjusted to recognize these specific risks.

### *5.5. Pollinator-Plant Interaction*

Pollination is the most important ecological service provided by insects to flowering plants. Pollinator assemblages comprise a wide range of insects, including blow flies (Calliphoridae) and fruit flies (Tephritidae) (section 3.3.1. regarding male horse flies). Most species in these families are opportunistic, non-specific pollinators. Therefore, the removal of the population of a single species is unlikely to impede pollination. Among the main dipteran pests targeted by the SIT, only some fruit flies comprise obligate pollinators. A mutualistic relationship has coevolved between species of *Bulbophyllum* orchids and a guild of *Bactrocera* spp. fruit fly species, including pest and non-pest species (Tan 2000). Male *Bactrocera* are attracted to orchid flowers by synomones, i.e. chemicals benefiting both the plant and the fly. These are consumed (pharmacophagy), and used further by the males as aggregation and sex pheromones to attract females. Apart from orchids, some species of the Araceae and Lecythidaceae are also pollinated by male fruit flies. It is evident that perturbation of species-specific flower-pollinator systems may result in reproductive

failure of the plant. In this case, applying the SIT against pollinator fruit flies within their natural range may not be an environmentally acceptable control option. However, apparently, no specific flower-pollinator relationships exist for the principal SIT targets. Furthermore, the Mediterranean fruit fly, the oriental fruit fly, the Solanum fruit fly *Bactrocera latifrons* (Hendel), and the melon fly *Zeugodacus cucurbitae* (Coquillett) are often controlled as non-native pests mainly outside of their natural range.

### *5.6. Predator-Prey and Host-Parasitoid Interaction*

There are apparently no obligate predators of insects targeted by the SIT (Laird 1977; Nagel 1988, 1995). In fact, most predators have opportunistic feeding habits. Therefore, ecologically relevant effects on predator populations are unlikely. The role of parasitoids, however, is much more specific, and needs to be discussed in more detail.

Many hymenopteran larval and egg parasitoids attack fruit flies. Their potential as biocontrol agents has been explored on various scales in several classical and augmentative biological control programmes (Montoya and Liedo 2000). The host range of parasitoids among tephritids varies, but none seems to be host-specific. Therefore, a risk to parasitoids from fruit fly eradication, resulting from an AW-IPM programme using the SIT, is not anticipated.

Contrary to the species-rich Tephritidae and Calliphoridae, the Glossinidae comprise only 23 species. The most frequent parasitoids of tsetse puparia are *Chrestomutilla* spp. (Mutillidae) and *Exhyalanthrax* spp. (Bombyliidae). In tsetse flies, about 40 parasitoid species have been reported, some of which appear to be hyperparasitoids (Greathead 1980). *Exhyalanthrax* spp. have a wide host range among tsetse flies and other dipterans. Some species have been reared from only one tsetse species (Greathead 1980). *Chrestomutilla glossinae* (Turner) appears to be restricted to *Glossina* spp., while *Nesolynx glossinae* (Waterston) (Eulophidae) is believed to have hosts other than tsetse (Greathead 1980). The rate of natural parasitism rarely exceeds 20%, and often is considerably lower. Although some speculation remains with regard to host specificity, experience from other taxa suggests that several parasitoids are specific to certain tsetse fly species (but only about 5–7 tsetse species are of economic importance). Therefore, the possibility remains that parasitoid species would be eliminated along with their hosts resulting in a loss of biodiversity and, possibly, in a diminution of natural control in case of tsetse fly reinvasions.

Females of *C. glossinae* are long-lived, and have exceptional host-finding ability. These traits can be used in biological control approaches. Knipling (1999) proposed tsetse eradication tactics that combine augmentative releases of *C. glossinae* with the SIT. The logical end, however, should the eradication of all hosts from their whole range be achieved, would be the demise of the parasitoid. Even though, at this stage, this scenario is merely hypothetical, measures to conserve mutillid parasitoids should be components of full-range eradication programmes. Conservation can be achieved by establishing and maintaining combined tsetse/parasitoid rearing facilities. This would also provide insurance against the possibility that mutillids or

other parasitoids are eliminated but not their hosts. Such undesirable effects have been observed in previous tsetse programmes targeting eradication at the population level (Fiedler et al. 1954). In this case, parasitoids could be released to re-establish natural biological control.

### *5.7. Host-Vector Interaction*

Tsetse flies are the main vectors of African trypanosomes. Metacyclic (infective) forms of the parasites colonize the salivary glands, and are transmitted during blood meals. Apart from trypanosomes, saliva may also contain viruses (Sang et al. 1999), bacterial symbionts (Beard et al. 1998), and rickettsia-like organisms (Weyda et al. 1995). This suggests that tsetse could also transmit pathogenic bacteria and viruses, or antigenic fragments of them, to their hosts, evoking concomitant immuno-responses. Therefore, wildlife immunization against bacterial or viral diseases may be enhanced by exposure to pathogens and/or antigens transmitted by tsetse (and other blood-sucking insects), thereby improving the health and fitness of wildlife. However, there is as yet no evidence on which to base such a hypothesis. Some salivary viruses are known to be pathogenic to tsetse flies (Sang et al. 1997; Abd-Alla et al., this volume), but their pathogenicity in vertebrates is unknown. Even if wildlife pathogens and/or antigens were transmitted by tsetse, their contribution to the overall load of transmission would probably be low compared with more abundant blood-sucking species such as horse flies or stable flies *Stomoxys* spp. (Muscidae). So "vaccination services" provided by tsetse may be seen as an odd and far-fetched scenario. Nevertheless, as long as epidemiological data are insufficient to unambiguously dismiss this hypothesis, this topic should be put on the research agenda.

Pre-release immunizations against viral and bacterial diseases are important steps in programmes of wildlife translocation and release. If the animals are to be released in high-density tsetse areas (Woodford 2000), existing protocols even suggest moderate pre-release exposure to vectors of trypanosomes and other parasites to enhance immunization. Allsopp and Phillemon-Motsu (2000) predicted that the eradication of a tsetse population in a given area may cause a temporary rise in endemicity of trypanosomosis. If tsetse disappear from areas in which trypanotolerant breeds were reared, the more productive trypanosusceptible Zebu cattle might be introduced and the genetic trait of trypanotolerance lost. In the event of a reintroduction of tsetse, this loss would seriously disrupt livestock production. These examples show that host-vector interactions should be evaluated beyond established views.

This is substantiated by experiences in the temperate zone, showing that management traditions may be ill-founded. In areas in the UK, with high bovine tuberculosis infection rates, it has been a long-standing practice to cull Eurasian badgers *Meles meles* (L.), the main non-bovine reservoir of *Mycobacterium bovis* Karlson and Lessel. Surprisingly, field trials revealed that culling increases rather than controls the incidence of bovine tuberculosis in cattle, indicating that transmission pathways and dynamics are highly complex and not fully understood (Donnelly et al. 2003).

These arguments are not raised against livestock-insect pest eradication programmes. Instead they aim to encourage and extend epidemiological research to non-haemoparasitic diseases in eradication zones, and to emphasize the importance of trypanotolerance in wildlife populations and livestock breeds.

### *5.8. Effects of Tsetse Eradication on Land Use*

The area-wide control of disease vectors and parasites may cause a strong increase in the number of domestic and wild herbivores, resulting in significant changes in land-use dynamics and patterns. This issue is particularly controversial with respect to tsetse flies (Grant 2001; Peveling and Nagel 2001). On the one hand, it has been suggested that tsetse flies provide insurance against human encroachment of wilderness areas (Jordan 1986; Chater 2003), and against environmental degradation caused by cattle overgrazing in the ecologically vulnerable Sahel zone (Ormerod 1990). Grzimek and Grzimek (1960) wrote about the tsetse fly:

> It is the only true friend the elephants and zebras have left, for it makes their homeland uninhabitable for men.

Other authors dismiss these notions on the grounds that it is the enforcement of regulations and not tsetse that protects wildlife areas (including gallery forests and dense woodland), and that new areas are opened up to cultivation as a result of human population pressure, independent of tsetse presence or absence (Nagel 1994; Kinley 1998; Feldmann and Hendrichs 2001). Furthermore, African landscapes now plagued with tsetse were thriving pastoral lands rather than wildlife havens until the rinderpest pandemic swept over the continent in the 19$^{th}$ century, depriving once prosperous pastoral societies of their livelihood (Pearce 2000; Feldmann and Hendrichs 2001). From this perspective, fighting tsetse flies means reclaiming land that had already been used by humans for thousands of years. Arguments can be raised in favour of either standpoint (Feldmann et al., this volume).

Pearce (2000) holds rinderpest responsible for the spread of tsetse flies in the 19$^{th}$ century — the demise of cattle led to the transformation of pastures into savannah woodland, providing new habitats for tsetse flies. This mechanism, however, is hypothetical. Typically, cattle promote bush encroachment by selectively exploiting the grass biomass, which in turn favours the growth of tree seedlings and shrubs. Furthermore, because the fuel load of the standing grass crop in heavily grazed savannahs is low, seasonal bushfires are less destructive to the woody vegetation. This idea, that tsetse flies benefited from land-use changes, was already put forward by Ford (1971). In his view, these changes resulted from activities of cultivators and pastoralists who transformed forests into savannah woodland long before trypanosomosis and rinderpest struck the area.

Historical evidence suggests that tsetse flies prevented the migration of early pastoralists into the tsetse "belt" of Africa. Surely tsetse flies and trypanosomosis were a constraint to the colonization of African landscapes for animal husbandry and agriculture, but their presence did not halt this process. For example, a study in Côte d'Ivoire found no indications that recent land-use changes and deforestation were governed by tsetse control (Erdelen et al. 1994; Nagel 1994). Studies in Ethiopia

found expanding agriculture in areas where tsetse suppression was successful, but overall changes in vegetation cover and structure were low (Reid et al. 1997; Wilson et al. 1997). In other parts of Africa, tsetse suppression may have had a greater impact on rural development (Jordan 1986; Stevenson 1988; Bourn et al. 2001). Conversely, rural development may affect the distribution of tsetse flies. Some species have disappeared due to the expansion of cropland, and the destruction of woodland and riverine forest habitats. Others have adapted to rural landscapes, where they feed mainly on domestic animals (Jordan 1986; Dye 1992).

It has been proposed that the eradication of economically important species of tsetse flies may enable a more-even distribution of livestock, thereby reducing over-grazing and erosion in the labile Sahel and highlands, and may also reduce the poaching intensity in national parks and wilderness areas since eliminating wildlife reservoirs of trypanosomes would no longer be practiced (Feldmann and Hendrichs 2001). This is a desirable but unlikely scenario. The following issues are considered to be equally important determinants of resource allocation and exploitation: food supply and security, land tenure, access to regional and global markets, and political and socio-economic stability. Decisions by people are based on the specific combination of these factors (Jordan 1986, 1992). The key to the sustainable use of natural resources is strategic land-use planning and implementation that mitigate deleterious changes (Grant 2001). This is true irrespective of the severity and extent of tsetse infestations.

In conclusion, it is true that wilderness and protected areas in Africa may harbour dense populations of tsetse flies. However, the conservation of many of these areas is also due to the fact that they are unsuitable as arable land. Moreover, some tsetse species have become resident in rural agricultural areas. Thus, the notion that tsetse flies are key protectors of wilderness areas cannot, as a general rule, be maintained. Finally, human/livestock health and wildlife conservation should not be traded against each other. Both are objectives in their own right, and they require concerted efforts to realize one without hampering the other.

## 6. CONCLUSIONS

In this chapter the principal environmental risks of SIT application and related activities have been reviewed. Some of them have been substantiated by reliable scientific evidence, while others are merely hypothetical and warrant further investigation.

SIT-related activities *sensu stricto* comprise the mass-rearing, sterilization, and release of sterile insects. Few environmental risks are associated with these activities, as long as safety standards and good field practices are guaranteed. However, SIT implementation also involves other supporting activities, and some of these may have adverse effects on ecosystems.

The first relates to pre-release population suppression. Insecticide applications may be harmful to the environment. In many situations, suppression can be achieved with more selective insecticides, some of which have been certified as organic, as well as ecologically sound techniques, such as traps and targets. These can be used alone or in combination, and may provide an environmentally acceptable alternative

or supplement to spraying non-persistent insecticides. However, adverse effects on selected biota or ecological processes and interactions cannot be ruled out for either method.

Secondly, area-wide control leading to the suppression or eradication of pest populations may have adverse indirect effects. These are often related to insufficient land-use planning and/or the lack of appropriate means of implementation, which in turn may lead to the unsustainable use of natural resources.

The third aspect is of particular importance if native species are targeted. Eradication of a species throughout its range may lead to a loss in species diversity of target and non-target species, including parasitoids and hyperparasitoids. Thus, the SIT can adversely affect host-parasitoid systems. Another aspect refers to the risk to pollinators, which has to be taken into account in all AW-IPM programmes that integrate the SIT. Finally, the immunological and epidemiological consequences of the transmission of non-haemoparasitic disease agents by vector insects, and the consequences of a loss of trypanotolerance in wildlife and livestock populations in tsetse infested areas, are open questions.

Optimum combinations of different control methods, resulting in the lowest cumulative risk, while achieving the highest possible effect on target populations, vary among species, regions and ecosystems. Thus, environmental assessments may reach different conclusions in different environmental situations, and pest management solutions must be adjusted accordingly.

## SUMMARY

Effective management of area-wide integrated pest management (AW-IPM) programmes that integrate the sterile insect technique (SIT) is key to their success. Programme planning includes collection of baseline data and technical and financial feasibility assessments. Programmes should be initiated only if there is strong stakeholder support and political long-term commitment. The optimal management structure permits the programme to be implemented effectively and flexibly, as independent as possible of government politics and routine bureaucracy that can impede timely goal achievement. At the same time, high-level oversight is required to avoid corruption and to benefit from expert committees that provide independent technical advice. Ideally, programmes include a mixture of public management and the outsourcing of some routine tasks to private management. They require strong and steady financial support. Governments and donors are the most common sources of funds, but a mixture of public, community, and private funds is now the trend. Interrupted cash flow severely restrains programme performance. Physical support of programme infrastructure and operations must be reliable, and led by a maintenance professional. It is essential to have full-time, well-paid, and motivated staff led by a programme manager with technical and management experience. Poor management and inadequate support often result in programme failure.

## 1. INTRODUCTION

Even though the technical elements of area-wide integrated pest management (AW-IPM) programmes that include the sterile insect technique (SIT) are critical to their success, the management components are of equal importance. However, more emphasis is usually placed on getting the "science right" than getting the "management right". Failure of an area-wide programme is usually due to poor management and inadequate support and not to how well the scientific technology is implemented.

Management is important for AW-IPM programmes with an SIT component because, firstly, these programmes affect large segments of the community, as do other more generally accepted area-wide activities such as police protection, electricity supply, or other services, where virtually everyone within the concerned area is involved (Knipling 1980; Lindquist 2001; Hendrichs et al. 2007; Klassen and Vreysen, this volume). This necessarily involves public financing, public accountability, legislation, enforcement, community participation, substantial infrastructure and organization, long-term support, and high levels of managerial skill. Secondly, as the SIT requires the successful handling of live insects, which have a very short "shelf life", as well as a number of other activities that need to be carried out in a defined time and space sequence, flexibility and high levels of technical responsibility to conduct and coordinate operations effectively and in a timely manner are essential.

Reyes et al. (1988) described the general organization and structure of an AW-IPM campaign involving the use of the SIT. This chapter discusses generic aspects of programme management and its impact on programme success or failure.

## 2. FEASIBILITY ASSESSMENT

Technical and economic feasibility assessments are essential, e.g. DeBiasio (1988) on the codling moth *Cydia pomonella* (L.). They address financial issues such as funding and budgets (costs and benefits) (Rhode 1975; Mumford, this volume), expected benefits other than financial, the biological and practical feasibility of achieving the goal of pest suppression or eradication (Rhode 1970), details of the proposed organization and administration, and activities needed to conduct the programme. Also, the pest situation, current control methods, impact of the pest on agriculture, the environment and human health, and the complexity of the human, biological and physical environments must be assessed. An assessment of the political and fiscal stability of a country, government priorities, governance, public and programme security, social and economic values, and economic development all impact on how feasible it would be to conduct an AW-IPM programme that applies the SIT.

The baseline data needed for a feasibility assessment are: (1) data on the area and commodities (for domestic consumption or export) or livestock/human population to protect, (2) data on population ecology, dynamics, and distribution of the insect pest in the proposed area using geo-referenced data, and an assessment of potential immigration of the insect into the area, (3) assessment of the pest problem (Tween 1993) — losses, both direct and indirect, caused by the pest, and the impact of the pest on human health, agriculture and the economy, (4) cost and effectiveness of current pest control methods, and their disadvantages, and (5) impact of the pest and of current control methods on the environment (Tween 1993; Vreysen et al. 1999; Nagel and Peveling, this volume; Vreysen, this volume). Decision-support tools, such as geographic information systems (GIS), remote sensing (RS), population genetics (Krafsur and Ouma, this volume), and mathematical modelling (Bouyer et al. 2010; Barclay, this volume; Bouyer et al., this volume) can greatly assist in feasibility assessment and planning of these programmes.

## 3. PROGRAMME PLANNING

A programme can be planned properly only if the baseline data are available, and all required feasibility assessments have been carried out.

If such assessments show that a programme is technically feasible, economically viable, and socio-politically acceptable, detailed plans can then be made and incorporated into a programme document or business plan (FAO/IAEA 2008). Such a document provides details of programme strategy, milestones, operational procedures (including standard operational procedures (SOPs)), budgets, plan for public relations activities, and management policies and procedures.

A legal agreement between the programme organization and commercial farmer associations, other stakeholder groups, and local and regional authorities, may be needed (Lindquist 2000). This agreement would describe responsibilities and authorities of all parties, in terms of financial and in-kind contributions, monitoring activities, the required level of pre-release suppression, sterile insect quality, expected insect deliveries, identification and handling protocols, expected degree of insect control, penalties for lack of compliance or poor results, and insurance coverage (Nelson et al. 2021).

Unfortunately, there is a tendency to begin implementation before planning is complete (Vreysen et al. 2000; Itô et al., this volume). A premature start can easily cause the programme to fail, or at least perform poorly, leading to discouragement, and possibly to abandonment of the programme. All components of the programme must be ready and harmonized, including a carefully selected and properly trained staff, before operations can begin. Sometimes programmes can begin on a pilot scale, to provide hands-on training for staff and to test all components, or start with areas in which success can be more easily achieved, and then move on to larger or more difficult areas. The lessons learned in the pilot programme are useful in making plans for the large-scale programme, and in any case flexibility (Norton 1986) is always needed as programmes proceed. In cases where a pest emergency occurs, such as an invasion or introduction of a new pest (Patton 1984; Hendrichs, Enkerlin et al., this volume), a rapid response is essential and proper planning is usually not done, and ad hoc procedures have to be adopted with the attendant high risk of failure. However, in spite of the crisis of the New World screwworm *Cochliomyia hominivorax* (Coquerel) invasion into Libya, the appropriate time was still taken to develop a plan of action for an AW-IPM programme (Lindquist et al. 1992).

If programmes are aimed at eradication, especially of pests that attack export crops, plans to continue the appropriate activities indefinitely, e.g. pest monitoring, quarantine, and contingency plans and readiness to re-eradicate outbreaks if needed, should be included (Krafsur et al. 1987; Reyes et al. 1988; Lindquist et al. 1992; Barclay et al., this volume; Hendrichs, Vreysen et al., this volume; Vreysen, this volume).

## 4. MANAGEMENT STRUCTURE

AW-IPM programmes tend to be large in size, complex, comprehensive, flexible, dynamic, intense, and demanding, and are relatively long-term. They require multidisciplinary teams of technically knowledgeable people with special skills to integrate different control methods, an organization involving whole communities and thus needing public and political support at many levels, and significant facilities and equipment. It is a real challenge to conduct such programmes, and both public and private sectors of society need to be educated and encouraged to play their essential roles in the programmes (Dyck, Regidor Fernández et al., this volume; Enkerlin, this volume).

AW-IPM programmes cannot be conducted by individual beneficiaries such as a farmer on a single farm or one individual in a community. Instead, an organized

group, in the area defined by the distribution of the pest population, must be formed that coordinates the implementation of harmonized activities on an area-wide basis (Tweddle 2002; Vreysen et al. 2007; Klassen and Vreysen, this volume). Therefore, it is essential that coordination among all stakeholders is effective, and that tasks and procedures are well described and clear responsibilities shown.

### *4.1. Government Management*

Traditionally, SIT-related programmes have been managed "top-down", where the planning and directing is done by hired programme managers, usually government employees such as was the case in the melon fly *Zeugodacus cucurbitae* (Coquillett) programme in Japan (Yamagishi et al. 1993), where national and prefectural technical specialists directed the activities. The eradication programme for the New World screwworm in Libya (FAO 1992) was strongly supported by the national government and international donors, and managed by a team of international technical specialists and their Libyan counterparts. Strong support for a programme from its stakeholders is essential for its success (Hendrichs 1986).

A government-led programme has the advantage of political, social, and legal authority in the programme area, and therefore persons in the public sector appropriately may be programme staff members. This may involve provincial and/or federal laws which can authorize the appropriate office and personnel to direct the programme, and also provide a revenue source and budget. For example, in Mendoza, Argentina, the provincial law number 6333 (1995) determines responsibility for plant and animal protection. A self-governing institute, ISCAMen, was created to deal especially with the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann). Each year ISCAMen receives a budget provided by law through the Provincial Congress; its economic independence permits funds to be dispersed without diversions elsewhere and enable it to fulfil its legal commitments.

Political independence and power in the hands of a few managers, even though usually an advantage for an action programme where some flexibility in decision-making is essential and operations are time-critical, can nevertheless under certain conditions become a disadvantage. Empowerment of people can become a real detriment to success if the programme then becomes burdened by political concerns and vested interests. Those not accustomed to having access to large amounts of money and authority may be tempted to use it unwisely, jeopardizing the programme. Therefore, empowerment needs to be accompanied by some oversight regime and should not be granted unilaterally, but only after individuals and groups have demonstrated the ability to manage resources in the best interests of the programme.

However, AW-IPM programmes almost always require both "top-down" and "bottom-up" elements for effective management. The local community and direct clients can influence the programme from the "bottom-up", such as the initiative shown by ranchers in the USA to get screwworm flies eradicated (Baumhover 2001), and by fruit growers in Canada to study the feasibility of a sterile insect release programme for the codling moth (Dyck et al. 1993). Community participation, at some level, is also essential to obtain the cooperation of farmers

(and sometimes the community at large) for pest suppression activities prior to the release of sterile insects, pest monitoring, quarantine, and publicity. Where pest suppression has to be carried out in residential areas, e.g. in the case of *Aedes* spp. mosquitoes, the active participation of homeowners is essential. When an outbreak of the New World screwworm was discovered in the Florida Keys, the travelling public was required to stop at roadside checkpoints to permit pets to be inspected in case they were infected (Robles 2016; USDA/APHIS 2017).

Nevertheless, the area-wide nature of programmes, and the technical activities of sterile insect production and release, almost always need a centralized organization led by experienced and knowledgeable managers. For transboundary programmes involving more than one country (where the pest distribution range includes areas in two or more adjacent countries), a multinational or international organization is required to coordinate the activities (FAO 1992). Such an organization may introduce cost savings that are not feasible if there is only a national programme, and a regional approach to pest control often has technical benefits (Enkerlin et al., 2017). Selection of a management structure for a programme must be made carefully since, once it has started, it will probably be impossible to change it.

### *4.2. Private Management*

Ideally, AW-IPM programmes include a mix of public and private management, but the balance depends on the local situation, and each case is different. Private companies are often cost-effective and dependable for routine tasks, e.g. maintenance and security of a rearing facility, purchase of materials, insecticide applications, aerial release of insects, and research contracts, but supervision of any out-sourced activity is essential to maintain the quality of the programme (Barnes 2007; Bassi et al. 2007; T. Matsuyama, personal communication). However, the final cost to the community may be high if there is not enough competition among companies, and private firms may take a large profit. In Mexico, an international institute contracts with the government to provide administrative services (with an 8% overhead charge) in the *Anastrepha* spp. rearing facility, resulting in an efficient work force and no labour union conflicts. In Argentina, a public-private foundation, hired by ISCAMen, provides contracts to personnel for the programme.

Another option is for a private firm to manage a programme, especially a permanent suppression programme, and where there is a continuous demand for sterile insects. A private company in The Netherlands (de Groene Vlieg Bio Control b. v.) (DGVBC 2018) produces and releases sterile *Delia antiqua* (Meigen) flies as a suppression pest control method for onion growers who request this; these growers pay for the monitoring and release of sterile flies on their fields (Loosjes 2000; DGVBC 2018). This programme now covers about 40% of the onion production area in The Netherlands (M. Loosjes, personal communication). In South Africa, FruitFly Africa (Pty) Ltd. handles insect rearing, sterile fly distribution to release areas, coordination of aerial baiting, and technical support for a Mediterranean fruit fly suppression programme (Barnes et al. 2015; Barnes 2016), and another company, Xsit (Pty) Ltd., was created to produce and release sterile false codling moths *Thaumatotibia leucotreta* (Meyrick) (Hofmeyr et al. 2015). A private company

established to produce and release sterile codling moths in South Africa operated on a pilot scale for several years, but closed down in 2014 (Barnes et al. 2015).

Interest is increasing for private companies to supply sterile Mediterranean fruit flies in Israel and Croatia (FAO/IAEA 2012a; Bio-Fly 2018), and tsetse flies *Glossina* spp. in Slovakia. The risks of a business based on biology, and of matching correctly the demand for, and production of, sterile insects, are a significant challenge for private business (Barnes 2007; Bassi et al. 2007). Production contracts must specify the required quality of the insects. Nevertheless, commercialization of sterile insect production, with the potential cost reductions (as already shown by successful companies producing biological control agents), is likely to become increasingly common (Quinlan and Enkerlin 2003; FAO/IAEA 2008). Companies involved in the SIT strengthen the local economy because they produce value-added products and create jobs (Hofmeyr et al. 2015). However, the area-wide nature of SIT field operations, with the consequent involvement of various stakeholders and the public, complicates privatization of these activities. To attract private investors, the industry supporting an AW-IPM programme must be robust and strong.

If insect rearing and field operations are managed by two or more different organizations, it is important that misunderstandings and poor coordination between them do not develop. A lack of coordination would be awkward at best, and disastrous at worst, for a programme. One organization with all programme components is the easiest to manage — the programme manager has authority over, and can coordinate, all components. However, when this is not the case — such as a programme that purchases sterile insects from another, possibly distant, organization, and a third one is contracted to release them (Quinlan and Enkerlin 2003; Cayol et al. 2004; Enkerlin and Quinlan 2004; Dowell et al., this volume) — ways must be found to ensure strong cooperation between the organizations. If a programme is implemented by more than one agency in a joint undertaking, the roles of each agency must be clearly defined. To maximize effectiveness and efficiency, it is essential that the authority for day-to-day operations be held by the executing organization (Rhode 1969).

Corruption can be a significant problem for programme managers, and AW-IPM programmes with large budgets, such as those that use the SIT, are especially vulnerable to it. Examples of corruption are: (1) diversion of funds and materials for personal use or for other units of government, (2) personal use of equipment such as vehicles, and (3) personal or political favouritism or nepotism in selecting or rewarding staff, and in selecting (or obtaining kickbacks from) suppliers or companies providing services. Paying bribes, e.g. to customs personnel, cannot be done officially, but sometimes for the sake of programme efficiency it is possible to reward cooperators in a culturally acceptable way. Political disturbances and civil unrest are also a threat to programme operations (Rhode 1969).

## 5. OPERATIONAL FLEXIBILITY AND INDEPENDENCE

Due to the rather unique challenges of managing an AW-IPM programme, there will almost always be better results if the organization is politically and financially autonomous, and independent of the usual government bureaucracies, and politics,

and sometimes corruption, that reduce efficiency and block progress (Hendrichs 1986; Box 1). Insufficient operational independence, and the burden of stifling administrative restrictions, can cause programme failure.

*Box 1. Tsetse Eradication Programme in the Niayes Region of Senegal (Vreysen et al. 2021)*

The programme adopted an "adaptive management" approach (which included monthly project coordination meetings with the various stakeholders, including researchers) that, as stated in EXPO 2015 (2015), ensured transparency and decision-making by consensus. Decisions were based on scientific (not political, personal or emotional) principles, and were guided by analysed field or other data. Day-to-day operational and financial problems were openly discussed and solutions found. Any decision that required follow-up action by the different actors was immediately implemented according to project plans. The collaboration between internal stakeholders and international partners, and a policy of "non-interference" by government ministries, enabled a smooth implementation of the programme.

Operational independence, with a focused and goal-directed agenda, can produce stability and remarkable achievements. The melon fly programme in Japan was conducted through a special organization, the Okinawa Prefectural Fruit Fly Eradication Project Office. This office was independent, like a trust, and had considerable flexibility and freedom to conduct operations and follow procedures conducive to programme success. The prefecture also provided administrative support. The Mexico–United States Commission for the Eradication of the Screwworm, established in 1972 for the AW-IPM programme on screwworm flies (Krafsur et al. 1987; Vargas-Terán 1991; Wyss 2000; Baumhover 2001), represented such an independent but legal body that had the authority but also the flexibility to "get the job done" effectively and efficiently. This commission, or its current follow-up, the Panama-United States Commission for the Eradication and Prevention of the Screwworm (COPEG), was exempt from the usual bureaucratic rules, and decentralized from government with an independent management, with its own regulations, accountability, and financial audits (Tweddle 2002). Another example is the Programa Moscamed, which implements a trinational (Guatemala/Mexico/USA) Mediterranean fruit fly programme (Enkerlin et al. 2017). The eradication programme for the New World screwworm in Libya (FAO 1991, 1992; Lindquist et al. 1992) was operated under a specially created organization, Screwworm Emergency Centre for North Africa (SECNA), which had the required independence and authority to achieve its objectives. The same is true for programmes operated by ISCAMen in Argentina – Mediterranean fruit fly, codling moth, European grapevine moth *Lobesia botrana* (Denis and Schiffermüller), and other species (section 4.1.).

On-site programme managers have not only the responsibility to make a programme successful, but also require the authority to make management decisions in a timely manner so that the programme can achieve its goals. This should include authority to dismiss an employee for unproductive or disruptive performance (Rhode 1969).

## 6. PROGRAMME STAFF

An adequate number of qualified, competent, responsible, goal-oriented, motivated, dedicated, and hard-working staff members, having a high level of performance and morale, are essential to programme success (Lorraine and Meltsner 1987). Employees must have "can do" and "do it today, not tomorrow" attitudes. Staff recruitment should be done well in advance of the time when employees will be needed.

Staff, especially the managers, ideally must be full-time workers to encourage a high level of commitment and provide strong leadership, preventing other interests or responsibilities from diverting attention away from the programme (Hendrichs 1986). In the past, some programmes have suffered greatly because the leading professional staff could not spend the required time on the programme due to other duties or insufficient government salaries (Box 2). In the programme in Senegal (Box 1), project staffing (managers and technical personnel) was stable, with little turnover in 12 years. This created a staffing culture of reliability, transparency, and trust, ensuring the necessary institutional memory (Vreysen et al. 2021). To prevent the loss of accumulated knowledge about programme operations, competent staff must be encouraged to remain in the job and not be subject to staff rotation for bureaucratic reasons.

It is important to provide incentives for staff to maximize job commitment and continuity, and to improve their performance on the job. For example, higher than normal salaries, or special incentive pay based on performance, can be given to prevent staff taking on competing extra jobs to earn more money. High salaries also attract the best workers and discourage resignations to take more lucrative positions elsewhere. Staff members taking higher risks than usual, such as persons supervising the release of sterile insects from aircraft, should receive appropriate compensation and life insurance coverage. If the organization is unique or independent of government, promotion and the accumulation of pension benefits may not have much relevance to employees of the programme, and therefore a high salary is justifiable.

Job security and opportunities for promotion help to maintain job satisfaction. To make workers feel comfortable and able to concentrate on their tasks, safe practices in the work environment should always be a priority. It is vital that there be a high level of *esprit de corps*, using various forms of recognition and reward for good performance to encourage employees and make them feel proud to be a part of the programme; a positive work environment also discourages thoughts of sabotage. A biological programme has a high degree of dependence on the good performance of the programme's workers; sloppy work from one employee can negatively impact the whole programme.

The appropriate expertise needed for all of the various operations must be available among the programme staff, not only biological and scientific but also engineering and managerial expertise. This is especially true of the management of insect production (Fisher 1984; Leppla 1984; Schwalbe and Forrester 1984; Fisher 2009). If the appropriate persons needed to operate a programme are not available, it

is better not to start than to start and fail. Incompetent management leads to programme failure.

*Box 2. New World Screwworm Eradication Programme in Jamaica — Lessons Learned (Vreysen et al. 2007)*

The programme began releasing sterile flies in 1999, but by mid-2004 little progress had been made. A special management configuration, which could operate independently of existing inflexible regulations of the government, was never established. Instead, the programme was embedded in existing government structures, and senior staff continued with their normal animal health responsibilities. It was technically and financially supported by several "outside" stakeholders. The Government of Jamaica purchased the sterile flies from the Mexico-US Commission that, at that time, operated the only screwworm mass-rearing facility in the world (located in Tuxtla Gutiérrez, Mexico).

The programme was implemented on the premise that the screwworm SIT technology was infallible. Consequently, emphasis was placed on operational procedures rather than on strategic considerations that took local conditions into account. Most of the problems encountered in the programme were not related to the SIT technology *per se,* but were due to a reluctance to address problems in a scientific way. Although there were many factors that contributed to the lack of programme progress, the following were the most significant:

- The importance of collecting appropriate and sufficient baseline data on screwworm population ecology and dynamics prior to the initiation of sterile insect releases was not recognized. Sterile insects were dispersed using long-established protocols (which proved their usefulness in other countries under different environmental conditions) that did not take into account the distribution, and spatial and temporal fluctuations in density, of the local screwworm population. Consequently, the density of the screwworm population was greatly underestimated, and insufficient attention was given to adequate population suppression prior to and during the releases. The programme adhered to a dogmatic belief in the "supremacy" of the sterile flies, and ignored an important lesson from history, i.e. screwworm SIT cannot succeed without efficient field operations that continuously suppress the native fly population.
- Appropriate field data to monitor programme progress (Vreysen, this volume) were not collected. Evaluation of the programme was based solely on the number of reported positive screwworm cases, a very crude parameter influenced more by the willingness of farmers to collaborate and submit samples than by the effect of sterile flies. No attempts were made to systematically collect information on mating frequencies between sterile male and wild female flies. It was always assumed that the released sterile insects would perform adequately, and any potential inferior competitiveness was not considered. Many decisions were based on assumptions, the underlying causes of the lack of progress were never identified, the real problems were never rectified, and the programme was allowed to "drift along" for several years.
- Privatization of the veterinary services created a conflict of interest for veterinarians working for the screwworm programme. The more animals they treated against screwworms, the more money they received; this discouraged the veterinarians from working towards screwworm eradication.
- AW-IPM programmes that integrate the SIT are inherently complex, and require flexibility to react swiftly to changing pest population distributions and densities, and to solve emerging problems. A flexible and proactive management style is required to ensure continuity in the implementation of all important programme components. Any interruption in a critical component will automatically result in severe setbacks. This is especially true in programmes against the New World screwworm fly (which has a very short life cycle — 21 days in optimal conditions). Fig. 1 shows that, for the Jamaica programme in 2003, optimal implementation conditions, i.e. continuity in all important components, were achieved only 52% of the time (during 27 of 52 weeks). Although some of the problems such as the interruption in the dispersal of sterile flies, or the accidental release of fertile flies, were beyond the control of the programme, the malfunctioning of the chilled fly unit (which reduced both fly quality and the number of sterile flies released), and the interruption in the employment of all or at least some temporary field inspectors, could have been avoided.

*Box 2. Continued*

- The lack of an independent centralized management structure, with the responsibility, authority and flexibility to implement all programme components, was a major constraint and at the core of many persistent problems:
  - Programme staff members were usually civil servants, and especially the senior persons were assigned many other duties and responsibilities outside of the screwworm programme. The complex nature of AW-IPM programmes demands the full commitment and complete dedication of senior staff, and the many diversions caused by the other duties were detrimental to the programme.
  - Due to the absence of locally available SIT-related expertise at the onset of the programme, expert advice had to be provided continuously by internationally recruited technical advisors. However, these scientists were authorized only to give advice and thus could not play a significant role in programme decision-making. Many management decisions were unduly influenced by political concerns instead of scientific principles and field data.
  - Government regulations, that imposed severe restrictions on programme implementation, had to be followed, e.g. the programme could not employ temporary field staff according to the changing needs of the programme over time.
  - Some critical components of the programme were beyond the control of the managers. For example, there was only one source of sterile screwworm flies, the screwworm production facility in Mexico. Delivery of sterile insects to Jamaica was interrupted twice due to labour unrest at the facility. The second interruption (in 2001) lasted for 38 days, a time equal to almost two screwworm generations, and as a result all progress made earlier was lost. Another catastrophe occurred in January 2003 when, due to a malfunctioning irradiator at the production facility (Merrell 2003), a batch of at least 400 000 fertile insects (potentially 200 000 fertile female flies) was delivered to Jamaica. The upsurge in screwworm cases after this incident is hardly surprising in view of the very large potential for female screwworm flies to proliferate (each fertile female can, in her lifetime, produce several egg masses, each with up to 400 eggs). A third disaster occurred when a hurricane passed through the area, causing damage to the fly release facility and interrupting sterile fly releases.
- The importance of culturally determined factors, such as the attitude of the public and farmers towards animals, was severely underestimated. The rough handling of pets and livestock, creating small wounds (and oviposition sites for flies), generated ideal and persistent opportunities for the fly population to sustain itself. Obviously, the public education activities were not enough to change this attitude. This problem could have been circumvented by not relying on farmer participation, but instead employing more permanent or temporary field staff to proactively screen animals and treat both infested and uninfested wounds with insecticide; government regulations and a tight budget prevented such actions.
- The programme was impaired by having too many stakeholders, each with a slightly different interest and agenda. Often the result was political and diplomatic dithering rather than firm and focussed decision-making. As a consequence, an attitude of "getting the job done", a prerequisite for programme success, was never developed.

If there is a conflict of interest, such as between insect production and field work, or between insect production and quality control, the lines of authority must permit staff to report their results to managers who will not be biased, e.g. product quality control activities should be done by an organizational unit that is not responsible for sterile insect production (FAO/IAEA/USDA 2019; Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume).

In addition to producing a quality product, applying quality management practices in field operations, releases and administration, based on the implementation and certification of standards from the ISO (International Organization for Standardization), ensure the best and systematic procedures

without using subjective standards. Therefore, written procedures for all strategic steps in the various processes should be followed, e.g. field operations, mass-rearing, sterile insect release, etc.

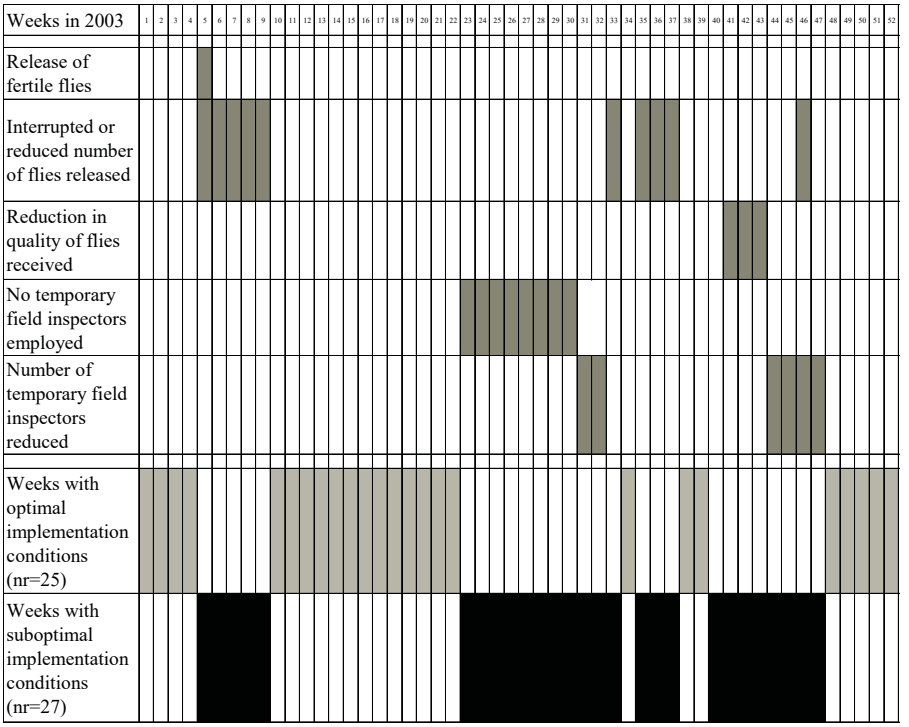

*Figure 1. Diagram showing, during one year, the weeks with suboptimal and with optimal implementation of the sterile fly releases and field activities in the New World screwworm programme in Jamaica.*

Labour-management relations must be kept positive to maintain staff morale (H. Hofmeyr, personal communication). Refusal to accede to union demands can lead to strikes or work sabotage, while capitulation results in the programme becoming a hostage and subject to blackmail. A labour strike, and the consequent failure to operate a biologically robust programme, can severely retard and even jeopardize the programme's success. Labour strikes at the New World screwworm production plant in Tuxtla Gutiérrez, Mexico, caused delays in the progress of the Jamaican screwworm eradication programme because it depended on this sole source of sterile screwworms (Box 2).

Especially if staff motivation is low, negative personal habits, attitudes, and values, and even local customs, can create significant problems. If not taken into account and creative solutions found, holidays, religious practices, personal behaviour patterns and conflict among staff members can reduce programme efficiency, and lead to programme losses. Rearing and handling sterile insects is a

24-hours-per-day and 365-days-per-year job. In ways that do not offend individuals and local customs, the insects must somehow be given the first priority. After a clear explanation of the reason for timely actions, properly motivated workers will usually respond with the kind of behaviour that is good for the programme, especially if recognition and compensation for exceptional work are being given.

The need for timely action is not only true for the biological elements of a programme, but managerial actions must also be carried out at the appropriate time (Kakinohana et al. 1993). A delayed management decision, just like a delayed biological activity, could result in programme termination. In the Jamaica New World screwworm eradication programme (Grant et al. 2000), interruptions in critical programme components, such as the employment of temporary field inspectors, resulted in severe programme setbacks (Box 2, Fig. 1).

In addition to holding training courses on the specific skills needed in the various tasks in the programme, e.g. field operations, mass-rearing, sterile insect release, etc. (section 6.1.), a Human Resource Management team in the programme or "parent institution" is needed to provide onsite training on all aspects of management and decision-making.

Due to a shortage of funds, or for convenience, volunteers such as local farmers may be recruited to perform certain tasks, e.g. set up insect traps or distribute a lure-toxicant (Teruya 2000; T. Matsuyama, personal communication). The screwworm programme in Central America developed an honorary-inspector scheme that effectively complemented the activities of programme field workers. However, experience has shown that sometimes volunteers do not perform properly, and therefore close supervision is indispensable; the critical operations of a programme should not be assigned to volunteers.

### *6.1. Training*

Specialized training for the various tasks related to SIT implementation is essential; it improves performance directly, and also represents an incentive for staff. It is important to train back-up employees so that the work usually done by a person who is absent can continue.

There are many national training programmes on insect pests, e.g. Florida State Agricultural Response Team (FSART 2012), as well as degrees in entomology offered by universities, but virtually none focuses on aspects of area-wide pest control and SIT application (one example is the specialized course "International Insect Rearing Workshop" (MSU 2018) offered periodically by Mississippi State University). Therefore, on-the-job training often has to be provided internally by the programmes themselves. For example, in the tsetse mass-rearing insectary in Ethiopia, the colony's performance improved substantially after the implementation of a permanent training programme. This programme was conditioned on the performance of the project and aimed at motivating the staff in two ways: by delivering specialized training on the SOPs in the different activities of the project, and by stimulating the staff to attend training sessions after the regular working time with an overtime compensation fee. Another powerful motivation tool is to offer deserving staff (those who have shown an outstanding aptitude and level of

performance) the possibility of enrolling in flexible postgraduate studies (MSc, PhD) in local universities, as long as this doesn't interfere in the performance of their daily activities in the programme and the topic of the research component is on an operational aspect of the programme. This requires an additional effort on the part of the student and on that of the programme, but benefits both the student's personal career and the programme's technical capacity (R. Argilés Herrero, personal communication).

Over many decades the FAO/IAEA (Food and Agriculture Organization of the United Nations/International Atomic Energy Agency) has been providing specialized national and regional training courses on various aspects related to implementing the SIT. Such courses provide opportunities to accommodate specific language and local issues, e.g. training courses on applying the SIT against insect pests in Brazil, Asia and Africa (IAEA 2016). Training courses may include a wide range of subjects: insect biology and mass-rearing, induction of sterility, field operations -- monitoring and sterile insect release, and management issues such as economics, financial planning, staff management, project implementation, public relations (Nature 1975; Jayaraman 1997; Dyck, Regidor Fernández et al., this volume), import/export requirements, and risk management. Most importantly are specialized training opportunities and in particular comprehensive interregional training courses for managers that are organized periodically by the FAO/IAEA at sites of operational programmes (FAO/IAEA 2018a).

If a programme results in pest eradication, there would appear to be little need in the future for the acquired knowledge and skills on that pest in that area. Nevertheless, experience shows that the knowledge and generic skills on AW-IPM acquired in a successful programme can be used by animal and plant health authorities in area-wide programmes against other pests or the same pest in other areas.

### *6.2. Risks*

There are significant risks associated with the manned aerial release of sterile insects. Every effort must be made to employ (or contract companies with) experienced and skilled pilots, and competent maintenance workers, and to use the best available equipment and facilities. Nevertheless, aircraft accidents do occur.

There were ongoing fatalities due to aircraft accidents in the New World screwworm eradication programme in Mexico and Guatemala from 1972 to 1992. However, for more than 25 years now, there have been no aircraft-related fatalities during the Central America and Panama programmes (J. H. Wyss, personal communication). Also, the aerial release of sterile false codling moths using gyrocopters in South Africa was not accident-free -- three pilots were lost in accidents. Subsequently, releases were made using fixed-wing aircraft (S. Groenewald, personal communication). To avoid risk to the lives of pilots and accompanying personnel, a significant effort is now being made in several programmes to test remotely operated drones for releasing sterile insects; this is a welcome development (PFR 2018; Boersma 2021; Dowell et al., this volume).

Also, workers using irradiators must face risks, even though extensive safety features are built into modern irradiation equipment (Bakri et al., this volume). In most countries, the use of irradiators is not permitted by national nuclear authorities unless programme operators have been thoroughly trained in regulatory and safety procedures, using written guidelines and supervised by an instructor certified by the national nuclear authority.

## 7. PROGRAMME MANAGER

The management of AW-IPM programmes that integrate the SIT is multifaceted and intensive. Administrative tasks can be done by persons with a business orientation, but the senior managers have a much larger responsibility — to give overall leadership to the programme! Ideally, besides being able to manage personnel, infrastructure, finances, and the political side of the programme, and to make difficult decisions, managers should also have theoretical and practical knowledge about relevant technical matters, and have experience in conducting area-wide and complex insect control programmes. Many of the day-to-day decisions in a programme require sensitivity to critical biological issues, including environmental issues (Kinney 1993). Managers must be convinced that the technology being used will achieve the programme's objectives. Area-wide programmes require strong and persuasive leadership. Managers must be able to communicate effectively with the programme's stakeholders (Patton 1984; Dyck, Regidor Fernández et al., this volume), but still promise only realistic deliverables (Barnes et al. 2015).

An "ideal programme manager", i.e. a person who has all of the qualifications needed in a programme manager, is difficult to find. In science-related institutions the senior manager is usually a scientist, and all of the other needed skills and knowledge are acquired secondarily. However, sometimes the senior manager is an administrator, and the scientific skills and knowledge are acquired secondarily. Both situations can function satisfactorily, but most often there is a need for additional personnel to be hired to complement the programme manager in the subject areas that need strengthening, e.g. administration or technical matters. Such a team-approach is the one most likely to manage a programme successfully.

Quite often the nomination of programme managers is done at the political level. Although there is an undeniable political dimension to large operational programmes, and strong links to political authorities is an important asset, it is also true that such programmes can be logistically complex and technically demanding, requiring an adaptive management to be successful. Therefore, it is essential to have a technical manager with knowledge and experience in all SIT-related activities (including field activities, sterile insect releases and mass-rearing) and with an executive capacity for decision-making at the technical level (R. Argilés Herrero, personal communication).

The programme manager, and similar senior positions in the management structure, must be chosen subsequent to official competitions that really provide for fair, thorough, and unbiased assessment and selection procedures.

Since there are relatively few persons in the world who have all of these required qualifications, hiring an experienced manager from outside the country may, at least

initially, be appropriate (FAO/IAEA/TANZANIA 1994). In fact, due to cultural norms, an "outsider" can sometimes achieve things more efficiently than a local person. However, for a number of local reasons, an external expert is often only accepted as a co-director (FAO 1992) or as an advisor to the national director, which can have negative consequences (Box 2). Normally, a programme manager operates under the guidelines and oversight of a board drawn from the official supporting agencies.

If a government takes a leadership role in programme management, it can produce mixed results, since standards of good governance vary tremendously among countries. A risk of government-run programmes is that senior management positions may be seen as political rewards, independent of managerial and technical competence. Also, if a government changes, there is the potential for staff changes, and this lack of continuity could disrupt a programme (Rhode 1969).

The suggestions made by Lorraine and Chambers (1989) in the context of the 1980–1982 California Mediterranean Fruit Fly Programme are worth noting. In urban entomology, with today's increased participation of community activists and special-interest groups, it is a major challenge to deal with complex public policies and programme activities that are not derived from experimental sciences. In modern life, there is no longer a "best solution" but only bargained negotiated compromises that more or less balance competing interests. Coping with the public's desire to participate in decision-making, and even having public confrontations over technical issues, are rather new experiences for most managers of AW-IPM programmes.

## 8. FINANCIAL SUPPORT

AW-IPM programmes using the SIT may operate over large areas, and sometimes involve major facilities and equipment. The financial resources required may also be large. Even though a programme might be economical on a benefit/cost basis (Mumford, this volume), it is not always affordable, and obtaining start-up and operating funds can be the most important issue facing a programme. The type of financing used affects programme strategy and operations, the duration of programme support, and the reliability of this support.

Enkerlin (this volume, section 3.1.) provides an extensive summary of various funding options for AW-IPM programmes that apply the SIT, and discusses the strengths and weaknesses of the various options. Table 1 shows the various complexities of different funding arrangements (J. Hendrichs, personal communication).

### *8.1. Financial Support from Various Levels of Government and/or Private Sources*

AW-IPM programmes can be financed through a variety of funding sources and financial operating systems. Many programmes are funded from one or another level of government, or a mix of levels, ranging from national governments, state/provincial governments, and regional/district/local governments. In many cases this support is essential to the stability and success of the programme, e.g. melon fly

in Japan (Kakinohana et al. 1993), New World screwworm in the USA, Mexico and Central America, oriental fruit fly *Bactrocera dorsalis* (Hendel) in Thailand, Mediterranean fruit fly in Latin America (Rhode 1975; Patton 1984; Dowell et al., this volume), and codling moth in Canada (Nelson et al. 2021). However, sometimes government support is unreliable or not delivered in a timely manner; delays create uncertainty for managers (especially if political considerations become dominant), unnecessary repetition of work, and even programme failure (Hendrichs 1986). Convincing government officials (who may reside far from, and have very different concerns than, the people in the programme area) to support a programme is often a huge challenge.

*Table 1. Funding Situation for Various Types of Programmes*[1]

| Funding Situation | AREA-WIDE PROGRAMMES (with central coordination and government involvement) | | NON-AREA-WIDE PROGRAMMES |
|---|---|---|---|
| | Federal and State Government Programmes | Local Community Government Programmes | Local Individual Stakeholders Programmes |
| Programme managed and implemented as government service (including contracting out some services) | Yes | Yes | No |
| All citizens, including non-beneficiaries, contribute indirectly to programme funding through generic government taxes | Yes | No | No |
| Only local beneficiaries contribute directly to the programme, mostly through local taxes, and sometimes also through other in-kind or cash contributions | No | Yes | No |
| Local beneficiaries are involved in the decision-making on programme funding and governance | No | Yes | Yes |
| Beneficiaries contract and fund services individually, without any local coordination or government involvement | No | No | Yes |

[1] Source: J. Hendrichs (personal communication)

In one way or another, taxation provides the resource that governments use to support their activities. Sometimes citizens have no direct influence on how money is spent. However, all government-based funding systems have some level of accountability to the stakeholders, and if a programme is largely funded by a local government, then the stakeholders will probably have a greater influence on the programme activities than a programme funded by a national or state government.

Community involvement usually benefits a programme; stakeholder participation can improve programme delivery and effectiveness. If the tax base used to support a programme is drawn from a specific community that includes programme beneficiaries, e.g. farmers or members of a larger community (Dyck et al. 1993; OKSIR 2018; Seymour 2018; Nelson et al. 2021; Mumford, this volume; Simmons et al., this volume), then residents of a community can influence local government decisions, e.g. decisions on support for an AW-IPM programme, through elections and support of, or opposition to, a particular feature of the programme or a change in the tax rate. Mosquito abatement districts are the most common examples of such locally organized, managed and taxed programmes, with Florida alone having currently 61 local mosquito control programmes (UF 2018). This involvement of the community creates an opportunity to obtain broad public support, but also for uninformed people to influence the programme; therefore, the role of public education becomes very important in such cases (Dyck, Regidor Fernández et al., this volume).

If governments provide the finances to operate a programme, this can foster a culture of dependence and reduce the incentive for stakeholders, e.g. farmers in an agricultural setting, or citizens in public health campaigns, to be involved actively. If stakeholders do not contribute in some way to the pest control programme, e.g. managing pest "hot spots", eliminating mosquito breeding areas, or checking insect traps or pest damage to crops, their lack of supportive actions could reduce the effectiveness of the whole programme. Therefore, to ensure programme success, it is usually essential to keep stakeholders involved in programme activities, even if most funding comes from governments or donors (I. Pla Mora, personal communication). In area-wide programmes, the participation of farmers is essential in view of their first-hand knowledge of the pest situation on their farms, and their cooperation is necessary even if they are reluctant, for whatever reason, to take advice from programme staff.

Direct programme beneficiaries, such as growers, orchardists, and ranchers, are goal-oriented, and the pest or its control directly affect their livelihoods, environment, or even health. They have a personal stake in the programme's success. Such stakeholders are usually supportive of the programmes since they will reap many of the benefits of success, but often are also "cash poor", even if sometimes "asset rich", and tend to offer quite limited financial resources to a programme. Those farmers whose products for export must be residue-free, or even completely free of quarantine pests, are often very supportive. Even though in some programmes there is little or no contribution from the direct beneficiaries, many programmes obtain contributions "in cash" or "in kind" from stakeholders, e.g. fruit growers in Argentina and South Africa (Barnes et al. 2004, 2015) support the field operations of Mediterranean fruit fly programmes, cotton growers in California, USA, helped fund the pink bollworm *Pectinophora gossypiella* (Saunders) eradication programme, and cattlemen in the south-western United States made contributions to a New World screwworm programme (Wyss 2000; Baumhover 2001).

Support from programme beneficiaries is good from an operational point of view, but the financial aspects are often less stable than government funding.

Contributions need to be reliable, and therefore probably compulsory. If market returns are low, or the economic health of an industry is poor, the participants in that industry will be reluctant to continue supporting a programme. In addition, as in many AW-IPM programmes, not all beneficiaries tend to be supportive and educated in technical matters. They are also sometimes poorly organized, and reluctant or even opposed to cooperating in joint area-wide activities.

There are good reasons for a community to contribute financially to an AW-IPM programme that applies the SIT, especially if the insects for release are reared locally -- quantifiable economic and social benefits to the region, e.g. employment, purchase of locally produced materials, increased tourism because of a safer environment, and a potential for higher market returns of the commodity, such as fruit, being produced largely insecticide-free (Mumford, this volume).

A mix of public and private funds seems to work best in some programmes, and this is now the trend (Barnes et al. 2015; IAEA 2015; I. Pla Mora, personal communication). For example, the successful *Anastrepha* spp. fruit fly programme in northern Mexico is funded one-third by grower associations, one-third by state authorities, and one-third by the national government. However, the larger the number of funding sources, the greater the complexity of financial management, but probably also the greater the funding stability.

A few programmes are largely or completely operated through the direct payment by stakeholders and members of a community to a commercial company. The onion maggot programme in The Netherlands is conducted entirely with funds from individual growers that contract for the service of pest monitoring and suppression in their onion fields, including the release of sterile flies (Loosjes 2000). In the case of mosquitoes, it is quite common for citizens of a county or community to fund their mosquito-abatement districts, including the recruitment of professional managers and entomologists. However, in cases where individual farmers have sterile insects applied but not as a part of a coordinated area-wide approach, as in the example of the onion maggot, such support would mainly benefit the farmers who contracted to have the SIT applied. Neighbouring farmers, who are "free riders", obtain benefits from dispersing sterile flies without paying for them, while farmers that pay for the SIT suffer when mated fertile female flies enter their land from nearby farms that are not part of the programme (Klassen et al., this volume).

### *8.2. Financial Support from Donors and Foreign-Aid Programmes*

In developing countries, it is common for donor organizations and government-sponsored foreign-aid programmes to provide some support to national governments in area-wide pest control programmes, e.g. the New World screwworm programme in Libya (FAO 1992; Lindquist et al. 1992), and the tsetse fly *Glossina austeni* Newstead programme in Unguja Island, Zanzibar, United Republic of Tanzania (FAO/IAEA/TANZANIA 1994; Dyck et al. 1999). In Ethiopia, non-governmental organizations (NGOs) provide some financial support for the control of tsetse flies, although most funds are received from the government. It is also common, at the request of developing countries, for international organizations to provide some multilateral support to national governments (LaChance 1993), such as in the

screwworm programme in Libya (FAO 1991, 1992; Lindquist et al. 1992), and the tsetse fly programme in Zanzibar (FAO/IAEA/TANZANIA 1994; Dyck et al. 1999). Most such support is provided "in kind", and focused on important expert services for training, capacity building, and feasibility studies, as well as the provision of special equipment. However, sometimes the equipment provided is not appropriate to the practical operations, or difficult to maintain locally, and may therefore become unusable. Thus, some "in cash" support, although not common, is also very useful to a programme for some local purchases and to overcome local constraints and cover needs not foreseen in inflexible government budgets.

In many countries the FAO/IAEA has provided financial support for some applied research activities, capacity building, and pilot operational programmes related to applying the SIT, e.g. South Africa (Barnes et al. 2015).

## 9. MANAGING FINANCES

Often the biggest problem in managing finances is interrupted cash flow due to delays in receiving funds from financial supporters of a programme, be it from government or other sources. Budget cuts, caused by economic downturns or political decisions, especially if unexpected, have a strong negative impact on the progress of a programme (Patton 1984). Sometimes a shortage of money is caused simply by bureaucratic delays. If there is no money or money is delayed, usually the programme activities have to be restructured, curtailed, or even stopped, and this can be disastrous for a biological programme that requires continuity and where "timing is everything" (Lorraine and Meltsner 1987). Insect rearing and release activities cannot be "put on hold" and resumed later when money becomes available. Failure to sustain activities can result in a total loss of previous achievements and the necessity to start the programme again (Box 2). On the other hand, if a programme suddenly receives an excess of funds shortly before the end of the fiscal year, panic spending could lead to the inefficient use of money. One way to minimize the problem of local cash flow is for the funding organization to regularly advance money to the programme manager, who can anticipate expenses and budget these funds accurately.

A back-up plan must be included in the programme planning document so that, when a programme supporter fails to deliver promised money, funds can still be made available, and the programme can proceed on schedule. A possible mechanism to solve this problem would be for one financial supporter to agree, in advance, to provide contingency funds. In any case, a contingency fund is needed to cope with emergencies.

Reliability in funding and cash flow, and also the provision of larger amounts of money at those times of year when biological operations require it, are essential for an AW-IPM programme involving the SIT. In the case of seasonality of programme implementation, financial planning is further complicated. This emphasizes the need for a separate organization (section 5.), located at the site of the programme, with its own financial accounting system and audits, which can control cash flow and prevent unauthorized use of money.

Especially in poor countries, payment of incentive bonuses to complement on a regular basis the low staff salaries is important for maintaining staff morale and a high level of performance, both of which are essential for effective field operations and the production of high-quality sterile insects for release.

Declining exchange rates between local and foreign currencies can be a major problem for programmes that have some of their expenses in foreign currencies. Under these conditions the conversion of funds has to be carefully managed, as a rapid decline makes it more difficult for a programme to purchase foreign-produced goods such as technical equipment or aircraft services.

## 10. LOGISTICAL AND PHYSICAL SUPPORT

Even though the quality of the human input into an SIT-related AW-IPM programme is a top priority, programme staff cannot do the work alone, and logistical support and the physical infrastructure are essential to achieve a programme's objectives. Materials and equipment must be of appropriate specifications and quality, cost-effective, procured in a timely manner, and properly maintained. A well-executed procurement plan should take into account that biological processes, once started, must be completed, and that the lack of even one item could mean disaster. Stability in the supply of critical materials, and an adequate stock of essential items, are required. For example, in mass-rearing, tested diet ingredients for at least 3–6 months operation are required, and warehouses have to be sized accordingly (Parker, Mamai et al., this volume).

Local rather than foreign procurement would appear, at first glance, to be the best policy, and can be advantageous in terms of availability, lower costs, and reduced transport expenditures. However, purchasing products from another country may be necessary in some cases to obtain a high-enough quality or items that simply are not available locally. Flexibility in procurement procedures is required to enable the correct materials to be purchased, and to permit quick action when biological events demand it. The lowest bid on an item is often not the correct criterion on which to base a purchase decision. Diet ingredients require especially stringent quality control procedures (Parker, Mamai et al., this volume).

The location of a mass-rearing facility has an impact on operational efficiency, and on the availability of materials and appropriate staff (Rhode 1969; Hendrichs 1986; Phillimore 2002; FAO/IAEA 2004, 2012b; Cáceres et al. 2012; Dowell et al., this volume; Parker, Mamai et al., this volume). If the programme is located in a difficult-to-access place, procurement must be done long before items are needed. This applies especially to insect rearing and release materials and equipment, and to field monitoring supplies.

To protect the environment and maintain respect for nearby communities, diet should be biodegradable and the disposal of spent diet through treatment of waste solids and water is an essential activity in facilities mass-rearing fruit flies, moths and screwworms, requiring appropriate infrastructure (Wyss 2002; Nagel and Peveling, this volume).

The production and release of a perishable product like sterile insects need a strong support system to ensure that investments are not wasted by the absence of,

or having low-quality, materials and equipment. Proper maintenance of equipment is essential so that mechanical failures do not result in the production of fewer or low-quality insects. Equipment should not be more complex than necessary (Rhode 1969), but of good quality to minimize breakdowns that lead to inefficient operations. Back-up equipment and plans for all critical operations, and a stock of spare parts for essential equipment to minimize equipment downtime, are necessary. Accidents and emergencies do happen, and therefore redundancy is needed to avoid negatively affecting field operations or to prevent declines in quality insect production. For example, even though several smaller independently operated rearing rooms cost more to build and operate than one large room, the smaller rooms provide much more production security than one large room (Tween 1987; Dyck et al. 1993; Phillimore 2002; Dowell et al., this volume; Parker, Mamai et al., this volume). For the sake of maximizing efficiencies and productivity, competition among workers responsible for the performance of different rooms can be fostered.

Ideally, utilities must be reliable, but back-up systems, e.g. electricity generator, should always be available so that temperature controls and other essential activities can continue operating.

Vehicles, including release aircraft, must be adequate in number and maintained properly to provide reliable and safe service. The aerial release of sterile insects has sometimes been done from aircraft owned by the programme. However, it may often be appropriate to contract out aerial release activities to private or government aircraft companies (Dowell et al., this volume). Nevertheless, to maximize programme effectiveness, programme staff must still supervise release operations. The high cost of aerial release necessitates a careful assessment of operational procedures to accommodate any concerns with economic, efficiency or technical issues (Teruya 2000).

In selected cases it may be realistic and appropriate for a large regional mass-rearing facility to produce enough sterile insects for the needs of a whole region, from where sterile insects are sent to the various emergence and release centres for handling and release. Sometimes it is more efficient and economical to construct a regional facility than for each programme to have its own facility (Dowell et al., this volume). However, this is risky in view of unforeseen catastrophic or political events, and can lead to complete dependence on the supply of insects, especially if there is only one production facility in the world, as is currently the case for the New World screwworm, currently in Panama (Vargas-Terán et al., this volume). Such a monopoly situation had a negative impact on the Jamaica New World screwworm programme (Box 2). In the absence of competition, dependence on the operating procedures and policies of, and the cost charged by, the only external source of sterile insects might not be in the interest of a particular programme; therefore, such a system is “the exception rather than the rule”.

## 11. EXPORTING/IMPORTING STERILE INSECTS

Sterile insects have routinely been shipped across borders for decades (see Table 2 for history of transboundary shipments), which is facilitated by the fact that sterile insects are non-invasive agents that leave no “ecological footprint” because they

cannot become established due to their sterility. In 2005 the shipment of sterile insects across national borders was facilitated further by a decision of the International Plant Protection Convention (to which most countries are parties), formally categorizing sterile insects among beneficial organisms (IPPC 2017; Klassen et al., this volume).

*Table 2. History of transboundary shipments of sterile insects*[1]

| Year | Tephritid species | Site of production | Approximate amount shipped (million pupae) | Recipient | Observations |
|---|---|---|---|---|---|
| 1963–1990 | Mexican fruit fly *Anastrepha ludens* | Monterrey, Mexico | Unknown | Texas, USA | |
| 1970/1971 | Mediterranean fruit fly | Seibersdorf, Austria | Unknown | Procida, Italy, and Greece | Relatively small amount since sterile flies were used for field trials |
| 1970 | Mediterranean fruit fly | Costa Rica | Unknown | Nicaragua | Relatively small amount since sterile flies were used for field trials |
| 1975–1977 | Mediterranean fruit fly | Madrid, Spain | 302 | Canary Islands | |
| 1978 | Mediterranean fruit fly | Seibersdorf, Austria | Unknown | Guatemala | Sterile pupae shipped from the IAEA laboratories (Seibersdorf) to a packing and emergence facility in Guatemala for field trials and staff training in SIT techniques |
| 1979–2017 | Mediterranean fruit fly | Metapa, Chiapas, Mexico | 357 600 | Guatemala | Transboundary shipments have been carried out periodically for the past 36 years |
| 1989–1994 | Mediterranean fruit fly | Metapa, Chiapas, Mexico | 6670 | California, USA | To assist the CDFA in eradication of medfly outbreaks |
| 1989–1990 | Mediterranean fruit fly | Seibersdorf, Austria | Unknown | Israel | Pilot trials |
| 1990 | Mediterranean fruit fly | Metapa, Chiapas, Mexico | 552 | Chile | Sterile flies donated by the Mexican government to Chile |
| 1990–1991 | New World screwworm (NWS) | Tuxtla Gutierrez, Chiapas, Mexico | 1800 | Tripoli, Libya | To assist the eradication of a NWS outbreak |
| 1993–2006 | New World screwworm | Tuxtla Gutierrez, Chiapas, Mexico | 107 000 | Central American countries | To assist NWS eradication in Central America |

*Table 2. Continued*[1]

| Year | Tephritid species | Site of production | Approximate amount shipped (million pupae) | Recipient | Observations |
|---|---|---|---|---|---|
| 1990–1998 | Tsetse fly *Glossina* spp. | Seibersdorf, Austria | 8 | Tanga, Tanzania | To assist tsetse eradication in Zanzibar |
| 1994 | Mediterranean fruit fly | Seibersdorf, Austria | 60 | Tunisia | Pilot trials |
| 1996–2000 | Mexican fruit fly | Metapa, Chiapas, Mexico | 2511 | California, USA | To assist the CDFA in eradication of Mexican fruit fly outbreaks |
| 1994–2017 | Mediterranean fruit fly | El Pino, Guatemala | 152 100 | California, USA | Preventive Release Programme and to eradicate medfly outbreaks |
| 1997/1998 | Mediterranean fruit fly | Madeira, Portugal | 206 | Israel | In support of pilot suppression programme |
| 1997–2000 | Mediterranean fruit fly | El Pino, Guatemala | 3700 | Israel | In support of pilot suppression programme |
| 1998–2017 | Mediterranean fruit fly | El Pino, Guatemala | 97 720 | Florida, USA | Preventive Release Programme and to eradicate medfly outbreaks |
| 1999–2000 | Mediterranean fruit fly | El Pino, Guatemala | 720 | South Africa | In support of pilot suppression programme |
| 2003–2006 | Mediterranean fruit fly | Mendoza, Argentina | 1681 | Valencia, Spain | In support of suppression programme |
| 2011–2013 | Mediterranean fruit fly | Valencia, Spain | 425 | Croatia | In support of suppression programme |
| 2008–2017 | Mediterranean fruit fly | Bio-Fly Israel | 650 | Jordan | In support of suppression programme |
| 2010, 2012, and 2014 to 2017 | Mediterranean fruit fly | Bio-Fly Israel | 3289 | Croatia | In support of suppression programme |
| 2010–2018 | Tsetse fly | Slovakia | 9 | Senegal | To assist tsetse eradication in Senegal |
| 2014–2017 | Mediterranean fruit fly | Valencia, Spain | 600 | Morocco | In support of suppression programme |
| 2015–2017 | Mediterranean fruit fly | El Pino, Guatemala | 4000 | Dominican Republic | In support of eradication programme |
| 2016–2017 | New World screwworm | COPEG, Panama | 194 | Florida, USA | To assist the eradication of a NWS outbreak |
| 2008–2017 | Mediterranean fruit fly | El Pino, Guatemala | 260 000[2] | Metapa, Chiapas, Mexico | In support of eradication and containment programme |
| | TOTAL | | 1 001 797 | | |

[1] Data from FAO/IAEA (2018b), reproduced with permission
[2] Only in this case, insects shipped as eggs

There is a long history of successful shipments of live sterile insects across national borders, especially insects in the pupal stage, e.g. Mediterranean fruit fly, New World screwworm. In future, there is no doubt that this practice will continue (Dyck 2010; Blomefield et al. 2011; Seck et al. 2015; FAO/IAEA 2017). As stated in FAO/IAEA (2018b),

> The transboundary shipment of sterile insects has taken place on a continuous basis for 55 years. The total number of sterile insects shipped has been estimated at more than 1 trillion [thousand thousand million] in thousands of shipments across borders to 23 recipient countries from 50 sterile insect factories in 25 countries. During this long period and many precedents, no problems associated with possible hazards have been identified, and thus the shipment of sterile insects has never been subjected to any regulatory action. The table shows the history of transboundary shipments which started in 1963 with the shipments of sterile Mexican fruit flies *Anastrepha ludens* (Loew) from Monterrey, Mexico, to Texas, USA.

The Okanagan-Kootenay Sterile Insect Release (OKSIR) Program in British Columbia, Canada (OKSIR 2018), has during the winter season in Canada shipped sterile adult codling moths to South Africa and New Zealand for use in both research and field control programmes (Taret et al. 2010; Blomefield et al. 2011; Horner et al., 2016; Suckling et al. 2017; Fries 2018; Nelson et al. 2021). However, recently there was a delay in shipments to New Zealand because of quarantine concerns (in New Zealand an Import Health Standard and permit to import live animals is necessary under the Biosecurity Act) (R. M. Horner, personal communication). Eventually, the requirement for a veterinary certificate was revised; an official letter of verification from the OKSIR (declaring that the shipped live insects are sterile codling moths produced at the OKSIR mass-rearing facility) was deemed acceptable, and shipments were allowed to resume. Nevertheless, even though such problems can usually be resolved, this illustrates the potential for difficulties in shipping sterile insects across borders (Quinlan and Larcher-Carvalho 2007; C. Nelson, personal communication; Klassen et al., this volume).

Shipments from the OKSIR to researchers in the USA, which initially would appear to be a simple matter given the proximity of supplier to the users, has become complicated. Hand-carried shipments work well, but such arrangements are always ad hoc and not sustainable. Alternatively, import fees, official inspections, and difficulties in finding carriers that can transport live insects quickly can be barriers to cross-border shipments. Export shipments sold at a profit are a vital component of the financial plan of mass-rearing facilities that operate year-round but need the produced sterile insects only during the growing season (Fries 2018; C. Nelson, personal communication).

The Nagoya Protocol (2018) was established in 2014 under the Convention of Biological Diversity as an organized system to permit the fair exchange of biological control organisms among countries, and to share the benefits of such exchanges with all involved. This system now exists in principle, but it is so restrictive that it has recently brought about an almost complete stop to natural enemy exploration for classical biological control programmes (van Lenteren 2021). In future, it could affect the free movement of sterile insects across some national borders.

## 12. PROGRAMME EVALUATIONS AND INDEPENDENT ASSESSMENTS

Programme managers, and even standing advisory committees and associated research scientists and institutions, need regularly to invite independent external experts and consultants to evaluate a programme and then give constructive advice and guidance. Both national and international consultants play valuable roles. External reviews of a programme reduce the likelihood of failure due to the "cannot fail syndrome", the unreasonable confidence that a process done correctly cannot fail to achieve the goal, and success does not need to be monitored (Dowell and Wange 1986). Experience gained in other programmes using the SIT can provide invaluable information and ideas to resolve problems and help achieve the programme's goals as efficiently as possible. Advice is often available, but usually at a cost, from university professors and other technically trained persons that are not affiliated with the programme's organization. The advice should be impartial, unbiased, and given "at arm's length". Sometimes it is appropriate to bring in full-time experts to advise the programme manager, especially on technical issues. If a programme claims to have eradicated an insect pest in a given region, it is important to obtain an in-depth assessment from a group of experts (Barclay et al., this volume).

There are numerous examples of good and helpful advice obtained from short-term consultants in many AW-IPM programmes. One is the international Technical Advisory Panel that recommended in 1994 an area-wide preventive release programme to deal with the recurring Mediterranean fruit fly outbreaks in the Los Angeles basin (Dowell et al. 2000). A more recent example is the Technical Advisory Committee (also composed of international experts) that advised the Dominican Republic on eradicating the Mediterranean fruit fly (Zavala-López et al. 2021).

However, there are also examples of bad advice that have damaged programmes (Box 3) (Klassen et al., this volume). Some caution in selecting consultants is needed since persons with no stake in a programme might in fact be biased, unrealistic, or too theoretical. External reviewers are not always correct in their assessments or recommendations, but it is extremely difficult politically for a programme manager to reject them. It is also difficult for non-technical managers, and representatives of donor organizations who hire technical consultants, to know if a consultant is biased or not, and has the required practical field experience. Therefore, external reviews need to be managed carefully, but on balance in most cases they are very valuable.

## 13. PROGRAMME SUCCESS OR FAILURE

Even though often blamed for programme failure, problems with technical issues in fact usually only delay the successful achievement of a programme's objectives, and rarely lead to failure. However, several programmes have failed because of bad management, and inadequate funding and political support.

*Box 3. Mediterranean Fruit Fly Invasion of Central America*

In Costa Rica, the Mediterranean fruit fly was first found in 1955, and by 1962 it had spread to southern Nicaragua. Field trials to contain the northwards invasion of the fly demonstrated that the technology (including the use of the SIT) was adequate, but that more funds, a vision to achieve the goal, and an organization were required (FAO/IAEA 1970). However, the advice given in 1970 by a three-person review panel of university professors (with no experience in managing area-wide programmes) was to abandon any containment efforts in Nicaragua. The panel did not accept that eradication should be the goal, questioned the cost and feasibility of the programme, and instead recommended to "live with the pest" with a focus on enhancing biological control. Preconceived conservative notions against AW-IPM, and the economics and politics of the situation, evidently "ruled the day"; an opportunity to eradicate, or at least contain, the invasive fly was lost. Abandoning all containment efforts resulted in the fly rapidly invading the next three neighbouring countries (Honduras, El Salvador, and Guatemala), and reaching southern Mexico by 1977. A costly trinational emergency programme had to be initiated to prevent the Mediterranean fruit fly from invading Mexico and the USA (Enkerlin et al. 2017). Since then, the great amount of effort and money that has had to be spent each year (currently over USD 40 million), to prevent this invasion from continuing and to reverse the trend, is at least an order of magnitude larger than the budget (USD 1.5 million for 4 years) that the experts had rejected for the Nicaragua programme (FAO/IAEA 1970). The economic problems caused by the fly invasion are still present in Central America, with significant losses and conventional control costs, and representing the major limitation of countries in the subregion, i.e. developing a tropical fruit industry and access to the nearby US export market. In comparison, Mexico recently celebrated 40 years of keeping the country free of the Mediterranean fruit fly, as a result of which the fruit and vegetable exports have exploded to over USD 4000 million per year. Thus, in the case of the Central American region, the recommendation of the external panel turned out to be bad advice. Meanwhile, the trinational Moscamed Programme has resulted in major economic and other benefits for Belize, Guatemala, Mexico, and the USA (Enkerlin, this volume).

Many lessons about programme management have been learned from past and ongoing AW-IPM programmes that integrate the SIT (Vreysen et al. 2007). Programmes have a high probability of success if:

- Thorough baseline data collection and feasibility studies are implemented for proper programme planning.
- They are managed by a flexible, independent and efficient management structure.
- They have carefully selected technical staff that work full-time for the programme, and also offer specialized training for the different tasks related to implementing the SIT.
- They have strong and reliable financial support, and also strong political stakeholder support.
- They have adequate and appropriate logistical support and physical infrastructure.
- They seek expert advice, especially technical advice where needed. Even when pilot programmes encounter problems, eventual success can be achieved if adequate applied research support (probably provided from outside the operational AW-IPM programme), good cooperation, and international technical support and consultation are available.

However, other lessons show that programmes will risk failure, or have significant difficulties, if:

- They have unrealistic objectives and expectations.

- They are immature, based on inadequate knowledge, patterned after other programmes without recognizing unique local characteristics, or are started too soon or with too little advance planning.
- They lack operational flexibility and independence, and carry the burden of stifling administrative restrictions.
- Their managers have inadequate (especially scientific and SIT-relevant) knowledge and experience, have a predominantly profit-oriented attitude (where the programme is a commercial enterprise), or do not work full-time in the programme.
- They have inadequate funding (Chinvinijkul et al. 2016), and staff lacks training or technical support.
- They have inadequate communications with the stakeholders, political leaders and the general public (Dyck, Regidor Fernández et al., this volume).

## 14. ACKNOWLEDGEMENTS

Information provided by R. Argilés Herrero, A. Bello Rivera, W. R. Enkerlin. S. Groenewald, D. Haraguchi, J. Hendrichs, H. Hofmeyr, A. Honma, R. M. Horner, W. Klassen, T. Matsuyama, C. Nelson, G. ## SUMMARY

Effective stakeholder communication and engagement is an essential component of area-wide integrated pest management (AW-IPM) programmes that integrate the sterile insect technique (SIT) because it has a large impact on programme success. Full-time professionals should direct communication activities and help secure vital support and "goodwill" from governments and community organizations. Good and frequent communication among programme staff, and between programme staff and stakeholders, is required to maintain engagement and support, and to keep the work goal-oriented even when some programme activities are controversial. The importance of engaging stakeholders in the programme is emphasized. The media can be valuable and effective partners by informing stakeholders and the general public about the facts and activities of a programme, especially if this is done in a non-technical and straightforward way. Methods of communication, including the use of videos and social media platforms, are described. Ongoing research helps overcome controversial aspects of programme technologies. Programme failure can result from poor communication and inadequate stakeholder support.

## 1. INTRODUCTION

Effective communication in area-wide integrated pest management (AW-IPM) programmes that include the sterile insect technique (SIT) is critical to success. The overall communication of programme goals, objectives, and activities is often not given as much attention as are the technical aspects of a programme, and inadequate stakeholder support can be a cause of failure. Good stakeholder communication is just as important for AW-IPM programmes as is good management (Dyck, Reyes Flores et al., this volume) because these programmes affect whole communities (Lindquist 2000, 2001; Pennington et al. 2021; Klassen and Vreysen, this volume).

AW-IPM programmes are visible; they may involve large communities or even several contiguous communities. The participation, support, and possibly the financial contributions of many, if not all, members of these communities, even if disparate, are essential for success. When urban areas have to be included, it is also necessary to inform this more complex segment of the community about the need for the programme, its objectives and progress. Quarantine checkpoints established to maintain pest free areas affect travellers who may not live within the programme area (Hendrichs, Vreysen et al., this volume). Since it is environment-friendly, the SIT technology is likely to be accepted by the public when properly informed. However, sometimes problems arise from the field and regulatory activities of AW-

IPM programmes, and these need to be resolved in a transparent manner (Reyes et al. 1988).

Stakeholders need to be pro-actively informed about area-wide programmes, with emphasis on the benefits that a programme brings to the community and country (Lindquist 2000, 2001; Mau et al. 2003). Communication activities require a strategy, implementation plan, and a budget just like other components of a programme; they are an integral part of it. Essential equipment and staff for these activities must be available at the beginning of a programme.

Before a programme is initiated, a survey should be made to identify the important stakeholders, the segments of the community that will be affected by the programme, and their likely primary concerns. A strategy of communication and engagement, and a plan for appropriate activities for each segment of the community, can then be developed and implementation started before initiating programme activities.

The details of the communication plan, and messages to the audience, will be unique to each programme. The type of media used should be suited to the communication plan and the situation (P. Rendón, personal communication). Translation of the messages into local languages may be necessary, and certainly the content, style, and format should fit the intended audience (Schwarz-Gehrke 1983). A periodic evaluation of the stakeholder communication programme is a valuable way to monitor and if necessary improve the communication strategy and activities.

Since technical specialists are often not good communicators, a full-time professional, with appropriate training and experience in communication, and a good knowledge of all aspects of the programme, should be appointed to lead the stakeholder communication activities (Dyck, Reyes Flores et al., this volume). Several persons together could form a communications team. Good interpersonal skills will help ensure an effective communication programme delivery. Consideration should be given to contracting public companies that can organize major media campaigns.

## 2. COMMUNICATING WITH STAKEHOLDERS

Regular and timely communication with a programme's stakeholders about programme objectives and benefits is an indispensable prerequisite to obtaining their support and participation. However, educating the public at large is difficult, and requires considerable effort and resources. Besides informing people about various aspects of AW-IPM and the SIT, using creative and effective methods is necessary to pre-empt the development of resistance that often develops when area-wide activities are initiated (Klassen and Vreysen, this volume).

Information provided on programme progress must be clear, reliable, up-do-date, relatively simple, practical, and sensitive to people's concerns. An opportunity for feedback should be provided. It must be recognized that perceptions among the various stakeholders will not be the same. The same issue may require more than one explanation, depending on the audience. Issues will relate to both technical and administrative matters. If prejudices or resentments are involved, not all issues may be solved satisfactorily.

Potential urban-rural conflicts, such as in an agricultural programme involving insects attacking tree fruits, can often be alleviated through information exchange and one-on-one meetings with antagonists. Obtaining the early support of labour organizations is highly desirable, and often essential, to assist in informing their members. Indigenous people should be informed about a programme and, where relevant to area-wide activities, their permission obtained to enter traditional or sacred areas.

Obtaining area-wide community support and cooperation is perhaps the most difficult aspect of stakeholder relations (Patton 1984; Tween 1993; Pereira 2001; Allwood and Vueti 2003). Even when the majority of stakeholders has understood a programme's approach and benefits through an education campaign, there are always some individuals who are not supportive of a public good that is beneficial to the community as a whole. In Canada, the most difficult group (that needed to understand the value of area-wide codling moth control) was the urban property owners who had a few apple or pear trees in their backyards. Some of these persons did not want to cooperate with the programme, or cooperated reluctantly, and in an area-wide programme it is essential that all cooperate. In urban areas where there are no direct stakeholders or beneficiaries, e.g. programmes against pests that attack fruit, activities of AW-IPM programmes applying the SIT may appear to be strange, intrusive, or even annoying, e.g. aerial release of sterile insects in bags or boxes, or formerly the application of aerial bait sprays over the Los Angeles basin in California, USA (Lorraine and Chambers 1989; Mangan and Bouyer, this volume).

In the case of insect pests of animals, and where the programme may include urban animals such as pets and stray dogs, it is often difficult to get urban residents to inspect and treat these animals (Dyck, Reyes Flores et al., this volume). In 2016 travellers on roads in the Florida Keys, USA, were required to pass checkpoints so that any pets being transported in private vehicles could be inspected by government personnel for possible screwworm infestation (Staletovich 2016; USDA/APHIS 2017a, b).

Obtaining formal support from stakeholders may require endorsement through local referenda or the passing of legislation by public bodies (Dyck et al. 1993; El-Lissy and Grefenstette 2007). Prior to a public vote or formal response to a programme's plans, a thorough information campaign will contribute to ensuring that the public has a good understanding of the issues at stake, especially if public funds or taxes are involved.

It is exceptionally difficult to conduct a programme in areas of political or civil unrest. Under these conditions, programme staff members who live in the area should be the ones contacting the local people -- they are probably more acceptable to the local population, and more aware of sensitivities, in finding ways to address the specific concerns of the people.

Local organizations, such as farmer associations and citizen groups, special-interest or donor groups, non-governmental organizations (NGOs), and industry-related groups, can be important supporters of a programme, and may even be helpful in addressing protests that impede programme operations. Such organizations are in a position of influence in a community, and can use this position to communicate information to particular stakeholder groups. If the livelihoods of

local stakeholders are at risk, e.g. being able to export their produce, they can help convince governments to support a programme (Dowell et al., this volume). They often care deeply about the specific issues that support the use of the SIT, such as environmental concerns. Nevertheless, local organizations may be small and therefore can be influenced by a few vocal or persuasive individuals; if they decide to oppose a programme, it will have a significant negative impact.

Admittedly, explaining technical issues to stakeholders is difficult. Technical experts have to realize that technical advice may not always be value-neutral (Lorraine and Chambers 1989). The public does not easily understand the concepts of AW-IPM and the SIT, and may be sceptical (especially about the need to control established pests). Special efforts have to be made to communicate the facts simply but effectively, using a variety of formats to ensure clarity. The public may require proof of the effectiveness of the technology. If not explained properly, using radiation to sterilize insects is easily misunderstood. Objections to releasing irradiated insects, which may be thought to be radioactive, must be handled carefully so that the facts are made clear and fears alleviated (Whitten and Mahon, this volume).

The response in Costa Rica to naturalists who objected to the eradication of the New World screwworm *Cochliomyia hominivorax* (Coquerel) was a public relations campaign called "The Ecological Fly"; it emphasized the value of using the SIT to help preserve endangered species in the forest.

Mass media can have a powerful effect on a programme. For example, the programme in India supported by the World Health Organization (WHO), where research on using sterile mosquitoes for control of the vectors of dengue haemorrhagic fever was conducted, had to be terminated by Indian authorities after severe negative publicity, wherein the programme staff was falsely accused by journalists of working on developing biological warfare. A timely rebuttal in the international media, to openly defend the programme and clarify the scientific issues, should have been made (Nature 1975), but this was not done properly, and the true facts were not made public until a clear rebuttal was published much later (WHO 1976; Jayaraman 1997).

Probably the hardest task for a programme manager, in regard to the media, is handling criticism, both fair and unfair. Much criticism arises from incorrect information or a lack of information (Klassen and Vreysen, this volume). However, sometimes there are significant issues at stake. It is important to keep stakeholder support for a programme strong; admitting to failure could weaken that support. Temporary programme setbacks need to be explained within the perspective of the overall goals. It is not helpful to become too technical; people will be more supportive if they understand the basics of the programme. For example, if people object to regular flights (for sterile insect release) over their homes, the need for these flights should be explained in a simple way. It is important to be positive, sincere, and timely, and to prevent small issues from becoming large issues. It is also vital to describe how the programme impacts on the residents of the community, the benefits people will get from it, and how they can contribute to it, e.g. by controlling pests on their own property.

It is usually an advantage to receive support from an international organization. Such a body lends stature to a programme. International support can stabilize a programme even if local support fluctuates or diminishes, but it cannot replace local commitment and "ownership". The FAO/IAEA has a long history of providing some support to AW-IPM programmes that apply the SIT (Barnes et al. 2015).

Financial supporters require regular reports on the financial status of a programme. However, in addition, donors and governments need to know that there is public support for the programme. Articles in the national press, or items on television and radio, provide indirect support.

Effective communication among programme staff is essential. Programa Moscamed, which involves three countries (Guatemala, Mexico, and USA) and includes several mass-rearing facilities and field centres distributed over vast territories in southern Mexico and Guatemala, uses an internal website to improve the information flow and allow programme staff to have instantaneous access to an enormous amount of data. Having the appropriate information helps to keep workers motivated, focused, coordinated, and productive. Opportunities should always be given to staff members to express their ideas on how the programme is progressing, offer suggestions for improvement, and participate in planning, assessment, and decision-making. A team that is informed encourages cohesive behaviour and mutual support.

To facilitate operational efficiency and effectiveness, a reliable communications system between insect-production facilities and field operations is needed (Rhode 1969; Dyck et al. 1999). The rapid sharing of data among staff members is essential for appropriate and timely decision-making, and fostering good cooperation and coordination (Vreysen, this volume).

Field staff members at all levels must be well-informed about programme goals and activities; they interact directly with the community, and therefore play an important role in informing stakeholders about the programme.

## 3. COMMUNICATION AND STAKEHOLDER ENGAGEMENT

Not only do the biological and geographical characteristics of an AW-IPM programme impact the required features of an effective stakeholder communication programme, but so do the sociology of a community, the type of inhabitants, culture, traditions, economics, politics, and even the security concerns involving rebel groups and the military.

Barnes et al. (2015) pointed out that the beneficiaries of a programme need to cooperate actively, e.g. implement effective sanitation in their backyards, fields and orchards, carry out husbandry and other cultural controls in a standardized and timely manner, contribute to accurate field data recording, have realistic expectations of what the deliverables will be, and fully understand how they need to be involved. As Dyck (2017) asserted in another context – stakeholder involvement matters!

A participatory approach to extension methods is appropriate for knowledge-intensive technology. Stakeholders learn more when they are involved and engaged. Field days with "hands on" demonstrations, "farmer field schools", visits to "model

farms" where the SIT is being applied, and "open house" days at project facilities are all helpful extension tools (Peshin and Dhawan 2009). Stakeholder meetings, e.g. meetings of farmer cooperatives and associations (Kakinohana et al. 1993), are useful for informing all interested parties of plans, progress, and problems. If there are language barriers among stakeholders, meetings provide opportunities for multi-language explanations and discussion (Rhode 1969).

A detailed example of involvement with the community is described by Bustamante et al. (2014), De Urioste-Stone et al. (2015), and Sommerfeld and Kroeger (2015) in connection with a programme to control Chagas disease in Guatemala. Researchers spent considerable time living in the communities that were being studied in relation to the control of the vector; the communities actively participated in proposing solutions to the pest and disease problem (community-based participatory and partnership strategy) that led to empowerment; "bottom-to-top" and "top-to-bottom" strategies were combined, and community volunteers were trained and supervised in applying cultural and other pest-control measures.

In preparation for an experiment in which transgenic mosquitoes were released in an urban area of Brazil, a major public awareness and engagement campaign was conducted (Capurro et al. 2016), emphasizing participatory action and a community-based programme involving frequent communication with local, state and national leaders. The social aspects of regulatory issues of the releases and project activities were assessed, including people's perceptions after releases stopped, and then followed by feedback and joint evaluation. The procedures in this study provide an example of methods that can be used to prepare for and measure the social impact of mosquito releases on an urban human population.

In a similar project on dengue in Australia, the effectiveness of community engagement was studied; stakeholder acceptance of the open-release field trials (release of *Wolbachia*-infected mosquitoes) was essential for the project to proceed (Kolopack et al. 2015). Note a similar project in Singapore (Liew et al. 2021).

As a result of the long history of applying the SIT in Okinawa, Japan, public awareness is high. Local people cooperate readily in assisting field operations. However, a lack of risk awareness in relation to maintaining the pest-free status can result from the long-standing familiarity with such projects (T. Matsuyama, personal communication).

## 4. METHODS OF COMMUNICATION AND STAKEHOLDER ENGAGEMENT

AW-IPM programmes need to communicate with the public! It is vital to build good relations with community leaders, as well as several media outlets and people in the media business, so that opportunities to communicate with the public become available, and the best way of reaching the right audience is found. The appropriate media outlets must be carefully discerned to maximize the desired communication to the target audiences.

Information provided to leaders and the media must be correct, authoritative, and also realistic about both the problem and the solution so as not to oversell a programme (Barnes et al. 2015). When the message is clear and straightforward, the SIT and related activities can be promoted effectively through the media.

When the various groups of stakeholders are identified, methods of communication can be selected that fit the groups. For example, programmes in Mendoza, Argentina, used television and radio broadcasts of sporting events to communicate short key messages about their activities. Press kits may be a useful way of giving information to journalists. Sometimes communication in more than one language is required, but always in a format and style appropriate to the audience. Monitoring media coverage reveals which issues interest the public.

Drawings of the basic concepts of the SIT (sequence of insect rearing, sex separation, irradiation, release of sterile insects, and monitoring) are shown in many outreach materials, enabling everyone to understand the processes involved. As an example, a simple and humorous cartoon used in Thailand (based on an original cartoon from MOSCAMED, Guatemala) is shown in Fig. 1. Such drawings get the message across in an easy-to-understand manner. Another drawing is given in Broll (2016), illustrating the application of the SIT against mosquitoes. The basics of the SIT are described on the FAO/IAEA website (FAO/IAEA 2018e). The FAO/IAEA also produced a tri-fold leaflet with explanatory text about the SIT (FAO/IAEA 2018f). The SIT is also explained in simple terms in many of the videos and photo essays listed in section 5., e.g. FAO/IAEA (2015a; 2016a, e); other examples are in Engelking (2017) and Viegas and Gil (2018).

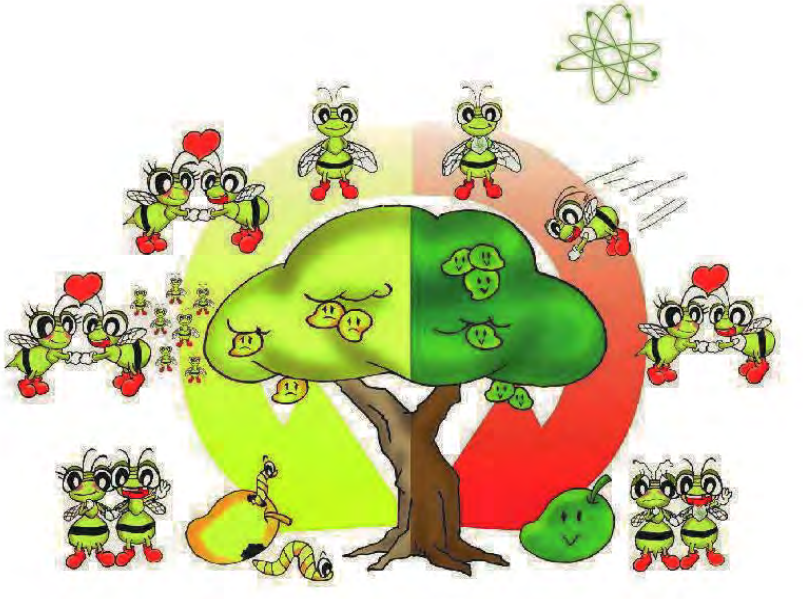

*Figure 1. Cartoon illustrating the basic principles of the SIT applied against fruit flies. (Cartoon from Thailand, reproduced with permission from Watchreeporn Orankanok.)*

Exhibits in public places and fairs are useful to create awareness of a programme. A display about the Okanagan Kootenay Sterile Insect Release (OKSIR) Program in Canada was set up in a museum (on the history of the fruit industry in the region), attracting local people and tourists.

House-to-house visits are often a good way to ensure that residents are informed about the programme and the need for their cooperation. Communication through the mail, telephone messages or public meetings is useful, but in many cases there should be direct communication at a personal level (P. Rendón, personal communication).

Opportunities can be created in rural areas — informal meetings and using speakers on vehicles — to communicate with farmers and those who do not readily get messages through large-scale media services (Patton 1984).

A toll-free telephone number should be available for persons to ask questions about the programme and to report on related activities. Also, a "Frequently Asked Questions" (FAQ) or "Questions and Answers" (Q&A) item on a programme website is useful for the general public and other stakeholders (OKSIR 2018a; OPG 2018).

Universities are expanding the teaching of the principles of AW-IPM and the SIT (Lindquist 2001). In Madeira, Portugal, Caldeira (2001) emphasized the need to use both technical and non-technical materials, in a variety of formats, and in various public settings, to inform urban dwellers, including school children, of the objectives and activities of the Mediterranean fruit fly programme. Informing members of school clubs in Ethiopia stimulated cooperation in setting up tsetse fly traps. Students in South Africa and Argentina (Box 1) learn about AW-IPM programmes through official additions to the school curriculum. In Argentina, an interactive computer game helped teach the basics of the SIT to children, allowing players to release bags of sterile insects to hit target infested trees displayed on a screen (P. Rendón, personal communication).

*Box 1. Students in Argentina Learn about the Sterile Insect Technique*

The BioContainer Programme of ISCAMen, Argentina, was developed for 6th-degree school students (12–13 years old) to study the biology of the Mediterranean fruit fly, its role as a fruit pest, and the eradication programme (R. Mellado, personal communication). The BioContainers (Fig. A) are paper boxes containing sterile male pupae, provided by de Biofactory of Mendoza. Boxes include written information and instructions about the fly's life cycle, and how sterile insects control the pest. The emergence of adults from pupae can be observed through a window in the box. After flies have emerged, students are asked to release them on host fruit plants in their own or someone's backyard, assisting local pest control, and engaging the students and their families in the control process in urban areas. In the past 5 years the Programme has given boxes to 108 050 students, leading to an estimated 432 200 personal contacts, e.g. parents, siblings, and friends.

Before boxes reach students, school teachers are trained in the biology of the pest and the use of the BioContainer. In 2018, 1580 school teachers participated in the BioContainer Programme.

After using a BioContainer, students have the opportunity to visit de Biofactory. The factory has a circuit of glass bridges from which one can see the whole process of raising insects from egg to pupae, and the subsequent irradiation process, without actually entering the plant. In the past 5 years, 2650 students have visited de Biofactory.

*Figure A. Left: BioContainer logo. Centre: BioContainer containing living sterile male fruit flies. Right: Opened BioContainer showing emerged flies. (Photos from R. Mellado, reproduced with permission.)*

### *4.1. Press Releases*

Below are some examples of press releases related to AW-IPM programmes:

- International Atomic Energy Agency (IAEA 2017). 27 April 2017 – Atoms for peace and development in the 21st century
- New Zealand: Plant and Food Research (PFR 2018a). 14 March 2018 - Scientists discuss sex-less insects; 22 March 2018 - Dropped in for fruitless sex
- International Atomic Energy Agency (IAEA 2018a). 19 April 2018 – IAEA conducts successful test of drones in fight against disease-transmitting mosquitoes.

### *4.2. Web Stories and Web Audio Interviews*

Below are examples of web stories:

- Gaspar (2016a), IAEA, 7 June 2016 – South African experts advance in researching nuclear technique to fight malaria, sugarcane pest
- Gaspar (2016b), IAEA, 28 June 2016 – How a nuclear technique helped save the Western Cape's orange industry
- Gil (2017a), IAEA, 14 December 2017 - Argentina uses nuclear technology to control insect pests
- Jawerth (2018), IAEA, 5 September 2018 – Irradiated fruit flies: the secret to protecting Thailand's premium fruit exports
- Marais (2019), IAEA, 14 March 2019 – Integrated pest management to boost dragon fruit production in Viet Nam
- Rawat (2019), India Today, 24 January 2019 – Horny mosquitoes in high demand: why scientists are developing sexually active mosquitoes (contains links to videos describing the SIT).

Below is an example of a web audio interview:

- UN News (UN 2018), 20 April 2018 – Breakthrough drone-powered mosquitoes: "absolutely no impact" on other species.

### *4.3. Other Methods of Communication*

- Engaging directly with stakeholders -- personal visits of programme staff to project sites, e.g. farms, to hold discussions with the property owners
- Stakeholder engagement survey, e.g. OKSIR (2018d)
- Meetings and presentations to farmer cooperatives and grower associations, citizen groups, schools, and the general public
- Articles in newspapers, books, and magazines, e.g. Gil (2017b); Paquette (2019)
- Newsletters, e.g. OKSIR (2016), brochures, fact sheets, and calendars
- Manuals such as those produced by the FAO/IAEA (2018b, f)
- Expositions, public displays and demonstrations, and giving away key chains with a project logo (A. Bello Rivera, personal communication)
- Postage stamp, e.g. a stamp featuring the SIT and Dieter Enkerlin, a pioneer in applying the technology in Mexico (Fig. 2)

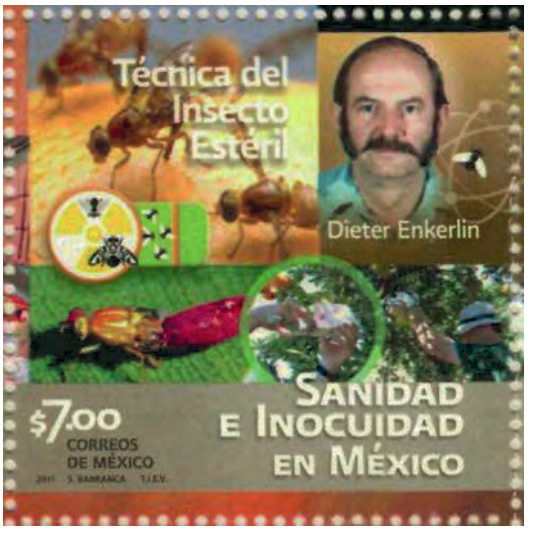

*Figure 2. Postage stamp issued in Mexico in 2011 featuring the SIT and Dieter Enkerlin. (Stamp reproduced with permission from W. R. Enkerlin.)*

- In Okinawa, local advertisements (including in airports and seaports) of project activities, and flyers and newspaper inserts, are widely distributed (T. Matsuyama, personal communication)
- The Moscamed Programme in Guatemala promotes bee-keeping; this enables growers to see for themselves that aerial sprays applied to suppress the Mediterranean fruit fly in pest hot spots do not kill bees (P. Rendón, personal communication)
- Programme logo – using an attractive, simple but self-explanatory logo gives a programme an identity and an enhanced public image, and encourages staff to be proud of the programme (Fig. 3)

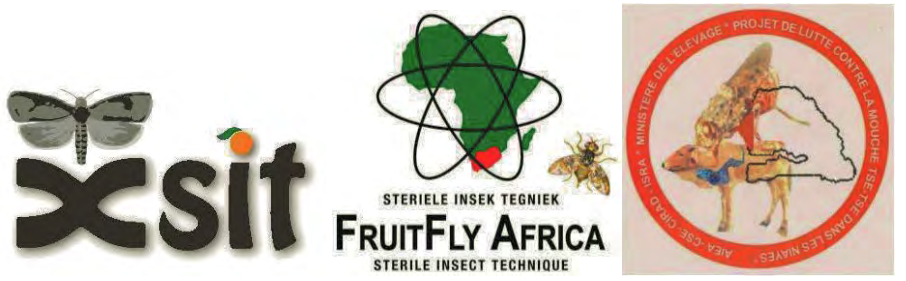

*Figure 3. Examples of programme logos: Left - Xsit in South Africa; Centre - FruitFly Africa in South Africa; Right – Senegal tsetse fly eradication project in the Niayes region (Senegal 2018). (Reproduced with permissions from T. Lombard, N. Baard, and B. Sall, respectively.)*

- Online information sources, e.g. project websites -- providing programme information, publications for download, links, and videos, e.g. OKSIR (2018a, c), OPG (2018). Real-time data and information can be provided, e.g. the weekly area-wide distribution and population densities of the pest based on results from trap and other monitoring, and assisting farmers with timely advice on field operations (Nelson et al. 2021)
- Online forums; blogs maintained by interested stakeholders
- Email, electronic messages on smart phones
- Telephone calls, call centre.

## 5. VIDEOS AND PHOTO ESSAYS

In recent years there has been a large increase in the number of videos and photo essays available online - for viewing and sometimes for downloading. A partial list of those available through the FAO/IAEA is provided in FAO/IAEA (2016a, 2018a).

### *5.1. The SIT and AW-IPM*

- Science, sex, superflies (FAO/IAEA 2007a)
- Using nuclear science to control pests (FAO/IAEA 2015a)
- The SIT - an environment-friendly method of insect pest suppression and eradication (FAO/IAEA 2016a)
- How a nuclear technique is helping the Dominican Republic win the war against the Mediterranean fruit fly (FAO/IAEA 2016c)
- Using nuclear science to control mosquitoes (FAO/IAEA 2016e)
- Using nuclear science to control pests (FAO/IAEA 2017a)
- Area-wide management of insect pests (FAO/IAEA 2017b).

### *5.2. Fruit Flies*

- The Middle East's fruitful valley – Israel (FAO/IAEA 2007b)
- Olive fly: nuclear technology to protect an ancient fruit (FAO/IAEA 2009)
- Medfly eradication: what to expect (FAO/IAEA 2011)
- Better fruit for Neretva Valley (FAO/IAEA 2012)
- Nuclear techniques keep insects at bay in Croatia's Neretva Valley (FAO/IAEA 2015b)
- Tackling fruit flies with nuclear technology in the Dominican Republic (FAO/IAEA 2016b)
- How a nuclear technique is helping the Dominican Republic win the war against the Mediterranean fruit fly (FAO/IAEA 2016c)
- How a nuclear technique helped save the orange industry in Western Cape, South Africa (FAO/IAEA 2016g)
- Using nuclear technology to control pests (FAO/IAEA 2017a)

- Nuclear technology helps the Dominican Republic fight insect pests (FAO/IAEA 2017c)
- Nuclear technique helps prevent insects from harming your coffee beans (FAO/IAEA 2017d)
- Successful control of the Mediterranean fruit fly in Jordan (FAO/IAEA 2017e)
- Argentina tackles fly pests using nuclear technology (IAEA 2018b)
- Irradiated fruit flies: protecting Thailand's fruit exports (FAO/IAEA 2018c)
- Video Programa Moscamed Guatemala (PMG 2018a)
- Video Programa Moscamed (SS 2013, 2018a, b)
- Web novela: Misión Moscafrut (SS 2018c)
- Control y erradicación de la mosca de la fruta (SS 2018d).

### *5.3. Mosquitoes*

- With IAEA support, Sudan suppresses mosquito populations (FAO/IAEA 2015c)
- Preventing procreation: IAEA and mosquito control (FAO/IAEA 2015d)
- Zika crisis – the IAEA responds (FAO/IAEA 2016d)
- Using nuclear science to control mosquitoes (FAO/IAEA 2016e)
- Drones for good 2016: FAO/IAEA's ROMEO system for aerial release of sterile male mosquitoes (FAO/IAEA 2016f)
- 20 million sterile mosquitoes for release - California (Haridy 2017; Debug 2019)
- Video on rearing mosquitoes in Singapore (Co 2019)
- Nuclear technique helps fight mosquito-borne illnesses (FAO/IAEA 2019a)
- Technique de l'insecte stérile, Le moustique tigre. Videos, in French (TIS 2020).

### *5.4. Moths*

- Pink bollworm eradication program: informational video (NCCA 2009)
- Photo Essay: How a nuclear technique helped save the orange industry in Western Cape, South Africa (FAO/IAEA 2016g)
- Falling Moths. Unmanned aerial vehicle (UAV) releasing codling moths in New Zealand (PFR 2018b)
- Palomilla del Nopal (*Cactoblastis cactorum*) (SS 2018e)
- Accessing SIR trap counts online (OKSIR 2018b)
- False codling moth in South Africa (Xsit 2018, 2019).

### *5.5. Tsetse Flies*

- Photo Essay: Eradicating flies to improve lives -- IAEA helps countries in Africa to combat tsetse fly (FAO/IAEA 2013)
- Paving the way for tsetse eradication – Ethiopia's journey (FAO/IAEA 2014)
- A farewell to tsetse (FAO/IAEA 2016h)
- The IAEA and food – tsetse fly eradication – Senegal (FAO/IAEA 2017f).

### *5.6. Screwworms*

- SIT pilot test against New World screwworm (*Cochliomyia hominivorax* Coquerel) in Artigas, Uruguay (FAO/IAEA 2018d).

## 6. TECHNICAL INFORMATION ON AW-IPM AND THE SIT

A source of technical information on AW-IPM and the SIT is the Insect Pest Control Section at the FAO/IAEA (FAO/IAEA 2015a; 2016a; 2017b; 2018a, b, e, f, g):

- Information on AW-IPM and the SIT (FAO/IAEA 2018e; Wikipedia 2018)
- Publications arising from major conferences and symposia on insect pests (FAO/IAEA 2018h), e.g. FAO/IAEA (2000, 2007c, 2021)
- Publication of results from research conducted by entomologists at FAO/IAEA (lists of scientific papers and annual reports) (FAO/IAEA 2018b, i, m)
- Coordinated Research Projects (CRPs) -- results are published in peer-reviewed journals (FAO/IAEA 2018j), e.g. ZK (2015), FE (2016)
- Special issues of journals on research related to the SIT, e.g.: EEA (2017)
- Technical reports (consultant and advisory group meetings) (FAO/IAEA 2018k)
- Manuals and protocols (FAO/IAEA 2018l)
- Newsletters and annual reports (FAO/IAEA 2018m)
- Thematic plans (FAO/IAEA 2018n)
- Information and knowledge management (FAO/IAEA 2018o)
- Forthcoming meetings (FAO/IAEA 2018p)
- FAO/IAEA technical cooperation projects (FAO/IAEA 2018q)
- News from the FAO/IAEA on the SIT (FAO/IAEA 2018r)
- Regularly updated databases, e.g. IDIDAS, DIRSIT, TWD, IDCT (Bakri et al. 2016; FAO/IAEA 2018b; TWD 2018)
- Online glossary of SIT-related terms with definitions, references, and a search function (FAO/IAEA 2018g)
- E-learning course available online (FAO/IAEA 2019b).

## 7. SOCIAL MEDIA

Social media are interactive computer-mediated technologies that facilitate the creation and sharing of information and other forms of expression via virtual communities and networks. Social media platforms, e.g. Facebook, Twitter, YouTube, and LinkedIn (Fig. 4), are now a part of everyday communications. More than 100 000 000 registered users in the world have social media accounts. However, as is seen in recent times, precautions are needed when using social media to protect the privacy of stakeholder data, and to prevent the misuse of data.

**FACEBOOK TWITTER YOUTUBE LINKEDIN**

*Figure 4. Some popular social media platforms.*

The trend in the increasing use of social media also includes some AW-IPM programmes that apply the SIT:

- Guatemala - Programa Moscamed Guatemala (PMG 2018b)
- Mexico - Campaña Nacional Contra Moscas de la Fruta Nativas (CNCMFN 2018), SENASICA SAGARPA (SS 2018f)
- South Africa - FruitFly Africa (FFA 2018)
- USA - Animal and Plant Health Inspection Service (USDA/APHIS 2018)
- Plant and Food Research, New Zealand (PFR 2018c)
- Tephritid Workers Database (TWD), managed by the FAO/IAEA, invites workers to follow the TWD on Facebook (TWD 2018).

Most of the above programmes are associated with "parent organizations" that have social media accounts, e.g. the Insect Pest Control Section at the FAO/IAEA (FAO/IAEA 2018b). However, a major exception is Programa Moscamed Guatemala as described below.

### *7.1. Programa Moscamed Guatemala*

Programa Moscamed Guatemala has its own website (PMG 2018b), and has social media accounts – Facebook, Twitter, and LinkedIn.

In a review of these social media at Programa Moscamed Guatemala (social media are part of its regular communication activities), the following points were made:

- The programme website was created in 2008. According to Google Analytics, from 2011 to 2017 the programme website was visited about 13 000 times per year. In 2018, website visits originated in 42 countries (71% of visits from Guatemala), 85% of which were made by new visitors. The majority (60%) of visitors were quite young – 18–34 years of age.
- In 2015 a space in the digital encyclopaedia Wikipedia was opened, and a link to the platform LinkedIn was initiated.
- Facebook is the most popular platform used in the programme; people from both urban and rural areas (including people on farms), and also people from various organizations and institutions, use Facebook.
- Facebook and Twitter are used to convey technical information on the community-support actions and activities of the programme, and on the availability of technical assistance and training, but also to obtain feedback from stakeholders. Most communication involves requests for clarification on programme activities and technical assistance, and for advice on agricultural

issues. Comments and questions from the public are mostly positive. However, a few negative and critical comments are also received, and these need to be handled promptly; such comments often relate to the environmental impact of aerial release and the chemicals applied in ground control of hot spots.

- The programme recommends that an area-wide programme should have a well-maintained website, use social networks, and set up information repositories such as databases and pages in Wikipedia. Each programme should have a full-time professional communicator to supervise the handling of information and communication with stakeholders. Support from programme leaders is essential.

## 8. SUPPORT FROM GOVERNMENTS

Obtaining the support of national, regional or local governments is dependent largely on the perceived importance of the commodity at stake, e.g. plant products for export (Buchinger 1993; Kinney 1993), health of livestock that are vital to the economy of the region, survival of subsistence farmers, human health threatened by insect vectors of disease, and recreational areas that require no or few environmental hazards such as insecticides that discourage tourism.

It is often difficult to obtain government support and the legislation and regulations needed to operate a programme. Considering the competing demands on financial resources, governments may regard pest control programmes as a low priority because they usually benefit only some, not all, segments of a community. Positive examples of exceptional support from national governments are the fruit fly programmes in Chile, Japan and Mexico. These successful programmes resulted in the opportunity to export crops to previously closed markets (MAG/SAG 1995; SAG 1996; Reyes et al. 2000; Teruya 2000; Enkerlin et al. 2015; Enkerlin, this volume).

Legislation and regulations are usually required to support the implementation of complex area-wide programme activities. Programme staff and others, possibly perceived as plant or animal health inspectors, will need to enter private property, monitor the pest population, inspect and treat crops or livestock, possibly remove derelict host plants, and enforce treatment and quarantine activities. Legislation to collect funds from the community, and to obtain enforcement authority, may be needed, but outreach activities to educate stakeholders and increase public awareness tend to reduce the need for enforcement actions (Dyck et al. 1993; Seymour 2018; Nelson et al. 2021). The approval of legislation and enforcement is an indication of government support for an AW-IPM programme. For example, legislation that regulates the culture of alternate hosts of the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) was recently passed in Spain to support an AW-IPM programme to control this major pest of citrus (W. R. Enkerlin, personal communication). Also, in California, USA, where fruit infested by this fly is sometimes smuggled into the state, legislation was passed to try to prevent this, and to levy fines against those who are caught smuggling banned fruit (CDFA 2005).

Besides fines or other negative enforcement actions, positive incentives can also be provided to obtain the cooperation of people living within the area of an AW-IPM programme, e.g. trees for urban property owners to replace those that are

susceptible to the target pest (OKSIR 2018a), and free insecticide for farmers to treat cattle against pests (Dyck et al. 2000).

Strong government support helps to stabilize, legitimize, and empower a programme so that it can operate effectively. Ideally, governments have a long-term view, and an all-embracing view, of a whole community's welfare; this is needed to support the characteristically long-term AW-IPM programmes that apply the SIT. Endorsement of a programme by a government helps encourage the provision of the necessary resources, e.g. skilled personnel and facilities to rear and irradiate insects. Also, programme endorsement by a government, offer of technical assistance, or other kinds of incentive from another country that may represent a potential but important export market, will encourage programme success.

Nevertheless, political conditions change over time, and can change frequently (Patton 1984). Some politicians may have other objectives. Long-term support from a government is never a certainty. A programme needs to be protected from changes in government so as to provide the stability required to attain its goals.

In government programmes, the assignment of new key personnel can radically change the support given to a programme. Therefore, new people appointed to key positions need to be informed quickly about the programme. Political leaders are usually not technical experts. Therefore, efforts should be made to educate influential people.

Political sensitivities (Patton 1984) can negatively affect a programme. Political uncertainties and civil unrest have impaired the implementation of SIT-related programmes, e.g. in the case of the Mediterranean fruit fly, the area-wide eradication programme in southern Mexico and Guatemala, or the transboundary suppression programme in contiguous areas of Israel, Jordan and the Territories Under the Jurisdiction of the Palestinian Authority (Enkerlin, this volume; Hendrichs, Vreysen et al., this volume).

A high level of support from governments means the involvement of high-level officials, both decision-makers in the executive branch and those who approve programme funds or appropriations in the legislative branch of government. It is useful to identify a knowledgeable "champion" of the programme who can highlight the programme's benefits vis-à-vis politicians. Obtaining the authority and support from a senior government official, who understands the programme and its objectives, is a big advantage.

One of the important roles of government in successful pest eradication programmes is the official declaration that a particular species has indeed been eradicated in a certain area (Teruya 2000; Barclay et al., this volume; Vreysen, this volume).

## 9. TECHNICAL SUPPORT

AW-IPM programmes need the support of local, national, and international technical experts. This gives a programme technical credibility. Opposition from scientists, for whatever reason, tends to discredit a programme (Winston 1997; DFID 2002; Whitten and Mahon, this volume). Papers in technical journals, presentations at scientific meetings, and participation in training programmes and collaborative

research projects are essential to foster an open and fair exchange of information (P. Rendón, personal communication).

Frequent communication between programme staff and the scientific community is essential to generate "programme ownership" and "goodwill", as well as to interest and involve researchers in improving technology (and thereafter possibly obtain the new technology for use in the programme). There are costs and operational limitations to adopting new technologies frequently, but programme managers must always be open to improve the techniques being used. Therefore, the technical and operational aspects of a programme, especially a long-term programme, needs to evolve over time (Buchinger 1993; Kinney 1993).

Applied research on various aspects of a programme conducted by a supporting technical unit, often called "methods development", helps to ensure its success (Lindquist et al. 1992; LaChance 1993; Tween 1993; FAO/IAEA 2018j). The melon fly *Zeugodacus cucurbitae* (Coquillett) programme in Japan received very strong support through basic and applied research conducted at national institutions and agricultural experiment stations by entomologists in the country; certainly this contributed to the programme's success (Kakinohana et al. 1993; Yamagishi et al. 1993; Itô et al. 2003; Koyama et al. 2004).

## 10. PROGRAMME SUCCESS OR FAILURE

Even though adequate internal and external technical support is fundamental to progressively increasing programme effectiveness and efficiency, technical issues are rarely the main reason for programme failure. Some AW-IPM programmes with an SIT component have failed, or achieved limited success, because of poor communication and engagement with stakeholders and inadequate public support.

Many lessons regarding stakeholder communication, engagement and support have been learned, some positive and some negative (Vreysen et al. 2007; Dyck, Reyes Flores et al., this volume):

- Stakeholder support at various levels is vital for the operation of an AW-IPM programme.
- Communication among programme staff, with the programme's stakeholders and its financial supporters, and with the general public, is essential for a programme to receive the support it needs.
- Leaders in a community are role models; they are particularly influential in spreading the adoption of new technologies, and are important for promoting the acceptance of AW-IPM programmes.
- Continuing input from technical experts is needed to keep programmes up-to-date with the latest research findings, and to maintain technical credibility.
- Even though potentially costly and often not recognized by financial supporters, communication and engagement with stakeholders and the public is as important to a programme's success as is effective management (Dyck, Reyes Flores et al., this volume).

TABLE OF CONTENTS

Pages 841–884
*V. A. Dyck, J. Hendrichs and A. S. Robinson (eds.), Sterile Insect Technique. Principles and Practice in Area-Wide Integrated Pest Management. Second Edition.*

## SUMMARY

The four strategic options, "suppression", "eradication", "containment", and "prevention", in which the sterile insect technique (SIT) can be deployed as part of area-wide integrated pest management (AW-IPM) programmes, are defined and described in relation to the contexts in which they are applied against non-native invasive or naturally occurring major insect pests. Advantages and disadvantages of these strategic options are analysed, and examples of successful programmes provided. Considerations that affect decision-making in relation to the selection of a strategic option, e.g. pest biology, whether the pest is a disease vector or agricultural pest, the pest's status in the target area, and the target market for the produced crop or livestock commodities, are reviewed and discussed in terms of a phased conditional approach to programme planning, preparation, and implementation. If an option is changed during implementation of the SIT, unrealistic expectations often result, leading to high political costs and the discrediting of the technology. Before embarking on an AW-IPM programme with an SIT component, the choice of a strategic option needs to be assessed carefully, and preparations should be supported by considerable baseline data, technical and economic feasibility assessments, and detailed planning.

## 1. INTRODUCTION

E. F. Knipling developed a theoretical model of the sterile insect technique (SIT) in the early 1940s (Klassen 2003; Klassen et al., this volume), but it was not until 1954 that the technique was successfully demonstrated with the elimination of the New World screwworm *Cochliomyia hominivorax* (Coquerel) from the island of Curaçao following continuous releases of sterile insects for 6 months (Baumhover et al. 1955). Since then, in line with Knipling's basic model, the SIT has on numerous occasions been confirmed in field programmes as an effective and very powerful method of insect pest management. In spite of this history of successful SIT applications, the existence of puzzling terminology, conflicting definitions, and inappropriate utilization of concepts/strategies continue to cause confusion.

Baumhover et al. (1955) referred to the strategy applied in the Curaçao experiment as screwworm "control". Both Knipling (1955) and Lindquist (1955) proposed "control" and "eradication" as possible strategic options in using the SIT (Lindquist et al. 1990). While Lindquist (1955) used the term "control" to refer to the general use of the SIT, Knipling (1969) defined for the first time "eradication" and "suppression" as the two major strategic options. Knipling suggested that the terms "suppression" and "management" could be used interchangeably (Knipling 1979). During the decade that the screwworm programme in the south-west of the USA was maintaining a "containment" buffer along the Mexican border, he explained that it was erroneously referred to as an "eradication" programme, and argued that, since long-range migrating flies reinvaded the area every year, the term eradication was misleading in this context when compared with the Curaçao and Florida programmes.

Referring to programmes such as the one against the Mexican fruit fly *Anastrepha ludens* (Loew) in southern California, Knipling (1979) described "prevention" as another possible strategic use of the SIT:

> As more experience is gained in the use of sterile insects for insect suppression and with greater confidence in the value of this technique, releasing sterile insects routinely in certain areas may be more expedient to prevent establishment of major pests than eliminating them after they become established.

Since 1996, this principle has been applied in the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) Preventive Release Program in the Los Angeles Basin, California, USA (Dowell et al. 2000) (section 4.1.).

In 2005, the International Plant Protection Convention (IPPC) adopted the revised International Standard of Phytosanitary Measures (ISPM) 3, "*Guidelines for the export, shipment, import and release of biological control agents and other beneficial organisms*"; for the first time sterile insects were included among beneficial organisms (FAO 2017a). The guidelines promote the safe use of biological control agents and beneficial organisms such as sterile insects, but do not involve special regulatory requirements such as those needed for the release of genetically modified insects. The inclusion of the SIT in the revision of ISPM 3 was a consequence of the growing acceptance of its application as part of an area-wide integrated pest management (AW-IPM) approach against key non-native or naturally occurring insect pests. This change in the mindset of decision-makers and stakeholders is driven mainly by the demands of large retailers (who are responding to consumer requests for cleaner food and a safer environment). It is also driven by the need for alternatives to the indiscriminate use of insecticides, and by the increase in globalization and concomitant international agricultural trade, which requires enforcement, through national animal and plant protection organizations, of the Agreement on the Application of Sanitary and Phytosanitary Measures (the "SPS Agreement") under the World Trade Organization (WTO 1994).

The programmes applying the SIT tend to become grander in scale and scope, thereby increasing their commercial impact and simultaneously reducing their relative operational costs, mainly due to economies of scale and improvements in the technology of rearing and releasing large numbers of sterile insects (Hendrichs 2000). An extreme example of a very large programme is the Moscamed Mediterranean fruit fly containment effort in Guatemala and southern Mexico, which operates on an annual budget of ca. USD 30 million (data from 2003), (Enkerlin et al. 2015, 2017). Within such contexts and under these pressures, the authorities deciding on AW-IPM campaigns are facing crucial choices regarding the inclusion of the SIT, and which strategic option to apply. In fact, as noted by Klassen (2000), "the terms of reference and contingencies have a tremendous influence on the selection of strategies", which then are "the real decision-makers".

The objectives of this chapter are to review the terminologies, the main characteristics and strengths and weaknesses of the various strategic options where sterile insects can be used, and to propose definitions in accordance with international agreements. In addition, the chapter reviews briefly the phased conditional approach to programme implementation, and addresses important species and case-specific issues, e.g. biology of the target insect, buffers, release densities, topography, etc., that

require careful analysis before selecting one of the four strategic options under which to integrate the SIT into AW-IPM programmes.

## 2. FOUR STRATEGIC OPTIONS: DEFINITIONS AND DESCRIPTIONS

The Food and Agriculture Organization of the United Nations (FAO), through its IPPC, whose international phytosanitary standards are accepted by signatory countries under the SPS Agreement of the WTO, defines "control" of a given plant pest (FAO 2017b) as encompassing:

> Suppression, containment or eradication of a pest population.

These three strategies would apply to most AW-IPM programmes with an SIT component, including those against insect pests of medical and veterinary importance. However, the most efficient and cost-effective "control" programme is the one that aims at *preventing* the entry of a pest (movement of a pest into an area where it is not yet present (FAO 2017b)) rather than at dedicating resources to suppress, eradicate or contain an *introduction* (the entry of a pest resulting in its establishment (FAO 2017b)) once it has occurred (Knipling 1979). On this basis, four strategic options, i.e. "suppression", "eradication", "containment", and "prevention", will be discussed.

### *2.1. Suppression*

The FAO (2017b) defines suppression as:

> The application of phytosanitary measures in an infested area to reduce pest populations.

Thus the main objective of a suppression programme is to maintain the pest population below an agreed and acceptable economic injury level and/or prevalence level. Until the early 1990s, the SIT was generally considered an appropriate technique for eradicating certain insect pests. This view largely resulted from the high visibility of the successful screwworm eradication programme in North and Central America (Baumhover 2002; Klassen et al., this volume), and the assumption that the SIT was too expensive to compete with other control methods for routine pest management. In recent years, however, suppression of a pest population is increasingly being viewed as a suitable strategy to apply the SIT as part of an AW-IPM approach for some pests of agricultural importance (Hendrichs et al. 2007) due to: (1) crucial improvements made in the rearing and release techniques for some key insect species, which have significantly improved the cost-effectiveness of SIT application (Caceres et al. 2004; FAO/IAEA 2017; Parker, Mamai et al., this volume), (2) increased restrictions imposed on the use of insecticides (Matteson 1995) and more stringent regulations on their residues, (3) increasing development of insecticide resistance in arthropods (Whalon et al. 2008), (4) increased intermingling of commercial production areas and human settlements, which complicates the routine use of insecticides, (5) increased customer health consciousness and the demand for low-residue or even "organic" products (Economist 2001; Greene et al. 2017), and (6) difficulties in maintaining effective quarantines to keep an area pest free (Mumford, this volume).

One major advantage of applying a suppression strategy is the significantly lower investment needed to monitor the pest population as compared with the more intensive monitoring required during and after an eradication campaign (Table 1). Moreover, the set-up and rigorous implementation of effective quarantines (which demand legislation and considerable investment) to protect a pest free area (FAO 1999) are not needed or demand less attention and resources when a suppression strategy is applied (Table 2). Another strength of the suppression strategy is the focus on environmental benefits compared with conventional control methods (Table 1). These trends have culminated in the implementation of suppression programmes using the SIT as an environment-friendly replacement for the use of insecticides (no longer disrupting pollination and the biological control of secondary pests) (Hendrichs et al. 1995; Enkerlin et al. 2003). This strategy has gained acceptance mainly for pest insects of phytosanitary importance, since a certain level of "crop damage" to agricultural commodities is usually acceptable. However, this concept has in general been considered less applicable to insect pests of veterinary, and particularly medical, importance. However, a suppression strategy against disease transmitting mosquitoes would be feasible, provided that only sterile males are released, without sexing errors, as the males are not the disease transmitting sex (Bourtzis et al. 2016).

It should be emphasized that implementing a suppression strategy in an area does not preclude exporting agricultural commodities from that area to countries that have a pest free status. Export markets that accept only pest free commodities can be accommodated within the context of a "systems approach" (FAO 2017c), whereby an effective preharvest suppression programme with an SIT component can be integrated with other efficient pest risk-mitigation measures (for example, postharvest treatments) to guarantee pest free agricultural products. This strategic approach is successfully applied, e.g. in the Arava Valley of Israel, where the use of greenhouses, as an additional risk-mitigation measure, has allowed the export of Mediterranean fruit fly-free vegetable commodities from this area to the USA (Cayol et al. 2004).

Whereas eradication aims at eliminating the last individual of a population in the target area, a suppression strategy can tolerate a certain residual pest population, and lead to the establishment of an "area of low pest prevalence" (FAO 2016b). Suppression can be achieved much more quickly than eradication, is less complex, resource demanding, and management intensive, and therefore less expensive in the initial years (Enkerlin and Mumford 1997; Mumford, this volume). Nevertheless, a suppression strategy requires continuing releases of sterile insects, often combined with other suppression measures, to maintain a low pest population level (Table 1). However, adopting a suppression or other strategy does not exclude eventually progressing towards an eradication strategy once low pest populations are maintained sustainably and new situations arise (Suckling et al. 2014; Staten and Walters 2021).

On the other hand, while the permanent application of a suppression strategy, including continuing releases of sterile insects, could be considered disadvantageous when compared with the sustainable elimination of a pest from an area, this permanent need for sterile insects could stimulate and promote investment in, and the commercialization of, the mass production of sterile insects (Enkerlin and Quinlan 2003) (Table 2). A similar demand has already resulted in a rapidly growing augmentative biological control industry (ANPB 2005; IBMA 2017).

*Table 1. Strengths and weaknesses of the four strategic control options applied in AW-IPM programmes integrating the SIT, depending on the type of area*

| Control Strategy | | | | |
|---|---|---|---|---|
| Suppression (infested area) | Eradication (infested area) | Containment (pest infested and pest free area) | Prevention (pest free area) | Eradication (introduction into pest free area) |
| **Strengths** | | | | |
| Decreased pesticide use<br>Lower investment in long-term monitoring and in short-term capital and operational costs<br>No need for quarantine measures<br>Access to markets discriminating for low pesticide residues | Insecticide use eliminated eventually<br>Access to specific pest free export markets[1] as well as to markets discriminating for low pesticide residues without pre-export treatment<br>Most activities and costs limited in time<br>Strengthened quarantine infrastructure also against other pests<br>Strong public and political support for disease vectors | Protection of neighbouring pest free areas<br>Environmental and economic benefits for protected area<br>Pest free area can be expanded gradually<br>Threat of further pest expansion helps to obtain public and political support for activities<br>Maintains export markets | Proactive rather than reactive approach (risk mitigation)<br>In case of introduction, effective sterile to wild insect ratios (low wild population density)<br>No trade disruption in case of outbreak in release area<br>Infrastructure for SIT is in place in case of other outbreaks in the region<br>Maintains export markets | Establishment of pest precluded (if action taken immediately)<br>Much cheaper in medium and long term than having to "live with" new pest forever<br>Infrastructure and experience gained can be applied against other invasive pests<br>Success in avoiding pest establishment promotes preparedness plans for other invasive pests<br>Maintains export markets |

[1] Only for agricultural pests, excluding insect pests of medical importance

*Table 1. Continued*

| Control Strategy | | | | |
|---|---|---|---|---|
| Suppression (infested area) | Eradication (infested area) | Containment (part infested and part pest free area) | Prevention (pest free area) | Eradication (introduction into pest free area) |
| **Weaknesses** | | | | |
| Permanent control activities<br>Post-harvest treatments required for export<br>More active participation and better organization of grower associations needed | High short-term investment<br>Intensive public relations campaign<br>Long-term investment in permanent monitoring networks<br>Continuous rigorous quarantine set-up | Cooperation between infested and non-infested areas<br>Intensive public relations campaign<br>Disruption of trade and free movement of commodities between infested and non-infested areas | Investment while the targeted pest is not present (political aspect)<br>Not all areas at high risk of introduction can be protected<br>Difficult to appreciate benefits of programmes that run for long time frames and thus susceptible to budget cuts when financial situation becomes difficult | Species-specific preparedness needed (plan of action, SIT technology and sterile insect supply, etc.)<br>Early detection and quarantine to delimit and isolate incursions<br>Long-term investment in permanent monitoring networks<br>In some situations, temporal disruption of trade. |

While insecticide costs have been increasing rapidly following the removal of many older products from the market, and crop protection companies facing higher costs and steeper regulatory hurdles for launching new pesticide products (CropLife 2016), using sterile insects as part of a suppression strategy for some key fruit fly and moth pests has become cost-competitive with conventional or other population reduction methods (Pereira et al. 2013; Vreysen et al. 2016) (Table 3). Examples of suppression programmes are: Mediterranean fruit fly in Israel and Jordan (Bassi et al. 2007), Croatia (Bjelis et al. 2016), South Africa (Venter et al. 2021), and Valencia, Spain (Primo 2003); codling moth *Cydia pomonella* (L.) in British Columbia, Canada (Bloem et al. 1998; Nelson et al. 2021); false codling moth *Thaumatotibia leucotreta* (Meyrick) in South Africa (Boersma 2021); and some are under development for other species of Diptera and Lepidoptera. These programmes are driven by the need to decrease insecticide use to comply with minimum residue levels required for export and/or local markets and communities, or to offer an alternate method of control for pests that have become resistant to many available insecticides, such as the false codling moth and diamondback moth *Plutella xylostella* (L.).

*Table 2. Characteristics of the major strategic control options applied in AW-IPM programmes integrating the SIT, depending on the type of area*

| Adjunct Issues | Control Strategy | | | | |
|---|---|---|---|---|---|
| | Suppression (infested area) | Eradication (infested area) | Containment (part infested and part pest free area) | Prevention (pest free area) | Eradication (introduction into pest free area) |
| Quarantine | No | Yes | Yes | No | Yes |
| Investment in monitoring | Low | High | Varies along gradient (Fig. 1) | Medium | High |
| Investment / operational costs | Medium | High | High | Medium | Low |
| Trade advantage | Low (but postharvest treatments can guarantee pest free products) | High | Medium | High | High |
| Demand for sterile insects | Continuous | Short term[1] | Medium term (but can be continuous) | Continuous | Short term |
| Potential for commercialization of SIT | High | Low[1] | Medium | Medium | Low |

[1] Nevertheless, where the target area is very large, requiring a division into many blocks or phases, there could be a long-term demand for sterile insects and increased potential for commercialization

### *2.2. Eradication*

Eradication is defined (FAO 2017b) as:

> Application of phytosanitary measures to eliminate a pest from an area.

This definition, which is accepted and used by the agricultural community, clearly implies the *elimination of an isolated local population* of a pest. Nevertheless, for public health (used by the World Health Organization (WHO) mostly for human diseases), the term eradication is restricted to *global extinction* of a pest at the species level (WHO 2001). Classical examples are the eradication of small pox (Fenner et al. 1988), rinderpest (OIE 2011), or the current worldwide efforts to eradicate polio (Lahariya 2007).

*Table 3. Examples of AW-IPM programmes that have applied the SIT according to major control strategies in relation to the type of area*

| Control Strategy | | | | |
|---|---|---|---|---|
| Suppression (infested area) | Eradication (infested area) | Containment (part infested and part pest free area) | Prevention (pest free area) | Eradication introduction into pest free area) |
| Carob moth[1]: Tunisia; Diamondback moth[3]: Mauritius | New World screwworm[2]: N. and C. America (1958–2003) | New World screwworm: Panama (2004–present) | | New World screwworm: Libya and the Florida Keys |
| Mexican fruit fly[4]: North-east Mexico | Mexican fruit fly and West Indian fruit fly[5]: North-west Mexico | Mexican fruit fly: Sinaloa, Mexico | Mexican fruit fly: Baja California and Rio Grande Valley (Mexico-USA border) | Codling moth: Brazil |
| Codling moth[6]: British Columbia, Canada | Pink bollworm[7]: So. USA and northern Mexico (2001–2012) | Pink bollworm: San Joaq. Valley in California USA (1969–2000) | | Cactus moth[8]: Yucatán peninsula, Mexico |
| Mediterranean fruit fly[9]: Brazil, Croatia, Ecuador, Israel, Jordan, Morocco, South Africa, Spain | Mediterranean fruit fly: Argentina (Patagonia) (1992–present), Chile (1992–1995), Mexico (1978–1982), southern Peru 2002–2008) | Mediterranean fruit fly: Guatemala-Mexico (1983–present), Peru-Chile (1996–2002) | Mediterranean fruit fly: Los Angeles Basin in CA, USA (1996–present), Tampa-Miami in Florida USA (1998–present), Chile-Peru border (2008–present) | Mediterranean fruit fly: Los Angeles Basin in California USA (1980s-1996), Southern Australia, Dominican Republic (2015–2017) |
| Oriental fruit fly[10]: Thailand, Vietnam | Melon fly[11]: Japan (1982–1994) | | Melon fly: Japan (is. near Taiwan) (1995–present) | Painted apple moth[12]: New Zealand |
| Onion maggot[13]: The Netherlands | Sweetpotato weevil[14] and West Indian sweetpotato weevil[15]: Japan | Queensland fruit fly[16]: South-eastern Australia | | Queensland fruit fly: Western Australia |
| Greenhouse whitefly[17], sweetpotato whitefly[18], and Amer. serpentine leafminer[19]: Europe, USA (greenhouses) | Tsetse fly: Unguja Island[20] (Zanzibar) (1993–1998), Niayes[21], Senegal | | | Old World screwworm[22]: Australia[23] |
| False codling moth[24]: South Africa | | | | |

[22] *Chrysomya bezziana* (Villeneuve)
[23] Although free of the Old World screwworm, Australia maintains a contingency plan against potential incursions of this pest (AFF 2002)
[24] *Thaumatotibia leucotreta* (Meyrick)

An eradication strategy also leads to a reduction in the use of insecticides that is often larger and longer-term (once eradication is eventually achieved) as compared with a suppression strategy, although pre-release population reduction and "hot-spot" treatments may temporarily require increased localized use of insecticides. In addition, eradication allows the establishment of internationally recognized "pest free areas" (Malavasi et al. 1994; FAO 2016a, 2017b) which can permit access to otherwise closed export markets. These trade advantages are often the major motivation for eradication programmes against insect pests of agricultural importance. The eradication of the Mediterranean fruit fly in Chile (SAG 1996) opened trade opportunities annually worth several thousand million USD, and the eradication of the Mexican fruit fly and the West Indian fruit fly in north-western Mexico allows fruit trade with the USA without the need for costly postharvest treatments (Reyes F. et al. 2000; Enkerlin, this volume).

In the past, most AW-IPM programmes integrating the SIT aimed at eventual eradication of the target population, and sterile insects were often released only during the last phase of the programme (section 3.). The eradication strategy is applied mainly in two different situations (Tables 1 and 2):

- Eliminating an established pest population, e.g. the tsetse fly *Glossina austeni* in Unguja Island (Zanzibar) (Vreysen et al. 2000),

- Eliminating outbreaks of an invasive species before full establishment of the pest can occur, e.g. the painted apple moth in New Zealand (Suckling 2003) (additional examples in Table 3).

The second situation is likely to increase, with more pest introductions due to globalization, pest survival in previously inhospitable climates due to climate change, and the growing awareness by governments of the need for monitoring networks for early detection to facilitate eradication (hendrichs, enkerlin et al., this volume). Once the target pest has been eliminated from a given area, it is imperative to maintain this area pest free. This will require efficient, permanent, and stringent quarantine procedures to preclude reinvasion.

To declare eradication, two very important decisions (which have significant economic implications) have to be made: (1) the period of time in which releases of sterile insects should continue after the last wild insect has been detected (Vreysen, this volume), and (2) the duration of continued monitoring after releases have stopped, to be able to declare with sufficient confidence the status of eradication (Barclay et al., this volume). When creating a new pest free area, this period of no detections can last up to a whole year or longer for some insect pests such as tsetse flies (Vreysen et al. 2000). For the eradication of fruit fly pest outbreaks in free areas, ISPM 26 established a period of zero detections equivalent to a *minimum of three life cycles* after catching the last wild fly (FAO 2016c). This approach has been criticized as unscientific (Carey et al. 2017), but historically has proven effective (McInnis et al. 2017; Shelly et al. 2017). Moreover, in practice and for trade purposes, the actual period required is often established bilaterally between trading partners.

Various mathematical models have been developed that, given the biology of the specific pest species, and the efficiency and density of the deployment of monitoring tools, determine the time required to ascertain, within certain confidence limits, the probability that the target population has been eliminated. These models, which are important complementary decision-making tools, have confirmed the overall effectiveness of the three-life-cycle period (Manoukis and Hoffman 2014; Collier and Manoukis 2017). Agent Based Simulations are a very recent approach to model invading pest populations such as the MED-Fly Outbreak and Eradication Simulation (MED-FOES) that aims at modelling invading Mediterranean fruit fly populations to determine the effective duration of the quarantine and other eradication measures following the last detection of an incursion (Manoukis and Collier 2021).

The decision to establish a pest free area (and then maintain its free status) is sometimes questioned in view of the permanent threat of reinvasion, which would result in a loss of the investment. The likelihood of reinvasion of a pest insect is related to its biology, its geographic distribution, the volume of travel and trade into the free area (Liebhold et al. 2006), the efficiency of the quarantine infrastructure, and the location and size of the pest free area. Therefore, the selection of an eradication strategy will also be influenced by these parameters.

The reinvasion potential of a species in a given area is also inherently linked to the economics of the various strategic options, which will therefore significantly influence the decision to select a suppression or eradication strategy. "*Sequential eradication*" in a target area can still be economically beneficial, notwithstanding periodic reinvasion, if the average period between reinvasions is long enough so that the economic and

environmental benefits of each pest free period between reinvasions exceed the costs of having to "live with" the pest and the effects of the continuous control.

J. Mumford (personal communication) proposed the concept of "*serial eradication*", which entails the elimination of a pest population in a certain target area without heavy investment to prove the "status of eradication". If the area is reinvaded, the eradication effort is simply repeated. Not having to constantly "demonstrate the pest free status" could save considerable sums of money, although the trade benefits of a certified pest free status would be continuously in jeopardy and therefore not fully available, similar to situations of "near zero" or "low prevalence" populations (FAO 2016b).

Serial eradication could be applied in conjunction with the concept of "pest free place and site of production", where the pest free status needs to be maintained only for a fixed period, for example the harvest season (FAO 2016a). To illustrate, melons from Honduras are being exported to Taiwan from registered and qualified places of production maintained pest free only during the harvest season (IAEA 2017). This concept is normally associated with a situation where the commodity is considered a poor or only "conditional host" of the regulated pest (FAO 2017d). However, when the commodity of interest is considered a "good host", to obtain the trade advantages, the concept of serial eradication would require a "systems approach" (FAO 2017c), which includes a combination of low-cost monitoring, postharvest and other treatments, and occasional intensive area-wide suppression actions.

The decision to adopt a strategy of permanent suppression or periodic eradication is, however, based not only on economics and trade. The affordability of "living with" a disease vector population, even when suppressed, also needs to be considered. Eradication of major vectors of human or livestock diseases (or potentially even plant diseases) is often the preferred option, since a low density of the pest population does not necessarily lead to low levels of disease transmission (Otieno et al. 1990; Feldmann and Hendrichs 2001).

### *2.3. Containment*

Containment is defined (FAO 2017b) as:

> Application of phytosanitary measures in and around an infested area to prevent spread of a pest.

Containment programmes are adopted to avoid the spread of invading pests that have become established in part of an area, or to consolidate progress made in an ongoing eradication programme. Several examples are given in Table 3. Some of these programmes are largely stationary and thus become permanent containment efforts (e.g. the Mediterranean fruit fly programme on the border between Mexico and Guatemala, or the screwworm programme in eastern Panama), whereas others successfully advance or gradually retreat and eventually collapse. An example of the latter is the Queensland fruit fly Tri-State Fruit Fly programme. It was conducted since 1988 in eastern Australia to protect an area that contains much of the horticultural production areas of southern New South Wales, northern Victoria, and eastern South Australia (Jessup et al. 2007), but eventually had to be converted into an area-wide

suppression programme due to the expanding range of the Queensland fruit fly. On the other hand, the pink bollworm programme in California is an example of a containment programme that, after many decades of successfully protecting cotton production in the San Joaquin Valley, eventually advanced towards successful eradication of the pest from south-western USA and north-western Mexico once technological change (i.e. *Bt*-cotton), the political situation, and stakeholder commitment favoured it (Henneberry 1994; NCCA 2001; Staten and Walters 2021).

A typical containment situation is illustrated spatially or geographically in Fig. 1, showing a gradient in the density of the pest population from an infested area (NAPPO 2004) on the left to a pest free area on the right. In between there is a relatively steep wild population decline across the various operational areas where the pest is being contained.

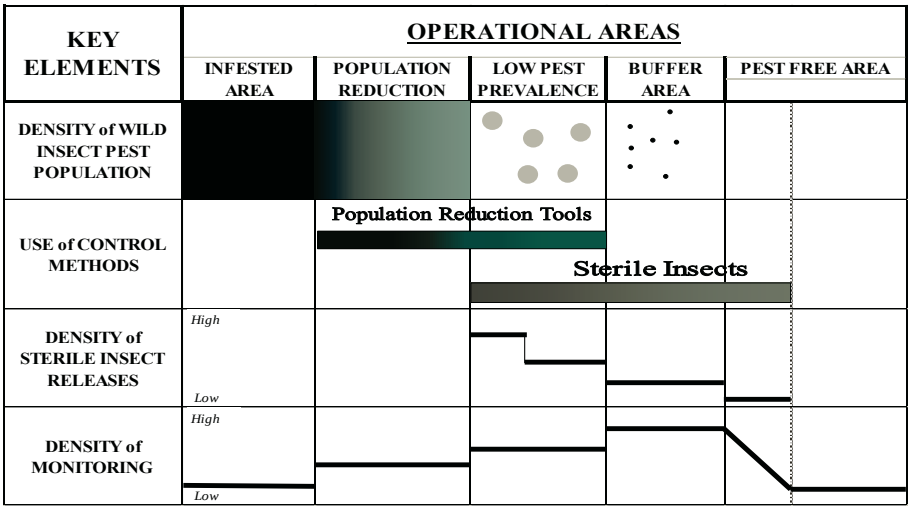

*Figure 1. Schematic representation of containment (and also rolling-carpet approach to eradication in large blocks, section 7.1.), illustrating geographically the gradient in pest population density and degree of activities in the different operational areas, including some preventive sterile insect releases in the pest free area closest to the buffer area.*

Various population reduction tools have to be integrated in areas and hotspots where pest levels are too high for sufficient numbers of sterile insects to be released, whereas the SIT is increasingly implemented over lower population levels, mainly low pest prevalence areas with some pest remnants or *incursions* (FAO 2017b)). Sterile insects are particularly effective in adjacent areas that already are largely pest free, but that are subject to regular pest *entries* (FAO 2017b). Ideally, sterile insects are also released as a safety measure in a buffer zone and over parts of the contiguous pest free areas, in view that the pest may occasionally be moved by the transport of infested host material. The degree of population reduction, sterile insect release, and monitoring efforts along this gradient are also indicated in Fig. 1, reflecting requirements to maximize their effectiveness. For example, to be able to detect as

early as possible any entry or incursion, monitoring activities have to be the highest in the buffer zones and adjacent pest free area.

### *2.4. Prevention*

The prevention strategy is defined here as the "application of phytosanitary measures in and/or around a pest free area to avoid the introduction of a pest" (however, it applies also to the preventive application of sanitary measures against animal pests). Preventive sterile insect releases have been applied effectively where the invasion pressure is very high, and quarantine activities are not sufficient to maintain the area pest free (table 3). An example is the permanent release of sterile melon flies over the okinawa islands closest to taiwan (kuba et al. 1996). In situations where the invasion risk is not very high, sequential or serial eradication approaches are probably more viable economically (section 2.2.).

For agricultural trade, the strategic options of containment and prevention are designed to maintain market accessibility, although the prevention option is most desirable in terms of cost, as it is always cheaper to prevent a pest problem than to deal with it later (Knipling 1979). (Enkerlin (this volume) provides a more detailed explanation of the costs of containment and prevention.)

## 3. TEMPORAL PHASES OF AREA-WIDE IPM PROGRAMMES INTEGRATING THE SIT

Irrespective of the strategic option selected, AW-IPM campaigns that include the SIT will likely have similar basic elements and be implemented following distinct temporal phases, i.e. from research to feasibility assessments and pilot studies, all the way to operational field implementation (Hendrichs et al. 2007):

- *Pre-intervention Phase*
  a. The collection of baseline data on the distribution, dispersal, and population dynamics of the target species in space and time (Itô et al., this volume; Vreysen, this volume),
  b. Research and development, evaluation and validation of control methods to be integrated,
  c. Technical feasibility and benefit-cost assessments (Mumford, this volume), and adequate programme planning, including obtaining external technical expert advice, and
  d. Assuring political commitment and support from major stakeholders and community leaders, and mobilizing adequate financial resources (Dyck, Reyes Flores et al., this volume).
- *Preparatory Phase*
  a. Staff training and human capacity building, including stakeholders that need to be involved in some activities,
  b. Launching a public relations campaign (Dyck, Regidor Fernández et al., this volume),

c. Establishment of funding mechanism, organizational structure and semi-autonomous institutional set-up under public-private operation and oversight,
d. Development of physical infrastructure (including the mass-rearing and sterilization facility, emergence and release centres) or contractual arrangements made to procure sterile insects from established mass-rearing facilities and to outsource the release of sterile insects (Dowell et al., this volume; Parker, Mamai et al., this volume),
e. Implementation of small pilot tests to validate the approach and train staff, and
f. Review by independent external experts to confirm readiness to embark on the operational phase (can also provide periodic reviews during this phase).

- *Operational Phase*
  a. Population reduction. Control measures are applied, with varying intensity depending on the strategy and seasonal variation in pest population levels, to reduce the density of the target population prior to the release of sterile insects. Various population reduction methods are available, depending on the target insect (Mangan and Bouyer, this volume). However, these are not always required, e.g. when the pest emerges in low numbers after a winter, or when the population undergoes a natural decline as a result of environmental conditions.
  b. Release of sterile insects. The systematic release of sterile insects over the target area to reduce the target population to a pre-determined level (suppression strategy), to drive the target population to extinction (eradication strategy), or to avoid pest establishment (containment and prevention strategies). This second part of the operational phase can in some instances overlap with continued population reduction, e.g. combining larval suppression and the use of insecticide-impregnated bednets to kill biting mosquito females with the release of sterile males (Mangan and Bouyer, this volume); concurrent treatment of wounds in livestock with insecticides and the release of sterile insects in screwworm eradication campaigns; or the simultaneous application of the male annihilation technique and the SIT as part of a male replacement approach for *Bactrocera* fruit flies (Barclay et al. 2014).
  c. Maintenance of control. To sustain the low prevalence status (suppression strategy) or the pest free status (containment and prevention strategies) through the permanent implementation of activities, or
  d. Verification and preservation of pest free status. To confirm and maintain the pest free status (containment and eradication strategies) through permanent implementation of quarantine and early detection and response activities (Barclay et al., this volume).

Progressing from each of these major phases to the next should ideally follow a *phased conditional approach*, e.g. fulfilment of the activities and requirements of a phase as the basis and precondition for entering the subsequent one. It is particularly important when deciding to embark on the operational or programme implementation phase that all previous pre-intervention and preparatory activities have been completed successfully. Preferably this readiness is confirmed by an independent review by a team of external experts (Vreysen et al. 2021).

## 4. STRATEGIC CONSIDERATIONS IN RELATION TO PEST STATUS AND TARGET MARKETS

The selection of a control strategy is influenced significantly by whether the pest is a disease vector or an agricultural pest. For major vectors of plant, animal or human disease the relevant issue is whether a suppression strategy (releasing only sterile males) can largely maintain the population below a transmission threshold, or whether even low pest populations can result in considerable disease transmission, requiring the eradication option.

For agricultural pests two main factors are of relevance in decision-making: the status of the pest in the target area, and the target market for the produced crop or livestock commodities.

### *4.1. Target Area and Pest Status*

Pest status depends not only on whether the insect is present or absent in the target area, but also on the specific situation and national plant and animal health legislation of the importing and exporting countries in relation to that pest; thus, a pest can be *non-regulated* or *regulated* (both *quarantine* and *regulated non-quarantine* pests (FAO 2017b)). The pest status in a given area, together with the specific situation of the pest (non-regulated or regulated) (Tables 1, 2 and 3), are the primary factors (Klassen's "decision-makers") that will influence the type of strategy(ies) that are economically viable and feasible to be developed and implemented:

- An area is considered as *infested* (NAPPO 2004) when the pest is naturally occurring or non-native pest *establishment* (perpetuation, for the foreseeable future, of a pest within an area after entry (FAO 2017b)) has taken place and the pest has *spread* (expansion of the geographical distribution of a pest within an area (FAO 2017b)). A suppression or eradication strategy can be applied under these circumstances depending largely on the economics as well as isolation and ease of establishing/maintaining quarantine regulations, e.g. a suppression programme against the Mediterranean fruit fly in Valencia, Spain (Primo 2003), and eradication of the same pest in temperate fruit-production areas in Mendoza and Patagonia, Argentina (De Longo 2000).
- Situations of multiple presence of major pest species in a target area necessarily complicate strategic considerations, although there are some suppression or eradication programmes where more than one species have been simultaneously addressed. Examples are the eradication of both the Mexican and the West Indian fruit flies from north-western Mexico (Reyes F. et al. 2000), or the eradication of three tsetse populations (*Glossina p. gambiensis*, *Glossina tachinoides* Westwood and *Glossina morsitans submorsitans* Newstead) from 3500 km$^2$ in Burkina Faso (Politzar and Cuisance 1984; Clair et al. 1990).
- An area is considered *pest free* when the insect pest is not present in that area (FAO 2017b). If there are frequent *entries* (FAO 2017b) of a major invasive pest, and the area is *endangered* (area where ecological factors favour the establishment of a pest whose presence in the area will cause economically important loss (FAO 2017b)), the most cost-effective strategy to protect the area from any potential

introductions will often be preventive releases of sterile insects, a successful example being the Preventive Release Programmes in California (Dowell et al. 2000; Enkerlin, this volume). About 150 million sterile male Mediterranean fruit flies are being released per week in the Los Angeles Basin, a "high-risk" area for introductions of this pest because of favourable ecological factors, the huge amount of international trade, the substantial volume of international postal shipments with infested fruit, high traffic in contraband fresh commodities, and the large number of fruits carried illegally by tourists (Liebhold et al. 2006).

- Simultaneous to strengthening quarantine measures, the threat of entry and introduction into a pest free area can be reduced by requesting postharvest treatments and pre-clearance actions, as well as proactively supporting *offshore pest risk-mitigation* activities in places where the pest originates (i.e. neighbouring countries or regions), e.g. Chile's support to the release of sterile Mediterranean fruit flies north of and along the border between Chile and Peru to avoid reinvasion of this pest from Peru into Chile (Enkerlin et al. 2003). Another example is the USA's support of the Moscamed programme along the Guatemala/Mexico border.
- A pest free area, contiguous to an infested area, can be protected by a containment strategy, e.g. the release of sterile pink bollworms over decades to prevent the spread of this pest from infested areas into the cotton production areas of the San Joaquin Valley in California, USA (Henneberry 1994); more recently this programme successfully shifted to an eradication strategy (Staten and Walters 2021).
- When establishment of an invasive insect pest has taken place recently, and the *outbreak* (a recently detected pest population, including an incursion, or a sudden significant increase of an established pest population in an area (FAO 2017b)) has not yet spread significantly out of the outbreak area, the recommended strategy is a rapid response to achieve eradication as soon as possible, e.g. elimination of the New World screwworm in Libya (Lindquist et al. 1992; Krafsur and Lindquist 1996; Vargas-Terán et al., this volume) or the Mediterranean fruit fly in the Dominican Republic (Zavala-López et al. 2021). Containment is the second-best strategic option for this situation, but only when immediate eradication is no longer feasible or has failed.

### *4.2. Requirements of Target Market*

For agricultural pests, the type of market targeted for the commodity produced plays a major role in selecting a control strategy. There are four major potential markets that can be accessed (IAEA 1995) (Table 4):

- *Domestic markets* are normally the least demanding, but also the least lucrative, and a suppression strategy using sanitation and other conventional methods is normally sufficient. Only when there are important local markets having special requirements in terms of low pesticide residues is the use of more environment-friendly pest control methods warranted.
- *Non-discriminating export markets* also often have no special requirements, and thus may be similar to domestic markets. However, increasingly, as a result of globalization, these markets tend to decrease in importance, whereas export

markets demanding lower pesticide and/or pest presence in commodities are growing.

- *Low-residue export markets* are typically in developed countries that have demanding supermarket chains (in terms of maximum allowed residue levels) and a growing demand for such products. These markets either already have the pest or have climates in which the pest cannot become established. A suppression strategy involving application of more environment-friendly methods is suitable to gain access to these markets.

*Table 4. Access to potential markets using available control strategies*

| Control Strategy | Potential Markets | | | |
|---|---|---|---|---|
| | Domestic markets | Non-discriminating export markets | Low-residue export markets | Pest free export markets |
| Suppression (infested area) | | | | |
| Conventional control | Yes | Yes | No | No |
| Low pesticide including the SIT | Yes | Yes | Yes | No |
| Low pest prevalence and systems approach | Yes | Yes | Yes | Yes[1] |
| Eradication (pest free area developed) | Yes[2] | Yes[2] | Yes[2] | Yes |
| Containment (pest free area protected) | Yes[2] | Yes[2] | Yes[2] | Yes |
| Prevention (pest free area maintained) | Yes[2] | Yes[2] | Yes[2] | Yes |

[1] Only when combined with complementary measures, such as post-harvest treatments, except for marginal hosts of the pest

[2] Development, protection or maintenance of pest free areas, involving quarantines and intense monitoring, is usually not cost-effective for these markets unless they target mainly pest free export markets

- *Pest free export markets* are the most demanding, with zero tolerance for the presence of the pest in the export commodities. Accessing these markets requires an eradication strategy to establish certified pest free areas. Alternatively, a suppression strategy can be followed to establish a low prevalence area, but this strategy demands in addition a systems approach involving integration with complementary pest risk-mitigation measures such as, in some instances,

postharvest treatments to guarantee pest free commodities. In situations where the exporting areas are already partially or fully pest free, the logical approaches to protect or maintain these markets are containment or prevention strategies, respectively.

## 5. STRATEGIC CONSIDERATIONS IN RELATION TO PEST BIOLOGY AND ECOLOGY

There are several factors related to the biology and ecology of the pest that influence the selection of a control strategy, and affect both planning and implementation, e.g. Pest mobility, pest densities, average lifespan, potential for direct and indirect damage, and ecological aspects such as topography, vegetation, and climate, as well as the capacity to monitor pest presence, together with gene flow, to determine the degree of isolation of the target population.

### *5.1. Pest Dispersal*

One of the most critical aspects is the degree of isolation of the target population and, associated with it, the dispersal ability of the target insect (Vreysen, this volume). Knowledge about dispersal ability is essential to assess the likelihood of invasion or reinvasion, which remains an important consideration in selecting and developing a strategy. Highly mobile insects can be advantageous for programmes that release sterile insects, as this trait will increase the probability of finding and mating with virgin wild female insects. However, at the same time, the greater the dispersal of the wild insect, and in particular wild females, the more difficult it will be to protect pest-cleared areas (Lance and McInnis, this volume).

Mark-release-recapture studies, using both wild and sterile insects, can also be used to study dispersal, but this approach, although valid, can be expensive and cumbersome (Itô et al., this volume).

An alternative is the analysis of the gene frequencies of target and neighbouring populations as an indirect approach to dispersal (Krafsur and Ouma, this volume; Vreysen, this volume). Pest dispersal ability is a decisive component in strategy selection, in assessing the minimum size of an intervention block where the SIT can be effectively applied (section 8.; Barclay et al. 2011; Klassen and Vreysen, this volume), and in determining the need for temporary and permanent buffer zones (section 9.).

### *5.2. Release Density*

Itô et al. (this volume) provide detailed mathematical guidance on estimating absolute densities of insect populations and growth under different situations and for pests with different biology. An estimate of these parameters of the pest population in the target area is key to determining the need and extent of population reduction required before the application of the SIT, and to make accurate estimates of the required number of sterile insects. The latter will obviously influence the total cost of the programme, and

will represent a major consideration when selecting a strategy (Mumford, this volume).

The cost of the SIT component of AW-IPM programmes has traditionally been calculated using data from the production of sterile insects, and the cost associated with handling and release operations. Even though very large variations in the production and release costs of different insect pests exist, i.e. from only USD 0.25 to produce 1000 Mediterranean fruit flies to USD 85 to produce the same number of tsetse flies (Table 5), the ultimate cost of an SIT operation will also be determined by the number and frequency of sterile male insects per unit of surface that are needed to obtain adequate sterile to wild male overflooding ratios. A comparison of costs per surface and time unit for different pest species is presented in Table 5.

*Table 5. Comparison of costs of AW-IPM programmes that release sterile insects (data for codling moth calculated from information provided by R. Fugger and L. Tomlin, Sterile Insect Release Program, Canada, and Bloem et al. 1998)*

| Pest species | Cost of producing sterile male insects (USD per 1000 insects) | Cost of handling and releasing sterile males (USD per 1000 insects) | Total cost (production and release) (USD per 1000 insects) | Release rate (number of sterile males per $km^2$ per week) | Cost of sterile male production and release (USD per $km^2$ per year) |
|---|---|---|---|---|---|
| Codling moth[1,2] | 1.9 | 0.65 | 2.55 | 100 000 | 5167 |
| Mediterranean fruit fly | 0.25 | 0.15 | 0.4 | 200 000 | 4160 |
| *Glossina austeni* (savannah tsetse species) | 85.0 | 33.0 | 118.0 | 80 | 491 |
| New World screwworm[2] | 1.0 | 0.4 | 1.4 | 2500 | 182 |
| *Glossina p. gambiensis* (riverine tsetse species) | 85.0 | 96.0 | 181.0 | 15 | 141 |

[1] Data for codling moth based on releases for only 20 weeks per year
[2] Both sterile males and females are released

For example, following application of population reduction measures, only 15 sterile male *Glossina p. gambiensis* (riverine species of tsetse) are required per $km^2$ per week, whereas for the Mediterranean fruit fly, ca. 200 000 sterile males per $km^2$ per week are needed. Consequently, although the production and release costs of Mediterranean fruit fly are very low and for tsetse very high, the costs per $km^2$ per week of the SIT operation are much higher for Mediterranean fruit flies (USD 80) than for riverine species of tsetse (USD 2.7). Therefore, considering the cost of the sterile

fly requirements per surface and time unit provides a much more accurate indicator of the economic implications of SIT operations.

### *5.3. Pest Aggregation*

Aside from the absolute population density, the degree of population aggregation or dispersion is important. Sterile insects are usually released by air, and are thus distributed fairly homogeneously over the target area, irrespective of whether the target pest is distributed evenly or clumped. Pest insects with a clumped distribution require effective hotspot detection and suppression (Shiga 1991), as well as higher release rates as compared with those with a homogeneous distribution, to obtain the required sterile to wild male ratios (Barclay, this volume), and thus pest aggregation also affects strategy selection and its cost. Only if the released insects can find the same aggregation sites and aggregate in a similar manner as wild insects (Vreysen et al. 2011), so that adequate sterile to wild male overflooding ratios are obtained in those sites, is there no need to increase release rates to compensate for such clumping (Vreysen, this volume).

### *5.4. Sterile Male Longevity*

The density of the sterile male population in the field, which fluctuates in relation to the release frequency and the sterile male mortality rate, should not decrease below that needed to maintain the critical ratio (Fig. 2, upper graph) (Kean et al. 2007; Barclay, this volume). Therefore, the frequency and number of sterile males released has to be carefully assessed in relation to the average longevity or survival of the sterile males, to effectively avoid periods when insufficient sterile males are present in the field (Fig. 2, lower graph).

As generations normally overlap in multivoltine species, releases have to be continuous, with survival determining whether they have to occur on a weekly (New World screwworm), twice a week (Mediterranean fruit fly, tsetse), or even daily basis (*Drosophila suzukii* (Matsumura) in greenhouses). The importance of assessing the survival of sterile male insects in the natural habitat must be emphasized here (Vreysen, this volume), as their actual survival in open field conditions is often drastically lower than in protected field-cage situations, where sterile males have easy access to food and are protected from predation (Hendrichs et al. 1993). In addition, mass-rearing conditions often inadvertently select for short-lived individuals (Cayol 2000). A shorter sterile male lifespan, although not directly representative of competitiveness, often requires higher release frequencies, and thus can significantly increase programme costs compared with longer-lived sterile insects.

### *5.5. Topography and Other Conditions of Target Area*

The topography of the target area, combined with the density of roads, has major implications for programme implementation and the selection of an intervention strategy. A flat terrain and a well-developed road network will facilitate most field

activities (including ground release in some cases), whereas mountainous areas, dense vegetation, and the absence of roads will make implementation more challenging. In most of the larger programmes, releases and some of the population reduction activities use fixed-wing aircraft (Vreysen et al. 2000; Dowell et al. 2000), helicopters (Koyama et al. 2004), gyrocopters (Vreysen et al. 2021), or more recently even unmanned aerial vehicles (Benavente-Sánchez et al. 2021; Dowell et al., this volume), and the topography and presence/absence of a road network are less critical.

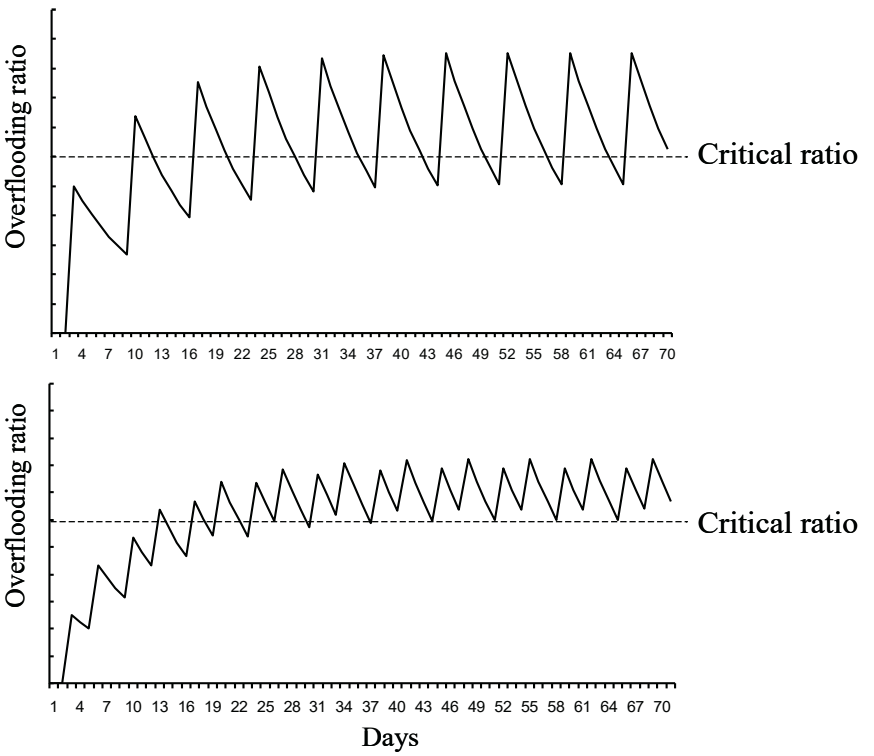

*Figure 2. Effect of sterile insect longevity (assume daily mortality rate of sterile males is 0.1) on sterile to wild overflooding ratio. Upper: Due to only weekly releases, sterile insect population routinely decreases significantly below the critical overflooding ratio; Lower: twice-a-week releases overcome this problem.*

Actually, the absence of a good road network is often advantageous for the establishment of efficient quarantine procedures in support of an eradication strategy. Monitoring, however, is mostly ground-based, and extreme terrain conditions make eradication campaigns (which have a more intensive monitoring component) much more complex and costly than programmes following a suppression strategy (which have less intensive monitoring activities). Likewise, topography influences the requirements of sterile insects or bait sprays, e.g. mountainous areas have a larger surface area per square kilometre as compared with flat, two-dimensional conditions,

demanding higher sterile insect release rates. Furthermore, helicopters, which are more expensive to operate than fixed-wing aircraft, are often needed in difficult terrain for safety reasons and to properly treat narrow valleys.

### *5.6. Capacity to Monitor and Delimit Pest Presence*

The distribution of the target population has to be known accurately; direct and indirect monitoring methods are usually available to assess this for the different target species. Each monitoring tool, however, has its limitations, and none is perfect. Knowledge about the efficiency and limitations of the monitoring methods is essential to assess the accuracy of, and the ability to demarcate, the total distribution of the target population (Vreysen, this volume).

The different phases of programme implementation require specific adjustments to the monitoring system according to the pest density (Fig. 1). The intensity of deploying monitoring tools, or of indirect surveys, gradually changes from the initial relatively low monitoring effort during the baseline data collection to increased activity during the initial population reduction, low-prevalence, and eradication activities (highest need for detection capability), and will decrease again during maintenance/verification (FAO/IAEA 2018). Therefore, along the gradient in pest population density, the density of monitoring tools will also vary according to their efficiency in the different operational areas. For an eradication strategy, very efficient monitoring tools are particularly important once populations have decreased to very low densities; the same is true for population remnants or entries and incipient incursions (Fig. 1). In pest free areas, monitoring efficiency is important also for early detection of, and delimiting, the population of a new introduction. Inefficient monitoring tools to assess the status of eradication, or for delimiting purposes, will increase the cost of programmes — high deployment densities are required to compensate for the lower efficiency, and longer deployment times to obtain the required confidence limits (McInnis et al. 2017).

## 6. STRATEGIC CONSIDERATIONS IN RELATION TO PEST DISTRIBUTION

The characteristics of the spatial distribution pattern of the target population will be a crucial factor when selecting a strategy and developing an implementation plan. An insect population can be confined to an island, or have a fragmented or continuous distribution on a continent.

### *6.1. Island Distribution*

Targeting a pest population confined to an island is the ideal and simplest situation for which to develop an AW-IPM programme, e.g. New World screwworm on various islands in the Caribbean, cactus moth on islands off the Yucatán Peninsula in Mexico (Bello-Rivera et al. 2021), and melon flies or sweetpotato weevils on islands of the Okinawa archipelago (Kohama et al. 2003; Koyama et al. 2004), etc. Islands can be relatively small, making area-wide intervention easier, and, if the size is not too large,

the insect population can be tackled at one time. Typically, insect populations on islands are isolated, with the ocean being an ideal natural barrier. Sustaining such areas pest free after eradication is only a minor concern for species such as the tsetse fly *G. austeni* which was eliminated from Unguja Island of Zanzibar, whereas for other species the establishment of quarantine procedures is facilitated by the island situation. However, migration over considerable distances has also been reported for species such as the melon fly (Koyama et al. 2004), where movement between Taiwan and islands in southern Japan has been recorded routinely (Kuba et al. 1996).

### *6.2. Fragmented Distribution*

Insect populations on continents are fortunately not always distributed continuously, but often appear to be fragmented and confined to "ecological or population islands". Examples are the carob moth in date palm oases in the Mediterranean Basin and the Near East, the mosquito *Anopheles arabiensis* Patton confined to isolated mosquito habitat along the Nile River in Sudan (Malcolm et al. 2009), and various tsetse species confined to valley systems in south-western Ethiopia, fragmented habitat in the Niayes of Senegal (Bouyer et al. 2010), and in river basins in West Africa (Bouyer et al. 2015).

Although the distribution of insect populations is sometimes perceived as vast and continuous, topographical features (e.g. mountains, lakes, deserts), and factors such as host availability, climate, and vegetation, often result in the division of populations into smaller population units. This subdivision occurs more easily at the edge of the distribution, where the insects are confined to those areas with favourable conditions. Field surveys assisted by a GIS-based analysis, supported by satellite imagery and population genetics studies (Feldmann and Ready 2014; Bouyer et al., this volume; Krafsur and Ouma, this volume), are needed to determine the degree of reproductive isolation between such smaller population units.

Since detailed data on the distribution of the target population are often not available when needed, satellite-derived parameters are used increasingly to develop models to predict the probability of presence or even abundance of a certain pest in a given target area (Bouyer et al., this volume). These prediction models can greatly facilitate the demarcation of the pest's distribution, and provide the foundation for developing an adequate intervention strategy, as was done for *G. austeni* and *Glossina brevipalpis* Newstead in KwaZulu Natal, South Africa, and Matutuine Province, Mozambique (Kappmeier Green et al. 2007) (Fig. 3). However, the fragmented nature of the distributions of the two species predicted by the distribution prediction model (AVIA-GIS 2002) was later refuted through more extensive surveys that sampled both species where they had not been found before (de Beer et al. 2016).

Insect populations are rarely stable in space and time, and temporal changes in their dispersal potential can significantly affect the isolated nature of seemingly distant population pockets. Seasonal changes in vegetation cover can be particularly dramatic in subtropical and tropical environments, with important consequences for insect dispersal, e.g. populations can be confined to "vegetation islands" during the dry season, when conditions for survival are harsh, but during the rainy season dispersal potential increases, spatial distribution expands, and larger distribution areas are

created. Likewise, some moths and other pest populations are confined to limited overwintering areas in the subtropics from where they migrate each spring covering vast temperate areas (Wu 2007).

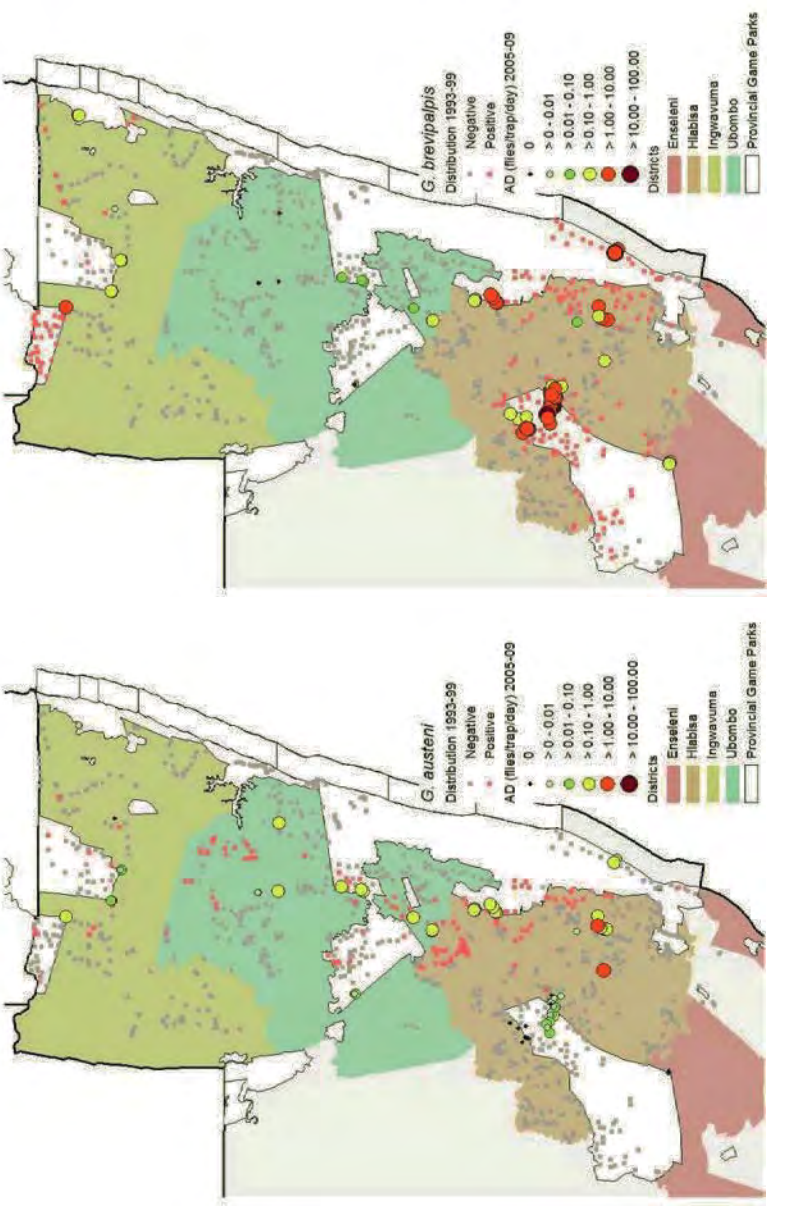

*Figure 3. Distribution of* Glossina austeni *(left) and* Glossina brevipalpis *(right) in KwaZulu-Natal in South Africa, derived from trapping data from the 1993–1999 and 2005–2009 surveys. (Maps reproduced with permission from C. de Beer.)*

### *6.3. Continuous Distribution*

The most complex scenario is when insects are distributed continuously over very large areas. For both suppression and eradication strategies, a vast distribution of the pest will make it technically, logistically and economically impossible to tackle the entire infested area at one time. Consequently, the AW-IPM programme has to be developed and implemented in different stages, and thus the target area has to be subdivided into "intervention blocks". The appropriate block size will depend on the sterile insect production capacity and the biology of the particular species (section 8.), but has to be large enough to preclude migration of mated fertile females into the core area of each block.

Determining the exact size and precise demarcation of the blocks is a very challenging task, as it could determine success or failure (Barclay et al. 2011). Topographical and ecological features (e.g. major cities, mountain ranges, rivers, non-host areas, and arid or open areas of unsuitable habitat), which constitute natural barriers for the target insect, should separate to the maximum possible extent adjacent intervention blocks. In principle, to reduce the probability of migration among blocks, the size and number of temporary buffer zones between the blocks should be limited.

## 7. STRATEGIES FOR CONTINUOUS DISTRIBUTION

For large target populations that are distributed continuously, the "rolling-carpet principle" or the "wave principle" can be used to plan and implement AW-IPM programmes. Intervention according to the rolling-carpet principle entails advancing along a unidirectional front (Figs. 1 and 4), whereas for a bidirectional or multidirectional front the intervention follows the wave principle (Fig. 5). The different blocks have to be demarcated and selected in such a way as to minimize the invasion pressure from various directions. Multiple fronts complicate a programme, and necessitate the establishment of temporary buffers, which obviously can reduce the probability of success. In both approaches, it is of prime importance that the starting point of operations be selected carefully. Once the programme has started, it must be continued in view of the continuous pest distribution, and cannot be interrupted until a pest free area (eradication strategy), or a low pest prevalence area (suppression strategy), has been obtained in all blocks. Ultimately, in most cases, a permanent containment barrier will need to be established in a block at a more easily defensible location, e.g. Darien Gap for the New World screwworm programme (Klassen et al., this volume; Vargas-Terán et al., this volume).

### *7.1. Rolling-Carpet Principle*

The rolling-carpet principle is dynamic. The basic activities described in section 3. (baseline data collection as part of the pre-intervention phase, and population reduction, releases of sterile insects, and maintenance/verification of low prevalence/pest free areas as part of the operational phase) are carried out simultaneously in a progressive manner along the adjacent blocks (upper part of Fig. 4). Obviously, this approach with overlap of releases in adjacent blocks is more time

and cost-efficient than without an overlap, in which each of these interventions would be implemented only in a given block before proceeding to the next block.

The diagram in the lower part of Fig. 4 shows the implementation of the rolling-carpet principle in space, i.e. the programme is initiated with the collection of baseline data and capacity building in block 1 (stage 1), and these activities are progressively shifted to adjacent blocks. Simultaneously, reduction of the population, release of sterile insects, and maintenance/verification of low prevalence/pest free areas will be carried out in those blocks where the previous activities have been completed. The approach in stages will entail a gradual increase in operational activities (and operational complexity) during the first four stages, with expanding needs for funding, personnel, and logistics.

Since the duration of each new operational stage can be different, the different stages of the rolling-carpet principle should be considered not only in space, but also in time (upper part of Fig. 4), i.e. baseline data collection (stage 1) usually has to take into account temporal changes in the density, distribution, and structure of insect populations, and often takes at least one full year to complete, whereas reduction (stage 2) of the target population is often implemented in shorter periods.

To achieve the desired population reduction, sterile insects must be released for a period of several generations (Knipling 1979). The duration of sterile insect releases to obtain a pest free area (eradication strategy), or to establish an area of low pest prevalence (suppression strategy), will depend on the reproductive rate and the generation time of the target species. For species such as tsetse flies, which have a long lifespan and long generation times, the release stage can take up to 18 months. Theoretically, this will be less for insects that have shorter generation times, like mosquitoes or fruit flies, but their high rates of reproduction can be a complicating factor.

The exact timing and initiation of each activity will be crucial for efficient implementation of the programme, e.g. a too-early start of the population reduction stage could result in a reduction of the target population before sterile insects are available for release. Therefore, the availability of sufficient sterile males should be taken as the "baseline", and all other activities should be scheduled in relation to the releases. These, in turn, depend largely on the production capacity of the mass-rearing facility. The overlap of releases in certain blocks (upper part of Fig. 4) has important implications for the cost of the programme, the time to reach programme goals, and the need to establish protective buffer zones (section 9.).

For example, in the hypothetical case with an overlap of releases for 12 months in two adjacent blocks (and even an overlap of 6 months in three blocks), the maintenance/verification period in the last low prevalence or pest free block can be initiated in the third quarter of year 5, whereas if there is no overlap of releases in adjacent blocks, this is delayed until the third quarter of year 8. In addition to the more advantageous implementation time, the first example offers a much more effective operation when compared with the second example, since the insect population in the block adjacent to the release area is always under active population reduction that minimizes the dispersal of gravid females into the release area (Fig. 1).

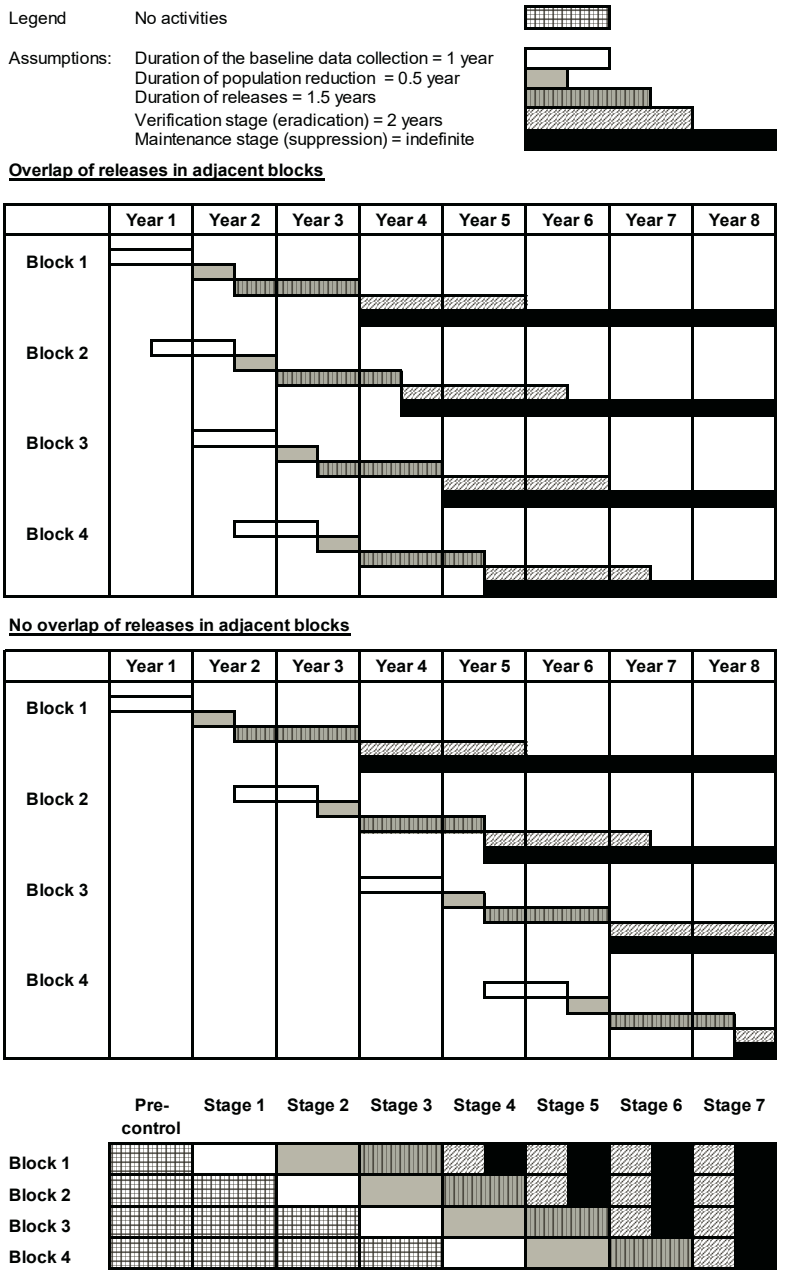

*Figure 4. Example of temporal (upper, with or without overlap of releases in adjacent blocks) and spatial (lower) diagrams of the "rolling-carpet principle" applied in four intervention blocks using eradication or suppression strategic options against a pest population distributed continuously.*

On the other hand, in the second example the population reduction activities in block 2 are only initiated 12 months after the initiation of releases in block 1, requiring the establishment of temporary buffer zones to prevent the migration of females from the still "untreated" block 2. It is equally important that the contiguous part of the area that is already pest free be treated preventively with sterile insects as a biological buffer zone (Fig. 1), an ultimate insurance that individual entries or incipient incursions cannot become permanently established in the freed area.

### *7.2. Wave Principle*

The wave principle entails an expanding operational block size with each new operational stage (Fig. 5), and this must be considered when designing a production facility. For example, if an intervention were initiated in a 10 x 10 km (100 $km^2$) area, and in each stage expanded by 10 km to the east, west, and south, the total intervention zone would expand from 100 $km^2$ in stage 1 to 6600 $km^2$ in stage 6 (Fig. 6).

In an eradication strategy, the release area (shaded area in Fig. 6) would expand from 100 $km^2$ in stage 1 to 500 and 2100 $km^2$ in stages 2 and 6, respectively. If the release density of sterile males were 200 000 per $km^2$, the sterile male requirements in each stage would increase linearly by 80 million insects, i.e. from 20 million sterile insects in stage 1 to 420 million in stage 6.

In a suppression strategy, however, the sterile insect requirements would be different. If sterile males were released at a density of 200 000 per $km^2$ during the release stage (shaded area), and at a density of 50 000 per $km^2$ during the maintenance stage of low prevalence areas (white area), the sterile insect requirements would increase more dramatically with each stage when compared with an eradication strategy, and are best described by the following equation:
$y = 2E + 0.7x^{1.9119}$ (Fig. 6).

The number of sterile males needed for each stage is also very different in a strategy using the wave principle compared with that using the rolling-carpet principle. In the rolling-carpet principle, subsequent intervention blocks are often approximately the same size (Fig. 4). In the wave principle approach, the requirements of sterile males and other resources will increase with each stage; therefore, there will be a limit beyond which the operations cannot be sustained. At a given point, the programme will need to advance in one direction (for example south), and temporary or permanent buffer zones have to be established in the west and east to protect the low prevalence or pest free zones achieved (Fig. 5).

A mobile, modular insectary approach, e.g. containers as production modules, would in some situations have the advantage that, if the target area were expanding, modules could be added relatively easily (Tween 2004). Furthermore, the entire insectary could be moved with the expanding eradication or low pest prevalence front. This would reduce the transport time and cost between a stationary factory and the release area (in the case of an eradication strategy, the distance between the target zone and the factory increases with each new operational stage).

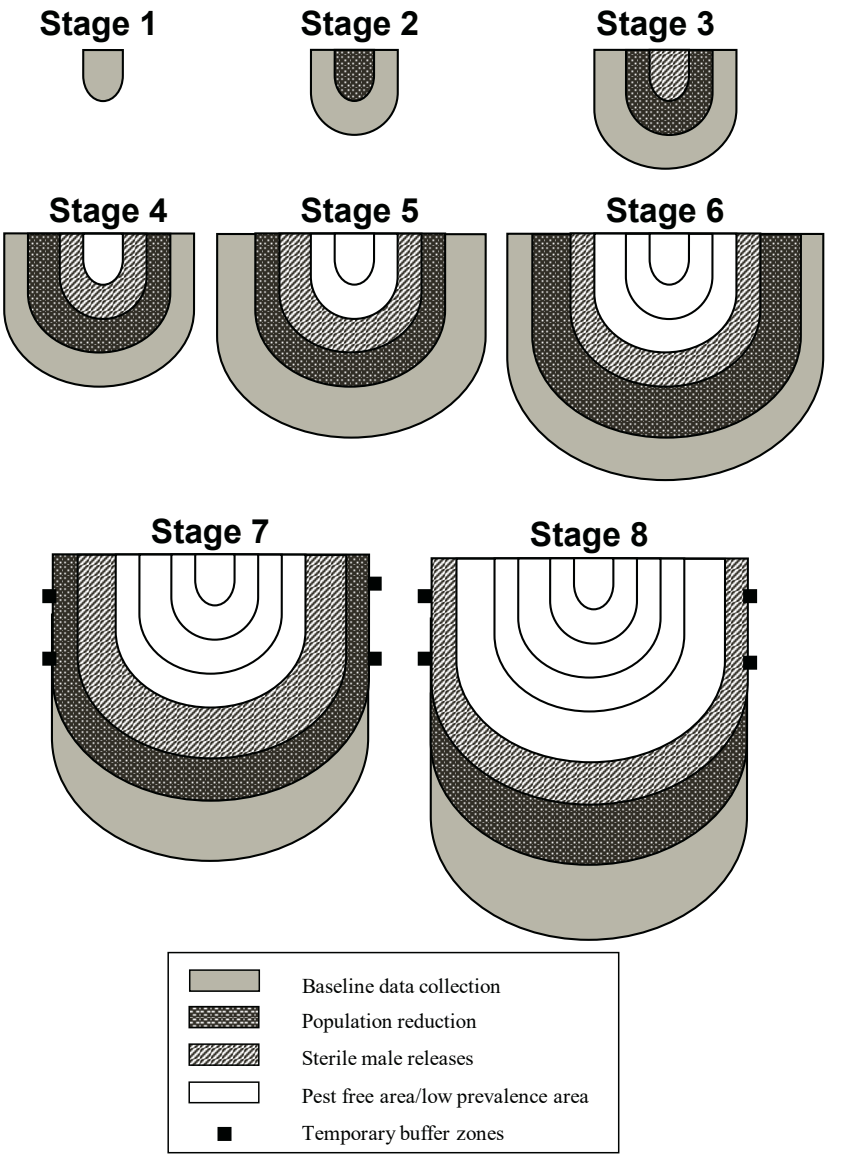

*Figure 5. Diagram of different activities and stages of an AW-IPM programme using the SIT according to the "wave principle" against a pest population with a continuous distribution. In this theoretical example, the intervention starts at the edge of the pest distribution and develops along a multidirectional front in the first 6 stages, until full production capacity of sterile males is reached. Beginning in stage 7, the intervention continues along a one-directional front, having either reached natural barriers or requiring the establishment of temporary buffer zones that includes suppression and quarantine activities as well as the release of sterile flies.*

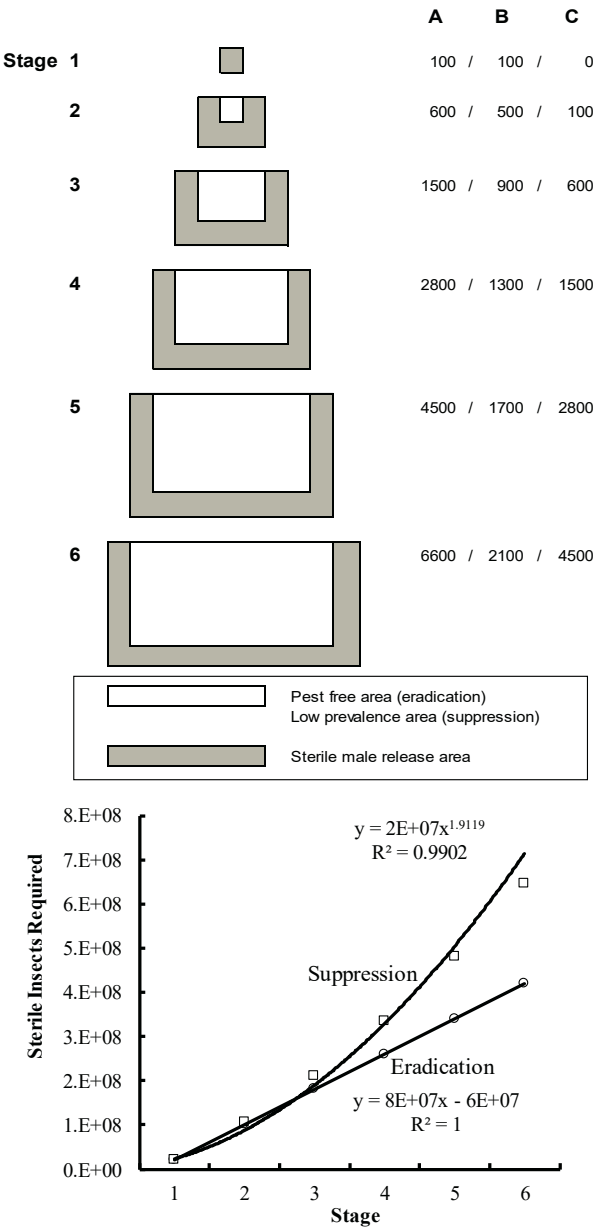

*Figure 6. Diagram of the wave principle (upper drawing) and sterile male requirements (lower graph), with an expanding intervention front of 10 km south, east, and west, and each stage using eradication and suppression. Numbers indicate:* ***(A)*** *total surface area in km² /* ***(B)*** *area in km² where sterile males are released /* ***(C)*** *pest free area in km² (eradication) or low pest prevalence area (suppression). (More details in the text.)*

A mobile insectary could be relocated occasionally to areas where the pest is still present, and, in the case of eradication, expensive insect-proofing systems would not be needed. However, the relative merits and economics of insect-proof systems and increasing transport time versus relocation costs of the modules need to be considered. An example was the New World screwworm mass-rearing facility in Tuxtla Gutiérrez, Chiapas, Mexico. As the programme succeeded and then advanced southward into Central America, the factory remained in an area now free of screwworms, requiring expensive and cumbersome biosecurity measures. These included the continuing release around the facility of several million sterile insects per week to deal with any fertile flies that might have escaped accidentally from the facility. Eventually, a new facility was established in Panama and the Tuxtla Gutiérrez facility closed (Vargas-Terán et al., this volume).

## 8. SIZE OF INTERVENTION BLOCKS FOR AW-IPM PROGRAMMES

At what spatial scale is an area-wide approach no longer technically and economically feasible? Is there a minimum size of the target area below which effective implementation of AW-IPM programmes using the SIT becomes technically impossible and economically unjustifiable (Barclay et al. 2011)? These questions are of major importance since the SIT, similar to mating disruption (Cardé 2021), does not kill the pest and hence is particularly susceptible to immigrating gravid female insects, which are largely unaffected by the sterile males, although in some target pest species females do remate (Von Borstel 1960).

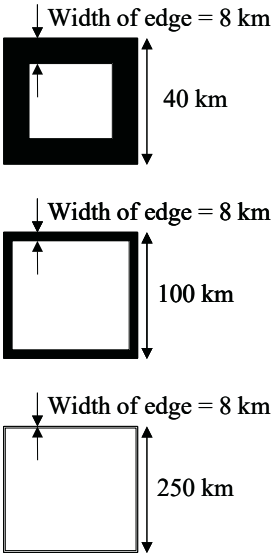
Intervention blocks are composed basically of two distinct areas, i.e. the core and the edge areas. The core area contains the commodity that is being protected (e.g. crop, cattle, humans in urban area, etc.), whereas the edge area, although included in the treatment zone, is defined by the edge effect: a certain level of infiltration by gravid wild females from the surroundings into the area under treatment (Fig. 7). In some situations the edge area completely surrounds the core area, often requiring the establishment of a protective buffer zone (section 9.) to minimize this edge effect.

The size of both core and edge areas is determined mainly by the combined effects of the dispersal potential of the pest species and the degree of protection required for the target area, which depends on the strategic objective of the programme: higher for eradication, lower for suppression. Other biotic and abiotic factors, such as presence of natural barriers, ecological and topographic characteristics of the area, tolerable nuisance or damage level, acceptable economic threshold, and managerial-logistic capacity, are likewise of relevance.

If the selected target area were completely isolated, e.g. an island, there is no need to establish protective buffer zones unless the pest can reach the island from other areas (Kuba et al. 1996). However, when a continuous pest population surrounds or is adjacent to the selected core area, the size of each block must be much larger to absorb the edge effect without affecting progress in the core (Fig. 7). For pests having a high dispersal rate, individual blocks will have to be larger (Barclay et al. 2011).

The size of the blocks will also affect the strategic approach and the economics of each approach. If the goal is to eradicate the pest and to maintain an area pest free, larger blocks will most likely be required to reduce the relationship of edge to core

area (Fig. 7). However, if pest suppression is the strategic goal, a certain damage threshold is usually acceptable, thus relatively smaller blocks and smaller protective buffers are acceptable (Larcher-Carvalho and Mumford 2004; Barclay et al. 2011). This confirms earlier observations that, by nature, eradication is a more extensive and intensive strategy when compared with suppression (sections 2.1. and 2.2.).



Total area is 1600 km$^2$
- Core area: 576 km$^2$
- Edge area: 1024 km$^2$
- Ratio of core to edge area: 0.56:1

Total area is 10 000 km$^2$
- Core area: 7056 km$^2$
- Edge area: 2944 km$^2$
- Ratio of core to edge area: 2.4:1

Total area is 62 500 km$^2$
- Core area: 54 756 km$^2$
- Edge area: 7744 km$^2$
- Ratio of core to edge area: 7.1:1

*Figure 7. Relationship of core area to edge area at three different scales of block size. An edge effect based on pest dispersal of 8 km is assumed, and square core areas for either pest free (containment and eradication) or low pest prevalence (suppression) area.*

The ratio between the size of the core and edge areas is related to this, i.e. the larger the core area, the smaller the edge area in relation to the whole block surface. Also, the relative effort needed to maintain protective buffer zones becomes proportionally smaller with larger block areas. The following example illustrates this point. Assuming that the core areas are squares, and that dispersal can occur into an edge with a width of up to 8 km (Fig. 7), the percentage of the total surface area represented by the edge area decreases from 64 to 29 to 12% for a core area of 1600, 10 000, and 62 500 km$^2$, respectively. For the small block of 1600 km$^2$, the effort going into the edge area is relatively larger than the one going into the core area. Such a situation could only be justified if the value of the commodity being protected outweighs the costs incurred to maintain protective activities in the relatively large edge area.

The scale of application will also influence programme economics, especially when it includes the initial capital investment of a mass-rearing and sterilization facility, as well as emergence and release facilities. Particularly in those cases, the programme needs to be applied on a scale large enough to become economically

viable and competitive with alternative control options (which operate at real economies of scale, i.e. production of insecticides). Therefore, larger blocks incur a lower cost per surface unit or per unit of the commodity that is being protected. This relates directly to the size of the mass-rearing facility; experience has shown that the cost of a unit of produced sterile insects is inversely related to the level of mass production (Enkerlin 2003). Higher fixed costs are associated with factories designed to produce relatively small numbers of insects.

The size of blocks has ranged from tens of square kilometres, as was the case of the oriental fruit fly pilot suppression programme in Thailand (Sutantawong et al. 2004), to thousands of square kilometres in the case of large programmes such as the New World screwworm eradication campaign, where each treatment block encompassed at least one and a half of the Central American countries (Vargas-Terán et al., this volume).

A conceptual model was developed for assessing the minimum size area for AW-IPM programmes (Barclay et al. 2011). It is primarily based on a diffusion coefficient that uses the dispersal rate of the target insect, and considers other main variables such as the fertility rate and mortality involved to produce estimates of minimum-size intervention blocks for different pests and programme objectives. It can be used as a guideline to recommend quantitatively the minimum intervention size for the range of different conditions where sterile insects can be released.

## 9. BUFFER ZONES

To address the edge effect as described above, there is often a need to establish buffer zones (FAO 1999, 2005) to protect containment or eradication efforts, or to maintain low prevalence commercial production areas. This may necessitate the application of conventional control methods or the release of sterile insects or both in the buffer zone, and may be either temporary or more permanent.

### *9.1. Temporary Buffer Zones*

Eradication programmes that proceed in stages or blocks, irrespective if a rolling-carpet or wave principle is adopted, might require buffer zones between the intervention blocks to temporarily protect achievements made in each new operational stage of the advancing programme. These temporary buffer zones have two main objectives:

- To prevent a massive influx of the pest from areas where it is still uncontrolled to blocks where sterile insects are being released. Population reduction activities, normally implemented in blocks adjacent to the release blocks, often serve as temporary buffer zones (Figs. 4 and 5).
- To consolidate progress in areas where the pest has already been eliminated. Preventive sterile insect releases and other control activities are implemented in these areas adjacent to the population reduction and low prevalence areas (Fig. 1). Hence, these buffer zones attempt to ensure that any migrating gravid females, or

those that are transported across a permeable quarantine, cannot re-establish new populations.

Temporary buffer zones were established during the progressive eradication campaign of the New World screwworm in Mexico and Central America (Vargas-Terán et al., this volume). The programme was implemented according to the rolling-carpet principle, and always included (at the back end of the moving eradication front) a large screwworm-free buffer area in which sterile insects were released as an insurance in case screwworm-infected cattle was moved into the pest free area.

Such buffer zones are only established temporarily in the dynamic rolling-carpet or wave-principle approaches, and are progressively moved from block to block with the advancement of the eradication campaign (Fig. 4). Occasionally, special buffers are needed when the increasing size of the intervention front of an expanding programme exceeds the available resources, e.g. at a given stage, the multidirectional moving front of a wave-principle strategy will be shifted to a front that proceeds temporarily in only one or two directions (Fig. 5). The areas where such buffer zones have to be established should be identified during the collection of baseline data and programme planning activities of the pre-intervention phase.

### *9.2. Permanent Buffer Zones*

Permanent buffer zones are often established for containment (Fig. 1). These buffers should have a width sufficient to intercept any immigrating insect and the capacity to deal with progeny of any gravid female that enters the area. In tsetse flies, for example, which are relatively poor fliers and have no free-living immature stage, the dispersal potential is much lower (Feldmann and Jannin 2001) than that of new world screwworms (Lance and McInnis, this volume). However, the potential for reinvasion of screwworm flies is much lower than that of polyphagous fruit flies, which are present in innumerable small hosts that can contain larvae, and are easily transported by travellers or postal shipments. Therefore, in addition to buffer zones, rigorous quarantine measures/procedures have to be established to intercept any insect that is transported passively with animal or plant commodities, e.g. fruit fly larvae in fruit, screwworm larvae in livestock, pets, and humans, codling moth pupae in packing boxes, and tsetse flies resting on vehicles.

A good example of a permanent buffer zone is the one that has been established permanently in eastern Panama as part of the New World screwworm programme to prevent this pest from dispersing from Colombia to the screwworm-free areas of Central and North America (Fig. 8). Aircraft release ca. 15–20 million sterile insects per week over a 30 000-km$^2$ area bordering with Columbia (APHIS/USDA 2001), and adjusting release densities based on risk areas within the barrier (3000 sterile flies per nautical mile$^2$ in low-risk areas and 6000 in high-risk areas). The large size of the Darien buffer zone is required because of the high mobility of screwworms; individual flies can cover distances up to 290 km (Hightower et al. 1964).

Another example is the sterile Mediterranean fruit fly buffer zone that has been maintained for approximately 40 years between Mexico and Guatemala as part of the Moscamed containment programme (Villaseñor et al. 2000; Enkerlin et al. 2015, 2017). The requirements and optimal dimensions for efficient buffers are often

underestimated and, when combined with insufficient resources, frequently result in the establishment of localized inefficient buffers that "leak".

Permanent buffer zones are also needed around low pest prevalence commercial production areas where suppression, rather than containment or eradication, is the strategic goal. The objective is to reduce the impact of gravid females moving into such areas by applying conventional methods of pest control or extending the sterile insect releases beyond the core commercial production areas. Once low pest prevalence has been achieved, releases could be decreased in the core area, while the buffer would continue with higher release rates and other population reduction activities (Larcher-Carvalho and Mumford 2004). In cases where the core area is well managed so that it does not contribute to the pest population (i.e. growers routinely remove all infestation sources of fruit flies such as fallen fruit, or citizens eliminate all *Aedes albopictus* (Skuse) mosquito breeding sites in an urban area), area-wide releases can focus mainly on the sources of the pest in the surrounding natural vegetation areas from where the pest reaching the core area originates (Kovaleski and Mastrangelo 2021; Liedo et al. 2021).

Since suppression is the strategic objective in these situations, these permanent buffer zones do not require the establishment of rigorous quarantine procedures, and can be much more modest than those required for containment or eradication programmes. Nevertheless, the width of these buffers also needs to be determined, taking into account pest mobility, host density, tolerable damage threshold, and population pressure from the surrounding areas (Barclay et al. 2011).

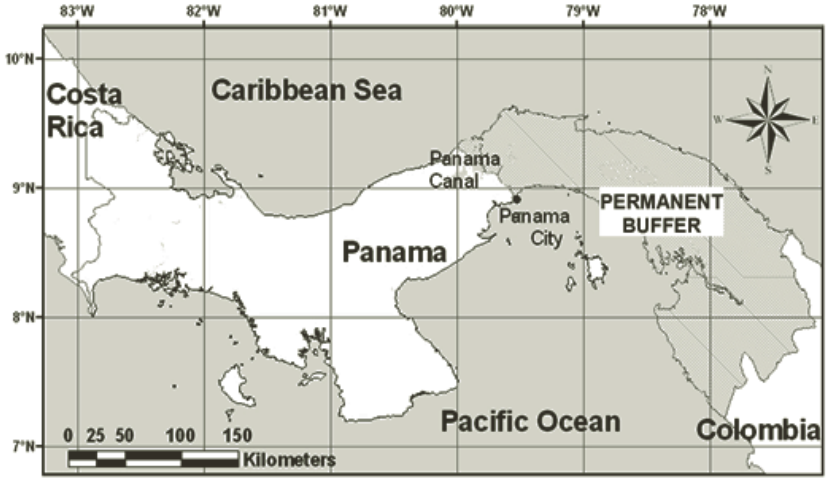


*Figure 8. The permanent buffer zone in the Darien Gap in Panama, consisting of the weekly release of sterile New World screwworm flies. (Map from R. B. Matlock, adapted.)*

## 10. CONCLUSIONS

Insect pest control using an AW-IPM approach with an SIT component is more complex and management-intensive than applying simpler control methods, and hence requires more initial baseline data collection, feasibility assessments, careful planning, and stakeholder involvement to ensure effective implementation. The SIT is a very powerful technique; for more than a half century it has been applied successfully for the eradication, suppression, containment or prevention of major insect pests. Unfortunately, too often it has been promoted as a "silver bullet", resulting in unrealistic expectations that then often cannot be fulfilled.

Programmes that attempt to eradicate a target insect population are particularly ambitious and challenging, but in reality are often poorly prepared, frequently underfunded, and lacking in public and in regulatory support to achieve their objective. In some cases, such programmes are operating without even the indispensable establishment of quarantine measures to protect a pest free area. In some of these situations, changing the strategy from eradication to containment or suppression is a more realistic option, but changes during ongoing implementation are politically costly, even if eventually successful. More modest initial goals, starting with a suppression objective to reduce insecticide use, or a containment effort to stop the spread of a pest, are often more realistic. If successful, such strategies can, under more favourable political, financial or technical situations, eventually be upgraded to an eradication strategy (Staten and Walters 2021).

Before embarking on an AW-IPM programme with an SIT component, the choice of strategy must be carefully assessed and prepared during pre-intervention and preparatory phases, ideally following a phased conditional approach, so that the programme is based on a thorough understanding of the target pest population as well as on adequate planning and implementation of the operational phase.

## SUMMARY

The rapid expansion of international travel and trade are facilitating the spread of non-native species, while climate change is creating new ecological niches enabling the establishment of pests in previously inhospitable regions. The temporary large-scale application of insecticides and "scorched earth" approaches are often indispensable to deal effectively with such outbreaks of invasive pests. However, even when the political will is there to implement the required systematic eradication efforts, they often result in public resistance to drastic actions such as the destruction of infested crops, herds, and orchards, and the indiscriminate insecticide spraying that raises concerns about damage to the environment and human health. Furthermore, such campaigns can still fail to achieve final eradication of all remnants of incipient populations. Therefore, and also in response to the enactment of environmental laws and regulations, increased efforts are needed to develop new and effective early detection and eradication tools that can prevent the establishment of a new pest in a less disruptive and more environment-friendly way. The sterile insect technique (SIT) is a proven method to prevent, contain, and eradicate outbreaks of invasive insect pest populations. It is an effective and ecology-friendly method that, unlike insecticides and other control methods, acts in an inversely density-dependent manner, and as a result increases its efficiency with decreasing population density. Therefore, it is particularly well-suited to eliminate incipient invasive-pest introductions and outbreaks when applied as part of an area-wide integrated pest management (AW-IPM) approach. When flooding a target pest population with sterile males, the wild virgin females (that are not controlled with other methods) are actively located and mated by the sterile males, producing no offspring. Some examples of eradication include incipient invasive populations of the painted apple moth *Teia anartoides* Walker in New Zealand, and the cactus moth *Cactoblastis cactorum* (Berg) in Mexico; major outbreaks (*Cochliomyia hominivorax (Coquerel)* in Libya); and all the way to fully established invasive pest populations (pink bollworm *Pectinophora gossypiella* (Saunders) in the southern USA and northern Mexico, and melon fly *Zeugodacus cucurbitae* (Coquillett) in the archipelagos of southern Japan). The SIT is also being used to contain invasive pest populations, such as *Ceratitis capitata* (Wiedemann) in southern Mexico, and preventively by releasing sterile insects over areas with a historically high risk of invasive pest incursions (*C. capitata* in California and Florida). There is great potential to expand the SIT application to similar situations against other major invasive insect pests. This chapter compares some eradication campaigns in the pre-SIT era with those integrating the SIT to eradicate, contain or prevent the establishment of non-native insect pests, and discusses the constraints and needs for contingency planning, including a proactive approach to develop the SIT package for other potential major invasive insect pests.

# 1. INTRODUCTION

## *1.1. Biological Invasions and their Cost*

Among the urgent major steps required to safeguard the imperilled biosphere, contained in a warning to humanity by more than 15 000 concerned world scientists from 184 countries, is the need to constrain the spread of alien invasive species (Ripple et al. 2017). These can interfere with ecosystem services or disrupt whole ecosystems, and cause the decline of many of the native species that are now listed as endangered or threatened (IUCN 2000; Charles and Dukes 2007; CBD 2018). When such invasive species no longer face the natural enemies and other direct competitors with which they evolved, they may breed without restraint, an "ecological release" that can have devastating effects on agriculture, public health, and the environment. The impacts of invasive species are second only to habitat destruction as a cause of global biodiversity loss (Pimentel 2002).

The global movement of non-native species is one of the costliest, most underestimated, and least known aspects of globalization (Bradshaw et al. 2016), resulting in massive ecological destruction and the spread of diseases, costing hundreds of billions [hundreds of thousands of millions] of US dollars a year to countries' plant and animal resources (CBD 2018). In North America, species of foreign origin constitute approximately 40% of the 600 serious arthropod pests which warrant control measures, and cause as much as 50% of the total economic losses by pest species (Klassen 1989; Kim 1991). Pimentel (2002) estimated the damage to the world economy inflicted by invasive alien species to be about 1.4 trillion [thousand thousand million] US dollars, which in 2002 represented about 5% of the total world economy. These significant costs of invasive-pest control and forgone output are an international "weakest link" public good, requiring effective regional and international coordination (Perrings et al. 2002).

## *1.2. Increasing International Travel, Trade, and Invasive-Pest Introductions*

The rapidly increasing international travel, transport and trade, moving people, agricultural commodities and animals as never before among geographic regions, has also significantly increased the probabilities of introducing invasive pest species into new regions (Lock 2019). Invasions are exacerbated by rising human populations, movement, wealth and international trade (Bradshaw et al. 2016). The rising volumes of shipped goods, the speed and containerization of transport, the high-volume air freight, and the establishment of trade agreements that facilitate international movement of goods, are all important components of globalization, which is directly linked to the fast spread of alien invasive species (Bright 1999). The rate of non-native species introductions has been growing in the past 200 years, from an average of 7.7 per year between 1500 and 1800 to a record 585 in 1996 (Hulme 2009; Nature 2017). For example, in Europe, the pattern of plant pest introductions since the early 1900s has increased steadily, with 67% of the introductions occurring in the second half of that century (Waage et al. 2008). Over time, arthropods and other invertebrates have increasingly become the most effective invaders (Fig. 1).

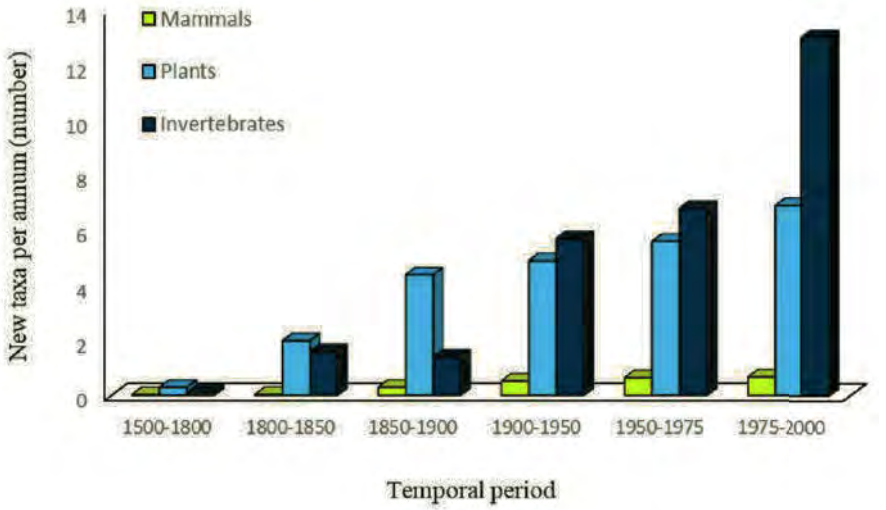

*Figure 1. New invasive taxa introduced per annum into Europe. (Modified from Hulme 2009, used with permission from Wiley & Sons.)*

Managing invasion pathways and this surge of exotic plant diseases and other potential pests is an ongoing challenge for many countries (VanDersal 2007; Hulme 2009). In spite of the application of more resources and improved technologies, inspection capacities for incoming cargo and passengers at ports of entry, the primary exclusionary strategy, are being overwhelmed in most countries in view of the rapidly rising flow of international passengers and cargo (Liebhold et al. 2006). Consequently, safeguard systems are often breached with potential for permanent, unintended, and often unpredictable disruption of ecosystems and economic damage.

Unfortunately, in relation to new pest invasions, the future is one of further increases in international travel and trade (Hulme 2009), while at the same time there is pressure to decrease insecticide residues and to liberalize and deregulate some sanitary and phytosanitary barriers to international trade (Perrings 2002; WTO 2018). Therefore, more invasive-pest introductions can be foreseen even if exclusion programmes are fortified based on new and improved technologies, stronger quarantine regulations, and less-lax enforcement of them at ports of entry, as well as the establishment of offshore risk-mitigation strategies and measures that are increasingly being implemented by some developed countries (Klassen et al. 2002; VanDersal 2007).

### *1.3. Interaction of Globalization and Climate Change*

Changes in climate due to the emission of anthropogenic greenhouse gasses are not only inducing changes in the distribution of many species, but are also facilitating increased survival of invasive pests in previously inhospitable regions (Ziska and Dukes 2014). Whereas the increase in movement and exchange of goods is

accelerating the redistribution of many insect pests, climate and related land-use changes will likely create new ecological niches, enabling the establishment of new pests in new territories and significant species-range shifts. Climate change projections to 2050 predict a net average increase of 18% in the area of occurrence of arthropod invaders (Bellard et al. 2013). This expansion applies not only to plant pests, but is also very relevant for vector-borne diseases (Higgs 2018), affecting not only the spatial-temporal distributions and population dynamics of the vectors, but also speeding up their life cycles, including those of parasites, their mode of transmission, opportunities for development in new hosts, etc. Higher temperatures can increase the rate of development of pests and pathogens, shortening their generation times and increasing the number of generations per year, which can lead to higher pathogen/parasite population sizes (Harvell et al. 2002; Barber 2016). To mitigate or address these climate- and globalization-induced new pest problems, new legislation and policies are required to manage the public good (Perrings et al. 2002, 2005). Among these is the need to support the development of innovative control approaches to mitigate and manage these biological incursions, and to contain the geographical expansion of non-indigenous pest populations.

### *1.4. Deliberate Introductions of Non-Native Species*

Not all introductions of non-native species into new regions are accidental; some occur with intent (Thomas 2002; Worner and Gevrey 2006). All introductions in support of classical biocontrol are deliberate to manage invasions mainly of arthropods or weeds that have succeeded to invade and have already become established. Overall, classical biocontrol has been a remarkable success, and it is so attractive because it is self-perpetuating in all the successful cases (Simberloff 2008). However, unforeseen environmental effects resulting from such deliberate introductions have also been recorded, including non-target species impacts and even extinctions, as well as numerous cases of biological control agents becoming direct pests (Howarth 1991; Simberloff and Stiling 1996; Follett and Duan 2000; Wajnberg et al. 2001).

The above cases highlight the risks and the need for a cautious approach when assessing the introduction of more non-native species to reduce the adverse impact of past introductions (Myers et al. 1998), although on the other hand excessive regulation has recently brought about an almost complete stop to natural enemy exploration for classical biocontrol programmes (van Lenteren 2021).

Non-indigenous species have been moved, and are also being moved, intentionally across regions for other purposes. Two examples are the introduction of the African honeybee into Brazil, and the subsequent spread of an Africanized hybrid in the Americas, or the release and establishment of dung beetles to reduce accumulation of bovine dung in pastures and rangeland, thereby seeking to reduce livestock disease vectors and parasites (Thomas 2002). Establishment of others was the consequence of escapes from other deliberate introductions, such as the gypsy moth *Lymantria dispar* (L.) (Klassen 1989), or the ongoing lucrative international trade in non-native pets, aquarium and terrarium species, and live bait and live food (Thomas 2002; CBD 2014).

Unfortunately, such “biological pollution” is worse than other pollution; when such deliberate introductions have gone wrong, they are essentially irreversible (Campbell 1993). Once non-indigenous species are established, they become permanent in space and time, unless serious efforts are made to eliminate such unwanted populations (Simberloff 2008).

Finally, there is the potential risk of the intentional release of major non-indigenous pests and diseases as weapons of agricultural warfare or bioterrorism to cause major socioeconomic damage. Also, there were allegations that some Mediterranean fruit flies *Ceratitis capitata* (Wiedemann) were deliberately released in California by opponents of aerial spraying used as part of eradication campaigns (Bonfante 1990; Cameron et al. 2001). Any such intentional events will also require early detection and rapid response capacities to be mitigated or eliminated.

In this chapter we describe how the sterile insect technique (SIT) (Knipling 1960), deployed as an important component of an AW-IPM approach (Hendrichs et al. 2007), is particularly suited for prevention, containment, and eradication of the described invasive insect pest problems (Knipling 1966), offering considerable social and environmental advantages over area-wide aerial spraying of insecticides and other drastic “scorched earth” interventions, which are increasingly no longer accepted by the public and strictly limited by environmental regulation.

## 2. MULTILATERAL TREATIES AND INVASIVE SPECIES

### *2.1. SPS Agreement and the WTO*

The Agreement on the Application of Sanitary and Phytosanitary Measures (the "SPS Agreement") entered into force with the establishment of the World Trade Organization (WTO) in 1995. It sets out the basic global rules for food safety, and animal- and plant-health standards, which should be applied only to the extent necessary to protect human, animal or crop life or health. Harmonized regulations must be based on science, and should not arbitrarily or unjustifiably discriminate among countries as an excuse for protecting domestic producers (WTO 2018).

The WTO’s objective is to ensure that international trade flows as smoothly, predictably, and freely as possible (WTO 2018), and its SPS Agreement has been relatively successful in its intended deterrence of regulatory protectionism, while significantly increasing safe trade opportunities (Heather and Hallman 2008). However, this objective, at least in some countries or regions with poor animal health and plant protection infrastructure, may enable the spread of invasive species. Nevertheless, even though the WTO is largely focused on overcoming and minimizing protectionist barriers to trade, the SPS Agreement does support the enforcement of measures, such as postharvest treatments and other exclusion and risk-management approaches, to avoid the entry or establishment of non-indigenous pests and diseases of animals and plants.

This is the mandate of the World Animal Health Organization (Office International des Epizooties, OIE) and the International Plant Protection Convention (IPPC) based at the Food and Agriculture Organization of the United Nations (FAO); they safeguard world trade in support of the SPS Agreement by harmonizing sanitary

and phytosanitary measures, respectively, so that countries apply them in a transparent way based on international standards. Most countries are parties to these organizations, and are organized into regional animal health and plant protection organizations (Heather and Hallman 2008).

As relevant as the above organizations in terms of international standardisation is the Convention on Biodiversity (CBD), established by the United Nations Environmental Programme (UNEP) in the early 1990s, whose mandate is protecting biodiversity and the environment, and thus assessing the risks associated with the introduction of invasive species (CBD 2014, 2018). The CBD is supported by funding mechanisms such as the Global Environment Facility (GEF) and international partnerships such as the Global Invasive Species Programme (GISP), and the International Union for the Conservation of Nature (IUCN) with its Invasive Species Specialist Group (ISSG), which is a global network of scientific and policy experts on invasive species (IUCN 2000).

### *2.2. Terminologies and Definitions*

Terminologies and definitions used in the different agreements and conventions in relation to invasive species vary considerably. Most relevant are those available from the CBD, the IPPC, and the OIE. Besides varying, they often have distinct meanings (Box 1). This is understandable because the focus of the CBD is on protecting biodiversity and the environment, but the mandates of the OIE and the IPPC are more oriented towards protecting commercial agriculture and related trade, respectively, covering sanitary and phytosanitary issues in support of the SPS Agreement.

For example, for CBD purposes, an *alien species* is already present in the area that is not within its native distribution, whereas the IPPC is more concerned with organisms that are not yet present in the area of concern, i.e. *quarantine pests*. Thus, for IPPC and OIE the term "*alien*" is not appropriate. Even though terms such as "*exotic*", "*non-indigenous*" or "*non-native*" have been used in the International Standard for Phytosanitary Measures (ISPMs), the term "e*xotic*" is not considered suitable because it presents translation problems (IPPC 2018); therefore "*non-indigenous*" or "*non-native*" are favoured by IPPC and OIE (Box 1).

Another difference is that for CBD a species that is non-indigenous and has entered an area through natural means is not an alien species; it is simply extending its natural range. On the other hand, for IPPC purposes, such a species could still be considered as a potential *quarantine pest* (IPPC 2018).

Other relevant terms used in relation to invasive species and responses to them can also differ significantly (Box 2). For example, whereas *eradication* is complete and permanent at the species level *worldwide* for WHO, for IPPC and OIE it is the local *elimination* of a pathogenic agent or pest population from *a country, area* or *zone* (Heymann 2006). On the other hand, *elimination* is the term used by WHO for the local reduction to zero (or a very low defined target rate) of new cases of an infectious disease, requiring continued measures to prevent re-establishment (Heymann 2006).

In view of the definitions in Boxes 1 and 2, since SIT implementation in relation to invasive species is applied mainly against insect pest populations in the context of agriculture and agricultural trade, or against populations of disease vectors in the context of public health, primarily the IPPC and OIE terms will be used in this chapter.

*Box 1. Definitions of Terms Related to Invasive Species*

*Alien Species (= Non-Native Species, = Foreign Species)*

A species, subspecies or lower taxon, introduced outside its natural past or present distribution; includes any part, gametes, seeds, eggs, or propagules, of such species that might survive and subsequently reproduce (CBD 2018). "Alien" refers only to the location and distribution of an organism compared with its natural range. It does not imply that the organism is harmful (IPPC 2018).

*Alien Species*

Alien species are taxa that are introduced outside of their natural range, either intentionally or unintentionally (IUCN 2000).

*Exotic Species (= Introduced Species)*

A species occurring in an area outside of its historically known natural range as a result of intentional or accidental dispersal by human activities (IUCN 2000).

*Hitchhiker Organism*

Organism that has an opportunistic association with a commodity or vehicle/vessel or container, and which may be transported unintentionally to a new environment (OIE 2012).

*Introduced Species*

An introduced, alien, exotic, non-indigenous, or non-native species, or simply an introduction, is a species living outside its native distributional range, which has arrived there by human activity, either deliberate or accidental (Wikipedia).

*Invasive Species*

Species that tend to spread beyond their native range to new areas. Invasive species are those plants, animals, and microbes not native to a region which, when introduced either accidentally or intentionally, cause economic or environmental harm or harm to human health (NAL 2008).

*Invasive Alien Species (= Alien Invasive Species*)

An *alien* species whose introduction and/or spread outside its natural past or present distribution threatens biological diversity and whose impact involves significant harm (CBD 2018).

*Invasive Non-Native (or Invasive Alien) Animal*

Animal that has been introduced and subsequently become established and spread outside its native distribution area and caused harm to the environment, animal or human health, or the economy (OIE 2012).

*Native Species (=Indigenous Species)*

Species that have historically occurred as part of an ecosystem in a specific location (Wikipedia).

*Non-Indigenous Species*

An *invasive alien species* (CBD) is an exotic or non-native species that by its establishment or spread has become injurious to plants, or that by risk analysis is shown to be potentially injurious to plants (IPPC 2018). For CBD a non-indigenous that has entered an area through natural means is not an alien species; it is simply extending its natural range.

*Quarantine Pest*

A pest of potential economic importance to the area endangered thereby but not yet present there, or present but not widely distributed and being officially controlled (IPPC 2018**).**

*Box 2. Definitions of Other Relevant Terms in Relation to Invasive Species*

*Containment*

Application of phytosanitary measures in and around an infested area to prevent spread of a pest (IPPC 2018).

*Elimination*

Reduction to zero (or a very low defined target rate) of new cases of disease or infection in a defined geographical area as a result of deliberate efforts; continued measures to prevent re-establishment of transmission are required (WHO, Heymann 2006).

*Entry*

Movement of a pest into an area where it is not yet present, or present but not widely distributed and being officially controlled (IPPC 2018).

*Eradication*

The complete and permanent *worldwide* reduction to zero new cases of an infectious disease through deliberate efforts; no further control measures are required (WHO, Heymann 2006).

*Eradication*

Application of phytosanitary measures to eliminate a pest from an *area* (IPPC 2018).

*Eradication*

The elimination of a pathogenic agent from a country or zone (OIE 2012).

*Establishment*

Perpetuation, for the foreseeable future, of a pest within an area after entry (IPPC 2018).

*Establishment*

The process of an alien species in a new habitat successfully producing viable offspring with the likelihood of continued survival (CBD 2018).

*Incursion*

An isolated population of a pest recently detected in an area, not known to be established, but expected to survive for the immediate future (IPPC 2018).

*Introduction*

The entry of a pest resulting in its establishment (IPPC 2018).

*Introduction*

The movement by human agency, indirect or direct, of an alien species outside of its natural range (past or present). This movement can be either within a country or between countries or areas beyond national jurisdiction (CBD 2018).

*Intentional Introduction*

The deliberate movement and/or release by humans of an alien species outside its natural range (CBD 2014).

*Outbreak*

A recently detected pest population, including an incursion, or a sudden significant increase of an established pest population in an area (IPPC 2018).

*Phytosanitary Measure*

Any legislation, regulation or official procedure having the purpose to prevent the introduction and/or spread of quarantine pests, or to limit the economic impact of regulated non-quarantine pests (IPPC 2018).

*Point of Entry*

Airport, seaport, land border point or any other location officially designated for the importation of consignments, or the entrance of persons (IPPC 2018).

*Spread of a Pest*

Expansion of the geographical distribution of a pest within an area (IPPC 2018).

### *2.3. Three-Stage Hierarchical Response, and Principle of Regional Solidarity*

Although legally non-binding, the above multilateral conventions prescribe that countries shall, as far as possible and where appropriate, follow a "three-stage hierarchical response approach" to mitigate the risk of non-native species invasions (CBD 2018):

#### *2.3.1. Prevention of Introduction*

Priority should first be given to exclusion to prevent the entry of harmful non-native species which threaten ecosystems or livelihoods. Prevention is generally far more cost-effective and environmentally desirable than measures taken following introduction and establishment of a non-native invasive species (CBD 2018).

The cornerstone of safeguarding systems is exclusion based on effective quarantine procedures and thorough inspection at ports of entry. Nevertheless, these can only minimize entries, but are not the most reliable line of defence for exclusion (Liebhold et al. 2006, 2016). Therefore, at least for trade in agricultural commodities, pest risk-mitigation measures at the points of origin are among the more viable approaches to strengthen pest exclusion, as well as identifying paths of high risk to develop improved preventive measures (Klassen et al. 2002).

To mitigate the arrival of invasive-pest risks, the USA has been focusing on offshore strategies. One of these is the Offshore Pest Information System (OPIS) -- a secure web-based information sharing tool that allows users to communicate in an organized manner about offshore plant and animal health events and issues. The OPIS was designed to allow the USA to respond quickly and effectively to offshore plant pests that could potentially threaten the USA (VanDersal 2007).

#### *2.3.2. Prevention of Establishment*

In case the quarantine system is breached and incursion of an invasive pest has taken place, the next priority should be eradication over control (containment or suppression) to eliminate the invasive population as soon as possible. Where it is feasible, eradication is often the best course of action to deal with the introduction and establishment of invasive species (CBD 2018). Thus, the CBD *precautionary principle* does not apply, in the same way, for the elimination of populations of species that have invaded areas outside their native range (CBD 2018).

The best opportunity for eradicating invasive species is in the early stages of invasion, when an outbreak has occurred and incipient populations are still relatively small and localized. This requires early detection systems focused on high-risk points of entry, and availability of contingency plans (see USDA (2015) for examples of action plans) and emergency response funds, to allow rapid action against the invasive populations. This is the preferred response because preventing establishment is a much more viable and cost-effective approach than having to permanently "live with" a new pest. However, appropriate technology specific for the invading species, required for early detection and eradication, is often lacking, causing delays in the initiation of response actions (Liebhold et al. 2006). On the other hand, generic eradication tools such as insecticides or systematic elimination of plant or animal

hosts are generally less effective to achieve eradication at the low pest densities common at early stages of invasion. Therefore, more eradication tools are needed that are environment-friendly and effective at low to very low densities.

### *2.3.3. Prevention of Spread and Damage*

The third priority is *containment*, if possible to prevent or slow the spread of the pest into free areas. It involves the application of *sustainable long-term control measures*, including the establishment of containment barriers (Barclay, this volume), based on the analysis of benefits and costs (environmental, economic and social). However, this third response in the three-stage hierarchy should be chosen only in case eradication is not technically feasible or resources are not available for eradication. Control measures within the containment barriers should focus on reducing the damage caused as well as the numbers of the invasive species population. Effective control will often rely on a range of integrated management techniques, implemented according to existing national regulations and international codes.

### *2.3.4. Principle of Regional Solidarity*

According to the SPS Agreement, countries are only technically justified in protecting plant and animal life and health on their own territories. Thus, invasive-pest introductions into a region generally lack regional cooperation, and are managed at the national level, if at all.

However, most countries have contiguous territory with neighbouring countries and are not isolated islands. Therefore, it is in their interest, under "the principle of regional solidarity" (EPPO 2003), to proactively cooperate directly in support of weaker neighbouring countries, or to join forces through regional animal health and plant protection organizations, to prevent pest establishment anywhere within a region, and not only when the introduction reaches their own territory.

Equally, if the establishment of a major invasive pest in one country presents a risk of natural spread to neighbouring countries, these countries also need to act in regional solidarity, even if they face lesser risks than other countries in the region, by taking all necessary measures to prevent the spread of the pest beyond their territories, and to accept support from neighbours and regional partners to eliminate the outbreak (EPPO 2003).

Moreover, according to IPPC Article VIII, contracting parties should cooperate with one another to secure coordinated effective action to prevent and control the introduction and spread of pests that can affect agriculture, food security, and biodiversity (IPPC 2012). The regional plant protection organizations (RPPOs) are important partners to the IPPC in terms of developing concrete actions to fulfil its objectives including the implementation of capacity-building programmes.

## 3. "SCORCHED EARTH" APPROACHES IN INVASIVE-PEST ERADICATION CAMPAIGNS

### *3.1. "Scorched Earth" Eradication Approaches*

Success is not guaranteed in campaigns that attempt eradication of invasive-insect pest introductions and outbreaks, even when the political will and resources are available to implement the required eradication efforts. In addition, such campaigns often lack the tools to surgically remove all individuals of a target population and must rely, once the decision to eradicate has been made, on what has been called a "scorched earth" approach (Ayers 1957; Griffing et al. 2015). This usually entails the large-scale application of insecticide sprays, often indiscriminately affecting target and non-target organisms, as well as the drastic removal of all infested animals and plants, or even the massive destruction of whole herds, crops, and orchards. Even though generally very unpopular, such large-scale application of insecticides and other "scorched earth" interventions and their temporary negative effects must often be accepted when no better tools are available in dealing with outbreaks of major pests that warrant no compromise (Klassen 1989). This applies not only to insect pests but also to other pests, both in agriculture and increasingly in conservation; therefore, the development of new and more species-specific eradication techniques is essential (Owens 2017). Examples of such "scorched earth" eradication campaigns are described below.

#### *3.1.1. Mediterranean Fruit Fly Eradication in the Pre-SIT Era*

When the Mediterranean fruit fly invaded Florida in the early twentieth century, there was a complete absence of methods for its detection and control. Ayers (1957) described the 1929 *C. capitata* eradication programme in Florida as

> based on a veritable scorched earth policy, in which host plants and produce were destroyed in eliminating all possible breeding sites for the Mediterranean fruit fly. A huge field force of more than 5000 men was needed to carry on this programme, gathering host fruits and vegetables, uprooting many host plantings and spraying host trees with a baited insecticide

(which consisted of lead arsenate with syrup, molasses, and sugar). National Guardsmen manned quarantine roadblocks to limit the movement of infested plants and produce. Nevertheless, the 1929 invasion still moved into 20 counties before it was finally eliminated using this drastic approach.

In the 1956 Florida outbreak, the pest invaded 28 counties, and it took 21 months and another major campaign to finally achieve eradication (Ayers 1957). This time no host trees were destroyed, although mass-trapping was applied, together with aerial malathion bait sprays, with full coverage of the huge infested area that included Miami, as well as south and central Florida. The aggregate total area covered was more than 2.6 million hectares sprayed. In addition, extensive dieldrin treatments were made to the ground to kill larvae and pupae.

The Mediterranean fruit fly invaded the island of Bermuda around 1860, and was established there for the next 100 years (Hilburn and Dow 1990). The first eradication programme, started in 1907, and based mainly on eliminating all major host trees and stripping unripe fruit from other hosts, eventually failed. A second attempt was initiated in 1957 in the wake of the recent successful programme in Florida. It was also based mainly on intensive trapping and malathion bait sprays applied in orchards every 8–10 days, augmented with sprays of dieldrin to the ground. These activities continued until 1962 when eradication was achieved.

The approach followed in these large Mediterranean fruit fly programmes in the pre-SIT era, when only very crude methods were available that significantly inconvenienced growers and the public, confirmed the need to develop more species-specific, and therefore more environment-friendly, eradication tools.

#### *3.1.2. Codling Moth Eradication in Southern Brazil*

Another example from plant pests is the codling moth *Cydia pomonella* (L.), first detected in the early 1990s in mostly urban areas of apple-growing regions in southern Brazil. A National Programme for the Eradication of the Codling Moth installed and monitored more than 10 000 traps and destroyed close to 100 000 host and potential host trees in Santa Catarina and Rio Grande do Sul, states that produce 95% of Brazil's apples. Social mobilization was also required to overcome public opposition to these eradication measures. For example, the owners in urban and suburban areas, by agreeing to the removal of all their host trees, received in exchange for uprooted plants the same amount of non-host plant species. The eradication of the isolated populations of the codling moth in the four infested urban settings was concluded in 2011 (Kovaleski and Mumford 2007; Capra 2014).

#### *3.1.3. Tsetse Eradication in Principe Island*

One example in the livestock area is the control of tsetse flies (*Glossina* spp.) in sub-Saharan Africa. During colonial times, one component of early tsetse eradication programmes involved complete removal of bush and woody vegetation from target areas, as tsetse tend to rest most of the time on the trunks of trees. This destruction of the flies' habitat made an area inhospitable to them, and protected humans and livestock from the tsetse-vectored diseases (Leak 1999; Bouyer and Vreysen 2018). This strategy is no longer accepted, although rapid human population growth, resulting in the opening of new agricultural lands, is having a similar effect.

Another early technique used in tsetse eradication included slaughtering all the game and wildlife that tsetse fed on, leading to the disappearance of the fly through starvation. For example, the Portuguese island of Principe in West Africa, where tsetse apparently only invaded in 1825 with the importation of cattle (trypanosomosis arrived only in 1877), was entirely cleared of feral pigs and dogs in the 1930s which, together with other measures, led to tsetse elimination (Leak 1999).

#### *3.1.4.* Anopheles gambiae *Eradication in North-Eastern Brazil*

An example in the public health area is the eradication of *Anopheles gambiae* Giles in north-eastern Brazil. This vector of malaria was introduced to Brazil in 1930 from

Senegal, facilitated by the establishment of mail service by seaplanes between Dakar and Natal that started in 1928 (Griffing et al. 2015). In 1931 in Natal there were already 344 deaths, and in response the Rockefeller Foundation's yellow fever service helped the Brazilian government eradicate the Natal outbreak using Paris green (copper acetoarsenite). Nevertheless, *An. gambiae* still spread along the coast, at an average speed of 64 km per year, and by 1938 reached the north-west of Natal, where in some areas 10% of the population died, and crops were no longer planted.

The Government and the Rockefeller Foundation decided that an autonomous, well-funded and highly trained organization needed to be created to eradicate *An. gambiae*. In 1939 President Getúlio Vargas decreed the creation of the North-East Malaria Service (*An. gambiae* having spread 483 km to the west of Natal -- more than 30 000 $km^2$). As it raised the spectre of eventually reaching the Panama Canal, the Rockefeller Foundation assisted in the financing and organization of the new service, using the infrastructure created for the yellow fever service. Frederick Soper directed this project from 1939–1941, managing these war-like efforts with a "scorched earth" approach to a 16-km perimeter around *An. gambiae* range limits (Griffing et al. 2015). The entire area was mapped from the air to ensure no collections of water were left untreated with larvicides within the perimeter or the infected zone. Homes were sprayed with insecticides, and every car and train that left the area was fumigated, as well as every boat and plane disinfected before leaving for uninfested ports. The last *An. gambiae* larva was reported in 1940. Eradication success was aided by the indoor-biting behaviour *An. gambiae*, the use of staff that had previously worked on the *Aedes aegypti* (L.) campaign, and a militaristic approach to programme management. The success in eradicating *An. gambiae* rehabilitated the concept of malaria eradication through vector control (Griffing et al. 2015).

### *3.2. Unsuccessful "Scorched Earth" Programmes and Public Outrage*

It is no surprise that such "scorched earth" measures increasingly resulted in significant public resistance. Most resented were the indiscriminate insecticide applications by air that raised public concern and outrage about possible damage to the environment and human health. As described dramatically in Rachel Carson's *Silent Spring* (Carson 1962), which called for more applied ecology, the early synthetic insecticide era led to several ill-conceived invasive-pest eradication campaigns, sometimes promoted by vested interests. These relied excessively on large-scale aerial sprays of highly residual insecticides, with broad-spectrum action, applied repeatedly with devastating impact on wildlife and the environment, but often also resulting in the development of resistance before achieving eradication.

Referring to such unsuccessful large-scale eradication campaigns, van den Bosch (1978), in his book "The Pesticide Conspiracy", was very critical of some APHIS-USDA programmes (Animal and Plant Health Inspection Service of the Unites States Department of Agriculture) in the 1950 to mid-1970's, calling it the "scorched earth insect eradication agency". His book is a story of insecticide industry-driven eradication programmes, greed and politics, that led to the so-called "pesticide treadmill" during the 1950–1970s, but likewise the surge of opposing forces that promoted more ecologically based approaches and the beginning of the IPM era.

Also, Ehrlich (1979) referred to "numerous scorched-earth spray campaigns in which huge areas were doused with biocides in unsuccessful major efforts to eradicate pests such as the Japanese beetle *Popillia japonica* Newman, spruce budworm *Choristoneura* spp., and the red imported fire ant *Solenopsis invicta* Buren". According to Metcalf (1996), these failed and thoroughly detrimental invasive-pest eradication programmes were responsible for much of the ensuing public disenchantment with entomologists and insect control.

Among the largest of these programmes, exemplifying how a lack of suitable eradication tools can doom a programme, even when there is strong political will to succeed, was the one against red imported fire ants. This invasive pest was introduced from South America into the south-eastern USA in the 1930s, and eradication was attempted in various campaigns, the largest in the 1950s, involving the aerial dusting and spraying of millions of hectares of urban, agricultural, and natural land in the south-eastern United States. All areas within the vast fire ant control region, whether treated with heptachlor or dieldrin, reported major collateral damage to wildlife and domestic animals, and disastrous effects on aquatic life, while success was not achieved (Carson 1962). A follow-up campaign between 1962 and 1975, this time using mirex, another very toxic, residual, and lipophilic hexachlorocyclopentadiene, applied approximately a quarter of a million kilograms of this product in the form of baits, again with very negative environmental impact. The programme was finally suspended without succeeding, and the use of mirex was banned in 1978. On the other hand, the cost of the ecological and financial failure has been the continued spread of this major pest throughout the southern USA, also reaching southern California. Furthermore, the USA is now spending more than USD 5.5 billion (thousand million) annually to manage and "live with" this agricultural, recreational, and public health problem (Klassen 1989; Vander Meer et al. 2007).

### *3.3. Boll Weevil Eradication Programme*

The above cases of unsuccessful, invasive-pest eradication programmes, relying excessively on synthetic insecticide sprays, unfortunately left in academic circles and the public a negative disposition towards large and controversial eradication campaigns, even though the described situation resulted in the establishment of environmental legislation and its strict application in such programmes by USDA and other governments. Nevertheless, Myers et al. (1998) still concluded that eradication programmes have largely been ecological and financial disasters, while the benefits of eradication are generally overestimated, and the costs are understated. Nonetheless, often the careful elimination of an invasive pest, despite some temporary ecological disruption, can in the end be more environment-friendly than forever having to "live with" a new major pest that requires permanent and significant additional insecticide use.

A recent example of a more carefully executed large eradication programme is the boll weevil *Anthonomus grandis* Boheman that invaded the USA in the late 19th century from its native distribution in Central Mexico. By the 1920s it had infested all USA cotton-growing areas, devastating the industry with significant social impacts (such as mass-migration of farm labourers to industries in the north), and resulting in

a drastic increase in insecticide use in cotton cultivation. This in turn caused several species of moths and other insects to develop into important secondary pests because of the elimination of their natural enemies, which in turn resulted in even more insecticide application in spite of major efforts to develop IPM programmes.

Following the above negative cases, there was understandably much opposition in academia to embarking on a large boll weevil eradication campaign. Nevertheless, in view of the economic and environmental problems posed by this pest and its control, and strong cotton industry and USDA leadership, successful pilot projects were carried out in the late 1970s showing the potential of combining area-wide application of cultural and quarantine practices with limited insecticide applications to achieve eradication. Even though there was disagreement with academia on the outcome, in 1983 the boll weevil eradication programme was started (Klassen 1989; El-Lissy and Grefenstette 2007). Initiation of the programme in each new county was preceded by grower referendums (2/3 of the vote required) to obtain the growers' agreement and commitment. Grower funds, with some state support, accounted for over 70% of the programme operational budget, with less than 30% of funds provided by the federal government (Kazmierczak and Smith 1996).

The eradication programme was based on thorough mapping of host areas, using pheromone-baited traps for detection, and sound cultural practices (uniform times for planting and harvesting, and residue destruction) applied rigorously on an area-wide basis, together with carefully timed aerial applications of malathion ultra-low volume in the spring. Releases of sterile *A. grandis* were not included because of the midgut damage caused by sterilizing radiation doses (Riemann and Flint 1967).

In some regions, sprays temporarily reduced seasonal mean densities of predators, with populations of beet armyworm *Spodoptera exigua* (Hübner), heliothine and other lepidopteron larvae, and the cotton aphid *Aphis gossypii* Glover, often increasing substantially in cotton fields under boll weevil eradication (Knutson et al. 2011). Nevertheless, the programme was a major success with the boll weevil eradicated from all USA cotton regions (from Virginia to California, as well as a portion of north-western Mexico, except for an area still under treatment in Texas and infested areas of northern Mexico), covering many millions of hectares of cotton production, and resulting in increased yields and much declined pest control costs. Most important are the ensuing environmental benefits in view of the dramatic and sustained reduction in overall insecticide use, largely sparing biological control agents that control *Helicoverpa* spp. and other secondary cotton pests (Klassen 1989; El-Lissy and Grefenstette 2007). This programme, together with the New World screwworm *Cochliomyia hominivorax* (Coquerel) eradication programme (Klassen et al., this volume; Vargas-Terán et al., this volume), are among the biggest and most successful insect control programmes in history.

## 4. STERILE INSECT TECHNIQUE, AN ENVIRONMENT-FRIENDLY ERADICATION TOOL

In contrast to the above described approaches, the SIT is a proven, clean technique that can eradicate, contain or prevent the establishment of an invasive population without raising public opposition or leaving an "ecological footprint". Since it is

species-specific, and therefore does not affect beneficial and other non-target organisms, it is an ideal tool to eradicate invasive insect pest populations. Its integration, especially in the later phases of eradication campaigns, is particularly effective in view of its inverse density-dependence: the lower the target population, the sooner it will reach the objective of eradication. It also integrates well with other biologically based suppression methods. It can be applied by air, and consequently is effective over irregular topography and areas with limited access, which are often major challenges in eradication campaigns that need to address the invasive pest population on an area-wide basis (Dowell et al., this volume; Hendrichs, Vreysen et al., this volume; Klassen and Vreysen, this volume; Klassen et al., this volume; Mangan and Bouyer, this volume).

### *4.1. Successful Cases of SIT-Based Eradication of Invasive-Pest Outbreaks*

Below several cases exemplify the successful integration of the SIT as an environment-friendly eradication tool, starting with the elimination of:

a) incipient populations in beachheads or bridgeheads and small areas/islands (gypsy moth in parts of the USA (Simmons et al., this volume); painted apple moth in New Zealand; cactus moth in Yucatán, Mexico; melon fly *Zeugodacus* (= *Bactrocera) cucurbitae* in the Mariana Islands; Mediterranean fruit fly in California, Chile, South Australia; solanum fruit fly *Bactrocera latifrons* (Hendel) in Yonaguni Island, Japan; Queensland fruit fly *Bactrocera tryoni* (Froggatt) in South Australia and Tasmania; sweetpotato weevil *Cylas formicarius* (F.) in Kume Island, Japan; etc.); to
b) major outbreaks over larger areas (*C. hominivorax* in Libya; *C. capitata* in the Dominican Republic, in southern Mexico; etc.); all the way to
c) fully established invasive pest populations in whole regions (pink bollworm in south-western USA and north-western Mexico; melon fly in all archipelagos of southern Japan; etc.).

#### *4.1.1. Painted Apple Moth in New Zealand*

The Australian painted apple moth is a polyphagous pest that is native to south-eastern Australia and Tasmania. An incursion of this moth into New Zealand in May 1999, infesting an area of ca. 12 000 hectares in West Auckland, threatened the country's natural ecosystems, as well as its horticulture crops and plantation forestry (Suckling et al. 2007).

The presence of this non-native pest triggered the establishment of an area-wide eradication programme managed between 1999 and 2006 by the New Zealand Ministry of Agriculture and the Forestry Biosecurity Authority. The programme integrated ground searches, the deployment of irradiated sentinel virgin females within traps (there was no effective pheromone), host removal where possible, ground and some aerial applications to host trees in hot spots using chlorpyrifos, deltamethrin and the biopesticide *Bacillus thuringiensis* (Berliner) var. *kurstaki* (*Btk*), and the first use of the SIT against this pest. The SIT was favoured because of its effectiveness as an "end game tactic" at very low population levels, and the strict environmental

requirements in New Zealand that seriously limited the application of other eradication tools (Suckling et al. 2007).

Development of mass-rearing provided the sterile females for an array of up to 2000 georeferenced traps that were serviced weekly. In addition, marked sterile males were also used for dispersal studies. The lower irradiation dose chosen (100 Gy), needed to induce inherited sterility, offered the best trade-off between sterility and male competitiveness (Suckling et al. 2005). Irradiated males were recaptured in the field up to 10 km away, showing good flight capacity, although they were only 66% as successful as non-irradiated males in seeking females (but their ability to copulate was not affected).

After delimitation of the infested area in 1999–2000, ground applications in 2001–2002 were followed by aerial *Btk* sprays. After suppressing the pest population to ca. 1% of the original population level, releases of sterile insects started in January 2003 and lasted until April 2004 to eliminate remnants of the population. Achieving overflooding ratios up to 100:1 (based on trapping data) drove the wild population to extinction (Suckling et al. 2005). Small-scale releases were reinitiated in 2005 and 2006 because of captures of several males (genetic analyses indicated that they originated from separate incursions) (Suckling et al. 2007).

If no action had been taken to eradicate the invasive painted apple moth populations, the economic and ecological impact of the moth's incursion was estimated at approximately USD 30–213 million over 20 years (Suckling et al. 2007). The authors have called such cost-effective small-scale programmes, targeted at eradicating early detected populations, where only limited numbers of sterile insects must be released each week, as “boutique” SIT.

#### *4.1.2. Cactus Moth in Yucatán*

*C. cactorum* occurs naturally in Paraguay, Uruguay, northern Argentina, and southern Brazil. Considering its wide host range within the Opuntioidea, it represents a great threat to important *Opuntia* ecosystems and cultivation in North and Central America. In Mexico, Cactaceae have the greatest diversity, and *Opuntia* cacti are viewed as having major ecological, socio-economic, and cultural importance (Zimmermann et al. 2007).

The cactus moth is regarded as one of the most successful classical biological control agents. For example, in Australia, the cactus moth effectively controlled approximately 25 million hectares of non-native *Opuntia* that had invaded and densely colonized cattle-grazing lands (Dodd 1940). In the 1950s the cactus moth was released for this same purpose in some Caribbean islands, but has since then been expanding its range in this region. From there it subsequently invaded Florida in 1986, and has been gradually advancing along the Gulf of Mexico coast of Alabama, Mississippi, Louisiana, and more recently Texas, increasingly representing a serious threat to the semiarid ecosystems in the south-western USA and Mexico (Bloem et al. 2007; Hernández et al. 2007).

In view of this threat, the Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture encouraged the Mexican Ministry of Agriculture to establish a permanent monitoring programme for the cactus moth in risk areas throughout Mexico (IAEA 2003). This trapping network detected outbreaks of the pest in Isla

Mujeres in July 2006, and in Contoy Island National Park in May 2007, as well as moth presence on the Quintana Roo mainland near Cancún in January 2007. In response, a Programme for the Eradication of the Cactus Moth in the Yucatán Peninsula was launched, involving coordinated efforts among the Mexican Ministry of Agriculture, USDA, and the Joint FAO/IAEA Division (Bello-Rivera et al. 2021). To eradicate these incipient pest populations in Mexico, the outbreak areas were delimited through increased surveillance, and an AW-IPM approach was implemented -- involving the establishment of sentinel sites, moth egg-stick removal and host removal in some areas, followed by the release of sterile moths produced by USDA in Tifton, Georgia (Hight et al. 2005; Bello-Rivera et al. 2021).

Following a two-year campaign, the outbreaks were officially declared eradicated in February 2009 after three biological cycles without any pest detection since the last moth find (Barclay et al., this volume; Vreysen, this volume). Significant damage was avoided to the economically important Mexican cactus and prickly pear industries, as well as to whole ecosystems based on *Opuntia*. Routine surveillance has continued, and through the project Mexico developed the capacity for early detection and eradication of the cactus moth from its national territory (Bello-Rivera et al. 2021).

#### *4.1.3. Melon and Oriental Fruit Flies in Mariana Islands and Okinawa Archipelago*

The first successful use of the SIT against an insect pest, other than the New World screwworm, was the eradication in 1963 of the melon fly in Rota in the Mariana Islands (Steiner et al. 1965). Considered native to India, this very destructive pest of cucurbit crops and other fruits has spread to many regions and is now found in more than 40 countries in South and Southeast Asia, sub-Saharan Africa, and the Pacific region (CABI 2017). It reached the islands of Rota, Saipan, and Tinian by 1943, interfering with the export of fruits and vegetables that the farmers in these islands had been commercially producing for many years, and resulting in the need for costly phytosanitary treatments to permit the continuation of export shipments.

The eradication campaign conducted in Rota involved first surveillance (1960–1962), followed by bait sprays in host areas to suppress the melon fly population by ca. 75%, and then weekly releases of between 5 and 11 million sterile flies by ground and air (1962–1963). These were mass-reared in Honolulu and shipped by commercial flights to Guam, where some were emerged and then shipped to Rota for aerial release, while others were transported directly to Rota where they emerged in the field. Overall 257 million sterile flies were released, and eradication was achieved in ca. six months, although releases continued for some months after that (Barclay et al., this volume; Vreysen, this volume). In 1963, the neighbouring islands of Saipan, Tinian, and Aguigan were also freed of the melon fly. Rota, however, being the closest island to Guam, experienced reintroduction of melon flies eight times up to June 1971. Each time the development of a melon fly population was prevented by prompt releases of sterile flies (Chambers et al. 1970).

Rota and the other Mariana islands were also freed of the oriental fruit fly *Bactrocera dorsalis*, another major invader, although mainly by area-wide application of the male annihilation technique (MAT), deploying toxic methyl eugenol baits. In the case of Guam, however, *B. dorsalis* eradication was achieved by the weekly release of 16 million sterile flies between September 1963 and February 1964, also

shipped from Hawaii, but only after a hurricane had drastically reduced the wild population (Steiner et al. 1970).

In the archipelagos of southern Japan, the oriental fruit fly was eradicated based only on MAT implementation (1968–1986), but not in the Ogasawara Islands where two years of area-wide MAT application failed to eradicate the *B. dorsalis* population. This lack of success appeared to result from males evolving a non-responsive behaviour to the methyl eugenol baits. Therefore, the SIT was added after suppressing the population with the MAT along with other methods, enabling the eradication of *B. dorsalis* also from these islands (Habu et al. 1984).

A much larger undertaking was the Japanese melon fly eradication campaign (Table 1). Between 1919 and 1977, *Z. cucurbitae* gradually invaded all the archipelagos of south-western Japan, where populations became fully established, causing major damage and the loss of cucurbit vegetable and fruit exports to mainland Japan, as well as threatening islands further north. Based on the positive experiences gained in Rota and other Pacific islands, in 1972 a major eradication programme was launched to gradually free each of the island groups that the melon fly had invaded.

*Table 1. Island groups in south-western Japan that* Zeugodacus cucurbitae *invaded and from where it was eventually eliminated following a major SIT-based eradication campaign between 1972 and 1993*

| Island group | Number of islands | Approximate total surface ($km^2$) | Year of melon fly invasion | Year of start of SIT releases | Year of final eradication |
|---|---|---|---|---|---|
| Yaeyama/Yonaguni | 32 | 586 | 1919 | 1989 | 1993 |
| Miyako Islands | 8 | 227 | 1929 | 1983 | 1987 |
| Kume Island | 1 | 60 | 1970 | 1972 | 1978 |
| Okinawa Islands | 9 | 1439 | 1972 | 1986 | 1990 |
| Okierabu Islands | 2 | 94 | 1973 | 1985 | 1987 |
| Amami Islands | 6 | 936 | 1974 | 1985 | 1987 |
| Daito Islands | 3 | 44 | 1977 | 1986 | 1990 |
| Total Region | 61 | 3386 | 1919 | 1972 | 1993 |

At first, important basic and applied research was carried out, including a pilot project in Kume island (1972–1978), to improve and refine integrated SIT applications, and to assure the success of the eradication project (Itô et al. 2003; Koyama et al. 2004). Following population suppression by the aerial distribution of cotton strings soaked with cuelure, a male attractant, and naled, the SIT was then systematically applied to the different island groups to eradicate the melon fly. In 1993 the impressive goal of complete eradication was achieved in all of the archipelagos of southern Japan, all the way to the Yaeyama islands closest to Taiwan (Kakinohana et al. 1997).

#### *4.1.4. Mediterranean Fruit Fly in the Dominican Republic*

The Mediterranean fruit fly originated in East Africa, from where it has spread to many regions of the world. However, the Caribbean region was still free of this major horticultural pest until its presence was reported in March 2015 in the Dominican

Republic, where this polyphagous pest had already invaded more than 2000 km$^2$ in the eastern part of the country. The outbreak was centred around the Punta Cana region, a major tourist destination, suggesting that the pest was introduced by tourists carrying infested fruits. Trading partners responded by establishing an immediate ban on exports of most fruits and vegetables from the Dominican Republic, causing a loss of USD 40 million in the remaining nine months of 2015, and putting 30 000 jobs at risk. Moreover, the whole Caribbean region and its trading partners were at risk of significant direct losses and the loss of their export markets (Zavala-López et al. 2021).

As an emergency response, the government, through its Ministry of Agriculture, established the Moscamed Programme in the Dominican Republic, providing the required financial and operational support to perform all required surveillance and eradication activities. FAO, IAEA, and USDA guided and assisted the country in establishing a national monitoring network to delimit the distribution of the outbreak and contain its spread, as well as to initiate an eradication campaign with support also from regional organizations such as OIRSA and IICA. The Guatemala-México-USA Moscamed Programme assisted through staff training, technology transfer, and the provision of sterile flies. Even though the pest had already spread to such a large area, an external Technical Advisory Committee confirmed that eradication was still feasible, and recommended the implementation of an AW-IPM programme integrating the SIT with quarantines and other controls (Zavala-López et al. 2021).

Once the extent of the infestation was well defined, suppression activities were intensified, including some host-tree pruning and fruit destruction in hot spot areas, ground and in some cases aerial bait sprays, and placement of bait stations in inaccessible or sensitive tourist areas. After pest population suppression in hot spot areas, SIT application was started in October 2015 and continued until April 2017, three months after the last wild fly was detected in January 2017. An average of 72 million sterile males of a genetic sexing strain were released per week by air, covering a total of 42 000 ha in the provinces of La Altagracia and La Romana (Dowell et al., this volume). In addition, an average of 15 million sterile flies was released per week by ground along the coast in touristic zones subject to considerable drift due to coastal winds. In total, more than 4 thousand million sterile males were released over the affected areas (Zavala-López et al. 2021). After two years of intense eradication efforts, involving up to 300 staff, in July 2017 official eradication was declared by the government (IAEA 2017). Intensive trapping and fruit sampling continued for another six months after the discontinuation of sterile male releases and nine months after the last wild-fly detection (Barclay et al., this volume; Vreysen, this volume).

#### *4.1.5. New World Screwworm in Libya*

The New World screwworm is native to the tropical and subtropical Americas, invading Florida in 1933 (Skoda et al. 2018). Its larvae produce myiasis by feeding on the living tissue of warm-blooded animals, including humans. Its damage to the livestock industry was the initial motivation for the development and successful application of the SIT in a 50-year area-wide campaign that started in Florida and culminated in the eradication of this pest from all of North and Central America (Klassen et al., this volume; Vargas-Terán et al., this volume).

In the spring of 1988, the presence of the New World screwworm was detected in Libya. Shipments of live animals from Latin American countries were the likely source (Libya covered ca. half of its livestock needs with imports). The initial beachhead discovered extended already to more than 18 000 km$^2$, representing a major threat not only to Libya and North Africa, but to the whole Mediterranean region, as well as to wildlife throughout Africa (Vargas-Terán et al., this volume).

Supported financially and technically by a multi-institutional, multi-donor international effort, FAO took the lead in coordinating the emergency programme that not only focused on containment and eradication in Libya, but also on surveillance activities in the surrounding 7 first-line countries and 10 second-line countries. A Screwworm Emergency Centre for North Africa (SECNA) was established at FAO in Rome and the field programme in Tripoli, Libya. An intensive campaign informed and requested support from livestock owners and the general public in Libya and neighbouring countries. In addition, every 21 days more than 90 roving teams inspected the estimated 7 million head of livestock in Libya, treating wounds prophylactically. As a result of this major effort, together with the establishment of 13 quarantine stations to control livestock movement, containment was successful and no new foci developed elsewhere in Libya or the region. Nevertheless, by the time eradication activities were initiated, the New World screwworm had expanded to 25 000 km$^2$, and the severity of the infestation had increased significantly (FAO 1992).

Mating studies with wild Libyan screwworm flies were carried out to confirm sexual compatibility with the mass-reared screwworm flies produced in the mass-rearing facility in Mexico. Once it was confirmed, and the required infrastructure was established, weekly aerial shipments of sterile pupae from Mexico to Tripoli were initiated in December 1990. In total, until October 1991, 1300 million sterile pupae were transported, and sterile flies released over 41 000 km$^2$, with higher release densities over hot-spot areas. Releases were supported by surveillance, sentinel animals, wound treatment, and quarantine activities. The last myiasis case was detected in April 1991, although releases continued for another six months to assure the elimination of any remnants. Surveillance and quarantine inspection activities continued until June 1992, when eradication was declared (FAO 1992; Lindquist et al. 1993; Barclay et al., this volume; Vreysen, this volume).

Success was achieved earlier than foreseen, largely favoured by determined government support, effective management, and the decision to start the sterile fly releases in winter, when screwworm populations were naturally low. Nevertheless, there were some critical voices that claimed that the cold winter was responsible for screwworm eradication. However, as shown by Krafsur and Lindquist (1996), the screwworm population clearly did overwinter, and eradication would not have been achieved without SIT application. Originally estimated to cost USD 117.5 million, the actual cost of the eradication campaign was only ca. USD 80 million. An independent economic study commissioned by FAO estimated annual benefits of USD 300 million for the region, with a benefit/cost ratio of 50:1 (FAO 1992).

There have also been multiple interceptions of New World screwworm-infested animals at ports of entry, and incipient outbreaks or reinvasions that have been eradicated, including in Aruba, Curaçao, Mexico, Florida Keys, etc., using the SIT (Skoda et al. 2018).

### *4.2. Successful Cases of SIT Preventive Releases in Areas of High Risk of Pest Establishment*

The above cases illustrate the effectiveness and environment-friendliness of SIT integration in achieving eradications of invasive pest populations -- simpler in the case of incipient and still-small incursions, and more costly and complex when large outbreaks are detected late or when the populations are already fully established. On the other hand, when repeated introductions occur into points of entry considered as high risk in view of historical evidence, and where the increasing flow of passengers and cargo is outdistancing inspection capacities, a preventive SIT approach is most cost-effective as shown by the following examples.

#### *4.2.1. Preventive Release Programmes against Mediterranean Fruit Fly in California and Florida*

California and Florida have been increasingly subject to incursions of the Mediterranean fruit fly, leading to repeated detections and outbreaks in urban areas, especially those with international airports, e.g. Los Angeles and San Diego in California, and Miami, Tampa, Ft. Lauderdale, and Palm Beach in Florida. The incursions have been linked to fruit smuggling, and the rapidly growing volume of shipments and air traffic. Liebhold et al. (2006) confirmed passenger baggage as a common pathway for entry of the Mediterranean fruit fly, and found a direct relationship between number of interceptions and travellers per year. They showed that, in spite of fines, dog brigades, and scanning devices or other equipment aiding the screening of baggage for quarantine material, this invasive pest arrives at a sustained level with fruit carried by passengers, explaining its repeated detection in urban areas but not in fruit-production areas.

Since the first Mediterranean fruit fly outbreak in 1975 in Los Angeles county, agriculture authorities in California have been responding to an ever-larger number of outbreaks, some triggering extensive and costly eradication programmes, initially largely based on aerial malathion bait sprays over urban areas that caused much public outrage (Scribner 1989; Mangan and Bouyer, this volume). Increasingly, the SIT was also included in a limited radius around outbreaks to eradicate them. Nevertheless, by 1993, this reactive localized strategy appeared to be no longer effective, since Mediterranean fruit fly infestations were being detected in 39 cities in five counties in the Los Angeles Basin, and there was no doubt that some population propagules had spread before achieving eradication (Dowell et al. 1999).

In response to an international advisory panel recommending an area-wide approach, a basin-wide sterile insect release programme was initiated in 1994 in 2358 $km^2$ that included all existing Mediterranean fruit fly infestations and areas in the Los Angeles Basin where Mediterranean fruit fly infestations had been eradicated in the

previous 7 years. In addition to limited malathion bait sprays to hosts around fly finds, sterile flies were released basin-wide at a weekly rate of ca. 155 000 per km$^2$. This area-wide approach was very successful, with wild Mediterranean fruit fly captures decreasing from 400 in 1993, to 7 in 1994, and to no wild flies within the basin-wide area in 1995. It was also more cost-effective than the localized reactive approach, and avoided the expensive quarantine areas around each new incursion that are very disruptive to horticultural trade, both nationally and internationally.

In view of the success of this area-wide approach, and the continuous risk of Mediterranean fruit fly introductions, a permanent Mediterranean fruit fly Preventive Release Program (PRP) was initiated in 3470 km$^2$ that included the basin-wide programme area, and an additional 1112 km$^2$ in Riverside, San Bernardino, and Orange counties. Due to its preventive nature, the PRP reduced the weekly release rate of sterile flies by half to ca. 78 000 per km$^2$ (Dowell et al. 2000). The PRP has been in operation without interruption since 1996.

A similar PRP was established in Florida as a proactive approach to the heightened threat of new Mediterranean fruit fly introductions, due largely to increased international trade and travel and the high growth rate of urban areas. Since 1998, sterile Mediterranean fruit flies have been released weekly on a preventive basis in areas historically shown to be at high risk for new introductions (USDA 2014).

The fully operational fly emergence and release facilities have also enabled an effective response to detections of the Mediterranean fruit fly, and also some *Anastrepha* spp. fruit flies outside the PRP areas. This success has continued, and both PRPs are still fully operational but with some adjustments in the area and release densities. Therefore, the area-wide preventive SIT strategy has been a major success, substantially reducing the risk of Mediterranean fruit fly establishment in California and Florida. The PRPs provide protection to multi-billion-dollar (multi-thousand-million-dollar) industries, while emergency project costs have been reduced by 85%. Compared with pre-PRP years, outbreaks in California have been reduced by more than 98%. In PRP areas in Florida, no Mediterranean fruit fly outbreaks have occurred (USDA 2014). As a result, in spite of continuous incursions of this invasive pest, the continental USA is still internationally recognized as Mediterranean fruit fly-free. This has been disputed (Papadopoulos et al. 2013; Carey et al. 2017). However, as pointed out by McInnis et al. (2017) and Shelly et al. (2017), trading partners and foreign consumers have never detected larvae in Californian/Florida produce, and flies are not trapped in rural areas, where the vast majority of commercial horticultural production is located.

#### *4.2.2. Other Preventive SIT Programmes*

There have been other PRPs to protect free areas from pest invasion. One involved the release of sterile *Anastrepha ludens* (Loew) fruit flies near the Mexico border in southern California -- to prevent the entry of this pest from Baja California Norte (Klassen et al. 1994). This programme, in operation since 1964, was continued until the mid-1990s when it was no longer needed because Mexico eradicated *A. ludens* and *A. obliqua* (Macquart) from all of north-western Mexico (Reyes et al. 2000). A similar programme, also against *A. ludens*, has been in operation in the Rio Grande Valley in southern Texas (Klassen and Vreysen, this volume).

As described above, the melon fly was eradicated from Okinawa. Nevertheless, there is evidence of isolated fly movement (probably wind-assisted) over considerable distances, based on captures in traps in some Japanese islands that are closer to Taiwan, but no infested fruits have been detected. Therefore, to prevent recolonization of the melon fly in Okinawa after eradication, sterile fly releases are carried out at lower densities in areas where the possibility of invasion is relatively high, e.g. near international airports, U.S. military bases, and residential areas (Kuba et al. 1996). A similar situation applies to the invasive solanum fruit fly after its eradication from Yonaguni Island, next to Taiwan, and which is therefore threatened by reinvasion.

### *4.3. SIT Releases to Contain Invasive Pest Populations to Protect Free Areas*

Sterile insects have also been used effectively to contain the spread of invasive pest populations into regions free of that pest, and where sterile insects are released along the front of the invasive pest population (see Fig. 1 in Hendrichs, Vreysen et al., this volume). Two large operational programmes stand out:

#### *4.3.1. Pink Bollworm Containment Programme in California*

The pink bollworm, originally native to Asia, has invaded most of the cotton-growing regions in the world. It first reached the cotton belt of the southern USA in 1917, and gradually advanced towards the south-western cotton region, where it became a major pest in the arid desert areas. It finally established in the cotton-growing Imperial and Palo Verde Valleys in southern California and north-western Mexico, and threatened to invade also the large San Joaquin Valley. In response, a sterile moth release containment programme became operational in 1968, funded largely by the cotton industry, with the objective of stopping the spread of the moth into this important valley. For more than three decades, sterile moths were released in 400 000 hectares as part of pink bollworm IPM; during this long period the pest was successfully excluded, thereby contributing to the survival of cotton production in the valley (Staten et al. 1993). Subsequent to the extensive planting of *Bt*-cotton, starting in the mid-2000s, this effective containment programme finally became unnecessary when the pink bollworm was gradually eradicated from all of south-western USA and north-western Mexico, largely through the integration of *Bt*-cotton and the SIT (Staten and Walters 2021; Simmons et al., this volume).

#### *4.3.2. Guatemala/Mexico/USA Moscamed Programme*

The other large programme, that has been applying the SIT effectively to contain the spread of an invasive insect pest, is the joint Mediterranean fruit fly programme between Guatemala, Mexico, and the United States (Enkerlin, this volume). This pest invaded Costa Rica in the 1950s, eventually spreading to neighbouring Central American countries, where it caused major damage to fruit and vegetable production, and resulted in the loss of important export markets, in particular the large USA market. Coming from El Salvador, it invaded and crossed Guatemala in only one year (1976), and in January 1977 was detected in Mexico close to the border with

Guatemala. This threat to the horticultural industries of Mexico and the USA triggered the tri-national MOSCAMED Programme; while the first large mass-rearing facility was being built, a major aerial bait-spraying effort was made to contain the rapid advance of the pest (Schwarz et al. 1985). Even so, by early 1979, it had already spread along a 330-km coastal transect into the neighbouring State of Oaxaca. Once sterile male releases were added to the area-wide eradication campaign in 1979, the infested area in Mexico was gradually cleared of the pest (Hendrichs et al. 1983). Since 1984 to the present, this programme has been containing the fruit fly by releasing sterile males in a belt on both sides of the invasion front along the Guatemala-Mexico border, maintaining Mexico and the USA free of this pest, while also protecting Mediterranean fruit fly-free Belize and northern Guatemala (Enkerlin et al. 2015, 2017).

Another successful containment programme for the Mediterranean fruit fly is the one that was implemented along the Chile-Peru border from 1996 until the mid-2000s, after northern Chile was freed of this invasive pest; Peru's two southern provinces, Tacna and Moquegua, are now free of this pest (Enkerlin, this volume).

## 5. TRENDS, CONSTRAINTS, AND CONTINGENCY PLANNING FOR FUTURE SIT APPLICATIONS

The above cases illustrate different situations where the SIT has been effective in eradicating small or established invasive pest populations, in containing their spread, or in preventing their establishment in an environment-friendly way. There is great potential for integrating the SIT in similar situations against major invasive insect pests, particularly in situations where the implementation of "scorched earth" approaches is becoming increasingly difficult.

### *5.1. Social Issues and Trends*

A major trend probably favouring the expanded use of the SIT in invasive insect eradication programmes is public opinion in increasingly complex social landscapes (Epanchin-Niell et al. 2010). Establishing and maintaining public support is becoming a major challenge, especially in eradication campaigns in view of their "all or nothing" nature, and requiring the buy-in from major stakeholders (Perkins 1989; Myers et al. 1998)

Issues of free riders, public participation, and disagreements over the financing of public good, have in several cases severely hampered the positive outcome of area-wide programmes; this stresses the need for attention not only to ecological, environmental, and economic aspects, but also to social and management dimensions (Hendrichs et al. 2007). Therefore, under such circumstances, effective and professional management of all social issues related to eradication campaigns is becoming increasingly important (Owens 2017).

Among the consequences of the global phenomenon of rapid urbanization is a decreasing understanding and support for agriculture and related pest eradication or containment campaigns, especially if they involve the application of drastic control methods such as habitat destruction, area-wide removal of animal and plant hosts, and

large-scale insecticide spraying. Campaigns that were possible in the past may no longer be possible today, and probably will not be acceptable to the public tomorrow. Even in the public-health sector, the human population no longer accepts unquestioningly area-wide action against invasive pests.

For some eradication programmes there have been public attempts to halt drastic actions, such as the mentioned Mediterranean fruit fly aerial spraying eradication campaigns in the Los Angeles Basin in the 1980s. Others were actually stopped by judicial action following public outrage, e.g. causing the failure of the citrus canker eradication programme in Florida between 1995 and 2006. More recently, efforts starting in late 2013 to stop the infection of olive groves in southern Italy by the bacterium *Xyllela fastidiosa* (vectored by the meadow spittlebug *Philaenus spumarius* (L.)) have been hampered repeatedly by local growers, environmentalists, and local authorities and prosecutors, allowing the spread of the disease northwards. Although the European Court of Justice finally officially backed the drastic eradication measures, including the removal of healthy trees within 100 m of a diseased tree, in this case it may be too late (Oggi 2016; Abbott 2017).

Such instances of public outrage are likely to increase because of the increasing frequency of invasive pests becoming established at ports of entry, such as near international airports, seaports, and elsewhere in urban and surrounding suburban areas (Hendrichs et al. 2007; Liebhold 2014). Under these situations, where the public can be non-supportive or even hostile, the integration of the SIT or mating disruption has considerable social advantages over aerial spraying and other drastic interventions, especially in urban/suburban settings, to avoid inconveniencing the public and raising public opposition (Dowell et al. 2000; Gamble et al. 2010). Nevertheless, also SIT-based area-wide campaigns should include a strong and well-designed public outreach component to anticipate any negative public reactions, and be proactive in mitigating those aspects that may cause outrage (Klassen 1989; Dyck, Regidor Fernández et al., this volume).

### *5.2. Constraints to SIT Applications against Invasive Pests*

For many pest species that have not yet arrived in regions or countries currently free of them, it is a matter of when, rather than if, they will invade. The exploding global travel and trade makes it increasingly likely that any species can reach anywhere in the world. This is compounded by a warming climate, allowing pest populations to survive and spread in previously inhospitable areas, for example the invasion of several disease-transmitting *Aedes* species into Europe (Cunze et al. 2016).

Expanding the use of the SIT to potential invasive pest insects is not straightforward. In some cases, the biology of the target non-native insect pest is not amenable to SIT application, or at least not practical economically (Lance and McInnis, this volume). Even when this is not the case, often the SIT package is only partially or not available for new invasive pests. Developing the missing technology in the short term, once an outbreak has occurred, is often complicated, although the described case of the painted apple moth in New Zealand is a successful example where the pest was suppressed and contained while the SIT was validated. Cases of taxonomically related pest species, for which the SIT is already being applied, are

generally also feasible in view that the technology is easier to transfer and adapt, e.g. among the various tephritid fruit flies (IAEA 1999). On the other hand, the light brown apple moth (LBAM) *Epiphyas postvittana* (Walker) is an example of an attempt to develop the SIT as an eradication tool after detection occurred in California in 2007. The effort was eventually abandoned in 2008 because of public opposition to aerial spraying of mating disruption pheromone to suppress this pest (Bloem et al. 2014; Liebhold 2014), and the fact that it became widely established in the meantime. Analysing the origin of this environmental controversy, Lindeman (2013) concluded:

> CDFA [*California Department of Food and Agriculture*] lost the battle over LBAM aerial spraying largely because of a report and other supporting grey literature documents [*that are not available in the academic literature*] that expressed highly disputable facts, evidence, and conclusions.

Nevertheless, 10 years later, as a consequence of this case and the continued push from environmental advocates for overall tighter restrictions, the courts issued an injunction requiring the state of California to stop using 79 insecticides when combating non-indigenous pest outbreaks (McClurg 2018).

In view of the above, it would be very worthwhile for countries or regions to prepare themselves before the eventual expected invasions, at least for the potentially most-feared invasive pest species, both in terms of developing the surveillance capacity for early detection of incursions, as well as contingency plans and other tools to enable eliminating incipient outbreaks with the least social and environmental disruption. The Port Information Network database maintained by APHIS-USDA is a potentially valuable source of information on the most common invading pest incursions intercepted, and for understanding the pathways by which potential invaders arrive. There are also a number of invasive species lists and databases that compile information on invasive species (Lowe et al. 2004; NISIC/USDA 2017; Invasive Species Compendium 2018). Actual and potential worst arthropod invaders feature prominently on these lists, along with their risks of invasion, and potential damage and distribution; such lists help guide countries in preparing in advance for such events (Baker 2002; Klassen et al. 2002; NRC 2002; Worner 2002; Worner and Gevrey 2006; Wan et al. 2009; ISSG 2018).

When incursions occur, rather than waiting to pay for the accrued damages of an invasion, it is certainly much cheaper to have the technology ready for effective early detection and response. However, the full benefit might not always be realized when the investment occurs long before any impacts are experienced (Bradshaw et al. 2016). Therefore, it is often difficult to convince decision-makers to divert funds towards preparing for future pest problems that have not yet arrived.

### *5.3. Contingency Planning and Future SIT Applications*

The development of the SIT for the false codling moth *Thaumatotibia leucotreta* (Meyrick), a major potential invasive pest that is indigenous to sub-Saharan Africa, is a successful example of such forward-planning that now enables rapid SIT integration into area-wide eradication campaigns if this key pest were to invade other regions. It has a large host range and has already spread to several islands in the Indian Ocean and Atlantic. Larvae have been intercepted by APHIS-USDA from a wide variety of

commercial hosts in shipments arriving in the USA from at least 16 different African countries (Carpenter et al. 2007). Since it became resistant to several insecticides, and a threat to South African exports, FAO/IAEA and USDA supported the South African citrus industry to develop the SIT as an additional method for effective false codling moth suppression, but also as an eradication method that can now be immediately used in future outbreaks of the false codling moth in the USA and elsewhere (Carpenter et al. 2007; Hofmeyr et al. 2015).

While the above false codling moth case resulted from a fortuitous alignment of interests that, in the future, would benefit the USA and other false codling moth-free countries, there has been very limited deliberate contingency planning and investment to develop environment-friendly tools to deal with future invasions of major insect pests. Among the exceptions, Australia and New Zealand stand out.

Australia has developed contingency plans to respond to a number of invasive pests, including the Old World screwworm *Chrysomya bezziana* (Villeneuve), a myiasis-causing fly in Africa, the Persian Gulf, India, and South-East Asia (Vargas-Terán et al., this volume). The Australian Veterinary Emergency Plan contains a strategy for Old World screwworm eradication should it gain a foothold in Australia (Anaman et al. 1994; Tweddle 2002; AHA 2017). The policy is to eradicate the screwworm in the shortest possible time, while limiting the economic impact. Therefore, Australia has made considerable effort to conduct research on the Old World screwworm and to develop the SIT against this livestock pest. Field trials in Papua New Guinea provided strong indications that the SIT would be effective in suppressing it, and later studies in Malaysia, which included the establishment of a 6-million-per-week pilot mass-rearing facility, validated the SIT for this screwworm species (Vargas-Terán et al., this volume).

New Zealand is probably the country most prepared in terms of major biosecurity threats. Among the most feared threats are the European grapevine moth *Lobesia botrana* (Denis and Schiffermüller), the Korean pumpkin fly *Zeugodacus depressus* Shiraki, the spotted-wing drosophila *Drosophila suzukii* (Matsumura), and the brown marmorated stink bug *Halyomorpha halys* Stål. If they became established, these species could wreak havoc in New Zealand orchards and vineyards. Therefore, Plant and Food Research scientists have been developing surveillance and eradication tools, including the SIT, for these potential invaders (Horner et al. 2016; Morton 2017; Welsh et al. 2017).

One of the limitations, in developing the SIT against a potential invasive pest that is still absent, is the need to establish partnerships with locations where the pest is present, e.g. the South Africa-USA collaboration on the false codling moth in South Africa, the Mexico-USA collaboration on the cactus moth in the USA, or the Australia-Malaysia collaboration on the Old World screwworm in South-East Asia. An alternative is to use model species, an approach being followed in New Zealand, where the southern green stink bug *Nezara viridula* (L.) is the model being researched in preparation for the brown marmorated stink bug. A further technical issue that needs to be managed, especially after successful eradications, is maintaining high-quality strains in mass-rearing facilities to be ready in case of new introductions (Kuba et al. 1996).

Another option is to establish contractual arrangements to procure the sterile insects when mass-rearing capacity exists elsewhere. New Zealand is free of major fruit fly pests, but if the Mediterranean fruit fly or the Queensland fruit fly, both present in Australia, became established in New Zealand, they would create significant damage to crops and cause market access issues (Worner and Gevrey 2006; Horner et al. 2016). Therefore, New Zealand has contractual arrangements in place with mass-rearing facilities in Australia that produce sterile Mediterranean and Queensland fruit flies, providing the option of eradication by the SIT in case there are early detections of outbreaks in New Zealand.

California, which is free of pest fruit flies of the genus *Anastrepha*, has, in case of outbreaks, similar stand-by arrangements in place with Guatemala, Mexico and/or Texas for the provision of sterile flies of various *Anastrepha* species. Many incipient *Anastrepha* infestations have been eradicated using the SIT -- in Arizona (1963–1967), Florida (1972), and California (1983–1984), and various times since then, including Texas (Klassen et al. 1994). Thus, USDA has been supporting these mass-rearing facilities with the understanding that the USA will receive priority for sterile flies in case of outbreaks.

## 6. CONCLUSIONS

Given the current trends of globalization, the sustained incursion of non-native invasive insect pests will continue. Also, transboundary quarantine measures will not be fully effective, even with major improvements in exclusion efforts and technologies at ports of entry to increase interceptions without affecting travel and trade (Liebhold et al. 2006). Thus, reliable surveillance, effective action plans, and rapid outbreak-eradication capacities will increasingly play an indispensable role in excluding major non-indigenous pest species (Liebhold et al. 2016).

This entails investment in effective area-wide surveillance systems for major invasive pests, especially in high-risk areas, to increase the probability of detecting incipient populations before infestations reach an unmanageable size. This will be facilitated by the development of multiple-species traps to maximize the cost-effectiveness of surveillance systems for major invasive-pest threats (Brockerhoff et al. 2013). Early detection and rapid response to outbreaks of invasive pest populations significantly reduce the cost of eradication and the direct economic losses resulting from quarantine restrictions.

At the same time, the more established an invasive pest population is, the less likely eradication will be seen by decision-makers as a viable option (and the less likely that SIT may be used, unless it is combined with the application of effective population suppression measures). Also, the potential for controversy and non-target impacts is higher, and the investment, as well as social and political commitment required to eradicate it, are higher (Myers et al. 1998; Simberloff 2008; Pluess et al. 2012; Tobin et al. 2014; Liebhold et al. 2016; Suckling et al. 2016).

Implementing this exclusion strategy will also require better communication methodologies and more information provided to the public, as well as improved approaches to engage the community (Kolopack et al. 2015), and to include the main stakeholders in the decision-making process; social tolerability will increasingly

define which eradication tools will be allowed (Gamble et al. 2010; Liebhold et al. 2016).

The eradication of invasive pest populations is feasible in many cases (Pluess et al. 2012; Tobin et al. 2014), but environmental constraints and public resistance to "scorched earth" eradication policies and treatments, commonly accepted in the past, has been increasing over the years, in conjunction with an urbanizing human population networked via social media. Thus, in future, only selective, economically justified, and socially palatable eradication measures, that allow achieving the objective of eradication with the least disruption, will be acceptable.

The SIT is a species-specific, environment-friendly, and inverse density-dependent method that is particularly suited to eliminate incipient invasive pest populations. It combines with Allee effects, representing considerable constraint to population persistence due to the difficulty of finding a receptive mate for sexual reproduction at low population densities (Gordillo 2015; Liebhold et al. 2016; Barclay, this volume). As the cases described illustrate, it has a very positive record of eliminating small or even large outbreaks of a number of invasive insect pests, in containing their spread, or in preventing their establishment.

There is great potential for integrating the SIT in similar situations against other major invasive insect pests. However, the SIT package is often only partially or not available when new invasive-pest outbreaks occur. Therefore, it is important to develop the SIT package for the worst potential non-indigenous pests that are amenable to SIT application (NRC 2002; ISSG 2018), although decision-makers are often reluctant to divert funds towards preparing for future pest problems that have not yet arrived. Nevertheless, benefit/cost analyses generally show that preparations for incursions that enable a rapid and effective response are much cheaper than having to run large and costly eradication campaigns with uncertain success, or letting a major pest become permanently established that then requires long-term control. According to Liebhold et al (2016), the eradication of many invasive pest populations would, in hindsight, have been economically beneficial; the magnitude of the potential impacts of the pest was often greatly underestimated (Bradshaw et al. 2016).

## SUMMARY

Procedures are presented for declaring an area to be "pest free" following an area-wide eradication programme against a population of an insect pest. These involve two probability models to deal with null trapping results, and a growth model to help verify that pests were no longer present when control actions were stopped. The two probability models are presented for a situation in which trapping for adult insects of the pest (and/or sampling for its immature stages) is ongoing, and for which the results are all negative. The models calculate the probability of such negative results if in fact insects were present. If this probability is sufficiently low, then the hypothesis that insects are present is rejected. The models depend on knowledge of the efficiency of the traps, and also the area of attractiveness of the traps. The possibility of a rebound of an incipient but non-detectable population that remains after control measures are discontinued is considered. Using a growth model, the rate of increase of an insect population that starts from one or two insects is examined. An example is given for tsetse flies — both means and confidence limits are calculated for a period of 24 reproductive periods after control has been terminated. If insects are disease vectors, it is also suggested that the progress of the disease be monitored to detect continuing transmission. This should be done in conjunction with a disease transmission model.

## 1. INTRODUCTION

Following an area-wide programme that has attempted to eradicate an insect population from a specific area, it is important to confirm the "pest free status". The criterion of programme success used is that the pest population has been eradicated from the target area (FAO 1996), a very different concept from that of the World Health Organization (WHO) regarding species eradication at a global level (WHO 2001).

There have been several successful insect pest eradication programmes, e.g. the New World screwworm *Cochliomyia hominivorax* (Coquerel) has been eradicated from North and Central America (Galvin and Wyss 1996; Wyss 2000a, b; Klassen et al., this volume; Vargas-Terán et al., this volume), and from Libya, using the sterile insect technique (SIT) together with wound treatments and quarantine measures (FAO 1992; Lindquist et al. 1992; Krafsur 1998; Wyss 2000b; Vargas-Terán et al., this volume). Many tephritid fruit fly populations around the world have been similarly eradicated by integrating the SIT with other methods (Sproule et al. 1992; MAG/SAG 1995; Kuba et al. 1996; Reyes F. et al. 2000; Villaseñor et al. 2000; Koyama et al. 2004; Enkerlin, this volume) or the male annihilation technique (MAT) for *Bactrocera* species that respond to the strong attractant methyl eugenol (Steiner et al. 1970; Koyama et al. 1984; Hancock et al. 2000; Seewooruthun et al. 2000; Suckling et al. 2016).

If continued attempts to trap adult insects or detect immature stages after the termination of control actions are unsuccessful, this could be taken as evidence that the population has been eliminated from the target area, but with the realization that null results do not necessarily imply non-existence (Mitchell 1980; Richards and Tarry 1992; Clift and Meats 1997; Barclay and Hargrove 2005; Hargrove 2005;

Meats 2014). Low-density populations are often very difficult to detect. For example, even when trapping the mountain pine beetle *Dendroctonus ponderosae* Hopkins using pheromones that are known to be effective, if the species is endemic and at a very low density (e.g. one infested tree per 10 hectares), it may be almost impossible to trap beetles (Bartos and Schmitz 1998; L. Safranyik, personal communication).

Perkins (1989) listed seven scientific questions pertinent to eradication, including:

> What accommodations need to be made for the limitations in the detection methods of ultra-low populations?

In interpreting null trapping (or other sampling) results, some knowledge of the detectability of the species (when using specified traps), as well as a measure of the area of attraction surrounding traps, must be available (Shelly et al. 2010). Once these measures are known, probability estimates of non-existence can be formulated from null results. An added complication arises if detectability itself is density-dependent, or if the area of attraction depends on weather or other factors.

The Food and Agriculture Organization of the United Nations (FAO) recognizes three categories of pest status: presence, absence, and transience (FAO 1999). Absence is determined by one or more of the following factors: (1) the lack of any records of its presence, (2) the action of eradication, (3) a shift in a pest's range, or (4) the interpretation of positive records as being only temporary. The three stages in the establishment of a pest free area are: (1) systems to establish freedom from pests, (2) measures to maintain freedom, and (3) checks to verify that freedom has been maintained (FAO 1996). However, since these guidelines are very general (applying to all pests — plant, animal, and microbial), they do not include methods specifically applicable to insects.

At present, insect population eradication is usually declared after the pest has not been detected for a reasonable period of time, which includes a considerable safety margin. The usual procedure is to continue control measures for several generations after the last insect was captured, then monitor the area intensively for additional generations (section 2.2.), and finally, if no more insects are detected, declare success. The New World screwworm in Costa Rica was declared eradicated about 1 year after the last fly was found (Galvin and Wyss 1996; Wyss 2000b, 2001). In Libya, sterile releases were discontinued 6 months after the last wild fly was trapped, and eradication was formally declared 8 months later (FAO 1992; Lindquist et al. 1992; Wyss 2000b). The Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) was considered eradicated in Chile after trapping (with a parapheromone and food attractants) for three generations without catching any wild flies (C. Flores and J. Gonzalez, personal communication). On the island of Kume, Japan, the melon fly *Zeugodacus cucurbitae* (Coquillett) was considered eradicated 6 months after the last capture, and following examination of 70 000 fruits (Iwahashi 1977). When the population of *Glossina austeni* Newstead was eradicated using an integrated approach on the island of Unguja, Zanzibar, sterile releases were maintained for six generations (after the last wild fly was captured) before eradication was deemed complete (Vreysen et al. 2000). The oriental fruit fly *Bactrocera (papayae) dorsalis* (Hendel) was introduced into Mauritius in 1996, and,

immediately after detection, eradication activities were begun. The last fly was trapped in May 1997, and trapping continued for 2 years, after which time eradication was declared (Seewooruthun et al. 2000). Following detection of the last wild fly, and a 4-month effort using the MAT and SIT, the oriental fruit fly was declared eradicated from the Mariana Islands (Steiner et al. 1970). One year (about six generations) after the detection of the last wild fly, the oriental fruit fly was considered eradicated from the Okinawa Islands using the MAT (Koyama et al. 1984). Subsequent to seeing the last individual, and trapping for 190 days and examining over 300 000 fruits, this same pest was judged eradicated on Amami Island (Ushio et al. 1982). In Perth, Australia, a large infestation of the Queensland fruit fly *Bactrocera tryoni* (Froggatt), after integrating the SIT, was declared eradicated 12 months after the last wild fly was trapped (Sproule et al. 1992). Using the MAT in north Queensland, Australia, against the oriental fruit fly *B. dorsalis*, area-freedom was claimed 12 months after the capture of the last fly, and after another 12 months eradication was claimed (Hancock et al. 2000).

Under the auspices of the FAO and the International Atomic Energy Agency (IAEA), a meeting was held in Vienna, Austria, in August 2003, to review the procedures for declaring areas free of tsetse flies and the trypanosomosis problem. The results of that meeting are described in section 2.1.3.

## 2. ASSESSMENT METHODOLOGIES

Three methodologies, suitable for addressing the question of the non-existence of insects in a given area, are presented. These include probability models to assess the results of trapping, a model of a rebounding population following suppression, and the use of disease transmission information in the case of pest species that are disease vectors. These methodologies are illustrated for tsetse flies *Glossina* spp. (Barclay and Hargrove 2005; Hargrove 2005).

### *2.1. Probability Models*

#### *2.1.1. Developments in Japan*

Itô (1977) apparently made the first quantitative attempt to solve the problem of declaring a species to be absent from the area of interest or at minimal density, but since it was published in Japanese, it received little attention outside of Japan. Itô (1977) recommended the use of Wald sequential sampling to determine the minimum number of samples required (such as the number of fruits) in SIT projects for fruit flies. However, Kuno (1978) pointed out that the lower limit in sequential sampling need not be considered in eradication projects, so he recommended that the sample size ($n$) be based on either the binomial distribution or the Poisson distribution, giving:

$$n = \log(\beta) / \log(1\text{-}p) \qquad (1)$$

for the binomial distribution, or

$$n = \log(\beta) / p \quad (2)$$

for the Poisson distribution, where $n$ is the sample size (the number of examined sampling units), $\beta$ is the error rate that is permissible, and $p$ is the permissible proportion of infested sampling units. The symbol "$\beta$" is usually used for this probability instead of $\alpha$, since it is related to Type II error rate rather than Type I error rate. The above sample size regulates the risk in the sense that the actual error rate is always smaller than $\beta$ if the actual proportion of infested units is larger than $p$. Equations (1) and (2) are not effective if the total number of existing sampling units for survey is limited. Hence, in a later paper, Kuno (1991) recommended another equation:

$$n = N (1 - \beta^{1/Np}) \quad (3)$$

where $N$ is the total number of sampling units. Kuno noted that the length of the sequence of zero captures increases nearly inversely with the size of the assumed $p_0$; $p_0$ is assigned to be some very small probability of pest occurrence that is deemed acceptable. Thus, for very small values of $p_0$, the required length of the sequence becomes impossibly long. For example, if $N = 50\ 000$, and the required value of $p_0 = 0.0001$, then the length of the sampling sequence yielding zero captures would need to be 30 095, even though this may be achievable if routine trapping is being done.

Yamamura and Sugimoto (1995) summarized the relation between equations (1), (2), and (3) as follows: let $Y$ be the number of infested units in the sample, $P$ be the actual proportion of infested sampling units, $N$ be the total number of sampling units, and $n$ be the sample size. Then one of the criteria used in the Japanese quarantine procedure is that

$$Pr(Y = 0|P = pt) < \beta \text{ for all } p_t \text{ satisfying } p < p_t \leq 1.$$

The probability $Pr(Y = 0|\ P = p_t)$ is most precisely expressed by a hypergeometric distribution:

$$Pr(Y = 0|P = p_t) = (N - N\,p_t)!\ (N - n)!\ /\ N!\ (N - n - N\,p_t)! \quad (4)$$

The minimum number of samples, $n$, which satisfy the above condition for a given set of $p$ and $\beta$, can be given approximately by a simple formula (Japanese Industrial Standards Committee 1956):

$$n = (N - (Np - 1)/2)\ (1 - \beta^{1/Np}) \quad (5)$$

The $n$ calculated by the above formula is slightly larger than the exact $n$ for given $\beta$, $N$ and $p$. In that sense, the above approximation is a slightly conservative approximation. We can use the more conservative approximation given by equation (3) if $p$ is sufficiently small. If the sampling proportion $n/N$ is sufficiently small, we can use another conservative approximation given by equation (1) based on the binomial distribution. If both $p$ and $n/N$ are sufficiently small, we can use a much

more conservative approximation given by equation (2) based on the Poisson distribution.

*2.1.2. Developments in Australia*

Clift and Meats (1997), using risk management software and trapping data up to May 1997, established criteria for 99% probability of localized eradication. Except for this last report, no probabilities were presented in any of the previous examples of eradication in Australia. Most authors simply did not provide the criteria on which eradication was judged, e.g. Schwarz et al. (1989).

An operational protocol, previously established in Australia (Clift and Meats 2004), specified that eradication could be claimed three generations (based on degree-day models) plus 28 days after the last fly was trapped. If one gets negative results, normally after three generations in some programmes (Tassan et al. 1983), one rejects the null hypothesis that flies are present. However, trapping records from a *B. dorsalis* campaign indicated that when trapping at only one trap per 1.5 $km^2$, 12 weeks of successive zeros could occur when flies were still present (Clift and Meats 1997; Clift et al. 1999). In addition, if there is a residual population and it is too small to be easily trapped or detected in fruit, then it will naturally increase when control stops, and so it becomes more detectable over time (Barclay and Hargrove 2005). In insects, such as tsetse, that have a slow rate of reproduction, this requires a long period, whereas for fruit flies, that have a much higher reproductive rate, any remnant population should soon become detectable (McInnis et al. 2017). The analytical methods of Meats and Clift (2005) represent a quantitative refinement of the ad hoc code of practice previously in use.

In countries such as Australia, Chile, Mexico, and the USA, cases of the eradication of spot infestations of pests (such as the Mediterranean fruit fly) in areas normally claiming area-freedom are much more common. Such eradications are virtually routine, and are not reported in the scientific literature (Suckling et al. 2016). Codes of practice for such procedures are also unpublished, and details differ according to both the country and pest involved. Meats et al. (2003) reviewed the codes of practice current in Australia for the Mediterranean and Queensland fruit flies, examined 25 years of data from spot eradications of each species, and calculated the radii of the areas of infestation where the probability of exceeding such radii was equal to probit 9 (containing 99.9968% of probability). If zones of area-freedom are to be established for other species, similar codes will be required. Obviously, it would be desirable if there were methods, with a pre-determined degree of probability, to calculate the radius of an affected area (where area-freedom would be suspended) and the length of the no-detection period needed to reinstate area-freedom within the previously calculated radius.

Clift and Meats (2004) and Meats and Clift (2005) assessed the probability of eradication of fruit flies in Australia by computing the probability that the fly population is below a certain density; this density can be adjusted to represent the critical density for population persistence, below which eradication would occur via the Allee effect (Allee 1931; Yamanaka and Liebhold 2009), whereby the rate of population growth declines or even becomes negative when the population declines below a given threshold (the Allee threshold). The number of traps and the length of

trapping time can then be computed knowing the maximum acceptable density, somewhat similar to the approach of Kuno (1991). The method of Meats and Clift (2005) involved a probability model using the concept of catch per trap per week, called $c_{tw}$, where $t$ is the number of traps and $w$ is the number of weeks. They defined

$$m = c_{tw}\, tw. \tag{6}$$

The zero term of the Poisson distribution was then used to calculate the probability, $P_0$, of a zero catch with time as

$$P_0 = \exp(-m) \tag{7}$$

Then, to calculate the number of weeks with zero catches to achieve a critical value of $P_0$ (e.g. 0.01, 0.001, etc.), one forms

$$w = (-\ln P_0, crit)(c_{tw}\, t) \tag{8}$$

This allows the specification of a lower catch limit, $c_{tw}$, that signifies a pest density that is below the Allee threshold; then the population can be left to decline to zero by itself without any additional control being required.

In a comprehensive review of the potentials and limitations of trap arrays for fruit fly detection, Meats (2014) examined the efficiency of detection systems, required spacing of traps, surveillance for resurgence following eradication attempts, effects of weather and insect age on trappability, and expectation of success in eradication and the ability to declare eradication. The efficiency of existing programmes in Australia and California is compared with recommendations for trap spacing. In addition, considerations of generation time, as predicted by heat accumulation and its use in predicting phenological events, are reviewed.

### *2.1.3. Results of 2003 FAO/IAEA Meeting on Tsetse Flies*

The following probability models are based on trapping (or other method of sampling) with zero results, while assuming that insects are present. The models then give the probability of a zero catch for this assumption; if the probability is sufficiently low, one can reject the hypothesis that insects are present. For simplicity, all sampling systems are referred to below as “traps”. Techniques for declaring that eradication has occurred are nearly the same as those for a declaration that an infestation has not yet occurred (Yamamura and Katsumata 1999).

Two models are presented: (1) local sampling involving one trap or one group of traps (suitable for spot infestations), and (2) area-wide sampling (suitable for an area-wide eradication programme involving either an established pest or a large outbreak). Both models involve sampling a population that is close to elimination. Either approach can be used, and the results should be rather similar; when residual population sizes are very low, the models converge (Barclay and Hargrove 2005; Feldmann et al. 2018).

For an insect to be caught in a trap on a given day, the following conditions must be met:

- A trap must be operative in the vicinity of the insect.
- The insect must be active.
- Given the above, the insect must succeed in finding the trap and be captured by it.

*Local Sampling with One Trap.* Regarding the probability of a zero catch in each of a number of traps, consider a single trap and the "circle" (area) of attraction around it, within which the probability of catching a given insect with a given trap during one day is $\sigma$, called the detectability; the probability of not catching a given insect is $1 - \sigma$. This assumes that detectability is constant within the circle; Meats (2014) has pointed out that attractiveness of baits falls off with distance, so the detectability might better be treated as a mean over the circle of attractiveness. If there are $k$ insects in the "circle", the mean number caught per activity period is $k\sigma$. If there are $k$ insects present, and if the insects are caught independent of each other, then the conditional probability of catching no insects during an activity period (or sampling period) is:

$$p(0|k) = (1 - \sigma)^k \tag{9}$$

The probability of both zero catch and a given number of insects being in the circle is $p(0 \cap k) = p(0|k)\ f(k)$, where the symbol $\cap$ refers to "and" or conjunction (Parzen 1960), and $f(k)$ is the probability of $k$ insects being present. The conditional probability of no catch, given that there is an undetermined positive number of insects present, is:

$$p(0|k>0) = \Sigma\ p(0|k)\ f(k) = \Sigma\ (1 - \sigma)^k\ f(k), \text{ where the sum is for } k \geq 1 \tag{10}$$

This equation could be used to construct probabilities of a zero catch, assuming that there are insects present near the trap. The problem arises in stipulating a distribution for $f(k)$, called the prior distribution on $k$.

Since the choice of a particular prior distribution is arbitrary unless there is some information about it, and since the probability given the presence of one insect has an easy closed form solution (i.e. $p(0|1) = 1 - \sigma$) and is more conservative, the latter probability is used in the development below (Barclay and Hargrove 2005).

The probability of a zero catch, given that there is one insect present, is $p(0|1) = 1 - \sigma$, so the probability of a succession of $n$ zero catches on $n$ independent sampling occasions is

$$P(0) = (1 - \sigma)^n \tag{11}$$

and this is true for each trap. For example, if the hypothesis (that there are pests present) is to be rejected at the $\beta = 0.01$ level, and if $\sigma$ was 0.1, then the number of trapping days, $n$, needs to be such that $(1 - 0.1)^n \leq 0.01$. This can be found using the

equation: $n = \log(0.01) / \log(0.9) = -2.0 / -0.0458 = 43.7 \approx 44$. More generally, the equation is:

$$n = \log(\beta) / \log(1 - \sigma) \tag{12}$$

where $\beta$ is the chosen rejection level. The base of the logarithms is immaterial, as long as both logs are of the same base. Once the rejection level has been chosen, and the value of detectability, $\sigma$, is known, the required value of $n$ can be computed easily (however, the number of trapping days should be linked to the generation time under defined climatic conditions).

*SAMPLING FRACTION OF POPULATION.* Each trap has an area of attraction such that, within that small area, the probability of catching a given insect approximates the average detectability. If the number of traps is not sufficient to cover the whole area, and therefore the sum of the areas of attraction is less than the area to be evaluated for "pest free status" (called the "assessment area"), then one of two scenarios may occur. If the pests are sufficiently mobile so that they move in and out of areas of attraction in their normal daily or weekly movements, then the detectability is simply reduced, compared with the situation in which they are in the area of attraction all of the time. Alternatively, the traps could be moved from day to day or week to week, so as to cover the assessment area; then the detectability would similarly be reduced. Assuming that every insect spends roughly the same amount of time in areas of attraction to traps, then the detectability will be reduced by the sampling fraction. If the sum of the areas of attraction to traps is a fraction $f$ of the assessment area, then the average detectability will be $\sigma f$. In that case, the criterion becomes:

$$P(0) = (1 - \sigma f)^n < \beta \tag{13}$$

and solving for $n$:

$$n = \log(\beta) / \log(1 - \sigma f) \tag{14}$$

The size of the area of attraction will be crucial to the calculation of the sampling fraction, and this area may depend on weather, since odour plumes from lures in traps will vary in size with wind speed, and may also vary with topography, season, competing natural stimuli, and surrounding vegetation.

*Area-Wide Sampling.* Another way of looking at the problem, which leads to the same kind of result, is to consider area-wide or total population sampling, covering the whole assessment area. Having selected one or more sampling systems, the next problem is to decide on the required intensity of sampling, and for what period of time, before a series of zero catches can be interpreted as indicating eradication at some specified level of probability.

The parameters are defined as follows:

$A$ Area sampled (km$^2$), assumed to be closed to immigration and emigration (either naturally or through the maintenance of a wide-enough barrier)

$k$ Total number of surviving pest insects, assumed to be randomly distributed in $A$

$\sigma$ Trap efficiency (detectability), i.e. the conditional probability that an insect is caught by a given trap, given that there is only one trap present in a 1 km$^2$ area containing the insect, and given that the insect is active

$s$ Number of traps present in all of $A$

$n$ Number of days that each trap is operated

If there are $s$ traps in the assessment area deployed for $n$ days, and if $s$ is sufficiently small that the traps act independently of each other, then the probability ($C'(k,s,\sigma,n)$) that none of the traps catches any of the $k$ surviving insects is:

$$C'(k,s,\sigma,t) = \exp ( - s\, n\, \sigma\, k / A) \tag{15}$$

assuming that the capture probability is identical for all insects, and is independent of time $t$ (Hargrove 2003). The result of interest is the function relating to the probability, $p(0)$, of observing a sequence of zero results, if in fact insects are in the assessment area:

$$p(0) = \exp (-sn\sigma\rho) \tag{16}$$

where $\rho = k/A$ is the population density, and other symbols are as defined above. The objective is to know when a series of zero catches is sufficiently long that the null hypothesis of the existence of pests at the assumed level can be rejected. For example, for the probability of a sequence of zero catches in the presence of insects to be below 0.01, then it is required that:

$$\exp (-sn\sigma\rho) < 0.01 \tag{17}$$

from which

$$-sn\sigma\rho < \ln (0.01) = - 4.605 \tag{18}$$

One can solve for one of the variables in terms of the others that are known. For example, if $t$ is determined, $\sigma$ is known, and $\rho$ can be surmised, then

$$s > 4.605 / n\sigma\rho \tag{19}$$

When this condition is met, the required probability has been achieved. If this calculation leads to an unreasonably large number of traps being required, then a different criterion may be considered. The value of $s$ obtained from the inequality above assumes a risk level of 0.01 in concluding that no insects are present, and this is shown in Fig. 1 for various values of the number of traps used ($s$) and number of insects present ($k$).

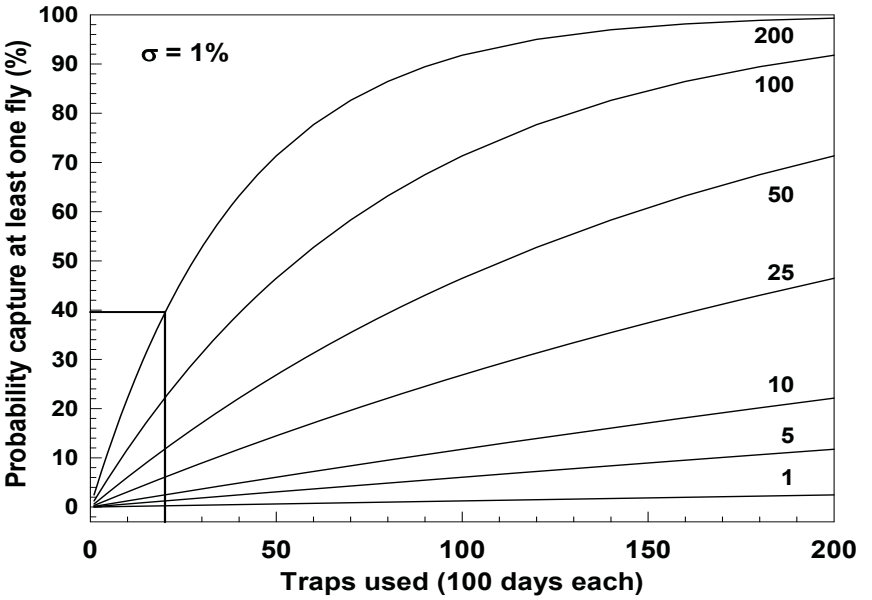

*Figure 1. Probability of catching a single tsetse fly in a small remnant population (numbers in body of figure) in an area of 8000 km$^2$ as a function of number of traps used and duration of trapping (when using a trap with efficiency of σ = 1%). (Figure from Barclay and Hargrove 2005, reproduced with permission.)*

It must be emphasized that the calculated number of traps ($s$) is independent of the size of the assessment area to be controlled (unless the area is very small). However, with a very large area, there is a greater probability that "pockets" of insects still exist (where the control treatments and/or released sterile males are locally overwhelmed), and these pockets must be identified and treated accordingly (Shiga 1991).

As a simple example of the application of the inequality (19) above, consider the insecticide aerial-spraying operation (sequential aerosol technique (SAT)) against tsetse flies in Botswana (Okavango Delta, about 16 000 km$^2$) (Allsopp and Phillemon-Motsu 2002; Tsetse News 2002), where apparently the last fly was caught on 30 August 2002, although very few traps had been installed in the Delta. Possibly the population of *Glossina morsitans centralis* Machado was actually eradicated in the SAT-treated area. However, suppose that 100 insects survived the sprays, what chance would there be of catching one of them? If the insects were distributed at random, 10 traps were deployed for about 3 months (90 days), $\sigma$ = 0.01, and using inequality (19), the probability of catching at least one insect is $C(k,s,n) \approx 0.06$. Thus, with this low level of trapping, there is a 94% chance that detection of the presence of insects will fail. To be 90% certain that at least one insect is detected (given that 100 insects were present), the application of inequality 19 suggests that more than 400 traps must be deployed for 3 months. To be 99% certain, this figure rises to more than 800 traps. Note that these figures assume a

rather even distribution of traps. Deploying traps for a longer period, such as 1 year to include all seasons, may permit a reduction in the number of traps. Spreadsheets, that incorporate a variable number of trapping days, are available to calculate the minimum number of traps required. (It is important to be aware of the possible existence of insects in places that were avoided or ignored by field personnel, substantially reducing the chances of detecting a residual population.)

In inequality 19, $\rho$ must be surmised; the size of any residual population is not known. To some extent, this uncertainty is balanced by the fact that, if there is a residual population and it is too small to be easily trapped, naturally over time it will increase since it is no longer under control, and it will become more detectable; this is the subject of the next section.

### *2.2. Incipient Non-Detectable Populations*

If control actions have reduced the pest population until very few insects are present, so few that they cannot be detected by trapping, then when control is terminated natural reproduction will cause the population to increase if the population is not below the Allee threshold. How long will it take for this small population to increase to a detectable level? (It is assumed that surveillance trapping will continue or be increased (detection trapping/sampling) until there is a decision regarding the "pest free status" of the area.) The population can be modelled by a simple equation:

$$N_{t+1} = \lambda N_t \tag{20}$$

where $\lambda$ is the rate of increase each generation, and $N_t$ is the population size at generation $t$. Starting with a very small initial population of size $N_0$ (following termination of the eradication activity), the size of the population $t$ generations later would be $N_t = N_0\lambda^t$. When $t$ is large enough for the population to have become easily detectable, but continued trapping still yields no insects, then a declaration of "pest free status" can be made. In calculating this critical value of $t$, allowance must be made for dormant or non-growing periods when equation (20) above does not apply. In addition, the time covered by $t$ generations must be adjusted based on available pest-specific degree-day models to make allowance for slow-growing periods during unfavourable climatic conditions. Furthermore, before such a declaration could be made, the allowance of an adequate time-buffer is needed to permit sufficient time to elapse for the population to increase to perhaps 10 times the minimal detectable level. Since equation (20) is deterministic, and events in nature usually involve random elements, reasonable lower limits of $\lambda$ should be used, not mean values (often used in calculations of ordinary population growth). This is illustrated below by examples from fruit flies and tsetse flies (which have much lower rates of increase than fruit flies or most other insect pests).

#### *2.2.1. Observed Populations of* Bactrocera dorsalis *in an Eradication Context*

Clift and Meats (1997) described the trap catches obtained during a population resurgence of *B. dorsalis* part-way through an eradication programme in tropical northern Queensland, Australia. In discussing localized extinction and reinfestation

of various areas within the pest-quarantine area, they noted intervals of up to 12 weeks between catches, and with the data available were unable to define localized extinction. After a declaration of eradication in 1999, subsequent data indicated that at least 16 weeks (favourable for the development of a fruit fly population) were needed to attain confidence that there were no flies in the area. Simulation data for 16 weeks were consistent with this result (Clift and Meats 2004). In practice, after 12 months of no catches under continued control, area-freedom was claimed, and after another 12 months with no catches and no control procedures applied, eradication was claimed. Throughout this interval, a 1 km grid of traps, with efficiency of at least 10%, was maintained over an 8000 $km^2$ area, and traps were checked at least weekly.

### *2.2.2. Monte-Carlo Simulation of Population Growth of Tsetse Flies*

Females give live birth to a larva about every 9 days (Hargrove 1994), which then pupates, and about 30 days later an adult emerges (Phelps and Burrows 1969a, b). Assuming this rate of reproduction, and the least detectable population (one gravid female), a Monte-Carlo simulation was performed to compute the mean population numbers after each of 24 reproductive periods (i.e. a simulation length of about 1 year, with the first period including the pupal maturation and the rest following at about 2-week intervals), assuming that gender determination of larvae is a random phenomenon, and that at meiosis males and females are equally likely. At each reproductive period in this simulation, a decision was made (on the basis of a random number) for each adult gravid female (whether her offspring was to be male or female), and then the new numbers were tallied. This was repeated for 10 000 24-reproductive growth periods.

Mean values for the 10 000 simulation runs were calculated for each of the 24 reproductive periods. A cumulative frequency distribution of population sizes was computed for each reproductive period, and the lowest 1% of the 10 000 runs was noted. Population values bounding these proportions for the $24^{th}$ reproductive period are shown in Table 1 (the bound for the proportion 0.01 is the upper bound of the first percentile). Four mortality values for adult flies were used (daily mortality of 0, 0.5, 1, and 2 %). If these are accumulated over a 2-week period, they translate into 14-day survivorships of 1.00, 0.93, 0.87, and 0.75, respectively, and these were used in the Monte-Carlo simulation. Since tsetse has a reproductive rate of half a female every 2 weeks (or 10 days, etc.), the fertility rate for 2 weeks is 0.5. Hargrove (1988) suggested that a tsetse population could not sustain 4%-added daily mortality regardless of the amount of density-dependence in its natural mortality.

Table 1 shows that, with 1% daily mortality, the mean number of adult females (after 24 reproductive periods) resulting from one gravid female reached almost 711, and one would expect that most of them would still be within some local common area, if it were suitable. Since these population numbers could vary widely, effective lower limits of the population were established (for the numbers below which it is expected that the total female population would be in 1 out of 100 cases) (Table 1). At this point, the questions become, “What is the minimum detectable density of flies?” and “What is the maximal tolerable error level?” Once these questions are answered, an appropriate waiting period can be determined.

The proportions of the 10 000 simulation runs that by chance ended in population extinction are shown in Table 2 (for the conditions used). Most extinctions occurred during the first five reproductive periods.

*Table 1. Number of tsetse flies (means and 1% confidence lower values) resulting from 10 000 simulated growing populations after 24 reproductive periods starting with one gravid female or with one male and one female*

| Initial population | | Survivorship per reproductive period | | | |
|---|---|---|---|---|---|
| | | 1.00 | 0.93 | 0.87 | 0.75 |
| One gravid female | Mean | 7480 | 2176 | 711 | 65 |
| | Below 1% | 830 | 1 | 1 | 1 |
| One male and one female | Mean | 11 211 | 3397 | 1157 | 112 |
| | Below 1% | 907 | 217 | 51 | 2 |

*Table 2. Proportions of 10 000 simulated growing tsetse populations that went extinct during 24 reproductive periods (table from Barclay and Hargrove 2005, reproduced with permission)*

| Initial population | Survivorship per reproductive period | | | |
|---|---|---|---|---|
| | 1.00 | 0.93 | 0.87 | 0.75 |
| One gravid female | 0.00 | 0.14 | 0.26 | 0.52 |
| One female, one male | 0.00 | 0.08 | 0.16 | 0.36 |
| Two gravid females | 0.00 | 0.01 | 0.04 | 0.18 |

### *2.3. Monitoring Vectored Infections*

If pests are difficult or impossible to detect at very low density, but nevertheless act as vectors of a disease, then, in addition to surveillance trapping, one supplementary method of detection is to use antigen tests and assess if the prevalence of vectored infections is decreasing (Delafosse et al. 1996). An epidemiological model using a zero-biting frequency could be applied to test the hypothesis that insects are absent (but bites from non-infected insects would not be monitored by this procedure (Dyck et al. 2000)). The models of Rogers (1988) or Baker (1992) could be used for tsetse, assuming that the insect density is zero. Infection rates in hosts should decrease with time. Also, if insects are truly absent, new host recruits should not be infected. A similar approach was used in the UK to decide if a warble fly (*Hypoderma* sp.) had been eradicated. In addition to trapping warble flies, blood sera from cattle were examined for antigens to the warble fly (Richards and Tarry 1992), and actually

these blood antigens were detectable for several years after the last capture of a warble fly in a trap.

However, as this method has problems associated with it, it should usually be used only to provide additional information. The vector population may be too low for effective transmission, in which case the disease would decline even in the presence of a small vector population. On the other hand, diseases that do not kill the host may linger for a long period in the population after the vector is no longer present. Also, in antigen tests, false positives and false negatives are possible, and disease symptoms may be present without the real presence of the disease (Tazé and Gruvel 1978), giving the impression that eradication of the vector is not yet complete. Nevertheless, if the vector species is difficult or impossible to trap, this method may be the only one available.

### *2.4. Summary of Requirements for Models*

- Select sampling methods that will sample all individuals and stages of the population.
- Determine the detectability of each sampling method; to obtain good estimates, this is best done before the eradication programme begins.
- Determine the range of attraction for each trap and other sampling method used.
- Determine the fraction of the assessment area that is actually being sampled (product of the number of traps and the area of attraction of each trap, divided by the total assessment area).

## 3. ACTIVITIES BEFORE, DURING, AND AFTER ERADICATION PROCEDURES

### *3.1. Pre-Eradication Activities*

Before embarking on an eradication programme for any insect pest, a variety of actions must be taken and information collected. These include the acquisition of scientific background information, and also the creation of a plan for these activities. This information will be of value for monitoring and surveillance activities during, and subsequent to, the eradication programme. At least one, and preferably several, sampling techniques suitable for each of the pest species must be available (Itô et al., this volume; Vreysen, this volume). Costs and logistic difficulties associated with each trap and other sampling method should be known.

#### *3.1.1. Data Requirements and Complicating Factors*

*Choice of Risk Level.* It is impossible to conclude with complete certainty that a population has been eradicated. The best that can be achieved is to state that the probability, that observed zero or null trapping/sampling results are consistent with the presence of insects, is sufficiently low to reject the hypothesis of insects being

present. For this hypothesis-testing approach, a level of probability (the $\beta$ or type II error level) must be specified; thus, when the probability of null results from trapping falls below this level, the hypothesis that insects are present will be rejected. The choice of $\beta$ is arbitrary, as it is in ordinary science where the rejection level, α, is usually 0.05. However, if human and animal lives, or a large investment in an eradication programme, are at stake, this level is probably too liberal. On the other hand, a lower level of $\beta$ means that more trapping is needed to satisfy the probability requirement. Thus, it is recommended that $\beta$ be 0.01, and this value is used below; Kuno (1991) also used this level. Kuno (1978) pointed out that null hypotheses are usually framed in terms of absence, rather than presence. Thus, he used a type II error with level $\beta$, the convention used by Kuno (1991) and Yamamura and Sugimoto (1995).

*Sampling Methods.* Different sampling methods, that sample different portions of a population, are often applied in area-wide integrated pest management (AW-IPM) programmes (Vreysen, this volume). Insects with free-living immature stages will usually require sampling methods different from those applicable to mature individuals, and hungry insects may be attracted to lures that are different from those that attract sexually active or ovipositing individuals (Jang et al. 1999). Traps that minimize the capture of sterile males, and instead capture mainly females, are a special advantage in the case of male-only sterile releases (Katsoyannos et al. 1999). In attempting to sample a sparse (or perhaps non-existent) population, careful planning is needed to ensure that all portions of the population receive attention. If there are portions of a population that cannot be trapped or sampled otherwise, then, before applying the probability models to them, sufficient time must be given for them to become responsive to a trap. Given the propensity of insects to congregate in certain areas, detection trapping needs to be done throughout the assessment area that will eventually be designated "pest free". Any information about the location of aggregated insects, times of greatest activity, and relative efficiency of various trap types and other sampling methods should be utilized to improve the chances of detecting insects that are at very low densities. In addition, to cover all life stages and physiological states, all effective trap types and other sampling methods should be utilized.

*Detectability.* Insect detectability (σ) can be estimated using a variety of methods (Thompson 2002); one method uses mark-recapture techniques (Shelly et al. 2010; Itô et al., this volume). Before an eradication programme commences, this should be done for each trap type used. Detectability can be estimated by the ratio of the number of marked individuals in the second sample (r) divided by the total number of marked individuals (m) released in the first sample:

$$\sigma = r / m \tag{21}$$

and $\sigma$ has an approximate variance given by

$$\mathrm{Var}(\sigma) = (n / mP)\,(1 - m/P)\,(P - n) / (P - 1) \tag{22}$$

in which *P* is either the known or estimated total population size (Thompson 2002). The standard error can be calculated from the variance. A further complication is that detectability may not be constant, but density-dependent. In the probabilistic approach outlined above, accurate measurement of detectability is of crucial importance; the way that detectability varies with density must be determined. If detectability declines at low density, then even estimating it presents a sampling problem since sparse captures will give a poor estimate of detectability. As an example of detectabilities that may be encountered in some pests, Table 3 shows the approximate estimated mean efficiencies for two tsetse species. The results in Table 3 underline the importance of selecting, for each pest species, the appropriate sampling systems, and of providing at least approximate estimates of the efficiency of each system that is used. If trap efficiency is unknown, it is necessary to conduct studies that estimate this parameter; only then can one use the technique to make defensible statements about the probability of an area being free of a pest species.

*Table 3. Estimates of probabilities (converted to percentages) of catching* Glossina morsitans morsitans *Westwood and* G. pallidipes *Austen using a variety of stationary and mobile baits (capture probabilities in this table for stationary baits apply to the probability for 1 day for flies in a 1 km$^2$ neighbourhood of the sampling device; for mobile baits the system may sample more than 1 km$^2$, but the time frame is the same (Vale (1974a, b) and Flint (1985) described the various sampling systems); table from Barclay and Hargrove 2005, reproduced with permission)*

| Baits | *Glossina m. morsitans* | | *Glossina pallidipes* | |
|---|---|---|---|---|
| | Males | Females | Males | Females |
| Mobile baits | | | | |
| Standard fly-round | 4.0 | 0.3 | 0.2 | c. 0.1 |
| Ox fly-round | 4.0 | 0.5 | 0.8 | 0.2 |
| Land Rover (electric net) | 12.3 | 2.4 | 1.5 | 0.7 |
| Decoy (electric net) | 5.6 | c. 0.1 | < 0.1 | < 0.1 |
| Trolley (electric net) | 9.5 | 2.1 | 3.9 | 1.4 |
| Stationary baits | | | | |
| Stationary ox | c. 0.1 | < 0.1 | 0.2 | 0.2 |
| Odour-baited F3 trap | c. 0.1 | c. 0.1 | 1.0 | 1.0 |
| Odour-baited electric net | c. 0.1 | c. 0.1 | 1.9 | 2.0 |

*Range of Trap Attraction.* To apply the concept of detectability, it is important to define the area in which a trap will attract insects. This area will differ for each trap type, and therefore each type must be estimated independently, and perhaps also in different seasons and weather conditions. If there are areas not covered by a trap,

then the traps should be moved around so that the total area is susceptible to trapping.

*Problem of Immigration*. Unless formidable natural barriers to movement exist, most insects will eventually move into a favourable habitat. Therefore, eradication is possible only if such barriers exist or eradication programmes have long-term commitments to address whole populations or treat large eradication areas sequentially (Wyss 2000a; Hendrichs, Vreysen et al., this volume). Even with barriers, such as large lakes, oceans, mountain ranges, forests, large tracts of grassland, etc., invasions may still occur occasionally as a result of phoresy, strong winds, persistent flying, etc. If trapping is not carried out systematically and at sufficient intensity, it may be difficult to distinguish between a reinvasion and an incipient population that went undetected, unless population genetics methods are used (Krafsur and Ouma, this volume). Indeed, to verify the eradication of the oriental fruit fly and melon fly in the Mariana Islands, trapping continued for several years; several reintroductions were detected (Mitchell 1980). (In this case, another fly species that was also attracted to the traps verified the traps' attractiveness.)

*Unequal Propensity to be Trapped.* There is genetic variability in virtually all biological characteristics. Many insects exhibit variability in their attraction to pheromones and other natural attractants (Yaninek and Geraud 1989; Clearwater et al. 1991; Whittle et al. 1991). If eradication is attempted using only traps with odour attractants, there is a possibility that insects with a lower propensity to be trapped will eventually predominate (Barclay 1990, 1996; Shelly 1997). As the population declines, ultimately it could form a residual population that would not be detected by further trapping, and from which a rebound could occur. To avoid this problem, eradication should follow an integrated approach combining various control tactics, and assessment of the status of the population should deploy simultaneously several methods of sampling.

### *3.1.2. Characteristics of Targeted Pest Species*

- *Population density.* Population density is important in assessing both the control method and the progress towards eradication, and in determining the detectability of the trap types and possibly the effects of density on detectability.
- *Reproductive capacity.* In population growth and ease of control, the following parameters are important: fertility rate, generation length, number of reproductive periods per individual, number of generations per year, probability of finding a mate at low density (the Allee effect), and density-dependence of fertility.
- *Mortality.* Age-specific and stage-specific mortality, and density-dependence of mortality, are important in assessing both the method and difficulty of eradication, and also the speed of rebound from a small population after an attempted eradication or a pest reintroduction. Mortality is also important in assessing the probability of a small population becoming extinct by chance.

- *Population movement.* Dispersal rate and distance, probability of exotic introductions, home range or territoriality, and density-dependence of movement are important in determining the size of sampling areas and the area to be covered with monitoring traps. Individuals may move from a suboptimal habitat into areas of known concentration that have been eradicated.
- *Periods of inactivity.* Certain portions of the population may be inactive and therefore cannot be trapped or otherwise sampled. Periods of inactivity are important in determining how long each trap type has effectively been trapping flies, and thus how many sampling periods may be counted in determining the probability that no insects are present.
- *Spatial distribution patterns.* Knowledge of spatial distribution is important in placing the control effort and simultaneous monitoring in the most effective positions. The distribution of the pest population within the targeted area, with particular regard to terrain, vegetation, and other features likely to affect distribution and density, should be ascertained. This information is important in case it is unnecessary or undesirable to uniformly apply control actions over the whole target area.

#### *3.1.3. Characteristics of Control Area*

- *Nature of terrain.* The topography, and availability and quality of roads, will determine the ease and cost of control and monitoring, and the logistics of trap location and visitation.
- *Boundaries, size of eradication areas, and barriers to reinvasion*. To prevent reinvasion, these must be known before eradication activities proceed.
- *Vegetation patterns.* These will affect the monitoring of insect density and distribution in suitable habitats.
- *Host availability.* This applies to host plant density for plant pests, or host animals for livestock or human pests.
- *Temperature and precipitation regimes.* Temperature will affect the speed of pupal development, influencing both the reproductive rate and the time required to ensure that no relict population exists after an eradication attempt, and precipitation regimes will affect the seasonal changes in vegetation patterns and also the availability of breeding habitats of insects such as mosquitoes.

### *3.2. Pest Control Phase: Suppression*

If the target insect is detected after eradication measures have stopped, delimitation trapping and more traps must be deployed immediately in the area where the insect was caught, and further control measures initiated. If, on continued monitoring, more insects are caught, control treatments should be continued (Mangan and Bouyer, this volume).

By collecting field data before and during control operations, the success of the control treatment can be assessed (Itô et al., this volume; Vreysen, this volume). As the density of the target population declines, the probability of a positive catch decreases. Simulation studies for tephritid fruit flies indicated that at very low

population levels (capturing 0.001 flies per trap per week), consecutive zero catches for 16 weeks occurred in at least 5% of simulation runs (Clift et al. 1999).

However, given that the trap grid includes all the areas where the insects could be present, any relict population will increase and hence be detected eventually (McInnis et al. 2017). In the case of tephritid fruit flies, this occurs after three generations (Lance and Gates 1994). Trapping records from *B. dorsalis* showed that 12 weeks of successive zero catches occurred, even though wild insects were still present (Clift and Meats 1997; Clift et al. 1999). Often this represents a trade-off; it is not practical to have an optimal trapping grid of, for example, 400 m throughout the assessment area, but if the existing 1 km grid is maintained, some insects may go undetected until numbers build up to a detectable level.

### *3.3. Post-Eradication: Detection Trapping*

The intensity of surveillance or detection trapping should be highest after control ceases (Hendrichs, Vreysen et al., this volume; Vreysen, this volume). Immediately following an eradication attempt, surveillance traps must be increased throughout the target area. These surveillance traps should be chosen for their efficiency in detecting the target species at low populations (Lance and Gates 1994; Katsoyannos et al. 1999; Papadopoulos et al. 2001). The trapping time needs to be sufficient to conform to the probability model, and allow the eventual probability of occurrence of any insect in the trapping area to be lower than the chosen risk level, e.g. a probability of 0.01 of being wrong.

Vreysen and Van der Vloedt (1992) described a sensitive biological method to determine whether or not eradication has been achieved. This consists of the release of virgin sterile female flies (female sentinels), and their recapture and dissection, to determine if, while in the field, they became inseminated by wild males.

It should be recognized that remnant insects might still exist in areas where control actions were less effective, e.g. sterile insects that did not reach narrow canyons or insecticidal sprays that did not penetrate dense vegetation. If there is a way to identify such potential problem areas before eradication activities start, then particular attention must be given to these areas.

### *3.4. Evaluation Phases*

The first evaluation phase would normally be the calculation of the probability of insects being present given a sequence of null trapping results while control actions continue. The calculation can be done using any of the probability models, either on a trap-by-trap basis (most useful for spot infestations), in which all traps must satisfy the risk criterion, or on an area-wide basis (more useful for most programmes dealing with established pests), which gives one probability. When this probability becomes small enough, then the conclusion is reached that no insects are present at that trap site.

If, after terminating control actions, the number of insects remaining is extremely low, such as one insect in 10 or 100 $km^2$, the small number of traps indicated by the second probability model might not catch any of the remaining insects, simply

because the insects never come into contact with the traps (they are too widely separated). In this case, either more traps must be deployed, or they should be moved around to ensure that for some time they are located in the vicinity of the insects. Alternatively, the SIT may be continued for some time as insurance, as in the eradication of *G. austeni* in Zanzibar (Vreysen et al. 2000).

The second phase involves stopping control actions but continuing detection trapping and waiting for an appropriate period (its length dictated by the population growth model (equation (20)) to assess the possibility of resurgence of a small remnant population. Generally, before declaring "pest free status", it would be advisable to wait long enough to allow the potential small population to grow to at least 10 times the minimum detectable level. If continued trapping proceeds without catching any insects, confidence in the eradication procedure will increase, either because elimination has succeeded, or an increase in the small remnant population would make detection easier.

In addition, there may be species for which, at present, no efficient trap exists. In this case, the trapping time would be unrealistically long or may even be incalculable, and there is little alternative except to wait (while still trapping) and see if a population rebound occurs during the minimal period. In such cases, a supportive technique proposed by Vreysen and Van der Vloedt (1992) is to release only virgin sterile females and, after recapture, assess if any of them had mated with wild males.

In both phases, it is advisable to monitor the progress of any diseases vectored by the insect pest, possibly using sentinel animals, trap trees, or other highly attractive features in highly suitable pest habitats. This is especially important in cases where detection trapping is very inefficient.

### *3.5. Criteria for Declaration of "Freedom from Pests"*

The criteria for making a declaration of eradication involve the above two phases of monitoring, and both should be satisfied before making a declaration. In the first phase, a series of zero results will have been obtained from surveillance traps (while still continuing control actions). From these results, the probability of such a sequence is calculated in accordance with one of the two probability models. If this probability is sufficiently low (below 0.01), then control activity can be stopped but surveillance trapping must continue. If the calculation results in an unreasonably large number of traps, then only the second phase of the criterion might be required.

The second phase involves calculating the minimal expected size of a population resulting from the rebound of a remnant population after a period of time. Calculating the population growth rate for the species is done using an appropriate population growth equation, such as the one in equation (20), and waiting until the expected population is at least 10 times the size of the minimally detectable population, assuming that a rebound is occurring. When both phases pass the numerical test, then eradication may be declared.

Throughout both phases, any diseases vectored by the pest should be monitored. By observing the presence or absence of new infections, especially in young hosts, the existence of continuing disease transmission can be ascertained (section 2.3.).

As an illustration, the practical implementation of both phases has occurred in Australia, where experience in eradicating incursions of both endemic and exotic tephritid fruit flies has accumulated for over 50 years (Madge et al. 1997; Hancock et al. 2000). If a fruit fly species is introduced (usually in infested fruit) into an area that was free of that species, the young adults will disperse from the point of introduction, and could take from 1 or 2 days to several weeks to mature, mate, and infest more fruit. Dispersal can happen during and after the pre-maturation period. In a fly free area, an invading group of flies will disperse into a mate free void, so that only the few that stay around the origin will be at a sufficiently high density to encounter each other and breed (Meats 1998a, b). However, once mated, a female can disperse any distance that her lifetime permits, and spread the infestation as a new generation. Thus, we can expect that the occurrence of adults in a usually fly free zone would be clustered around the origin, and that the occurrence of larvae would be even more clustered. Transport of infested fruit is often the main problem.

In the case of the Mediterranean fruit fly, catching one or more male insects in a male-targeted trap indicates that supplementary traps (preferably baited with food lures attractive to females (Katsoyannos el al. 1999)) should be set up around it (CDFA 1999). In addition, a search for larvae is made within the array of supplementary traps. A catch of three male insects in the same or adjacent traps within 14 days, a catch of one female, or the detection of larvae in fruit, indicate the beginning of an outbreak and the need for the release of sterile insects within a suitable radius of probable movement within the time elapsed since detection. Also, the localized movement of soil or fruit leaving that area has to be prohibited, and a wider “suspension zone” imposed. A formula is then applied to establish criteria for the reinstatement of “area-freedom” status, involving a period free of both control measures and fly detection. This period is equivalent effectively to 12 weeks, or the length of one generation plus 28 days, whichever is longer (Tassan et al. 1983; Madge et al. 1997; Hancock et al. 2000).

### *3.6. Quarantine Issues*

For agricultural pests that are transported in produce, it is feasible to impose quarantine on fruits, vegetables, etc. entering an area where a pest has been eradicated. Such quarantine would not cause financial hardship to local growers who benefit from the absence of the pest, although the quarantine process itself might be expensive. For pests of veterinary importance, it is advisable to establish a programme of quarantine and testing of hosts that are imported from infested areas. For pests of medical importance, humans are often the host and quarantine is not feasible. Therefore, a medical history should be required of people travelling to areas in which a disease has been eradicated; luggage should also be inspected to prevent the unintentional introduction of exotic pests.

## SUMMARY

The use of the sterile insect technique (SIT) in New World screwworm *Cochliomyia hominivorax* (Coquerel) eradication programmes has been successfully demonstrated. As a result of a 55-year area-wide campaign, suppression and eradication have been achieved in the USA, Mexico, Belize, Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica, Panama north of the Canal, some Caribbean Islands, and the outbreak in Libya, North Africa. The humans, livestock, and wildlife in these countries are now free of this dangerous pest. It has been estimated that the annual producer benefits are: USA – USD 896 million, Mexico – USD 329 million, and Central America – USD 88 million. In Libya, the estimated benefit/cost ratio was 5:1 in the infested zone, and 10:1 in the whole country; in addition, the pest never became established in the African and Mediterranean regions. If the New World screwworm were eradicated in South America, it has been estimated that each year about USD 3600 million would be saved. Small-scale field trials have confirmed that the SIT would also be effective for the area-wide control of the Old World screwworm *Chrysomya bezziana* (Villeneuve). Australia has developed extensive preparedness planning in case of potential screwworm outbreaks, which includes the application of the SIT to maintain its screwworm-free status.

## 1. INTRODUCTION

The application of the sterile insect technique (SIT), as part of an area-wide integrated pest management (AW-IPM) (Lindquist 2000) approach for the suppression and eradication of the New World screwworm C*ochliomyia hominivorax* (Coquerel), has been comprehensively demonstrated (Klassen et al., this volume). The similar biology of the New World screwworm and the Old World screwworm C*hrysomya bezziana* (Villeneuve) indicates that the SIT should also be effective against the Old World screwworm. Field trials in Papua New Guinea provided strong indications that the SIT would be effective in suppressing the Old World screwworm (Spradbery et al. 1989; Spradbery 1990), and later studies in Malaysia validated the SIT for this screwworm species (Mahon 2002).

Today, animal production is a high priority in world agriculture. There is an increasing demand for meat, dairy and egg production — major sources of animal protein for the world's growing population. To satisfy this demand, a diversity of livestock production systems is found in the different continents, including keeping cattle, buffaloes, sheep, goats, hogs, and poultry on traditional smallholder farms, and in extensive grazing or in more intensive systems, depending on the local circumstances.

In developing countries, animal production makes a major contribution to local and national food supplies. This production provides food security, cash income to a large number of rural people, and benefits to the whole economy. Commercial livestock-keeping increases total farm produce and income, provides year-round employment, and reduces the investment risk of raising livestock. Income from livestock products provides funds to purchase additional means to improve crops, or for other farm investment. Livestock production enhances the economic viability and sustainability of the farming system (FAO 1992).

Predictions made by the International Food Policy Research Institute (IFPRI), International Livestock Research Institute (ILRI), and Food and Agriculture Organization of the United Nations (FAO) suggest that, between 1993 and 2020, total world meat consumption will double from 180 to 300 million tonnes, and milk production will increase from 400 to 650 million tonnes (Delgado et al. 1999). To satisfy this growing demand, the world must find mechanisms to develop greater production efficiencies without damaging the already stressed environment. Part of this productivity increase can be realized through improvements in animal health.

Animal diseases affect the livestock sector directly through mortality, reduced fertility, and loss of weight, and together with other factors have chronic debilitating effects on livestock and their production. This results in inefficient utilization of scarce resources. Both ectoparasitic and endoparasitic diseases are recognized as major factors limiting production. The cumulative effect of parasitic diseases is perhaps a greater cause of economic losses than that of any other disease.

Myiasis is caused by an infestation of a living vertebrate's tissue or fluids by larvae (maggots) of flies (Diptera). Even minor infestations cause annoyance to animals, disrupting normal habits including feeding and resting. In some situations there is loss of milk, meat or wool production, or in the value of hides.

There are at least 20 species of flies responsible for myiasis, feeding specifically on living animal tissues to complete the larval stage of the life cycle (James 1947). Two of the most important obligatory parasitic myiasis flies are the New World screwworm and the Old World screwworm.

The New World screwworm was first described in 1857, infesting humans on Devil's Island in French Guinea (Coquerel 1858). In the Western Hemisphere's tropical and subtropical regions, the New World screwworm is one of the most damaging insect parasites of livestock. It alone represents economic losses each year of hundreds of millions of dollars (USD) (section 2.3.). Losses result not only from direct reduction in productivity due to sickness and death, but also from the labour and insecticide costs incurred by continuously having to inspect and treat wounds. In endemic areas the annual cost of controlling New World screwworm myiases in domestic animals was estimated at USD 4.82–10.71 per head (Rawlins 1985). These flesh-eating larvae also represent a serious human-health problem (Reichard et al. 1992; Vargas-Terán 2002a; Wyss 2002a).

Gravid female flies are attracted to wounds, even those as small as a tick bite. Eggs are laid in, and around the border of, such wounds. After the eggs hatch, the larvae begin feeding on the live body tissue. As the maggots feed, they enlarge the wound, making it attractive for other female flies to oviposit and also susceptible to secondary infection. Without treatment, it is common for the animal to die.

The New World screwworm has a high reproductive rate. Each female can lay several clutches of up to 400 eggs each. Under optimum conditions, a generation or life cycle can be as short as 3 weeks. Before suppression and eradication programmes commenced, the New World screwworm occurred naturally in subtropical and tropical North America, Central America, the Caribbean, and tropical and subtropical South America. Unintentionally, through animal movement, it spread to the USA, where it became established (FAO 1989); in the 1930s screwworms were present in the south-eastern United States (USDA/APHIS 2014).

The Old World screwworm causes myiases in Africa, Arabia, the Persian Gulf (Oman, Bahrain, Iraq, Iran), India, and South-East Asia (Spradbery 2002a). The life cycles of the Old World and New World screwworms are very similar, lasting about 21 days, and these species are a good example of co-evolution. However, the Old World screwworm is smaller than the New World screwworm, and the females are less fecund, producing egg clutches of 190–250 eggs.

The incidence and severity of the myiases depend on local conditions: livestock distribution and density, wildlife populations and their migratory habits, human population density, and the effectiveness of public health services. However, most important are the climatic conditions. Screwworm populations vary during the year, being most abundant in the hot and humid season. However, in the Middle East, the Old World screwworm is more abundant during the cooler months.

## 2. DIRECT AND INDIRECT BENEFITS OF NEW WORLD SCREWWORM ERADICATION

### *2.1. Benefits of Eradication in North America and North Africa*

The main direct beneficiaries of the elimination of the New World screwworm are livestock producers. However, direct and indirect benefits result for the community as a whole, through the increased availability of locally produced livestock and dairy products, reduced deficiencies caused by a shortage of meat and milk, and the increased availability of draught animals and manure. At a national level, economic benefits arise due to better-integrated agriculture and livestock production, and reduced dependency on food imports. There may also be public health benefits.

In North America, the economics of New World screwworm eradication programmes has been very positive, in spite of the high investment cost over the ca. 55 years of the programme (about USD 1300 million):

- USA: Cost to the United States Department of Agriculture (USDA) in 1958–1986 was about USD 650 million, in 2005 dollars (cost to producers and state governments not included) (Meyer 1994; J. H. Wyss, personal communication)
- Mexico: USD 413.5 million (FAO 2005)
- Central America: USD 268.4 million (Wyss 2002).

Estimates of annual producer benefits show the very large economic benefits that are accruing (Wyss 2000, 2002a), totalling USD 1300 million:

- USA: USD 896.1 million
- Mexico: USD 328.6 million
- Central America: USD 87.8 million.

Initially, the Libyan campaign was estimated to cost about USD 117.5 million (supported by a multidonor fund), but it was completed at ca. USD 80 million. This fund was established by the governments of Australia, Austria, Belgium, Finland, France, Germany, Ireland, Italy, Luxembourg, Netherlands, Spain, Sweden, UK, and USA, and institutions such as the African Development Bank, European Economic Community, International Fund for Agricultural Development (IFAD), Islamic Development Bank, Organization of the Petroleum Exporting Countries (OPEC) Fund, and the World Wildlife Fund. An independent economic appraisal showed that the programme was a remarkably profitable investment, with benefit/cost ratios of 5:1 in the infested zone and 10:1 in the whole of Libya (Grindle 1991; FAO 1992; Vargas-Terán 2002b).

Screwworms still cause significant human morbidity and mortality in the tropical regions of South America and the Caribbean, as well as dramatic effects on mammalian wildlife. It is estimated that, throughout the Americas, about 330 million people reside in New World screwworm-endemic areas. Where the pest is still endemic (in the non-eradicated areas), in most countries the human disease has been brought under control through strict medical surveillance and treatment, but where surveillance is relaxed it threatens to develop into epidemic proportions. For example, before screwworm eradication in El Salvador, humans were found to be the third-most affected species (Reichard et al. 1992), and eradication relieved everyone of the personal risk of myiasis.

### *2.2. Importance of Livestock in South America*

Livestock production in South America is based predominantly on medium- and small-sized farms raising small numbers of a variety of animal species. These animals are used for family consumption, draught power, and some for sale. However, there is also an industrial commercial sector, which is totally market-oriented, and based primarily on cattle exports. Since the general economic situation is making remarkable improvements, this sector is growing very rapidly. Therefore, South American animal agriculture is developing in a complex and dynamic environment. Livestock and human populations are shown in Table 1.

### *2.3. Potential Economic Significance of Eradication in South America*

Using data collected through surveys, and from economic studies carried out in the Caribbean region during the 1980s, Rawlins (1985) estimated the annual cost of New World screwworm surveillance and medication in various countries at USD 4.82–10.71 per head. If an average of USD 7.76 per animal per year is taken as the theoretical cost, then the annual costs of the New World screwworm in South America may be in the order of USD 3600 million (Table 2). Wyss (2002a) estimated the potential annual producer benefits for New World screwworm eradication in South America at USD 2800 million (Fisher and Romero 2018).

*Table 1. Number (x 1000) of animals and humans at risk of infestation by the New World screwworm (FAO 2014)*

| Country | Bovines | Equines | Suids | Ovines | Caprines | Total animals | Humans |
|---|---|---|---|---|---|---|---|
| Argentina | 51 646 | 3600 | 5100 | 14 700 | 4400 | 79 456 | 42 980 |

## 3. NEW WORLD SCREWWORM PROGRAMMES

### *3.1. Successful SIT Eradication Programmes in North America*

The elimination of a residual indigenous screwworm population, after an intensive suppression programme, requires the area-wide application of the SIT. The SIT can most simply be described as a form of insect population control (Knipling 1985; Wyss 2002b; Klassen and Vreysen, this volume), supported by other disease-control activities including epidemiological surveillance, wound treatment, animal-movement control, and quarantine (Mangan and Bouyer, this volume). The eradication programmes, that over about 55 years implemented this integrated use of the SIT, have been phenomenally successful, as shown in Fig. 1 and Table 3 (Wyss 2000, 2002a; Klassen et al., this volume; Klassen and Vreysen, this volume).

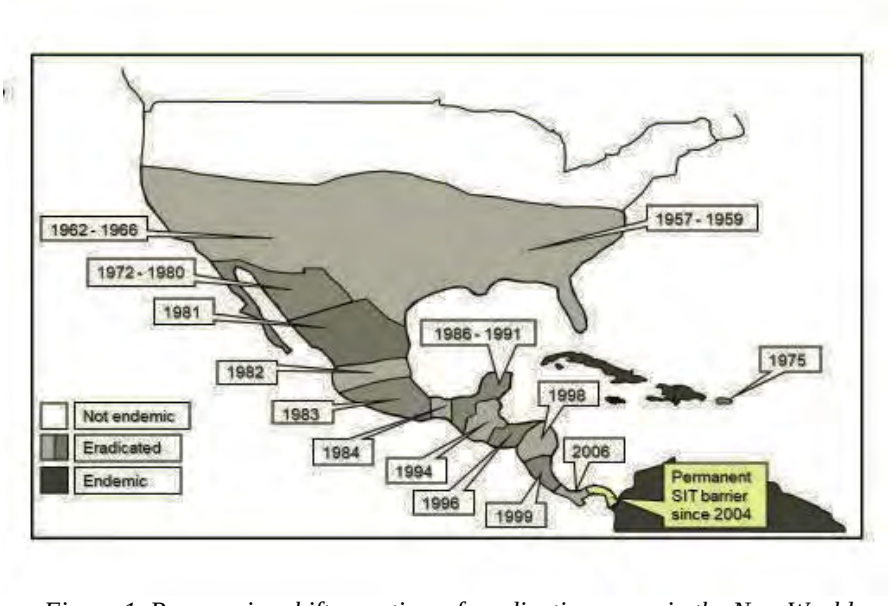

*Figure 1. Progressive shift over time of eradication zones in the New World screwworm AW-IPM programmes using the SIT from the southern USA to the countries of Central America. (Updated and modified map from Robinson 2002, reproduced with permission from Elsevier.)*

### *3.2. Naturally Free Areas in North America*

The countries and territories in the Caribbean, naturally free of the New World screwworm, are: Antigua and Barbuda, Bahamas, Barbados, Cayman Islands, Dominica, Grenada, Guadeloupe, Martinique, Montserrat, Netherlands Antilles (Bonaire), Saint Kitts and Nevis, Saint Lucia, Saint Vincent and Grenadines, and Turks and Caicos Islands.

*Table 3. New World screwworm eradication programmes*[1]

| Country | Eradication period |
|---|---|
| USA south-east[2] | 1957–1959 |
| USA south-west[2] | 1960–1966 |
| Mexico[2] | 1972–1991 |
| Guatemala[2] | 1988–1994 |
| Belize[2] | 1988–1994 |
| El Salvador[2] | 1991–1995 |
| Honduras[2] | 1991–1995 |
| Nicaragua[2] | 1992–1999 |
| Costa Rica[2] | 1995–2000 |
| Panama[2] | 1997–2000 |
| Curaçao[3] | 1954 |
| Curaçao (reinfestation)[4] | 1976 |
| Puerto Rico[5] | 1975 |
| US Virgin Islands[5] | 1971–1972 |
| British Virgin Islands[5] | 1971–1972 |
| Aruba (outbreak)[6] | 2011 |
| USA – Florida (reinfestation)[7] | 2016–2017 |

[1]Information extracted from [2]Wyss 2000, [3]Knipling 1985, [4]Coppedge et al. 1980, [5]Williams et al. 1977, [6]Information provided by J. B. Welch ARS-USDA and F. Pinilla COPEG, and [7]Delgado et al. 2016; USDA/APHIS 2017; Skoda et al. 2018.

### *3.3. Remaining Endemic Areas in North America*

Screwworm myiases continue to be a serious animal and public health problem in Cuba, Dominican Republic, Jamaica, Haiti, and Trinidad and Tobago (Vargas-Terán 2002a; Klassen et al., this volume). These countries pose a risk of New World screwworm reintroduction to those countries already free of the pest. Therefore, the FAO and International Atomic Energy Agency (IAEA) have been providing technical assistance for New World screwworm suppression and eventual eradication.

- *Cuba (1995).* The presence of the New World screwworm was officially acknowledged in 1995. From 1995 to September 2003, 88 985 cases were reported. The animal species most affected were cattle, swine, sheep, goats, horses, dogs, and humans (FAO 1999, 2003). For the period 2004 to 2015, the Cuban Veterinary National Institute (CVNI) reported the number of New World screwworm cases and identification operations, totalling 167 141 cases (100 634 in 2004–2009 but only 66 507 in 2010–2015). Given that there is no national screwworm eradication programme, livestock producers may be becoming reluctant to report cases to authorities (L. Méndez-Mellor, CVNI, personal communication).

  The Cuban Government and FAO signed an agreement to establish a national suppression programme and design a project plan to implement screwworm

eradication. The plan has two phases: (1) a pilot programme on Juventud Island, and (2) a full programme to cover the entire national territory. As a follow-up and part of the preparatory phase, the IAEA supported capacity building and an area-wide suppression trial on Juventud Island (García Rodríguez 2003; Garcia et al. 2007). The cost of New World screwworm eradication has been estimated at USD 62.5 million over 4 years. Recently, with the start of USA-Cuba communications, and in view of opening trade and the screwworm outbreak in Florida, there is a renewed interest in screwworm eradication in Cuba. The visit of the IAEA's Director General to Cuba in 2016 (Dixit 2016) was an indication of this interest.

- *Dominican Republic (1999).* Cases of the New World screwworm occur in all parts of the country, and without seasonal variation. Most neglected wounds and untreated navels of newborn animals soon become infested. Human cases are a common occurrence. In 1999, the governments of Jamaica, Haiti, and the Dominican Republic, and the FAO and IAEA, began regional technical assistance projects on capacity building and feasibility assessment of the suppression and possible eradication of the screwworm. As of February 2001, 1894 screwworm cases were diagnosed (FAO 2003). During the period 2004 to 2015 no major developments took place regarding the control of the New World screwworm (D. Vanderlinder, IICA, personal communication).
- *Haiti (1999).* The disease is endemic, with a high incidence throughout the country. It causes considerable losses in domestic livestock, and affects people of all ages. A Government of Haiti and FAO technical project reported 684 myiasis cases, of which 669 were positive for the New World screwworm; seven of those cases were in humans. When the project terminated in 2001, it was expected that a joint eradication programme with the Dominican Republic would be established (FAO 2003). Due to several factors, during 2004 to 2015 no progress was made on national or binational screwworm control (Max Millian, Chief, Veterinary Service, Haiti, personal communication).
- *Jamaica (1998).* Jamaica is one of the naturally screwworm-infested territories in the Caribbean. The high annual rainfall (over 1900 mm) and tropical climate sustain the very lush vegetation cover on the island, an ideal habitat for the New World screwworm. Consequently, the fly is widely distributed, regardless of season, altitude or ecological conditions. The island has about 400 000 cattle, 440 000 goats, and a large but unknown number of "stray" dogs. There are no wild animals, e.g. deer, rabbits, opossum, and peccaries, to support screwworm infestations. According to Snow et al. (1977), the New World screwworm is the second-most important arthropod pest of livestock, exceeded only by ticks. The annual economic losses inflicted by the screwworm on the Jamaican livestock sector, in terms of animal mortality and increased production costs, in 1998 amounted to USD 5.5–7.8 million (Vo 2000). Although all ways of keeping livestock are affected by the screwworm, its eradication from Jamaica would have the greatest implication for the many subsistence farmers who depend largely on small-animal holdings for their livelihood. The screwworm is also a severe human health problem, with 7 or 8 cases reported every month, and

probably many more are unreported (M. J. B. Vreysen, personal communication).

In July 1998, the Government of Jamaica began a New World screwworm eradication programme, with assistance from the USDA and the cooperation of the IAEA and FAO (Robinson et al. 2000). The estimated cost was USD 9 million, and it was anticipated that 3 years would be required for completion (Vo 2000). From November 1998 to October 2004, on average 258 screwworm cases were reported every month. Weekly treatment of the island with sterile screwworm flies began in August 1999, with the release of about 16 million sterile flies per week. In mid-2002, in response to the prevailing high number of reported cases, a new strategy was adopted (M. J. B. Vreysen, personal communication). There were several logistical problems associated with the programme, so in spite of the new strategy, and the continuing commitment of the Government of Jamaica to eradicate the screwworm, little progress had been made by the end of 2004, and the programme was terminated (Grant et al. 2000; FAO 2003; Box 1 in Dyck, Reyes Flores et al., this volume). Vreysen et al. (2007) analysed the reasons for this failure and described the lessons learned.

- *Trinidad and Tobago.* The New World screwworm is endemic, and cases are found throughout the year. Wounds left untreated usually become infested. The proximity of the islands to Venezuela, and possible immigration of flies, could complicate screwworm suppression and eradication.

### *3.4. Potential for Eradication in Remaining Endemic Areas of the Americas*

#### *3.4.1. Threat of Reinvasion*

The Panama and USA governments have established a permanent biological barrier, in the Darien Gap in Panama, by releasing 15 million sterile New World screwworm flies per week; this barrier is maintained to protect the non-infested North and Central American countries. However, as long as Cuba, Dominican Republic, Haiti, Jamaica, and Trinidad and Tobago in the Caribbean, and a majority of South American countries, remain infested, they represent a high risk of reinvasion to the eradicated territories and the naturally screwworm-free countries in the Caribbean basin.

There are several examples of failure to prevent screwworm reinvasion in territories where it had been eradicated. In 1966, after eradication from the USA, a biological barrier was established along the Mexico–USA border. However, in 1972, a massive failure of the barrier occurred (due to favourable weather conditions for the insect, and intensive legal/illegal livestock trade between the two countries); 90 000 cases were detected in the USA. As a result, the Mexico-United States Commission (COMEXA) initiated eradication activities in Mexico, and by 1984, eradication had been achieved down to the Isthmus of Tehuantepec, the narrowest part of Mexico, where another barrier zone was established (COMEXA 2002). Then, in 1985, several outbreaks occurred in the central and northern territories of Mexico, in spite of the implementation and operation of a good quarantine network.

The threat of reinvasion of the New World screwworm increases in proportion to the area eradicated, due to the risk posed by the international trade in animals, and the movement of pets and humans. Examples of screwworm outbreaks, both actual and potential, caused by such movements of infested animal/humans, are as follows: 1987 – dog from Honduras to the USA; 1988 – sheep from Latin America to Libya; 1989 – man from Panama to the USA; 1992 – woman from Brazil to New Zealand and Australia; 1994 – cattle from Central America to Mexico; 1998 – woman from Trinidad and Tobago to UK; and 2001–2002 in Chiapas, Mexico, due to the introduction of flies from Central America via a small aircraft. The cost of containment and eradication varies. The programme in Libya cost USD 80 million, Mexico's largest outbreak cost USD 8 million, and Aruba cost USD 200 000.

In 2016–2017 the screwworm was found infesting the wild deer population in the Florida Keys, probably due to reinvasion (Delgado et al. 2016). Sterile flies were released to re-eradicate the pest (USDA/APHIS 2017; Skoda et al. 2018).

The Mexico and United States governments, because of the cessation of its screwworm activities, in 2013 closed the sterile fly production facility of COMEXA in Tuxtla Gutiérrez, Mexico (SAGARPA 2013). Therefore, now the only existing screwworm production plant is in Panama, and belongs to the Panama and USA governments; it is operated by the Panama – United States Commission for the Eradication and Prevention of Screwworms (COPEG). Its weekly production of 15 million flies is used to maintain the Darien Gap sterile fly biological barrier to protect the screwworm-free countries in Central and North America. This facility is also the World Reference Laboratory for New World Screwworm Diagnosis of the World Organization for Animal Health (OIE). Presently, USDA-ARS is developing a genetically modified (GMO) male-only strain of screwworm to reduce potentially the costs of rearing, containment and eradication (COPEG 2015; Scott et al. 2017).

### *3.4.2. Caribbean*

The main objective of screwworm eradication in the Caribbean will be the promotion of sustainable agricultural development and food security, and simultaneously the protection of screwworm-free countries from reinvasion.

The Caribbean programme will demand the coordinated actions of all screwworm-infested and screwworm-free countries, as well as the institutions concerned with the suppression/eradication of the disease in the region. The experience and the resources accumulated by the Central and North American governments should be transferred to the infested countries in the Caribbean region.

The governments of the affected countries, with assistance from technical international agencies, will need to refine further national assessments of the current New World screwworm status, including geographical distribution, population genetics (Torres and Azeredo-Espin 2009), seasonal abundance, and economic impact, and to develop more economical methods to suppress the pest. Following these feasibility studies, a multidisciplinary mission should prepare a project proposal for the eradication of the New World screwworm from the Caribbean, to be submitted to potential donors for funding, or a strategic alliance be established with countries already screwworm-free in the region.

Before launching such a regional programme, the following prerequisites should be resolved by the participating countries, donors, and stakeholders:

- The governments involved will be fully committed to the New World screwworm eradication programme, and there will be no change in their policy.
- Adequate funds will be available as required.
- Adequate numbers of sterile insects of the desired quality will be available from the Panamanian and possibly other insect production facilities to be built.
- All infested areas in the Caribbean will be progressively treated.
- Trinidad and Tobago should not be included in the Caribbean phase of the regional programme, due to its proximity to the endemic countries in South America and the associated real risk of reinvasion. However, once screwworm eradication has been achieved in the Caribbean, and suppression/eradication activities are underway in the coastal areas of Venezuela, it should be given priority consideration.
- All screwworm-free countries will maintain strong inspection and quarantine services to prevent the introduction of infested animals from endemic areas.
- Full support will be needed from international trade associations (North America Free Trade Agreement (NAFTA), Caribbean Community Regional Integration (CARICOM), Dominican Republic-Central America Free Trade Agreement (CAFTA-RD)) and global and international health organizations (FAO, OIE, WHO, IAEA, Inter-American Institute for Cooperation in Agriculture (IICA), and Regional International Organization for Animal and Plant Health (OIRSA)).

### *3.4.3. South America*

The New World screwworm is endemic throughout most of the South American continent (Vargas-Terán 2002a). All countries are infested except Chile, where the pest was last found in 1959 (although it is possible that Easter Island, a Chilean territory, remains infested). Although Chile shares borders with countries infested by the New World screwworm, it has been able to maintain its screwworm-free status as a result of strict controls imposed on the importation of animals and animal products. In South America, with the possible exception of Chile, there are no natural barriers known to prevent the spread of screwworms among countries.

Progress has been made in understanding the genetic diversity and population structure of the screwworm in the Amazon (Mastrangelo et al. 2014), while the presence or absence of screwworms at different altitudes in the Andes still remains to be determined. In addition to this groundwork, population genetic studies are also being carried out (Lessinger et al. 2000; Robinson et al. 2009; Fresia et al. 2014) to understand more about screwworm population variation in the region, and the possible existence of isolated populations or cryptic species. Unless barriers can be found, for eradication purposes all of South America must be considered as one region (Fresia et al. 2014). Once started, the programme would have to be progressive and continue until the whole continent (and thus the Southern Hemisphere) is completely free of the New World screwworm. To consider South America as a target area, considerable preparatory groundwork would be needed. The governments and livestock producers in each country involved must be

convinced that eradication is technically, practically and economically justified. They must be ready to commit the resources and the energy to complete the task.

There will also be a need for mating compatibility studies among the different populations in the region (Mcdonagh et al. 2009; Robinson et al. 2009). Advances have been made on geographical information systems (GIS) and remote sensing applications (Bouyer et al., this volume) focused on improving the efficiency of the screwworm sterile fly barrier at the Darien Gap, and new fly strain collection locations have been identified to support the epidemiological case investigation (Phillips et al. 2004; Scott et al. 2017). Also, there is a better understanding of population genetics and distribution, and on how the biotic and abiotic factors influence community structure (Mastrangelo 2014), including screwworm historical movement among populations in endemic South American countries (Fresia 2014). These techniques will assist in identifying range shifts and expanded populations in the context of global environmental changes (Feldman and Ready 2014).

During 2007–2008, the governments of Brazil, Paraguay and Uruguay, with the support of the International Development Bank (BID) and COMEXA, carried out on the Brazil-Uruguay border a demonstration New World screwworm control programme to establish the basis for future programmes in the Southern Cone Common Market (MERCOSUR) countries (Muzio et al. 2009). In view of the advances in screwworm eradication in the Americas, and in response to the interest of South American countries, the FAO proposed in 2011 a "Road Map for the Suppression and Progressive Eradication of the New World Screwworm *C. hominivorax* in the Endemic Zones of the Western Hemisphere"; this would be a guide for regional efforts and avoid duplication of action among countries and international organizations (FAO 2011). In this context, the governments of Argentina, Brazil, Chile, Ecuador, Paraguay, Peru, Uruguay, and Panama requested technical assistance from the IAEA for screwworm control and prevention. The IAEA responded positively by approving in 2014 a regional project to "Support Capacity Building for Evaluation of Feasibility of a Progressive Control Programme for New World Screwworm" (W. R. Enkerlin, personal communication).

The following actions should be undertaken before the development and implementation of an eradication strategy:

- Conduct regional information campaign.
- Develop baseline data on New World screwworm case incidence in each country.
- Conduct studies on the economic impact of screwworms in each country.
- Develop an eradication strategy.
- Determine the cost of a regional screwworm eradication programme.
- Determine the benefit/cost ratio.
- Prepare an environmental-impact study on screwworm eradication in each country.
- Identify methods of financing its implementation (Vargas-Terán and Wyss 2000).

### *3.5. Successful Eradication in Libya (1988–1992)*

The discovery of the New World screwworm in North Africa in 1988 posed an immediate threat to Libya, the continent of Africa, and the Mediterranean region. It rapidly became clear that the price to be paid for the persistent and inevitable spread of this pest from its beachhead in the Libyan Arab Jamahiriya would be very great indeed — in terms of suffering and loss in domestic animal populations. Also, the potential impact on wildlife in Africa was a grave concern to wildlife conservationists and enlightened people throughout the world (Van der Vloedt and Butt 1990; Woodford 1992).

Based on a review of Libyan livestock importations, the source of the New World screwworm outbreak was thought to be sheep (infested with New World screwworms) imported from South America. This was the first report of the New World screwworm occurring outside the Americas, and this incursion confirmed the New World screwworm as one of the most important transboundary animal-disease threats.

Immediately after official confirmation of the New World screwworm in Libya, a series of governmental and United Nations activities began. The FAO established the Screwworm Emergency Centre for North Africa (SECNA), based in the Animal Production and Health Division in Rome, to coordinate surveillance and control activities; its field programme was set up in Tripoli, Libya (Vargas-Terán 2002b). The FAO undertook the New World screwworm emergency programme in Libya on behalf of the countries threatened by the disease, and the 22 countries and agencies that provided the emergency funds (section 2.1.), including the technical support of the IAEA and other essential support provided by other United Nations agencies — IFAD and the United Nations Development Programme (UNDP).

To contain the outbreak, veterinary services in Libya provided 90 teams to undertake periodic inspections involving millions of animals in and around the infested area. Wounds were treated prophylactically, and the movement of livestock was controlled. Prevention programmes in all neighbouring North African countries concentrated on surveillance, public information, and control of animal movements.

Containment activities were successful. The infested area around Tripoli had expanded only from approximately 18 000 to 25 000 $km^2$ by the time field eradication activities commenced. As a consequence of the control of animal movement, no foci developed elsewhere in the region. However, the infestation had become more severe within the affected area, and more than 10 000 cases were recorded in the second half of 1990, compared with less than 2000 in the same period of 1989 (FAO 1991a, b).

From December 1990 to October 1991, 1300 million sterile New World screwworm pupae were transported from Mexico to Tripoli, and the emerging flies were aerially dispersed over an area of 41 000 $km^2$ around Tripoli (Lindquist et al. 1993). The last New World screwworm case was reported in April 1991 (Krafsur and Lindquist 1996). After 14 months without evidence of the parasite, and under continuous surveillance and quarantine inspection activities, Libya was declared officially screwworm-free on 22 June 1992 (FAO 1992; Vargas-Terán et al. 1994; Hendrichs, Enkerlin et al., this volume; Klassen et al., this volume).

After eradication, the emphasis was on prevention. The FAO established the priority of improving surveillance technology and quarantine infrastructure to reduce the risk of screwworms spreading from endemic areas. This animal disease prevention approach is the background to the creation of FAO special programmes, such as the Emergency Prevention System for Transboundary Animal and Plant Pests and Diseases (EMPRES) and the Regional Animal Disease Surveillance and Control Network for North Africa, the Middle East, and the Arab Peninsula (RADISCON).

## 4. POTENTIAL OLD WORLD SCREWWORM PROGRAMMES

The Old World screwworm is widely distributed, primarily in the Indian subcontinent and South-East Asia as far north as Taiwan and to Papua New Guinea in the south-east. It is present throughout mainland Papua New Guinea, except at altitudes of more than 2500 m above sea level (Norris and Murray 1964), and high population densities of this screwworm have been found in the coastal swamplands adjacent to Torres Strait (Spradbery and Tozer 2013). The fly is present in New Ireland and New Britain, but not further into the Pacific. This screwworm species is also found in the Indian subcontinent and tropical and subtropical sub-Saharan Africa, and also in several countries in the Middle East (Spradbery and El-Dessouky 1998; Spradbery 2002a; El-Azazy and Metenawy 2004). Kloft et al. (1981) reported repeated "transit infestations", via livestock vessels, of the Old World screwworm in the Persian Gulf. The Old World screwworm was discovered in Iraq for the first time during a 1995–96 survey of filth flies around Baghdad City (Abul-Hab and Kassal 1998), and by late 1996 a major outbreak was apparent. Seasonal changes in screwworm myiases in Iraq showed a peak in December-January, and were at their lowest in July-August (Siddig et al. 2005). In 1998 the Old World screwworm fly was discovered in Yemen for the first time (Robinson et al. 2009).

### *4.1. Feasibility of Using the SIT for Suppression or Eradication*

At a conceptual level, any suppression and eradication programmes in South-East Asia should first be initiated in the archipelagos of Indonesia and the Philippines, and other island nations such as Sri Lanka. Area-wide programmes could also be applied in peninsulas, such as peninsular Malaysia and southern Thailand, although a permanent buffer zone would be required at narrow interfaces between the eradicated and endemic zones, similar to the arrangement now in place for the New World screwworm in Panama. Treatment of islands should be extended progressively within a region before moving into the continental landmass.

On the Asian continent, the challenge would be much greater, similar to that of South America. Natural "ecological islands", bounded by deserts or high mountains unsuitable for screwworm survival, should be amenable to eradication programmes. However, more ecological and genetic studies on the screwworm are required before such a strategy could be implemented. There may also be a potential, at the edge of the pest's distribution, to reduce the range. This would be more feasible if the screwworm had already been eradicated in the "ecological islands" and peninsulas.

If an eradication attempt were to be made on the continental landmass, it would be essential that a regional approach be adopted.

The screwworm outbreak in Iraq in the mid-1990s stimulated a combined response by the FAO, IAEA and the Arab Organisation for Agricultural Development (AOAD) with a view to containment and control in the region. Numerous initiatives were proposed (Hall 1997; Spradbery and El-Dessouky 1998), including a mobile mass-rearing facility on a dumb barge with a capacity for 50 million sterile flies per week that would be deployed initially in Muscat, Oman, and then be moved via the UAE towards Kuwait and Iraq as the programme progressed (Spradbery et al. 2002). The war in Iraq in 2003 and subsequent events put the Middle East screwworm control initiatives on indefinite hold.

Implementation of AW-IPM programmes using the SIT should target preferably the areas where the Old World screwworm is most damaging and vulnerable, and least able to migrate back to recolonize areas from which it had been eradicated.

### *4.2. Preparatory Activities*

In most areas where the Old World screwworm is endemic, there is a paucity of information about its population size, distribution, and possible seasonal variation. Anecdotal evidence suggests that the screwworm is a relatively minor problem under smallholder livestock production systems, but it becomes a serious production-limiting pest under more extensive grazing systems. Although farm records, where available, indicate that myiasis is a major animal-health problem under extensive grazing systems, screwworm suppression in large dairy herds is effective because the animals are observed closely every day, whereas herds of beef cattle and flocks of sheep require special mustering for inspection every few days, requiring a high labour cost that significantly reduces the efficiency of the production system.

Information about the incidence of Old World screwworm myiasis, and its significance for livestock production and public health, is limited. While this screwworm is reported widely, there are few reports of structured studies of the economic impact of the myiasis and of suppression measures; studies in Malaysia reported annual losses of USD 4.7 million (Feldmann and Slingenbergh 2002). If the screwworm became established in Australia, the estimated overall cost would be in excess of USD 794 million per annum (Kwabena Anaman, personal communication in Spradbery 2002b).

However, before an eradication programme is planned, an essential preliminary phase is the collection of comprehensive baseline data, including ecological and genetic studies to delineate the relevance of the problem (Hall et al. 2001), the infestation dynamics, and the economic, public health and environmental costs of the pest (Dyck, Reyes Flores et al., this volume). Priority areas include:

- Distribution and seasonal occurrence
- Population densities
- Incidence and severity of myiasis
- Economic impact studies
- Studies on screwworm migration behaviour

- Modelling of climatic and other effects on populations
- Application of geographic information systems (GIS)
- Genetic diversity
- Risk analysis.

### *4.3. Other Important Considerations*

Countries proposing to undertake an AW-IPM programme that integrates the SIT must have a strong commitment to it. This commitment must come not only from the government, to provide resources and an operational framework, but also there must be very strong support from, and involvement of, the livestock industry and relevant private-sector groups. AW-IPM programmes require considerable input from local people to support surveillance and monitoring programmes, and to suppress outbreaks of screwworms (Dyck, Reyes Flores et al., this volume).

Clearly, the programme must be economically viable, with a favourable benefit/cost assessment, and have adequate funds. Benefits accrue from increased livestock production (better performance of animals and fewer deaths), and reduced production costs and pesticide usage.

The AW-IPM programme may also provide considerable benefits that are hard to quantify economically, e.g. environmental benefits from reduced chemical usage and impact on wildlife, and possibly public health benefits. The large mammal fauna of northern Africa and Australia are at risk from incursions of screwworms. Reductions in native fauna would impact tourism and ecosystems. In remote areas, or in areas with poor health services, there could be significant numbers of human cases. (In the poorer regions of Central America, screwworm strikes in humans resulted in up to 40% mortality.)

### *4.4. Australian Preparedness Planning for Potential Outbreaks*

#### *4.4.1. Threat of Screwworm Introductions into Australia*

Australia is fortunate that neither the New World screwworm nor the Old World screwworm has become established in the country, although large parts of its northern areas are environmentally suitable for these pests (Sutherst et al. 1989). Atzeni et al. (1994) predicted that about 2.3 million $km^2$ could be colonized within 4–5 years of an incursion. The development of GIS for managing and predicting invasive screwworm populations (Gilbert and Slingenbergh 2008; Feldmann and Ready 2014; Bouyer et al., this volume) has led to the application of GIS to a prospective Old World screwworm incursion of Australia (Welch et al. 2014). Additionally, spatial analysis has been used to determine targeted surveillance for detecting a screwworm fly incursion into Australia (Fruean and East 2014).

The introduction and establishment of the New World screwworm into Australia is considered unlikely, but not impossible. In 1992, an Australian tourist returning from South America accidentally brought, in a neck wound, live New World screwworm larvae into Australia (Searson et al. 1992). In 2012 a woman, who had visited the Amazon rainforest in Peru, returned to Australia with a screwworm

myiasis in her scalp behind her ear, with 23 mature (up to 2 cm) live larvae of *C. hominivorax* (Lau et al. 2015). In both cases, the host patients lived on rural properties in south-eastern Australia, but the episodes occurred at a time of year when climatic conditions were unfavourable for the survival of the insect. These two case histories demonstrate the potential for inadvertent introduction into Australia via human transportation.

The Old World screwworm, prevalent in the neighbouring countries of Papua New Guinea and Indonesia, is a substantial threat to Australia. The export of live cattle from northern Australian ports to south-east Asian nations is an important export trade. In 1988 in Darwin harbour, several Old World screwworm flies were trapped by quarantine authorities aboard an empty livestock vessel that had just returned to Australia after delivering cattle to Brunei (Rajapaksa and Spradbery 1989). The Old World screwworm is also present near ports in the Middle East, such as Muscat in Oman, to which live sheep are exported from various Australian ports. Both of these situations provide an opportunity for the screwworm to enter Australia as pupae or adults in returning empty livestock-carrying vessels. While such vessels probably represent the most likely method for the pest to gain access to Australia, accidental transport on aircraft, active myiasis in humans or companion animals, are also distinct possibilities.

#### *4.4.2. Research on Screwworms*

In response to the threat of the Old World screwworm to the extensive pastoral cattle-producing areas in northern Australia, for many years Australia has conducted research on this pest. From 1973 to December 1991, the Commonwealth Scientific and Industrial Research Organization (CSIRO) studied the biology and ecology of the screwworm in Papua New Guinea. A study of dispersal by the screwworm fly demonstrated that adults could travel at least 100 km (Spradbery et al. 1995). In 1982, sterile chilled adult flies were dispersed from the air to evaluate their effectiveness in eradicating the Old World screwworm. In a small-scale field trial, it was found that up to 33% sterility could be induced in a wild population (Spradbery et al. 1989; Spradbery 1990). From 1995 to 2000, Australia and Malaysia undertook a collaborative myiasis control research project located at the Institut Haiwan, Kluang, Malaysia. The project assisted in suppression trials of the screwworm in Malaysia, and supported research that developed and evaluated improved Old World screwworm suppression and eradication techniques (Mahon et al. 2004). To confirm and provide confidence in the efficacy of the SIT, a demonstration to show that mass-reared and sterilized screwworms were fit and competitive in the field was implemented in 1986, with 62% sterility recorded (Mahon 2002, but see Spradbery 2006). Competitiveness of screwworms in the application of the SIT has been explored by Mahon (1996).

The sterile flies were produced successfully on a hydroponic diet. Most of the rearing methods for the Old World screwworm were based on techniques developed by the USDA for the New World screwworm (Wyss 2002b), but several innovations to mass-rearing larvae and harvesting chilled sterile flies for release were developed (Spradbery 1990). A small (6 million per week) pilot mass-rearing facility was built at the Institut Haiwan in Malaysia, where novel production-engineering methods

were applied to rearing this species (Mahon and Ahmad 2000). Nevertheless, there is considerable scope for improving the efficiency of mass-rearing the Old World screwworm and of releasing sterile flies in the field.

#### *4.4.3. Impact of a Screwworm Introduction*

In 1990, to enhance the state of preparedness, Australia's long-term Old World screwworm preparedness was reviewed and a plan developed. Models of the impact of the Old World screwworm indicated that the cost of an invasion would be high. Anaman et al. (1993) estimated that the annual cost (at 1991 values) of an endemic establishment, to beef-cattle, sheep and dairy producers in an average climate year, would be approximately USD 200 million. In comparison with the cost to the community (several times the producer losses), these costs would be trivial (McKelvie et al. 1993). The models indicated that large areas of tropical and subtropical Australia are suitable for year-round survival of the Old World screwworm, with further southern extensions in summer that would recede in winter (Atzeni et al. 1994).

Extensive cattle-grazing is the dominant industry throughout much of the northern pastoral areas of Australia. Based on experiences in the USA, it is likely that extensive cattle production, as practised in northern Australia, would not be viable if the Old World screwworm became established. Failure of the livestock industries would, in turn, impact severely on the small- to medium-sized towns servicing the industries, and, as there are few or no viable alternative business opportunities, many communities could collapse. However, by undertaking an eradication programme, an 8:1 benefit/cost ratio would be achieved (Anaman et al. 1993).

Australia's native fauna is naive to this pest, and inevitably, should an incursion occur, there would be some impact on the fauna, although it is impossible to predict the extent of it. Records from the Zoo Negara in Kuala Lumpur, Malaysia, confirmed that a Red Kangaroo and an Agile Wallaby were infested by screwworm fly (Spradbery and Vanniasingham 1980). Human cases of screwworm myiasis would also occur.

#### *4.4.4. Australia's Contingency Plans in Case Screwworms are Introduced*

Australia has developed contingency plans to respond to a number of exotic diseases, including the Old World screwworm, involving collaboration between the commonwealth and state governments and the livestock industries. The Australian Veterinary Emergency Plan (AUSVETPLAN 2007) contains a strategy for the suppression and eradication of the Old World screwworm should it gain a foothold on the continent (Tweddle 2002). The policy is to eradicate the screwworm in the shortest possible time, while limiting the economic impact, using a combination of strategies including the following:

- Treatment of individual animals and groups to prevent or cure infestation, especially before movement.
- SIT to suppress and eradicate the fly.

- Quarantine and movement controls in declared areas to prevent the movement of infested animals.
- Decontamination and disinfection of larvae-contaminated areas and things.
- Tracing and surveillance to determine the source and extent of the infestation, and provide proof of freedom from the disease.
- Zoning to define infected and disease-free areas.
- Public awareness campaign to encourage rapid reporting of suspected infestations, and to facilitate cooperation from industry and communities.

#### *4.4.5. Mass-Rearing Screwworms*

A fundamental plank in the eradication plan is to integrate the SIT, which at present is probably the only feasible method that can eradicate an incursion of the Old World screwworm (or New World screwworm) into Australia. It is envisaged that a facility producing 200–250 million sterile flies per week would be required, as it is difficult to predict how much a screwworm outbreak would spread before detection and containment. A facility with this capacity would be extremely expensive to construct, and there would be intense pressure to complete it as quickly as possible to prevent the screwworm from spreading and to minimize economic losses.

A design brief for a rearing facility (within Australia, if it were required), with a capacity to produce 250 million sterile screwworms per week, has been prepared (Phillimore 2002). Models have indicated that there is merit in constructing a facility, and then "mothballing it" until required. A multi-species sterile insect production facility was another attractive option evaluated by Anaman et al. (1993). In the multi-insect-facility concept, the facility would be used to produce sterile insects for the suppression or eradication of endemic pests, e.g. Queensland fruit fly *Bactrocera tryoni* (Froggatt) or Australian sheep blow fly *Lucilia cuprina* (Wiedemann) until an exotic pest incursion. After the exotic pest outbreak, the already-operational plant would fairly quickly be converted (in full or in part) to the production of sterile screwworms (or other exotic horticultural pests, e.g. the melon fly *Zeugodacus cucurbitae* (Coquillett)). Using such a multi-insect-facility, screwworm production would begin earlier in an outbreak, when the pest distribution was still restricted, and so a smaller capacity would be required.

A supplementary approach could be to maintain a culture of Old World screwworm in quarantine, e.g. Animal Health Laboratory, Geelong, Victoria, with regular infusions of wild material. A prefabricated and mothballed mass-rearing infrastructure that could be immediately deployed on a dumb barge near a future outbreak (see Spradbery et al. 2002), would provide an immediate response capability that is currently lacking. This initiative would also help maintain Australian-based expertise in culturing screwworm flies. Establishing a screwworm mass-rearing facility at an abandoned offshore detention centre on Manus Island in Papua New Guinea, for example, may be unrealistic.

#### *4.4.6. Geography and Genetic Variation of Screwworms*

The SIT could be ineffective if *Chrysomya bezziana* populations from different geographic locations proved to be a complex of sibling species (Strong and Mahon

1991; Hall et al. 2014; Wardhana et al. 2014; Krafsur and Ouma, this volume). Studies were conducted to determine the genetic variation of *C. bezziana* samples from as many localities as possible within its geographic range, using a range of techniques including allozyme studies (Strong and Mahon 1991), a hybridization study in which flies from Papua New Guinea were crossed with material from South Africa, United Arab Emirates, Sultanate of Oman, Malaysia and Indonesia (Spradbery 1989), cytogenetic studies (Bedo et al. 1994), and biochemical profiles of cuticular hydrocarbons analysed by gas chromatography (Brown et al. 1998). Using morphological and molecular analyses of Old World screwworm fly material from 14 different countries, Hall et al. (2001, 2014) deduced from mitochondrial variation that there were two distinct geographical races, one from Asia and the Persian Gulf region, the other from sub-Saharan Africa. Specimens from Iraq and Iran probably originated from nearby Arab countries of the Gulf (Hall et al. 2009; Navidpour et al. 2009), while populations within the Gulf exhibited only a small degree of genetic diversity, suggesting a Gulf colony of screwworm could be used to implement the SIT in an integrated control programme in the Asia region (Hall et al. 2009; Ready et al. 2009; Ready et al. 2014). A phylogenetic study of the screwworm confirmed African and Asian lineages, with four daughter haplotypes in Asia (Wardhana et al. 2012b), and a morphological principal component analysis separated the Asian haplotypes from Oman, Central Indonesia, Sumatra, and Papua New Guinea (Wardhana et al. 2012a, 2014).

While differences among populations do occur, the studies on geographical variation of the Old World screwworm indicated that it is not essential that the colony used to breed sterile flies for the SIT is derived from the same location as the targeted Old World screwworm population (Hall et al. 2009).

#### *4.4.7. Screwworm Surveillance*

Other components of the strategy are designed to minimize losses and supplement the AW-IPM eradication programme. An early-warning system, part of the North Australian Quarantine Strategy (NAQS), has been established. It is based on enhanced quarantine surveillance, education, and a regular trapping regime. A programme to improve baits and traps for surveillance of the Old World screwworm fly, carried out jointly by Australia and Indonesia over many years, resulted in a new bucket-trap design (LuciTrap) and a newly formulated bait Bezzilure (Urech et al. 2012). The sensitivity of the new trapping system, when compared with inspections of cattle for myiasis, demonstrated that the traps were a very effective monitoring and surveillance tool (Urech et al. 2014; see also Al-Taweel et al. 2014). Also, it was found that the addition of a cattle-derived synthetic odour to the Bezzilure bait used in sticky traps enhanced its attractiveness to screwworm flies (Sulston et al. 2014). The detection of small numbers of screwworm flies in trap catches containing large numbers of secondary blowflies of similar appearance has been vastly improved using a highly sensitive, real-time polymerase chain reaction (PCR) test capable of detecting a single screwworm fly in a sample of 1000 non-target species or up to 95.5% probability of detecting one in a catch of 50 000 flies (Jarret et al. 2010; Morgan and Urech 2014).

*4.4.8. Treating Animals*

Ivermectin and avermectin are effective systemic pesticides against the larval stages of the Old World screwworm (Spradbery et al. 1985), and would be used to treat infected animals and those wounded in the course of normal husbandry procedures. Ivermectin boluses prevent screwworm myiasis for 102 days (Wardhaugh et al. 2001). Ivermectin boluses, or another long-acting formulation such as insecticidal cattle ear tags (Tozer and Spradbery 2002), could limit the incidence and spread of the screwworm in extensive pastoral areas. This would reduce the population of screwworms, and perhaps thereby the incidence of myiasis, and certainly reduce dispersal. However, native and wild animals would be a problem since they cannot be treated effectively. The importance of insecticides, as an integral part of the application of the SIT, was emphasised by Wardhaugh and Mahon (2002). A review of chemicals that could be used to control the screwworm was undertaken by James et al. (2005). Subsequently, therapeutic and prophylactic studies in the laboratory and on animals were made in Indonesia to determine the efficacy of Australian-registered chemicals for potential use in screwworm fly control, with dicyclanil spray-on and ivermectin controlled-release capsule formulations giving longer protection than the currently recommended subcutaneous ivermectin (James et al. 2017).

Studies on vaccinations against screwworms showed that it is possible to induce dramatic immunological effects on feeding larvae, but a recombinant vaccine will prove elusive (Willadsen 2000; Willadsen and Partoutomo 2000).

*4.4.9. Public Awareness*

Public awareness and early reporting of a suspect myiasis are emphasized, both prior to, and in response to, an outbreak, especially in northern Australia. A video entitled "Recognizing exotic livestock disease number 7: screwworm fly" has been produced to train veterinarians and other health professionals. To encourage the submission of larvae from myiasis strikes, specimen collection kits have been supplied to producers (and health centres) in northern Australia. Spradbery (2002a) prepared a diagnostic manual, and people have been trained to identify the Old World screwworm and differentiate it from other species. A detailed diagnostic comparison of the two screwworm fly species has been published (Welch and Hall 2013). The "Old World Screwworm Fly Manual" published in 2002 is under revision with a new edition planned, possibly incorporating the latest diagnostic technologies from wing morphometrics to X-ray computerized tomography (CT) scanning (Beckett et al 2016; see also Animal Health Australia (AHA 2017)).

## 5. CONCLUSIONS

The myiasis caused by New and Old World screwworm flies, documented for its transboundary importance, is an animal and human disease that causes significant sanitary and economic damage when it enters a country previously free of the screwworms. Screwworm-free countries must be informed about its epidemiology and methods of suppressing it, and establish appropriate prevention measures to

avoid introducing it. Nowadays, with international transport, the globalization of economies, and the rapid long-distance movement of animals and animal products, mobilization of pets and the increase of adventure tourism, the risk of transporting pests and diseases has greatly increased. As a result, stronger quarantine measures are being applied, with the potential of restricting free world trade. Some risks can be mitigated if the causal factor is removed. The elimination of the New World screwworm in North and Central America has removed an obstacle to animal movement within this zone.

Although in some areas the traditional methods of suppressing screwworms apparently give good results, the use of modern area-wide tactics must be considered together with the "One Health" (FAO, OIE, WHO) initiative approach to eliminate the disease where extensive grazing or more intensive livestock systems are predominant. In addition, other positive benefits will arise. As a direct result of the screwworm eradication programme in North and Central America, national animal-health organizations in the region are now working closely together. Also, within each country, the government animal-health sector has built stronger bridges to producers. Since the screwworm programme directly involved producers, and depended on them to assist in the eradication, they also became part of the programme and took pride in the results; this stimulated cooperation in other programmes.

The modern area-wide approach to eradicate screwworm populations has proved to be successful. However, it is essential that the governments of affected countries in Africa, Asia, South America (Fisher and Romero 2018), the Caribbean, and the Middle East give political support where the elimination of the disease would be feasible and cost-effective, and thus avoid continuous economic losses. As well, because of myiasis in humans, screwworm eradication would also improve human health.

## 6. ACKNOWLEDGEMENTS

We thank Pamela L. Philips, USDA/ARS, Francisco Pinilla, COPEG, and John B. Welch, USDA/ARS, for describing recent progress in the use of the SIT in Panama and for providing unpublished data on the New World screwworm. Also, we thank Rudolf Urech and Peter Green, screwworm experts, and Geoffrey Chubb (Australian Government Department of Agriculture and Water Resources) for the inputs and review of the Old World screwworm sections of this chapter.

## SUMMARY

Measuring the impact of area-wide integrated pest management (AW-IPM) programmes, that use the sterile insect technique (SIT) to control fruit fly pests of economic significance, is complex. These programmes affect practically the whole horticultural food chain. In this chapter, the impact of the programmes is assessed by focusing only on the benefits generated to producers and traders of horticultural products, the direct beneficiaries. This is done first by describing the types of benefits accrued from these programmes, second by explaining some of the main factors that influence programme benefits, and finally by presenting several examples to illustrate how the SIT technology, when properly applied for eradication, containment, suppression, or prevention purposes, can generate substantial direct and indirect benefits to the horticulture industry.

## 1. INTRODUCTION

Recently, the FAO (Food and Agriculture Organization of the United Nations) estimated that, to meet the projected food demand by 2050, global agricultural production will have to increase by 60% (FAO 2016). Area-wide integrated pest management (AW-IPM) programmes, that use the sterile insect technique (SIT) to control insect pests, including fruit flies of economic significance, can substantially contribute to meeting this demand by enabling the production of more and better-quality horticultural products at a lower cost, increasing supply, diversifying markets, creating new jobs, and all in a more sustainable environment-friendly manner. Measuring the impact of such programmes integrating the SIT is a complex task.

This chapter will concentrate more on the direct benefits generated by such programmes to beneficiaries — the producers and traders of horticultural products, although benefits impact the whole food chain system from farmers to consumers, passing through all the intermediate links of packing, shipping, distributing to wholesale and retail markets, and selling. In addition, the benefits branch out to other related businesses, such as suppliers of farm inputs, packing and raw materials, and some other services.

In the past decades, several studies have prospectively assessed the economic feasibility of potential fruit fly programmes integrating the SIT. These studies have been the basis for deciding to invest or not to invest in such programmes (Reyes et al. 1991; IAEA 1995; Enkerlin and Mumford 1997; Larcher-Carvalho et al. 2001; Vo et al. 2002; Larcher-Carvalho and Mumford 2004; IAEA 2005; Mumford, this volume). However, more relevant to this chapter are similar retrospective studies to measure the economic returns and impact of ongoing programmes at different stages

of implementation (USDA/APHIS 1993; Mumford et al. 2001; Kakazu 2002; Knight 2002; IICA 2009, 2010, 2013; Mumford, this volume).

This chapter assesses the impact of fruit fly programmes integrating the SIT. The most common direct and indirect benefits to the horticulture industry, especially to the producers and traders of horticultural commodities, are reviewed.

## 2. DIRECT AND INDIRECT BENEFITS

Inefficient pest control practices, or no control at all, result in direct and indirect losses from fruit flies that translate into direct and indirect benefits when using more effective alternative control methods and approaches such as the area-wide application of the SIT. For example, if direct fruit fly damage would normally cause a 25% loss in fruit yield, the area-wide application of an improved technology that reduces damage by 80% would lead to a direct benefit of a 20% increase in yield. Another example is the indirect damage from secondary pest outbreaks caused by killing natural enemies with regular insecticide "cover" sprays. If an effective and environment-friendly control technology is used, the amount of insecticide applied is reduced and more natural enemies survive to suppress the secondary pest populations; in this situation, a 10% indirect loss would potentially become a 10% indirect benefit.

The direct benefits commonly used to measure the impact of programmes integrating the SIT are:

- Increase in fruit yield and quality through reduced damage,
- Reduction in production costs through a more cost-effective control method.

The indirect benefits commonly used to measure the impact of programmes integrating the SIT are:

- Increase in fruit and vegetable export volumes, and market retention or diversification, through effective control of quarantine pests,
- Increase in export volumes through reduced rejections of commodities which do not comply with pest absence or the insecticide residue levels,
- Increase in fruit yield through reduced secondary pest outbreaks,
- Savings in medical costs, and occasionally deaths, through reduced exposure to insecticides, and also in legal costs arising from damage to private or public property as a result of insecticide misuse,
- Greater protection of beehives resulting in increased fruit yield through increased crop pollination,
- New jobs created in the horticulture industry and related businesses and services,
- Better human nutrition due to a per capita increase in fresh-fruit intake,
- Savings in environmental and public health costs through reduced insecticide residues in fruit, water reservoirs, and soil.

These indirect benefits are very difficult to assess and quantify, and in most cases have been accounted for only qualitatively (Pimentel et al. 1992).

The impact of programmes integrating the SIT has focused mostly on the direct benefits, but attempts have been made to quantify some indirect benefits using ad hoc methodologies (Enkerlin 1997). To partially quantify benefits to the

environment from using methods such as the SIT, the monetary value of savings accrued from minimizing insecticide use has been estimated (Pimentel et al. 1992). For example, in 1997, it was estimated that some Middle East countries (Israel, Jordan, and Territories under the Jurisdiction of the Palestinian Authority) would over 6 years, if current control practices prevailed, spend USD 46.7 million for insecticides to suppress the Mediterranean fruit fly *Ceratitis capitata* (Wiedemann). This compares with only USD 5.8 million that would be spent on insecticides over the same period if pest suppression with the SIT were adopted, a direct benefit of USD 40.9 million in 6 years related to reduced insecticide use, in addition to the indirect environmental benefits (Enkerlin and Mumford 1997).

Another example of an indirect benefit is the per capita increase in fruit production. A study (Vo et al. 2002), to assess the economic feasibility of fruit fly control in the Central American region using the SIT, indicated that the average per capita production of fruits was 17.2 kg/year, substantially lower than the world's average annual per capita production of 75 kg in 2016 (FAO 2016). Effective fruit fly control in the Central American region would reduce current fruit damage and increase the annual per capita production of fruits in the short term by 10.5% to almost 19 kg/year, equivalent to 48 600 tonnes valued at USD 25 million/year. On a country basis, the amount of fruit (from fruit fly hosts) produced per capita per year is as follows: Costa Rica — 85 kg, El Salvador — 12.2 kg, Guatemala — 18 kg, Honduras — 11.5 kg, Nicaragua — 24.7 kg, and Panama — 16 kg. (There are no data available for Belize, but being a Mediterranean fruit fly-free country, with a traditionally friendly market under the Commonwealth umbrella, the per capita production can be assumed to be well above the regional average.) Clearly in Costa Rica, where the fruit industry is well organized and fruit production has been modernized, the annual per capita fruit production is comparable with the highest values in the world. On the other hand, in the other countries in the region, especially El Salvador, Honduras, and Panama, the annual per capita fruit production is extremely low — due to a lack of appropriate infrastructure, deficient growers' organizational schemes, and insufficient government incentives for fruit production and commercialization. Effective fruit fly control would permit the development of fruit fly low-prevalence and fly-free areas, paving the way for private investment in fruit production and commercialization for both the domestic and export markets, contributing to increases in per capita production, preventing chronic disease, creating new jobs, and stimulating the economy (Vo et al. 2002).

In Jordan, the cost of poisonings arising from using organophosphate insecticides against fruit flies was assessed. It was estimated that USD 1.6 million/year are spent for treatment of moderate to severe poisonings, and for labour-days lost. Each year an average of 94 tonnes of insecticide, i.e. technical material, are applied to control the Mediterranean fruit fly. This represents 33.8% of the total insecticide use in Jordan. Thus, assuming that sprays against this fruit fly cause a corresponding one-third of poisoning cases, about USD 550 000 are spent each year to treat persons poisoned when spraying against the Mediterranean fruit fly. In the assessment of total benefits that would be produced should the SIT technology be adopted to suppress this pest in Jordan, this cost was included in the indirect benefits (IAEA 2001).

Moreover, a study to measure the direct and indirect benefits of Mediterranean fruit fly control in the island of Madeira, Portugal (Dantas et al. 2004), was conducted using two valuation techniques. The first involves quantifying the costs incurred by society when dealing with the externalities caused by insecticides. In this case, only those costs that can be attributed specifically to the use of insecticides for Mediterranean fruit fly control in fruit crops are included. The second method, used for environmental valuation, is called "contingent valuation". This method is based on the choices people make when they are presented with a variety of goods and services; a "willingness to pay" (WTP) indicates a positive preference. Quantification of the indirect benefits accrued from using the SIT for Mediterranean fruit fly suppression in Madeira makes economic returns positive in two out of three control scenarios analysed (IAEA 2005).

The benefits generated by programmes that control fruit flies with an "integrated SIT approach" will be determined and shaped mainly by the characteristics of the pest problem, including pest status (presence or absence), level of pest risk, and access to the targeted market, as well as by programme strategic options (section 3.2.; Hendrichs, Vreysen et al., this volume). There are other factors that will influence the benefits: the type of organization (public, private or joint ventures) and organizational structure (centralized, decentralized or a combination) used to execute the programme, the level of participation of the main stakeholders, the readiness to take advantage of the improved phytosanitary condition, increased fruit production and quality including the necessary means for commercialization in national and international markets, global market supply-demand forces, and the strategic approach and tactics selected to achieve programme objectives (of particular relevance are the size of the intervention areas and the time period required to achieve the pest control goal).

A brief explanation of how some of these factors, in particular organizational structure, stakeholder participation, and programme strategic options, affect the benefits produced by programmes applying the SIT, and hence their impact, is presented in the following section.

## 3. FACTORS THAT AFFECT BENEFITS PRODUCED BY PROGRAMMES USING THE SIT

### *3.1. Organizational Structure and Stakeholder Participation*

To date, most fruit fly programmes integrating the SIT have been public projects, operated through a centralized federal government structure, with different degrees of participation from local governments, and with limited participation from the horticulture industry at the farm level. Often these have been prevention and emergency response programmes aimed at protecting the welfare of the horticulture industry, keeping out quarantine pests or eliminating outbreaks of recently introduced invasive pests. A typical example of such programmes is Chile's National Fruit Fly Programme aimed at maintaining fruit fly-free status through an effective early detection and emergency response system, operated by the

Agriculture and Livestock Service of the federal government (Olalquiaga and Lobos 1993; section 4.2.).

Other types of programmes include those where strong alliances have been formed among the federal and local governments and the fruit industry, which share capital investment, operational costs, and responsibilities. These programmes aim to control established key fruit fly pests that, by directly affecting production and commercialization, limit the development of the horticulture industry. A typical example of such programmes is the National Fruit Fly Campaign of the Mexican government (SAGAR/IICA 2001; section 4.6.).

As the SIT technology becomes more cost-effective when compared with other more-conventional methods of fruit fly control, interest from the private sector in its application has slowly increased. Public-private organizational schemes, in which governments, the horticulture industry, and other private and/or civil organizations form alliances and partnerships for financing and operating area-wide programmes integrating the SIT, are becoming more common. In some cases, the participation of federal and local governments will be limited to a supporting role, e.g. creating the legal framework for smooth implementation of programme activities, and setting standard operating procedures (SOPs) in the form of phytosanitary norms for the production, shipment, importation, and release of sterile flies. Also, when required, governments must enforce quarantine regulations. An example of a scheme where the private sector has become involved in area-wide fruit fly control is the fruit fly suppression programme in the Hex River Valleys and other fruit producing areas in the Western Cape Province of South Africa, in operation since 1997 (Barnes et al. 2004; section 4.4.), and covering more than 22 000 ha of commercial deciduous fruit and table grapes (Venter et al. 2021).

As predicted earlier, and given prevailing diverse political and economic environments, programmes integrating the SIT will operate under different types of organizational structure. Countries such as Argentina, Australia, Brazil, and Morocco are operating programmes run by government-private sector alliances, and even some programmes or segments of programmes are operated fully by the private sector, for example in Israel and South Africa, but other countries, e.g. Belize, Chile, Croatia, Dominican Republic, Peru, Guatemala, Mexico (Moscamed), Spain, and the USA conduct mostly government-managed programmes. A key element for success in government or semi-government programmes is that the financial resources must be available in sufficient amount and with no delays according to an agreed technical and financial operational plan. Resources should be administered under an unbureaucratic flexible scheme where the budget adapts to the requirements and dynamics of the programme's operations, and not the programme to the budget (Enkerlin et al. 2017; Dyck, Reyes Flores et al., this volume).

Government-run programmes come at a low cost to the direct beneficiaries, since most of the required capital and operational inputs are fully or partially subsidized, and normally governments do not seek cost-recovery. If the programme is effectively executed, the beneficiaries start to accrue benefits or profits quickly. However, these programmes rely on political and economic stability, and under certain conditions the managerial and technical capabilities of governments are more exposed to failure. Since programmes integrating the SIT are financially demanding

and management intensive, countries that decide to embark on such programmes must have a strong long-term political commitment and fulfil a minimum institutional capacity to manage them. Countries that begin a large-scale SIT governmental project, with little or no support and participation of the private sector, and no support from international organizations and other relevant stakeholders, are likely to fail in the endeavour. This situation contrasts with programmes that are established as strategic alliances between government and private sector, with the support of international organizations, and where the stakeholders are actively involved in programme execution or supervision. Under this scheme, with private assets and financial capital invested in the programme, there is little or no government subsidy. Direct beneficiaries and other stakeholders have to wait longer for payback of the initial investment, and for profits to start flowing. However, in the long term, since they are not so dependent on political stability and programme management is normally carried out more effectively, these programmes tend to be more sustainable.

### *3.2. Programme Strategic Options*

Based on the goals of the programme, and the status of the target pest in the area of interest, fruit fly programmes integrating the SIT can be grouped into four main strategic options, as follows: (1) eradication — eliminate from an area an established pest or an outbreak of an introduced pest to establish pest free areas, (2) suppression — reduce pest populations to establish low pest prevalence areas, (3) containment — apply phytosanitary and regulatory measures in and around an infested area to prevent the spread of the pest, and (4) prevention — apply phytosanitary and regulatory measures to prevent the introduction or reintroduction of a pest into a pest free area (FAO 2017; Hendrichs, Vreysen et al., this volume). Suppression, eradication, containment, and prevention programmes can provide the same types of direct and indirect benefits listed above (section 2.). However, in terms of required inputs, economic returns and subsequent impact, there are marked differences among these four types of programme.

In areas with a high risk of introductions, the most profitable strategy of using the SIT is prevention. It is always much more cost-effective to protect proactively a pest free area from the introduction and establishment of a pest than having to "live with" or eradicate it. However, when the target pest has already become established in an area, the options for using the SIT to control the pest are eradication, suppression, or containment.

Figure 1 shows a typical net-benefits trend for three control options — SIT suppression, SIT eradication, and insecticide-bait suppression. Net-benefits tend to be greater in an eradication programme than in a suppression programme. After eradication has been achieved, and the area has been certified fly-free, horticultural products can be exported to fly-free high-value markets without complying with expensive postharvest treatments and other quarantine regulations. Furthermore, the ongoing cost of maintaining an area fly-free (detection networks, quarantine regulations, and in some cases the release of sterile flies), although costly, would normally be lower than the cost of a permanent SIT suppression programme.

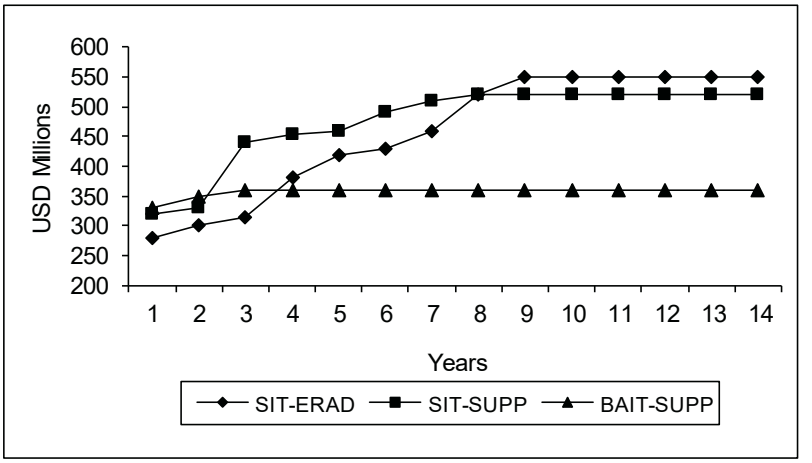

*Figure 1. Typical net-benefit trend for three control options: SIT eradication, SIT suppression, and insecticide-bait suppression. (Figure adapted from Enkerlin and Mumford 1997.)*

Once the eradication goal has been reached and benefits fully established, the combination of higher gross revenues at a lower cost makes the eradication approach more economical than the suppression approach (Fig. 1). However, an eradication strategy requires greater initial capital investment than a suppression strategy. In addition, after eradication has been achieved, the fly-free area will be exposed, depending on the situation, to a certain risk of reinfestation (quarantine operations are vulnerable and subject to some degree of failure). Recurrent pest outbreaks require costly emergency programmes to eradicate the reinfestations, and the enforcement of quarantine restrictions by trading partners can last for months or even years. This cost needs to be included when calculating the total cost of an eradication programme. There are situations where the risk of reinfestation is very high, and an eradication programme is not economically justifiable if there are recurrent outbreaks that disrupt agricultural trade; the stakeholders would be better off with suppression, which entails a lower risk. Alternatively, a preventive release programme can be cost-effective in situations where there is a high risk of reinfestation (Hendrichs, Vreysen et al., this volume; Mumford, this volume).

From technical and economic points of view, any one of the strategic approaches described above may, in a particular situation, be the best option. However, in some situations, the establishment and strict enforcement of quarantine barriers would be too disruptive to trade, excluding the eradication option. The choice depends on the conditions prevailing in the target area, such as the pest's status, the geography and ecology of the area, the available resources and overall plant protection and quarantine infrastructure, and the commitment and level of participation of stakeholders and their willingness to take risks. Therefore, it is critical that a decision to embark on one or the other approach is based on technically and economically sound analyses of the pest problem.

## 4. BENEFITS ACCRUED FROM FRUIT FLY PROGRAMMES USING THE SIT

The SIT can be a cost-effective component of the AW-IPM of some of the most important fruit flies of economic significance, such as the Mediterranean fruit fly, oriental fruit fly *Bactrocera dorsalis* (Hendel), melon fly *Zeugodacus cucurbitae* (Coquillett), Mexican fruit fly *Anastrepha ludens* (Loew), West Indian fruit fly *Anastrepha obliqua* (Macquart), Queensland fruit fly *Bactrocera tryoni* (Froggatt), and Caribbean fruit fly *Anastrepha suspensa* (Loew) (Nigg et al. 2004).

In the past, at least 27 AW-IPM programmes in the world have integrated the SIT to control fruit flies. In Table 1, they are grouped by the strategic options pursued, i.e. eradication, suppression, containment, prevention, and combinations thereof (section 3.2.; Hendrichs, Vreysen et al., this volume). A few programmes have been selected to illustrate the benefits that have been produced.

Most of the data available on programme benefits and impact are based on quantifications of direct benefits, and in a few cases indirect benefits are also included. However, most of the indirect benefits are usually not accounted for, and therefore in most cases the overall benefits of these programmes are underestimated. Nevertheless, it is very evident that, when the technology is applied properly, the programmes generate substantial benefits to the horticulture industry and to society.

### *4.1. Fruit Fly Prevention Programme — California, USA (Box 1)*

#### *4.1.1. Problem Definition*

The Mediterranean fruit fly is a serious threat to California's economy. For the fruit industry alone, the annual value of susceptible crops in 2002 was about USD 4700 million (CASS 2002; USDA/NASS 2002, 2003a, b). The rate of introduction of this non-native pest, which can attack more than 250 different crops (Liquido et al. 2014), has been increasing with growing trade and tourism. Since 1975, more than USD 256 million (in state and federal funds) have been spent to eradicate small and large infestations, primarily in urban areas of the Los Angeles Basin and the San Francisco Bay area.

*Table 1. Fruit fly AW-IPM programmes that integrated the SIT, grouped by strategic option*

| Strategic option | Programme |
|---|---|
| Prevention | Mediterranean Fruit Fly Preventive Release Programme (Los Angeles Basin, California, USA), 1996 – present |
| | Mediterranean Fruit Fly Preventive Release Programme (Tampa-Palm Beach-Miami, Florida, USA), 1998 – present |
| | Mexican Fruit Fly Preventive Release Programme (Rio Grande Valley, Texas, Mexico – US border), 1980s – present |
| | Mexican Fruit Fly Preventive Release Programme (Tijuana, Baja California, Mexico – US border), 1980s – present |
| | National Fruit Fly Control Programme (Chile), 1996 – present |
| Containment | Mediterranean Fruit Fly Programme "Programa Moscamed" (Guatemala, Mexico, USA), 1983 – present |
| | Binational Chile-Peru Programme for Mediterranean Fruit Fly Eradication, 1996 – present |
| | Queensland Fruit Fly SIT Control Programme (South-Eastern Australia), 1980s – present |
| Eradication | Mediterranean Fruit Fly Programme "Programa Moscamed" (Guatemala, Mexico, USA), 1978 – 1982 |
| | Melon Fly Eradication Programme (Okinawa, Japan), 1978 – 1993 |
| | Oriental Fruit Fly Eradication Programme (Guam), 1963 – 1964 |
| | National Mediterranean Fruit Fly Programme (Chile), 1990 – 1995 |
| | Carnarvon Medfly Eradication Project (Carnarvon, Australia), 2016 – present |
| | Mediterranean Fruit Fly SIT Control Programme (Southern Australia), 1980s – present |
| | Mexican Fruit Fly and West Indian Fruit Fly Eradication Programme (Northern Mexico), 1988 – present |
| | Mediterranean Fruit Fly Eradication Programme "PROCEM" (Mendoza – Patagonia, Argentina), 1992 – present |
| | Mediterranean Fruit Fly Eradication Programme (Altagracia, Dominican Republic), 2015 – 2017 |
| Suppression | Mediterranean Fruit Fly Suppression Programme (Arava, Israel), 1994 – present |
| | Mediterranean Fruit Fly Suppression Programme (South Africa), 1997 – present |
| | Oriental Fruit Fly Suppression in Pilot Areas (Thailand), 2000 – present |

*4.1.2. Major Achievements*

The Preventive Release Program (PRP) has resulted in a 96% reduction in the number of wild Mediterranean fruit flies caught in the treated Los Angeles basin, and more than a 96% reduction in the number of fly infestations. Before the change in 1994 to an area-wide approach (1987–1993), an average of seven or eight Mediterranean fruit fly outbreaks occurred every year, costing the state approximately USD 33 million per year (USDA/APHIS 1992). Since the implementation of the PRP in 1996, and after eliminating all outbreaks, the overall cost of the programme has been cut in half, and only a few small Mediterranean fruit fly infestations have occurred within the boundaries of the release area. These infestations remained confined and were quickly eliminated without applying aerial sprays of toxic bait and without trading partners establishing temporary quarantines for Californian exports.

*Box 1. Mediterranean Fruit Fly Preventive Release Programme (PRP) in the Los Angeles Basin, California Department of Food and Agriculture (CDFA 2002)*

After years of using the conventional reactive approach, i.e. detecting and eradicating Mediterranean fruit fly infestations at a local level, in 1994 the control strategy shifted to a proactive approach that emphasized area-wide measures over the whole Los Angeles Basin, including twice-weekly sterile-male releases. In view of its success, this release programme has continued preventively since 1996, and has become a major component of CDFA's comprehensive approach to prevent this pest from becoming established in California (Dowell et al. 2000). This programme is jointly coordinated and operated by county, state, and federal authorities.

*4.1.3. Estimated Benefits*

The impact of this programme has been measured in terms of the potential economic losses that the pest would inflict on the horticulture industry and home-garden fruit production if it became established in California. The parameters that have been used to measure the impact are the following: yield loss in agriculture and home-garden production, increased insecticide use (from 127 to 2270 tonnes/year of active ingredient), loss of export markets, and annual quarantine compliance costs (CDFA 2002). In 1991 it was estimated that a permanent Mediterranean fruit fly infestation could cost California's economy USD 1300–1900 million annually (yield loss, control costs, quarantine compliance costs, and loss of export markets, not including the social and environmental costs), with the loss of 14 000 or more jobs (Siebert and Pradham 1991). The current estimated benefit/cost ratio (BCR) of the PRP programme in California ranges from 87 to 187 (K. Hoffman, personal communication).

The insecticide savings (amount of active ingredient not used) have been very large. If the CDFA had continued to apply aerial toxic-bait sprays on the same 3800-$km^2$ area that was infested in 1994, some 458 tonnes of malathion would have been used (CDFA 2002). In contrast, since implementing the basin-wide sterile Mediterranean fruit fly releases, only a small amount of insecticide has occasionally been applied against pest incursions as part of the emergency reaction plan to some of the reduced number of Mediterranean fruit fly outbreaks that still occur periodically in California.

### *4.2. Fruit Fly Prevention/Containment Programme — Chile* (Box 2)

#### *4.2.1. Problem Definition*

An important component of the Chilean economy is the production and export of fruits and vegetables, worth about USD 2000 million annually. As a prerequisite to importing these commodities, some of the main commercial partners, e.g. USA and Japan, require that produce be grown in certified fruit fly-free areas. Except for Arica province at the northern tip of the country, and occasional outbreaks in other provinces, Chile has historically been regarded as a fruit fly-free country. However, some countries used the presence of the Mediterranean fruit fly in northern Chile as a pretext to close their markets to Chilean horticultural products; as a result, since the 1980s, this stimulated significant eradication efforts in Arica province. Following various failed attempts to eradicate the Mediterranean fruit fly from northern Chile using baits sprays, in late 1990 the SIT was introduced. After 6 years of an intensive integrated area-wide programme, in 1995 the fly was eradicated in Arica, and Chile was declared a fruit fly-free country (MAG/SAG 1995).

#### *4.2.2. Major Achievements*

Since its inception in 1980, Chile's National Fruit Fly Programme has, through effective surveillance and eradication activities, successfully kept the country free of economic species of fruit flies. Chile's programme to remain fruit fly-free is one of the best in the world.

Strengthening binational cooperation with Argentina and Peru, and formalizing binational cooperation with Bolivia, are the cornerstones that sustain Chile's fruit fly-free status.

#### *4.2.3. Estimated Benefits*

Since Chile was declared a fruit fly-free country, fruit exports have grown to an annual 320 million boxes of fruits, mainly table grapes, apples, stone fruits, kiwis, and avocados, valued in 2016 at USD 4000 million (ASOEX 2017).

Each year the government of Chile spends on average USD 4 million to keep the country free of fruit flies. If multiple outbreaks occurred in Chile's Metropolitan Region, the industry would lose an estimated USD 78 million per year, just in market loss and compliance with US quarantine regulations. Chilean exports of fruits and vegetables are valued at approximately USD 4000 million per annum. If this figure is divided by the average annual cost of the national programme, a BCR of 1000:1 is obtained. This ratio would be even higher if other cost factors, e.g. control costs, yield losses, and general social and environmental costs, were included (Lindquist and Enkerlin 2000; R. Rodriguez, personal communication).

Chile's National Fruit Fly Programme (Box 2) has been the driving force behind the expansion of the fruit and vegetable export industry, one of the main contributors to the country's gross domestic product (GDP).

*Box 2. National Fruit Fly Programme in Chile*

Chile's fruit fly-free status has allowed one of the most important export-oriented horticulture industries in the world to develop. To protect this valuable asset, in 1980 the Government of Chile, through the Servicio Agricola Ganadero de Chile (SAG) of the Ministry of Agriculture (MAG), created Chile's National Fruit Fly Programme — to prevent the introduction and establishment of any fruit fly species of economic importance, including the Mediterranean fruit fly and the economic species in the genera *Anastrepha* and *Bactrocera* (Olalquiaga and Lobos 1993).

The National Fruit Fly Programme in Chile operates through a centralized organizational structure of the Ministry of Agriculture. As part of a regional approach to the fruit fly problem, the Government of Chile has subscribed binational agreements with Argentina and Peru. Through these agreements the quarantine infrastructure and fruit fly control activities in these neighbouring countries have been strengthened, and thus the risk of introducing fruit fly pests from these countries has been reduced.

Chile has achieved its fly-free status by implementing two major strategic activities:

1. Effective national and international quarantine system (including interprovincial quarantine road stations and international quarantine at ports of entry), and an extensive and highly sensitive fruit fly-trapping network to detect fruit fly introductions at an early stage. Outbreaks of exotic fruit flies, mainly the Mediterranean fruit fly, have been eradicated through the effective execution of an emergency eradication plan based on detecting and eradicating infestations. A *B. dorsalis* outbreak on Easter Island was eradicated in 2011 at a cost of USD 100 000 (AGROMEAT 2017).
2. In Arica province, the ongoing Mediterranean fruit fly AW-IPM programme that integrates the SIT functions as a containment barrier to avoid the natural or artificial spread of fly populations into northern Chile, protecting the main fruit and vegetable production areas in the central and southern parts of the country.

For years, Chile has been subjected to increasing risks of pest introductions through more trade, tourism, and people coming from neighbouring countries. Consequently, there has been an increase in the rate of Mediterranean fruit fly detections and outbreaks. Nevertheless, the Government of Chile (through SAG) has strengthened its National Fruit Fly Programme by gradually incorporating state-of-the-art technology. This includes introducing an improved genetic sexing strain of the Mediterranean fruit fly into the mass-rearing facility in the Lluta Valley (Arica province), DNA-identification techniques to assess the geographical origin of introduced flies, updated fly-trapping systems, and X-ray machines at critical points of entry to facilitate detection and confiscation of fruit that are hosts of the Mediterranean fruit fly (Lindquist and Enkerlin 2000; Gonzalez and Troncoso 2007).

### *4.3. Fruit Fly Eradication Programme — Japan* (Box 3)

#### *4.3.1. Problem Definition*

In its current distribution range, the melon fly is the most destructive pest of cucurbit crops. It is found in Africa, India, South-East Asia, and islands in the Pacific (including Hawaii). In Japan, it was first discovered in 1919 in the Yaeyama Islands, and between 1919 and 1970 it invaded most island groups in the south of Japan. In Okinawa, this pest affected more than 40 important vegetables and fruits, inflicted substantial direct damage to fruits, and prevented the export of these infested commodities to fly-free areas.

Sugarcane was the most important cash crop in Okinawa, accounting for about 50% of cultivated land and 20% of all farm income. However, as a result of stagnant prices and productivity, as well as increased international competition, income from sugarcane production declined significantly. Okinawa's sugar industry survived only because of the government's price-support programme. As a result, farmers and the local government needed to diversify from monoculture sugarcane-centred agriculture into other cash crops, e.g. flowers, and tropical vegetables and fruits such

as mango. The other promising agricultural strategy was to produce "healthy" food, and for Okinawa to become a brand name for "healthy longevity" because of its world-renowned "healthy island" image.

Due to this situation in Okinawa, in the early 1970s the eradication of the melon fly became the top priority project at local and national levels. The problem was urgent since the fly was rapidly spreading to other islands and, unless specific eradication measures were undertaken, might spread to mainland Japan.

#### *4.3.2. Major Achievements*

- First successful use of the SIT for melon fly eradication in island communities,
- Eradication was achieved with no harm to the health of the public or the environment,
- Lifting of internal quarantine regulations to allow transport to non-infested areas resulted in significant expansion of major horticultural products,
- Training of foreign technicians in the AW-IPM of the melon fly.

*Box 3. Melon Fly Eradication Programme in Okinawa, Japan (Kakazu 2002)*

Okinawa's prefectural government, with the support of the Japanese national government and active participation of staff of municipalities (mainly in field operations) and agricultural cooperatives, operated the programme. In 1972, an experimental melon fly eradication project using the male annihilation technique (MAT) and the SIT was conducted in Kume Island. Following successful eradication, in 1978 a project was initiated that gradually covered most archipelagos in the south of Japan; it was completed in 1993. In view of the geographic closeness of the southernmost islands to Taiwan, where the melon fly is present, in these islands the programme currently conducts a continuous detection, quarantine, and preventive release operation against re-establishment of the pest.

#### *4.3.3. Estimated Benefits*

A post-programme economic assessment, prepared by the Research Institute for Subtropics (Kakazu 2002) using the methodology described by Enkerlin and Mumford (1997), clearly shows the benefits of melon fly eradication. The estimated net-benefits are those arising from the commercial shipments of commodities that are hosts of the melon fly. Not included in the assessment were indirect benefits for the island economies, such as human health and environmental protection, insecticide-free farming, preservation of natural enemies, savings in fumigation and quarantine costs, and above all preventing the insect from spreading to the mainland of Japan. Furthermore, due to data constraints, the indirect social benefits were not estimated. The programme proved to be economically viable, even though only the increase in commodity shipments was considered in the benefit equation.

If the northward spread of the melon fly had not been stopped, the potential loss for farmers and the horticulture industry in general would have been very substantial, and the cost of an eradication programme would have risen enormously. As a result of the successful eradication programme, the production of Okinawa's high-valued niche products, such as bitter melon and mango, have risen sharply. Between 1990 and 2000, bitter melon production rose from 2720 to 6220 tonnes, a 2.3-fold increase. Similarly, over the same period, mango production increased from 278 to 1290 tonnes, a 4.6-fold increase; all together this is equivalent to USD 335

million in 10 years. (These benefits are underestimated since the savings from fumigation and quarantine costs were not included in quantifying the benefits.) This figure should be compared with the much lower total programme cost, USD 172 million, during the 16-year eradication period (1978–1993).

In 1996, 3 years after achieving eradication in the last islands (Yaeyama Islands), the programme reached its break-even point and repaid the initial investment. Between 1997 and 2000, the programme cost was estimated to be USD 31 million, but gross revenues were USD 167 million (from the sale of commodities shipped to mainland Japan and other countries). If the total accumulated gross revenues are divided by the total accumulated costs during this time period, the BCR shows that 5.4 dollars were returned for each dollar invested. For a public investment project in Japan, it is a remarkable achievement that the programme was generating positive net-benefits only 3 years after eradication.

### *4.4. Fruit Fly Suppression Programme — South Africa* (Box 4)

#### *4.4.1. Problem Definition*

The Mediterranean fruit fly and the Natal fruit fly *Ceratitis rosa* Karsch occur in the Western Cape province, South Africa. The Hex River Valley is a major production area for table grapes; an average of 15.5 million cartons is exported annually. The dominant and economically important species is the Mediterranean fruit fly. It causes direct damage to fruit, requiring costly insecticide sprays, and infested fruit results in rejections of boxed table grapes by the phytosanitary inspectors of importing countries (Barnes and Eyles 2000; Barnes et al. 2015; Barnes 2016).

#### *4.4.2. Major Achievements*

Growers and scientists now understand the benefits of applying the concept of AW-IPM and the advantages to international trade of establishing low pest prevalence areas (FAO 2017). They also have effectively adopted the SIT technology and established the required infrastructure, which is now managed by the private sector. According to growers in the valley, integrating the SIT to suppress the Mediterranean fruit fly has been very successful. In the 3 years (1997–1999) before the release of sterile flies, fly mean population levels were 0.9–1 flies per trap per day, but in 3 years of the release period (2000–2002) the levels decreased to 0.1–0.4 flies per trap per day. From 1997 to 2002 insecticide use dramatically decreased (Barnes et al. 2004). These positive results have encouraged other associations of fruit growers outside the Hex River Valley to embark on SIT activities as well.

#### *4.4.3. Estimated Benefits*

By using environment-friendly technology, and reducing production costs and increasing revenues, the Mediterranean fruit fly suppression programme increased the profits of the table-grape industry in the Hex River Valley. By replacing insecticide applications with a combination of aerial and ground releases of sterile male flies at hot spots, the reduction in control costs was substantial, from USD

350 000/year with chemical control to USD 130 000/year with the SIT. Rejections, due to fruit fly infestation, of exported cartons of table grapes from the valley were reduced by approximately 50%. In 2000, a reduction of 60% in rejection of cartons by phytosanitary inspectors of importing countries represented savings of USD 150 000. For the 2001/2002 season, the direct benefits totalled USD 370 000/year, at a cost of USD 130 000, which is equivalent to a BCR of 2.8:1.

The expected medium-term impacts of the area-wide project include:

- Expanding export markets by meeting sanitary and phytosanitary restrictions,
- Creating new jobs in agriculture (not only for large producers, but also emerging small producers) and related industries,
- Strengthening regulatory, research and development support of the fruit industry,
- Protecting the environment and the health of farm workers.

*Box 4. South Africa Mediterranean Fruit Fly Suppression Programme (IAEA 2002)*

In 1997, a pilot project to control fruit flies integrating the SIT was implemented in 10 000 hectares (100 $km^2$) in and around the Hex River Valley. The goal was to suppress, in a cost-effective and an environment-friendly manner, the Mediterranean fruit fly populations to below the economic threshold, and then create an internationally recognized low pest prevalence area (FAO 2017).

The organizational structure of this project is rather unique. It is a partnership between Infruitec/Nietvoorbij (a branch of the Agricultural Research Council (ARC), a parastatal body, with a mandate to conduct research, technology development and transfer) and the Hex River Valley Research Services Trust (which represents the deciduous fruit growers). Through an export carton levy, the growers raise funds to support programme operations (Barnes and Eyles 2000). The sterile male production, initially established by the ARC, is now managed by the private sector, and growers manage the fly release and other field operations (Venter et al. 2021).

### *4.5. Fruit Fly Containment Programme — Mexico and Guatemala* (Box 5)

#### *4.5.1. Problem Definition*

The Mediterranean fruit fly was introduced into Costa Rica in 1955 (Enkerlin et al. 1989). It spread across Central America, causing devastating effects on fruit production, and limiting the development and growth of the fruit industry (section 2). The pest became established in Guatemala in 1976, and in 1977 was detected in the border zone between Guatemala and Mexico. By 1979, the fly had spread to the Mexican states of Chiapas and Oaxaca, beyond the coffee belt along the South Sierra Madre Mountains, and threatened the states of Campeche, Tabasco, and Veracruz. If the pest had advanced beyond the Isthmus of Tehuantepec, 600 km into Mexican territory, the USA government threatened to close its border to imported Mexican fruits and vegetables, and fly eradication would have been practically impossible (Schwarz et al. 1989).

Gutierrez (1976) estimated that preventing the establishment of the Mediterranean fruit fly in Mexico translated into annual savings of at least USD 2000 million in direct damage (including yield loss and cost of insecticide treatment) and indirect damage (including loss of the price differential obtained from selling the produce in export markets). In addition, if the pest became established, thousands of jobs across the production chain would be lost, and substantial

environmental costs would be generated by the tonnes of insecticides that would have to be sprayed to keep the pest under control.

*4.5.2. Major Achievements*

After 4 years of intensive eradication activities (1977–1982), the first programme objective was met — the Mediterranean fruit fly was eradicated from an infested area of 640 000 hectares (6400 $km^2$) in the state of Chiapas, Mexico, using an AW-IPM approach that included legal measures (e.g. quarantine regulations), various control methods (chemical, mechanical, and cultural), and the SIT (a mass-rearing facility, producing 500 million sterile flies per week, was completed in 1979). This was the first time that a tephritid fruit fly population was eradicated at a continental level, in a region of difficult topography, high ecological diversity, and using an environment-friendly technology (Hendrichs et al. 1983).

Since eradication was achieved in 1982, for 35 years (1982–2016) the programme successfully maintained a sterile fly containment barrier. This barrier has prevented the northward spread of the pest, protecting the horticulture industries in Mexico and the USA (worth thousands of millions of dollars) (Orozco et al. 1994; Villaseñor et al. 2000; Enkerlin et al. 2015, 2017). In addition, Belize and the area of Petén (northern part of Guatemala) have been kept free of the Mediterranean fruit fly. This fly-free status has been recognized officially by the Mexican and US governments, and benefits papaya fruit growers in Petén who can now export their produce to fruit fly-free countries. The value of papaya exports to the USA in 2013 was estimated at USD 13.6 million. Moreover, other Guatemalan fly-free and low prevalence areas have been certified — Quetzaltenango, where peaches are produced commercially, and Laguna de Retana, where tomatoes and peppers are produced and exported to the USA at an estimated value in 2014 of USD 30 million.

The programme has continued to develop and adapt technologies to large-scale conditions — new and more cost-effective mass-rearing, release and field technologies for Mediterranean fruit fly control, including the temperature-sensitive lethal (*tsl*) male-only fly strain (Cáceres et al. 2000, 2004; Franz et al., this volume), the more environment-safe insecticide spinosad (Rendón et al. 2000; USDA/APHIS/PPQ 2000), more sensitive female-biased trapping systems (Heath et al. 1995; IAEA 1999), more effective longer-lasting bait stations (Piñero et al. 2014), and more precise and intelligent chilled-adult release machines (Leal Mubarqui et al. 2014).

These technological advances, and continuing commitments from the governments of the three countries involved, have been the basis since 1999 for increased cost-effectiveness of the Mediterranean fruit fly eradication programme (Tween 2004). Moreover, it has created the basis for continuing eradication efforts in Guatemala, moving the leading edge of the infestation to the borders of El Salvador and Honduras, where the Central American isthmus starts and where the containment barrier would narrow to 50% of its current length (IICA 2013; Enkerlin et al. 2017; Rendón and Enkerlin 2021).

*Box 5. Mediterranean Fruit Fly Containment Programme "Programa Moscamed"*

Due to the threat that this pest posed to horticulture industries in Guatemala, Mexico, and the USA, in 1976 and 1977 the governments of the three countries, with the support of several international agencies (including the Food and Agriculture Organization of the United Nations (FAO) and the International Atomic Energy Agency (IAEA)), subscribed cooperative agreements to create the "Moscamed Programme", a Mediterranean fruit fly programme using the SIT, with the following objectives:

- Eradicate the Mediterranean fruit fly in infested areas of the state of Chiapas, Mexico,
- Establish a containment barrier at the Mexico-Guatemala boarder, and continue eradication activities in Guatemala to create a fly-free buffer area between the containment barrier and the leading edge of the infestation in Guatemala,
- Eventually eradicate the Mediterranean fruit fly throughout Central America and Panama.

In 2015, the bilateral agreements were merged into a single Trinational Moscamed Agreement, which has strengthened the programme by facilitating harmonization of technical procedures and providing legal certainty.

#### *4.5.3. Estimated Benefits*

The primary impact of the Moscamed Programme has been to protect the expanding horticulture industries of Mexico and the USA. As a result, and under the framework of the North American Free Trade Agreement (NAFTA), Mexico's gross revenues from horticultural products have tripled since 1994, to more than USD 9 billion per year (RIC 2017).

For Mexico, the net revenue (net present value) of the programme has been estimated at USD 39 300 million over 31 years (1978–2008), compared with the total cost of the programme in Mexico over the same period of time (estimated at USD 459 million), showing a remarkable economic return of USD 112 in crops and control costs saved for each dollar that was invested. The return is substantially higher for the USA, where the value of the fruits and vegetables that would be affected by the fly is several times higher than for Mexico. In addition, these returns are even underestimated, since no monetary value has been placed on the social and environmental savings obtained by preventing establishment of this pest.

The economic impact of the Moscamed Programme on the local economies of Chiapas (Mexico) and Guatemala has been substantial. The Moscamed Programme (which began operations in Chiapas) has permanently employed an average of 400 people (who sustain an estimated 2000 family members), apart from the hundreds that have been hired for temporary work in the factory and field operations. In 35 years, from the total programme budget, approximately USD 240 million have been spent in Chiapas, mostly for wages and the purchase of services, supplies, and equipment (Programa Moscamed 2002, 2015; IICA 2013). Moreover, maintaining the state of Chiapas free of the Mediterranean fruit fly has allowed the expansion of mango and papaya production areas and export volumes, valued at millions of US dollars per annum, and has created thousands of jobs in rural areas (IICA 2013).

Indirect benefits of the programme include:

- Strengthening the plant protection infrastructure in both Mexico and the USA, including the national and international quarantine, and national surveillance, systems — systems that protect the two countries from other exotic fruit fly pests, and also from other pests of quarantine importance that are intercepted through the same quarantine infrastructure and resources,

- Recognition of the programme, by regional and international organizations, as an International Fruit Fly Training Centre — contributing greatly to technology transfer in more than 40 countries of Latin America and other parts of the world (including the Caribbean, Africa, and Asia) through the hands-on training of hundreds of professional scientists, and
- Transfer of the SIT technology, that has been improved and validated on a large scale, to other fruit fly AW-IPM programmes integrating the SIT in other parts of the world.

Keeping Mexico and the USA free of the Mediterranean fruit fly has not only protected the horticulture industries of these countries but, for Mexico, it has also created an opportunity to develop the industry into a multimillion dollar export-oriented enterprise (Economist 2004).

### *4.6. Fruit Fly Suppression/Eradication/Prevention Programme — Mexico* (Box 6)

#### *4.6.1. Problem Definition*

Mexico has more than 1 million hectares planted to fruit crops, with an estimated annual production value of more than USD 2500 million (SAGAR/IICA 2001). The fruit industry is significantly hindered by four fruit fly species: Mexican fruit fly, West Indian fruit fly, guava fruit fly *Anastrepha striata* Schiner, and sapote fruit fly *Anastrepha serpentina* (Wiedemann). The annual direct damage that these native fruit flies cause is more than USD 230 million (Reyes et al. 1991). This amount does not include the cost of insecticide applications, and the losses due to restrictions in fruit commercialization. These restrictions prevent the industry from benefiting from price differentials, and more importantly from market diversification, negatively affecting the general development of the industry. Some other losses are also not included, e.g. cost to human health from moderate and acute poisoning arising from applying insecticides, shortage in the supply of fruits, and negative impact on the environment.

#### *4.6.2. Major Achievements*

- Fruit flies of economic importance have been eradicated in more than 35 000 hectares of commercial plantations of citrus, mango, apple, and peach in north-west Mexico, completely freeing from fruit flies of economic importance the States of Chihuahua, Sonora, Baja California Norte, and Baja California Sur (SAGARPA 2001).
- In the north-east and central regions including the states of Nuevo Leon, Tamaulipas and San Luis Potosi, SIT suppression activities have reduced fruit fly populations to low-prevalence levels in parts of the more than 30 000 hectares of commercial citrus production (Orozco-Dávila et al. 2017).
- By creating federal legal instruments in support of the campaign, the construction of additional interstate quarantine checkpoints, and installation of X-ray equipment at specific ports of entry, have been possible. This has strengthened the international and national quarantine system, providing greater protection from exotic fruit flies and other pests of plants and animals.

- Mobilization and organization of fruit growers at the local level into Plant Protection Committees that link the producer associations to the plant protection activities at the state and federal government levels.
- Through training courses and workshops, a work force of hundreds of professional scientists, specialized in the large-scale and area-wide operation of phytosanitary campaigns, has been deployed throughout the country.

*Box 6. Mexico National Campaign against* Anastrepha *Fruit Flies*

*Anastrepha* spp. fruit flies are major horticultural pests in Mexico. After a thorough economic feasibility study (Reyes et al. 1991), in which the returns of integrating the SIT into the control of fruit flies in major commercial fruit production areas were assessed, the Mexican federal government in 1992 approved the National Fruit Fly Campaign (Campaña Nacional Contra Moscas de la Fruta (CNCMF)), with the following objectives:

- To suppress, and in selected areas eradicate, fruit flies of economic importance in fruit production areas, using an AW-IPM approach including the SIT.
- To protect Mexico from the introduction and establishment of other economic fruit fly species that threaten the country.

The CNCMF is part of the Plant Protection General Directorate of the Ministry of Agriculture, Livestock and Rural Development (SAGARPA). The CNCMF operates through state governments and fruit-grower associations under compliance agreements subscribed to by the three parties (federal and state governments, and fruit industry).

The resources required to operate the programme are contributed in equal parts by the federal and state governments and the fruit industry, in financial and in-kind contributions. The federal government facilitates the legal instruments for smooth implementation of the programme, supplies the sterile flies, and operates international quarantine stations at ports of entry. The state governments, through their plant protection infrastructure, are responsible for distributing and releasing the sterile flies, and for conducting field activities outside the fruit production areas to assure area-wide control of the pests. Responsibilities also include operating quarantine interstate road stations. At the farm level, the programme is conducted by the fruit industry, through Plant Protection Committees, that link the producer associations with the state and federal governments. Activities of producers in orchards include trapping, applying bait sprays, and releasing sterile flies (Reyes et al. 2000).

### *4.6.3. Estimated Benefits*

In the first 4 years after 1997, when fruit fly eradication in north-west Mexico was officially declared, the direct benefits (reduced fruit fly damage and increased yield) amounted to USD 25 million. In addition, in the same time period, the benefits obtained from the price differential paid by export markets, and savings in postharvest treatments, totalled approximately USD 35 million. Thus, the total benefits in these fruit fly-free areas over 4 years amounted to USD 60 million, with a total cost of USD 4 million over the same time period, resulting in a BCR of 7.5 to 1 (SAGAR/IICA 2001).

A retrospective economic assessment was conducted to estimate the return on investment of the National Fruit Fly Campaign, specifically for mango and citrus, two of the mayor fruit crops produced in Mexico that are affected by fruit fly pests. Results indicated a BCR of 22 for mango and of 19 for citrus, clearly justifying the investment on fruit fly control done by the Mexican Federal Government and the fruit growers (IICA 2010).

The eradication of fruit flies, and subsequent international recognition and maintenance of the fruit fly-free status, permitted an expansion of the area planted to fruit crops in the north-western states to 50 000 hectares. No doubt this has resulted in substantial economic and social benefits to that region of Mexico.

### *4.7. Other Successful Programmes*

Section 4 describes examples of programmes that have produced substantial economic returns after applying area-wide SIT against fruit fly pests; economic assessments or detailed quantification of costs and benefits are available for these programmes. However, there are other successful programmes for which detailed economic assessments have not yet been done, but that have also generated substantial benefits. One of these programmes is the SENASA Fruit Fly Control Programme in Peru, where in 2008 the eradication of the Mediterranean fruit fly and *Anastrepha* fruit flies from the regions of Tacna and Moquegua, integrating the SIT, was declared officially. This was achieved through a joint venture of the Peruvian State, producers, exporters, and regional and local authorities; financial support was also obtained from the Inter-American Development Bank, and technical and financial support from the FAO and IAEA. Programme achievements included: avoiding annual losses of more than USD 12 million in the production of fruits and vegetables, generating direct benefits to 17 876 producers in approximately 38 000 ha, avoiding annual use of over 600 000 litres of insecticides, helping to preserve the environment, and creating opportunities for the national and international trade of horticultural products within the framework of trade agreements with the USA (FAO/IAEA 2008).

Another successful programme is the Moscamed Programme in the Dominican Republic. A large Mediterranean fruit fly outbreak, covering an area of 2000 $km^2$, occurred in March 2015 in the eastern part of the country. In only 10 months, USD 40 million was lost because of quarantine restrictions on exports of host commodities including tomatoes, bell peppers, and avocados. Eradication was achieved after two years of intensive area-wide integrated pest management including pest monitoring, population suppression using ground and aerial bait sprays and bait stations, and eradication using the SIT. Eradication was declared officially by the Ministry of Agriculture in July 2017; net revenues from fruit and vegetable exports have since been re-established. Eradication of the Mediterranean fruit fly benefited the Dominican Republic, and also protected the horticultural industries in the Caribbean region and in neighbouring countries including the USA and Mexico (FAO/IAEA 2017; Gil 2017; Zavala-López et al. 2021).

## 5. SUMMARY OF ECONOMIC RETURNS

The BCR achieved in some major fruit fly AW-IPM programmes integrating the SIT is high, ranging from 2.8 to 1000, clearly showing that the SIT technology, when properly integrated with other methods and applied on an area-wide basis, is feasible and economically viable (Table 2). Even when the types of benefits accrued from these programmes are similar, the returns on investment (BCR) vary widely, even among programmes with common fruit fly pest problems and similar strategic objectives. This is due to the different intrinsic characteristics of each programme, e.g. the magnitude of the pest damage, size and value of the crops being protected, targeted markets, commitment of the main stakeholders, resources available to execute the programme, and efficiency in programme management.

## 6. CONCLUSIONS

The high economic returns from some fruit fly AW-IPM programmes that integrate the SIT are possible primarily because of the environment-friendly and area-wide nature of the SIT technology. This technology allows cost-effective suppression, and in selected cases eradication, of insect pest populations, and also prevents the establishment of important fruit fly species in pest free areas through the use of pest risk-mitigation measures, such as SIT containment and prevention programmes. Such programmes protect, at a relatively low cost, high-value horticulture industries, such as those in Argentina, Australia, Chile, Mexico, and the USA. This is a major advantage of the SIT technology when compared with more conventional pest control methods such as insecticides (Enkerlin 2003). In contrast, the worldwide BCR of insecticides has been estimated at 4:1, if indirect costs are excluded, and only a 2:1 ratio if indirect environmental and public health costs are included (Pimentel 1991). As the use of the SIT technology for certain pests and crops expands, with increasing cost-effectiveness at economies of scale, it is expected that the release of sterile insects will gradually reduce the application of insecticides. The insecticide industry is gradually viewing the SIT as an opportunity for diversification rather than as a competing technology; this has already happened with other control methods that are biological in nature.

One of the unique features of the integrated application of the SIT is that, since its application is area-wide, the benefits spread beyond commercial fruit and vegetable producers to backyard gardens and subsistence farms in poor rural areas. In the future, the SIT will contribute even more to improved food security worldwide by increasing fruit and vegetable production in a cost-effective, environmentally clean, and sustainable manner.

## 7. ACKNOWLEDGEMENTS

The late Rita Andrea Garcia, who dedicated her professional career to the Moscamed Programme, provided valuable financial information that was used to assess the programme's benefits. Jesus Reyes made constructive comments on the manuscript. These contributions are gratefully acknowledged.

*Table 2. Estimated Costs, Benefits, and Benefit/Cost Ratios (BCR) for some Major Fruit Fly AW-IPM Programmes Integrating the SIT*

| Programme | Parameter used to measure benefits | Average annual cost[1] (USD million) | Average annual benefit (USD million) | Benefit/ cost ratio (BCR)[2] | References |
|---|---|---|---|---|---|
| Mediterranean Fruit Fly Containment Programme "Programa Moscamed" | Protection of horticulture industry in Mexico (includes only investment by Mexico and potential production losses and costs, and market loss) | 14.8 | 1660 | 112 | Gutierrez 1976; Reyes et al. 1991; IICA 2009, 2013 |
| Melon Fly Eradication Programme in Okinawa, Japan | Export of fruit commodities (mainly mango and bitter melon) after eradication was achieved | 7.7 | 41.7 | 5.4 | Kakazu 2002 |
| National Mediterranean Fruit Fly Control Programme in Chile | Export of horticultural products affected by fruit flies | 4 | 4000 | 1000 | MAG/SAG 1995; Lindquist and Enkerlin 2000; ASOEX 2017 |
| Hex Valley Mediterranean Fruit Fly Suppression Programme in South Africa | Savings in chemical sprays and table-grape rejections during the certification process | 0.13 | 0.37 | 2.8 | IAEA 2002 |
| Mexico National *Anastrepha* Fruit Fly Campaign | Savings in direct damage and value of fruit exports from the fly-free areas in north-west Mexico | 32 | 772 | 24 | IICA 2010 |
| Mediterranean Fruit Fly Preventive Release Programme in Los Angeles Basin, California, USA | Protection of California's horticulture industry from yield loss in agriculture and home-garden production, increased insecticide use, loss of export markets, and annual quarantine compliance cost | 15 | 1300–1900 | 87–127 | CDFA 2002 |
| Control of the Mediterranean Fruit Fly in Israel/Jordan | Export of vegetables from the Arava Valley | 0.8 | 8 | 10 | Cayol et al. 2004 |

[1]Includes fixed and variable operational costs, but not capital or financial costs.
[2]Assuming the whole benefit is lost in the event of fruit fly establishment and widespread infestation.

## SUMMARY

More than 22 lepidopteran species have been investigated as candidates for control using the sterile insect technique (SIT) or inherited sterility (IS). However, to date only three programmes have been operationalized on a large-scale. The pink bollworm programme was successful at eradication across a broad swath of the cotton production area in south-western USA and northern Mexico by operating an area-wide control programme across this region using a combination of *Bt*-cotton, mating disruption, sanitation, and the SIT. The codling moth suppression programme in British Columbia, Canada, and the false codling moth in South Africa, have both been successful at effective suppression of the pest populations, reducing insecticide use, and improving interactions between growers and the general public. Other smaller-scale programmes against outbreaks of gypsy moth, cactus moth, and painted apple moth have also been successful, contributing to local eradications of invasive populations. New programmes are being investigated for managing a range of other target pests, including European grapevine moth in Chile, sugar cane borer in South Africa, tomato leafminer (for glasshouse populations in Europe), carob or date moth in North Africa, and naval orangeworm in California. Methods to further reduce the cost of lepidopteran programmes might include combining the SIT/IS with other environment-friendly pest control tactics such as mating disruption or the release of natural enemies, the development of genetic sexing strains, or the application of molecular technologies to develop genetic markers, genetic sexing, and genetic sterility. In the future, the greatest potential for impact of lepidopteran SIT/IS programmes may be in combating key invasive threats, with examples such as the eradication of an outbreak of the painted apple moth in New Zealand and the cactus moth in Mexico, or by adding an additional tool to pest control programmes where the use of insecticides may be limited by the development of resistance or the objection by residents in urban areas to ongoing treatments.

## 1. INTRODUCTION

Lepidopterans are among the most devastating agricultural and forest pests in the world. In the United States of America (USA) seven of the eight most serious insect pests of agricultural crops are lepidopterans (Peters 1987). According to a list of the 37 worst invasive insect pest threats to US agriculture and plant resources, 19 are lepidopteran species (ESA 2001). A review of global eradications revealed 144 eradication efforts against 28 species of Lepidoptera (Suckling et al. 2017). Control of these pests relies largely on insecticides, and the development of resistance is becoming a serious problem for many species, e.g. codling moth (Varela et al. 1993), diamondback moth (Tabashnick et al. 1990; Shelton et al. 1993), navel orangeworm (Demkovich et al. 2015), and pink bollworm (Bagla 2010; Tabashnik and Carrière 2010). In addition, the indiscriminate use of pesticides has had a significant negative

impact on the environment. Of particular importance to agriculture is the destruction of crop pollinators and natural enemies that keep secondary pests in check (Edwards 2000; Zaller and Brühl 2019). Therefore, it is probably not surprising that more lepidopterans than any other group of insects have been investigated as potential candidates for integrated control using the sterile insect technique (SIT) or inherited sterility (IS) (a variation of the SIT that involves the release of partially sterile insects) (North 1975; LaChance 1985; Bloem and Carpenter 2001; Marec et al., this volume). At least 22 moth species have been investigated for their potential as SIT targets -- including those with completed radiation biology studies, with field tests, and with either pilot or operational programmes (Vreysen et al. 2016; Suckling et al. 2017).

In spite of the tremendous impact that area-wide control of key lepidopteran species could have, and that many species have been investigated in laboratory and field-cage studies for their suitability as candidates for SIT/IS programmes, field trials have been performed on only a limited number of species (Suckling et al. 2017). Of the 16 lepidopteran species that have been investigated in the field (Table 1), only three area-wide SIT/IS programmes have progressed to the operational stage. These are programmes against the pink bollworm in the southern USA and northern Mexico, the codling moth in British Columbia, Canada, and the false codling moth in South Africa. In these cases, partially sterile or sterile moths have been routinely released in the context of area-wide integrated pest management (AW-IPM) programmes that use a combination of pest control tactics.

*Table 1. Main moth pest species that have been investigated as SIT/IT candidates*

| Successful operational moth SIT/IS programmes | Past efforts to develop and apply moth SIT/IS | Ongoing methods development of moth SIT/IS |
|---|---|---|
| Pink bollworm *Pectinophora gossypiella* (Saunders) | Tobacco budworm *Heliothis virescens* (F.) | European grapevine moth *Lobesia botrana* (Denis and Schiffermüller) |
| Codling moth *Cydia pomonella* (L.) | Corn earworm *Helicoverpa zea* (Boddie) | African sugar cane borer[1] *Eldana saccharina* Walker |
| False codling moth *Thaumatotibia leucotreta* (Meyrick) | Light brown apple moth *Epiphyas postvittana* (Walker) | Navel orangeworm *Amyelois transitella* (Walker) |
| Painted apple moth *Teia anartoides* Walker | Oriental fruit moth *Grapholita molesta* (Busck) | Tomato leafminer[1] *Tuta absoluta* (Meyrick) |
| Cactus moth *Cactoblastis cactorum* (Berg) | European corn borer *Ostrinia nubilalis* (Hübner) | Carob/date moth *Ectomyelois ceratoniae* (Zeller) |
| Gypsy moth[2] *Lymantria dispar* (L.) | Asian corn borer *Ostrinia furnacalis* (Guenée) | |
| | Diamondback moth *Plutella xylostella* (L.) | |

[1] The SIT/IS has not been field-tested against these moth species.
[2] Even though successfully applied to eradicate gypsy moth outbreaks, the SIT/IS for this pest was discontinued eventually because more economic alternatives were developed (see section 3.1.).

In addition, the release of partially sterilized male painted apple moths was successfully added to an eradication effort in Auckland, New Zealand, with aerial applications of *Bacillus thuringiensis* var. *kurstaki* (*Btk*) and an intensive trapping programme for this introduced pest, using virgin female moths (Suckling et al. 2007). The same approach was used to eradicate outbreaks of the invasive cactus moth in Mexico (Bello-Rivera et al. 2021).

Although studies on *G. molesta, O. nubilalis, O. furnacalis,* and *P. xylostella* generally reported positive results from releasing sterilized insects (Rosca and Barbulescu 1996; Apu 2002; Genchev 2002; Maung 2002; Wang et al. 2002; Yang et al. 2002), not enough detailed information concerning the size of treatment areas, release rates, release methods, and methods for evaluating efficacy of releases was provided. The programme against *L. dispar*, even though successfully applied to eradicate outbreaks, was eventually discontinued because more economic alternatives were developed. Also, programmes for *H. virescens* and *H. zea* were deemed uneconomic following a number of large-scale field studies.

## 2. SUCCESSFUL OPERATIONAL MOTH SIT/IS PROGRAMMES

The primary impact of successful lepidopteran SIT/IS programmes that has been reported is the degree of pest suppression or eradication, or the extent to which establishment of an invasive pest has been prevented in the treatment area. Quantification of other benefits, e.g. lower commodity-production costs, access to new markets, and fewer farm-worker health and safety problems or decreased ground-water contamination as a result of reduced insecticide use, has for the most part not taken place. Therefore, rather than limit this discussion to the little information available on accrued benefits from lepidopteran operational programmes, the major achievements of lepidopteran field programmes that have been undertaken are more broadly discussed to include their impact on the target pest population, the stakeholders involved, and the advancement of the SIT/IS as a tactic for lepidopteran control.

### *2.1. Pink Bollworm*

#### *2.1.1. Development of the Programme*

The pink bollworm *P. gossypiella* was first reported in North America from Mexico in 1911, probably entering on cotton seed shipped from Egypt (Noble 1969). The first reported infestation in the USA was in 1917 in Robertson County, Texas (Scholl 1919). By 1926, this highly invasive insect had spread from Texas through New Mexico and into eastern Arizona, and then quickly established itself as one of the major pests of cotton in the south-western USA and north-western Mexico (Burrows et al. 1984). It is considered to be among the most damaging cotton pests worldwide due to feeding while protected within the cotton boll, high reproductive capacity, high mobility, and frequent development of resistance (Henneberry 2007). Past management of the pink bollworm relied on the extensive use of broad-spectrum insecticides, and growers experienced significantly increased production costs and

reduced yields (Watson and Fullerton 1969; Burrows et al. 1982, 1984). Ingram (1994) provided a worldwide perspective on the pest status and management of the pink bollworm, and Henneberry and Naranjo (1998) and Henneberry (2007) reviewed its status and the various integrated management approaches used for its control in the south-western USA.

Development of IPM strategies significantly improved the prospects for management of the pink bollworm in the south-western cotton belt which included the use of area-wide management with cultural controls, pheromone monitoring, coordinated insecticide applications, resistance monitoring, the widespread use of mating disruption, and the application of the SIT (Chu et al. 2006; Henneberry 2007; Lance et al. 2016). The work to integrate the use of the SIT into other AW-IPM tactics was based on research including mass-rearing and irradiation biology, extensive small-scale testing in field cages, several large-scale field trials, and demonstration projects (Staten et al. 1993; Henneberry 2007; Walters et al. 2009; Naranjo and Ellsworth 2010; Lance et al. 2016).

Stewart (1984) described the mass-rearing of the pink bollworm. Staten et al. (1993) and Walters et al. (2009) summarized the history and operational details of the programme. Miller et al. (2001) reviewed the efforts to enlarge the rearing facility in Phoenix, Arizona, developments like the twin-screw extruder technology to make high-volume and high-quality diet, and mechanization of the rearing process. These changes dramatically increased sterile-insect production capabilities at reduced costs, and opened up the possibility that sterile moths could be integrated into other AW-IPM programmes in the cotton belts of south-western USA and north-western Mexico.

Other developmental work included several field-cage studies and open-field trials to evaluate the potential of the SIT to control the pink bollworm. While the field-cage studies showed positive results, many of the early open-field trials failed or were only partially successful. These early failures were attributed to a lack of isolation from migrating moths, and the low competitiveness of mass-reared sterilized male moths that necessitated high (more than 60) sterile to wild overflooding ratios (Bartlett 1978). Henneberry and Keaveny (1985) provided detailed information on a large-scale SIT field trial in St. Croix, US Virgin Islands. Henneberry (1994) made a thorough review of all sterile-moth release trials for pink bollworm control, including the St. Croix project and the San Joaquin Valley programme.

#### *2.1.2. Containment in the San Joaquin Valley*

The history of development of the SIT for the pink bollworm included a long-term area-wide preventive sterile-moth release programme in the San Joaquin Valley, which was the only cotton-growing area in the south-western USA not infested with the pink bollworm. The long-term prevention of pink bollworm establishment in that valley was attributed to an ongoing area-wide monitoring and SIT containment programme that had been in continuous operation since 1967 (Staten et al. 1993; Henneberry 1994; Walters et al. 2009). The objective of this programme was containment rather than suppression or eradication (Henneberry 1994; Hendrichs et al. 2007; Lance et al. 2016; Hendrichs, Vreysen et al., this volume). This was achieved by operating an area-wide monitoring and coordinated sanitation programme, and included the release of large numbers of sterile moths each year relative to the number

of immigrating wild moths (Walters et al. 2009). The fact that the pink bollworm did not become established in the San Joaquin Valley, despite the annual immigration of moths from infested cotton-growing valleys to the south (Staten et al. 1993), and the demonstrated ability of the moth to successfully overwinter in the area (Henneberry and Keaveny 1985; Venette and Hutchison 1999), showed that the programme had been effective. The programme was financed by a self-imposed grower levy on cotton bale assessment, and USDA support for sterile moth release (Walters et al. 2009; CDFA 2019). Compared with cotton-production areas where the pink bollworm was established and not suppressed, growers saved an estimated USD 248–371/ha (CDFA 2019).

#### *2.1.3. Area-Wide Integrated Pest Management*

The success of the San Joaquin Valley containment programme, coupled with the development of other biorational tools such as pheromone mating disruption and later *Bt*-cotton, created the opportunity to test the feasibility of using combinations of these tools for the integrated management of established pink bollworm populations on an area-wide basis. The first test was conducted in 1986–1989 involving 30 cotton fields in the Coachella Valley, California, using a high-rate pheromone disruption system and sterile insects. During the 4-year project, pink bollworm populations were maintained at low densities, and major reductions in conventional insecticide use were achieved (average of 7.3 insecticide applications per field per y decreased to 1.2) (Staten et al. 1993; Henneberry 1994).

A second area-wide pest suppression trial, combining the SIT with mating disruption, *Bt*-cotton, and cultural controls, was conducted in the Imperial Valley, California, from 1994 to 2000. Walters et al. (2000) reviewed the strategic objectives and results of this integrated management trial for the period 1994–1998. During 1994–1996, sterile moths were released on 6 d/wk in all fields at variable rates (70–560 moths per ha per d) calculated to deliver an overflooding ratio of at least 60:1 as measured by trap captures. Sterile moth releases were supplemented with mating disruption if a 60:1 sterile to wild moth ratio was not maintained. In 1997 the cotton planted in the Imperial Valley consisted of 81% *Bt*-cotton, 17.5% conventional or non-*Bt*-cotton protected with mating disruption, and 1.5% conventional untreated cotton as a refuge. Releases were reduced to 40 sterile moths per ha per d, 3 d/wk, throughout the Valley. The trial was expanded in 1998 to include the Blythe and Palo Verde Valleys, California, where there also was widespread use of *Bt*-cotton. The trial was terminated in 2000 after having achieved a high degree of suppression of established pink bollworm populations in all areas using essentially no insecticides.

#### *2.1.4. Area-Wide Eradication*

Based on the success of these trials, a large area-wide eradication was launched to eradicate the pink bollworm from all cotton-producing areas of the USA and adjacent areas of northern Mexico (NCCA 2001, 2009; El-Lissy et al. 2002; Antilla and Liesner 2008; Tabashnik et al. 2010; Staten and Walters 2021).This large programme used a combination of tactics including mating disruption, regional widespread planting of genetically modified cotton expressing the *Bt* toxin, cultural control

methods and the SIT (Grefenstette et al. 2009; Tabashnik et al. 2010; Liesner et al. 2014). Each of the programme areas used grower-planted *Bt*-cotton, and pheromone applications for mating disruption, for 1 or 2 y to lower the pest population levels. Then, in the following 2 or 3 y, sterile-insect releases were to be included to complete the eradication process. In 2001, the programme was initiated in Texas and Chihuahua, Mexico, and moved to New Mexico in 2002, south-western USA, and north-western Mexico; in 2006 the programme proceeded into Arizona and the lower desert production area in southern California, bringing all programme areas under full eradication (Antilla and Liesner 2008; Lance et al. 2016).

Sterile pink bollworms were released at variable rates of up to 250–600 moths per ha per d on conventional cotton, and at a lower rate of 36 moths per ha per d on *Bt*-cotton (Antilla and Liesner 2008; Grefenstette et al. 2009). The data before and after the eradication programme in Arizona show a steep decline in larval infestation of bolls and moth captures (Fig. 1) and pesticide applications (Fig. 2).

For the Arizona programme, the release of sterile moths over *Bt*-cotton pioneered a new use of the SIT, enabling the planting of 100% *Bt*-cotton without using the EPA-mandated *Bt*-resistance management strategy, i.e. planting a refuge of 10% conventional cotton. Using sterile insects in this manner works as a form of resistance management by reducing the probability that a moth with a rare resistant recessive allele would encounter another moth of the same genotype (Wu 2010).

This was a novel use of the SIT, enabling eradication programme officials to obtain an EPA (Environmental Protection Agency) section 24C local-use variance that permitted the planting of 100% *Bt*-cotton in all programme areas. The area-wide (near 100%) planting of *Bt*-cotton was credited as a major factor in the success of the programme (Henneberry 2007; Tabashnik et al. 2010; Liesner et al. 2014).

After 2009 no larvae were observed in the field, and after 2012 no wild moths had been caught in any of the programme areas (Blake 2014; Liesner et al. 2014; Lance et al. 2016). Since 2014, all programme areas were under a four-year "Confirmation of Eradication" designation where the area-wide cultural practice of planting nearly 100% *Bt*-cotton continued in most areas, but all other control activities, including sterile-insect release, ceased (Liesner et al. 2014). Area-wide monitoring continued with pheromone traps, a mandatory "plough-down" host-free period, and a small maintenance level of production of the pink bollworm to support a response with sterile insects in the event of pink bollworm captures (Liesner et al. 2014; Lance et al. 2016). After completion of the 2018 cotton-growing season, pink bollworm eradication was declared for all USA programme areas (Fitchette 2018; USDA 2018; Staten and Walters 2021).

Even though the eradication campaign is a success, the pink bollworm remains a threat for reinvasion and a significant worldwide pest. The pink bollworm is still the primary cotton pest in all major cotton-producing areas of the world, and resistance to *Btk* in transgenic cottons has been reported in India (Bagla 2010; Tabashnik and Carrière 2010). In North America, there are some parts of eastern New Mexico and the Southern Plains region of Texas not included in the eradication programme; in these areas pink bollworm populations have been historically low, and the status is uncertain (Pierce et al. 2013). Outbreaks in 2009–2011 were confined to a small number of fields planted to non-*Bt*-cotton (Pierce et al. 2013). In 2012, these

populations were addressed by increased planting of *Bt*-cotton and releasing sterile insects; the area is considered eradicated (Pierce et al. 2013).

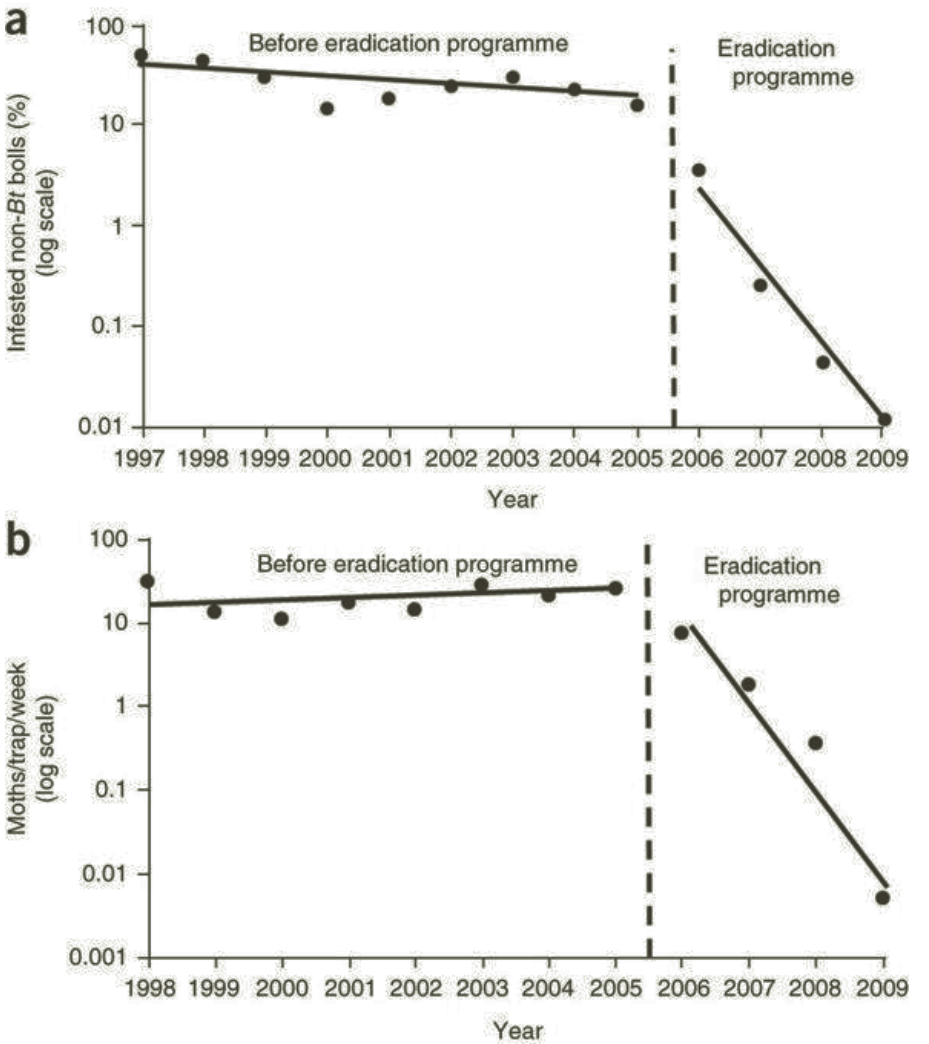

*Figure 1. a) Pink bollworm larval infestation of non-*Bt*-cotton bolls from 1997 to 2009 in Arizona, USA. b) Wild male pink bollworm moths trapped in* Bt*-cotton fields from 1998 to 2009. Analysis of covariance shows that the number of moths caught per trap per week (log transformed) was significantly affected by year, treatment (before versus during the eradication programme), and a year-by-treatment interaction ($P < 0.0001$ for each factor and their interaction, $r^2 = 0.95$). Linear regression shows that the slope, which indicates the change in moths trapped per year, was significantly negative from 2006 to 2009 (−1.0, $r^2 = 0.92$, $P = 0.04$), but did not differ significantly from 0 from 1998 to 2005 (0.017, $r^2 = 0.071$, $P = 0.52$). (Figure adapted from Tabashnik et al. 2010.)*

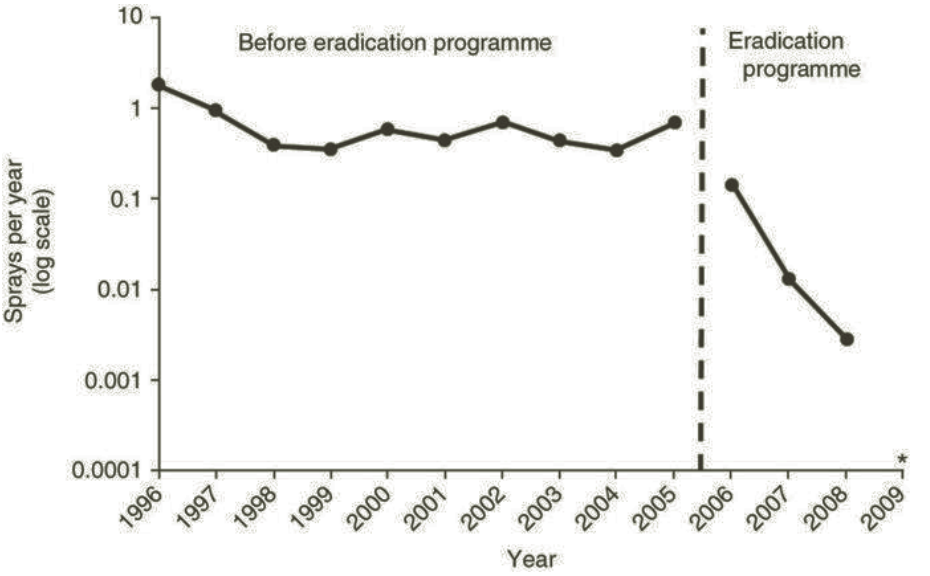

*Figure 2. Decline in insecticide applications to cotton in Arizona, USA, by comparing sprays per year before and after the initiation of the pink bollworm eradication programme. (Figure adapted from Tabashnik et al. 2010.)*

Other areas of concern include areas of central Mexico and the Caribbean where the pink bollworm remains a threat, and/or the status remains uncertain. Continued monitoring, mandatory "plough-down", and quarantine enforcement will be needed in US cotton-production areas to ensure that the pink bollworm does not reinvade.

The economic impact of the pink bollworm to US cotton producers was estimated at more than USD 32 million per year for the entire infested area -- from yield losses and control costs related to the pink bollworm (El-Lissy et al. 2002; Frisvold 2006; Antilla and Liesner 2008). The removal of the pink bollworm from cotton-production systems, and reductions in the need to treat with insecticides, has enabled the development of better IPM programmes for other key cotton pests, e.g. *Lygus hesperus* Knight and *Bemisia tabaci* (Gennadius). Also, overall, it has reduced costs and insecticide use to record low levels, making cotton-production systems in the western USA more economical and environmentally sustainable (Henneberry 2007; Naranjo and Ellsworth 2010).

### *2.2. Codling Moth*

The codling moth *C. pomonella* is the key pest of apples and pears in most regions of the world where pome fruit is grown (Vreysen et al. 2010). The larval stage burrows into the fruit, rendering it unmarketable and in breach of phytosanitary restrictions for trade. As a consequence, from the 1950s, organophosphate insecticides were applied to kill larvae as they emerge from eggs and before they can penetrate fruit. Control failures during the past 60 years, due to the development of insecticide resistance and

concerns about the impact of insecticides on the environment, have led researchers in different parts of the world to make numerous attempts to use the SIT/IS against the codling moth.

The Agriculture and Agri-Food Research Centre in Summerland (in southern British Columbia, Canada) provided the extensive initial investigations (Proverbs 1962, 1969, 1974, 1982; Proverbs et al. 1973, 1982) that led to the implementation of an operational AW-IPM programme that routinely releases irradiated moths (Dyck et al. 1993; Bloem and Bloem 2000). After the ground-breaking work of Proverbs, notable examples include the work of scientists at the USDA/ARS laboratory in Yakima, Washington, USA (Hutt et al. 1972; Butt et al. 1973; White et al. 1976a, b; Hutt and White 1979), and the research in Switzerland that used diapaused $F_1$ sterile larvae released into small pome-fruit orchards (Charmillot et al. 1973, 1976a, b; Charmillot 1977).

Research targeted gamma radiation (Proverbs and Newton 1962a, b, c), an inexpensive, agar-free meridic diet (Brinton et al. 1969), design of a rotating oviposition cage (Proverbs and Logan 1970), and ground-release devices to distribute chilled moths in the orchard (McMechan and Proverbs 1972). These components are currently in use in the OKSIR Program (Dyck et al. 1993; Bloem and Bloem 2000; Bloem et al. 2007a; Dyck 2010; OKSIR 2019).

### *2.2.1. Okanagan-Kootenay Sterile Insect Release Program*

The Okanagan-Kootenay Sterile Insect Release (OKSIR) Program in Canada was launched in early 1992 (Dyck et al. 1993), more than a decade after Proverbs et al. (1982) had demonstrated in a 3-year (1976–1978) pilot project that local eradication of the codling moth was possible. Unfortunately, at that time, the cost of delivering this technology was about 2.4 times greater than the use of conventional insecticides (Proverbs et al. 1982). Between 1978 and 1992 several benefit/cost analyses were conducted at the request of growers to reassess the economics of the SIT (Holm 1985, 1986; Jeck and Hansen 1987). Following the more positive outcomes of these studies, an implementation plan was developed (DeBiasio 1988). A 2-year clean-up or sanitation phase (phase 1) was followed by 3 years of sterile moth releases (Phase 2) at an initial overflooding ratio of 40:1. Two zones, each containing about 4 000 ha, were treated sequentially, and urban trees were included in the programme. In addition, sterile codling moths were released along the USA-Canada border (phase 3 — containment) (Hendrichs et al. 2007; Hendrichs, Vreysen et al., this volume), which was (incorrectly) considered the only plausible route for reinfestation.

Construction of a mass-rearing facility at Osoyoos in the Okanagan Valley was completed in March 1993. Sterile moths were released into orchards for the first time in the spring of 1994. Unfortunately, clean-up activities during 1992 and 1993 were not entirely successful, and a higher-than-anticipated wild population resulted in poor overflooding ratios and poor control. In 1995, to help turn the programme around, reduce the wild population, and enable a 40:1 sterile:wild overflooding ratio to be achieved, growers received a one-time compliance grant of USD 115 per ha to support insecticide applications. Other strategic changes included tougher enforcement of codling moth control bylaws and an expanded communications campaign (Bloem and Bloem 2000; Bloem et al. 2007a).

As a result of these strategic changes, the average wild codling moth captures in pheromone traps in the Zone 1 treatment area were reduced from 13 moths per trap per week during the first generation, and 2.5 during the second generation (in 1995), to 0.08 moths per trap per week during both first and second generations (in 2000). The amount of codling moth fruit damage at harvest was significantly reduced; in 1995 42% of orchards in the treatment area had no detectable level of codling moth damage at harvest.

The programme for commercial orchards in Zones 2 and 3 commenced with the sanitation phase using a combination of mating disruption and insecticide sprays. Releases of sterile moths in these zones began in 2002 (Bloem et al. 2007a). It was expected that by the end of 2005 all zones would have achieved minimal codling moth population levels similar to those achieved in Zone 1, but the reduction in wild moth trap catch and fruit damage did not occur as rapidly as observed in Zone 1 (Bloem et al. 2007a). The reasons cited were the larger urban areas in these zones with untreated backyard trees, and the use of mating disruption in these zones which may not have been as effective as insecticide treatments in Zone 1. Despite this initial slow start, since 1999 moth captures and fruit damage decreased in all programme areas to below the treatment action threshold of 2 moths per trap per week (Fig. 3). Since 2015, the economic damage threshold was met, with less than 10% of programme areas having >0.2% fruit damage (Nelson et al. 2021).

During the life of the programme, insecticide use was reduced by 96% of pre-OKSIR Program amounts (Fig. 4) (Nelson et al. 2021). Although other factors have contributed, the decreased reliance on insecticides for codling moth control has resulted in local packing houses encouraging their apple growers to consider switching to certified organic production or following new “Growing with Care” production practices where no insecticides are applied in orchards between blossom and fruit harvest.

Finally, the Canadian OKSIR Program is a model of the development of support from the general public to implement more environment-friendly AW-IPM programmes. From its inception, home and business owners were encouraged to recognize the value that apple growers brought to the community — in terms of quality of life and economic benefits through agriculture and tourism (Dendy et al. 2001). As a result, area residents took responsibility for helping growers to implement a mutually beneficial AW-IPM programme by paying a portion of the annual budget and actively participating in activities such as the removal of unmanaged host plants.

Despite ongoing success, the operation of a long-term sustainable pest-suppression programme is threatened by that same success; reduced pest pressure may result in decreased funding support because the pest is no longer perceived to be a problem. Ironically, the unique public-funding model of this programme may contribute to this perception. An additional economic threat is the low profitability of pome-fruit production and the consequent conversion of some orchards to higher-value wine grapes and sweet cherries; this has led to a decrease in pome-fruit production areas and a decrease in the need for sterile moths (Carpenter et al. 2014; Nelson et al. 2021).

To provide additional support to maintain a sustainable programme, OKSIR has been working with researchers from other regions to supply sterile or fertile codling moths to develop further area-wide management of the codling moth with pheromone

mating disruption and sterile-insect releases (Carpenter et al. 2014; Horner et al. 2016; Nelson et al. 2021). Based on the successful pilot shipments from Canada to South Africa (Bloem et al. 2010), and using insects shipped "out-of-season" from Canada, since 2014 New Zealand researchers have been conducting a pilot programme in an isolated apple production area using mating disruption and regular sterile-moth releases (Horner et al. 2016).

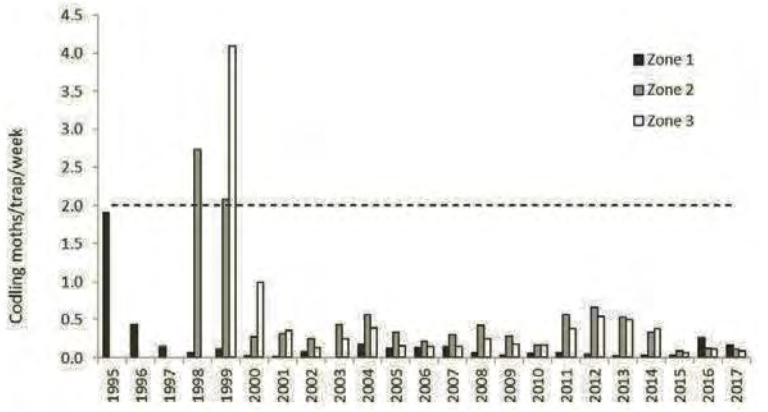

*Figure 3. Mean number of wild codling moths captured per trap per week for each zone managed by the OKSIR programme in Zone 1 (from 1995), in Zone 2 (from 1998), and in Zone 3 (from 1999). The dashed line indicates the recommended threshold (two codling moths per trap per week for two consecutive weeks) at which insecticide controls supplementary to the SIT would be required. (Figure from Nelson et al. 2021.)*

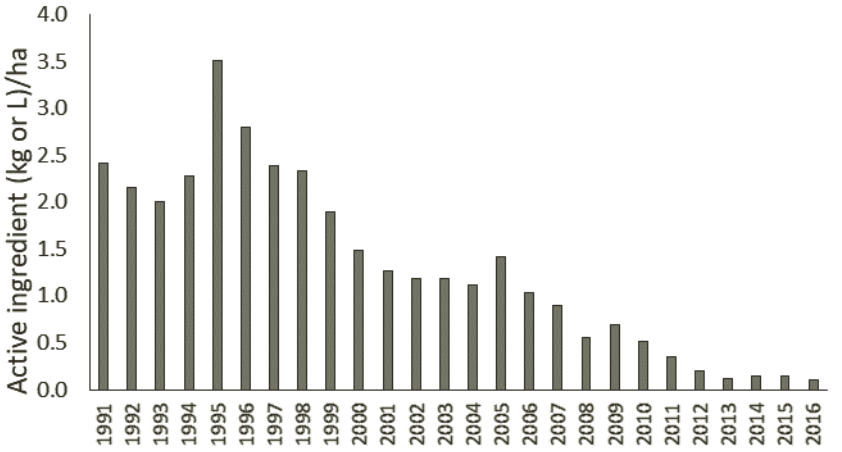

*Figure 4. Estimated insecticide active ingredient (kg or L) applied per ha per year for all zones managed by the SIR programme based on the estimated proportion of sales for the 15 products registered for use against the codling moth (note: some of these insecticides are also applied for other pests and/or crops). The estimates of active ingredients are divided by the area (ha) of planted pome fruit in the programme area to account for changes in sales due to the amount of pome fruit under cultivation. (Figure from Nelson et al. 2021.)*

### *2.3. False Codling Moth*

The false codling moth *T. leucotreta* is an indigenous pest in sub-Saharan Africa, and also in Atlantic Ocean islands off the African coast, islands in the Indian Ocean, and Israel (Newton 1998; Malan et al. 2018). It is a significant pest of several important crops, with citrus as one of its main hosts (Newton 1989; Hofmeyr et al. 2015; Malan et al. 2018). The larvae feed internally, causing fruit lesions (Malan et al. 2018). Until about 1969, it was unknown in the fruit-growing regions of the Western Cape province, South Africa, but by the end of the 1970s it had spread throughout all the important ones (Hofmeyr et al. 2015). The false codling moth can have 5–6 generations per year.

This moth is not present in North America, Europe and Asia -- this has phytosanitary implications for fruit exports to those regions (Hofmeyr et al. 2015; Malan et al. 2018; Boersma 2021). The South African citrus industry developed integrated pest management tactics to suppress the false codling moth, including sanitation, mating disruption, and chemical, microbial and augmentative biological controls (Newton 1998; Hofmeyr et al. 2015; Malan et al. 2018; Boersma 2021). However, the pest management programme was not adequate for effective moth control, insecticide resistance developed, and export markets increased in importance. Therefore, the citrus industry developed a more comprehensive area-wide control programme with the SIT as an additional method to suppress false codling moth populations (Bloem et al. 2003; Carpenter et al. 2007; Stotter et al. 2014; Hofmeyr et al. 2015; Boersma 2021).

A comprehensive research programme was organized by the industry, with support from the FAO/IAEA and USDA, to investigate the potential for applying the SIT against the false codling moth. There were several well-organized phases -- determine the radiation biology, evaluate mass-rearing technology, and conduct small-scale field-cage tests and subsequently a pilot project. The radiation biology experiments demonstrated that female moths were completely sterile at 200 Gy, but male moths were partially sterile with residual fertility of 5% at 350 Gy when crossed to fertile females (Bloem et al. 2003; Hofmeyr et al. 2015). Evaluating the fertility of the $F_1$ progeny showed that treatments of 150 Gy to male moths resulted in 100% sterility of their $F_1$ progeny, and demonstrated that an effective dose for an IS programme would be between 150–200 Gy. The field-cage test found that a dose of 150 Gy was effective for a mixed-sex release at a ratio of 10:1 sterile to fertile, and resulted in the highest percentage of uninfested fruit (Hofmeyr et al. 2005).

Based on these results, the pilot phase began with a treatment to 35 ha of citrus with a season-long release of moths treated at 150 Gy for a period of 29 weeks; the goal was to maintain an overflooding ratio of at least 10 to 1 over the course of the season. This trial resulted in a 95–97% reduction in fruit loss compared with the control plots (Fig. 5) (Hofmeyr et al. 2015).

Given the positive results of the first three phases of testing, and in support of a new operational SIT programme, the South African citrus industry constructed a mass-rearing facility (1900 $m^2$); the goal was to produce 21 million moths per week (Hofmeyr et al. 2015). The facility incorporated many new improvements to the rearing system and infrastructure, including a new mass-rearing diet, improved oviposition cages, a new moth-collection system, an irradiation source, and new

release systems using ground-based and aerial release vehicles. Operational releases started in the 2007–2008 citrus-production season (Hofmeyr and Pretorius 2010; Hofmeyr et al. 2015).

During this period there was significant programme success, but also there were obstacles to overcome -- leading to a change to an extruded-diet production, a change in the release systems (using helicopters for sterile-moth release), and increasing the irradiation dose to 200 Gy (Xsit 2018, 2019). Over the next decade, the operational programme steadily continued to expand, reducing wild moth populations and fruit damage to low levels -- 95% or more below pre-programme levels, and reducing export-fruit damage-rejection levels (Fig. 6) (Hofmeyr et al. 2015; IAEA 2016; Boersma 2021).

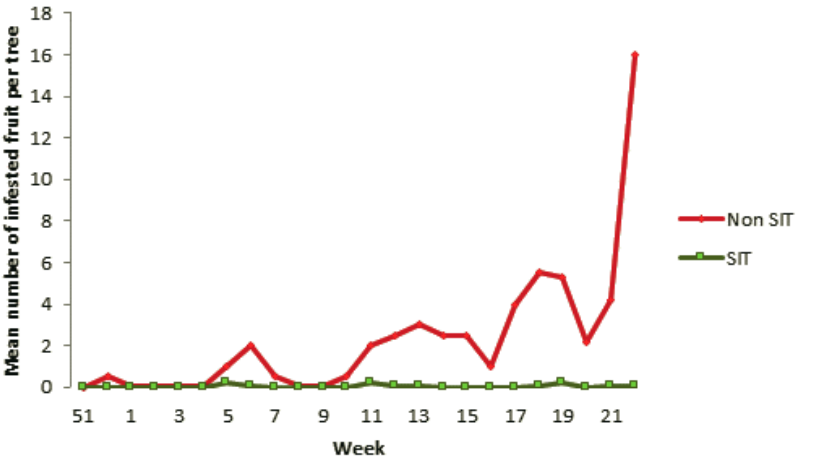

*Figure 5. Fruit drop due to* T. leucotreta *infestation in non-SIT and SIT-treated citrus orchards (35 ha) as part of an SIT pilot project conducted in the Citrusdal region during the 2005–2006 season. (Figure from Boersma 2021.)*

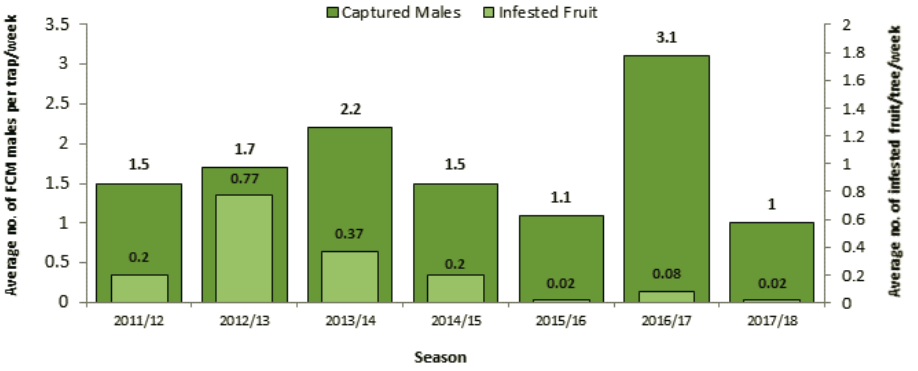

*Figure 6. Reduction in the number of wild* T. leucotreta *males and infested fruit in the Sundays River Valley, Eastern Cape Province, South Africa, as a result of sterile insect releases (data obtained from Xsit). (Figure from Boersma 2021.)*

The programme has gained additional participation, increasing operations to encompass nearly 20 000 ha of the programme's three main operational treatment areas in citrus of the Western Cape and the Eastern Cape provinces (Boersma 2021). The programme attributes its success to focussing on a single crop industry, with broad support from growers to focus on the demands of the export market, integrating the SIT with other area-wide control tactics, and making the necessary investments in research and methods development to improve rearing, handling, and release procedures to maintain high moth quality and competitiveness (Boersma 2021).

### *2.4. Cactus Moth*

The cactus moth *C. cactorum* is famous as a very successful biological control agent of invasive cacti (*Opuntia* spp.) in Australia, South Africa, and other regions, but it has proved to be a "two-edged sword" (Suckling and Sforza 2014). Following its accidental introduction into Florida, and subsequent spread along the coast of the Gulf of Mexico, and subsequent detections in Mexico (Fig. 7), the threat posed to native *Opuntia* ecosystems and agricultural production led to the launch of a binational emergency response against this invasive pest (Bloem et al. 2007b; Hernández et al. 2007; Bello-Rivera et al. 2021).

*Figure 7. Location of Isla Contoy and Isla Mujeres near Cancun, Quintana Roo, in the Caribbean Sea, where infestations of* Cactoblastis cactorum *occurred but were later eradicated. (Map from Bello-Rivera et al. 2021.)*

To address this threat, an area-wide control programme, with containment and eradication as the main goals, was implemented (Bloem et al. 2007b; Hernández et al. 2007; Bello-Rivera et al. 2021). This was a challenge because few control or surveillance tools were available (Stiling 2002; Bloem et al. 2005). The main methods

of cactus moth control consisted of insecticide treatments and hand-removal of infested cladodes and egg sticks. No pheromone was available for use in a detection system or for mating disruption (Bloem et al. 2003). Manual removal methods are effective but labour intensive (Hight et al. 2005), and insecticide treatments cannot be applied over large natural areas (Leibee and Osborne 2001; Zimmermann et al. 2004).

To address the limited number of tools available, research was initiated to improve monitoring methods, and to develop the SIT for eradication, barrier establishment, and as a resource to increase hosts for natural-enemy establishment (Carpenter et al. 2001a, b; Bloem et al. 2003; Hight et al. 2005; Heath et al. 2006). An artificial diet and mass-rearing system were developed (Carpenter and Hight 2012). A dose of 200 Gy was selected for implementation of an IS release programme where females were 100% sterile and male moths had residual fertility of between 40–50% (Carpenter et al. 2001; Hight et al. 2005).

The operational programme used surveillance, removal of host plants, sanitation efforts, and releases of sterile moths to contain and reduce cactus moth populations along the US Gulf Coast, and to eradicate this invasive pest in Isla Mujeres and Isla Contoy, preventing an invasion into the mainland of Mexico (Fig. 8) (Carpenter et al. 2008; NAPPO 2009; Hight and Carpenter 2016; Bello-Rivera et al. 2021).

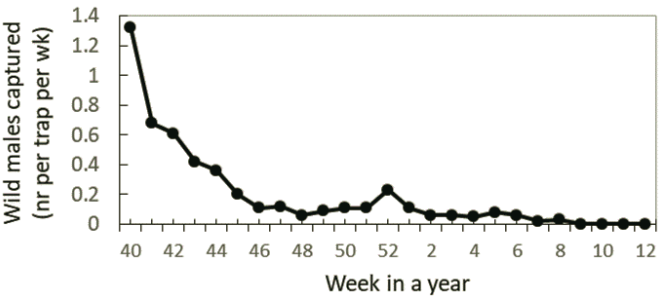

*Figure 8. Wild* C. cactorum *male moths caught per week in pheromone-baited traps from October 2006 to March 2007 in Isla Mujeres, Mexico (66 traps were deployed, except 115 in the last month). (Figure modified from Bello-Rivera et al. 2021.)*

### *2.5. Painted Apple Moth*

The painted apple moth *T. anartoides* is an Australian tussock moth species with flightless females (Fig. 9). There was concern that larvae would feed on many different plants of importance to horticulture in New Zealand, e.g. apple, forestry, e.g. plantation pine, and native ecosystems (Stephens et al. 2007). In fact, it has since been shown that the potential host range was wider in male than in female moths (Suckling et al. 2014); this has not been recorded previously in insects. This invasive pest was estimated to have a potential total cost to New Zealand of USD 52–203 million.

An eradication programme was approved, with a budget of up to USD 52 million (including communications and human-health monitoring costs). Operations began in January 2002, initially applying aerial sprays of *Btk*. In February 2003, releases of partially sterile males irradiated as pupae at 100 Gy (Suckling et al. 2002; Wee et al. 2005) were initiated at three sites with known or suspected painted apple moth

breeding populations. Regular quality assessments of males were made in a wind tunnel (Fig. 9). By May 2003, 45 000 males had been released. In virgin female-baited traps, recapture ratios of sterile to wild males averaged ca. 100:1.

Outbreaks of this invasive pest in Auckland, New Zealand, were eradicated in 2007 (Suckling et al. 2007).

Earlier modelling of the impact of the aerial *Btk* spray programme on the insect pest population suggested that a protracted programme would be needed to achieve eradication using this tactic alone. The addition of IS to eradication efforts was welcomed by public factions that opposed the spray applications. However, an assessment of the full benefit of the addition of IS to the successful eradication of the painted apple moth is not possible because of confounding among several techniques used together. Nevertheless, because reared virgin females were being used a lot as lures in a trapping grid across Auckland, the additional cost of rearing, sterilizing, and releasing males was rather minor (less than USD 145 000 per year). All indications from the IS programme were positive, including a highly favourable benefit/cost analysis (Brockerhoff et al. 2010) and little public resistance (Gamble et al. 2010).

## 3. PAST EFFORTS TO DEVELOP AND APPLY MOTH SIT/IS

### *3.1. Gypsy Moth*

The gypsy moth *L. dispar* was accidentally introduced into the USA in 1869 near Boston, Massachusetts, from where it has been gradually expanding its distribution. The area infested by the gypsy moth in North America is confined to the eastern USA (behind an advancing front slowly moving in a south-westerly direction) and the eastern provinces of Canada (Sharov et al. 2002a; Liebhold et al. 2021). It remains an important forest defoliator that periodically builds to outbreak levels resulting in serious economic, environmental, and public nuisance problems (Liebhold et al. 2000; Thorpe et al. 2006). Since 1924 more than 32.8 million ha of US forests have been defoliated by the gypsy moth (USDA Forest Service 2001).

The potential of using the SIT to contain and manage gypsy moth leading-edge populations, and to eliminate isolated outbreak areas resulting from the accidental transportation of egg masses and other life stages through commerce and recreation, led to the initiation in 1957 of radiation biology studies (Godwin et al. 1964). Based on several criteria, the gypsy moth appeared to be well suited for population management with the SIT — females do not fly, males may mate several times, and females typically mate only once, producing an egg mass in the fall from which larvae hatch the following spring (Reardon and Mastro 1993).

Mastro et al. (1981) and Reardon and Mastro (1993) provided good reviews of the considerable amount of research that was conducted throughout the 1960s, 1970s, and 1980s. This research defined the sterility effects of various doses of radiation when applied to different gypsy moth developmental stages, assessed and developed methods to optimize competitiveness of sterile gypsy moths, and quantified the impact of releasing sterile and partially sterile insects. Three different release strategies were investigated (Reardon and Mastro 1993): (1) field-placement (from the ground) of male pupae (sexed visually by size and form) treated with at least 150 Gy that emerged as fully sterile adults, (2) deployment (from the ground) of substerilized male pupae treated with 100 Gy, and (3) broadcast release (from the ground or air) of diapausing $F_1$ sterile eggs produced from untreated females mated with males treated with 100 Gy. Schwalbe et al. (1991) discussed the gypsy moth problem in North America and the rationale for focusing on the use of $F_1$ sterile eggs to eradicate isolated infestations. Unfortunately, the programmatic details of the various field trials that were conducted are lacking, with the exception of a few key pilot tests (Berrien County, Michigan, 1980–1982, using fully sterile male pupae; Horry County, South Carolina, 1982, using partially sterile male pupae; and Bellingham, Washington, 1984–1985, using sterile $F_1$ egg masses) (Mastro and Schwalbe 1988; Mastro et al. 1989; Schwalbe et al. 1991; Reardon and Mastro 1993).

What little additional information exists on gypsy moth SIT is contained principally in a series of unpublished annual progress reports by the United States Department of Agriculture (USDA), Animal and Plant Health Inspection Service (APHIS) Laboratory, at Buzzards Bay, Massachusetts. However, in a report to the USDA, Agricultural Research Service (ARS), National Technical Advisory Board, LaChance (1976) provided some information on early gypsy moth field tests.

Small SIT field trials to suppress the gypsy moth also were conducted in Yugoslavia in 1969–1971 (Maksimović 1971, 1972, 1974). Even though it was concluded that the release of sterile males reduced wild population levels, an assessment of the actual impact of these releases is difficult given the experimental design that was used (LaChance 1976).

### *3.1.1. Release of Irradiated Pupae and $F_1$ Sterile Egg Masses*

In general, the release of irradiated pupae was effective in eradicating isolated infestations and in suppressing low-density populations along the leading edges of spreading infestations. However, despite the technique's effectiveness, several operational difficulties were identified, and the technique was judged to be impractical for large-scale use (Mastro et al. 1989). Some of the problems were: (1) pupae were fragile and required special care in packaging and shipping (Reardon and Mastro 1993), (2) pupae had to be released in emergence cages that were expensive to deploy and maintain (Reardon and Mastro 1993), (3) pupae and newly emerged adults were sometimes subject to intense predation, (4) overcrowding in emergence cages resulted in poor-quality adults (LaChance 1976), and (5) since released males lived only 2 or 3 d, frequent releases were necessary to maintain high ratios of released to wild insects (Schwalbe et al. 1991; Reardon and Mastro 1993). In addition, since male flight activity lasts only about 4 wk, a mass-rearing facility would be underutilized for most of the year (except potentially for producing the gypsy moth nuclear polyhedrosis virus) (Mastro 1993; Reardon and Mastro 1993).

As a result of the difficulties in releasing pupae, research efforts were refocused on the release of $F_1$ sterile egg masses. Male pupae were irradiated with 100 Gy, and then these males were mated to fertile females; the $F_1$ egg masses were stored in diapause until needed for release the following spring. In this way, in theory, some $F_1$ sterile larvae would emerge and develop in the field in synchrony with the wild population. This technique had the advantages that the $F_1$ sterile egg masses were easier than pupae to handle and ship, could easily be produced and stockpiled in diapause throughout the year using a relatively small rearing facility, and required only a single release per season (Schwalbe et al. 1991; Reardon and Mastro 1993). In spite of these advantages, the additional population suppression that IS offers (suppression by the release of partially sterile males followed by the field production of their $F_1$ sterile progeny) could not be taken advantage of when this approach was used. Also, some larvae (the feeding stage) resulting from the released $F_1$ eggs might cause some plant damage (although it was never actually observed) (Mastro et al. 1989; Mastro 1993).

Although the early use of gypsy moth $F_1$ sterile egg masses was successful in eradicating an isolated population in Bellingham, Washington (Mastro and Schwalbe 1988; Mastro et al. 1989; Schwalbe et al. 1991; Reardon and Mastro 1993), similar results were not consistently obtained in subsequent trials against isolated outbreak populations, and the technique proved inadequate for managing gypsy moth populations along invading fronts of established infestations (Reardon and Mastro 1993). Apparently, the low efficacy and inconsistent results of releasing $F_1$ sterile egg masses were due to the fact that the resulting sterile adults that developed in the field were less competitive than the wild population, and were actually less competitive than laboratory-reared males irradiated and released as pupae. Part of the poor

competitiveness was due to developmental asynchrony with wild moths, which was likely exacerbated by variably delayed development that was subsequently shown to be caused by low bioavailability of iron in the diet of the maternal parent (Keena et al. 1998). Nevertheless, between 1988 and 1992, eight isolated populations of the gypsy moth were treated with $F_1$ sterile egg masses with apparently "generally positive results" (Reardon and Mastro 1993). Between 1980 and 1992, infestations covering a total of 2385 ha were eradicated using sterile gypsy moth releases of all types (USDA Forest Service 2001). However, after nearly 35 years of study and application, it was determined that the SIT/IS was not sufficiently cost-effective relative to other less-expensive options. After 1993, this technology was no longer employed against the gypsy moth.

Current programmes for gypsy moth suppression rely on the use of *Btk*, a gypsy moth nuclear polyhedrosis virus, and the synthetic sex pheromone disparlure (Sharov et al. 2002b; Lance et al. 2016). In recent years, sterile gypsy moths have been used only for such purposes as calibrating trapping grids to confirm that phenological models are giving reasonably accurate estimates of the timing of egg hatch, and determining parasitoid host preferences. Nevertheless, the investigations associated with the development of the SIT for this pest led to a better understanding of its biology and behaviour that is being utilized in ongoing management activities (Mastro et al. 1989).

In Europe, more recent investigations have been conducted on the release of $F_1$ sterile egg masses in advance of imminent gypsy moth outbreaks; the objective is to enable natural enemy populations to build-up early, and thus reduce the magnitude of an outbreak (Zúbrik and Novotný 2009).

### *3.2. Tobacco Budworm*

The tobacco budworm *H. virescens* is a key pest of cotton and tobacco, and has been developing resistance to most insecticides used for its control (Harris et al. 1972; Elzen et al. 1992). In an attempt to develop an alternative control strategy for the tobacco budworm, Laster (1972) discovered hybrid sterility in $F_1$ male moths when male *H. virescens* were hybridized with female *Heliothis subflexa* (Guenée). The $F_1$ (hybrid) females produced from this cross, when backcrossed to *H. virescens* males, produced sterile male and fertile female progeny. This male sterility persisted in all subsequent backcross generations. Genetic studies of tobacco budworm backcross sterility discovered abnormalities in the sperm of hybrid and backcross males (Richard et al. 1975; Goodpasture et al. 1980). LaChance (1985) and Laster et al. (1988) reviewed in detail the different biological mechanisms responsible for sterility in the hybrid, including the early backcross and subsequent backcross generations. The potential use of backcross sterility was examined using population models (Makela and Huettel 1979; Levins and Parker 1983) that predicted a decline in a natural population of tobacco budworm following the release of backcross insects. Following encouraging results from many studies of host-plant preference, mating preference, and mating competitiveness (Laster et al. 1988), a pilot release programme was planned for the island of St. Croix, US Virgin Islands.

The objectives of the pilot programme on St. Croix during 1977–1981 were to introduce a measurable amount of backcross sterility into the natural population of tobacco budworm, and to evaluate the population suppression and the level of backcross sterility in subsequent generations. This project was a cooperative effort between the USDA and the Mississippi Agricultural and Forestry Experiment Station. During 1979 and 1980, four separate releases were made (Proshold et al. 1983). Male sterility in tobacco budworm wild populations continued to increase as long as backcross insects continued to be released. During the last 6 weeks of 1981, 94% of wild tobacco budworm males were sterile (Proshold 1983). However, as the backcross frequency declined following the last release, tobacco budworm populations returned to pre-release levels. Proshold and Smith (1990) were not able to detect the backcross phenotype five years after the last release, presumably because of genetic drift and selection.

Following the pilot release programme on St. Croix, in 1991–1993 a pilot test was conducted in the central delta of Mississippi, USA, to study the effects of released backcross insects on natural tobacco budworm populations in a typical agricultural production area (where it overwinters and from where it annually undergoes long-distance dispersal to northern states and Canada (Laster et al. 1993, 1996; Hardee and Laster 1996). Backcrossed moths were released by placing pupae in emergence boxes at the test location, a 16.7-$km^2$ area in Washington and Sunflower Counties, Mississippi, in 1992, and in Bolivar County, Mississippi, in 1993. Control areas of the same size were used for each year. In 1992, the backcross to budworm overflooding ratio achieved was 3:1. After releases had ceased, this ratio declined to 1.3:1 during June, and to 1:2.3 during July. In 1993 the backcross:budworm ratio in the same area was 1:2.2 (29.9% sterility) for the overwintering generation. Releases in Bolivar County during 1993 achieved a backcross:budworm ratio of 2.6:1. After releases had ceased, this ratio declined in June to 1:1.6, in July to 1:3.6, and in August to 1:4, producing in 1994 a 12.1% sterility carry over. Hardee and Laster (1996) concluded that backcross release results were favourable. However, considering the survival and migration potential of the tobacco budworm, higher overflooding ratios of released to wild insects would be needed on an area-wide basis in overwintering areas of the budworm to achieve more sustainable results.

### *3.3. Corn Earworm*

The corn earworm *H. zea* is a major pest of maize, cotton, and many other field crops in the Western Hemisphere. Due to the importance of this pest, a method to mass-rear the corn earworm was developed (Burton 1969), and several attempts to eradicate this pest using the SIT in St. Croix, US Virgin Islands, were made (Snow et al. 1971; Laster et al. 1988). The first eradication trials were conducted for 3 months in 1968, and 6 months in 1969, with a second campaign being conducted from 1972 to early 1974.

Many problems were encountered during the 1968 trial, including an unexpected increase in the area planted to maize, inconsistent releases of irradiated insects, and poor and inconsistent insect production resulting from disease contaminants in the laboratory colony. Shipping and disease problems were reduced in 1969, but still

caused periodic slumps in the supply of sterile corn earworms. Nevertheless, when there was no slump in the insect supply, releases of corn earworm males (treated with 320 Gy) resulted in sterile to wild overflooding ratios of 10:1–15:1. As a result of the 1969 programme, there was a reduction in the field in the number of fertile corn earworm eggs, rather than an increase in the number of sterile eggs. It was concluded that this reduction in oviposition was caused by a high incidence (50%) of locking (failure of mating pairs to disengage upon completion of copulation) between released and wild adults (Snow et al. 1971; Laster et al. 1988).

For the 1972–1974 eradication campaign, changes were made in the rearing system to improve the insect quality and reliability of supply of insects for release. In general, only males were released, and the radiation dose used to sterilize males was reduced from 320 to 225 Gy (Hamm et al. 1971; Young et al. 1976). However, several times during the course of the campaign, changes were made in the radiation dose actually used, and in the sex (males alone or mixed sex) of the insects actually released. Local eradication of the corn earworm population was not achieved during either campaign, but much knowledge and experience were gained concerning the operation of an area-wide programme against a lepidopteran pest. Laster et al. (1988) concluded that improved rearing techniques and more competitive insects were critical, and suggested that using a lower radiation dose would improve the efficacy of future AW-IPM programmes against the corn earworm.

To assess the influence of released males treated with a substerilizing dose of radiation (100 Gy), and to measure the level of IS induced in wild populations of the corn earworm, Carpenter and Gross (1993) conducted a pilot test in small mountain valleys in western North Carolina, USA, from 1986–1990. They found that the number of wild males captured per ha was positively correlated with the distance from the release site of the substerilized moths. Analyses of seasonal population levels of wild corn earworms, estimated from mark-recapture data, indicated that seasonal increases of wild males were significantly delayed or reduced (or both) in mountain valleys where substerile males had been released. The incidence of corn earworm larvae with chromosome aberrations (indicating they were progeny of irradiated, released males) collected from the test sites during the growing seasons demonstrated that substerile males were competitive with wild males in mating with wild females, and were successful in producing sterile $F_1$ progeny that further reduced the wild population. These significant reductions (73.5%) in populations of the corn earworm resulted even though the average overflooding ratio of irradiated to wild males (5.3:1) was low compared with that of other programmes that release sterile insects.

The use of the SIT has not been implemented into operational programmes for the control of either *H. virescens* or *H. zea*. Although hybrid backcross sterility and $F_1$ sterility suppressed pest populations in the field, the cost of rearing the insects, the highly mobile nature of these species, and in particular the development and adoption of effective *Bt* transgenic crop varieties, make it economically impractical at the present time to use the SIT to control these pests. However, preventive releases of sterile moths at overwintering sites, when wild populations are concentrated and are present in naturally low populations, would be an opportunity to apply IS to minimize the moth populations migrating north in the spring (Hardee et al. 1999).

### *3.4. Light Brown Apple Moth*

The light brown apple moth *E. postvittana,* a native to Australia, was first detected in California in 2007 (Brown et al. 2010). As a pest, the light brown apple moth is best known from tree fruits (e.g. apples, pears, citrus, peaches, nectarines, and apricots), vines, berry fruit, and to a lesser extent from forestry, and vegetable and flower crops (Wearing et al. 1991). The suspected-host list is estimated at about 500 species (Brockerhoff et al. 2010; Suckling and Brockerhoff 2010). The potential for harm from this pest triggered a major response from the USDA and the State of California agricultural authorities (Suckling and Brockerhoff 2010). Infested areas in the core California coastal areas were quarantined, and regulatory and control measures were put in place (including a large-scale effort to apply aerial pheromones in an attempt at eradication). As the programme progressed, with both public opposition leading to some challenges to the State's authority to implement a pheromone-based control programme (Lance et al. 2016), and the realization that more control tools were needed to contain this pest, a research and pilot project to develop the SIT was launched. It developed mass-rearing technology, examined both pupal (Soopaya et al. 2011) and adult irradiation biology (Jang et al. 2012), and conducted field trials in New Zealand and California (Suckling et al. 2011; USDA/APHIS 2011; Stringer et al. 2013). Modelling the overflooding ratios showed that, at 300 Gy, the population extinction was 95% probable when the ratio of released to wild males in monitoring traps exceeds 6.4 (Kean et al. 2011). Higher overflooding rates would achieve eradication more rapidly. There was an advantage to using IS over full sterility early in such a programme (due to the superior fitness of males at lower doses) (Kean et al. 2011; Suckling et al. 2011). A male-biased sex ratio was shown (Soopaya et al. 2011), adding to the multiplier effect of matings by sterile $F_1$ offspring.

In 2011, a pilot SIT project was initiated in California; it included sterility testing of adult moths, confirming the dose of 300 Gy for full sterility (shown by Soopaya et al. 2011). The mass-rearing and adult-collection systems were adapted from methods used in the pink bollworm and codling moth, and a sterile-insect field release trial followed in a 2.6-km² residential area in a coastal city in southern California. Twice-weekly releases of sterile moths (60 000–70 000 sterile moths per week) were made by hand on a grid system for 11 weeks, with a total release of 650 000 sterile moths. Due to the high population of wild moths in the area, satisfactory overflooding ratios were not achieved. However, moth quality appeared to be high, with moth recaptures of about 0.1% in the widely spread trap grid, with dispersal distances of up to 0.5 km, and field longevity of released adult moths observed for greater than 2 wk after release. At the end of 2011, the project was stopped -- due to financial constraints, and the evolution of the project away from a control programme towards a regulatory programme designed to limit further spread out of the quarantine areas.

## 4. ONGOING METHODS DEVELOPMENT OF MOTH SIT/IS

### *4.1. European Grapevine Moth*

Historically the European grapevine moth *L. botrana* has been a pest of the Mediterranean regions of Europe, North Africa, and Asia. Recently, it was introduced into the Americas region, with first detections in Chile in 2008, California, USA, in 2009, and Argentina in 2010 (Varela et al. 2010; Gilligan et al. 2011; Ioriatti et al. 2011, 2012). A successful eradication campaign was completed in the USA in 2016 (Schartel et al. 2019; Simmons et al. 2021), but there is increasing pest pressure in the South America region. Infestations in urban areas are difficult to treat, and market-access problems affect the trade of other hosts, e.g. blueberries. Increasing problems for grape production in the Mediterranean regions are related to the development of insecticide resistance, warmer growing seasons with climate change, and the high cost of mating-disruption treatments (Martin-Vertedor et al. 2010; Ioriatti et al. 2011; Gutierrez et al. 2018). These factors have increased interest in the development of the sterile insect technique for *L. botrana* (Mansour 2014; Saour 2014, 2016).

Saour (2014) found complete female sterility when irradiating adults at 150 Gy, but a much higher dose of 400 Gy was needed to achieve near 100% sterility in males. A dose of 150 Gy was recommended for use in an IS strategy, a trade-off between high field competitiveness, as measured by flight ability, and higher residual male fertility (Saour 2016). (Higher irradiation doses significantly impacted the flight ability of male moths compared with a dose of 150 Gy.) At 150 Gy, the frequency of $F_1$ male progeny increased, and these had high sterility levels (Saour 2014).

In Chile, *L. botrana* was first detected in Santiago in urban grapes, and is now present in grape production areas in the central region of the country (Ioriatti et al. 2012; SAG 2019), and has also caused problems for the export of the large and valuable blueberry (*Vaccinium* spp.) crop. In urban areas (that are near grape and fruit production areas) many Chileans grow wine grapes in their gardens; this is a significant problem for the control programme because urban treatments can be very expensive and logistically challenging (residents can refuse treatments). The government's national control programme strategy for urban areas includes the use of mating disruption. A pilot project to test releases of sterile moths and parasitoids has been initiated (SAG 2018, 2019; H. Donoso, personal communication).

For the development and evaluation of the SIT as a control tool, the Chilean government and the fruit industry have formed a partnership to develop *L. botrana* mass-rearing systems, determine the radiation biology, and in 2016 began field-cage and pilot-scale field releases (H. Donoso and S. Izquierdo, personal communication). These trials were designed to measure the field-performance traits of irradiated males (e.g. dispersal, longevity, and mating with wild moths), determine release rates and frequency, and identify any needed changes in the rearing and handling of moths to improve performance.

The programme developed a sterile-insect laboratory in Arica with a capacity to produce >100 000 mass-reared moths per week to support a larger programme; currently it is producing 50 000–75 000 per week. This project has access to the gamma irradiator (Bakri et al., this volume) used for Chile's Mediterranean fruit fly

programme. The work in Arica has focused on optimizing the adult diet, developing quality-control procedures, and developing methods to collect and irradiate adult moths. The programme is also working with its fruit-industry partner Fundación para el Desarrollo Frutícola (FDF) to develop mass-rearing procedures, verify previous radiation-biology studies, and begin pilot-scale releases of sterile moths. Production capacity at the FDF mass-rearing laboratory in Santiago exceeds 100 000 pupae per week. The FDF programme is focused on methods of pupal collection and irradiation. Even though it is challenging to collect and irradiate pupae for large-scale moth SIT programmes, there are advantages to using pupae, e.g. a decrease in the impact on moth quality compared with handling and storage of adults. Early results from the programme suggest that it is having success – good insect dispersal performance and recapture rates. However, while a system of using irradiated pupae may be suitable for a small-scale programme targeting residential areas (Sucking et al. 2007) and selected vineyards (Stringer et al. 2013), a larger production effort for the area-wide release of sterile moths over a region will likely require the collection and irradiation of adult moths.

In 2018, the programme initiated several larger pilot-release evaluations in residential areas measuring 12.5 to 25 ha, and for a longer period of time releasing up to 16 700 sterile moths per week (FAO/IAEA 2018; SAG 2018; H. Donoso and S. Izquierdo, personal communication). This programme was expanded in 2019 to release 50 000 moths per week for a season-long project in a 25-ha residential area next to commercial vineyard and agricultural production areas. The goals of this larger phase of testing are to evaluate dispersal, field longevity, overflooding ratios, and suppression of wild populations, and also to develop the operational procedures needed to conduct an SIT programme. While it remains to be seen whether this pilot project will succeed and lead to operational releases, the first results are promising. The Chilean programme is making substantial progress, and may be the only solution available to reduce the extent of *L. botrana* movement from residential into production areas.

### *4.2. African Sugar Cane Borer*

The African sugar cane borer *E. saccharina* is a native pest in several regions of Africa. It infests sugar cane, maize, and sorghum, as well as other grain crops of the grass family, and several native grasses and sedges (Walton and Conlong 2016a, b). The larvae's boring activity causes crop loss and reduced yields in sugar cane (Conlong 1994). After its spread into South Africa, the sugar cane industry launched a large effort to understand its biology, use of other hosts, methods of biological control, and prospects for area-wide management using various habitat management strategies. Efforts to determine if the SIT could be incorporated into the current area-wide programme were launched with work on mass-rearing, radiation biology, mating competitiveness, and modelling (Barnes et al. 2015; Mudavanhu et al. 2016; Walton and Conlong 2016a, b; Conlong and Rutherford 2017).

Work by Walton and Conlong (2016b) showed complete sterility of females at 200 Gy and residual male fertility of 20%, and suggested the potential of an IS approach for this species using 200 Gy. Mudavanhu et al. (2016) found that reared males,

irradiated at a dose of 200 Gy, were as competitive as wild fertile males, and have a high mating compatibility with wild females, suggesting that the effects of colonization, mass-rearing, and irradiation would not greatly affect the competitiveness of mass-reared irradiated moths.

### *4.3. Navel Orangeworm*

The navel orangeworm *A. transitella* is the key pest of California tree nuts: almonds, pistachios, and walnuts. It causes feeding damage on kernels that can also lead to the introduction of aflatoxin producing the *Aspergilli* fungus. The insect has a wide host range that includes other tree and fruit crops such as oranges, figs, pomegranates, pecans, and ornamental species (Bentley et al. 2016; Ferguson and Haviland 2016). These crops are planted on more than 768 900 ha, and valued at more than USD 6200 million per year. For all of these crops, tolerance to pest damage by the navel orangeworm is extremely low, especially for pistachios (because of the difficulty of sorting out damaged nuts while still in the shell). Contamination by aflatoxin can impact quality and marketability. Levels of navel orangeworm damage are directly correlated with those of aflatoxin contamination. Standards of aflatoxin and insect damage for export markets are very demanding; this is a prominent concern (Bentley et al. 2016; Ferguson and Haviland 2016).

In view of concerns about the long-term sustainability of the current navel orangeworm management methods, there is interest in developing the SIT as an additional tool for navel orangeworm control; also, there is support to develop an area-wide control programme (Northcutt 2015). Work on radiation biology by USDA scientists in California (Light et al. 2015), and strong support shown by the tree-nut industry, has led to a pilot project to develop mass-rearing and to field-test sterile navel orangeworms (Wilson and Burks 2019). The USDA-APHIS-PPQ pink bollworm sterile-insect mass-rearing facility in Phoenix, Arizona, may be used to rear navel orangeworms (Blake 2015). An earlier demonstration project developed and evaluated navel orangeworm area-wide control measures (mating disruption, sanitation, and coordinated applications of insecticides), and showed that navel orangeworm control could be improved by using area-wide tactics. Since the use of the SIT is complementary with area-wide control, development of the SIT as a new tool would be especially useful for the long-term sustainability of navel orangeworm management in California.

Development of mass-rearing (focusing on evaluations of diet, rearing trays, and adult collection at the USDA-APHIS-PPQ facility) shows that there is a potential to produce several million navel orangeworm per week. That this was accomplished (without making significant changes to a system optimized for the pink bollworm) demonstrates that much higher numbers of navel orangeworm could be produced if the entire facility was committed to rear navel orangeworm on a much larger scale. Current production levels are being maintained to support the pilot-project field testing needed to develop an SIT system. Field trials were initiated in 2018, and are ongoing in 2019.

### *4.4. Tomato Leafminer*

The tomato leafminer *T. absoluta* is an emerging pest of solanaceous crops from the neotropics that has expanded into North America, Europe, the Middle East, Africa, and parts of South-East Asia (Biondi et al. 2018; Biondi and Desneux 2019; Han et al. 2019). Internal feeding damage to fruit, leaves, and stems may cause losses as high as 100%; such damage increases the need for insecticide applications, but they disrupt the integrated management programmes of other tomato pests. Given its rapid range expansion and adaptability to diverse climatic conditions, this pest is predicted to have a high impact on tomato growers throughout these regions (Biondi et al. 2018).

Current control practices often rely on insecticide applications, but more sustainable control practices are needed (there are several reports in several regions of the development of insecticide resistance) (Biondi and Desneux 2019; Guedes et al. 2019; Silva et al. 2019). Furthermore, augmentative biological control using Neotropical parasitoids may not be available in other regions due to increased biosecurity that is increasingly excluding non-native natural enemies. Thus, there is interest in developing the SIT for the tomato leafminer for use in greenhouses (as an alternate tool to insecticide treatments) which would be compatible with biological control-based tactics (FAO/IAEA 2016, 2019).

Recent work includes completion of radiation-biology studies, field-cage testing showing pest suppression on infested tomatoes, and incorporation of predator releases with sterile-moth releases in glasshouse tomato production (Cagnotti et al. 2016; Kuyulu and Hanife 2016; Vreysen et al. 2016; FAO/IAEA 2019). Radiation-biology data for *T. absoluta* suggest that doses of 200–250 Gy could be used to induce IS in males (Cagnotti et al. 2016; Carabajal Paladino et al. 2016).

### *4.5. Carob/Date Moth*

The carob or date moth *E. ceratoniae* is a major pest of dates in North Africa. The use of *Btk*, parasitoids, and postharvest fumigation does not provide sufficient pest control to enable the industry to reap the potential economic benefits from increased exports of dates.

Laboratory and field studies have been carried out in Tunisia and Algeria, with a view to integrating the SIT into AW-IPM programmes for date and pomegranate plantations. A mass-rearing system was established, and some small-scale releases of partially sterile moths were made (Dhouibi et al. 2000; Mediouni and Dhouibi 2007; Chakroun et al. 2017).

## 5. IMPACT, CHALLENGES, AND FUTURE DIRECTIONS

The long list of pestiferous lepidopterans (with increasing development of resistance to insecticides, and their tremendous impact on agriculture and forestry) necessitates an ongoing search for more efficient, economical, and environment-friendly ways of dealing with these pests. The SIT/IS is a species-specific technique that is highly compatible to integration with other pest management tactics, including the use of ground or aerial spraying of selective or biorational insecticides, mass-trapping,

cultural controls, sanitation, host removal, host-plant resistance, and biological control (Carpenter et al. 2007; Vreysen et al. 2016; Suckling et al. 2017; Mangan and Bouyer, this volume). It is likely to be especially effective when combined with other inversely density-dependent tactics such as mating disruption (Suckling et al. 2012).

### *5.1. Effectiveness and Impact*

The overall effectiveness of the SIT/IS has been demonstrated to reduce lepidopteran pest populations in several operational programmes, resulting in the successful eradication of the pink bollworm in four states in the south-western cotton belt in the USA and in northern Mexico, and the eradication of outbreaks of the gypsy moth in the USA, painted apple moth in New Zealand, and cactus moth in Mexico. The application of the SIT/IS continues (in suppression programmes) to manage moth pests in the OKSIR programme against the codling moth in Canada, and now New Zealand, by reducing fruit-damage levels and reliance on insecticides. Within a comparatively short timespan of about 15 years, a programme targeting the false codling moth was developed in South Africa; it is effectively expanding the SIT-based area-wide control to additional citrus-production areas to reduce fruit-damage levels below demanding export thresholds.

At the same time, efforts started in recent years are continuing to develop the SIT against several emerging pests: the programme in Chile on European grapevine moth has moved into pilot-phase testing, with interest from several other countries; progress has been made towards the SIT for the African sugar cane borer in South Africa for a potential addition to a programme of comprehensive AW-IPM; and radiation-biology studies, and the development of mass-rearing systems, to develop the SIT are targeting the navel orangeworm. Also, research is underway to enhance the potential for the SIT to manage the carob moth in date production for export from North Africa, as well as the tomato leafminer in greenhouses (an emerging pest of solanaceous crops that has expanded into new regions).

### *5.2. Challenges*

Despite these successes, there remain serious challenges to be met to make the SIT/IS for Lepidoptera more cost-effective relative to other pest-management tactics (Simmons et al. 2010; Vreysen et al. 2016; Suckling et al. 2017). Development of lepidopteran mass-rearing systems are complex endeavours, cost-effective meridic diets are difficult to develop, insect developmental times are long, larvae are often cannibalistic, sanitation measures must be stringent to prevent pathogen contamination (fungi, viruses, microsporidia) (Abd-Alla et al., this volume), and the insects, especially adult moths, are fragile.

Unlike in dipteran SIT programmes, methods to collect and irradiate the more robust pupae have not been widely developed for operational programmes. Using pupae in moth SIT programmes could reduce costs related to handling, storage, irradiation, and transport. However, the collection, handling, and irradiation procedures for current operational programmes are based on adult moths, which require optimized protocols to maintain high quality and low mortality rates of sterile

insects for release. This is in part because, for many moth-rearing systems, larvae pupate within the diet, and are difficult to separate out easily. Also, compared with dipteran mass-rearing systems, collections of pupae from lepidopteran rearing systems are of a less uniform physiological age, ranging from young pupae several days from emergence to pharate pupae (G. S. Simmons, personal observations). There are significant reductions in moth quality and emergence rates when irradiating pupae that are less developed than the pharate state. While there are some examples of small-scale programmes based on pupal irradiation and releases, there are significant obstacles for a larger programme to adopt these methods.

Another challenge, unlike dipteran SIT programmes (e.g. tephritid fruit flies and the New World screwworm), is that until recently relatively little attention had been given to development of procedures to maintain quality, fitness, and competitiveness traits in mass-rearing colonies of Lepidoptera (Simmons et al. 2010). While there have been no documented failures of Lepidoptera SIT programmes based on colony strain or mass-reared quality defects, in the past ten years there has been significant emphasis devoted to the importance of maintaining high quality in Lepidoptera to obtain mass-reared insects that are highly competitive (Simmons et al. 2010; Vreysen et al. 2016). This includes the idea of building rearing systems that can resist the negative effects of genetic drift and natural selection that can either result in the loss of important genetic variability associated with high performance in the field or selection for high reproduction and fitness in the rearing system that comes at the expense of high field performance (Woodworth et al. 2002; Simmons et al. 2010).

Important components to maintain in a mass-rearing system are the capacity to fly (e.g. using moths from an adult collection system in oviposition cages because they have to fly to reproduce) and the capacity for male moths to respond to a sex pheromone (Simmons et al. 2010). There is a general idea in many SIT programmes that high performance of an SIT release strain can be maintained by adding to or replacing on a regular basis the colony strain with new wild individuals. As Woodworth et al. (2002) and others show there is very strong selection for performance in captive populations, and the "wild" traits introduced with the field-collected individuals are quickly lost in a rearing system containing "captive" selected individuals. This process can occur in just a few generations, which will easily swamp the effect of new beneficial traits introduced into a mass-rearing colony, and will not improve SIT performance unless specific rearing procedures are in place to maintain competitive characteristics in the colony (Nunney 2001; Simmons et al. 2010; Hendrichs and Robinson, this volume).

Rearing large numbers of lepidopterans produces potent allergens due to the presence of scales and setae (Davis and Jenkins 1995; Parker, Mamai et al., this volume), requiring specialized equipment and air-filtration systems to reduce/mitigate allergic reactions suffered by workers. The fact that only a limited number of SIT/IS programmes for Lepidoptera have become operational has unfortunately also meant that they have not been able to take advantage of shared learning experiences in the way that the many fruit fly programmes have, and the beneficial impacts of such programmes are less well documented and accepted.

Methods to reduce the cost of lepidopteran programmes might also include combining the SIT/IS with other suppression tactics such as the release of natural

enemies. In this instance, the cost of rearing might be reduced by using the same facility to rear both insect species, while the efficiency and effectiveness of a combined programme can help meet objectives in a more timely fashion through synergistic action of both tactics. Especially in the case of implementation of an IS strategy, the residual fertility in the parental release generation can generate some field reproduction to produce a completely sterile $F_1$ generation that can provide a significant additional resource for the build-up of natural enemy populations (Barclay 1987; Knipling 1992; Carpenter 1993; Vreysen et al. 2016; Mangan and Bouyer, this volume).

As it has for dipteran programmes, the development of genetic sexing strains (Marec et al. 2005) would greatly reduce the costs of rearing and release in lepidopteran programmes. Marec et al. (2005) demonstrated genetic sexing in the Mediterranean flour moth *Ephestia kuehniella* Zeller, using a mutant-male strain that is trans-heterozygous for two lethal genes (Marec et al., this volume). However, there is not universal agreement that having the ability to develop single-sex male release strains is necessary for increased effectiveness of the SIT in Lepidoptera; a large number of female sterile moths released in the field can distract (through sex pheromone release) fertile wild male moths, thereby assisting with mating disruption (Stringer et al. 2013).

### *5.3. Future Directions*

The application of molecular technologies might be used to develop genetic sterility, sexing systems, and reliable genetic markers for the released moths (Peloquin et al. 2000; Miller et al. 2001; Marec et al. 2005, 2007; Simmons et al. 2007; Simmons et al. 2011; Morrison et al. 2012; Bolton et al. 2019; Häcker et al., this volume). Since about 2007 there has been significant progress to develop and evaluate transgenic technology for two of the most difficult moth pests, the pink bollworm and the diamondback moth. In the pink bollworm, there were two efforts to introduce a sterile release moth into an operational programme. Genetically marked strains with fluorescent proteins could provide more reliable monitoring methods for standard sterile release programmes; they could also provide a heritable marker enabling implementation of IS systems. Field production of highly sterile $F_1$ progeny (Simmons et al. 2007, 2011), and production of a genetically sterile strain, could avoid radiation treatments and enable the production of male-only release strains (Simmons et al. 2007; Morrison et al. 2012; Jin et al. 2013). Work on the diamondback moth has progressed to the stage of field-testing genetically sterile or self-limiting strains to determine their field performance and competitiveness compared with wild strains (Bolton et al. 2019). It remains to be seen whether these technologies will be applied in new or existing operational programmes, but with further development these technologies could enable the operation of more cost-effective programmes.

The SIT/IS has special attributes that make it a desirable and unique insect pest management tool. However, because this technique requires a large start-up investment and a management-intensive support system, candidate pest species to be controlled with the SIT/IS should be selected carefully. A decision process to evaluate the suitability of the SIT/IS for controlling a pest lepidopteran should consider many

factors including: (1) key pest status, (2) economic importance, (3) mass-rearing costs and technical feasibility, (4) favourable radiation biology, (5) migration ability, (6) potential for an area-wide approach to minimize the treatment area becoming reinfested, (7) host specificity, (8) availability of monitoring tools, (9) stakeholder and customer support, and (10) the availability and effectiveness of other compatible control options for the target pest (Simmons et al. 2010; Vreysen et al. 2010, 2016; Suckling et al. 2017).

In addition to selecting carefully the most appropriate candidate species to be controlled with the SIT/IS, the strategic objective and type of programme should also be evaluated (Hendrichs, Vreysen et al., this volume). Since prevention is far more cost-effective and environmentally desirable than long-term measures that would be required once a non-native invasive species has become established, future considerations for selecting target lepidopterans should emphasize key invasive threats, similar to the SIT preparedness model that was developed for use in Australia for the Old World screwworm *Chrysomya bezziana* (Villeneuve) (IAEA 1998; Tweddle 2002; Hendrichs, Enkerlin et al., this volume; Vargas-Terán et al., this volume). For example, the false codling moth, the leek moth *Acrolepiopsis assectella* (Zeller), the European grapevine moth, and the Central American potato moth *Tecia solanivora* (Povolny) are all serious invasive threats to the USA and other countries such as Australia and New Zealand (Suckling 2003). The proactive development of the SIT/IS technologies offshore at the point of origin offers the following advantages:

- Capitalization on contributions by foreign counterparts due to their interest in controlling the same pest,
- Reduction in pest pressure at the point of origin (offshore risk mitigation) and thereby the risk of the pest being accidentally introduced elsewhere, and
- Availability of the SIT/IS for invasive moth pests, allowing significant reduction in response time to implement an SIT/IS eradication programme should such pests become established in a new location while pest populations are still restricted geographically and at low densities.

Rapid responses to incursions rely on the ability of scientists to make use of existing knowledge, and quickly provide decision-makers with ready-response capabilities (Bloem et al. 2014). Market drivers for reducing insecticide use for IPM also provide grounds for optimism for the future of SIT/IS implementation, particularly against high-value pests of export horticulture, where the absence of insecticide residues on fruit increasingly creates market value (Walker et al. 2017). These technologies are versatile, and can be used for pest management as well as for eradication goals.

## 6. ACKNOWLEDGEMENTS

The authors thank D. Lance, V. Mastro, E. Miller, and A. McCluskey for providing important information for, and reviews of, the sections on the gypsy moth, pink bollworm, and codling moth. We thank L. LaChance, M. Holland, and J. Walker for critically reading earlier drafts of this manuscript, R. Stouthamer for discussion about the genetics of captive breeding programmes, and T. Greene for help with the literature search. We appreciate the assistance of I. Johovic in making graphs.

## SUMMARY

Hunger and poverty persist in rural sub-Saharan Africa. Many affected communities could produce enough food for themselves, and even for sale, if they had the basics — livestock and crops. In most of these communities, the presence of tsetse flies and the disease they vector, trypanosomosis, prevents optimal productive livestock-keeping and mixed farming, resulting in inadequate local food production. Since a vast majority of the rural communities depends on agriculture, the removal of a key development problem like tsetse and trypanosomosis (T and T) would permit increased local agricultural production, socio-economic and market development, and alleviate hunger and poverty. A sustained alleviation, if possible a complete lasting removal of the T and T problem, is therefore considered a prerequisite to rural self-sufficient agriculture, in which productive livestock can provide milk, meat, draught power to cultivate the land, and eventually generate higher income and market opportunities. Hence the removal of such a key problem would catalyse overall development in rural areas. However, the poverty and food security status of communities in Africa is rather heterogeneous, and reflects the impact of various constraining factors, including T and T, on the current agricultural production process and human well-being, as well as on the overall development potential. Correspondingly, the benefits to sustainable agriculture and rural development (SARD), resulting from an elimination of the T and T problem, will also vary from area to area. In view of the substantial funding required over the next decades to address this key problem, and the need for early "success stories" that show tangible benefits, it is important that the initial T and T control areas are carefully selected according to technical feasibility, and to the predicted potential of increasing agricultural productivity in the context of SARD. Trypanosomosis is a major, but technically solvable, development problem, and the effectiveness of the sterile insect technique (SIT), as a component of area-wide integrated pest management (AW-IPM) programmes, to create tsetse-free zones, has been demonstrated in Unguja Island, Zanzibar, and other locations. This chapter (1) outlines the causal relationship between the T and T problem and food insecurity, malnutrition, poverty, and related disease and development constraints, (2) describes the impact of the problem on African rural communities and the overall economy, and (3) indicates the benefits of a reduced T and T burden, or even of its zonal elimination from selected priority areas in support of sustainable rural development.

## 1. INTRODUCTION

Tsetse flies are the cyclical vectors of trypanosomosis, a disease occurring mostly in rural areas of sub-Saharan Africa where it gravely affects agro-pastoral activities. The fly infests an estimated area of 8.7 million km² where it transmits human African trypanosomosis (HAT) or "sleeping sickness" in humans and African animal trypanosomosis (AAT) or "nagana" in livestock. While human suffering and deaths from sleeping sickness have been declining and are confined to certain areas, livestock production in rural areas continues to be severely constrained by nagana. The resulting

food insecurity and the limitations on health, food production, and even survival, imposed by these vectors and transmitted diseases, make the tsetse and trypanosomosis (T and T) constraint one of the most underestimated and severe problems for sub-Saharan rural communities.

In 1997, sleeping sickness was a potential threat to 60 million people living in the infected areas, and up to 350 000 people were assumed to be infected. However, the number of reported cases decreased from >25 000 in 2000 to 7106 cases in 2012, and the areas at high or very high risk were reduced by 60% (Simarro et al. 2015; Franco et al. 2017). In 2017, less than 1600 new cases of sleeping sickness were reported to the WHO, which represents the lowest number of sleeping sickness cases ever recorded (WHO 2017; Jose Ramon Franco, personal communication). However, there appears to be a general consensus that active and passive surveillance of the human population alone will not be enough to reduce further the number of reported cases. Therefore, vector control needs to be embraced as a requirement to keep reducing the incidence of sleeping sickness (recommendation of the third WHO stakeholders meeting (Geneva, April 2018) on *gambiense* human African trypanosomiasis (g-HAT) elimination).

Considering the overall impact (large direct and indirect losses), and the causal relationship among poverty, food insecurity, and the tsetse-related rural development constraints, it is inevitable that, in the long term, the suppression of vector populations, and better yet the creation of tsetse-free zones, are both economical and moral imperatives. If the T and T constraint were removed in an area, thereby making it feasible for rural people in subtropical and tropical Africa to produce more food than for their subsistence through mixed livestock-crop farms, they will obtain better nutrition and higher incomes, and the poorest region of the world will experience improved economic and social development.

Although some livestock producers apply methods of suppressing tsetse flies and trypanosomosis with reasonable success, the benefits are partial and usually last only a short time (Vreysen 2006). The rural poor cannot generally afford and sustain enduring T- and T-control efforts. Therefore, it appears more appropriate to identify those T- and T-infested areas that have a high rural-development potential and contain isolated or at least geographically confined target tsetse fly populations, and then implement programmes aiming at removing vector populations in a phased, integrated, and sustainable manner by applying — where feasible and justifiable — the sterile insect technique (SIT) as part of an area-wide integrated pest management (AW-IPM) programme (Feldmann 2004; Vreysen et al. 2013a; Feldmann et al. 2018). The SIT lends itself to be the final component of an integrated programme for the creation of sustainable tsetse-free zones in some, e.g. humid riparian forests and moist savannah areas in West Africa, but not all, e.g. open savannah woodland in East Africa, ecosystems. The potential to eliminate the disease in a sustainable manner may open a new dimension of benefits, derived from introducing upgraded livestock breeds and cross-breds, resulting in more productive agricultural farming practices (Bouyer et al. 2014).

Although important for economic development and conservation of the environment (Ford 1973; Reichard 2002; Nagel and Peveling, this volume), the potential for changes in land use resulting from tsetse control is not discussed here.

## 2. POVERTY AND HUNGER

The International Fund for Agricultural Development (IFAD) stated in its 2016 rural development report that, although rural poverty declined in all regions, the Asia and the Pacific region, Latin America and Near East, North Africa, Europe, and Central Asia cut by half their rates of extreme poverty, whereas extreme poverty fell by only 10 per cent over the 1990–2010 period for eastern, southern, western, and central Africa (IFAD 2016). The annual growth of the gross domestic product (GDP) per capita in sub-Saharan Africa was reduced from 3.6% in 2000 to 1.2% in 2016 (WB 2016).

Reducing poverty in poor countries, especially in sub-Saharan Africa, is now the primary objective of development programmes. In 1990, 35% of the world's population lived in extreme poverty (USD <1.9 per day), but by 2013 this had declined to 10.7%. However, half of the extreme poor live in sub-Saharan Africa. During this same time period the number of poor in the region fell by only 4 million; in 2013 there were 389 million people living on less than USD 1.90 a day, more people than in all the other regions combined (WB 2018).

An initiative by the World Bank (WB) and the International Monetary Fund (IMF) to help the Least Developed Countries (LDC) (34 of 49 are in Africa), and especially the Heavily Indebted Poor Countries (HIPC) (34 of 42 are in Africa), to obtain debt relief, led to these countries preparing Poverty Reduction Strategy Papers (PRSPs) (UN 2000b, 2001). Significant debt relief was granted, which would, it was hoped, enhance food security and agriculture (FAO 2001a; IMF 2018). FAO has provided recent estimates; the number of chronically undernourished people in the world stands at 815 million. Most of the hungry live in low-income and lower middle-income countries, many of which have yet to make the necessary headway towards the structural transformation of their economies (FAO 2017). Although the prevalence of undernourishment in sub-Saharan Africa has decreased from 33.3% in 1991 to 18.6% in 2015, it is still higher when compared with the other regions, i.e. 16.3% in South Asia, 10.2% in East Asia and the Pacific, and 7.6% in Latin America (Roser and Ritchie 2018).

Sub-Saharan Africa remains the poorest region of the world. In 2010, average real per capita income was USD 688 compared with USD 1717 in the rest of the developing world. Over the past 30 years, GDP growth per capita in sub-Saharan Africa has averaged 0.16% per year (Chauvin et al. 2012). The World Bank estimates that the share of Africans who are poor fell from 56% in 1990 to 43% in 2012. Although the poverty rate may have declined, many more people are poor because of population growth, i.e. 330 million poor in 2012, up from about 280 million in 1990. Poverty reduction has been slowest in fragile countries, and rural areas remain much poorer, although the urban-rural gap has narrowed (Beegle et al. 2016). Poverty rates have declined only slightly in most sub-Saharan African countries, and have actually increased in Kenya and Zambia (FAO 2017).

In 2013, 6.3 million African children under the age of five died, i.e. almost 17 000 every day, and the risk of a child dying before completing five years of age is highest in Africa (90 per 1000 live births), about 7 times higher than in Europe (12 per 1000 live births). Approximately 3.1 million children die from hunger each year. In 2011 poor nutrition caused nearly half (45%) of deaths in children under five. Children who

are poorly nourished suffer up to 160 days of illness each year, and undernutrition magnifies the effect of every disease, including measles and malaria (Hunger Notes 2018).

Boosting poor-country agriculture is critical to reducing hunger (Economist 2002), and the sustainable removal of this key development problem appears to be a prerequisite for tackling poverty and food insecurity.

> A sharper focus on hunger and agricultural development is needed within the broader objective of poverty reduction (FAO 2001b).

Hunger leads to reduced productivity, to environmental degradation, and to conflict at national and international levels (FAO 2002a; Sachs 2004; Diamond 2005). It also increases sickness, which reduces productivity, quantifiable through the Disability-Adjusted Life Year (DALY) Index (Murray 1994; Murray and Lopez 1994). Every year, across the developing world, 66 million primary school-age children (with 23 million in Africa alone) attend classes hungry, which greatly impacts their ability to learn (Hunger Notes 2018)

At the 1996 World Food Summit, a goal was set to eradicate hunger in all countries, and to halve the number of chronically undernourished people in the world (from about 840 to 420 million) by the year 2015 (FAO 1996). The target, later called one of the United Nations' Millennium Development Goals (MDG), was to achieve sustainable food production and security for all. According to the Food and Agriculture Organization of the United Nations (FAO), in 2015, sub-Saharan Africa was the region furthest from reaching the MDGs, with the actual number of hungry people increasing rather than decreasing (FAO 2017).

As part of a new sustainable development agenda, in September 2015 countries adopted a new set of goals to end poverty, protect the planet, and ensure prosperity for all. These 17 global Sustainable Development Goals (SDGs) were set by the United Nations with specific targets to be achieved over the next 15 years. The SDGs cover a broad range of social and economic development issues, including poverty, hunger, health, education, climate change, etc. Although the SDGs replaced the MDGs, unlike the MDGs, they do not distinguish between "developed" and "developing" nations, and apply to all countries (UN 2015).

Programmes that feed the hungry with imported food, as important as they are at critical times, provide only temporary relief, and, if wrongly implemented, they can have a devastating effect on rural people whose livelihoods depend on the production and sale of staple crops (Clark 2001). The role of agriculture, in generating food supplies and incomes necessary for development and access to food, is paramount in developing countries, especially the Low-Income Food-Deficit Countries (LIFDCs) (FAO 2001d).

Agriculture employs on average 65% of Africa's labour force, but it accounts for only about 32% of gross domestic product, reflecting the relatively low productivity of the sector (Chauvin et al. 2012). Success in raising small-farmer productivity will lead to improvements in household food security, level of nutrition, and income. Efforts to eradicate hunger need to focus on empowering families to achieve inclusive food security, encouraging a maximum of self-reliance (FAO 2001c).

> As incomes grow and diets diversify during structural transformation, the demand for food generally shifts from basic staples to horticultural and livestock products. This leads to a shift in the overall structure of agricultural production. But evidence from Africa suggests that while such a shift is occurring in some countries, it is not yet the norm across the continent. Agriculture shows healthy growth in terms of both output and productivity, but it is not diversifying its commodity mix much. The picture that emerges is of an expanding agricultural sector, but one with weak fundamentals that are preventing a broad-based reduction in poverty and inequality (IFAD 2016).

## 3. LIVESTOCK AND CROP PRODUCTION

A major barrier to significantly improving agriculture in sub-Saharan Africa is the lack of productive livestock. Productive livestock are the key to agricultural improvement because they: (1) provide food (milk and meat), (2) aid in crop production, especially of staples and cash crops, through draught power to cultivate the land for crops and manure for fertilizer, and they can live off crop residues as well as grazing, (3) provide manure for fuel, hides for leather and power for transport, (4) act as a form of savings, a "walking bank", and thereby reduce risk, and (5) provide a vital, and often the only, source of income for the poorest and most marginal of the rural poor, such as pastoralists and those living on marginal land, sharecroppers and widows (Delgado et al. 1999). Livestock, for example a few cattle and goats, owned by each rural family are the means to food production on a continuing basis.

An estimated one-third of all children in developing countries, and perhaps a higher share of pregnant or lactating women, suffer from mild to moderate protein-energy malnutrition (FAO 2001d). People in developing countries typically consume annually only one-fifth to one-sixth the milk, and one-third to one-fourth the meat, of those in industrial countries (FAO 2000). In 1995–1997, people in developing countries obtained an average of only 11% of their calories, and 22% of their protein, from animal food products, compared with more than twice these figures (25% and 49%, respectively) in developed countries (FAO 2001d).

> These low consumption levels in developing countries indicate the potential for growth in the consumption of animal food products without adverse consequences on human health. Increased consumption, of even a relatively small additional amount of meat and milk, would supply the necessary protein and micronutrients, as well as needed additional calories, especially for children (FAO 2001d).

Farming families with small holdings must be enabled, through mixed farming, to increase agricultural productivity for their own immediate benefit.

> The integration of livestock and crop operations is the main avenue for sustainable intensification of agriculture in many regions of the developing world (FAO 2000). Zimbabwean smallholders, who combine livestock and crop production, have incomes twice as high as those with only crops (IFAD 2001).

Traditional agriculture in Africa is based on crops grown on land worked with a hand-hoe. According to the FAO, in sub-Saharan Africa, 89% of all primary cultivation is carried out by hand (Budd 1999). However, the hand-hoe is not enough to produce sufficient crops to feed rural Africa! Animal draught power enables a family to cultivate at least twice as much land as can be done by hand (2 hectares with a team of oxen compared with 1 hectare with a hoe) (Swallow 1999). Animal traction

has been shown to generate higher returns on land (25–45%) and labour (140%) than the hoe, partly from the advantage of using manure as a fertilizer (Swallow 1999).

If the land is not suitable for crops, then livestock can still be grazed on it. In the case of natural disasters, such as drought and floods, livestock provide longer-lasting food security, and more risk-free agriculture, than crops. Even landless people can own cattle or small livestock, which graze on communal-pasture land, or are kept indoors with feed brought to them (zero grazing).

## 4. TSETSE AND TRYPANOSOMOSIS (T AND T) PROBLEM

### *4.1. Human African Trypanosomosis (HAT) (Sleeping Sickness)*

Tsetse-transmitted human African trypanosomosis, sleeping sickness, has been a major burden on African people in rural areas between northern Angola (Independent Online 2004) and southern Sudan. If left untreated, the disease is inevitably fatal; it has been estimated that, at the beginning of the last century, 50 000–100 000 people died every year from the disease (Shaw 2004). Although the number of persons dying from the disease drastically decreased between 1900 and 1960, since many African countries obtained their independence in the early 1960's the number of people succumbing to the disease increased again until the end of the last century. However, since then, enormous progress has been made in reducing the disease prevalence in Africa, from many thousand new HAT cases in 2000 to 977 cases in 2018 (Fig. 1).

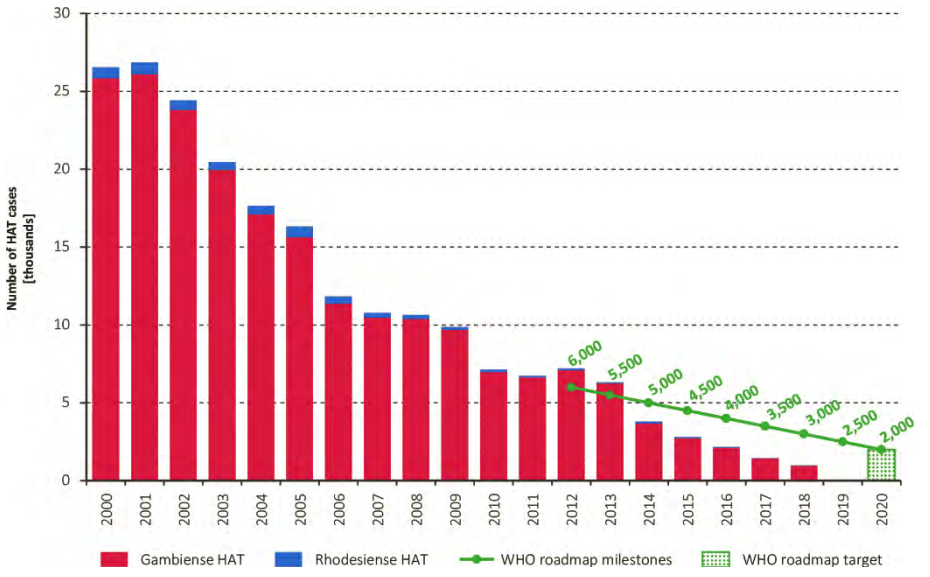

*Figure 1. Total number of reported cases of HAT* (gambiense *and* rhodesiense) *per year (2000–2018). The green line and the green bar show the milestones and target set in the WHO Roadmap for HAT elimination. (Reproduced from Franco et al. 2020.)*

### *4.2. African Animal Trypanosomosis (AAT) (Nagana)*

#### *4.2.1. Problem of African Animal Trypanosomosis*

Unlike HAT, the disease continues to be especially devastating to livestock, with 45–50 million animals at risk in T- and T-affected countries (Kamuanga 2003; Shaw 2004); in these countries, the vast majority of the animals are crowded into the few tsetse-free areas. In some areas, there is evidence that the problem is exacerbated by an expansion in the distribution of tsetse flies (Leak and Mulatu 1993; Stevenson 1998), even reaching, as in Ethiopia, higher altitudes than was previously recorded (Vreysen et al. 1999).

As stated in ILRI (1999),

> Trypanosomosis is probably the single greatest health constraint to increased livestock productivity in sub-Saharan Africa,

and it significantly impairs agricultural development (Swallow 1999). When not lethal, trypanosomosis in livestock leads to a chronic debilitating condition that reduces fertility (calving rates), weight gain, meat and milk offtake by at least 50% (USD 2750 million per year), and the work efficiency of oxen used to cultivate the land (Budd 1999; Swallow 1999; DFID 2001; Shaw 2004). However, if left untreated, it is often fatal (especially for calves), with at least 3 million cattle and other domestic livestock dying each year (Hursey and Slingenbergh 1995). The problem is getting worse rather than better.

Besides the direct impact of the disease on livestock, there are also indirect negative effects. It discourages using more-productive exotic and cross-bred cattle, depresses the growth and affects the distribution of livestock populations, reduces the potential opportunities for livestock and crop production (mixed farming) through less draught power to cultivate land and less manure to fertilize (in an environment-friendly way) soils for better crop production, and affects human settlements (people tend to avoid areas with tsetse flies) (Shaw 2004).

T and T are enormous barriers to raising productive cattle in most of the humid and sub-humid zones of Africa (FAO 2000), especially exotic breeds and cross-bred cattle, which are much better milk and meat producers than local breeds but more susceptible to the disease. At present, cattle (especially cross-breds) can only be raised relatively satisfactorily outside (or around the periphery) of the tsetse zone, or by giving regular treatments of expensive trypanocidal drugs, in addition to other health care. Therapeutic chemical treatments are expensive and must be administered regularly. It has been estimated that as many as 35 million doses of trypanocides are used annually in sub-Saharan Africa alone (Holmes 2013), which represents a figure suitable to treat only about one-third of the cattle at risk (Swallow 2000). Inclusion of trypanocides sold informally in the African market may substantially increase the total number of doses sold annually, which may be as high as 70 million doses (Giordani et al. 2016). This practice elicits drug resistance in the trypanosomes, in combination with the sale of fake trypanocides drugs (Melaku and Birasa 2013). Consequently, treatments are no longer effective, and the future of cattle production in these areas may become problematic.

The use of trypanotolerant cattle in West Africa shows some promise as a way of coping with the disease threat, but these animals are rather small (DFID 2001) and thus are less suitable as draught animals. Shaw et al. (2004) compared trypanotolerant, Zebu and cross-bred (trypanotolerant x Zebu) cattle in herd models. Benefits with and without T and T, expressed per head of cattle over a 20-year period, were highest with cross-bred cattle.

Current methods of controlling tsetse, and the disease in humans and livestock, are by no means perfect. The current situation with respect to AAT is untenable, with risk to the environment arising from high pressure on natural resources in uninfested areas where livestock are being concentrated. The problem remains a major barrier to meeting the basic livelihood needs of the rural poor.

### *4.2.2. Benefits of Controlling African Animal Trypanosomosis*

Everyone agrees that AAT

> . . . is sufficiently important for virtually any intervention to be beneficial (Shaw 2003).

*Livestock Production.* The benefits of T and T control are reduced disease prevalence or even disease elimination, reduced mortality rates and treatment expenses, and improved health and agricultural productivity. These benefits can be estimated using a dynamic herd model, which includes animal traction among the herd outputs. The reduced livestock production cost (38% and 25% per tonne of milk and meat, respectively) would increase the amount of milk and meat supplied by farmers, and lower the price for consumers. For areas freed of tsetse, milk and meat production would almost double, increasing by 83% and 97%, respectively. Benefits from traction power and manure production have been estimated to be, on average, 34% of the total value of livestock production (Kristjanson et al. 1999). The monetary values of losses and benefits are summarized in Box 1.

The 36 countries (10 million km², population 260 million) that have some level of tsetse infestation have about 172 million cattle, but only 45 million of them are kept in tsetse-infested areas, while the remainder are forced to crowd around the periphery, leading in some instances to land degradation (Swallow 1999). The overcrowding of cattle and people in tsetse-free areas is a problem for both good land-use practices, in terms of sustainable utilization of natural resources, and long-term community development activities.

It is expected that enhanced trypanosomosis control will allow the replacement of low-productive cattle by high-productive cross-breeds that can be kept at a lower average density per unit of land (with more rural families owning cattle) which will in many instances bring relief to the often fragile ecosystems in sub-Saharan Africa (Vreysen et al. 2021).

Therefore, the creation of sustainable T- and T-free zones, and the resulting rural development and the opportunities for profitable investment into productive agricultural and livestock systems, are not expected only to be major contributions in the fight against food insecurity and poverty, but also to reduce the environmental risks of a potentially large increase in the number of cattle.

*Box 1. Monetary Values — Estimates of Losses from the T and T Problem, and Potential Benefits of Controlling African Animal Trypanosomosis*

Hursey and Slingenbergh (1995) valued the direct annual losses in cattle production due to AAT at USD 1000–1200 million.

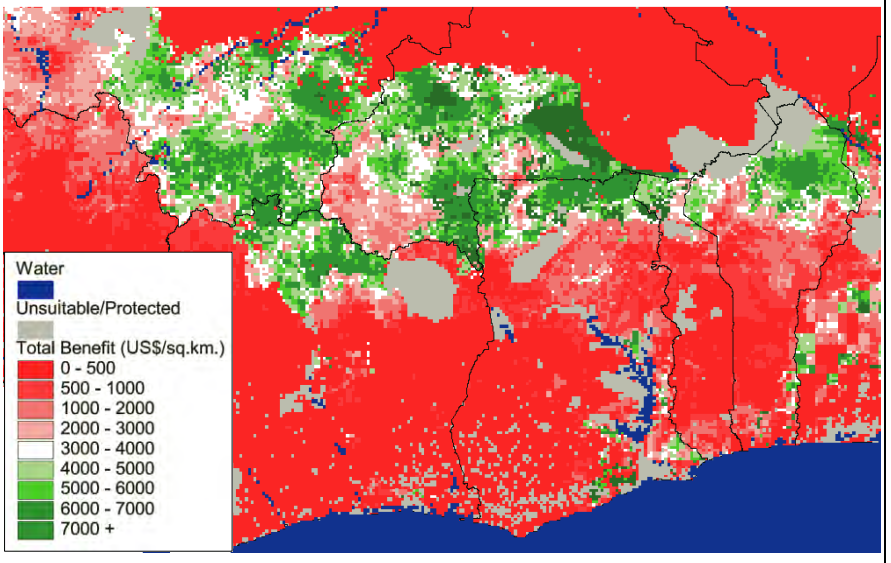
Shaw et al. (2004) created maps that show the estimated potential benefits from T and T control in Benin, Burkina Faso, Ghana, Mali, and Togo. The research modelled cattle density, animal draught work, rate of herd growth, and rate of cattle spread. If the disease were removed, the total benefits after 20 years (in the form of a present value discounted over 20 years) ranged from less than USD 500 to well over 5000 per km² (Fig. below). Benefits included milk, meat, draught power, the extra cattle present, and the spread of cattle. The estimated benefits from the removal of the tsetse fly from the Niayes were much higher, amounting to about USD 3250 per $km^2$ per year, mainly by replacing indigenous breeds with cross-breeds or exotic breeds (Bouyer et al. 2014; section 6.2.).

The potential benefit of enhanced trypanosomosis control in livestock in Africa is USD 700 million per year, arising from increased milk and meat productivity (Kristjanson et al. 1999). If one includes other potential benefits that would accrue from trypanosomosis elimination, such as animal traction and manure,

> …the total cost of the disease is likely to be well in excess of USD 1338 million per year (Kristjanson et al. 1999).

In 10 fully infested countries alone, the impact of T and T on the agricultural GDP was estimated to amount to 10% below a theoretical T- and T-free GDP level (Swallow 1999), which corresponds to USD 1000 million in monetary terms.

Estimates of the overall annual lost potential in livestock and crop production range from USD 1950 to 4500–4750 million (Budd 1999; DFID 2001; Shaw 2004; Gooding and Krafsur 2005).



*Total calculated potential benefit (USD per km²), after 20 years, of removing trypanosomosis (benefit range USD 0–500 [dark red] to 7000+ [dark green] per $km^2$). (Modified from Shaw et al. (2004) and W. Wint for the countries Benin, Burkina Faso, Ghana, Mali, and Togo; reproduced with permission.)*

*Crop Production and Mixed Farming.* In sub-Saharan Africa, livestock and crops are usually separated due to T and T, but there is a huge potential benefit if livestock and crop production can be integrated (Box 1).

In total, about 8.2 million $km^2$ in Africa are classed as cultivable land (but half of it is marginal) (Harrison 1996). Up to 6 million $km^2$, especially in Central and southern Africa, are not cultivated for various reasons (Ford 1973). The best potential for fodder production lies in the humid zones, 18% of Africa's land area, but only 6% of the livestock are found there (Harrison 1996). In some cases, tsetse flies deny access to fertile, arable land, and their removal makes it accessible to livestock-agricultural production.

> African animal trypanosomosis constrains agricultural production in the areas of Africa that hold the continent's greatest potential for expanded agricultural production (Swallow 1999).

### *4.2.3. Causal Relationship between T and T, Hunger, and Poverty*

Evidence for the causal relationship between the T and T problem and the prevalence of hunger and poverty is presented in this section. It cannot simply be a coincidence that most of the 37 tsetse-infested countries of Africa are also poor, debt-ridden, and underdeveloped. A comparison between the tsetse-infested areas and the 34 Heavily Indebted Poor Countries in Africa (WB 2001) (32 of which have tsetse flies), reveals a striking overlap (Fig. 2); it is logical to conclude that the T and T problem is a major contributor to hunger and poverty.

Of course there are other problems creating food insecurity, such as limited water and fertilizer supply, severe human diseases, lack of credit, poor governance, civil unrest and wars, as well as other livestock diseases, and these are also important, and some are interconnected and interdependent. Solutions to these problems must be found as well. However, to achieve rather quickly the objective of reducing hunger and poverty in such a needy region as sub-Saharan Africa, it is vital first to adopt the solution that will bring about the biggest change in the fundamental problem, and for which strategies and technology packages already exist and need to be integrated into the overall context of sustainable agriculture and rural development (SARD). It is a matter of giving a high priority to a problem that is fundamental, and to a solution that will have a great impact in the near future. This approach is part of the comprehensive policy of the Programme Against African Trypanosomiasis (PAAT), an international alliance comprising the FAO, African Union/Inter African Bureau for Animal Resources (AU/IBAR), International Atomic Energy Agency (IAEA), and WHO. The removal of T and T is expected to have a catalytic effect on overall rural development initiatives aimed at food security and poverty reduction.

### *4.2.4. Why is the T and T Problem so Hard to Solve?*

Why has the barrier of T and T remained so strong, and prevented a breakthrough in livestock and crop production? The T and T problem is a rural problem, and most political leaders, policy makers, and planners are probably already overwhelmed by various needs and deficiencies requiring immediate attention, ranging from water supply, infrastructure issues like roads and schools, to medical and other services.

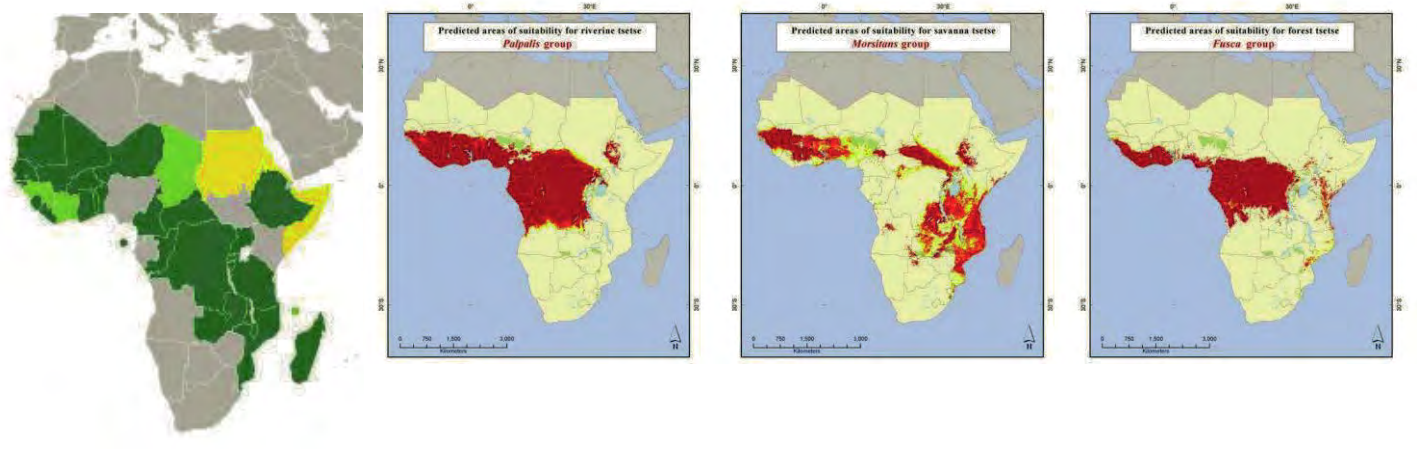


*Figure 2. Left map: Heavily Indebted Poor Countries (dark green – countries qualifying for full HIPC relief, light green – countries qualifying for partial HIPC relief, yellow – countries eligible for HIPC relief but have not met the conditions) (map by Christallkeks (2016) - Own work, CC BY-SA 4.0); Right maps: Predicted areas of suitability (yellow – 10–40%, orange – 40–70%, red – 70–95%, brown – >95%) for the* palpalis *(riverine),* morsitans *(savannah), and* fusca *(forest) groups of tsetse flies (FAO/DFID, reproduced with permission).*

Actions against a problem like T and T are expected to result in benefits only in the medium to long term, and thus may receive a low or inadequate level of attention and political support. The attention of donors and the media tends to focus on acute, novel, or emerging problems such as the Ebola (WHO 2016) and Zika (CDC 2016) crises of 2015–2016, and not on chronic problems such as T and T. This is probably a contributing factor why the HAT and AAT are considered to be "neglected tropical diseases". Since several efforts in the past to control the T and T problem did not lead to a sustainable improvement, it is difficult now to generate the necessary awareness and commitment among decision-makers.

Also, several influential scientists maintain the view that tsetse flies and the disease trypanosomosis cannot be eradicated, and that there is no alternative except to "live with the problem" at the lowest possible level of disease transmission. Many people have spoken out against "eradication" of tsetse populations, and many are pessimistic, believing that the "curse of tsetse" must simply be endured. This prevailing fatalistic attitude has led to a submissive acceptance of the seemingly inevitable need to suffer hunger and poverty, with no hope of change. This attitude and approach to the T and T problem has prevented farmers, governments, and donors from trying to create, and consistently and gradually expand in a sustainable manner, zones that are free of the problem.

In past years, several community-based programmes to reduce fly populations were initiated enthusiastically, and relatively successfully suppressed tsetse populations and consequently the disease risk. However, enthusiasm waned, suppression was neglected, and the flies and disease returned (Jordan 1995; Barrett and Okali 1998). Unfortunately, even during phases of good tsetse suppression, the flies were still efficient vectors, and therefore continued to discourage the introduction of productive livestock breeds. This was recently demonstrated again in the Mouhoun area of Burkina Faso where, despite a reduction in apparent density of the tsetse fly population from >10 flies/trap/day to 0.43 flies/trap/day, there was no impact on the prevalence of AAT (Percoma et al. 2018).

#### *4.2.5. T and T, and Sustainable Agriculture and Rural Development (SARD)*

Large-scale AW-IPM programmes against T and T should focus on priority development areas in affected countries. The selection of such priority areas in the context of SARD, and in view of the need for substantial funding over the next decades, should focus on areas where the required investments are expected to result in maximum benefits. FAO provided some criteria and guidelines for the selection of initial priority intervention areas (FAO 2002b; Cecchi et al. 2014, 2015; Diall et al. 2017.

To generate impact and benefits for the affected communities, it is essential that control measures against the T and T problem be firmly embedded in overall development efforts towards SARD. A programme called Farming in Tsetse Controlled Areas (FITCA), which was completed in 2004, aimed to improve the welfare of people through sustainable rural development, and to increase livestock productivity by improving animal health through community-based T and T suppression. FITCA had anticipated that the generation of integrated crop/livestock production systems would increase food production (Daily Nation 2003;

AU/IBAR/FITCA 2004). However, the last 20 years have shown that sustaining such community-reliant methods of T and T suppression beyond the phase of funded institutional assistance has been challenging if not impossible (Vreysen 2001, 2006). It has been demonstrated numerous times that, after the successful introduction of community-based tsetse suppression and a discontinuation of donor support, very few farmers pursue the work and pay for the traps, insecticides, etc. Whenever an approach, that necessitates continued action, is not sustained, no breakthrough is possible. Under such scenarios, sub-Saharan Africa will likely remain a "green desert", preventing sustainable self-sufficiency in food for the rural poor.

#### *4.2.6. PATTEC*

The African Heads of State and Government, at the 36th Ordinary Session of the Organization of African Unity (OAU) (now called African Union (AU)) summit meeting in Lomé, Togo, in July 2000, recognized the seriousness of the T and T problem and made an historic decision (OAU 2000). The year 2001 was declared as the "Year of the Control of Tsetse Fly" to mark the beginning of renewed efforts to suppress tsetse flies and trypanosomosis. This new effort, initiated by the OAU, is called the Pan-African Tsetse and Trypanosomosis Eradication Campaign (PATTEC) (PATTEC 2000; Pesticide Outlook 2002). The PATTEC Plan of Action to be implemented was approved at OAU's Lusaka meeting in 2001 (OAU 2001). This decision was received with great enthusiasm by the T- and T-affected countries; they anticipated that this new African-owned and African-led initiative would result in a useful contribution to reducing rural hunger and poverty. Despite the initial euphoria and high expectations, the reality after almost 20 years is more sobering and, with a few exceptions, little overall progress can be reported.

## 5. TSETSE- AND TRYPANOSOMOSIS-FREE ZONES

### *5.1. Concept*

To implement this approach of creating and progressively expanding T- and T-free zones in areas with great potential for livestock-agricultural development, properly developed plans and programme documents are needed. As the problem is complex, a major effort is required that necessitates full ownership, and a high, consistent commitment by the affected countries. Long-term partnerships with local, national, and international stakeholders, non-governmental organizations (NGOs), and the private sector will be instrumental in the gradual creation of zones free of the most important tsetse species in priority areas for rural development. The very large benefits of complete disease removal will only be realized if the disease threat is virtually non-existent, which would encourage poor producers to take the step of investing in productive cattle.

Whereas suppression of tsetse fly populations, to temporarily alleviate the burden of the disease, will remain important in many areas of sub-Saharan Africa, in certain ecological settings the creation and progressive expansion of sustainable T- and T-free

zones (Feldmann and Jannin 2001; UN 2001) will provide substantial benefits for the rural poor, enabling them to produce enough food (Feldmann 2004).

Given the current technologies available, it is not possible to apply this concept to the whole of tsetse-infested areas of sub-Saharan Africa. In addition, the use of the SIT against tsetse populations would only be justifiable in those ecological zones where the SIT would bring a comparative advantage. Successful examples, where the SIT was not used, include: 1) the combined use of insecticide applications by air and ground teams and habitat destruction, which resulted in long-lasting relief from the disease in northern Nigeria (Spielberger et al. 1977), and 2) the integrated use of the sequential aerosol technique (SAT) with trapping in the border areas, which resulted in the creation of a sustainable zone free of *Glossina morsitans centralis* Machado in the Okavango Delta of Botswana (Allsopp and Phillemon-Motsu 2002; Kgori et al. 2006). Both programmes followed, intentionally or not, the principles of AW-IPM, and capitalized on favourable agro-ecological or other relevant trends or developments.

#### *5.1.1. African Animal Trypanosomosis*

In animal trypanosomosis, tsetse suppression has an important role to play in immediate (but with long-term perspectives) problem alleviation in priority areas, and as a forerunner of creating tsetse-free zones (PAAT 2000).

The concept of creating and progressively expanding T- and T-free zones following AW-IPM approaches will require substantial funding over many decades (Vreysen et al. 2007). Initial resources must be focussed on a few selected priority areas — with strong demographic pressures, and high agricultural, livestock, and overall development potential — and must achieve good progress with early successes. An advantage that should be utilized is the fragmented distribution of some tsetse fly species, with discrete populations in isolated or well-confined habitats. In that respect, Bouyer et al. (2014) identified natural barriers that isolate populations of *Glossina palpalis gambiensis* Vanderplank in West Africa using a statistical model that assessed the genetic distance between 37 populations. Potentially isolated clusters of *G. p. gambiensis* habitat were identified based on a species distribution model and ranked according to their predicted genetic distance to the main tsetse population (Bouyer et al. 2014; Feldmann and Ready 2014; Vreysen, this volume).

The initially targeted areas will be those with such isolated or confined fly populations. Progressively, over time, the size of infested areas will be reduced. The transboundary nature of fly infestations requires a regional approach, based on the AW-IPM concept, to reduce substantially the risk of fly reinvasion.

The international T and T community has agreed that efforts to create and subsequently expand T- and T-free zones should be initiated in areas with a high potential for agricultural development, e.g. Southern Rift Valley in Ethiopia and the Niayes area in Senegal (Swallow 1999; Feldmann and Jannin 2001; FAO 2002b; PAAT 2002; Alemu et al. 2007; Zerihun 2017; Vreysen et al. 2021). Whereas the Moist Savannah Zone in West Africa has great potential for agricultural development, and the watersheds of the main river basins were initially considered as effective barriers to migration (Hendrickx et al. 2004), new data have indicated the potential of flies to cross these barriers, demonstrating the need for artificial barriers (Vreysen et

al. 2013b). In addition, the use of the SAT against *Glossina tachinoides* Westwood and *G. p. gambiensis* was shown to have its limitations in the Moist Savanna Zone of Ghana, West Africa. The SAT operations failed to achieve eradication in an area of ≈18 000 km$^2$, and both target species were still detected in the sprayed blocks, albeit at low densities (Adam et al. 2013). In view of the extreme low fly population densities obtained, the project in Ghana would most likely have been successful in creating a tsetse-free zone had the spraying operation been followed by the release of an adequate number of high-quality sterile males.

There may be opportunities to embark on projects for creating T- and T-free areas in several other countries, but further evaluations are needed, e.g. Chad (Mahamat et al. 2017), South Africa (Kappmeier et al. 2007), Kenya, Uganda, and the United Republic of Tanzania (IAEA 2001). In some of these areas, particularly where other vector suppression techniques face technical limitations, or for environmental or other reasons can only be applied as a temporary measure, the SIT may play a role.

To minimize ecological disturbances, and ensure environmentally appropriate utilization of natural resources, components of the environment, and land-use practices, must be monitored before and after removal of the vector population (Feldmann and Hendrichs 2001). Even though there is no factual basis for the fear that tsetse eradication will lead to ecological imbalance (AU 2002; Nagel and Peveling, this volume), it is wise to monitor continuously several components of the biological and physical environments to permit, at an early stage, the identification and correction of undesirable developments in the field.

#### *5.1.2. Human African Trypanosomosis*

In addition to efforts to create T- and T-free zones in selected areas that have great potential for agricultural development, T and T suppression needs to be pursued in the remaining sleeping sickness foci (Fig. 3). The neglected tropical disease roadmap of the WHO calls for the elimination of *gambiense* HAT (g-HAT) as a public health problem by 2020, and complete elimination of transmission by 2030 (Franco et al. 2017). In 2017, there were 1370 centres that were equipped to screen for *gambiense* HAT, and more than 600 centres were equipped to provide treatment. As a result, the number of cases reported in 2017 was low (<1600). Even though 80% of all the new cases were reported from the Democratic Republic of the Congo, they were still distributed over 17 countries (J. R. Franco, WHO, personal communication). In view of the ever-decreasing number of new *gambiense* HAT cases detected each year, there is evidence that vector control will gain in importance in the overall human sleeping sickness elimination approach (Mahamat et al. 2017).

### *5.2. Potential Role of the SIT*

The SIT has been demonstrated to be effective and efficient against tsetse flies under certain ecological conditions when integrated in a phased conditional manner with other suitable tsetse suppression methods (Cuisance et al. 1986; Clair et al. 1990; Oladunmade et al. 1990; Vreysen et al. 2000, 2021). The scientific principles of the technology against tsetse flies have been well studied in Africa, and have now been

proven (Offori 1993; Feldmann and Hendrichs 2001; Feldmann and Jannin 2001; Feldmann 2004; Vreysen 2006; Vreysen et al. 2021). When applied on an AW basis, the integrated approach benefits all segments of rural society, including poor farmers, because, instead of protecting selected animals or farms, entire economically important populations of tsetse flies are targeted (Klassen and Vreysen, this volume). Furthermore, because these programmes aim at a public good, local people would usually not be charged for the SIT component. This approach involves, in a first phase, the area-wide application of control tactics suited for tsetse suppression (e.g. insecticide impregnated traps/targets, pour-on for livestock, stationary bait technology, and the SAT) (Mangan and Bouyer, this volume), which, in certain ecological settings, are followed by a second phase – the release of sterile male insects to remove the remaining relic populations.

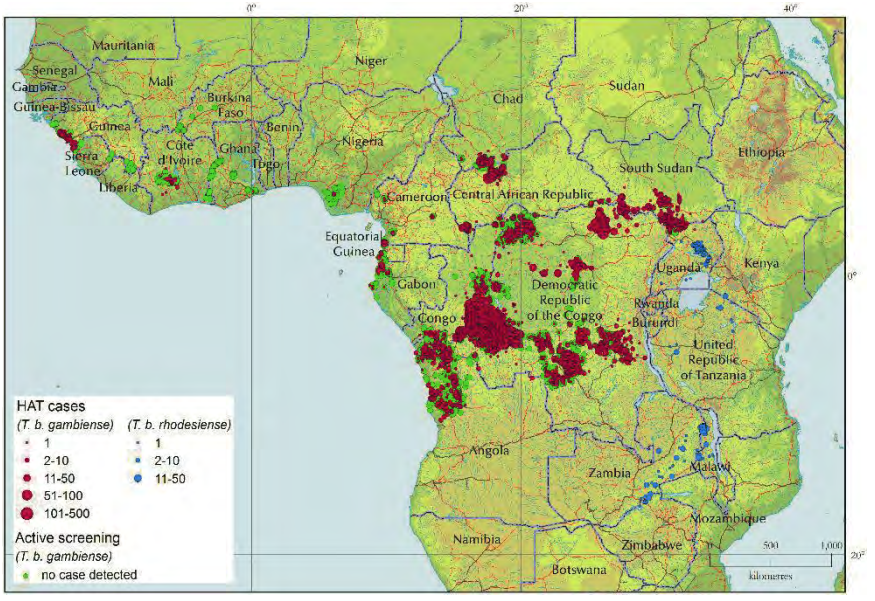

*Figure 3. Remaining foci of* gambiense *(red circles) and* rhodesiense *(blue circles) HAT in sub-Saharan Africa for the period 2010–2014. Green circles: active screening in which no HAT case was detected. (From Franco et al. 2017.)*

The SIT is one of the few control tactics that acts in an inverse density-dependent manner, and is therefore most efficient at low pest densities (Knipling 1979). Therefore, the SIT would best be applied when the pest density is naturally low or due to prior suppression. When the SIT is integrated as a final component into an area-wide pest management system, the treatment area can ultimately become a tsetse-free zone (Vreysen et al. 2000, 2021).

The insecticide-based and other suppression techniques, e.g. trapping, most often used in such integrated area-wide campaigns are environmentally acceptable, provided they are applied for a short time (Nagel and Peveling, this volume). The insecticide is applied in a localized way – on cloth targets, cloth traps, netting, or

livestock, and is therefore not dissipated in the environment. Even after the application of the SAT (repeated application of ultra-low-volume formulations of non-persistent insecticides, usually from aircraft) used to eradicate *G. m. centralis* from the Okavango Delta in Botswana (Kgori et al. 2006), Perkins and Ramberg (2004) showed that terrestrial and the vast majority of aquatic non-target invertebrates recovered within 1 year to the pre-spray composition and abundance. After the temporary use of such techniques to suppress efficiently the vector population to a very low level, the application of the SIT to remove the relic tsetse population involves using the only vector-control method that has no known side-effects on non-target organisms (Müller and Nagel 1994; Feldmann and Hendrichs 2001).

The weekly cost of tsetse SIT per km², i.e. USD 2.7–9.4, is in the range of, or lower than, the required expenditure (weekly, per $km^2$) in AW-IPM programmes integrating the SIT against other insect pests of agricultural and veterinary importance, e.g. codling moth *Cydia pomonella* (L.) (USD 100), Mediterranean fruit fly *Ceratitis capitata* (Wiedemann) (USD 80), and the New World screwworm *Cochliomyia hominivorax* (Coquerel) (USD 3.5) (Hendrichs, Vreysen et al., this volume). Therefore, in those ecological settings where the SIT brings a comparative advantage, integrating the SIT into area-wide programmes, and sustainably removing a target tsetse fly population, will be cost effective. If programmes to create and expand T- and T-free zones are focused, and relatively small incremental steps are taken following the phased conditional approach (Vreysen et al. 2021), financing field projects in African countries should be feasible. Budd (1999) stated that an

> . . . economic analysis indicates that the cost of controlling trypanosomosis through controlling the tsetse fly populations will be covered several times by the benefits of tsetse-free status.

## 6. BENEFITS FROM TSETSE ERADICATION

### *6.1. Benefits from Eradicating* Glossina austeni *in Unguja Island, Zanzibar, Tanzania*

In 1994–1997 it was demonstrated that, after pest suppression with insecticides, the SIT completely eradicated the *Glossina austeni* Newstead population in Unguja Island of Zanzibar (Vreysen et al. 2000); subsequently, trypanosomosis in local cattle could no longer be found (Vreysen et al. 2014). This successful AW-IPM programme created significant opportunities to improve livestock and crop farming, although Unguja Island is not the best example of the agricultural benefits that would accrue from eliminating the T and T constraint compared with the African mainland. Unguja Island has poor soils, and hence the contribution of agriculture to the GDP on Unguja has been rather low and not consistent, i.e. it declined from 38% in 1997 to 24.7% in 2007, but increased again to 30.8% in 2013 (Mwaseba et al. 2015). According to a government census in 2007/2008, crop production dominated agricultural activity, and engaged 86 509 households (66%); this compares with 43 844 households (33%) that were engaged in both crops and livestock, and 1840 households (1%) that were engaged in livestock only. According to the socio-economic survey of 2014 (Mwaseba et al. 2015), 57.4% and 27% of respondents listed farming and livestock

keeping, respectively, as their major occupation. This is a significant reduction when compared with earlier studies that indicated 88 or 89% of the population was engaged in farming (Tambi et al. 1999; Mdoe 2003).

Socio-economic studies were carried out in Unguja Island in 1997, 2002, and 2014 (Tambi et al. 1999; Mdoe 2003; Mwaseba et al. 2015) using collected local data, interviews with farmers, and relevant socio-economic parameters. The data illustrate the range of agricultural and socio-economic benefits that can accrue after removing the T and T constraint. (Sleeping sickness did not occur in Unguja, so no direct human health benefits were assessed.) It is important to recognize that the benefits began accruing as soon as the tsetse fly population and disease transmission were reduced, in some areas starting in 1985, using insecticides, and continued until, and especially after, the target fly population collapsed in 1996 as a result of applying the SIT. For the past 20 years or more, the island of Unguja has remained free of *G. austeni* and AAT (Saleh et al. 1999; Vreysen and Dixit 2016).

The following summarizes some of the benefits, but also some of the constraints experienced after the removal of the T and T problem. An analysis is made as to why agricultural development on Unguja Island has not expanded to its full potential.

### *6.1.1. Benefits to Livestock Farmers*

Although the contribution of the livestock sub-sector to the agricultural GDP increased from 12% in 1986 to 34% in 1997, in the following 15-year period (1999–2014) the percentage of the population engaged in global farming decreased, suggesting a significant shift to better paid employment opportunities other than farming. This is reflected in a reduction of the population engaged in farming as a principal and secondary occupation, i.e. from 88–89% in 1999–2002 to 57% in 2014 (as principal occupation), and from 40.7% in 2002 to 25% in 2014 (as secondary occupation).

#### *Livestock Keeping*

- Whereas the proportion of households raising improved cattle increased from 2% in 1985 to 18% in 1999 and to 24% in 2002, this percentage declined to 13% in 2014.
- Generally, there has been improvement in agriculture as evidenced by increases in crop and livestock numbers. Whereas from 1985 to 1999 the number of indigenous cattle increased by a factor of 1.5 and that of cross-bred cattle increased 7 fold, between 2009 and 2014 the number of improved cattle breeds increased by only 4%. However, during the same 5-year period, there was a significant increase in the numbers of improved chickens (82%), sheep and goats (69%), and donkeys (62%), and there was a decline in indigenous cattle (-21%), local chickens (-22%), and indigenous sheep and goats (-15%).
- Even though 38% of the farmers preferred local breeds of cattle, the majority (61%) preferred improved breeds, primarily because of their high productivity. Although the 2014 survey showed that farmers keep more local cattle breeds than improved ones, about 96% of those who preferred improved breeds said that they produced more milk than the indigenous ones. This is slightly higher than the 94%

reported in a similar study by Mdoe (2003). In 2014, a shortage of land and feeds was often mentioned as a constraint on increasing the number of livestock kept, especially dairy animals.

- Only about half (48.2%) of livestock keepers were using zero grazing in dairy production, down from 91.6% in 2002 (Mdoe 2003). The limited expansion and development of the dairy sector is largely explained by the constraints that the sector continues to face: low adoption of rearing improved cattle because of the high cost of improved heifers, low financial ability among poor farmers identified, and tick-borne diseases (especially East Coast Fever). There was limited use of by-products and supplements, perhaps because tethering rather than zero grazing is common in the area; as a result, farmers used grasses and legumes to feed their animals. These constraints have not been addressed properly, and as a result the potential of the dairy sector in Unguja has not been realized.
- The higher increase of improved breeds/cross-breeds of goats when compared with cattle may be explained by pressure on the land due to, among others, population growth, and therefore a limited availability of grazing land. In this context, it is easier to get enough feed for dairy goats than to meet the nutritional needs of dairy cattle.
- The 2014 study showed that among farmers who keep cattle, about 67% used local bulls for breeding, but about 20% used improved bulls, and only about 14% used artificial insemination. This is in contrast to 2002, when 72% of dairy farmers used artificial insemination while 68% of them used improved bulls [assuming that some farmers used both methods]. This might be related to the fact that famers find keeping local cattle cheaper in terms of operational costs, and the fact that exotic breeds are easily attacked by diseases. The absence of artificial insemination projects might also have contributed to this situation.
- There was an increase in meat production. The proportion of domestic versus imported cattle slaughtered for meat doubled (29 to 66%) between 1978–1985 and 1986–1995, indicating an increase in slaughter cattle obtained domestically. Between 1999 and 2001, the production of beef increased by 7%.

*Milk Production*

- Average milk production increased for both indigenous and improved cattle – for indigenous cattle from 2.4 to 2.5 to 4.6 litres per cow per day in 1997, 2002, and 2014, respectively, and for improved cattle from 8.2 to 8.3 to 9.7 litres per cow per day in 1997, 2002, and 2014, respectively.
- There was an increase in the number of farmers selling milk, and the quantity of milk being sold. Milk processing is not well developed in Zanzibar; only 1% of dairy-cattle keepers participated in some form of milk processing in 2014. Most of the milk is marketed in its raw form, and therefore this has not improved since 2002. However, producers have little difficulty in finding buyers – street vendors and hawkers provide a market outlet for about 73% of the milk produced. About 12% of the milk produced is consumed by local households, 4.4% is sold through collection centres, and 3.9% is sold to hotels and restaurants. An increase in milk

production and consumption probably contributes to an improvement in the nutritional status of rural households.

*Livestock-Crop Integration*

- Crop productivity in mixed-farming systems increased, resulting from a greater capability to use animal power (stronger and healthier animals) for ploughing and transporting farm products. The use of animal traction for land preparation is, in general, rather low, but it increased from 3% in 1997 to 5% in 2002 and to 10% in 2014. In 2002 about 21% and 18% of farmers used animals to transport their own and commercial products, respectively. By 2014, the percentage of farmers using animals for their own transport increased further to about 64% of sample households, but decreased to 10% for those who used them for commercial transport.
- Livestock-crop integration increased because more farmers used manure for crop production. About 51% of farmers in 1999, and 54% in 2002, grew crops on fields fertilized with animal manure. From 1999 to 2002, the increase in productivity of cassava, rice, maize, coconut, and vegetables may be attributed to the use of improved seed varieties and manure for crop production. In 2014 similar figures were found – 58% of respondents used manure for crop production. In addition, more farmers are using crop by-products to feed their animals. In 1999 only 13% of farmers were feeding crop by-products to livestock, but in 2002 this figure had increased to 22%. Also, farmers are increasingly feeding improved fodder to their cattle. Some 92% of dairy farmers raising improved breeds zero-grazed their cattle. The 2014 study found a limited use of by-products and supplements. Most farmers were using grasses (62%) and legumes (50%) to feed their animals (probably because tethering rather than zero grazing is common in the area).
- In the 2014 survey, 68% of respondents indicated that cultivated land has remained the same, whereas 25% and 8% of the farmers reported an increase and decrease in cultivated land, respectively. This compares well with the data from the 2002 study where 52%, 35%, and 7% cultivated the same land, increased or decreased the land cultivated, respectively. These findings suggest that farmers have not been able to expand the area under cultivation.

*Household Income.* Household income increased over time – in 1999 the average household income per month was estimated at USD 51.5, in 2003 USD 53.5, and in 2014 USD 116. A strong correlation was observed between household income and milk yields, milk sales, and use of manure and animal power for cultivation and transport. However, given the reduction in recent years in the percentage of families engaged in farming, the increase in household income might also be attributed to additional family income coming from employment outside of the agricultural sector, e.g. the growing tourism industry. Nevertheless, the economic benefits to those who continue to keep livestock are higher now than they were before the eradication of T and T.

*6.1.2. Red Colobus Monkey*

The number of Zanzibar red colobus monkeys *Pilicolobus kirkii*, an endangered and protected species found primarily in forests (also former major habitat of *G. austeni)*, increased from 1000–1500 in 1991 to more than 2500 in 1999 (Masoud et al. 2003). In the period 2013–2014, a systematic assessment of the demography and distribution of the red colobus monkey indicated a total population of 5862 individuals in Unguja, of which 2907 were present in the Jozani-Chwaka Bay National Park (formerly the Jozani Forest Reserve) (Davenport et al. 2017). Therefore, subsequent to eradicating *G. austeni* in Zanzibar, there was no decline in the monkey population. This contradicts the opinion of several conservationists that eradication of tsetse flies would lead inevitably to habitat destruction followed by a reduction in wildlife.

*6.1.3. Challenges – Constraints*

Much of Unguja Island is coral rag, and consists of low-fertile soils that are not really suited for permanent agriculture (Hettige 1990). This in itself poses a constraint on the development of more sustainable and efficient agriculture systems in general, and livestock systems in particular. There are several reasons why agricultural development on Unguja Island, after the sustainable removal of the tsetse fly and AAT, has not been realized to its full potential. The following provides a non-exhaustive analysis:

- Before the eradication of *G. austeni* in Unguja Island in 1997, AAT was the major constraint to the development of more effective livestock systems and the intensification of the dairy sector. Clearly, eradication of the disease offered real opportunities for the intensification of livestock production in Unguja. These opportunities were most evident immediately after the eradication programme, with a rapid increase in the number of improved cattle, more use of improved seeds that resulted in increased use of crop by-products as animal feed, use of manure for crop production, and use of animal power for ploughing and transport activities. However, the numbers of pure breed and cross-breed cattle increased only slightly between 2009 and 2014, although the numbers of improved sheep and goats were more impressive. These data suggest that, although intensification is on-going, it has in the last decade not evolved at the same rapid pace as in the 1999–2003 period.
- Improvement of the livestock sector requires the availability of improved cattle breeds. The 2014 study showed clearly that only 46% of respondents indicated that improved livestock breeds were readily available. In addition, some farmers, despite changes and development of the dairy industry in Unguja, still preferred to keep local cattle breeds largely because it is easier to raise them (76%), and they are more resistant to other diseases (21%). Other constraints that can partially explain the low adoption of improved dairy cattle are the high cost of improved dairy heifers, the low financial ability of resource-poor farmers, limited access to credit facilities, poor quality of cattle feed that consists mainly of local grasses with low use of concentrates and mineral supplements, high costs of veterinary drugs for disease treatment compared with the milk and meat prices (animal drugs and feeds increased by 92–110% in the period 2005–2008 compared with a 43% increase in food commodities), and the absence of a good milk-marketing system.

- The creation of a tsetse- and AAT-free Unguja removed a significant constraint to agricultural development on the island. However, livestock keepers still had to cope with other debilitating animal diseases such as the tick-borne disease East Coast Fever. Although the disease prevalence declined from 84% in 2002 to 56.9% in 2014, it is still very important. Other diseases that cannot be neglected are lumpy-skin disease and helminthiasis.
- The importance of market functions in terms of economic development, and the stimulation of agricultural production and development, should not be underestimated. The 2014 study found that the marketing system on Unguja Island tends to be highly controlled by a network of intermediaries, resulting in a situation that does not give farmers equitable benefits for their commodities but allocates high margins to the middleman (Mwaseba et al. 2015).

### 6.2. *Benefits from Eradicating* Glossina palpalis gambiensis *in the Niayes of Senegal*

In the Niayes of Senegal, an area located north-east of the capital Dakar, three main cattle farming systems can be identified – a traditional system that uses trypanotolerant cattle, and two systems that use more productive cattle breeds for milk and meat production. Before the project started, herd size was 45% lower, and annual cattle sales >3 times higher, in the improved farming systems as compared with the traditional farming system (USD 290 per head versus USD 86 per head, respectively) (Bouyer et al. 2014). In the tsetse-infested areas only a small proportion (6%) of the farmers kept improved breeds, whereas almost half (43%) of the farmers living in the tsetse-free areas owned more productive cattle (Bouyer et al. 2014).

An ex-ante socio-economic study that assessed the potential benefits of the sustainable removal of *G. p. gambiensis*, the only tsetse species present, considered two possible scenarios with respect to potential increases in cattle sales to be expected after eradication. The first, a conservative scenario, assumed an annual replacement rate of 2% of traditional by improved systems, and the second assumed a higher replacement rate of 10% five years after the removal of the tsetse fly population. The final annual increase in cattle sales was estimated at USD 3250/km$^2$ versus a total cost of the eradication campaign of USD 7430/km$^2$ (Box 1). In spite of this relatively high cost, the benefit/cost analysis indicated that the project was highly cost-effective, with internal rates of return (IRR) of 9.8 and 19.1%, and payback periods of 18 and 13 years, for the two scenarios, respectively (Bouyer et al. 2014; Bouyer and Vreysen 2018). The replacement of traditional local cattle with more productive exotic animals is already apparent in the areas that have been cleared from tsetse (Block 1) or are close to eradication (Block 2) (Paquette 2019; Vreysen et al. 2021)

### 6.3. *Prediction for the Ethiopian Southern Rift Valley*

The anticipated benefits of removing the T and T problem in the Ethiopian Southern Rift Valley are substantial (Alemu et al. 2007; Zerihun 2017). At the request of the Ethiopian government, Knight (2001) conducted a preliminary benefit/cost analysis,

pointing out that there are significant benefits to be gained from sustainably removing tsetse flies by involving the SIT as part of an AW-IPM strategy. For investments made to create a tsetse-free zone in the Southern Rift Valley, the break-even point should be reached in year 5 or 6, and the net present value (NPV) over 12 years is estimated at between USD 36.6 and 52.7 million. This represents an internal rate of return of between 33 and 43%.

### 6.4. *Benefits from a Planned Programme to Eradicate* Glossina austeni *and* Glossina brevipalpis *in KwaZulu Natal, South Africa*

The province of KwaZulu Natal in South Africa harbours two species of tsetse flies, *Glossina austeni* and *Glossina brevipalpis* Newstead. These populations were responsible for a major outbreak of nagana in 1990, prompting the government to assess potential benefits from a sustained removal of these populations (Kappmeier et al. 1998)

Kappmeier Green et al. (2007) developed an AW-IPM strategy to remove sustainably the two tsetse populations. It included two cycles of the sequential aerosol technique (SAT) followed by the release of sterile males. A benefit/cost analysis indicated that such an approach would reach a break-even point after 8 years, with a cumulative total net benefit (net present value, taking into account a discount rate of 8%) of USD 51 million, and an overall benefit/cost ratio of 3.4, over a 15-year period. These figures do not take into account additional benefits, such as improved agricultural productivity because of healthier draft animals. Starting in year 9, the project would reach the maintenance phase, and benefits would be fully established; the annual benefit/cost ratio would fluctuate between USD 90 and 493 for each dollar invested (year 9 to year 15). Moreover, the project would have an internal rate of return of 23%, meaning that the discount rate could be almost three times higher than the estimated value of 8% and the project would still break even in a 15-year time frame (Kappmeier Green et al. 2007; Bouyer and Vreysen 2018).

## 7. CONCLUSIONS

Keeping livestock, and especially operating a mixed farm, is fundamental to the rural poor being able to produce their own food. There are many problems of food security that, even though they limit the availability of adequate food supplies, can be solved, step-by-step. However, if approached from the viewpoint of conventional pest suppression, the T and T problem remains an insurmountable barrier to productive agriculture. A partial or unsustainable solution is really no solution. Without breaking this barrier to enable the introduction of higher productive agriculture and livestock systems, and without the resulting development and profitable investment opportunities, there is no hope that the hungry in sub-Saharan Africa will become food self-sufficient within a reasonable time period. The poor farmers of Africa, because of where they live, are helpless in the face of a problem that, even though they may be able to alleviate it temporarily, on their own they cannot remove it in a sustainable manner.

## SUMMARY

More than three thousand million people live with the risk of malaria. Due to the widespread resistance of mosquitoes to insecticides and of parasites to chemotherapies, previous gains made in disease reduction are being reversed. In addition to this perennial threat, there is now a rapid invasion of *Aedes* mosquitoes across the globe and the associated spread of the arboviruses (arthropod-borne viruses) they carry. One half of the world's population is now at risk of dengue, and chikungunya (having emerged from Africa) is an increasing public-health problem in Asia and the Americas. The economic and social costs of these diseases is so great that, in some areas, they have slowed the development of nations. Current vector-control methods are inadequate (especially against container-breeding species) because they are losing their effectiveness, the global burden of mosquito-borne diseases is increasing, and no specific drugs or effective global vaccines are available to treat or prevent the diseases. Therefore, there is a need for additional suppression methods to be applied as part of Integrated Vector Management (IVM). Since the early 2000s, there has been a renewed interest in applying the sterile insect technique (SIT) against mosquito vectors of disease. The explosive outbreaks of the Zika virus (and associated birth defects) across the tropics increased the urgency. The recent availability of technology to rear and release the sterilized males of many mosquito species on a large scale has increased the expectation that the SIT could help reduce the suffering caused by mosquito-borne diseases. Much progress has been made in developing the SIT technology for mosquitoes, based on historic SIT efforts and the experiences gained in the successful large-scale application of the technique against agricultural pest species. The SIT is a suitable technology for suppressing mosquitoes because: (1) they can be mass-reared in a laboratory, (2) natural sexual dimorphism in many species aids sex separation, and (3) females become refractory after mating. There has been a perception that mosquitoes are more vulnerable than many pest species to damage during handling, sterilization, and release. However, technological and methodological improvements can cope with this lower robustness, and indeed take advantage of their smaller size and weight. Nevertheless, the need for perfect sex separation for male-only release to preclude any biting and disease transmission by released females, remains a technical bottleneck to scaling the SIT beyond small-scale pilot trials. As a remedy for this, genetic sexing strains are being developed. However, until they are available, combining the SIT with cytoplasmic incompatibility conferred by *Wolbachia* infection (incompatible insect technique (IIT)) has been proposed as an advantageous strategy. The advantage of including the IIT is that *Wolbachia* infection may prevent potential disease transmission by any released females, whereas sterilization guarantees that such females cannot reproduce, avoiding the loss of the cytoplasmic incompatibility due to *Wolbachia* establishment in the target population. Another advantage of simultaneous IIT use is that it enables the radiation dose to be minimized. Other challenges remain, particularly in release technology and quality control. Nevertheless, in recent years, pilot trials have been conducted or have been initiated, e.g. China, Germany, Greece, Italy, Mauritius, Mexico, Singapore, and Thailand, achieving encouraging results in suppressing adult populations of *Aedes* species. Area-wide releases, focused on urban and suburban settings, appear particularly promising in terms of sustainable and cost-effective IVM of *Aedes* vectors (eventually provided commercially by the private sector) because they can protect many people concentrated in relatively small areas. In the case of *Anopheles* vectors, the SIT may become a useful complementary tool, especially against outdoor-biting species which are not well-controlled by mosquito nets.

## 1. INTRODUCTION

Mosquito-transmitted dengue is now the world's most common mosquito-borne viral disease; over the last 50 years the incidence has grown more than 30-fold (Bhatt et al. 2013). Dengue viruses are estimated to infect about 400 million people per year, and over half of the world's population is at risk of the disease. Moreover, chikungunya virus emerged from Africa in the mid-2000s, and spread across Asia and the Americas in 2013 (Mayer et al. 2017). Due to the increasing spread of invasive mosquito species (Kraemer et al. 2015), these arboviruses were already becoming a major international public-health concern, even before Zika virus outbreaks occurred in the South Pacific in 2013 and in the Americas in 2015 (Mayer et al. 2017). Epidemics of the Zika virus in the Americas were associated with cases of microcephaly and other congenital

abnormalities. On 1 February 2016 the World Health Organization (WHO) declared a public-health emergency of international concern. To date there are no drugs or effective global vaccines available to treat or prevent Zika; this situation led to calls for an urgent response against its *Aedes* vectors. Even though one of the best vaccines ever developed exists for yellow fever (another arbovirus), it is re-emerging in some countries (including Angola, Brazil, China, Democratic Republic of Congo, and Kenya (Zwizwai 2017)).

Subsequent to a major expansion of its geographical range, *Aedes aegypti* (L.) is the most important vector of arboviruses worldwide, particularly in tropical and subtropical urban settings (Mayer et al. 2017). *Aedes albopictus* (Skuse) is also a major public-health concern because it is a very good vector of several arboviruses including dengue, chikungunya, and Zika (Mitchell 1995). The epidemiological risks associated with *Ae. albopictus* are increasingly great in Europe, where significant disease outbreaks are now occurring (Gossner et al. 2018). While arboviruses are increasing in impact and notoriety, 3.2 thousand million people remain at risk of malaria, transmitted by Anopheline mosquitoes; in 2016 alone, an estimated 216 million new cases of malaria and 445 000 deaths occurred (WHO 2017b).

### *1.1. Burden of Disease*

Seven of the major vector-borne diseases (malaria, lymphatic filariasis, leishmaniasis, dengue, Japanese encephalitis, yellow fever, and Chagas' disease) share a largely overlapping pattern of global distribution; many parts of the world are at risk of up to six of these (Fig. 1) (Golding et al. 2015). Controlling the mosquito vectors would simultaneously combat several co-localized diseases, improving the benefit/cost ratio and sustainability of control efforts, particularly Integrated Vector Management (IVM) programmes, which could include a sterile insect technique (SIT) component. Alongside the human suffering (morbidity and mortality) caused directly by mosquito-borne diseases, they also exert a high financial burden -- direct costs of treatments and prevention activities, and indirect costs through loss of human productivity and subsequent impact on a region's economy. The concentration of malaria cases in Africa means that malaria in particular constitutes a major obstacle to sustainable development and poverty eradication on the continent.

The cost of treating cases of disease can vary greatly depending on the economic and social setting. The direct and indirect costs may fall on the state, on the patients and their families, or on both. In Ghana, for example, the treatment cost for each malaria episode varies from USD 5.70 to 48.73, depending on the severity of disease; the household is responsible for 55% of the treatment cost. Indirect costs, such as a funeral, can in some African countries be equivalent to one year's total household income (Sicuri et al. 2013). The Philippines carries the fourth-highest burden of dengue cases in South-East Asia; an analysis by Edillo et al. (2015) estimated that over 840 000 clinically diagnosed cases led to direct medical costs of USD 345 million (USD 3.26 per capita). Thirty-five percent of cases were treated as outpatients, representing 10% of indirect costs, compared with the 65% of patients who were hospitalized and constituted 90% of direct costs.

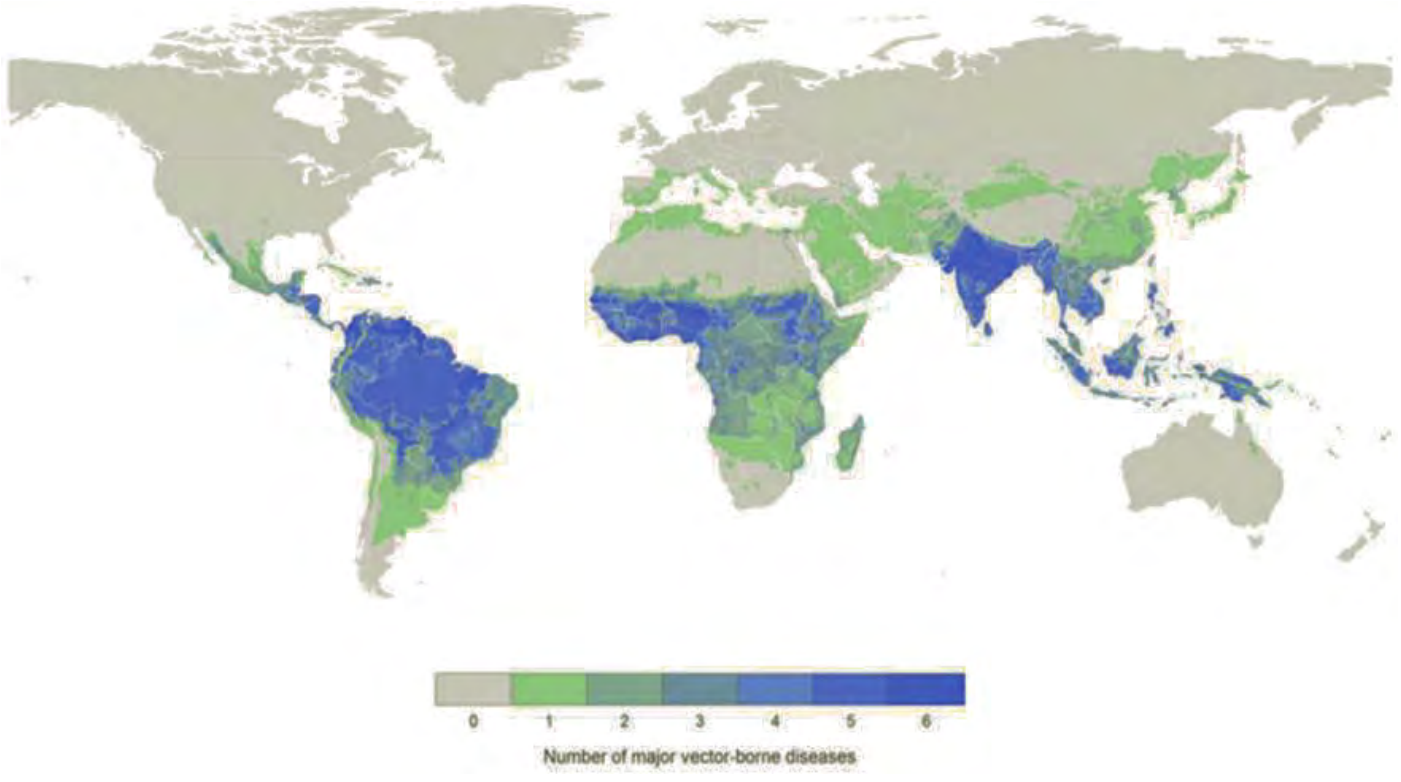

*Figure 1. Combined global distribution of seven major vector-borne diseases for which integration of vector control programmes may be beneficial: malaria, lymphatic filariasis, leishmaniasis, dengue, Japanese encephalitis, yellow fever, and Chagas' disease. Colours indicate the number of vector-borne diseases that pose a risk at each 5 x 5 km grid cell. (Map from Golding et al. 2015, reproduced with permission.)*

The cost of fighting dengue in 18 countries at purchasing power parity (PPP) was calculated at about USD 3.3 thousand million in 2015; using standardized PPP costs permits comparing socio-economic impacts in the different countries (Oliveira et al. 2019).

The economic burden of vector-control costs, in an attempt to reduce or prevent cases of disease, needs to be factored into estimates of the cost of disease to a country or region. To the USD 102.2 million direct cost of treating the almost 40 000 cases of dengue reported annually in Malaysia from 2007 to 2012, another USD 73.5 million (0.03% of Gross Domestic Product (GDP)) need to be added for the National Dengue Vector Control Programme, mostly for adulticidal fogging, increasing the cost by 72% (Raviwharmman Packierisamy et al. 2015).

Vector-control costs can apply even where a disease is not yet a problem or has previously been brought under control, e.g. countries (such as Mauritius) which are at risk from importation of arboviruses due to their high inflow of international visitors (Beesoon et al. 2008; Ramchurn et al. 2009) or those countries at risk of invasion by *Aedes* vectors. A balance must be made between potential disease costs and preventive vector control efforts. As the Zika virus was spreading through the Americas, the US president requested USD 1.8 billion from Congress in February 2016 to combat Zika in Costa Rica and Brazil, expenditure which was found to be justified in a study by Alfaro-Murillo et al. (2016). The judgement was based on estimated probabilities of microcephaly in babies born to infected mothers and direct medical costs, which both vary by country, and the loss of Disability-Adjusted Life Years (DALYs) per case of microcephaly (29.95 DALYs) and of Guillain-Barré syndrome (1.25 DALYs).

The wider benefits of disease reduction or eradication may be significant. A study conducted in Ghana into the economic-burden impact of malaria mentions that a 1% increase in malaria morbidity reduces economic growth by 0.41% (Asante and Asenso-Okyere 2003). Due to malaria, each business in the nation lost on average about a month's productivity per year; this corresponds to a drastic decrease in average income. A dynamic macrosimulation model to estimate the effects of eradicating malaria shows that higher economic development can be achieved in the long-term (within 30 to 50 years) from malaria eradication (Ashraf et al. 2009).

While the burden of agricultural pest insects is usually felt by individual growers and sector cooperatives, the burden of vector-borne diseases is felt by the whole population; therefore, the management of such diseases is commonly the responsibility of local organizations (including non-governmental mosquito control districts (Foley IV et al. 2021)) or supplemented by governments as part of their social policy, where it is a constitutional requirement to provide health care. Tang et al. (2004) developed a framework outlining for the USA the ten coordination and regulatory roles that government may play in health-care quality (which could be applied in any country):

> (1) purchase health care, (2) provide health care, (3) ensure access to quality care for vulnerable populations, (4) regulate health care markets, (5) support acquisition of new knowledge, (6) develop and evaluate health technologies and practices, (7) monitor health care quality, (8) inform health care decision-makers, (9) develop the health care workforce, and (10) convene stakeholders from across the health care system.

Each role proposed above would have an impact on the control of neglected diseases. In facing the continuous increase in the number of cases and disease expansion to new areas, item six highlights how critical it is to develop an effective contribution to reducing the number of transmitted cases over time -- by incorporating new strategies and control methods for vector-borne disease control (Araújo et al. 2015; Bourtzis et al. 2016).

Various countries have developed their own guidelines and protocols to deal with vector-borne diseases (based on guidelines developed by the WHO (WHO 2009, 2012)) in which they formulate evidence-based strategies and policies. For example, the Brazilian health ministry developed the National Dengue Control Plan (PNCD), operating since 2002. It comprises a great range of activities and instructions in an effort to reduce the number of dengue cases all over the country. This plan evolved after the first attempt to eradicate the mosquito in the 1970s -- aggregating and developing strategies based on different approaches including epidemiological and entomological surveillance, frequent house inspections, and insecticide application (Braga and Valle 2007). Until now, the PNCD's objectives have not been fully achieved, and the fact that dengue epidemics can still be expected every year illustrates the need for a full review and evaluation of the strategies and control methods applied. There are local problems related to achieving full implementation of the plan (a result of insufficient support from stakeholders), in addition to growing resistance to the commonly used temephos larvicide and deltamethrin adulticide (Valle et al. 2019), and the general challenge of eradicating populations of container-breeding *Aedes* vectors. Brazil alone always represents more than 95% of the number of dengue cases in Latin America (Pessanha et al. 2009; Salles et al. 2018). Until effective universal vaccines, and safe, effective, and inexpensive drugs, are developed and become available, control of the mosquito vectors of disease is likely to be the most effective method of reducing cases of disease and controlling their spread.

### *1.2. Need for Better Vector Control*

Currently most mosquito control strategies rely primarily on the use of insecticides, but with the increasing spread and significance of resistance in vectors of malaria (Ranson and Lissenden 2016) and arboviruses (Ranson et al. 2010; Moyes et al. 2017) there is a need for sustainable tools that enhance the arsenal against key vectors, particularly in the face of public concern about the human health and environmental impact of widespread insecticide use. Although great gains have been made in reducing the burden of malaria (e.g. there were 20 million fewer malaria cases in 2017 than in 2010 (WHO 2018)), these gains have been achieved through applying artemisinin combination therapies (ACTs) and especially insecticide-treated bednets (ITNs). The 2018 World Malaria Report suggested that these gains are being reversed; no significant progress was made in reducing cases between 2015 and 2017 -- due in large part to drug and insecticide resistance becoming increasingly established and widespread (WHO 2018).

In its global vector control response 2017–2030, the WHO pointed out the urgent need for the development and integration of innovative mosquito control methods, including the SIT, particularly against *Aedes* vectors (WHO 2017a). A major

advantage of suppressing a mosquito vector population with such an integrated approach is that it can address several diseases at once; different diseases, such as arboviruses, are often transmitted by the same *Aedes* vectors, whereas other approaches, e.g. vaccination, need to be developed for each new emerging disease.

The behavioural ecology of anthropophilic mosquitoes, and in particular their use of disseminated microhabitats as oviposition sites, challenges the integrated control of these insects in many countries and climatic conditions, and prohibits a satisfactory level of population reduction (Reiter 2016). Moreover, the application of many insecticides is more and more restricted worldwide; this reduces the available vector control options, particularly in the face of spreading resistance against all but the newest classes of insecticides in vectors of both malaria (Sokhna et al. 2013) and arboviruses (Ranson et al. 2010; Grigoraki et al. 2017; Pichler et al. 2018). In addition, insecticide-treated bednets are not effective in combating *Aedes* vectors (which are active during the day).

Therefore, new techniques to control mosquitoes are under development and being evaluated in the field, including genetic control strategies targeting the reproductive capacity of disease-transmitting mosquitoes (McGraw and O'Neill 2013; Lees et al. 2015; Bourtzis et al. 2016; Flores and O'Neill 2018). Amongst these, the SIT and the incompatible insect technique (IIT) show great promise (Oliva et al. 2014).

### *1.3. Integration of the SIT Offers the Potential for Sustainable Mosquito Suppression*

Pilot trials against mosquitoes started in about 1960 in the USA, with the goal of assessing the potential of the SIT to reduce populations of *Ae. aegypti* and *Anopheles quadrimaculatus* Say, but in both cases there was no evident population suppression in the target areas after 43–48 weeks of releases of sterile males (irradiated with gamma rays) (Morlan et al. 1962; Weidhaas et al. 1962). Many other pilot projects took place with various mosquito species in various countries using different rearing protocols, irradiation sources, and methods of sterilization (chemosterilization, translocations, inversions, and cytoplasmic incompatibility (CI)) (Benedict and Robinson 2003; Dame et al. 2009; Klassen et al., this volume). Some were able to demonstrate suppression and even elimination/eradication of the target population, e.g. elimination of *Anopheles albimanus* Wiedemann in El Salvador (Breeland et al. 1974; Dame et al. 1974).

Interest in applying the SIT against mosquitoes had waned since these intial trials in the 1960s and 1970s. Rather than technical failure, this was due largely to political instability affecting their implementation and insufficient practical governmental support (Klassen et al., this volume). Moreover, in view of the availability of new insecticides, mosquito control has relied heavily on the use of a limited number of insecticides. Recently, there has been a resurgence of interest due to: (1) increased pressure exerted by emerging arboviruses and the spread of resistant malaria, (2) the loss of current methods of control because of malaria resistance to drugs and resistance to insecticides in both *Anopheles* and *Aedes*, and (3) the availability of molecular techniques that have enabled the development of improved strains for the SIT (Bourtzis and Hendrichs 2014; Bourtzis and Tu 2018; FAO/IAEA 2018c; Lutrat et al. 2019) and made alternative versions of genetic control possible (Alphey 2014).

Releasing insects sterilized by ionizing radiation has been a very important method for the area-wide suppression, containment, and even eradication of major insect pest populations (Klassen et al., this volume). Given the experiences obtained in those programmes applying the SIT, there is reason to believe that it could also be applied -- in combination with other control methods as part of an area-wide integrated pest management (AW-IPM) approach -- to suppress disease vectors below the threshold required for disease transmission. Building on previous experiences in the 1960s and 1970s to develop the SIT for disease vectors, many parameters have been investigated to better understand, enable and optimize the application of the SIT against mosquitoes, including mass-rearing procedures, sterilization methods, transport and release methods, and trapping systems (Pepin et al. 2013; Puggioli et al. 2013; Balestrino et al. 2014a, b; Carvalho et al. 2014; Codeço et al. 2015; Lees et al. 2015; Eiras et al. 2018; Bakri et al., this volume; Dowell et al., this volume; Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume; Vreysen, this volume). Part of the development of the SIT against mosquitoes has also been based on the experiences of successful programmes against other insects, e.g. those against *Ceratitis capitata* (Wiedemann) in the USA, Guatemala, Mexico, and Chile, and *Cochliomyia hominivorax* (Coquerel) in Central and North America, as well as Libya (Enkerlin, this volume; Klassen et al., this volume; Vargas-Terán et al., this volume). However, more research and testing need to be done before "mosquito SIT" reaches the same level of development as these programmes (Krafsur 1998; Vargas et al. 2008; Enkerlin et al. 2015).

Several features of mosquito biology make mosquitoes suitable targets for the SIT (Beier et al. 2014). Most of the key mosquito disease vectors can be colonized and reared in the laboratory, adapting to feeding on artificial larval diets and taking blood meals through artificial membranes. Therefore, the production of sufficient numbers to achieve an overflooding release ratio is feasible, even if reducing natural population densities using other complementary suppression techniques will often be necessary against mosquitoes, particularly the reduction of larval populations and habitats (Mangan and Bouyer, this volume).

Sexual dimorphism, particularly in *Aedes* species, can be exploited to help remove females prior to sterilization and release of males, which is an essential requirement for applying the SIT against mosquitoes -- females are the disease vectors, and releasing even small numbers that may transmit disease is problematic for the public and regulators, even if not for technical efficacy.

In comparison with fruit and tsetse flies, mosquitoes are smaller and lighter, making the challenges of handling, transport, and release more tractable (especially to take advantage of new technologies such as automated release from unmanned aerial vehicles (UAVs) (Dowell et al., this volume)). However, their small size also confers some fragility; this must be taken into account to prevent a reduction in survival or quality of released males. Finally, female mosquitoes are mostly refractory to remating -- not an absolute requirement of the SIT but beneficial in reducing the numbers for, and frequency of, release required to induce sterility in the female population (Lance and McInnis, this volume; Whitten and Mahon, this volume).

The container-breeding species, such as *Ae. aegypti* and *Ae. albopictus*, are particularly challenging to control because their life cycle relies on oviposition in

small, and often temporary, sources of water. To mitigate the risks of a whole egg batch being lost due to a small body of water drying out before the offspring can emerge and escape, and also predation or competition for space or nutrition, an Aedine female will lay her egg batch, up to 100 eggs per gonotrophic cycle, in multiple sites. Many of those sites (such as discarded drink cans or tree holes) are very small and difficult to target with chemical control, and many are difficult to remove or treat (such as water butts used to collect rain water in areas of unreliable piped-water supply or buckets in fishing communities), and may be located in urban sites which are not amenable for control, e.g. abandoned lots or balconies of apartments in high-rise buildings. This cryptic behaviour also means that females often rest in locations which are not reached by insecticide applications (Dzul-Manzanilla et al. 2017). The advantage of sterile males is that they will locate mates, which then will lay non-viable eggs, and negate the need to find and treat these hard-to-reach oviposition sites. Increasing global trade and urbanization, as well as reliance on disposable containers without sufficient waste disposal infrastructure in many areas affected by mosquito-borne disease, help explain the rapid growth in distribution of *Aedes* vectors. In this context, the reliance on the dispersal of sterile males rather than human operators is an important advantage of control efforts that integrate mosquito release over other methods; a similar advantage applies to autodissemination stations for juvenile hormones.

In the case of *Anopheles* females, these are targeted by conventional vector-control methods while they are trying to take a blood meal through an insecticide-treated bednet or resting on a wall treated with indoor residual spray (IRS), but those that remain in untreated houses or communities will be unaffected. Moreover, some exophilous species (such as *Anopheles arabiensis* Patton) that bite mainly outside will not be impacted by these methods. One major benefit of SIT application against *Anopheles* mosquitoes, in particular *An. arabiensis* which is the sole vector of malaria in most of its area of distribution, is that human operators do not need to find and treat these sites or target every mosquito, but instead male mosquitoes are released to seek out and sterilize females, whose eggs (wherever she lays them) will then be sterile.

## 2. DEVELOPMENT OF THE SIT TECHNOLOGY AGAINST MOSQUITOES

Increasing interest in applying the SIT, and other control methods relying on the large-scale rearing and release of insects, has led to a rapid improvement in the available technology and methodology to mass-rear, sterilize, assess the quality of, and release and conduct surveillance on, *Aedes* and *Anopheles* mosquitoes (Benedict et al. 2009a; Lees et al. 2015). A significant requirement of applying the SIT against mosquito vectors of disease is the need for male-only release, not only to maximize the efficacy of releases and the efficiency of rearing efforts, as in other insects (Franz et al., this volume; Häcker et al., this volume), but also for the public perception and regulatory challenges surrounding the release of even a small number of potentially disease-transmitting females. Pilot trials of the SIT and associated techniques have been conducted or initiated in recent years in a number of settings, against both genera of mosquitoes, and evidence of the potential for the SIT to suppress mosquito populations is being produced.

### *2.1. Rearing and Sterilizing Males*

#### *2.1.1. Colonization and Mass-Rearing*

The need for effective colonization and rearing to maintain essential qualities in mosquitoes released for vector control have been reviewed by Benedict et al. (2009b). Colonization and establishment of a new mosquito colony is a painstaking process (FAO/IAEA 2017a, 2018b). Blood-fed females, or immature developmental stages, are collected from a field site where the species of interest is likely to dominate, and individual families are reared while morphological and/or molecular analysis is used to confirm the species. Conspecific families can then be pooled to establish a colony which is often small, and must go through a bottleneck as it becomes adapted to artificial rearing conditions, particularly feeding from an artificial membrane instead of a natural host. Once a colony is established and stabilized, laboratory-adapted mosquitoes are relatively amenable to large-scale rearing, though for a release programme to be efficient each element of the rearing process must be optimized (Parker, Mamai et al., this volume).

Key to affordable production of high-quality adults is the selection of a larval diet which provides all the nutrients needed by developing larvae to grow and establish the nutritional reserves they will require as adults for foraging and mating. Ideally, these should consist of locally available ingredients, be reliably available and of a consistent quality, and even if inexpensive yet still effective in producing high-quality adults (Khan et al. 2013 give *Anopheles stephensi* Liston as an example). A well-proven diet (consisting of tuna meal, bovine-liver powder, and vitamin mix) is effective for rearing *An. arabiensis* (Damiens et al. 2012), *Ae. albopictus* (Puggioli et al. 2013), and *Anopheles gambiae* Giles (Yahouédo et al. 2014). The addition of Brewer's yeast increases the protein content; it is particularly helpful for improving sexual dimorphism in *Aedes* rearing (Balestrino et al. 2014a). Given the cost and difficulty in obtaining bovine-liver powder, alternative diets have been validated (e.g. Bimbilé Somda et al. 2017), and other cheaper proteins, e.g. insect proteins, are also being developed (Bimbilé Somda et al. 2019).

Since they have an aquatic larval stage, rearing mosquitoes is more labour-intensive than other insect species targeted by the SIT. In addition, the pupal stage, lasting only 24–48 h, must be collected and transferred to a cage before adult emergence. Therefore, some level of automation and large-scale equipment for larvae and adults are required to prevent labour costs from becoming prohibitive. A tray-and-rack system (consisting of 50 trays stacked in one rack for easy filling using piped water, seeded with first-instar larvae, reared to pupation, then tilted to recover pupae for transfer to adult cages) has been validated to rear up to 200 000 *An. arabiensis* larvae (Balestrino et al. 2012) and about 900 000 *Ae. albopictus* larvae (Balestrino et al. 2014b). Accurate quantification of eggs or larvae used to seed a rearing tray is critical because density-dependent competition acts at the larval stage (affecting the speed and synchronicity of development, the size and nutritional status, and hence the performance of the resulting adults). Trays can be filled in a standardized way using a larval counter (Mamai et al. 2019). Once the trays have been tilted, *Anopheles* pupae can be separated from remaining larvae (on the basis of their different buoyancy) using a cold-water vortex system (Balestrino et al. 2011), and *Aedes* pupae are

separated using the Fay-Morlan separator (Focks 1980). Pupae are quantified volumetrically, and then the required number is transferred to adult emergence cages. In China and Singapore, ongoing programmes recover 70–80% of male pupae in only one tilting event, and sex separation is very efficient (only 0.3% female contamination). An automatic sex sorter based on a robotized Fay-Morlan separator has been developed by the Wolbaki company, with the same efficiency and a throughput of up to 150 000 pupae per hour (Xi, Z., personal communication).

Adult cages, inspired by those used for mass-rearing fruit flies, have been validated for up to 25 000 *Ae. albopictus* (Balestrino et al. 2014a; FAO/IAEA 2017b) or 15 000 *An. arabiensis* (FAO/IAEA 2017a) pupae. Adults must be blood-fed so that females can develop eggs. Adults are blood-fed using a Hemotek membrane feeder modified for mass-rearing (Damiens et al. 2013). *Anopheles* eggs are collected in water on the bottom of the oviposition cage which is then flushed out (Maïga et al. 2016); *Aedes* eggs are laid on wet filter paper which can then be removed and dried for storage (Zheng et al. 2015). Eggs can be quantified at this stage (Zheng et al. 2015; Maïga et al. 2016) before they are stored (*Aedes* only) or hatched. Mass-rearing using this system does not appear to impact male quality significantly (Soma et al. 2017) as judged in a laboratory setting. A new cheaper mass-rearing cage for *Aedes* has also been validated recently; it costs 90% less than the former IAEA reference cage and can be produced locally in any country (Maïga et al. 2019). Alternative designs for mass-rearing cages are also proving to be effective (Zhang et al. 2018).

It is essential to separate males (destined for release) from females (potential disease vectors). A perfect method for sexing mosquitoes on a mass-scale has not yet been developed (Gilles et al. 2014), although promising methods are being evaluated (section 4.1.). Nevertheless, currently *Aedes* can be separated on the basis of sexual dimorphism (differential speed of development and pupal size) (Fay and Morlan 1959; Focks 1980). In addition, the mass-removal of female *Anopheles* can be achieved by spiking blood meals with toxicants such as ivermectin (Yamada et al. 2013).

### *2.1.2. Irradiation*

There is a perception by some that mosquitoes are more susceptible to somatic damage caused by irradiation (with the resulting reduction in performance) than other species targeted by the SIT (Bakri et al., this volume). There are reports from historic mosquito SIT projects that failures were due to poor male performance (Dame et al. 2009). Nevertheless, it is possible to select a suitable dose to induce sufficient sterility without inflicting unacceptable somatic damage, although rearing is key to ensuring a consistent high-quality output of sterile males for release (Parker, Vreysen et al., this volume). A key observation during historic mosquito SIT releases (Darrow 1968) -- that field-collected *Culex tarsalis* Coquillett males subsequently irradiated as pupae were competitive following re-release, unlike mass-reared and irradiated males -- points to the mass-rearing and handling process, and not irradiation, as the more important factor impacting male-mating success.

At the present time, sterile males for release are obtained by irradiating pupae -- they are more easily handled and less damaged by radiation than adults (Helinski et al. 2006, 2009). However, strong density-dependent efficiency related to water content and anoxia suggests a method for irradiating chilled compacted adults (that is

presently under development) will provide better results (H. Yamada, personal communication). On the other hand, pupae can be irradiated at a high density in a small volume of water, minimizing the volume to be irradiated and thereby increasing the uniformity of dose. Protocols and dose-response relationships have been established (to achieve an optimal balance between a high level of sterility and a low impact on male performance) for *Ae. albopictus* (Balestrino et al. 2010), *An. stephensi* Liston (Akram and Aslamkhan 1975), *Anopheles pharoensis* Theobald (Wakid et al. 1976), and *An. arabiensis* (Helinski et al. 2006). Even though gamma irradiators are commonly available, X-ray irradiation offers a more convenient and less costly alternative, with lower security requirements (Ndo et al. 2014; Yamada et al. 2014; Bakri et al., this volume).

### *2.1.3. Quality Management and Monitoring*

Quality management and monitoring of sterile males are critical for the SIT -- to ensure good mating performance and that released males are competitive (Parker, Vreysen et al., this volume; Vreysen, this volume). Quality-control monitoring of rearing conditions is also essential to assure sexual dimorphism in *Aedes*, synchronous pupal production, consistent productivity and quality, and a reliable number of adults for release (Parker, Mamai et al., this volume; Parker, Vreysen et al., this volume). Regular measurement of important life history traits and mating competitiveness is critical in a colony reared for release. Rearing should be as standardized as possible to ensure consistent quality of material for release, and predictable synchronized development. In *Aedes* colonies it is important to maximize sexual dimorphism (key to sex-separation). Parameters such as water temperature and larval density must be optimized to consistently produce high-quality adults (Mamai et al. 2018).

A useful method for assessing if rearing conditions are optimal for a given species in a given setting was described by Valerio et al. (2016). To quantify and help minimize the impact of mass-rearing, irradiation, and handling on sterile male mosquitoes, several methods to judge the consistency, quality, and predicted performance following release have been suggested. The relative impact of different handling treatments, and combinations of different parameters, could be estimated by comparing the longevity of exposed males (Chung et al. 2018; Culbert et al. 2018b). Longevity is an important parameter of released males, also sometimes used as a proxy measure of quality.

Balestrino et al. (2017) proposed for *Aedes* pupae a system of quality control based on flight performance (an improvement on the conventional flight cylinder), and a further development has been designed (Fig. 2), to measure the flight ability of adult mosquitoes; it may be the most practical and robust of the tests for proxies of success. This parameter has been validated as a predictor of survival (a product of being able to forage for food and evade predators) and mating capacity in *Ae. aegypti* (Culbert et al. 2018a). However, it may be necessary to assess more than one quality indicator to fully understand the impact of colonization, mass-rearing, and manipulations on the overall quality of sterile males (Poda et al. 2018).

Semi-field experiments have demonstrated the ability of sterile male mosquitoes to attract and compete for mates (e.g. Howell and Knols 2009; Bellini et al. 2013a; Madakacherry et al. 2014; Yamada et al. 2014). *An. arabiensis* adults transported by

air survived and competed for matings to an acceptable degree in field cages near the intended release site in Sudan (Helinski et al. 2008). Although it is difficult to judge the effect of irradiation and other manipulations in an open field setting, this is a valuable step in evaluation. Field observations of sterile *An. arabiensis* males participating in swarms within 2 h of release (Ageep et al. 2014) is a very encouraging measure of the potential success of applying the SIT to control these mosquitoes.

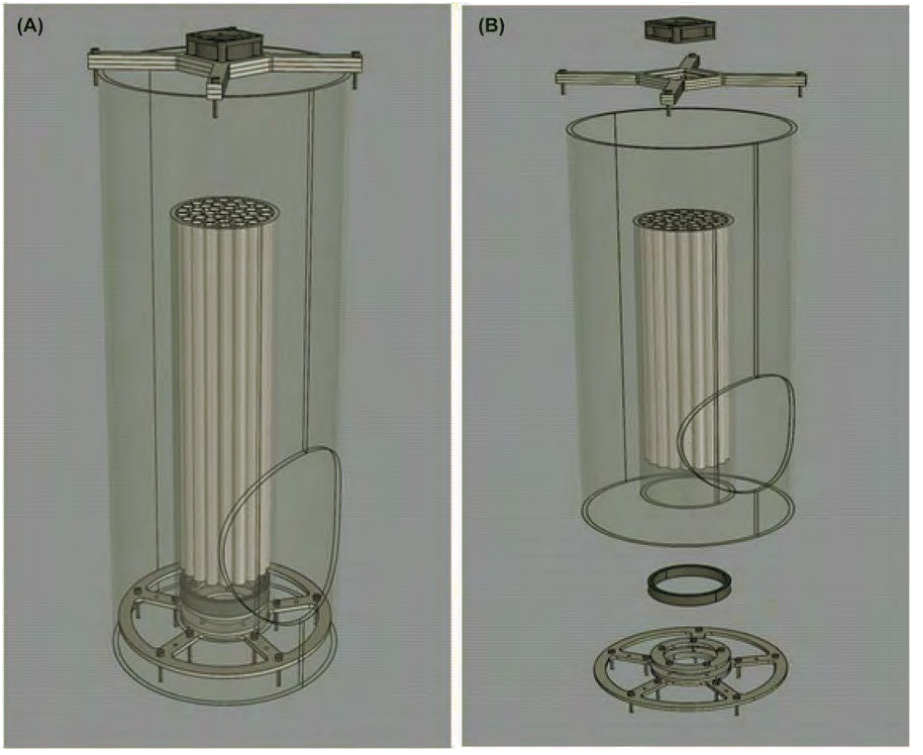

*Figure 2. A: Flight test device; B: Device showing components. (Drawings from Culbert et al. 2018a, reproduced with permission.)*

### *2.2. Release and Monitoring*

Until now the pilot releases of sterile male mosquitoes have been small enough to permit manual release from small plastic containers. Male pupae emerge directly into these containers; they are transported to the field and opened by hand at set ground release points to release the males. This method of release has been used in all of the SIT field pilots until now, as well as in the release of 10 000 transgenic *Ae. aegypti* males per week in Juazeiro, Bahia, Brazil as part of a RIDL (Release of Insects carrying a Dominant Lethal) suppression trial (Carvalho et al. 2015; Häcker et al., this volume). However, the large-scale releases required for operational application of the SIT will necessitate more sophisticated methods of handling, transport, and release,

i.e. methods that are less labour-intensive and have the capacity to be standardized between sites. The most likely scenario is that adult males will be chilled, loaded into a release device with some level of compaction, and released either aerially or from a motorized vehicle (FAO/IAEA 2014; Chung et al. 2018). In some situations, existing infrastructure may be used, e.g. designing a release device and strategy that utilizes the coverage of large cities by bus routes, or shipping sterile mosquitoes from rearing facility to release site by commercial courier (Mains et al. 2019). Release by UAVs will probably be used to reach areas that are not reliably accessible by road, such as dense favelas or isolated rural hotspots, and importantly to increase the speed of release and uniformity of coverage while reducing costs (Benavente-Sánchez et al. 2021; Dowell et al., this volume).

It is important that release procedures do not unduly damage the males or impact their subsequent performance and survival. Laboratory studies show that mosquitoes are damaged to some degree by chilling, packing, compaction, and release into simulated field conditions (Chung et al. 2018; Culbert et al. 2018a, b). However, some degree of chilling improves survival during compaction (Chung et al. 2018), and parameters such as the chilling temperature can be optimized to minimize the impact. Also, conditions can be optimized by ensuring sufficient ventilation during chilling and transport. For example, the best chilling-temperature range for the transport of compacted *An. arabiensis* adults is 8–11°C (Culbert et al. 2017). Aedine mosquitoes appear to be more robust than Anophelines, and the time of release is likely to be more critical in the latter case.

For an SIT project to be effective, sufficient sterile males must be released in relation to the target population. In an efficient programme, males should be directed to the target area at a fine scale; this requires an understanding of the behaviour, size and spatial distribution of the population before intervention (Lees et al. 2014). Such data are also crucial in monitoring the progress, and demonstrating the success, of the project as it progresses (Vreysen, this volume). During the planning and development phase of an SIT project, it is important to trap male mosquitoes (during mark-release-recapture experiments) to make assessments about the survival of released males, distance dispersed, and level of mating competitiveness. Ongoing monitoring of the fate of released males, and the size of the target population, is necessary as an SIT programme progresses. The benefits of detailed population data are increased by making releases assisted by automated geographic information systems (GIS) (Bouyer et al., this volume). Software is available which allows releases to be tailored according to real-time surveillance data for maximum efficacy.

Since female mosquitoes are the vectors of disease, most existing traps have been designed to collect females for surveillance, and in some cases for control. It is necessary to produce male-specific tools, or to adapt the timing, location or baiting of traps to target males specifically. For *Aedes* surveillance, males and females can be collected indoors using aspirators. The BG-Sentinel trap is effective for collecting males, but most of the effective traps attract only gravid females. Thus, there is an especially urgent need for effective methods to survey Anopheline mosquitoes (Batista et al. 2019; van de Straat et al. 2019). The CDC light trap often catches few *Anopheles* mosquitoes, and other tools such as the Suna trap, sticky resting boxes, baited traps, and human-landing catches require better standardization. Swarm capture

is a powerful approach but requires great expertise, and this technique is not possible in all locations (Bimbilé Somda et al. 2018). Better understanding of the cues which attract male mosquitoes is leading to traps with improved efficiency, e.g. the Sound-GAT (Johnson et al. 2018). In Singapore, mosquito surveillance is achieved using a network or more than 30 000 GAT traps monitored weekly (N. Lee Ching, personal communication). Emerging technology for automated passive mosquito surveillance shows great promise; in theory, a network of intelligent traps could automatically identify in real time the species, sex, size, and marker status of insects entering or passing close by (FAO/IAEA 2019a).

## 3. PILOT TRIALS AGAINST MOSQUITO VECTORS

In this new era of interest in applying the SIT against mosquito vectors, until now the pilot trials have been on a small scale, usually focussed on isolated villages or islands. It is perhaps no coincidence that the first projects to reach pilot-scale demonstrations of the SIT are to control Aedine mosquitoes, given their relative amenability to mass-rearing and sex separation. These small-scale trials are sufficient to demonstrate an impact on some entomological indicators, usually the number of eggs collected per ovitrap, egg-hatch rate, and adult-catch rate. These indicators suggest success, but for the technique to be taken up by abatement districts, governments or charities for implementation on an operational scale, evidence of epidemiological impact of the SIT (reduction of disease incidence) as part of integrated management schemes will be required, involving much larger area-wide trials. Transmission of disease by mosquitoes occurs not just in the home, but also in schools and workplaces, and therefore, unless a community is very isolated with little human movement outside a given area, it will be a challenge to demonstrate disruption of transmission or case reduction. Moreover, in some circumstances, female *Aedes* appear to disperse much farther than males (up to 800 m) (Honório et al. 2003); this will make demonstration of efficacy by current randomized cluster trials very challenging. Current equipment and techniques, in particular sex separation and release methods, will need to be improved dramatically, particularly against Anophelines, before such large-scale trials are possible. Through small-scale pilot trials, many lessons are being learned, which will inform the development of larger projects, e.g. the significance of *Ae. albopictus* immigration from neighbouring vegetation into urban or semi-urban areas targeted with the SIT, and the requirement for reduction of target populations using conventional methods or IVM prior to, and in conjunction with, applying the SIT.

### *3.1.* Aedes albopictus *in Italy*

Feasibility studies on using the SIT to target invasive *Ae. albopictus* mosquito populations were started in northern Italy in 2000 (Bellini et al. 2007). The studies included several releases of irradiated males; promising levels of induced sterility were achieved. Where release ratios were high enough, population reduction occurred (Bellini et al. 2013b).

Between 2008 and 2012, six pilot studies of sterile *Ae. albopictus* male releases were made to test the efficacy of the SIT approach to suppress mosquito populations.

The release sites were selected as being representative of urban conditions, small enough (10–17 ha) to achieve the required release ratio given the level of sterile-male output that was possible in the Bologna mosquito production unit, and well-isolated from other urban areas. The dynamics of the mosquito populations were monitored weekly in the release and control areas, using standard ovitraps. Eggs collected from the traps were counted under a stereomicroscope and hatched using standard procedures to assess fertility and, conversely, induced sterility (Bellini et al. 2007). Sterile males, released at the rate of 900–1500 males/ha/week, induced sterility levels between 15 and 70% of the background fertility of the local population. Where induced sterility reached 70%, a similar reduction was found in egg numbers collected by ovitraps. Therefore, inducing sterility levels of >80% in the native *Ae. albopictus* females for an entire season was expected to be sufficient to suppress effectively the mosquito population.

A recent meta-analysis of these trials (R. Bellini, personal communication) found that the released males demonstrated a mean competitiveness value of 0.188 (SD±0.33). This competitiveness (measured as the Capacity to Induce Sterility or CIS index) was highly variable between pilot trials despite very similar environmental conditions being experienced among the sites and similar sterile-male release methods being used in all studies. A strong temporal variability was observed, with lower values found at the beginning and at the end of the summer season (when the wild population density is usually lower and therefore the male sterile:wild ratio is higher) (Albieri et al. 2010; Carrieri et al. 2011). The strong negative correlation between the sterile:wild ratios and the competitiveness values demonstrated in this study was also observed in previous trials conducted under semi-field and field conditions using irradiated and transgenic sterile males (Harris et al. 2011; Damiens et al. 2016). In practical terms, an optimal ratio must be used in SIT operations to maximize cost-effectiveness; increasing the release ratio will not result in a proportional increase in induced sterility.

### *3.2.* Aedes albopictus *in Mauritius*

As part of its Operational Plan for Prevention and Control of Chikungunya and Dengue, the Ministry of Health and Quality of Life in Mauritius is evaluating integrating the SIT to control *Ae. albopictus* populations; the objectives are to prevent outbreaks and the re-establishment of arboviruses in an island benefitting from large numbers of international visitors (Beesoon et al. 2008; Ramchurn et al. 2009). Several characteristics of Mauritius make it a very suitable country in which to test the feasibility of applying the SIT. Identifying potentially suitable sites for pilot-trial releases, and corresponding control areas, is straightforward due to the largely agricultural nature of the island of Mauritius. Small discrete villages exist, often located on the coast or surrounded by sugar cane fields providing geographical isolation. In some villages *Ae. albopictus* is the only Aedine mosquito present or at least the dominant species. Two suitable villages were selected for the first pilot trial: Pointe des Lascars (0.3 $km^2$, consisting of 203 houses and 800 inhabitants) and Panchvati (0.03 $km^2$, consisting of 67 houses and 270 inhabitants) (Iyaloo et al. 2014). The villages, located 1.6 km from each other, are well-matched in terms of the human

inhabitants, natural geography, infrastructure, and mosquito populations. Routine monitoring and mark-release-recapture experiments showed that the majority of ovitraps are positive for eggs throughout the year, with peaks in December-March and troughs in July-September (Iyaloo et al. 2019).

To determine survival and dispersal of sterile males in this ecological setting, three mark-release-recapture (MRR) experiments (Itô et al., this volume; Vreysen, this volume) were performed in Pointe des Lascars (Iyaloo et al. 2019). A release rate of 6000 males/ha was applied during the winter season, and at least twice that number in the summer. When assessed in a laboratory, marking males (with a fluorescent dust) did not affect their performance (Dowell et al., this volume). After applying a dose of 40 Gy with a gamma irradiator, tests showed that: (1) dispersal was not affected by irradiation, and (2) irradiated males survived up to 12 days; on average, unirradiated males survived 4 days longer (Bakri et al., this volume).

In parallel with baseline mosquito surveillance (using ovitraps and BG-Sentinel traps), a colony of mosquitoes from the pilot villages was established in a climate-controlled insectary at the Vector Biology and Control Division. For larval diets, two animal feeds were shown to be suitable and cost-effective (USD 1/kg); they are manufactured locally (important for an island nation) (Iyaloo and Facknath 2017). Mosquitoes were reared using the tray and rack system described by Balestrino et al. (2014b), and large commercially available adult cages. Sex separation of release cohorts, done on the basis of pupal size (using graded sieves), achieved a maximum of 4% female contamination. Adult females were further removed from the release cages with an aspirator. Batches of 2000 male pupae were irradiated at 30–40 hours old, as was done for the MRR trials, and allowed to emerge into small adult cages containing a sugar meal. Adults were transported to the field in the small cages for release 3 days after emergence.

Prior to the pilot trial, staff of the Ministry of Health and Quality of Life went from house to house (in the release and control sites) inviting people to attend sensitization meetings, held in the village hall, during which the project was explained, and also a cage of male mosquitoes was used to demonstrate that they do not bite. During the trial, field officers working in the pilot sites were mobilized to talk to the public at least once per week to hear and address any concerns (D. P. Ilyaloo, personal communication).

In the first mosquito SIT trial in Mauritius, IVM was applied during the first two months of the project, applying larval-source reduction, weekly *Bacillus thuringiensis israelensis* (*Bti*) applications, and biweekly pyrethroid fogging alongside sterile-male releases (Mangan and Bouyer, this volume). Each week, for 9 months, 60 000 sterile males were released, equally distributed among 10 release sites in Panchvati for the first 6 months and 20 sites for the remainder of the trial period. Ovitrap surveillance within (and in a 150-m radius around) Panchvati and within Pointe des Lascars, and biweekly 24-h collections using 8 BG-Sentinel traps in both villages, showed a significant decrease in oviposition and the adult population as a result of the IVM treatments. This was reversed in the control village when vector treatments were halted, but not in the village where sterile-male releases alone continued. Egg fertility remained stable throughout the trial period in Pointe des Lascars, but was significantly lower in Panchvati during the period of releases (except for a period in the immediate

aftermath of tropical cyclone Berguitta). During the period of sterile-male releases, induced sterility reached more than 30%, the number of eggs collected per ovitrap dropped by more than 50%, and adult catch was less than one half that in the control village (D. P. Ilyaloo, personal communication). Ovitraps in the area surrounding Panchvati tended to collect more eggs than within the village, suggesting that immigration of fertile females into the treatment area was acting against the population suppression efforts.

As in the Italian SIT pilot studies, releases were more effective the lower the initial population density at the target site; low densities enabled a higher release ratio given the rearing resources available, and possibly also a greater competitive advantage for the sterile insects. Permitting sterile males to mature, and take a sugar meal before release, improved mating competitiveness. In the ecological setting of Mauritius, initiating the targeted release of sterile males in the winter season is likely to be most effective in reducing the peak summer adult population, but sustained releases over several years would be required to sustainably reduce, or even locally eliminate, populations due to the stockpile of eggs of the wild population; these eggs are laid each season and hatch when the rains arrive.

### *3.3. Other Pilot Trials against Mosquitoes*

Many other pilot trials are ongoing or have been completed in various countries, and many more are in the planning stages (Table 1), indicating the current high level of interest and ongoing activities to develop and integrate the SIT and/or IIT, as well as transgenic approaches, against disease-transmitting mosquitoes.

## 4. LOOKING TO THE FUTURE

The major elements required to apply the SIT against major mosquito vectors of disease are in place. The remaining challenges, that need to be overcome before it can be applied operationally on a large scale, are just technical improvements and upscaling, particularly in terms of sex separation, methods of releasing males, and accurate monitoring of male populations.

The technology for mass-rearing mosquitoes is well advanced (section 2.1.1.; Parker, Mamai et al., this volume): mass-production of larvae in racks of large trays (Balestrino et al. 2014a), separation of larvae from pupae (Balestrino et al. 2011), and housing and feeding of adults for egg production and storage (Balestrino et al. 2014b; Maïga et al. 2017). Methodological improvements are ongoing to increase efficiency and decrease costs (directly and through automation to reduce the labour required). For example, the reuse or recycling of larval-rearing water (Mamai et al. 2017) is a significant factor in the feasibility of mass-rearing mosquitoes in water-limited environments. The costs of mass-rearing equipment are being reduced (Maïga et al. 2019) and adult and larval diets improved (Bimbilé Somda et al. 2017, 2019). Currently, two issues are still being addressed (to enable mass-deployment) -- the need for a sex-sorting system (section 4.1.) that is efficient on a large scale (particularly for Anophelines), and the development of technologies to release mosquitoes aerially using UAVs (Dowell et al., this volume).

*Table 1. SIT, IIT, and transgenic pilot trials against mosquitoes*

| Type of approach used | Mosquito species | Location | Trial staus | Reference |
|---|---|---|---|---|
| SIT pilots[1] | *Aedes aegypti* | Mexico | Concluded | FAO/IAEA 2018c |
| | *Aedes albopictus* | Italy, Mauritius | Concluded | Bellini 2013b; D. P. Iyaloo, personal communication |
| | | La Réunion (France), Germany, Greece, Italy, Montenegro, Spain | Ongoing | TIS 2019; R. Bellini, personal communication; I. Pla Mora, personal communication |
| SIT/IIT pilots | *Aedes aegypti* | Thailand | Concluded | Kittayapong et al. 2018; Kittayapong 2021 |
| | | Singapore | Ongoing | FAO/IAEA 2018c |

| | *Aedes polynesiensis* | Raiatea (French Polynesia) | Concluded | O'Connor et al. 2012 |
| | | Tetiaroa (French Polynesia) | Concluded | Bown 2019; Strugarek et al. 2019 |
| IIT pilots for population replacement -- releasing also *Wolbachia*-infected females | *Aedes aegypti* | World Mosquito Programme -- Australia, Brazil, Colombia, India, Indonesia, Mexico, Pacific Islands, Sri Lanka, Vietnam | Ongoing | Flores and O'Neill 2018; WMP 2019 |
| Transgenic mosquito pilots | *Aedes aegypti* | Oxitec -- Brazil, Cayman Islands, Panama | Concluded | Harris et al. 2011; Carvalho et al. 2015; Gorman et al. 2015 |
| | | Oxitec – Brazil, Panama, USA | Ongoing | Oxitec 2019 |

[1]In addition, pilot SIT projects will begin in 2019 against *Ae. aegypti* in Brazil, Cuba, Indonesia, Malaysia, the Philippines, and the USA (Florida), and against *An. arabiensis* in South Africa.

The process of handling and transporting sterile males from a mass-rearing facility to release sites could be streamlined and standardized so as to minimize the impact on male survival and performance, and to enable upscaling the release technology. For example, handling could be minimized by loading sterilized male pupae into emergence cages; after emergence the adults can be fed a sugar meal and then chilled and concentrated into transport cassettes (with the emergence cages removed) which are loaded into ground- or aerial-release vehicles.

Aerial release of mosquitoes will enable the SIT to be applied in a wider range of circumstances, including situations where access by road is difficult or the labour costs of the fine-scale release of sterile males are prohibitive. A releasing system on a UAV was tested successfully in Brazil (FAO/IAEA 2016a, 2018a). The survival of aerially released *Ae. aegypti* males was not significantly different from that of males released on the ground, suggesting that the impact of the aerial release system on insect quality was minimal. Moreover, at a sterile:wild ratio of only 3:1, the induced egg sterility reached 50% in the release area; this is very promising (J. Bouyer, unpublished data). However, further fine-tuning of the technology and approach, and the likely involvement of the private sector, will be needed to produce reliable industrial versions of the release system, and enable it to be used, eventually also commercially, in operational vector-control programmes (Dowell et al., this volume).

The priority for the operational development of the SIT against mosquitoes is to upscale field trials, demonstrate impact on mosquito populations, and ultimately prevent cases of disease. The FAO/IAEA and WHO are presently collaborating to develop common operational guidance on applying the SIT to control mosquito-borne diseases, and to offer technical guidance to countries planning to integrate the SIT into their integrated management strategies. This guidance will cover all practical aspects relating to the trial and early application of the technology, e.g. production, transport, and release of sterile males, associated quality-control parameters, clearly defined entomological and epidemiological indicators of efficacy in large-scale entomological trials, and frameworks to assess risk, safety implications, and cost-effectiveness. Guidance will follow a phase-conditional approach, and will include strategies for community and media engagement, disease surveillance under large-scale deployment, monitoring, and evaluation of success, and a description of legal frameworks for registration and regulation related to operational SIT programmes (FAO/IAEA 2019b; Bouyer et al. 2020; WHO/IAEA 2020).

### *4.1. Need for Scalable and Effective Sex Separation*

Although perfect sex separation may not be an absolute requirement for the efficacy of the SIT, in the case of mosquitoes (where females are the vectors of disease) the tolerance for even low-level female contamination in the release population is very low (section 2.1.1.). Options for improved sex-sorting that are currently available include using classical genetics to produce a genetic sexing strain (GSS), such as the dieldrin-sexing strain in *An. arabiensis* (Yamada et al. 2012). This system was very effective in sorting males (resistant to rearing solutions containing 2 to 4 ppm dieldrin, unlike females) but presented two drawbacks: a reduced egg fertility and thus low strain productivity, and the presence of dieldrin residues on the released males and the

associated risk of bioaccumulation in the environment (Yamada et al. 2015). Another option is to exploit the fact that only female mosquitoes feed on blood, i.e. add a toxicant to the blood meal (Yamada et al. 2013); though effective on a small scale, this may not be feasible for mass-rearing, particularly where a 100% male-release population is absolutely required.

Significant effort is being expended to develop new methods of sex separation (Papathanos et al. 2009, 2018; Bourtzis and Tu 2018). Sorting systems have been developed in *Aedes* species based on their sexual dimorphism, attempting to improve on the Fay-Morlan separator (Fay and Morlan 1959; Focks 1980) for larger-scale rearing. They enable mature pupae to be separated automatically on the basis of sex (Fig. 3) (Araújo et al. 2018; Bellini et al. 2018; Zacarés et al. 2018); at small-scale rearing up to 99% of males are recovered, and contamination by females is lower than 0.1%. An automated sieving system has been developed to separate *Ae. aegypti* pupae on the basis of smaller (male) pupae being able to pass up through openings in a submerged surface while larger (female) pupae are trapped below (Justia Patents 2017; Debug-Verily 2019). Another automatic pupae sex-separator, that can sort up to 150 000 pupae per hour with a female contamination rate below 0.3%, has been developed for *Ae. albopictus* by Wolbaki Biotech in China (Baton et al. 2021).

The size difference between *Anopheles* male and female pupae is less pronounced, and they are less robust and more easily damaged, making such sorting impossible (Mashatola et al. 2018). However, a similar system is under development to sort mature pupae of a sexing strain expressing sexual dimorphism in eye colour (K. Bourtzis, personal communication), which may be more amenable for *Anopheles* sex sorting, and the two systems may be combined to further improve the purity of the male-only release population. Nevertheless, these sexing systems are based on the sorting of pupae, making it necessary to produce female larvae; if females could be removed earlier in development, production costs could potentially be reduced by one half. Also, these methods are labour-intensive; it is very challenging to remove every female without losing a large proportion of males, further escalating the rearing costs.

Mechanical systems are unlikely ever to separate the sexes with 100% efficiency, and certainly not on a large scale; a few females will always be released. There is then a danger of "population replacement" when using only the IIT, but when the IIT and radiation-sterilization are combined, this cannot happen – any released females are sterile (and cannot transmit disease because of the *Wolbachia* infection) (section 4.2.).

A more efficient method of separation will be required before the SIT can be applied to mosquitoes on an operational scale, most likely relying on a GSS. A GSS in *An. albimanus* was produced in the 1970s for the SIT project in El Salvador but was lost after the trial was terminated (Dame et al. 2009). Producing GSSs by classical genetics is lengthy and labour-intensive because it relies on mutagenizing and screening large numbers of individual families (due to the low probability of mutagenesis producing the desired linkage event) (Lebon et al. 2018; Ndo et al. 2018). In *Aedes*, species sex is determined by a male-determining factor located on a small, non-recombining M locus on chromosome 1 and not on a heteromorphic sex chromosome (Hall et al. 2015), making it more unlikely and therefore more laborious to achieve translocation of the selectable marker to the sex-determining chromosome (Papathanos et al. 2018).

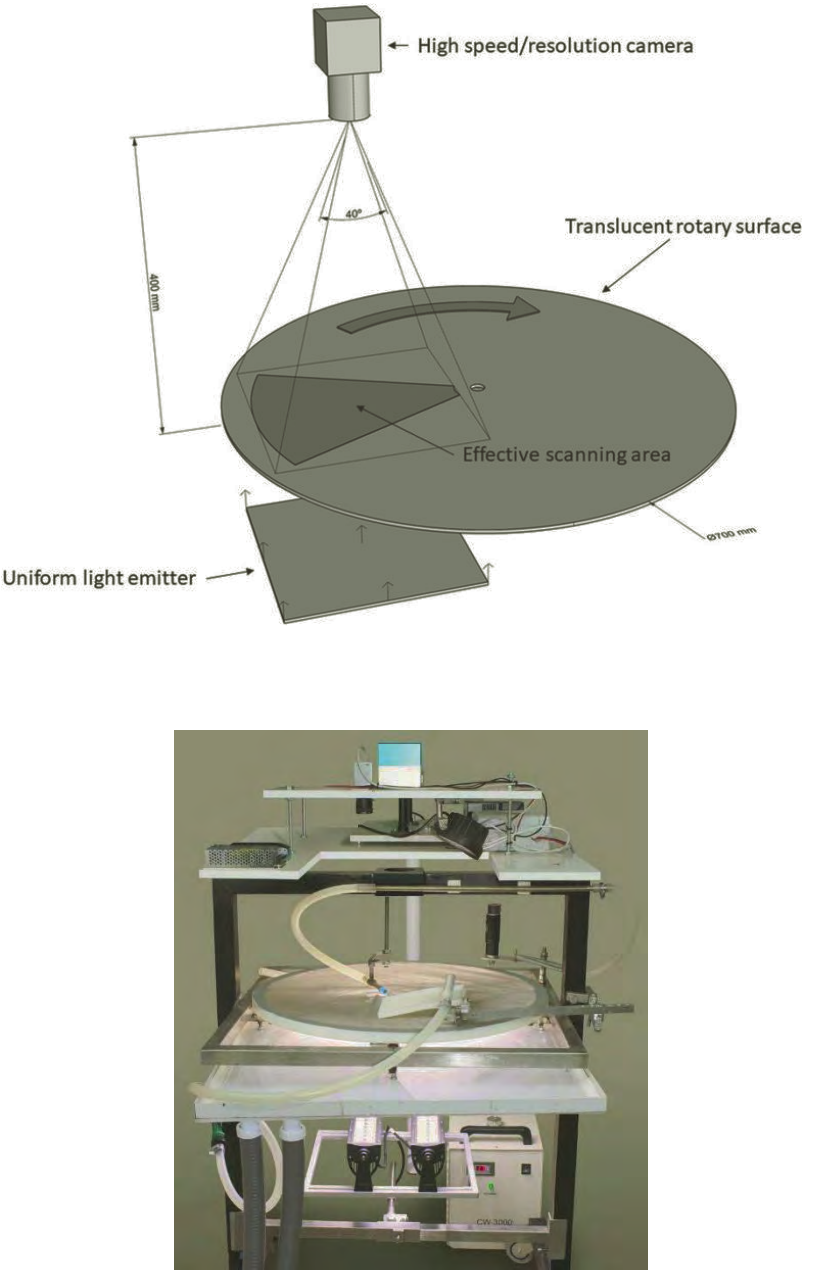

*Figure 3. Upper drawing: Camera set-up for sorting male and female* Aedes *pupae based on size dimorphism. (Drawing from Zacarés et al. 2018, reproduced with permission.) Lower photo: Prototype laser sex-sorting machine (Bourtzis 2019).*

However, a promising approach, using modern molecular techniques, is to identify *temperature-sensitive lethal* (*tsl)* genes, and to link them to sex-specific genes to enable the removal of females as first-instar larvae or even as embryos through classical genetics (as is done for *C. capitata* (Franz et al., this volume)). Modern molecular tools that can be used to produce transgenic as well as non-transgenic sexing strains have been widely reviewed (Catteruccia et al. 2009; Bernardini et al. 2018; Häcker and Schetelig 2018; Lutrat et al. 2019; Häcker et al., this volume).

An alternative approach could be to feed double-stranded RNAs (dsRNAs) to mosquito larvae (Whyard et al. 2015). By targeting both the testis genes and a female sex determination gene (*doublesex*) to induce RNA interference (RNAi), female development can be successfully inhibited (Häcker et al., this volume). To be effective, the dsRNA must be available constantly during relevant developmental stages to guarantee the silencing effect, though the cost of producing these dsRNAs may be reduced through the culture of transformed bacteria or yeast.

Flow cytometry machines (COPAS®, Union Biometrica) could be used for high-throughput separation of males from females based on the sex-specific expression of a fluorescence marker, e.g. sperm-specific expression in the testes (Marois et al. 2012). This approach is still being upscaled for mass-rearing, but relies on the use of transgenic strains, whose "open release" is limited or prohibited in some countries. Irradiating these transgenic strains to sterilize them before release would enable them to benefit from a non-GMO status in European countries, where only fertile material is considered as an organism. Under the Nagoya protocol (CBD 2014), even the release of sterile GMOs is tightly controlled, though their release is authorized in Europe (Lutrat et al. 2019). Using approaches such as CRISPR/Cas engineering, targeted mutagenesis through gene editing could be used to create GSSs which do not contain exogenous DNA and thus are not classed as transgenics, facilitating their acceptance for release (Kandul et al. 2019; Häcker et al., this volume).

### *4.2. Combined SIT/IIT Approach to Control* Aedes

In parallel with the increased interest in applying the SIT against mosquito vectors of disease, there has also been much interest in developing and applying the incompatible insect technique (IIT), and exploring its potential through *Wolbachia*-based approaches to enhance the SIT (Zabalou et al. 2004; Moretti et al. 2018; Baton et al. 2021). The IIT relies on cytoplasmic incompatibility (CI) between released males (which carry a *Wolbachia* infection) and wild females (with no infection, or a different and incompatible infection), thus resulting in sterile matings. Moreover, introduced *Wolbachia* infection makes females refractory to arboviral transmission. Starting in 2011 in Australia, field trials releasing *Wolbachia*-infected *Ae. aegypti* females and males have been successful at population replacement (Hoffmann et al. 2011). However, such *self-sustaining* releases (Alphey 2014) have the intent to establish permanently the *Wolbachia* strain in the target population, a process (that unlike the SIT) is irreversible and leaves an "ecological footprint". On the other hand, releasing only *Wolbachia*-infected males is *self-limiting,* and results in population suppression similar to the SIT, without any permanent changes in the target population (Bourtzis et

al. 2014, 2016); it is essential that only males are released, otherwise population replacement can take place.

Until effective genetic sexing strains become available for large-scale SIT application, combining the SIT with the IIT provides important benefits for an operational scale (Arunachalam and Curtis 1985; Bourtzis and Robinson 2006; Brelsfoard et al. 2009). A strain of *Ae. albopictus,* carrying three strains of *Wolbachia* (*w*AlbA, *w*AlbB, and *w*PiP), has been shown to express strong cytoplasmic incompatibility and good mating competitiveness in semi-field tests after irradiation at 28 Gy (a fully sterilizing dose for females) (Zhang et al. 2016). Thus, due to the sterility given to males by cytoplasmic incompatibility, a lower irradiation dose can be used to sterilize females, minimizing the impact on male performance (Zhang et al. 2015a, b). At the same time, including the IIT precludes potential disease transmission by any inadvertently released females (which make up at least 1% of the release population in upscaled SIT releases using current sexing systems). On the other hand, simultaneous sterilization guarantees that such inadvertently released females cannot reproduce; this will prevent *Wolbachia* from becoming established in the target population (resulting in the loss of cytoplasmic incompatibility and creating resistance to the IIT approach) (Lees et al. 2015; Bourtzis et al. 2016; NEA 2018). However, in Europe, this approach is at present limited by the absence of regulation.

An early pilot trial of the combined IIT and SIT approach against *Ae. aegypti*, conducted in a village in Chachoengsao Province, eastern Thailand, showed a significant reduction in hatch rate, and a lower total adult catch, during 6 months of weekly releases compared with the control area (Kittayapong et al. 2018; Kittayapong 2021). Released males were infected with *Wolbachia* collected from a local *Ae. albopictus* strain, irradiated as pupae with 70 Gy using gamma rays, and confirmed to be sterile by crossing a sample of each release cohort with non-irradiated *Wolbachia*-infected females to score fertility. In a small-cage laboratory test, released males were shown to be equally competitive to non-irradiated *Wolbachia*-infected males. A total of 10 000–25 000 one-day-old males was released (100–200 per household per week) for 6 months from delivery containers in which pupae had emerged and been provided with a sugar feed. Local support was garnered in the pilot site through strong community engagement and public awareness activities, even involving householders in the releases (Dyck, Regidor Fernández et al., this volume). Adult abundance was monitored monthly using sticky traps, and collections were made with portable vacuum aspirators. Ovitraps were collected weekly to monitor hatch rate (Vreysen, this volume).

### *4.3. New Opportunities in the Integrated Management of Mosquito-Borne Diseases Offered by the SIT*

The SIT technology is ready to be applied in pilot trials and small-scale population suppression programmes for integrated mosquito control (FAO/IAEA 2015; Lees et al. 2015). In the efforts to control malaria, the SIT may, under specific conditions (particularly against exophilic species such as *An. arabiensis* where conventional control by insecticide-treated nets and indoor residual sprays is less effective), become a powerful adjunct to other technologies. This would be in accordance with the World

Health Organization's Roll Back Malaria strategy (Nabarro 1999), and more recently the WHO's Global Vector Control Response 2017–2030 (WHO 2017a), which promote integrated vector management rather than reliance on any single approach to control malaria. Given the advanced state of development of the SIT against *Ae. aegypti*, and in response to the widespread epidemic of the Zika disease in 2015–2016, FAO/IAEA proposed the technology as part of an integrated Zika management strategy (FAO/IAEA 2016b).

Advances in molecular biology and biotechnology have provided several potential genetic methods to manage mosquito populations, offering different opportunities and challenges relative to the SIT (Catteruccia et al. 2009; Alphey 2014; Bouyer and Marois 2018; Flores and O'Neill 2018; Häcker et al., this volume). Also, it has been proposed that the SIT can be boosted by treating the males with biocides, like juvenile hormone analogues or specific biopesticides like densovirus, before release (Bouyer and Lefrançois 2014; Bouyer et al. 2016). During mating, or even mating attempts, sterile males could transmit these biocides to females, which would in turn transfer them to oviposition sites. As an example, treating sterile male *Ae. albopictus* with pyriproxyfen may enable the number of males released into a given area to be reduced by more than ten-fold, and achieve a more reliable and sustainable impact on dengue transmission (Pleydell and Bouyer 2019). The principle has been tested with success on a very small scale against *Ae. aegypti* in Kentucky (Mains et al. 2015), and further trials are planned in Spain and France.

The fact that the SIT is self-limiting, unlike population replacement based on *Wolbachia* or gene drive of transgenic traits, is one of its advantages. However, this is also a drawback -- releases must be sustained over time, involving permanent costs to prevent disease transmission in a given area. Other advantages of the SIT are that it is species-specific, and has no regulatory requirements (unlike most other proposed genetic control methods that require approval for releases) (Reeves et al. 2012; Hendrichs and Robinson, this volume). Also, it has a positive public perception and no restrictions on intellectual property rights -- each country is able to use its own local mosquito strains to apply the technology.

Finally, random mutations, chromosome breakages, and gross gonad damage caused by radiation eliminates the risk of resistance development – unlike insecticides and potentially other genetic control methods (Alphey et al. 2011; Eckermann et al. 2014; Handler 2016; The Economist 2017; Häcker et al., this volume; Hendrichs and Robinson, this volume; Whitten and Mahon, this volume). Contrary to a wrong perception that this sterilization process is necessarily associated with a loss of competitiveness of the sterile males, field trials of alternative technologies, especially RIDL, demonstrated that competitiveness of transgenic males can be much lower than what has been observed with irradiated males (Benedict and Robinson 2003; Facchinelli et al. 2013). This is related primarily to the fact that in mosquitoes the SIT is based on local strains that are well-adapted to local environments, whereas transgenic strains have often been colonized for decades.

In other insects, e.g. tsetse flies, it has been demonstrated that a loss of competitiveness is usually the result of a combination of factors such as mass-rearing, handling, chilling, and transport rather than irradiation itself (Diallo et al. 2018). This will affect equally all genetic control methods based on the mass-release of males.

Optimizing the rearing conditions is critical to minimize the impact of laboratory adaptation and other manipulations on adult male quality (Bargielowski et al. 2011).

An understanding of the reasons for a negative correlation between competitiveness and the sterile:wild male ratio (seen in the SIT trials in Italy) will be instrumental for planning future mosquito control programmes that have an SIT component. One of the major hypotheses for this phenomenon is that a proportion of the female population might be protected from sterile males regardless of the release ratio because they are located in cryptic habitats, and it is difficult for the released sterile males to access these. This illustrates the importance of released sterile males matching the behaviour of wild males by, for example, aggregating in the same micro-habitats (Vreysen at al. 2011). Also, there probably is an optimum ratio of sterile to wild males beyond which no increase in the ratio results in a higher induced sterility. It is important to identify this optimal ratio because accurate estimates of sterile-male release densities would maximize the cost-efficiency of SIT projects.

Another reason might be immigration of fertile females into the target area from neighbouring sites where sterile males are not released (the females have a much higher dispersal capacity than males) (Honório et al. 2003). Therefore, a tailored distribution of sterile males in the target area and surroundings is needed so as to achieve an adequate overflooding ratio even where wild populations are at high densities, especially when releasing into urban settings characterized by many favourable cryptic micro-habitats. Hot spots with a high mosquito population density should be identified and targeted appropriately, although this is challenging with existing monitoring tools and is not currently achievable on a large scale.

The SIT is not a stand-alone technology, and needs to be applied in combination with other pest control methods as part of an area-wide integrated pest management (AW-IPM) approach (Hendrichs, Vreysen et al., this volume; Klassen and Vreysen, this volume; Mangan and Bouyer, this volume). In particular, population reduction achieved through public participation in larval-site reduction will usually be a prerequisite, and will require that there is a strong stakeholder engagement in all projects (Dyck, Regidor Fernández et al., this volume).

## 5. CONCLUSIONS

At present, many SIT pilot trials against mosquitoes are ongoing or in preparation (Table 1). These field trials will create important knowledge needed for future upscaling of the technology. The most illustrative recent example is the SIT/IIT pilot trial in China that successfully suppressed, and nearly eliminated, two field populations of *Ae. albopictus* over a two-year period. Millions of sterile males were released, with prior pupal irradiation. Community support for the SIT/IIT approach strongly increased following mosquito releases, as nuisance-biting decreased. This successful field trial has fully demonstrated the feasibility of area-wide application of SIT/IIT for mosquito vector control (Zheng et al. 2019).

Area-wide releases, focused on urban/suburban settings and touristic sites, appear particularly promising in terms of sustainable and cost-effective IVM with an SIT component (eventually provided commercially by the private sector), as they can protect many people concentrated in relatively small areas.

The potential impact of the successful control of mosquito vectors, through the combined use of the SIT and other control methods, can be estimated based on previous successful programmes. When the Panama Canal was constructed, mosquito control during a period of 5 y had a significant economic and social impact on the region – eliminating yellow fever and drastically reducing malaria transmission, enabling the Panama Canal to be completed, and promoting the development of the entire area (RES 2014). In Brazil in the 1930s and 1940s, similar benefits were seen when a broad range of strategies was used to eradicate the invasive *An. gambiae* (Hendrichs, Enkerlin et al., this volume). In each of these cases, the community saw these programmes as drastic, due to, for example, the use of military force to achieve the goals, but the resulting impact on morbidity and development overcame the negative reactions (Severo 1956; Ockenhouse et al. 2005; Griffing et al. 2015).

Between 1990 and 2010, the global burden from neglected tropical diseases declined by 27%; however, this reduction occurred mostly in upper-middle-income countries. If the latest WHO targets are met between 2010 and 2020, a 55% reduction in the global burden in each country would be achieved, with an even greater reduction in low- and lower-middle-income countries (Stolk et al. 2016). It is expected that including the SIT among methods used to control mosquitoes will contribute to achieving the WHO goal, and result in increased human well-being, reduced deaths from vector-borne diseases, and increased development in deeply affected areas.

## SUMMARY

Science-based modern agriculture and international trade in agricultural commodities have achieved that, even though the world population has doubled in the last 40 years, the absolute number of people in poverty and hunger has been falling steadily. The major challenge in the immediate future is to consolidate these positive gains, while simultaneously expanding sustainability through environment-friendly agricultural and public-health practices. Within this context, the sterile insect technique (SIT), as part of area-wide integrated pest management (AW-IPM) programmes, will continue to gain momentum for application against certain key insect pests. This is in response to the demands for cleaner food and a better environment, the need to facilitate increasing international trade by overcoming pest related trade barriers to the movement of agricultural commodities, and the imperative of dealing with the increasing invasion of invasive pests and disease vectors. As the use of the technology increases, changes will continue to be made to improve the overall efficiency of the technique for those species where the SIT is already being used, and to expand the use of the technique to new key species. Modern biotechnology and paratransgenesis will increasingly also contribute to improving SIT efficiency in terms of strain marking, genetic sexing, molecular sterilization and disease refractoriness. However, whereas the shipment and use of *Wolbachia*-infected male insects as part of combined SIT/IIT (Incompatible Insect Technique) strategies for disease vectors is making considerable progress, public opposition and regulatory hurdles have largely limited to a few countries the release of transgenic insects. There appears to be much promise in improving sterile male performance by exposing male insects to hormonal, nutritional, microbial, and semiochemical supplements. Furthermore, the management of mother colonies will be significantly improved to reduce the effects of colonization and to slow down mass-rearing effects on key behavioural parameters that often result in rapid colony deterioration. Progress will also need to be made in the cost-effectiveness of all components of SIT implementation, from cage design to facility design, and from programme planning to evaluation. The trend of increasingly using sterile insects for routine pest suppression rather than eradication, particularly in commercially important commodities, will favour the involvement of the private sector and hence accelerate these improvements. Commercial producers of beneficial insects will probably be the natural investors, in view of the complementarities with sterile insects, experience in managing living organisms, and understanding the biological control market. As programme implementation is logistically complex, management will remain the key issue determining the success or failure of any area-wide approach to insect control. Thus, in spite of the many successes achieved and to be expected, in many least-developed countries the SIT may be a technology that is "ahead of its time" and beyond the animal and public health, as well plant protection infrastructures. Failures in SIT application, mostly confined to such countries, have not been due to science but to the poor management of large-scale operations. Increased involvement of the private sector in such countries probably would assure effective implementation.

## 1. INTRODUCTION

It is likely that the use of sterile insects in area-wide integrated pest management (AW-IPM) programmes will continue growing as increasing constraints are placed on the use of chemical pesticides responding to the public's growing demands for a cleaner environment and residue-free food. Global food chains increasingly link agricultural production with powerful supermarket chains that compete to offer their customers higher quality food in terms of maximum residue levels of insecticides. Even without these constraints, resistance problems and the cost of development and

regulatory approval of new insecticides will continue to increase. Added to this, more species-specific methods to control key pests, such as mating disruption or sterile insects, will play a more important role to complement the increasing use of biological control agents, which are often disrupted by insecticide applications. Moreover, as a result of the global spread of mosquitoes and other vectors, vector-borne and zoonotic diseases are on the rise (Higgs 2018). In the absence of vaccines and efficient, safe and inexpensive drugs to combat the emerging diseases they transmit, interest in the genetic control of public health pests is undergoing a revival (Lees et al., this volume). Furthermore, the international standards that regulate global agricultural trade, including measures for pest management where these affect trade (under the World Trade Organization's (WTO) Agreement on Sanitary and Phytosanitary Standards (SPS), are having a major impact on agricultural production and trade, and this is creating an environment in which area-wide approaches to the management of insect pests have a comparative advantage (Devorshak 2007; Klassen and Vreysen, this volume).

With this expansion in the use of the technology, the basic components of the sterile insect technique (SIT) — mass-rearing and release of sterile insects — are hardly likely to change. However, changes will continue to be made to improve the overall effectiveness and efficiency of the technique for those species where the SIT is already being used, and research needs will be addressed to expand the use of the technique for new key pest species. For some potential candidate species, technical bottlenecks have already been identified that prevent the development of the technology, e.g. artificial rearing systems or obligate diapause, which often can be addressed by a concerted research effort, whereas other pest species, because of their biology, are not amenable to SIT application (Lance and McInnis, this volume).

Expanding globalization will inevitably lead to a further rise in the invasion of non-native or invasive insect pests into new areas, where they increasingly survive in previously inhospitable areas due to a changing climate. The concept of using the SIT against such pest incursions to preclude the establishment of such invasive populations has proven effective (Hendrichs, Enkerlin et al., this volume) and will probably gain increasing support. This can take the preventive approach of the California model in which sterile Mediterranean fruit flies *Ceratitis capitata* (Wiedemann) are continuously released in areas of high risk of establishment (due to the regular incursions into the region) (Dowell et al. 2000; Enkerlin, this volume). Alternatively, it can take the form of the Australian approach where the technology, expertise, and contingency plans are developed to be able to respond should an introduction of the Old World screwworm *Chrysomya bezziana* (Villeneuve) occur (Tweddle and Mahon 2000). The trend to counter the impact of increasing globalization, by moving plant protection "offshore" for risk mitigation of non-native pest incursions, will open up new opportunities to integrate the SIT into the process of creating pest free or low prevalence areas under a systems approach (FAO 2016a, b, 2017a), from which agricultural products can be safely exported.

Currently there is no interest from pesticide companies to become involved with the SIT technology, probably because it is not impacting on their market to any significant extent. Even with continued expansion, the SIT will remain a niche market. Commercial producers of pollinators and other beneficial insects will probably be the

natural investors, in view of their experience in managing living organisms and their understanding of the biological control market. Such companies aim to offer a complete "biological package", i.e. the SIT can be used to manage some of the major key pests, while the reduced insecticide applications allow a significant expansion of the sales of parasitoids and predators to control secondary pests. The use of sterile insects for routine pest suppression rather than eradication, thus creating a sustainable demand analogous to the current use of augmentative biological control, will favour the involvement of the private sector (Hendrichs et al. 1995). However, for commercial companies to become more involved in the SIT, some issues including intellectual property rights (IPR) and regulation may have to be addressed (Barnes 2007; Bassi et al. 2007) (although see section 2.6.).

Programmes with the strategic goal of eradication can suffer from the price of success, e.g. maintaining staff and infrastructure in the face of a successful but declining programme. In such cases it is important to have a long-term vision, developing alternative uses of the rearing facility and programmes for other relevant pests. Converting the pink bollworm *Pectinophora gossypiella* (Saunders) mass-rearing facility to navel orangeworm *Amyelois transitella* (Walker) production, and from melon fly *Zeugodacus* (formerly *Bactrocera*) *cucurbitae* (Coquillett) to sweet potato weevils, are examples in the USA and Japan, respectively.

For future expansion of the SIT, a major constraint that will always need to be addressed is the significant upfront cost of constructing a facility. Of course, industrial plants producing and formulating insecticides represent larger investments, and compared with the costs of insecticide development, the costs of SIT development are minimal. Nevertheless, raising funds is not easy, and so far most rearing facilities have been constructed with public funds, and the beneficiaries often pay, partially or fully, for the sterile insects and/or the field operations. (The costs to beneficiaries usually do not include costs for constructing the facility; this is in contrast to the costs of insecticide where the development costs are recovered in the pricing policy of the company). In some situations, true commercialization may be a way out of the dilemma (section 2.1.).

Another constraint that must be overcome at the start of an area-wide programme is to involve, and get the commitment of, all or at least a majority of stakeholders in the programme (Loosjes 2000). Again, this free-rider problem is not faced in a local pesticide situation; an individual farmer can make his/her own decision, and be approached on an individual basis by chemical companies.

Quality control protocols, both for the product, i.e. the sterile insect, and the process, i.e. the procedures used to produce, sterilize, and distribute the sterile insect, will need to be further improved, and in some way standardized (Parker, Vreysen et al., this volume). This has already been done for sterile fruit flies, where an internationally agreed set of protocols is used to monitor the quality of the sterile insect (FAO/IAEA/USDA 2019). It is reasonably straightforward to develop the protocols and to update them regularly. This is a pre-requisite for commercialization. Producers and users require harmonized protocols to measure sterile insect quality, and the increasing transboundary shipment and trade in sterile insects will gradually ensure that all programmes implement them (Enkerlin and Quinlan 2004; Dowell et al., this volume).

Management remains the key issue determining the success or failure of any area-wide approach to insect control (Dyck, Reyes Flores et al., this volume). Since the SIT is logistically complex and management intensive, its implementation requires flexible procedures and non-bureaucratic management structures. In general, the scientists who have been closely involved with developing the technology should not be responsible for programme implementation, as other skills are needed. Also, research activities should not be part of an operational programme; instead, a separate unit (but associated with the programme) is needed for problem-solving and continuous fine-tuning of procedures; technology can always be improved to increase cost-effectiveness. The "secret" is to find a balance between sterile insect quality and operational stability, predictability, and innovation (Rull et al. 2012).

## 2. UTILIZATION OF THE SIT TECHNOLOGY

### *2.1. Commercialization*

Almost all of the field programmes integrating the sit described in this book have been carried out by public-funded organizations, with or without some financial support from the direct beneficiaries. Although area-wide programmes often address a public good, in the long run full reliance on governments may not be sustainable. Furthermore, continued expansion of the technique will be facilitated when commercial enterprises become involved. Even if public funds are used initially to establish a programme, governments, to increase implementation efficiency, subcontract private companies to provide services or operate the whole programme or parts thereof. However, thus far commercialization of the sit has been a difficult concept to promote, for the following reasons: (1) there are no equivalent models through which commercial confidence can be generated, with the possible exception of the growing biological control industry (Steinberg and Cayol 2009), (2) currently there are only some international agreements or regulations for the production and transboundary shipment of sterile insects (but see section 2.6.), (3) only a very few detailed business plans for the production and use of sterile insects have been developed (FAO/IAEA 2008), (4) the initial capital cost of constructing a mass-rearing facility is rather high (although this can be mitigated by following a gradual modular approach, where new rearing modules are added only with expanding sterile insect demand (Tween 1987)), (5) some public-funded programmes have been providing sterile insects at subsidized prices, thus undercutting competition from private sector companies that have to sell at real prices that include the cost of capital (Barnes 2007; Bassi et al. 2007), and (6) the area-wide nature of sit programmes requires at least some degree of organization and coordinated participation of stakeholders. In spite of this list of constraints to the commercialization of sterile insect production, rather paradoxically there is currently no shortage of customers who would purchase sterile insects if they were available. While the use of sterile insects only for eradication of pest populations is normally not an attractive proposition for commercialization because these are time-limited programmes, the permanent use of sterile insects for suppression, containment and prevention programmes (Hendrichs, Vreysen et al., this volume) provides some continuity in the

need for sterile insects, and has already resulted in some private investment (Steinberg and Cayol 2009; Boersma 2021; Venter et al. 2021).

Commercialization of the SIT can involve the delivery of a complete package, or more likely be partitioned into several different components, depending on the type of programme. A commercial company could be responsible for rearing, shipping, emerging, and releasing sterile insects, and charge customers (who would only manage the field monitoring) according to the number of insects released or the area treated. This would be suitable where there are large agricultural areas growing mainly one crop, or where governments contract such turnkey operations to deal with pests of animal or public health importance. In an alternative strategy, a grower cooperative could buy sterile insects from a supplier, manage the monitoring and fly emergence, and subcontract the release activities; the Mediterranean fruit fly programme in Patagonia, Argentina, already follows such an approach. On the other hand, in The Netherlands, onion growers individually contract with a commercial producer of sterile onion maggots for the combined service of monitoring and suppression to guarantee maintaining the pest in their onion fields below a pre-agreed threshold level (Loosjes 2000; Fournier 2014; Everaarts 2016).

Another strategy that lends itself to commercialization is the production of eggs in a large facility for satellite facilities (maybe even in another country) which then only rear, sterilize, and release the insects. This removes the necessity for every programme to manage mother colonies and to maintain a large egg production colony, an expensive and highly skilled operation, especially if genetic sexing strains are being used (Caceres et al. 2004; sections 3.1.1. and 3.1.2.).

### *2.2. Non-Native Pest Incursions*

Globalization, increased movement of agricultural products, and changes in climatic conditions will all lead to increases in the spread of pests and in their ability to establish in new locations. This increasing problem of non-native or invasive species incursions and outbreaks is causing much concern; often no remedial actions can be taken when such a pest enters a new area, or no environment-friendly eradication tools are available that are acceptable to the public (Hendrichs, Enkerlin et al., this volume). A good example of how such problems can be addressed is the accidental introduction into Libya in the 1990s of the New World screwworm *Cochliomyia hominivorax* (Coquerel). In the case of this incursion, fortunately a solution was at hand; the technology was already available for this pest, and sterile pupae could be brought from Mexico. For the eradication in 1990–1991, 40 million irradiated pupae pre-packed in boxes for release were air-freighted from Mexico each week in aircraft (especially outfitted for long-distance transport of chicks). The insects were released in Libya, and the large outbreak was successfully eradicated (FAO 1992; Lindquist et al. 1992). Of course, the major drawback to this approach is that a monitoring and rearing/release system must be in place, and the procedures must be implemented rather quickly.

The Australian government has taken this proactive approach and developed offshore a mass-rearing system for the Old World screwworm; should there be an incursion of this devastating pest into the country, the needed expertise and experience

are available (Mahon and Ahmad 2000; Vargas-Terán et al., this volume). The recurrent incursions (through cargo ships) of the Asian gypsy moth *Lymantria dispar* (L.) into British Columbia, Canada, and north-western USA, but also as far as New Zealand, are also potential targets for integrating the SIT with repeated aerial *Bt* sprays, increasing the effectiveness of ongoing efforts to eradicate such outbreaks (Suckling 2003). New Zealand also has contractual arrangements in place with mass-rearing facilities in Australia in the case of early detections of incursions of Mediterranean and Queensland fruit flies *Bactrocera tryoni* (Froggatt) (Horner et al. 2016).

Countries or regions may decide to identify their most important non-native insect threats, and then in advance develop the required pest-specific technology and expertise, as well as the general legal and physical infrastructure, that provide some degree of remedial action (Suckling 2003; Horner et al. 2016). This could include the SIT; it has a unique ability to eradicate incipient outbreaks of non-native insects in an environment-friendly way and with minimum public resistance (Hendrichs, Enkerlin et al., this volume). For example, one of the most feared non-native pests is the false codling moth *Thaumatotibia leucotreta* (Meyrick), still largely confined to the southern part of the African continent. To prepare for any future outbreak, the US government has supported in South Africa the development of the SIT against this major polyphagous pest (Carpenter et al. 2007; Boersma 2021).

### *2.3. SIT Application to Environmental Problems*

Non-native insects, as well as causing problems for humans, their livestock and crops, can have a devastating impact on the environment. A textbook example of successful classical biological control is the deliberate introduction of the cactus moth *Cactoblastis cactorum* (Berg) to Australia to control invasive *Opuntia* cacti. However, after its accidental arrival in North America (where *Opuntia* cacti are endemic), *C. cactorum* has become an invasive pest. It has spread from the Caribbean to the south-eastern USA, attacking endangered cacti. If this pest reaches the American southwest and Mexico, it is expected that it will have a devastating effect on whole ecosystems based on *Opuntia* cacti. In response, radiation biology, mass-rearing, and pheromone studies have been carried out on *C. cactorum.* The aim is to apply SIT/inherited sterility to contain this environmental pest, in its westward spread along the Gulf of Mexico, before it reaches the south-western USA (Zimmermann et al. 2004; Bloem et al. 2007).

Since the SIT has virtually no environmental impact, it is an ideal tool for use in protected areas such as natural parks and biological reserves where other kinds of control are prohibited. One example is the eradication of an outbreak of the cactus moth on the island of Contoy, Mexico, which is a natural park where the mechanical removal of host cacti was not possible (Bello-Rivera et al. 2021). Other examples are some national parks in Africa where conventional tsetse control is no longer acceptable, but sterile insects can be released without any impact on biodiversity (Nagel and Peveling, this volume). Similarly, the SIT plays a special role in the large organic coffee production areas of Central America where suppressing the Mediterranean fruit fly using conventional bait sprays is prohibited.

SIT/inherited sterility also has considerable potential to assess under natural conditions the environmental impact of introducing non-native herbivores as biological control agents of invasive weeds (Hendrichs et al. 2009). There is increased awareness of possible risks of non-target effects (Follett and Duan 2000). To obtain importation and release permits for such species, increasingly stringent host specificity testing is required. Tests carried out under unnatural quarantine conditions often overestimate the host range, leading to rejection of effective candidates. Releasing sterile herbivores can be another risk-management tool for host-range assessment under natural conditions. There can be no leakage of genetic material into the gene pool because there is no native population present, and in the case of inherited sterility, released females are fully sterile. The survival of $F_1$ larvae under various abiotic and biotic conditions can be assessed, and if non-target species are attacked, releases can be suspended with no risk of permanent establishment.

This concept is being developed in Florida for an herbivore of the Brazilian peppertree *Schinus terebinthifolius* Raddi (Anacardiaceae), a major invasive non-native that is altering native plant communities in many subtropical regions. The South American leaf-rolling moth *Episimus utilis* Zimmerman (Tortricidae) has been imported into Florida for quarantine evaluation, and radiation biology studies have already been conducted to determine the dose that results in full female sterility (Moeri et al. 2009).

### *2.4. New Target Species*

The biological criteria, to be considered before embarking on an AW-IPM programme integrating the SIT for a particular species, are described by Lance and McInnis (this volume), but the external conditions under which a pest population can become a candidate for the SIT are changing continually. For example, problems in the citrus trade between Spain and the USA led to the incorporation of the SIT into the area-wide control of the Mediterranean fruit fly in Valencia's large citrus-growing areas (Juan-Blasco et al. 2014), which until then had been based largely on insecticide bait sprays. The same has been occurring in Morocco's main citrus exporting region in Agadir (Qadda et al. 2017). Therefore, increasing concerns about biosecurity, food safety, and residues will also impact positively on the economics and desirability of using sterile insects.

The rapid adoption and expansion in the area planted to crops expressing *Bt* toxins had been expected to reduce the demand in some candidate species for SIT integration. For example, the use of *Bt*-cotton would remove insect pests of this crop from consideration as potential SIT targets. Nevertheless, even though transgenic cotton is now planted annually on many million ha, there is increasing resistance developing in some of the targeted moth pests because the area-wide compliance of farmers in following the refuge strategy has not always been adequate (Tabashnik et al. 2010). The systematic maintenance of refuges, by planting non-*Bt* plants on parts of their fields, is supposed to delay development of pest resistance by producing susceptible insects to mate with resistant insects. Another disadvantage of this strategy, besides the potential for resistance development, is that populations of the pest need to be maintained so that refuges can fulfil their role (Fig. 1) (Wu 2010).

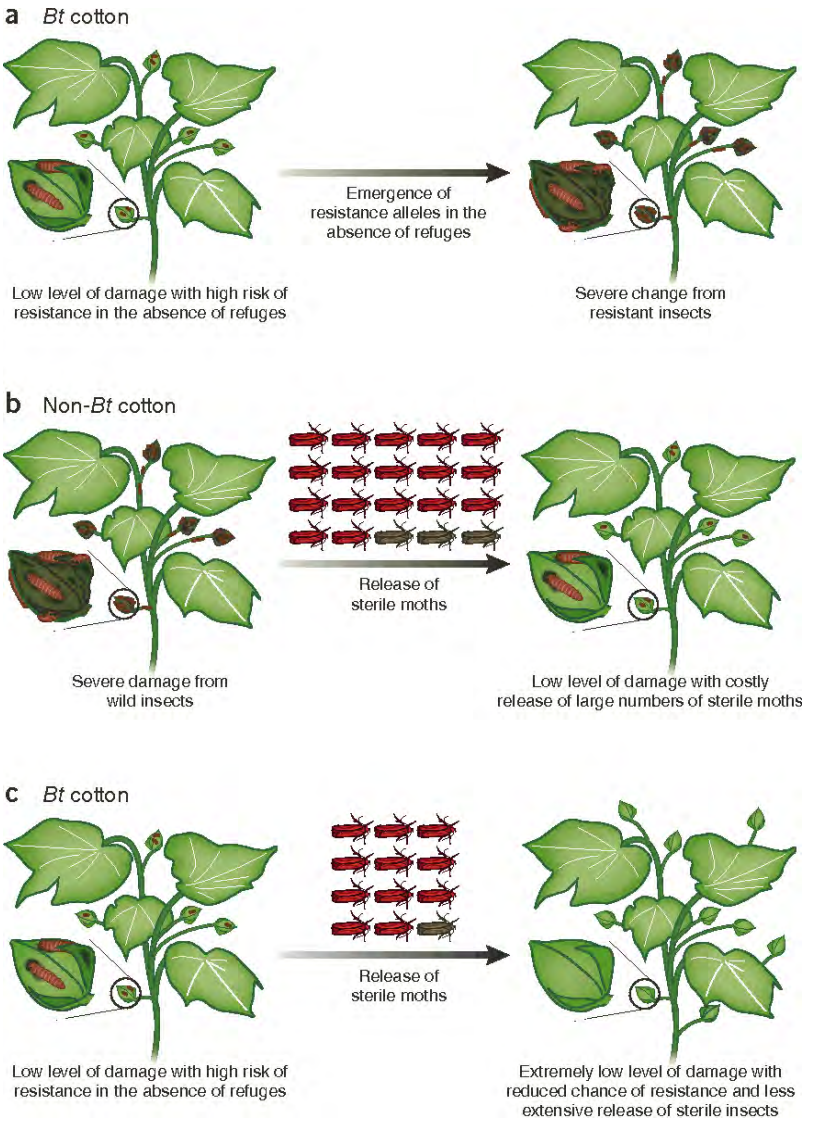

*Figure 1. Use of the SIT together with transgenic cotton expressing the* Bt *transgene suppresses the growth of the pink bollworm population and facilitates management of resistance to* Bt *toxin. The pink bollworm feeds only on cotton bolls and does not damage other tissues. (a) Sustainable use of* Bt*-cotton to control pink bollworm populations is threatened by the emergence of resistance. (b) Although costly, repeated release of sterile pink bollworm moths (red) in vast excess to the number of wild moths (brown) can suppress the growth of pink bollworm populations. (c) Combined use of* Bt*-cotton and the SIT ensures that the release of fewer sterile moths can suppress the growth of pink bollworm populations while preventing the emergence of resistance to* Bt *toxin. (Figure from Wu 2010, reproduced with permission.)*

An alternative strategy in such situations where refuges may be insufficient to mitigate permanently the development of resistance, and taking advantage of the *Bt*-suppressed pest populations, is to combine the use of the *Bt* crop with the simultaneous release of sterile insects so that they mate with, and suppress the reproduction of, the resistant insects (Fig. 1) (Tabashnik et al. 2010; Wu 2010).

This synergistic approach was successfully applied against the low pink bollworm populations (resulting from the extensive growing of *Bt*-cotton) and motivated the upgrading of the existing containment programme to an eradication programme (Henneberry 2007). The application of the complementary SIT, mating disruption, and transgenic technologies, requiring a less extensive release of sterile moths, succeeded in eradicating all populations of this pest from the south-western USA and northern Mexico, while also eliminating insecticide sprays against this key invasive pest (Staten and Walters 2021; Simmons et al., this volume). Therefore, while area-wide application of the SIT can help delay the establishment of resistance in a pest population exposed to *Bt* crops, and allows growers to avoid planting non-*Bt* refuges and the related damage, the area-wide expression of the *Bt* toxin without refuges suppresses drastically the pest population, thereby increasing efficacy and economic feasibility of SIT application (Wu 2010).

Pest lepidopterans constitute a major threat to many agricultural crops, resulting in the use of large amounts of insecticide. Currently there are already several operational programmes being implemented against this group of pests (Simmons et al., this volume), supported by much research that has been conducted in this area (IAEA 2002; Marec et al. 2005; Kean et al. 2007; Vreysen et al. 2010, 2016; Marec et al., this volume). Thus, the number of lepidopteran species, for which SIT technology will be developed, will probably increase, but this will be only gradual since its application is usually more expensive compared with dipteran species, transgenic crops primarily target moth pests, and mating disruption is most effective in lepidopteran pests (Cardé 2021).

Insect vectors of malaria and other human diseases continue to exact a huge toll in human lives and livelihoods, and in the 1970s many SIT pilot projects against vectors were implemented with varying degrees of success, including a very successful field trial in El Salvador (Weidhaas et al. 1974; Klassen et al., this volume). Since that time, many technologies related to SIT development and implementation have changed dramatically, and the use of this technology against important vectors is being re-evaluated. This trend will be accelerating because of the increasing burden of mosquito-borne diseases and the global spread of emerging diseases such as chikungunya, dengue, yellow fever and Zika, growing public awareness and concerns about the impact of chemical control on human health and the environment, the increasing incidences of resistance to insecticides, and recognition by the WHO (World Health Organization) and other major stakeholders of the need for more sustainable, effective and biologically based methods that are complementary to current control (WHO 2017).

The technical problems in suppressing mosquito populations using the release of sterile males are quite formidable, but significant progress is being made in developing the SIT and the combined SIT/IIT (Incompatible Insect Technique) (Zabalou et al. 2004) strategies for important vectors such as *Aedes aegypti* (L.), *Ae.*

*albopictus* (Skuse), and *Anopheles arabiensis* Patton (Bourtzis and Robinson 2006; Beier et al. 2014; Lees et al. 2015; Bourtzis et al. 2016; Zheng et al. 2019). The problems in developing and implementing the SIT are significantly smaller for *Aedes* than *Anopheles* populations, and a number of mosquito pilot programmes that are ongoing or in preparation are focusing mainly on suppressing *Aedes* populations in urban areas (Bellini et al. 2010; Lees et al., this volume).

### *2.5. Integration with Other Measures*

The SIT is always applied in combination with other methods of pest management; in eradication programmes it is often the final component of an integrated sequential approach (Mangan and Bouyer, this volume). Knipling (1992) suggested that the combinatorial approach involving the simultaneous release of natural enemies together with sterile insects may be extremely efficient in population suppression and eradication. Theoretical modelling (Barclay, this volume) has confirmed the effectiveness of this integration. While sterile insects have their impact on receptive adult females, parasitoids target the immature stages, and pathogens and predators all life stages of the pest. Although there has been limited experimental work to assess the veracity of this prediction, an expansion of this approach can be foreseen.

In Lepidoptera, where the release of partially sterile insects offers greater suppressive potential than the release of fully sterile insects, the synergism of combined augmentation of natural enemies and inherited sterility has been repeatedly demonstrated, with released biological control agents reproducing/feeding/infecting on sterile or substerile offspring (Mannion et al. 1995; Carpenter et al. 1996; Hamm and Carpenter 1997; Bloem et al. 1998; Seth and Barik 2009).

Seeding substerile or sterile supplemental hosts or prey in the field to increase the initial survival of inoculatively released biological control agents, or to increase the early build-up of native biological control agents in advance of pest population build-up, also has potential (Fatima et al. 2009). This approach is currently providing effective management of several species of sugar cane borers in a 40 000-ha area of sugar cane in Pakistan.

Integration of augmentative releases of natural enemies and sterile insects can also increasingly be expected in protected or greenhouse crops, where insecticide use must be avoided so as not to interfere with the release of pollinators and biocontrol agents controlling other pests (Kaspi and Parella 2006, 2008; Steinberg and Cayol 2009; Robinson 2018). Already a number of SIT studies are ongoing to address *Drosophila suzukii* (Matsumura) (Lanouette et al. 2017; Nikolouli et al. 2018) and other greenhouse pest problems, such as whiteflies (Calvitti et al. 2000), leafminers (Cagnotti et al. 2012; Walker 2012; Sultan et al. 2017), and the pepper weevil *Anthonomus eugenii* Cano (Robinson 2018), for which other biological control solutions are not available or sufficient as part of a complete biologically based control package. Also, in terms of integration of mass-production processes, biological control and the SIT can be complementary, reinforcing the applicability and cost-effectiveness of these augmentative technologies (Steinberg and Cayol 2009).

Today the control of mosquitoes relies heavily on the use of *Bti* for the suppression of immatures, and insecticide-treated bednets that target female mosquitoes during

their host-seeking behaviour. These technologies are very compatible with the release of sterile male mosquitoes; they do not seek the host for feeding but rather target the mate-seeking behaviour of female mosquitoes. Similarly, success in New World screwworm eradication programmes requires the simultaneous treatment of wounds with insecticides, which are directed at the immature stages, and the systematic release of sterile insects, which are directed at the adult stage.

There will be increased efforts to achieve field sterilization or inoculation through deploying pathogen- or chemosterilant-baited traps or autodissemination devices (Charmillot et al. 2002; Navarro-Llopis et al. 2011, 2015; Maniania and Ekesi 2013; Bouyer and Lefrançois 2014; Toledo et al. 2017). Such approaches attempt to achieve autosterilization and dissemination through slow-acting compounds (such as insect growth regulators, chitin synthesis inhibitors and pathogens) that are transferred by contact or the ingestion of a bait and spread in the target population through intraspecific interactions. In the case of chemosterilants, this effect can be especially complementary to the release of sterile insects because, unlike wild insects, they are not affected. Nevertheless, the potential for large-scale application is limited to special areas and situations; high-density deployment of such devices is not practical for area-wide implementation, and the environmental impacts on non-target species must be thoroughly assessed.

### *2.6. Regulatory Issues*

Future expansion of the SIT will be facilitated by a regulatory framework to support the commercial production, trade, shipment, and release of sterile insects. Historically, since they are not self-replicating, sterile insects were not considered to be biological control agents, and therefore not included in the regulatory framework provided by the International Plant Protection Convention (IPPC) in the form of International Standard for Phytosanitary Measures (ISPM) Number 3 "Code of Conduct for the Import and Release of Exotic Biological Control Agents" (FAO 1996), which specifically dealt with the import and release of biological control agents. Notwithstanding this lack of a regulatory framework, over the last 60 years there have been significant transboundary shipments of sterile insects, totalling over a trillion (million million) insects (Enkerlin and Quinlan 2004; FAO/IAEA 2018a). This significant international transport of live sterile insect pests testifies to the inherent safety of radiation-induced sterility and its general acceptance by the international plant protection community.

The increasing interest shown by some commercial companies in producing sterile insects emphasized the importance of having a regulatory framework. In response, in 2005, ISPM Number 3 was revised by representatives of national and regional plant protection organizations, resulting in the "Guidelines for the Export, Shipment, Import and Release of Biological Control Agents and Other Beneficial Organisms" (FAO 2017b). In this revised ISPM 3, the definition of biological control agents has been broadened, sterile insects have been specifically included as "beneficials", and the SIT is now officially accepted internationally as a type of biological control. In addition, the terms "sterile insect" and "sterile insect technique" have been defined for inclusion in the ISPM Glossary of Phytosanitary Terms (FAO 2017c; Klassen and Vreysen, this volume). Thus, the application of sterile insects as part of the integrated

management of plant pests is now recognized by the IPPC, and this should facilitate their transboundary shipment and use, especially in terms of their commercial use. Since this framework only covers those cases where plant pests are involved, the use of the SIT against insects of veterinary or public health importance, that are vectors of disease, will require other regulatory action, possibly through the Office Internationale des Épizooties (OIE) and the WHO. While the shipment and use of sterile and/or *Wolbachia*-infected male mosquitoes as part of the SIT, IIT (EPA 2017), or combined SIT/IIT strategies (Bourtzis et al. 2016; Zheng et al. 2019; Lees et al., this volume) for such vectors are recently making considerable progress, the lack of regulation has limited (largely to a few countries) the transport and release of transgenic male mosquitoes and other insects (Carvalho et al. 2015; Miller and Cohrssen 2018).

### *2.7. Resistance to the SIT*

The increased use of sterile insects to suppress pest populations may bring with it concerns about the development of resistance (Itô et al. 2003; Lance and McInnis, this volume; Whitten and Mahon, this volume). As suppression programmes by definition are long-term, this will provide opportunity for natural selection to select individuals that can, in some way, differentiate between a released sterile male and a fertile wild male. This may be especially relevant where an island population is targeted on an area-wide basis because it represents an isolated genetic environment (Itô et al., this volume). The danger for resistance to occur is probably more remote when a population is targeted for eradication, although the development of resistance in suppression programmes will be modulated by the occurrence of immigration and refugia from where "susceptible" individuals re-enter the target population.

For resistance to develop and be selected, three conditions must be fulfilled: (1) a recognizable difference or differences between a sterile male and a wild male that a wild female can recognize, (2) a fitness cost to the wild female if she mates with a sterile male, and (3) a genetic basis for the recognition of the sterile male by the wild female. It is not inconceivable that, for certain species, all these conditions could be met. For condition (1), routine application of quality management systems should identify any significant anomalies (Cáceres et al. 2007), allowing correction through the introduction of a new strain and better mother-colony management; for (2), as the fitness of a wild female mating with a sterile male is zero, this condition will always be met in a programme integrating the SIT, and for (3), for most species this is largely unknown. The development of resistance in a target population can be dealt with by re-colonizing a population from the target field site and replacing the original colony. This becomes slightly more problematic when specialized strains, such as genetic sexing strains, are used for release (Robinson et al. 1999). Field cage tests under semi-natural conditions, that continuously monitor the effectiveness of sterile males when competing with wild males to mate with wild females, become a very critical component of all programmes (Hendrichs et al. 2002).

In those programmes where sterile females are also released, tests need to evaluate the ability of wild males to discriminate between sterile females and wild females. If wild males mate only with wild females, but sterile males cannot distinguish and mate with both types of females, modelling indicates that a doubling of the sterile insect

release rate is required to overcome this wild male discrimination against sterile females (Vreysen et al. 2006).

## 3. TECHNICAL IMPROVEMENTS

### *3.1. Improving Insect Quality*

A critical factor determining the success or failure of a programme that includes an SIT component is the ability of the released sterile males to effectively inseminate wild females with sperm that is competitive with normal sperm (although in some species aspermic sterile males can also inhibit female remating at the same rate as normal matings involving sperm transfer (Itô et al. 1993)). This ability is generally termed "competitiveness", and is determined by many factors related both to the treatment of a particular cohort of released insects and the developmental history of the mass-reared strain used to produce the cohort for release. Both sets of factors can impact negatively on the competitive ability of released insects, and efforts will continue to be made to minimize these negative effects. As the "production philosophy" still tends to dominate decision-making, even though theoretical models continue to stress the importance of insect quality over the number of insects released (Itô et al., this volume), more efforts to educate decision-makers and managers are needed. A major component of any quality improvement strategy is to have in place a series of quality control protocols that can be used as a baseline to evaluate the effect of any experimental changes on insect quality (Cáceres et al. 2007; FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume).

Since quality refers only to a field parameter, then it would seem appropriate to develop field-based protocols for its assessment, unless laboratory-based protocols can be identified that correlate directly with field competitiveness (Boller and Chambers 1977). In the past, probably too much attention was focussed on laboratory-based protocols that had very little predictive value in terms of field performance. Quality is relative; it is dependent on the space and complexity of the testing arena. In a restricted space, for example in a small laboratory cage with a reduced distance between individuals, sterile males are often more effective than wild ones, but in larger cages the effectiveness of the same sterile males decreases significantly, and in field cages with vegetation it decreases even further (Soemori et al. 1980; Miyatake and Haraguchi 1996). It is also of little value to develop quality control parameters using only mass-reared insects, especially for species with a mating system in which the females choose among mating partners (Lance and McInnis, this volume). Therefore, the quality of mass-reared insects must increasingly be measured directly under semi-natural or natural conditions and in competition with wild insects (FAO/IAEA/USDA 2019; Parker, Vreysen et al., this volume).

In fruit flies, a standard field-cage system, including host plants, has been developed, where mass-reared sterile insects have to compete with wild insects (Cáceres et al. 2007; FAO/IAEA/USDA 2019). A similar system has also been developed for tsetse flies (Mutika et al. 2001). This type of approach needs to be expanded and refined to include semi-field cage systems that contain a cycling wild population, and in which the competitiveness of sterile insects can be maintained and

assessed. This has already been done for the Mediterranean fruit fly (McInnis et al. 2002) and for mosquitoes (Knols et al. 2002).

The key field parameter to assess the quality of mass-reared sterile males is the amount of sterility induced in wild females; improved protocols need to be developed that provide information on this parameter. In screwworms (collection of egg masses), tsetse flies (aberrations in the reproductive system of dissected wild females), and moths (mating tables), the opportunity to monitor the behaviour and fertility of a field population under challenge from sterile insect releases is a tremendous advantage to routine programme evaluation (Vreysen, this volume). In fruit flies, on the other hand, this is not practical, although molecular tools now allow identifying the origin of sperm in captured wild females as an indicator of the degree of induced sterility in the target population (San Andrés et al. 2007; Juan-Blasco et al. 2013, 2014). In mosquitoes, sugar-feeding of males before release with a rhodamine dye can be used to stain their sperm and seminal fluid that can then be detected in the wild females of the target population (Johnson et al. 2017).

To a limited extent, compensation for low insect quality is possible by releasing a larger number of sterile insects. However, there is a limit to this in terms of the overall economy of a programme, and there is a biological limit in that, below a certain quality value, increasing the number of released insects will simply not be effective (Barclay, this volume; Itô et al., this volume). In future, much more attention should be paid to sterile insect quality as opposed to quantity, irrespective of the cost of producing a specific insect.

The introduction of a colony mass-rearing protocol based on the filter rearing system, currently used to maintain stability in genetic sexing strains (Parker, Mamai et al., this volume), can also make a major contribution to the quality of mass-reared insects (section 3.1.2.).

### *3.1.1. Colony Initiation and Maintenance*

There are virtually no procedures or protocols on how to establish an initial colony of a species for future mass-rearing (McDonald 1976). Questions about the number of insects that should be sampled, where they should be sampled, and when the sampling should be done, remain largely unanswered. Even if guidance could be given on the above points, there is still the well-known phenomenon of a "bottleneck" which occurs during the first one or two generations of laboratory rearing, and which can negate the effects of any science-based approach to field sampling (Cayol 2000a; Rull and Barreda-Landa 2007; Hoffmann and Ross 2018; Parker, Mamai et al., this volume).

The answer to the question, "How many insects should be sampled?' is generally, "As many as possible". Of course this is not very satisfactory, and the number of insects used is usually influenced by the logistics involved in collecting insects in the field, coupled with the known size of the bottleneck that occurs during initial colonization. If the aim of the initial sampling of the field population is to sample the available genetic variability, then, based on population genetic studies of natural populations, samples of 20–100 insects generally reveal most of the genetic variability present in a field population, indicating that a sample in the hundreds is probably sufficient for most situations, provided that most individuals reproduce in the

laboratory. Then the major task becomes the preservation of that variability during initial colonization and subsequent mass-rearing in the laboratory (Hoffmann and Ross 2018).

From where in its distribution should the field population be sampled? Preferably this should be from the target population, although again logistics tends to determine the specific location of sampling sites and hence the parts of the insect distribution that are sampled. A related question to this concerns the strengths and weaknesses of using a single mass-reared strain for all regions where a particular species is a pest. This is especially important for species that are distributed worldwide, e.g. the codling moth *Cydia pomonella* (L.) and the Mediterranean fruit fly, and even for other species showing very discontinuous distributions. To a point, this can be tested by conducting mating compatibility studies, using the target populations from the different regions and the mass-reared strain (Cayol 2000b; Taret et al. 2010). Even if tests reveal no mating problems between the two populations, still programme managers often request that a particular genetic background be backcrossed into the strain to be used, despite the absence of any evidence that this is beneficial. In biological control circles, there has been much discussion on whether to sample marginal or central populations, but some of the hypotheses proposed to answer this question are, in practice, very difficult to test (Mackauer 1976).

The underlying assumption made during this discussion is that the level of genetic variability, per se, in the mass-reared colony is correlated with the overall quality of an insect once sterilized and released in the field, and hence is important to maintain. Krafsur and Ouma (this volume) challenge this assumption, and suggest that inbreeding, i.e. reduction of overall variability during colonization and mass-rearing, may not always affect competitiveness in the field. At the moment, probably there are insufficient data to make a general conclusion regarding the correlation of genetic variability in the mass-reared colony with competitiveness of the insects in the field. As suggested by Krafsur and Ouma, in the future, quality control procedures should be expanded to include routine measurements of genetic diversity in the colony over time, coupled with effective tests to monitor the competitiveness of the insect in the field. In the colonization strategy for the New World screwworm, procedures have been developed that involve the establishment of isofemale lines, followed by their evaluation and subsequent hybridization to establish a strain for mass-rearing (Mangan 1992).

The decision-making procedure, as to when a strain needs to be replaced, has to be improved. Since strain domestication or deterioration is normally correlated with the number of generations under selective mass-rearing conditions, at present programme managers usually establish a time-based replacement schedule. Better tools need to be developed to monitor the quality of released sterile insects in the field. A science-based and data-driven approach to strain initiation and replacement is needed (but see next section). Also, mother-colony maintenance procedures that slow strain deterioration should be developed, thus extending the life of a strain under mass-rearing. These will probably include a combination of the following actions:

- Maintaining founder/back-up strains under cryopreservation to guard against genetic drift and laboratory adaptation (Leopold et al. 2001; Leopold 2007),
- Holding mother colonies under relaxed, preferably semi-natural, rearing conditions that introduce some variation and complexity, and from which the rearing colonies are regularly derived (see filter rearing system below),
- Making simple modifications to the rearing processes and holding conditions of the mass-reared colony that reduce the selective pressures that result in directional changes in some of the key behavioural processes (Miyatake and Haraguchi 1996; Liedo et al. 2007), and
- Implementing an "active" quality control programme that establishes heritabilities and genetic correlations between desirable traits such as mating behaviour and traits that can be counter-selected during routine mass-rearing (Miyatake and Yamagishi 1993; Miyatake et al. 1997; McInnis et al. 2002; Sánchez-Rosario et al. 2017).

### *3.1.2. Strain Replacement Procedures and the Filter Rearing System (FRS)*

For all insect species that are mass-reared, the artificial environment of a facility presents the insect with a tremendous challenge, i.e. to adapt to the artificial conditions, both biotic and abiotic. Such conditions impose new selective pressures that are not present in nature (for example, high densities), while selective pressures that are strong in nature are weakened or absent (for example, predation) (Hoffmann and Ross 2018). While holding large colony sizes and refreshing them with new wild insects can help minimize genetic drift, they will generally not ameliorate adaptation (Schneider 2009). Therefore, successful colonization will inevitably result in the often rapid selection for adapted genotypes, and this can impact negatively on the competitiveness of a sterile insect once it is released in the field (Miyatake and Haraguchi 1996; Briceño and Eberhard 2002; Hoffmann and Ross 2018).

Most mass-rearing protocols follow the principle of large cycling colonies, whereby a proportion of the production is used for sterilization and release, while the remainder is returned to maintain the production colony. In this system, over time there is an inevitable accumulation of highly selected genotypes, such as early reproduction, faster development, and simplified courtship behaviour (Briceño and Eberhard 2002), some of which can significantly compromise the quality of the insects released in the field. This fact has prompted most operational programmes to replace their strains regularly, and to establish improved quality control procedures that monitor the overall competitiveness of the mass-reared strain. Strain replacement is a major logistical exercise, and invariably the new strain requires considerable time before it is as productive as the old strain. It is not clear how much of the overall quality of a strain is lost during this adaptation process, and how often a strain needs to be changed. Rull and Barreda-Landa (2007) found that new colonies established by exclusively crossing wild males and laboratory females enabled the restoration of male mating competitiveness without compromising mass-rearing production. Nevertheless, improved methodologies to monitor strain quality are needed.

As discussed by Franz et al. (this volume) and Parker, Mamai et al. (this volume), the use of genetic sexing strains in Mediterranean fruit fly programmes incorporating the SIT required the development of a filter rearing system (FRS) to maintain the

integrity of the sexing strain (Fisher and Caceres 2000; Caceres et al. 2004). The FRS relies on the maintenance of a mother colony that each generation is checked for unwanted individuals (which are then removed). Eggs from this colony are harvested as required, and following 3–4 generations of mass-rearing amplification the males are sterilized and released. In the FRS, no insects that have been through mass-rearing are returned to the mother colony, and therefore there is no accumulation of highly selected genotypes in the colony.

The FRS can, of course, be used for purposes other than maintenance of the integrity of genetic sexing strains, and can make a major contribution to the overall competitiveness of mass-reared strains. The mother colony can be kept under more natural environmental conditions, at reduced adult and larval densities, and with reduced selection pressure for genotypes adapted to mass-rearing conditions. In addition, a more natural environment, preferably under greenhouse conditions with hosts and natural light, could also help address the major problem of loss of irritability and predator-evasion behaviour in mass-reared insects, requiring significantly higher overflooding ratios as a result of the high mortality suffered by released insects due to predation (Hendrichs et al. 2007).

A major advantage of developing a mass-rearing system based on the FRS is that strain replacement becomes a much simpler procedure, and can be done without major disruption of the production process. The size of the population in the initial small mother colony will, of course, depend on the production level required in the facility, but it will probably not exceed several thousand individuals. Therefore, a new strain can be introduced into the FRS in a sequential manner during one generation, and there will be little interruption in production. This procedure has been used to introduce new Mediterranean fruit fly genetic sexing strains into production facilities (Caceres et al. 2004).

### *3.1.3. Larval Diets*

All insects that are mass-reared are maintained on an artificial diet. For most species, the larval and adult stages need to be fed. One exception is tsetse flies where larval development takes place in the female, and only adults need to feed. The larval diet of many species is an expensive component of mass-rearing costs, and presents logistical problems if the diet includes components that are poorly defined, requiring bioassays before undertaking large bulk purchases to verify their quality. From the perspective of quality control, defined diets would be preferable, but very few are available, and anyway these would be too costly for mass-rearing purposes. Nevertheless, one can foresee the commercial availability of pre-mixed diets (Thomas et al. 2018).

Disposal of large quantities of spent larval diet can also be a concern, although some facilities sell it as livestock feed, after sterilizing with a steam extruder or other method to kill any live insects remaining in the diet. Since the spent larval diet can still be rich in organic matter, recycling of some components has been considered (the larvae do not actually exploit part of the nutritional value of the diet), but the problem of metabolite accumulation in the diet has yet to be overcome, and thus far no effective practical procedure for any larval diet has been identified.

A challenge for the future of larval diets is to include micro-organisms that naturally contribute nutrients (Kyritsis et al. 2017; Stathopoulou et al. 2021; Augustinos et al., this volume). Inoculation of diets with such probiotic symbionts would not only reduce the need for diet preservatives, but also for the protein supplements, normally the costliest ingredient that larvae often only partially use (Chan Jr. et al. 2000). Whether such probiotic bacteria can be mass-produced cost-effectively for the larval diet, compared with protein supplements, is being investigated (Stathopoulou et al. 2021).

Books by Schneider (2009) and Cohen (2015) review and highlight many critical issues related to insect diet development and rearing. More research on ways to artificially rear several important pest species otherwise amenable to SIT application is required. The lack of cost-effective mass-rearing procedures for these species has been the major obstacle to the implementation of area-wide control programmes.

### *3.1.4. Post-Factory Sterile Male Performance*

By applying nutritional, probiotic, hormonal or semiochemical supplements or other bioactive materials to post-teneral sterile males before their release, there is a great potential to improve their subsequent performance or impact in the field (Pereira et al. 2013). Until recently, research on the critical period between the arrival of sterile pupae at emergence facilities and the release of adults in the field has been neglected. Current and future research could result in significant breakthroughs, and it may be possible to recover some of the quality deterioration that has occurred due to colonization, mass-rearing, and irradiation (FAO/IAEA 2017a; Pereira et al., this volume). Thus far, operational programmes have only gradually been adopting the findings already made on this subject.

Juvenile hormones (JH) are known to regulate the development of reproductive capacity and sexual signalling in Diptera and other insect orders. Hormonal treatments in the form of JH mimics such as methoprene, applied to emerging sterile males, have been shown to advance significantly sexual maturation. For example, in *Anastrepha* spp. fruit flies, treated males mate 5–7 days earlier than untreated males (Teal et al. 2000). Also, in *Bactrocera* spp., early sexual maturation is promoted by methoprene- or raspberry ketone-treatment of immature sterile males (Akter et al. 2017; Akter and Taylor 2018; Adnan et al. 2019). This acceleration of reproductive development is crucial for improved SIT application in insects with a long imaginal pre-maturation period, where normally a majority of released sterile males are lost to predation and other causes before they reach sexual maturity in the field (Hendrichs et al. 1993).

Nutritional supplements are equally critical for sexual development and signalling in anautogenous species, in which the imaginal stage has to forage for protein sources to be able to reach sexual maturity. Therefore, adding protein to the diet fed to sterile males prior to release often significantly increases sexual performance (Shelly et al. 2002a; Yuval et al. 2002; Gavriel et al. 2011), although the form of delivery and the ratio of protein to sugar requires fine-tuning for each species. Often in such insects the adults are adapted to ingesting bacteria as protein sources, generally a scarce resource under natural conditions (Lauzon et al. 2004). In tephritid flies this adaptation is reflected in mouthparts that allow the ingestion of only liquids and suspended particles less than 0.5 μm in size, such as bacteria of the Enterobacteriaceae

(Vijaysegaran et al. 1997; Coronado-Gonzales et al. 2008; Augustinos et al., this volume). Nevertheless, the importance of bacteria in the behavioural ecology of some target insects, for example their role in nitrogen fixation and by making other nutrients available through enzymatic degradation, is still not fully understood (Behar et al. 2005). Current mass-rearing practices may even be promoting non-beneficial or harmful bacteria. Thus, the inoculation of post-teneral diets with probiotic diets, i.e. a diet that contains beneficial gut micro-organisms, is an area with much potential to improve sterile male performance (Niyazi et al. 2004; Akami et al. 2019; Stathopoulou et al. 2021; Augustinos et al., this volume).

Combining hormone exposure and protein-enriched or probiotic adult diets results in synergistic interactions, thus increasing sterile male competitiveness many-fold when compared with either only protein or only hormone treatments (Teal et al. 2007; Haq and Hendrichs 2013; Haq et al. 2014). Such hormonal and nutritional therapies are affordable, easily incorporated into protocols followed at fly emergence and release facilities, and earlier release reduces costs associated with holding maturing sterile males (Pereira et al., this volume).

#### *3.1.5. Sterile Males as Carriers of Bioactive Materials*

There is also great potential to use semiochemical supplements or treatments to boost post-factory sterile male performance. Some species that are attracted to natural attractants sequester these as pheromone precursors into their pheromonal systems, and subsequently release them during courtship. For example, sterile males of *Bactrocera* spp. exposed to such components before release can significantly improve their mating competitiveness (Haq et al. 2018), and, in addition, such components can act as very potent allomones to deter predators (Tan 2000). Furthermore, pre-release exposure to such attractants can significantly reduce sterile male response to male-annihilation baits in the field (Shelly 1994). On the other hand, non-exposed wild males would still be attracted and killed by male annihilation technique (MAT) baits, thus potentially allowing a "male replacement" strategy, consisting of the simultaneous application of male annihilation and sterile male release. Modelling such a concurrent synergistic SIT/MAT implementation confirmed that it is an extremely powerful control strategy, enabling the sterile fly release rate to be reduced to only ca. 5% of that when the SIT is applied alone (Barclay et al. 2014).

The mating competitiveness of wild or mass-reared Mediterranean fruit fly males is similarly enhanced considerably by exposure of pre-release sterile males to ginger root oil and citrus peel oils (Papadopoulos et al. 2001; Shelly et al. 2002b; Kouloussis et al. 2013, 2017). This has great potential in increasing the cost-effectiveness of deploying sterile males, and even exposure to vapour has this effect on emerging males, thus enabling the development of an "aromatherapy" that has facilitated application in fly emergence and release facilities (Shelly et al. 2004a, b; Pereira et al., this volume). Another advantage of aromatherapy is that wild females mated initially with wild males are more likely to remate with ginger root oil-treated sterile males, and furthermore, initial matings with ginger root oil-treated sterile males reduce the likelihood of wild female remating with wild males (Shelly et al. 2004a, b). This is important since, in fruit flies, normally the final male partner fertilizes the majority of the eggs in multiple-mated females.

The identification of the stimulatory cuticular hydrocarbons in New World screwworm female flies, which elicit mating responses in screwworm males, opens the possibility of applying them to sterile females (Carlson et al. 2005). Commonly, after rearing a newly colonized screwworm strain for a few generations under mass-production conditions, screwworm females experience the loss of these cuticular pheromones, and only sterile males accept them as partners; wild males consistently reject them and mate only with wild females (Vreysen et al. 2006). Similar pheromonal compounds may exist in the ecological spheres of other pest species, and still await discovery for post-factory application to boost sterile insect performance.

Finally, there is a great potential to use sterile males or sterile females as carriers of various other bioactive materials (Knipling 1979). One possibility is autodissemination, in which sterile insects would be inoculated with electrostatically charged powder formulated with slow-acting insecticides or entomopathogens (Vickers et al. 2004), which would be spread throughout the pest population through intraspecific interactions (Howse et al. 2007; Bouyer and Lefrançois 2014). Large-scale field application against Mediterranean fruit flies showed that sterile males used as vectors or disseminators of *Beauveria bassiana* Vuillemin can result in effective area-wide suppression, with at least 57% of the wild fly population becoming infected in the treatment area, resulting in total population reduction of over 90%, compared with 0% infection in the non-treated area (Flores et al. 2013; Toledo et al. 2017). The additional cost when used in combination with the SIT appears low when compared with the benefit obtained from the complementary effect of using both techniques. Such a combined approach can obtain high levels of population suppression prior to the release of sterile insects, thus achieving favourable sterile-to-fertile ratios and sterility induction in the wild population (FAO/IAEA 2019).

Another possibility is autoconfusion, a type of mating disruption particularly suited for moth pests, in which released sterile males would carry on their bodies pheromone particles that attract wild males. This would transfer particles to them, and subsequently these males would contaminate other males, resulting in increased mating disruption (Knipling 1979; Howse et al. 2007). Since the few released males that would eventually encounter pheromone-calling females are sterile, autoconfusion and the SIT are clearly compatible. This approach may be more cost-effective for area-wide application than conventional mating disruption or even the establishment of a reduced number of dispensers in the field where wild males would get contaminated. A further possibility is simultaneous mating disruption of a moth pest and releases of another sterilized pest that is much cheaper to mass-rear (Suckling et al. 2011). The moth pheromone-inoculated sterile males, e.g. Mediterranean fruit flies, would significantly increase the mating disruption of the target moth pest population due to a higher overflooding ratio, and simultaneously suppress the local Mediterranean fruit fly population.

There are probably many other possibilities of applying bioactive materials to emerging sterile males, but so far these are mostly theoretical, and much research is required to explore the various possibilities and to assure the environment-friendliness of such approaches.

*3.1.6. Hybrid Vigour*

Hybrid vigour relies on the crossing of two inbred strains to produce an $F_1$ generation that exhibits increased fitness. It is a general phenomenon, used widely in plant breeding to improve the fitness of plants in the field. To be applied to the SIT, it would require that two inbred strains be reared in a facility, and a simple way exists to select males and females from both strains for directed mating to produce $F_1$ insects for sterilization and release. At present, in most species, it is not possible to do this automatically. However, it can be tested in the Mediterranean fruit fly, where genetic sexing strains are being mass-produced. In facilities using these strains, two separate sexing strains, both based on pupal colour and temperature sensitivity, could be maintained in separate production modules. In the generation before release, male pupae (brown) from one strain could be placed with female pupae (white) from the second strain, and vice versa, in adult cages and $F_1$ eggs collected. These could then be heat-treated, and the surviving males reared, sterilized, and released. This procedure could even be carried out without the need for a pupal colour sorter since there is a difference in the developmental time of white and brown pupae in the genetic sexing strains (Franz et al., this volume). Some protocols based on this principle have been evaluated (Mangan 1992; Zapater et al. 1996; McInnis et al. 2002; Gilchrist and Meats 2014; Ekechukwu et al. 2015; Sánchez-Rosario et al. 2017).

*3.1.7. Radiation Dose*

Radiation is one of the many contributing factors to reduced competitiveness of sterile insects; the higher the radiation dose, the more the competitiveness of the insect can be compromised. In most programmes, the radiation dose used produces almost full sterility (as measured by percentage egg hatch from a mating involving either an irradiated male or female insect). Even though this parameter is convenient, it is probably not the only one to use when deciding on the appropriate dose. Measuring egg hatch in the laboratory does not take into account factors such as male competitiveness and sperm competitiveness that, in the end, will combine to determine the hatchability of eggs produced by females of the wild population. These last two parameters will be the major factors in inducing sterility in the wild insects, and they must be taken into account when deciding on the radiation dose to be applied. If the dose is reduced below that which gives full egg sterility, a more competitive insect is released, which in the end induces more sterility in the wild population (Toledo et al. 2004; Rull et al. 2007; Yamada et al. 2014; Marec et al., this volume). Thus, an optimum radiation dose based on induced sterility should be identified for each particular species and strain (Rull et al. 2012). However, better decision-making tools are needed to be able to identify the optimum radiation dose (Parker and Mehta 2007). Of course, the rate of increase of the target population must be considered; it determines the effectiveness of various combinations of male sterility and release ratios in reducing the target population (Klassen and Creech 1973).

### *3.2. Improving Technology*

As well as improving the quality of sterile insects, progress will need to be made in all components of SIT implementation, from cage and facility design, to mass-production and other processes, and to programme planning and evaluation. Improved and more reliable air-handling systems in mass-rearing facilities can have a major impact on the efficiency and cost of rearing. Several facilities now have centralized systems where environmental conditions throughout the facility can be monitored and adjusted as necessary. This centralized system brings with it some disadvantages; other facilities have been built using a modular design (Tween 1987). Facility design, equipment needs, cost, and space allocation for the different production processes are key components. Interactive spreadsheets are now available to integrate the relevant data for various production volumes. This facilitates the planning, financing, construction, and equipping of rearing facilities that produce different numbers of sterile males (Cáceres et al. 2012), as well as managing operations and product quality based on the timely analysis of information (FAO/IAEA 2018b).

#### *3.2.1. Shelf-Life and Shipment*

In many areas of the world, pest problems are seasonal, and thus operational programmes need to release sterile insects only during specific times of the year. Nevertheless, insects can be produced year-round in a rearing facility; it makes economic sense to keep a facility productive for most of the year. In species that have a facultative diapause, this behavioural trait can be used to stockpile insects during the time when they are not required for release; this appears to have been achieved for the commercial production of the onion maggot. This trait can also be exploited when shipping sterile insects (Bloem et al. 1997). However, many tropical and subtropical pest species have no diapause, and these insects cannot be stored, although in some insects eggs can be stored indefinitely in a dry state, e.g. eggs of *Aedes* spp. Mosquitoes enter into dormancy after a drying process (Zheng et al. 2015). However, for temperate-climate species that have an obligate diapause, this prevents the development of mass-rearing technology and thus limits the application of the SIT. Research on developing strains of these species that do not enter diapause, or in which diapause termination can be induced, is therefore needed so as to overcome this barrier (Colinet et al. 2015; Chen et al. 2016; FAO/IAEA 2017b).

Sterile insects are often transported over long distances and across international borders (Dyck, Reyes Flores et al., this volume). This is usually done when the insect is in the late pupal stage, and some form of cooling and/or anoxia is used to prevent adult emergence during transit. This procedure can reduce insect quality, particularly if the transport period exceeds 48 hours. Pupae are usually shipped in cardboard containers containing cool packs to maintain a low temperature, and then the packing materials are discarded, sometimes creating a disposal problem. It would be desirable if durable equipment were designed that would maintain the correct temperature and atmospheric conditions, and increase the safety of insect shipments (Dowell et al., this volume). There are constraints in transporting biological material, both within and between some countries, and anything that can be done to overcome such constraints or improve the biosafety of shipments is valuable.

There is now another way to ship insects. Fertile eggs are being shipped from egg production facilities to larval rearing facilities that only rear, sterilize, and release sterile adults. The egg reception facilities do not need to maintain mother and large adult colonies for egg production, and this greatly simplifies their operational protocols. It has been demonstrated that Mediterranean fruit fly eggs can be shipped over long distances for extended periods of time without losing their viability and affecting the quality of the insects that are subsequently mass-reared. This concept permits the egg production facility to concentrate its efforts on the maintenance of a mother colony and a large colony for production purposes (section 3.1.2.). In principle, one large central facility could provide eggs to several satellite insect rearing and sterilizing facilities. This concept has already been put into practice in the Moscamed Programme in Guatemala and Mexico, where ca. 100 million heat-treated eggs from a genetic sexing strain maintained at the mass-rearing facility in Guatemala are shipped daily to the male-rearing facility in Tapachula, Mexico (Tween 2004).

### *3.2.2. Rearing Systems*

The hardware used to produce sterile insects is continually being modified and improved. In countries with high labour costs and good maintenance practices, partial to full automation of mass-rearing systems will become common. Even in less developed countries, some degree of automation for key processes will be required to provide improved consistency in sterile insect quality (IAEA 2003). There are two key biological components, i.e. egg production and larval rearing, where new design components would have a major impact on mass-rearing efficiency. At present, the cages used for maintaining production colonies often allow females to produce only a portion of their full egg potential. This is caused mainly by males harassing the ovipositing females (cages have a high insect density) and a shortening of the female adult lifespan. New cage designs that address these issues will have an immediate positive impact on rearing efficiency and insect quality (Liedo et al. 2007).

Larvae are usually reared on an artificial diet held in a container. When the larval period is complete, larvae leave the diet or are separated from it and allowed to pupate. This process can be costly, wasteful, and in some cases unpredictable. In some species, the larvae pupate in the diet, and special procedures are required to obtain adult insects, i.e. by positive phototaxis (Dowell et al., this volume). The development of a defined liquid diet held in a type of fermenter, in which the larvae grow to maturation before being separated from the diet, would be a major change in rearing philosophy. Unless unexpected problems in rearing systems arise, the status quo tends to be maintained. Facility managers must ensure that innovations and new concepts are continually evaluated (Parker, Mamai et al., this volume).

### *3.2.3. Sterilization*

Insects are usually sterilized by ionizing radiation produced from $^{60}Co$ or $^{137}Cs$ sources. These irradiators are effective, but have some disadvantages. They require a considerable amount of regulatory support. The radioactive source declines with time, and thus radiation times get longer; eventually the source has to be recharged, a

complicated and expensive procedure. It is becoming increasingly difficult to arrange for the international transport of this type of source to some parts of the world.

At present, exposure to ionizing radiation is the best way to sterilize insects. However, in view of the logistical difficulties associated with shipping and using radioactive sources, other options are being explored (Bakri et al., this volume). Electron beam technology to generate electrons, or photons such as X-rays, is an option. These systems are being encouraged because they do not involve any radioactive materials, only require access to electricity and cooling water, and can be switched on and off as needed (IAEA 2012). They require no complicated regulatory framework, and avoid the complex and costly shipment of radioactive sources across international borders. On the other hand, at present their availability is limited, they are relatively expensive to purchase and operate, and require substantial maintenance expertise. Nevertheless, increasingly, information on the development and use of alternative equipment to sterilize insects is becoming available (Mehta and Parker 2011; IAEA 2017).

Sterility can also be generated biologically through cytoplasmic incompatibility (CI), when different insect populations of the same species are mated that carry endosymbionts of the genus *Wolbachia* (Townson 2002; Robinson, this volume). *Wolbachia*-induced CI will be used increasingly as a tool for vector population suppression in a self-limiting way (IIT), in combination with radiation to avoid the release of any fertile females, as well as to avoid the transmission of animal, human or plant diseases (Bourtzis and Robinson 2006; Bourtzis et al. 2016; Lees et al., this volume), or as a self-sustaining drive system to deliberately replace a target population (Alphey 2014; Hoffmann et al. 2014). The development of molecular methods (Häcker et al., this volume) of sterilizing insects is discussed in section 4.3.

### *3.2.4. Release Technology*

The area-wide approach to pest management requires that sterile insects be distributed as adults over large areas; this is usually done by aircraft, guided by the Global Positioning System (GPS) and Geographic Information Systems (GIS) technologies that have significantly improved the precision of sterile insect distribution (Bouyer et al., this volume).

Most programmes release chilled adult sterile insects into the wild by means of small fixed-wing aircraft. While this is the fastest method of release, providing uniform distribution over target areas, for some situations it is not the most appropriate or cost-effective release platform. Depending on the target insect and the scale of the programme, there are alternative types of aerial vehicles that should be assessed further since they have the potential for significant cost savings (Tan and Tan 2013). In recent years, technological developments related to Remotely Piloted Aircraft Systems (RPAS) have created opportunities for their use in releasing sterile insects under specific conditions and regulatory frameworks (Benavente-Sánchez et al. 2021). Their disadvantages, such as reduced payload and flight duration, are counterbalanced by advantages such as accuracy, increased safety, and cost-efficiency for small- and medium-scale operations, with the largest cost saving represented by eliminating the need for a pilot and related wages and fuel consumption. However, mandatory special operational permits are required from regulatory agencies, in

particular for operations beyond the visual line of sight (Benavente-Sánchez et al. 2021; Dowell et al., this volume). Cheaper alternatives to currently used aircraft will enable widening applicability of the SIT to smaller-scale programmes, for example mosquito suppression operations that are focused largely on urban and suburban areas.

The current practice is to release sterile insects via an auger or conveyor belt from a chilled container in the aircraft, removing the need to hold and release insects in bulky biodegradable containers, saving airplane space and thus greatly reducing flying time and hence costs. This procedure requires that adult insects, after emergence from pupae, be collected and placed in the chilled container. The logistics of this procedure for very large numbers of insects are daunting, given that insect quality must be maintained at as high a level as possible. The technology to hold insects at a low temperature for several hours in an aircraft, and to achieve the required distribution over a release area, has greatly improved (Leal Mubarqui et al. 2014). Nevertheless, there is still a major concern about the negative impact on insect quality from the stress of low temperature and high insect density in the release machine (Andress et al. 2012, 2013; Shelly et al. 2013). The low temperature, when combined with a high humidity, results in water condensation that makes the insects wet. In the dense holding columns such wet insects become stuck together, exiting the release machine in clumps instead of a continuous stream. Also, because the moving augers of the mechanical delivery system can damage the insects, conveyor belts will be increasingly preferred (Leal Mubarqui et al. 2014).

One indication of the future is new systems that are based on cryogenics (such as liquid $CO_2$ to make dry ice pellets) as the cooling component. Also, passive chilling systems like those based on the use of phase-change materials can maintain the required cool-temperature range in the insect-holding container at a low payload cost (Tween and Rendón 2007; Benavente-Sánchez et al. 2021). They simplify maintenance, eliminate the high electric load on the aircraft, and allow greater control over temperature and humidity, thus minimizing damage to the sterile insects. The cryogenic system is in use in Guatemala, can deliver up to 50 million sterile *C. capitata* males per flight, and enables the simultaneous release of several species of sterile insects and parasitoids (Tween and Rendón 2007). Computer software linked to a satellite-guided aerial navigation system is programmed to deliver an adjustable number of sterile insects (as needed in each release block), and to turn off the release machine when outside the target blocks. The performances of the pilot, aircraft, and machine are recorded, and can be analysed after each flight (Dowell et al., this volume).

### *3.2.5. Field Monitoring*

The widespread use of GPS/GIS technologies has dramatically increased the accuracy and ease with which insect populations can be monitored before, during, and after the implementation of a programme (Bouyer et al., this volume). This increase in precision is enabling much better use of programme resources, and rapid decisions to modify programme activities are now possible. The use of bar-coded traps, and the ability to enter field data directly into hand-held computers for rapid downloading at the field centre, will increasingly make a major contribution to the accuracy and accessibility of data, and enable managers to monitor the efficiency of trapping

personnel. New technologies are also allowing the development of automated insect monitoring systems to provide real-time alerts of the presence and location of a pest, as conventional monitoring systems can result in delays in the information reaching decision-makers, potentially risking outbreaks and the loss of markets. Such technologies will increasingly be deployed in countries with high labour costs because manual checking of thousands of traps is labour intensive and also costly in terms of vehicles and logistics (Potamitis et al. 2017; Schellhorn and Jones 2021).

Field monitoring also requires effective methods to attract and trap insects of both sexes, and in many species there is active research on trapping methods. Data from traps are used to calculate the ratio of released to wild insects, and to directly monitor the relative size of the wild population (Vreysen, this volume). Traditionally, since females are responsible for population growth and hence damage levels, most emphasis has been placed on developing efficient female traps. However, when sterile insects are released, it is important to monitor males in the field. Nevertheless, when all-male releases of Mediterranean fruit flies are made, traps biased to preferentially collect females are useful to minimize the recapture of sterile males, and to facilitate discrimination between wild and recaptured sterile flies (Epsky et al. 2014).

During monitoring it is useful that released insects be easily and unequivocally differentiated from wild insects trapped in the field. (However, it is acknowledged that the New World screwworm eradication programme in Central America was implemented without marking the released sterile insects.) To accomplish this, usually larvae or pupae destined for release as sterile insects are marked with a dye (Dowell et al., this volume; Parker, Mamai et al., this volume; Vreysen, this volume). When trapped insects are brought in from the field, their origin is determined by examining them for the presence of the dye. This process is very labour intensive, expensive, and subject to significant errors of interpretation. Hagler and Jackson (2001) and Johnson et al. (2017) have described several new technologies that may be improvements on these dyes. Morphological markers have often been suggested as possible ways to monitor insects in the field, but usually they are associated with reduced competitiveness and therefore cannot be used effectively in the field. In the Mediterranean fruit fly, a phenotypic mutation has been isolated; it may be useful in the field since it does not appear to be associated with reduced competitiveness both during mass-rearing and in field-cage competition tests (Niyazi et al. 2005). Molecular methods offer a solution to marking for special situations, e.g. to identify the genetic origin of the sperm in spermatheca as an indicator of the degree of induced sterility in the target population (San Andrés et al. 2007; Juan-Blasco et al. 2013, 2014; Smidler et al. 2018; Häcker et al., this volume), but generally they are not practical for routine screening of large numbers of trapped insects. As indicated below (section 4.2.), markers involving the use of transgenic insects would involve regulatory problems.

#### *3.2.6. Suppression*

Before releasing sterile insects, it is essential to suppress the field pest population so as to facilitate achieving favourable sterile to wild insect overflooding ratios. Since the SIT must be carried out on an area-wide basis, suppression techniques are included in this same requirement (Mangan and Bouyer, this volume). The area-wide approach will often require that pest populations have to be suppressed in inaccessible areas and

also in areas where there is no human population. Although sterile insects can be successfully distributed by aircraft, the same is not always possible with a suppression "technology", e.g. in many countries, it is not permitted to conduct aerial spraying with traditional insecticides, especially over organic crops or sensitive areas. This puts severe restrictions on the type of suppression technology that is appropriate for area-wide application.

Another difficulty involves suppression activities in urban areas, where many vector breeding sites or host plants may be located. The human populations in these areas need to be persuaded that what can be a very intrusive intervention will eventually benefit the health or economy of their community, but better and more selective suppression methods are needed. There is considerable interest in developing, for use in such sensitive areas, bait stations that both attract and kill insect populations (Piñero et al. 2014). Mass-trapping in urban areas significantly reduced *Ae. aegypti* density and disease prevalence in mosquitoes (Barrera 2017). Also, autodissemination stations from which adult mosquitoes transfer juvenile hormone analogue or insect growth regulators between resting and oviposition sites have been shown to be effective (Devine et al. 2009). The method has since been validated against various *Aedes* species, but is quite expensive because high densities of deployed dissemination stations are necessary (given their low attractiveness) to achieve a good suppression level.

Additional suppression technologies that can be applied by aircraft are highly desirable, and this has led to the identification of a new insecticide-bait formulation that is quite selective for fruit fly suppression. Spinosad is an insecticide developed from the bacterium *Saccharopolyspora spinosa* Mertz and Yao, and it has been incorporated into a protein bait spray that has been organically certified (Peck and McQuate 2000; USDA/APHIS/PPQ 2000; Mangan and Bouyer, this volume; Nagel and Peveling, this volume). However, this insecticide is not immune to the resistance problem; strains resistant to spinosad were rapidly selected in the house fly *Musca domestica* L. (Shono and Scott 2003).

Mating disruption of lepidopteran pests, and male annihilation for *Bactrocera* spp. fruit flies, are other effective and more compatible suppression methods that can also be delivered from the air (Vargas et al. 2014; Cardé 2021; Staten and Walters 2021). Normally, the MAT is applied before sterile males are released; however, the simultaneous implementation of the SIT/MAT is highly synergistic when sterile males have been exposed to the parapheromone methyl eugenol before release (Barclay et al. 2014).

Effective tsetse fly suppression is now possible using the sequential aerosol technique (SAT), where extremely low amounts of pyrethroid insecticide are delivered by low-flying aircraft at certain times when climatic conditions are optimal (Allsopp and Phillemon-Motsu 2002). Effective suppression technology, and an "environment" in which it can be used, will always be an absolutely essential component of AW-IPM programmes integrating the SIT.

## 4. TRANSGENESIS AND GENE EDITING

During the last 30 years, modern biotechnology has developed molecular technologies that allowed first to routinely introduce foreign genes (transgenesis) into the germ line of many pest species (Hoy 1992; Robinson and Franz 2000; Robinson et al. 2004), and more recently site-specific genome editing techniques such as the CRISPR/Cas system (clustered regularly interspaced short palindromic repeats) that permit the precise editing of genomes at pre-defined positions (Meccariello et al. 2017; Nielsen 2021). There are also RNA interference approaches under development that do not change genomic information, but instead influence gene expression (Baum and Roberts 2014).

All these modern molecular technologies have significantly increased, and will continue to increase, the potential for understanding and modifying the genetic information in support of SIT application (Häcker et al., this volume). They can be used for self-sustaining approaches that aim at population replacement strategies, e.g. using gene drives or *Wolbachia*, or for self-limiting approaches, such as the SIT, that require continuous releases but aim at leaving no ecological footprint. These molecular technologies may benefit operational programmes in the four areas outlined below (Handler 2002; Häcker et al., this volume).

There has been much investment and speculation in this area, but until now very few transgenic or gene-edited strains of pest insects have been produced and field tested in pilot projects. Their wider adoption has been slow because of the low public acceptance of such approaches (NAS 2002) and the regulatory requirements and approvals that are needed in most countries for their application (Reeves et al. 2012; EFSA 2013); however, paradoxically, the release of sterile transgenic insects is probably one of the lowest risk strategies for transgenic organisms (Hoy 1995, 2000; FAO/IAEA 2006).

### *4.1. Genetic Sexing*

As described by Franz et al. (this volume), the SIT can often be made much more effective if only males are mass-reared and released (Rendón et al. 2004; Lance and McInnis, this volume). However, in mosquitoes and other vectors, where the females transmit disease, developing effective genetic sexing systems is essential (Lebon et al. 2018; Ndo et al. 2018). Traditionally, genetic sexing strains have been based on classical Mendelian genetics, and use a combination of selectable markers and male-linked translocations to achieve sex-linkage. These strains have disadvantages — the mass-reared colony is only 50% fertile, females in the colony are homozygous for the marker, and they show reduced viability. Most importantly, the systems are not transferable to other species. Considering that the Mendelian sexing systems can take many years to develop for a single species, this is probably the major disadvantage.

Genetic sexing using molecular approaches, although they have to overcome similar problems such as strain stability and competitiveness, are expected to be more generic, and thus transferable between different pest species. They can either be targeted towards killing females or transforming putative female zygotes into males, and both systems require conditionality to ensure maintenance of colonies. As in

conventional sexing strains, if females are targeted for killing, then lethality should be induced at an early stage, ideally in the egg, as very large numbers of zygotes can be treated together. This requires that early-acting sex-specific promoters are identified and placed under conditional control, as has been achieved for *Anastrepha suspensa* (Loew) (Schetelig and Handler 2012), and then transferred to *C. capitata* (Ogaugwu et al. 2013), *Lucilia cuprina* (Wiedemann) (Yan and Scott 2015), *Anastrepha ludens* (Loew) (Schetelig et al. 2016), and *C. hominivorax* (Concha et al. 2016). Also, much progress has been made recently in mosquitoes (Bourtzis and Tu 2018).

Transforming females into males has the advantage of doubling the male output, and in the future will increasingly be pursued. It requires a detailed knowledge of sex determination in the species under study (Meccariello et al. 2019). While the sex-determining factor appears to be highly conserved in Diptera, Lepidoptera, and Hymenoptera, its sequence is not, and there is considerable variation in the functional relationships (Shearman 2002; Verhulst et al. 2010). Nevertheless, sex reversion via a transient RNAi effect has already been performed successfully in *C. capitata* (Pane et al. 2002), *Bactrocera oleae* (Rossi) (Lagos et al. 2007), and *L. cuprina* (Concha and Scott 2009), resulting in fertile fully transformed XX males. The same sex transformation effects have been demonstrated in *C. capitata* following transgenesis (Saccone et al. 2005). Furthermore, a CRISPR/Cas-based X shredder, that shreds the X chromosome in sperm during spermatogenesis, or the targeted disruption of the expression of female fertility genes (resulting in sex ratio distortion), have been developed for the *Anopheles gambiae* complex (Galizi et al. 2016; Kyrou et al. 2018; Fasulo et al. 2021).

### *4.2. Marking*

As indicated above, sterile insects for release are usually marked with fluorescent powders or other dyes (Dowell et al., this volume; Parker, Mamai et al., this volume; Vreysen, this volume); however, they are not reliable, and daily exposure during mass-rearing may be harmful to workers. Molecular techniques enable marking with fluorescent proteins. Using such genetic markers for released insects requires that the marker be dominant, and that it can be monitored even in dead adults, as insects are usually dead when removed from traps. Transgenic strains carrying fluorescent markers have already been developed in a wide variety of insect pests (Häcker et al., this volume), and their stability in dead specimens after trapping has been confirmed by fluorescence microscopy and PCR (Meza et al. 2011; Simmons et al. 2011). However, the fitness cost to the insect for the production of this exogenous protein is unknown. Also, no data are available on the effect of this marker on the behaviour of the insect in the field, or indeed on the response of conspecifics or predators to fluorescent insects. Assessing this is especially relevant since insects use the UV spectrum for vision.

Strains with fluorescent sperm can also be used to monitor the mating success of the released males by screening the spermathecae of wild females (Juan-Blasco et al. 2013). Furthermore, sex-specific expression of fluorescent markers can allow automated sexing, as shown for immature stages or adults of *Ae. aegypti* (Smith et al.

2007), *Anopheles stephensi* Liston (Catteruccia et al. 2005), or *An. gambiae* (Marois et al. 2012) using the Complex Object Parametric Analyser and Sorter (COPAS).

### *4.3. Sterilization*

The use of ionizing radiation has proven to be an extremely effective way to sterilize insects for release in the field (Bakri et al., this volume). To reduce somatic damage, the procedure is done at as late a developmental stage as possible. This physical process is a fail-safe procedure when the correct protocols are followed. It is also not subject to the development of resistance, can be used on any strain, and does not interfere with the mass-rearing process. As with all the procedures to which released insects have to be subjected, radiation does have some negative effect on the competitiveness of treated insects. However, the detrimental effects of radiation have sometimes been exaggerated. The overall competitiveness of a released insect is determined by a whole combination of different factors related to factory adaptation, selection, mass-rearing, transport, and handling and release procedures, etc. Itô et al. (this volume) strongly make the case that reductions in competitiveness in the field are much more likely to be due to colonization and long-term mass-rearing effects, as well as post-factory handling, than to radiation.

Reproductive sterilization can also be achieved through genetic approaches, eliminating the need for irradiation. Any system to induce sterility in the field through dominant lethality must be conditional in some way so that efficient mass-rearing can be carried out. This conditionality can be achieved by using transcriptional activation or suppression systems based on the presence or absence of antibiotics in the larval diet (Heinrich and Scott 2000; Thomas et al. 2000). The permissive condition in the facility will require the presence of an antibiotic or its analogue during the mass-rearing of the colony, although not the male production for release. Following release of the transgenic males, the female progeny of a wild female mated with such a male would die in the absence of the antibiotic.

Horn and Wimmer (2003) engineered reproductive sterility in a *Drosophila* strain by transferring embryonically lethal transgenes, so that both male and female progeny die as embryos. Subsequently, this sterilization system was adapted and transferred to tephritid pests such as *C. capitata, A. ludens*, and *A. suspensa* (Schetelig et al. 2009, 2016; Schetelig and Handler 2012). Alternatively, transgenic strains developed based on the RIDL system (Release of Insects carrying a Dominant Lethal) (Thomas et al. 2000), are late-acting conditional lethality systems that kill progeny in late larval or pupal stages. They have been designed for *C. capitata* and *Ae. aegypti* (Gong et al. 2005; Phuc et al. 2007; Harris et al. 2012). However, some of these strains will require further refinement because they are not completely sterile in matings with wild females, and thus their genome may become incorporated into the target population (Evans et al. 2019). The lethality in the late larval stage is another disadvantage, resulting in damage from crop pests. Nevertheless, for *Ae. aegypti,* open-field trials with transgenic mosquitoes, carried out in Grand Cayman (Harris et al. 2012) and Brazil (Carvalho et al. 2015), achieved over 80% suppression of local populations. Open-field trials are also planned for a transgenic sexing strain of the New World screwworm in Panama (Concha et al. 2016).

A specific concern regarding these types of systems (that require the addition of a bioactive compound to very large volumes of larval diet) is the disposal of the diet, e.g. the Mediterranean fruit fly facility in Guatemala produces about 25 tons of diet per day. This is a real issue since mass-rearing facilities often sell spent larval diet as cattle feed. In addition, maintaining the appropriate concentration throughout the diet will not be easy. A third concern is the effect of the diet on the level of antibiotic. As the diet is a microcosm of bacterial and fungal growth, it will not be easy to standardize the exposure of the larvae to the antibiotic. It will also be important to choose the appropriate type of dominant lethality with which to kill the progeny in the field. Any genes involved in cell death mechanisms, or which show general cell toxicity, would probably not be suitable and/or would raise environmental concerns. Since effective sterilization of wild females remains the key to a successful programme that includes the release of sterile insects, there is no room for error in the sterilization procedure, and any proposed biological system must be extremely robust, controllable, and accurate.

There has been much argument about the relative merits of using either biological or physical methods to induce lethality in field populations (Alphey and Andreasen 2002). While it may appear that the molecular approach has some potential advantages, it is important to distinguish the characteristics of these two methods in producing sterility in a field population. Both approaches, to be effective, must act in a dominant manner and induce lethality in eggs produced by wild females following mating with released males. The key difference, and the one that will finally determine whether the molecular approach has any practical value, is that molecular sterility is based on a single dominant factor. Any variation in the expression of the sterility factor following interaction with the large and heterogeneous genome in the field population will very quickly lead to selection for non-sensitive females and loss of sterility induction. This is a major weakness of any molecular approach; there is no practical way to evaluate the possibility that this might happen without compromising the eventual use of the technology. One solution that has been proposed is to introduce several constructs into the same individual, but the fitness costs of such multiple insertions still has to be determined.

In contrast, sterility produced by radiation is based on the action of an almost infinite number of dominant lethal mutations, and every released male carries a different set of sterilizing factors (Robinson 2002); thus, it is very difficult for a field population to develop any sort of resistance (Whitten and Mahon, this volume). Radiation-induced sterility has built-in redundancy, and in spite of some disadvantages it remains the only proven and environment-friendly technique for the introduction of sterility into field populations of pest insects.

### *4.4. Paratransgenesis*

A fourth area in which transgenic technology may benefit future programmes that include the release of sterile insects is manipulating their symbiotic organisms (Miller 2010; Augustinos et al., this volume; Häcker et al., this volume). Such mutualists are often required by some insect vectors for the transmission of important animal, human or plant diseases. Paratransgenesis of symbionts offers major possibilities to develop

vector strains that are refractory to transmission by introducing into the symbionts genes coding for proteins that prevent the vector from transmitting the pathogen. One example is *Rhodnius prolixus* Stål, an important insect vector of Chagas disease caused by *Trypanosoma cruzi*. *R. prolixus* is associated with the symbiont *Rhodococcus rhodnii*, which was modified to express proteins that are toxic to, or block the transmission of, *T. cruzi* (Beard et al. 2001). Another example is tsetse fly species, where the paratransgenesis has been developed to impede trypanosome transmission by blood-feeding sterile males (Abd-Alla et al. 2013; Demirbas-Uzel et al. 2018; De Vooght et al. 2018; Kariithi et al. 2018). Similar developments are in progress for several mosquito species using fungi, viruses, or bacteria (Wilke and Marrelli 2015).

An approach that is showing great potential is to harness, for paratransgenesis purposes, the *Wolbachia*-induced cytoplasmic incompatibility phenomenon that can be used to induce sterilization to suppress or modify natural populations (Zabalou et al. 2004; Bourtzis et al. 2016). Infection of *Ae. aegypti* by different *Wolbachia* strains can lead to several or different outcomes such as a shortened lifespan, resulting in: (1) a reduction in the female potential to transmit pathogens that must infect adult mosquitoes to complete their development cycle, (2) a limited susceptibility to infection with the dengue or chikungunya virus or the *Plasmodium* parasite, or (3) depending on the strain of *Wolbachia*, an induction of cytoplasmic incompatibility, apparently with no significant fitness cost and high horizontal transmission (Wilke and Marrelli 2015; Flores and O'Neill 2018). However, each specific vector situation endeavouring to use *Wolbachia* for paratransgenesis and cytoplasmic incompatibility will need to be assessed carefully (Hughes et al. 2014); also, there are cases where *Wolbachia* enhanced disease infection (Dodson et al. 2014).

Since 2011, the World Mosquito Program has been releasing successfully *Wolbachia*-infected *Ae. aegypti* males and females for population replacement in various pilot locations in Australia, and also more recently in Colombia and Indonesia (Flores and O'Neill 2018). Releases (for population suppression) of only male *Wolbachia*-infected *Ae. aegypti* are ongoing or planned in Brazil, China, Singapore, and the USA (Callaway 2016; Mains et al. 2016; Waltz 2017; Häcker et al., this volume; Lees et al., this volume).

### *4.5. Technical and Regulatory Constraints*

Any transgenic strain proposed for sterile insect release will have to meet stringent criteria regarding the expression of the specific trait that it carries and the overall quality of the strain itself. These are not inconsiderable technical constraints, as has been demonstrated for the introduction of sexing strains based on classical approaches (Franz et al., this volume). The impact of large-scale rearing under extremely stressful conditions, and the number of individuals reared (often exceeding millions/week), can uncover significant genetic and biological events that can never be induced and studied under typical laboratory conditions, and for which the consequences are at present unknown. It is safe to say that extensive evaluations of transgenic strains are required before they can be used operationally in the field.

Major constraints in using transgenic strains for area-wide field release, even when sterilized, are the often considerable opposition from the public and special interest groups such as organic farmers (Reeves and Phillipson 2017), as well as the regulatory aspect (Lehane and Aksoy 2012). Whereas there are no real regulatory constraints for strains based on classical approaches (section 2.6.), for transgenic strains there are a number of regulatory approvals required (Reeves et al. 2012) (that represent major hurdles to be overcome in a majority of countries) before transgenic insects can be released. Furthermore, regulatory frameworks for transgenic insects are not yet harmonized nationally and internationally (NAPPO 2007; EFSA 2013), usually requiring lengthy case-by-case evaluations.

An elegant way to overcome such constraints has been proposed in Lepidoptera, where females are the heterogametic sex. Transformation to develop sexing strains using dominant conditional lethals, only expressed in females, would result in only colony females carrying the transgenic constructs, with the resulting sterile males being non-transgenic (Marec et al. 2005). Alternatively, besides classical genetic approaches, other rapidly evolving non-transgenic technologies can be pursued for self-limiting strategies, such as CRISPR/Cas and RNAi approaches (Beetham 2018), although in Europe strains resulting from genome editing are being subject to the same stringent regulations as transgenic organisms. Fortunately, in many other countries, including Japan and the USA, such editing that results in small insertions or deletions will not be treated as transgenic organisms (Nature 2018), permitting, for example, the removal of genes required for sex determination to create non-transgenic sexing strains (Meccariello et al. 2019). RNAi methods also offer a way to work without transgenic organisms, as long as the dsRNA is not conditionally or constitutively expressed in the insect, and if it does not persist in the environment (Häcker et al., this volume).

On the other hand, there is the great potential in the future of using CRISPR/Cas gene drives for self-replicating purposes, to spread rapidly beneficial traits through interbreeding pest and vector populations, thereby eliminating the need for continuous mass-rearing and release. However, even though such approaches hold great promise for high impact and low cost, they have raised a number of societal concerns and regulatory demands that will necessitate careful consideration (James et al. 2018; Nielsen 2021). There are also technical issues that will first need to be overcome, such as the emergence of resistance and other evolutionary processes, before the application of such a promising approach can become reality (Champer et al. 2017).

## 5. CONCLUSIONS

Global trends towards a cleaner agriculture and less aggressive pest control will increase the demand for more target-specific, biologically based, and sustainable suppression methods such as the release of sterile insects. Globalization is resulting in more incursions and outbreaks of invasive pests, requiring effective and environment-friendly eradication tools such as the SIT. Furthermore, international trade is creating an environment in which area-wide approaches to the management of insect pests have a comparative advantage. Increasingly, overcoming technical and scientific constraints, and introducing new technological innovations such as refractory vectors,

diapause termination, sterile-insect stockpiling, and post-factory performance-boosting treatments for sterile males will enable the SIT to be used against new target pests, and improve cost-effectiveness against current targets.

Nevertheless, these innovations and improvements are no guarantee for the successful implementation of the SIT as part of AW-IPM programmes. These programmes are management-intensive compared with most other control operations. Close coordination among many simultaneously occurring activities is required; their execution requires precision in time and space. Since the area-wide approach also depends on the cooperation and participation of all stakeholders in the target area, excellent management of communications with all stakeholders is indispensable, paying close attention to political, socio-economic, and environmental sensitivities. Therefore, effective programme implementation depends on the establishment of an efficient management structure that is semi-independent of normal government bureaucracy and corruption; mosquito abatement districts are good examples of effective and largely autonomous self-governing programmes (Foley IV et al. 2021). A common denominator of failed SIT projects has been the lack of such dynamic management structures and dedicated leadership to respond flexibly to changing situations. Equally important is transparency, external technical advice, and an effective oversight structure to maximize limited resources and to attract stakeholder funding (Dyck, Reyes Flores et al., this volume).

A major unexploited opportunity is the integration of sterile insects and augmentative biological control. As long as key pests are treated with insecticides, natural and augmentative biocontrol is disrupted, and hence there is only a limited potential for growth in the application of pollinators or natural enemies to deal with secondary pests. On the other hand, when a key pest is managed using biologically based tools (e.g. host resistance, mating disruption, sterile insects, etc.), natural and mass-reared biological control agents can complement these methods, and also play an important role in controlling less important pests. Thus, the existing augmentative biocontrol industry (ANBP 2018; IBMA 2018) and the SIT appear to be natural allies, and the expected gradual progress in commercializing the SIT will probably advance within this context. The private-sector biocontrol industry already has the technical "know how" to manage the mass-rearing, quality control, handling, and shipping of beneficials, and therefore could make significant contributions that improve and advance the SIT technology. Adding sterile insects to their products can provide a complete "biological package". A pioneer in this approach is BioBee in Israel, which is expanding from greenhouse to field pest management (Bassi et al. 2007; Steinberg and Cayol 2009).

Also, there is much unexploited potential in applying sterility to natural enemy production and facilitation. This involves using sterile insects not to transfer sterile sperm but as sterile hosts/prey/vectors for parasitoids/predators/pathogens to facilitate the use, and enhance the efficacy, of biological control agents (Hendrichs et al. 2009). At present, considerable research is being conducted to exploit the many potential possibilities and applications to facilitate natural enemy production, handling, and shipment, and also to provide sterile hosts for the establishment and maintenance over critical periods, or early season build-up (or in border or trap crops), of natural enemy populations in the field.
