From the above, intermediate points increase the detail of the detected antenna displacements of the receiver and allow for a more accurate representation of the dynamics of the instrument's point of origin. Increasing the detail of the detection of displacements is in fact an increase in the accuracy of the coordinates of the antenna attached to a dynamic object, as a more detailed trajectory at any given time shows a closer approximation to the real position of the antenna [13].

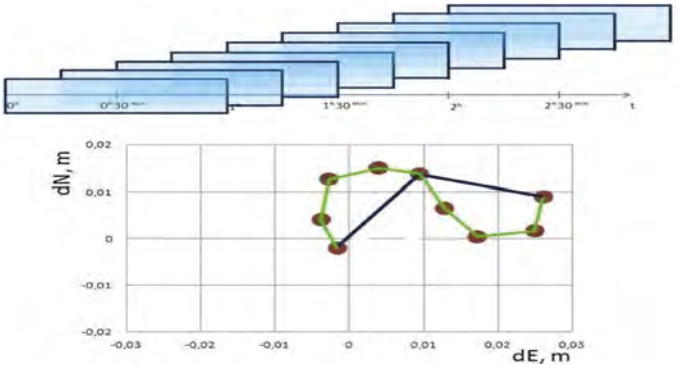

Figure 5. Diagram of displacements using the 1-hour interval treatment.

One of the parameters that characterise the accuracy of a measurement is the RMS value. According to theory, the RMS characterises the internal convergence of measurement results. If a systematic error is taken as a constant value, such as an error for signal over-reflection, this error will have a negligible effect on the RMS value. The RMS value may not be affected by a systematic error which is constant in magnitude, e.g. due to the effect of an over-reflected signal [14]. However, there is the potential for error in short acquisition sessions if the interreflected signal is active for the whole processing interval. One advantage of using the interval overlapping method is that the influence of the signal over-reflections on the measurement result is eliminated. This advantage is due to the fact that there will always be several intervals that include the start or end of an overreflected signal [15].

When selecting the interval length, it is worth paying attention to the drift rate of the permanently installed base station antenna. This value can vary depending on the type of object: for dams and low-rise buildings it can be millimetres, while for radio towers and TV towers the displacement is up to a metre. Accordingly, displacement rates are measured in mm/h to dm/h and, in exceptional cases, in m/h. Logically, when station displacement rates are high, processing using long intervals will produce poor quality results. In theory, the rate of change of position of some structural elements can be calculated from the original data on the parameters of the structure. However, as practice shows, these calculations do not always coincide with reality: this is due to many factors, for example, external conditions, period of operation, etc. [16].

In order to study the dependence of the interval value on the displacement velocity in more detail, test observations using GNSS receivers were carried out. In order to study the dependence of the interval limit value on the displacement rate of the receiver antenna attached to a dynamic object, we carried out observations using GNSS receivers capable of working simultaneously with the signals of most satellite geo-positioning systems.

From the results of the test field surveys, a graph was plotted showing the dependence of the interval value on the receiver antenna displacement rate (Figure 6). It allows determining the limit value of the processing interval depending on the displacement velocity of the structure. If, for a particular velocity, the interval length is greater than the limit values shown in the graph, an incorrect solution is likely [17].

For length intervals between 1 and 5 minutes, it is possible to process measurements even at high displacement rates, up to metres per hour. However, such results require input data with high accuracy and a clear signal. To summarise, the interval stacking method has a number of advantages but, like other methods, requires certain survey conditions. Sufficient number of satellites throughout the measurement period, monitoring network geometry, over-reflection of signals from extraneous objects - all this leads to a decrease in the accuracy of coordinate determination [18].

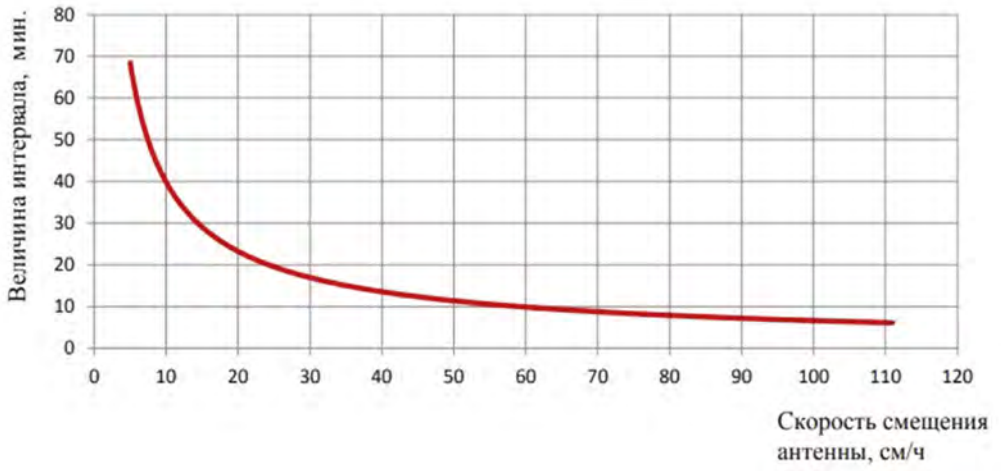

Figure 6. Plot of the interval value versus receiver antenna shift speed.

Developing a methodology to improve GNSS monitoring of dynamic objects

Zh.M. Aukazhiyeva, S.S. Sattarov, A.M Muratova & A.S. Sariyeva
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The issues and examples of remote monitoring, methods of technological improvement on the example of bridge structures are considered. After the analysis of the problems and examples of deformation monitoring was carried out, the next stage of the development of a technique for technological improvement began. As the analysis showed, the big problem of GNSS is the distortion of the signal from satellites. Also, international experience has shown under what conditions it is possible to use satellite coordinate determination. The first step in developing the methodology will be to study the conditions of monitoring and the object of research itself. And only then, starting from the specifics of the bridge structure, the optimal options for the provision of deformation monitoring with the use of satellite technologies will be considered.

1 LOCATION OF DEFORMATION MONITORING

The arch-cable-stayed bridge "Arkhar" is located in the center of the capital Astana and passes through the Ishim River. This object is one of several bridges connecting the left and right banks of the city. A four-lane highway runs along the bridge in two directions. Pedestrian paths are also laid along the edges. Figure 1 shows the bridge "Argali" [1].

Figure 1. "Argali" bridge in Astana.

DOI: 10.1201/9781003299127-329

The basis of the bridge design is two arches running along the bridge. Arches hold the roadbed with the help of a system of cables. This bridge is the first cable-stayed bridge built in the capital.

The width of the bridge is 40 meters with a length of the central part of 150 meters. During the development of the project, it was decided that the bridge would have an arched superstructure with a special configuration. According to the architects' plan, all connected structures and struts passing over the roadway were removed. This decision was made for the sake of a special architectural style. Therefore, special arches were designed for stability, located along the sidewalks on each side. One arched element consists of two interconnected flexible arches. The roadbed was supported by a cable-stayed system developed by the French company Freyssinet. This solution gave the lightness of the design and a positive perception from the point of view of architectural aesthetics. In fact, the bridge structure consists of two parallel arch bridges connected by a roadway with a beam cage.

Today, the bridge "Argali" is one of the main ways to cross the Ishim River. Every day, a relatively large flow of cars passes over the bridge. This is especially noticeable on weekdays, between 8:00-10:00 in the morning and in the evening at 19:00-21:00. These time intervals are considered rush hour, as many residents of the capital go to and from work. Consequently, in the morning and evening there will be fluctuations in the bridge due to the load of the traffic flow.

With regard to weather conditions, a sharply continental climate prevails in the capital. In summer, the temperature can reach up to +35 degrees Celsius. Solar activity exerts uneven heating on the bridge structure, resulting in deformation processes. It is also worth noting that Astana is located on a flat terrain. Therefore, a strong gusty wind is a normal phenomenon both in winter and in summer. The wind load causes fluctuations in the bridge structure. Such fluctuations are noticeable when walking across the bridge [2].

Having studied the features of the Argali Bridge and familiarized ourselves with the climatic conditions, we can begin to develop a methodology for technological improvement. During the development process, we will consider the above sources of error in GNSS surveys, and study ways to correct them. As a result, an up-to-date methodology for conducting deformation monitoring using GNSS technology for the Argali bridge is expected. As mentioned earlier, each object is a unique object, and in developing the methodology it is worth remembering this and starting from the real situation at the object.

Turning directly to the development, it is worth noting that satellite technologies represent a relatively new direction in geodesy. Satellite positioning technologies are becoming more advanced every year. And at the moment, the maximum accuracy of determining the coordinates of a point has reached a sub-centimeter indicator. Achieving such accuracy largely depends on the equipment used, since modern geodetic equipment is able to level the influence of errors to a minimum.

During the analysis of the problems of improving the GNSS monitoring methodology, it was decided to divide the workflow into two stages. The first stage is the technological improvement of field survey using GNSS. At this stage, possible improvements in point-by-point shooting will be considered. The second stage is the technological improvement of in–house processing with the use of up-to-date software. In the improvement plan, special attention will be paid to optimizing the processing of geodetic measurements, their further integration with GIS and final visualization.

2 IMPROVEMENT OF THE FIELD SURVEY METHODOLOGY

Technological improvement of the field GNSS survey technique consists in the selection of the optimal way to eliminate errors. To do this, let's go through each type of errors that occur during the geodetic survey. Figure 2 lists the main types of errors during GNSS shooting [3].

The main sources of satellite measurement errors are:

– desynchronization of satellite onboard clocks, ephemeris errors, unsuccessful geometric arrangement of satellites in the sky;
– errors resulting from signal delay when passing through the troposphere and ionosphere;
– errors related to the receiver (noise, signal re-reflection, etc.).

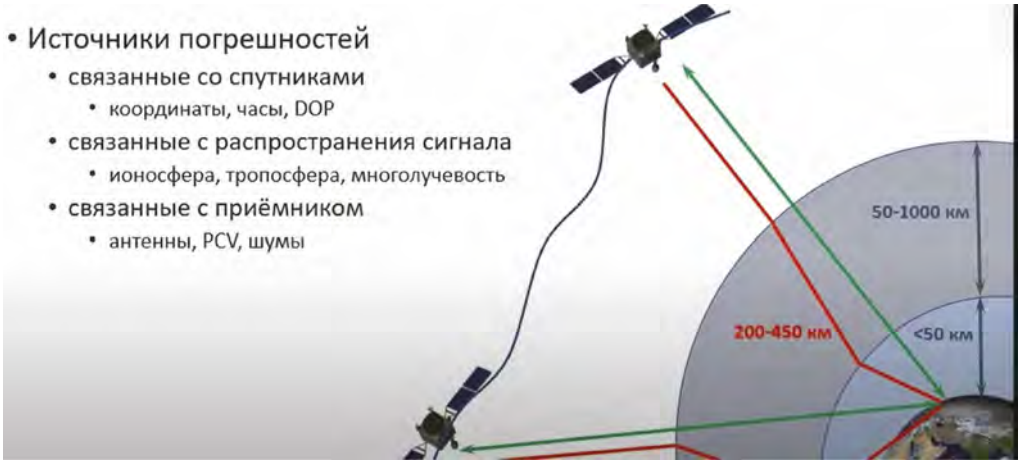

Figure 2. Sources of errors in GNSS shooting.

Let's start with the errors associated with the satellite segment. Ephemeris errors can be eliminated by updating the ephemeris database. Depending on the GNSS equipment used, the selection of current databases is made. Ephemeris data is available on the official websites of GPS, GLONASS, etc. Errors caused by the discrepancy between the clocks of the satellites and the receiver are leveled by calibrating the receiver. Therefore, when using geodetic equipment, it is always necessary to carry out alignment, after which several test measurements should be made at reference points. The error associated with the DOP (dilution of precision) indicator is eliminated by selecting the optimal shooting time. The DOP indicator itself means a concept used in the field of global positioning systems for parametric description of the geometric relative position of satellites relative to the receiver antenna. Figure 3 shows two examples of the location of satellites, where the first option is unsuccessful, since the close location of the satellites and a small angle give an incorrect result. Also, to work with GNSS, it is necessary that at least four satellites are available [4].

Next, in Table 1, we will look at the DOP values, which show us how optimal the spatial location of the satellites is. DOP indicators range from 1 to 50, where 1 is the best value.

Next, we will analyze the errors associated with the GNSS receiver. One of the common mistakes associated with the receiver antenna is the incorrect determination of the antenna phase center. Before installing the receiver in the operating state, it is necessary to determine the location of the phase center. This is usually done in the monitoring project setup menu. By default, the phase center of the antenna is located at the base of the receiver attachment to the vertex [5]. It is recommended to use this option, since when centering above the point, it will be easier to maintain the level of the axis relative to the plane of the device's standing. Also, the appearance of noise during the transmission of a radio signal is inevitable. But this error can be eliminated at the stage of desk work, since such measurements stand out strongly against the background of other correct ones. If the signal quality is poor, an additional antenna can be used [6].

Most of the listed errors can be compensated with the relative method of determining coordinates. Also, modern GNSS receivers coupled with controllers are able to eliminate the impact of gross errors. Most modern receivers operate at several frequencies at once, which helps to avoid the influence of signal delay through the ionosphere.

One of the most dangerous errors is the re-reflection of the signal, since the error greatly affects the accuracy. Multipath occurs as a rule in urban areas where there are many high-rise buildings. This problem is solved by correctly positioning the points in an open space. In our case, on the Argali Bridge, large distortions will occur under arched structures that overlap the horizon and the sky.

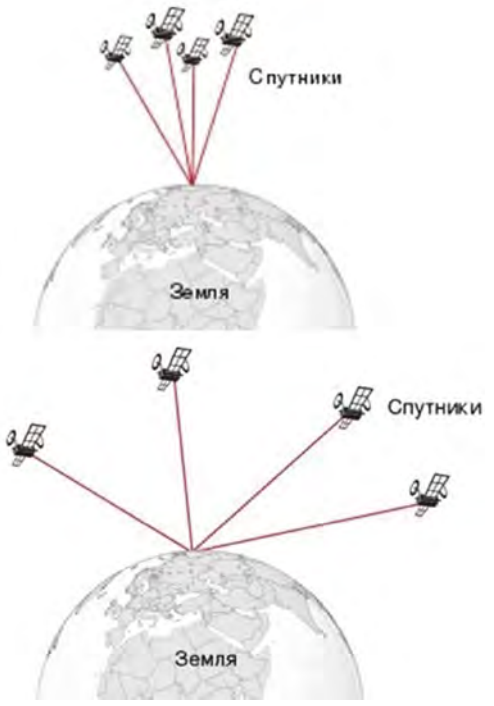

Figure 3. Variations of the spatial location of satellites in the sky.

Table 1. DOP values.

DOP values	Accuracy	Description
1	Ideal	The best indicator, recommended for work requiring maximum accuracy
2-3	Excellent	Sufficient accuracy when working with sensitive equipment
4-6	Good	The minimum allowable value for measurements used in production
7-8	Average	Acceptable results for navigation, it is recommended to try to go to a more open space to improve accuracy
9-20	Below average	The results can be used to determine the approximate location
21-50	Bad	The accuracy of determining the position is equal to half of the football field, the results are subject to rejection

Now let's move on to choosing the shooting mode. In previous chapters, we discussed the advantages of relative methods of satellite observations, namely the static mode. In static mode, the receiver stands still. But since we have the ability to connect the base station, the measurements will be carried out in RTK mode. This method is most suitable for deformation monitoring. After the rover is installed at the facility, we will use a SIM card to connect to the Geokurs base station, located not far within a radius of 5 km from the Arkhar Bridge. As a result, we will succeed, so that our rover in RTK shooting mode will calculate its location for a certain time. The resulting calculations will already go together with the differential corrections and with the postprocessing performed. The expected measurement accuracy should be a few centimeters. After completing the shooting at one station, we will move on to the next. In total, it is planned to make 6 observation stations. This amount will be enough for our research object. As a result, we expect to receive spatial data that displays up-to-date information about the vibrations of the bridge. At the experimental stage, we will determine the method of station placement and the choice of equipment used [7].

Hyung-Koo Yoon
Daejeon University, Daejeon, Republic of Korea

ABSTRACT: The objectives of this study are to classify ground penetrating radar (GPR) images using a deep learning network trained on raw GPR images and to verify the performance of GPR images treated with white noise. The image dataset includes manually labeled images with three classes: background noise, hyperbola, and manholes. In addition, white noise is introduced into the raw GPR images with different coefficients of variation and new images are used to train the deep learning model. The experimental results reveal that the deep learning model performs well on the raw GPR images, with high classification accuracy. Furthermore, the white noise added to the raw images increases the robustness of the deep learning model. The results of the present study demonstrate the application of a deep learning approach and white noise for classifying GPR images.

1 INTRODUCTION

Investigations of underground conditions using electromagnetic waves, such as ground penetrating radar (GPR), have been commonly applied for the detection of buried objects (Ko et al., 2012; Hong et al., 2018). GPRs use reflected electromagnetic signals propagating through media with different electromagnetic properties to investigate underground conditions (Saarenketo et al., 1998; Gutiérrez et al., 2011). As the reflected electromagnetic signals do not provide any visual pictures of the underground and must be manually analyzed to understand their implications, biased man-made decisions are a potential problem. To address this problem, numerous studies have applied learning networks, such as convolutional neural networks (CNNs) (Zhang et al., 2020) and support vector machines (Xie et al., 2013). Thus, the present study adopted a pre-trained CNN and two different methods of data augmentation using white noise. The augmentation using white noise comprises adding white noise to real GPR images.

The objectives of this study were to test the classification CNN on GPR images and to evaluate the data augmented using white noise. First, this study briefly describes the GPR data, augmentation using white noise, and the classification CNN. Next, the experimental results from the training are presented. In the following sections, the results are analyzed using gradient-weighted class activation mapping (Grad-CAM) to validate the decision-making of the CNN.

2 DATA AND METHOD

2.1 *Data*

The detection of buried objects, underground anomalies, or interfaces of different soil layers using electromagnetic waves is based on the electromagnetic response, which represents the reflections of the electromagnetic waves propagating through materials with different electromagnetic properties (Saarenketo et al., 1998; Hong et al., 2018). An electromagnetic wave is generated over

DOI: 10.1201/9781003299127-330

a single pulse and emitted into the ground via a sender antenna, and the reflected electromagnetic wave is detected via a receiver antenna.

In this study, GPR surveys were conducted at several construction sites in South Korea from 2018 to 2020. The GPR surveys conducted in the fields produced 3,000 black and white GPR images (GPR B-scan images) at 400 × 400 pixels (106 mm × 106 mm), which were classified as noisy reflection (NS), hyperbolic reflection (HB), and heavy loss-of-signal reflection (MH), such as reflections of metal covers of manholes. Typical sample images are shown in Figure 1. Figure 1 (a) shows a typical NS image, i.e., a random signal without any typical visual shape reflected from electrical noise in the field caused by electronic devices, vehicles, or nearby base transceiver stations. Figure 1 (b) shows a typical HB image, i.e., a typical hyperbola indicating the change in travel distance of the electromagnetic response as the GPR antenna signals move toward and pass buried objects, such as pipelines. Figure 1 (c) shows a typical MH image exhibiting a very strong reflection beneath the ground surface as the metal manhole cover does not allow radio waves to penetrate through. A stack of hyperbolic reflections follows as the radio waves meet the interface between the ground and air inside the manhole.

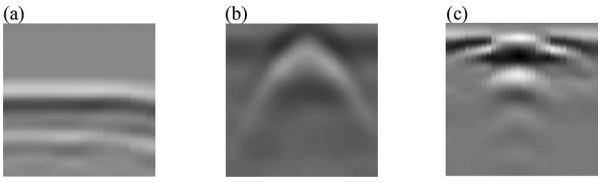

Figure 1. Typical images of 3 classes: (a) NS class; (b) MH class; (c) MH class.

2.2 *Method*

2.2.1 *Image augmentation*

To generate new augmented images, white noise was introduced into the raw GPR images. In particular, white noise with a coefficient of variation (cov) of 0.1 was sequentially introduced into the raw images, as shown in Figure 2. Figure 2 shows the original and augmented MH images. The newly augmented HB images became hazier when the noise was added.

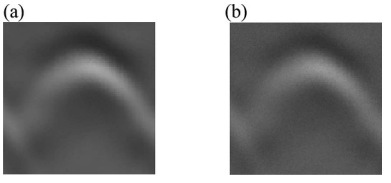

Figure 2. Image augmentation: (a) raw image; (b) augmented image.

2.2.2 *Classification*

A convolutional configuration was employed for the classification of the GPR images, as shown in Figure 2. The configuration includes a feature extractor for extracting deep features from the input images and a classification task for classifying the extracted features into the three designated classes. Herein, a well-known VGG16 network with approximately 138 million weights distributed on 16 layers (introduced by Simonyan & Zisserman (2015)) was adopted to extract the deep features.

For the classification experiment, the raw GRP images were used to train the models with a training and validation ratio of 6:4. In addition, to study the performance of the augmented im-ages, the augmented images were used to train the models with a training and validation ratio of 6:4.

3 EXPERIMENTAL RESULTS

3.1 *Training on raw data*

The results from the training and validation of the raw GPR data are shown in Figure 3. Figure 3 (a) shows the training loss versus epoch for the training and validation of the model on the raw images that the loss quickly decreased until the 20th epoch, and then gradually reached an early stopping point at the 157th epoch; at this point, the training loss continuously decreased, whereas the validation loss increased. Figure 3 (b) shows that the training accuracy quickly increased and approached 0.998 (the highest value) at the early stopping point. The validation accuracy exhibited a similar trend, i.e., quickly increasing in the first few steps and then slowly reaching the highest value of approximately 0.97 at the early stopping point. The validation exhibits an insignificant difference from the training and indicates no overfitting.

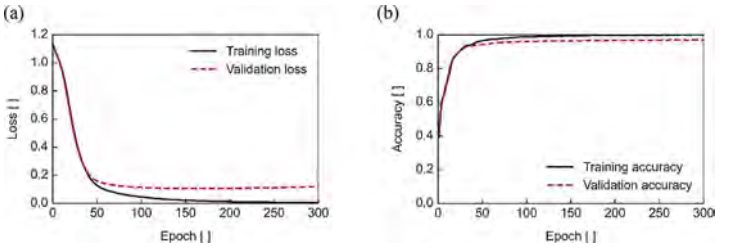

Figure 3. Training results on raw images: (a) Loss; (b) Accuracy.

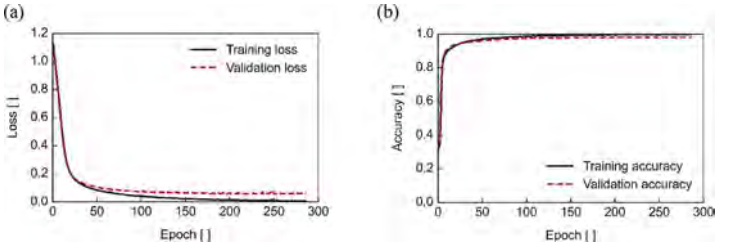

Figure 4. Training results on augmented images: (a) loss; (b) accuracy.

3.2 *Training on augmented data*

The training results for the models for the augmented images are plotted in Figure 4. Figure 4 shows that training on the augmented data exhibited a similar result with that on the raw images, where the training loss quickly decreased in the first few epochs. However, the validation loss quickly decreased, reached its lowest at the early stopping point, and then slightly increases. The training accuracy increased continuously to 1.0, whereas the validation accuracy exhibited a slightly lower value of 0.986 at the early stopping point.

4 ANALYSIS AND DISCUSSION

To analyze the performance, Grad-CAM (Selvaraju et al., 2019) was created by back-propagating from the last convolution layer to the input to indicate the contribution of a pixel to the decision-making of the models, as shown in Figure 5. Figure 5 (a) shows the Grad-CAM for an MH image using the model trained on raw images, whereas Figure 5 (b) shows the Grad-CAM for the same MH image using the model trained on augmented images. Figure 5 (a) shows a localization mostly covering all pixels containing the MH object; however, some parts on the right-hand side show less

of a contribution relative to the left. In contrast, Figure 5 (b) shows a symmetric localization covering the upper part of the MH object. Therefore, the white noise significantly improved the accuracy of the classification of CNN models and localization. This finding agrees with those of previous studies, such as Borji & Lin (2019), Fong et al. (2018), and Deng et al. (2019).

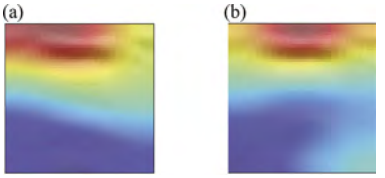

Figure 5. Grad-CAM performance by models trained on: (a) raw images; (b) augmented images.

5 SUMMARY AND CONCLUSIONS

The objectives of this study were (1) to classify GPR images using a deep learning network trained on raw GPR images and (2) to verify the performance of GPR images treated with white noise. Raw GPR images were collected through experiments at construction sites and labeled into three classes: BN, HB, and MH. For the data augmentation, white noise with cov = 0.1 was combined with the raw GPR images. For the classification task, a learning network consisting of a pretrained VGG16 feature extractor and classifier was adopted and used for the training of raw, Method A synthetic, and Method B synthetic data. Grad-CAM was used to evaluate the performance of the learning network. Based on the experimental results, the main observations were as follows:

- The performance on raw images was sufficiently high and avoided overfitting.
- The images augmented by white noise improved the performance of the CNN classification. Grad-CAM indicated that the localization of the model using augmented images is more accurate than that using raw images.

Construction tests of diaphragm wall with enlarged part

M. Kato, T. Watanabe & A. Iwata
Taisei Corporation, Yokohama, Japan

ABSTRACT: The increase in ultra-high rise building column intervals in recent years has meant that the direct bearing load applied to each column has increased. For this reason, the piles need increased bearing capacity and pullout resistance, and continuous underground walls are used in some cases. A diaphragm wall foundation with an enlarged part has been developed in order to achieve even greater bearing capacity and pull-out resistance. Field construction tests confirmed that with proper construction control diaphragm walls with an enlarged part can be constructed in the required shape, dimensions, and quality.

1 INTRODUCTION

It is reported that the increase in ultra-high rise building column intervals in recent years has necessitated the increased direct bearing load applied to each column. For this reason, the piles are now subject to increased bearing capacity and pull-out resistance, and continuous underground walls are used in some cases (Ninomiya et al. (2017)). To achieve even greater bearing capacity and pull-out resistance, a diaphragm wall foundation with an enlarged part has been developed. In order to cope with these problems, we have been studying the trench stability of diaphragm walls with an enlarged part both from numerical simulations and model tests (Iwata et al. (2022)). The purpose of this study is to confirm that with proper construction control diaphragm walls with an enlarged part can be constructed in the required shape, dimensions, and quality.

2 OUTLINE OF CONSTRUCTION METHOD

2.1 *Shape and constructable range*

A schematic view of a diaphragm wall with an enlarged part is shown in Figure 1(a), while representative dimensions and constructable range are summarized in Table 1. Maximum wall-thickness is 1.5m. Enlarged part has a fan-shape in the wall-thickness direction. Maximum constructable width of the enlarged part is 3.16m. Maximum design strength of concrete is set at 60N/mm^2 to make the diaphragm wall highly durable. Image of formed diaphragm wall with enlarged part is shown in Figure 1(b).

2.2 *Excavator for enlarged part*

Mechanism of an excavator for the enlarged part is shown Figure 1(c). The excavator is comprised with three-axis cutters consisting of three rods for excavating the enlarged part and upper and lower stabilizers for keeping them vertical. Enlarged part with a fan-shape in the wall thickness direction is constructed by swinging the three-axis cutters sideways while turning. A clinometer is installed in the upper part of the excavator and in three-axis cutters.

DOI: 10.1201/9781003299127-331

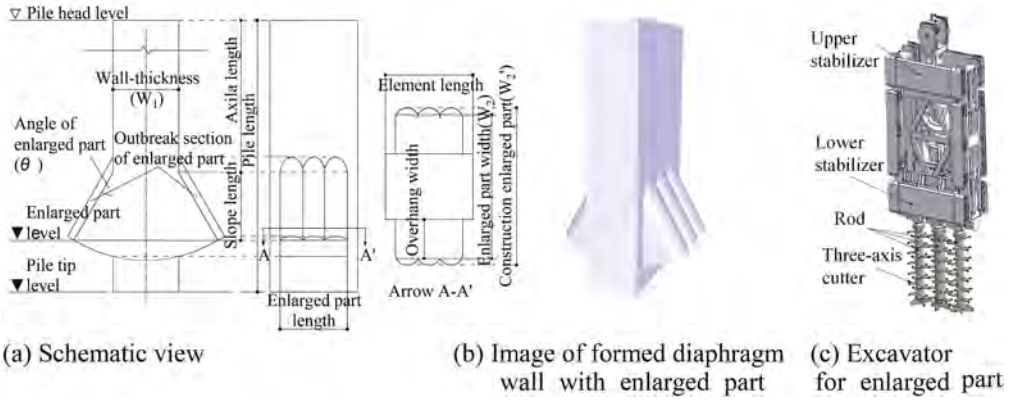

Figure 1. Outline of diaphragm wall with enlarged part.

Table 1. Measurement and constructable range.

Wall – thickness (W_1)	Enlarged part width (W_2)	Construction enlarged part width (W_2)	Maximum angle of Enlarged part (θ)	Pile tip level	Design strength of concrete
[mm]	[mm]	[mm]	[°]	[m]	[N/mm^2]
1200~1500	1300~3160	1615~3730	30.5	80	18~60

2.3 *Excavating procedure*

Main excavating procedure is shown in Figure 2. Axial part of the diaphragm wall is first excavated with the excavator of the reverse type from diaphragm wall top level to predefined tip level. The enlarged part is then excavated. Cut soil drops into the bottom end of the axial part. After excavating the enlarged part is completed, debris on base is removed by the excavator from the bottom of the axial part. Thereafter, resetting the excavator level to the enlarged part, remaining debris is scraped off. This completes the excavation procedure. This excavation process is hereinafter called "process control".

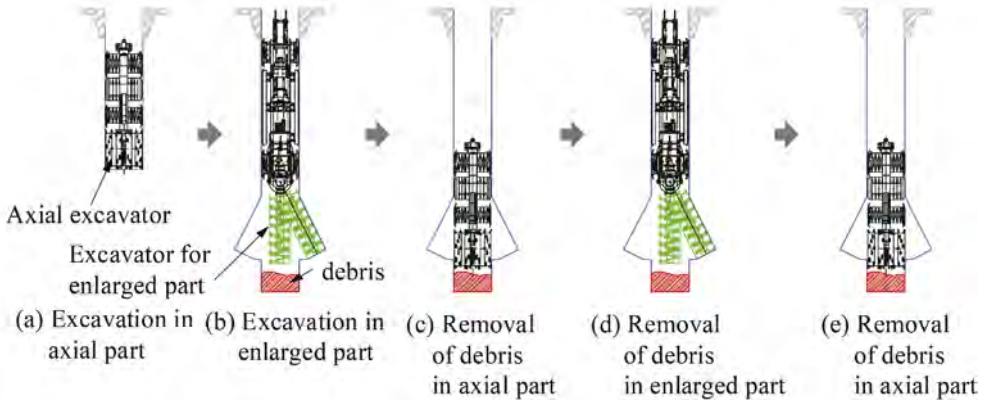

Figure 2. Excavating procedure.

3 SPECIMENS

An outline of field trial construction and main test diaphragm walls is shown in Table 2. Six Diaphragm walls are constructed under various conditions. In this paper, results of two specimens (14-1 and 14-5) which are characteristic in excavation depth and concrete strength are described.

Table 2. Outline of field trial construction and main test piles.

Specimen name	Wall – thickness [m]	Enlarged part width [m]	Angle of enlarged part [°]	Element length [m]	Pile tip level [m]	Enlarged part level [m]	Soil type (N-value)	Concrete strength [N/mm^2]
14-A	1.5	2.66	30.0, 15.0	3.2	5.7	4	*1	-
14-B	1.5	3.16	27.1	7.7	23.6	22	Find sand (about 30)	-
14-1	1.5	3.16	27.1	3.2	13.6	12	Find sand (about 15)	60
14-2	1.5	3.16	27.1	7.7	21.6	17	Find sand (about 50)	-
14-4	1.2	2.57	21.4	3.2	17.5	16	Find sand (about 50)	45
14-5	1.2	2.57	21.4	3.2	74.5	72.5	Silt mingled with sand (about 100)	-

*1. . .Improved ground, Uniaxial compressive strength (285 day material age): 1.43 N/mm^2

4 TEST RESULTS

4.1 *Deep layer excavation test in clayey soil (specimen 14-5)*

To confirm ability of excavator, shape of the enlarged part and verticality of the trench, the enlarged part was excavated to a maximum depth of 72.5m in a clayey soil with an equivalent N-value of about 100.

Shape of specimen 14-5 and its columnar section are shown in Figure 3(a). One gut of the enlarged part was excavated at an angle of 21.4 degrees in a hard silt layer at a depth of G.L.-72.5m.

Results of ultrasonic measurement for the trench are shown in Figures 3(b), (c) and (d). The results show error in the perpendicular direction to the trench is negligible. The ultrasonic measurement result confirms that the proposed excavation method satisfies the design dimensions, and that excavating in the hard clayey soil is possible at great depths.

4.2 *Field construction test for shape and size (specimen 14-1)*

After excavating the enlarged part and placing concrete, diaphragm wall was dug out and shape and dimensions we measured. In this result, validity of "process control" was confirmed. In addition, conducted were the compressive strength tests on core specimens collected from specimen 14-1.

Shape of specimen 14-1 and columnar section are shown in Figure 4(a). One gut of the enlarged part was excavated at an angle of 21.4 degrees in a sandy ground with an N-value of about 15. Results of ultrasonic measurement for the trench are shown in Figure 4(b). The figure also indicates the design dimensions calculated by clinometers and laser measurement results after specimen 14-1 was dug out. From the figure ultrasonic measurement results confirm that the proposed construction method satisfies the design dimensions and that the trench does not fail.14-1

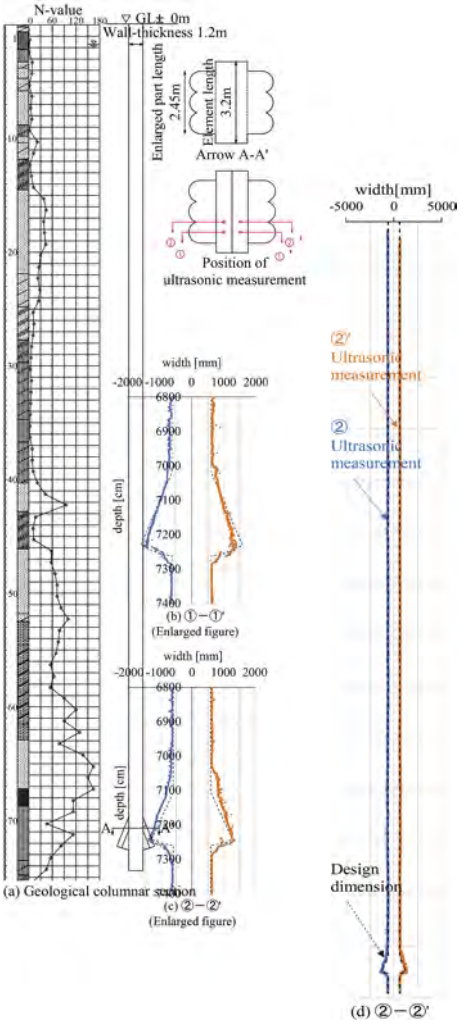

Figure 3. Outline and measurement results of 14-5 specimen.

specimen is dug out to investigate concrete strength, shape and dimensions of enlarged part. The enlarged part was appropriately cut into several pieces so as to retrieve it from underground. The enlarged part of specimen 14-1 is shown in Figure 4(c). It may be seen that the excavated enlarged part is a series of cylindrical holes at different angles. It is because it was produced by turning three-axis cutters of the excavator while swinging the excavator sideways. Changing the angles of the excavator from the vertical, the enlarged part with the groove of arc shape at the bottom is formed. The laser measurement results are generally consistent with the design dimensions. Compressive strength results on concrete cores are shown in Figure 5. Validity of "process control" is confirmed in this result. It was also confirmed that the prescribed compressive strength of concrete was developed.

5 CONCLUSIONS

This study presents workability and development of compressive strength necessary for diaphragm walls with an enlarged part. From the construction test results, the following conclusions are obtained:

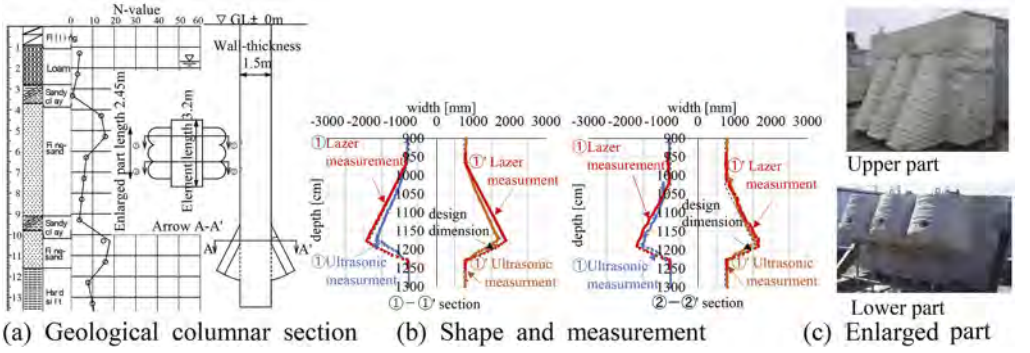

Figure 4. Outline and measurement results of 14-1 specimen.

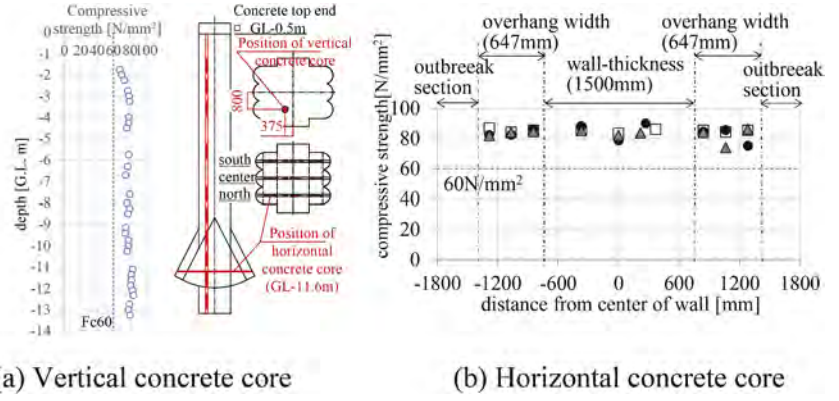

Figure 5. Compressive strength results.

1) The "process control" ensures that diaphragm walls with an enlarged part can be constructed in the required shape and dimensions.
2) It was confirmed that the prescribed compressive strength of concrete was developed.

Determination of the dynamic characteristics of the building and its base from the accelerograms of weak earthquakes

Vladimir Lapin, Yerken Aldachov, Nurakhmet Makish, Seric Aldachov & Alimzhan Ali
Kazakh Scientific Research and Design Institute of Civil Engineering and Architecture JSC, Almaty, Kazakhstan

ABSTRACT: An interesting local seismic event was registered on the Almaty territory. In terms of intensity, this is a two-point earthquake. The earthquake was recorded only by the stations of the engineering and seismometric service of KazRDICA JSC on October 18, 2017. The station is located in a 4-story frame building. Ground conditions – boulders and pebbles. Using AT 1105 sensors and an RSM-8 recorder, station No. 1 "Institute" recorded instrumental records of accelerations in the basement and on the building roof and plotted the spectral curves β. Period 0.43 sec corresponds to the value of the free oscillation period. It was revealed that even with a low-intensity local seismic impact, the dynamic characteristics of the building are exposed. The active operation of the building as a whole corresponds to the classical Biot spectral theory. The periods of oscillation of the building and soil of the base are quite accurately determined.

1 INTRODUCTION

The entire territory of the Almaty region is prone to earthquakes, which can pose a danger to buildings and structures on the Almaty territory.

The seismic hazard of Almaty is usually associated with the seismogenic zones of the Northern Tien Shan. Strong earthquakes with sources in these zones and magnitudes from 7.5 to 8.5, respectively, are possible, and the earthquake intensity in the city can reach from 8 to 10 points Mikhailova, (2015), Mikhailova, (2018), Sadykova, (2021), Galperin (1985).

The city was destroyed twice by the strongest earthquakes – Vernenskoe in 1887 with a magnitude of 7.2 and Keminskoe in 1911 with a magnitude of 8.2. These are the strongest earthquakes in Central Asia in the last 200 years. The city has repeatedly experienced less severe earthquakes. The Zhalanash-Tüp earthquake of 1978 with a magnitude of 6.9 and the Suusamyr quake of 1992 with a magnitude of 7.3 can be noted. On the city's territory, in different parts of it, they were felt with an intensity of 5 – 6 points Mikhailova, (2015).

For a long time, there was an opinion that there were no earthquake foci on the city's territory. It was believed that faults located on the city's part could enhance or weaken the passing seismic waves of earthquakes with foci in other seismogenic zones outside the city.

In the last 15 years, the appearance of earthquake foci has been noted on the city's territory, the seismic effect of which has so far been pointed out in the range of 2 – 4 points.

In Almaty, there are 10 engineering and seismometric stations on buildings, which also recorded earthquakes with foci in the city. The stations are equipped with digital and analog systems. It is planned to re-equip the stations with new digital systems Deng, (2019), Zhang (2017), Yang, (2018), Qiao (2018).

Every year, several hundred weak earthquakes of varying intensity occur, which are recorded by seismic stations. There is a need to use the accelerograms of such earthquakes to

DOI: 10.1201/9781003299127-332

determine the dynamic characteristics of buildings, to determine the rigidity and dissipative parameters. Determining the dynamic characteristics of buildings is solved using instrumental records of even weak earthquakes registered in the city.

2 MATERIALS AND METHODS

A series of weak earthquakes continue, recorded by the network of stations of the engineering and seismometric service of KazRDICA JSC Yerzhanov, (2017). On October 18, 2017, at 8:18 am, seismic station No. 1 "Institute" recorded a weak seismic event – a local earthquake. Such earthquakes are guaranteed to be recorded infrequently, so it is advisable to consider instrumental records in more detail.

There is no information on the earthquake on October 18, 2017, on the website of the Kazakhstan National Center for Seismic Data. It can be assumed that this is a local earthquake in the Almaty territory. Interestingly, the seismic event was recorded by only one station equipped with a digital instrumentation and measurement system.

Seismic station No. 1 "Institute" is located in a 4-story L-shaped frame building. The frame is reinforced concrete obtained (Figure 1). Now this is the building of the People's Bank of Almaty. Soil conditions – boulders and pebbles. The station was installed in 1968 and modernized in 2008. The devices are installed in the basement on the foundation and the building roof. Currently, the seismic station is equipped with analog sensors OSP and VBP and the instrumentation and measuring system RSM-8.

This station is the first of a network of engineering and seismometric stations on buildings in the Republic of Kazakhstan and, apparently, one of the first in the territory of the former USSR.

In 2016, ADXL sensors at station No. 1 "Institute" were replaced by AT 1105 sensors of Russian production. That made it possible to record even rather weak seismic events.

Thus, as part of solving the problem of determining the building's dynamic characteristics, experimentally obtained earthquake records are used. Spectral analysis methods are used based on the construction of reaction spectra at various registration points.

3 RESULTS

Instrumental records of accelerations – accelerograms were obtained (Figures 2–3). It should be noted that the instrumental records of the earthquake at the basement level have the form of the "white noise" type without areas of an apparent increase in the amplitude of the oscillations. That is due to the small amplitude of the seismic impact.

Of particular interest is the OX accelerogram at the basement level. It looks like a broken "white noise". Nevertheless, the building, even with this impact, makes free vibrations.

Instrumental recordings along the OY and OZ axes at the basement level are very similar to segments of "white noise."

However, at the roof level along the OY and OX axes, instrumental recordings take the form of ordinary accelerograms.

Table 1 shows the maximum acceleration values for each of the instrumental recording components. Lines 1 – 3 correspond to accelerations on the building roof, 4 – 6 – to the building foundation. The maximum values of acceleration along both axes within 1.5 – 1.7 cm/s^2. Spectral coefficients along the OY axis on the foundation and the roof are approximately the same.

Figure 4 shows spectral curves of seismic events on October 18, 2017. Acceleration peaks at the basement level correspond to an oscillation period of 0.03 – 0.10 sec. The building base, made up of boulders and pebbles, makes high-frequency vibrations. On the building roof, the period of the spectrum maximum along the horizontal and vertical axes logically increases. When exposed to the impulse type, the building vibrates freely. Period 0.43 sec corresponds to the value of the free oscillation period.

Figure 1. A frame-brick building with installed engineering and seismometric station.

Table 1. Maximum acceleration values and accelerograms parameters.

Component	Acceleration	Effective duration	Spectral Coefficient	Spectrum maximum period
	cm/s^2	s		s
OX-u1	1.52	37.70	3.11	0.43
OX-u2	1.78	2.54	2.82	0.12
OX-u3	1.28	70.85	3.90	0.07
OX-u6	0.23	70.69	2.93	0.03
OX-u7	0.13	71.69	2.76	0.10
OX-u8	0.20	70.85	3.39	0.03

It should be noted that, despite the low earthquake intensity, the spectrum along the OX axis on the building roof is very saturated and has several maxima. At the basement, the spectral curves have one maximum at high frequencies.

On the OX axis, the value of the maximum period of the spectrum coincides with the period of oscillations of the building in this direction. In Yerzhanov (2017) the values of the period of the spectrum maximum are given under the influence of two remote earthquakes on April 21, 2017, which occurred with an interval of 14 minutes. The value of the period of the maximum of the spectrum is 0.42 s, which is very close to the value of 0.42 s from Table 1.

Thus, it can be considered proven that even with a very weak seismic impact (Figure 3), the value of the oscillation period of the building along the OX axis is determined.

Thus, even based on the results of recording a very weak earthquake, it is possible to determine the main dynamic characteristics of the building and the soil of the base. Therefore, it is advisable to install engineering and seismometric service stations on buildings on standard buildings, high-rise buildings and at unique facilities. Unfortunately, the network of KazR-DICA JSC stations is the only one in the Republic of Kazakhstan. In the future, it is planned to install new seismic stations on buildings in the cities of Shymkent, Taraz, Kapshagai, Ust-Kamenogorsk, Zaisan.

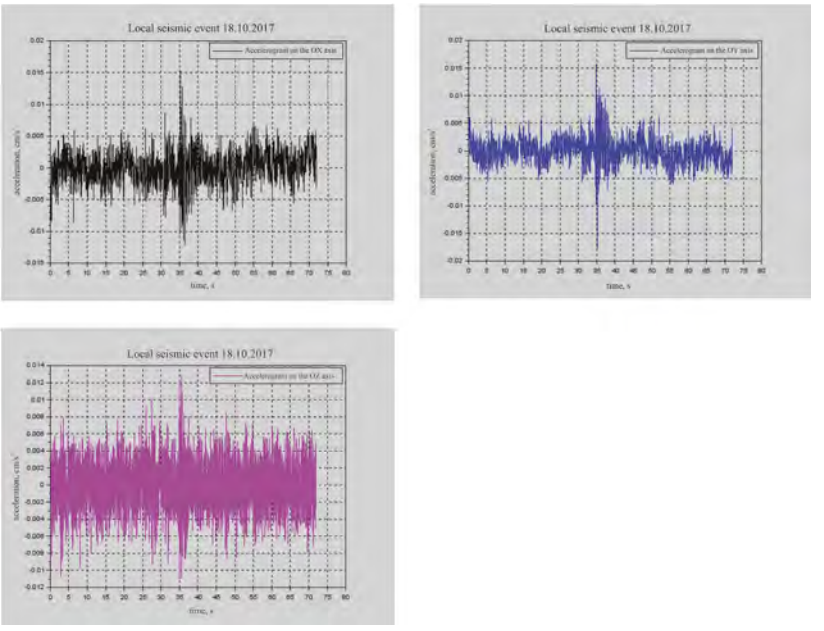

Figure 2. Accelerograms of the seismic event on October 18, 2017 (station № 1 “Institute”, roof).

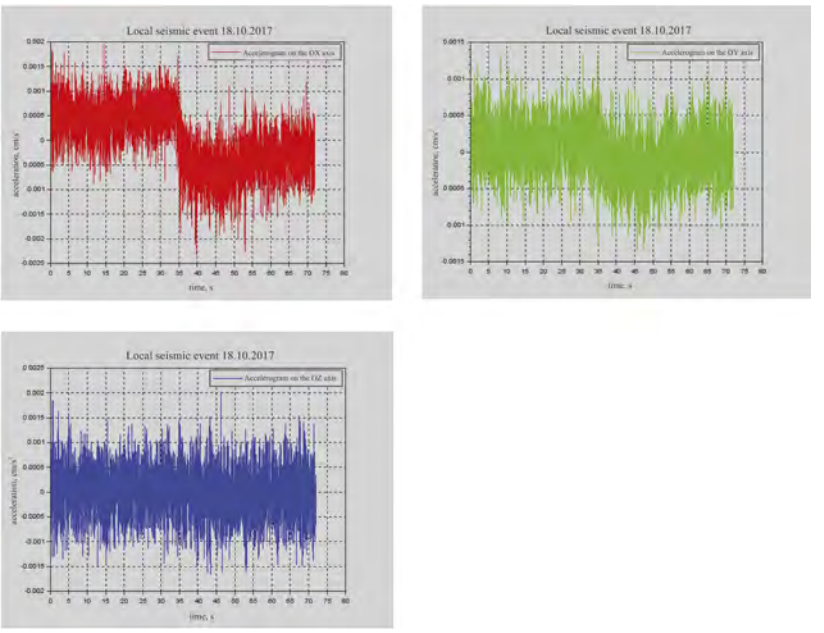

Figure 3. Accelerograms of the seismic event on October 18, 2017 (station № 1 “Institute”, foundation).

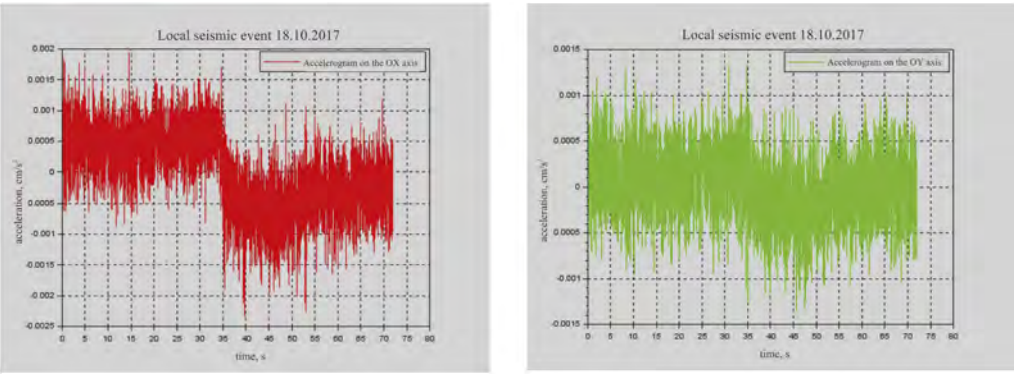

Figure 4. Spectral curves of seismic events on October 18, 2017 (top picture – roof, bottom one – foundation).

4 CONCLUSIONS

1. On October 18, 2017, seismic events are a weak local earthquake with an intensity of no more than 2 points in intensity and frequency composition.
2. Impact not identified by other sources. It is indicated the possibility of earthquakes with foci in the Almaty territory Mikhailova, (2015), Mikhailova, (2018).
3. The operation of the building as a whole corresponds to the classical Bio spectral theory, based on the dynamics of a single-mass oscillator. The structure makes free oscillations with a period along the OX axis equal to 0.43 sec. The period of oscillation of the base soil is within 0.08-0.1 sec.
4. Instrumental records of even very weak earthquakes provide sufficient information to determine the dynamic characteristics of a building. Therefore, to determine the dynamic characteristics of buildings, it is recommended to install temporary engineering seismometric stations that register seismic effects of various intensities, including the weakest.
5. The installation of new engineering and seismometric service stations is recommended to be carried out on buildings with new structural solutions, complex shapes, or built using various seismic isolation systems Bulat (2018), Ahmad (2009), Dyrda,(2019), Bulat (2019), Lapin (2019) . In addition, seismic stations should also be installed on buildings built on sites with difficult ground conditions Zhussupbekov (2015). In connection with intensive high-rise construction, it is advisable to equip high-rise buildings with a height of 20-40 floors with seismic stations. It is planned to install new seismic stations on buildings in the cities of Shymkent, Taraz, Kapshagay, Ust-Kamenogorsk, Zaysan.

Recent RE Wall failures - Lessons learned

S.M. Dasaka
Professor, Department of Civil Engineering, Indian Institute of Technology Bombay, India

Ammavajjala Sesha Sai Raghuram
Postdoctoral Fellow, Department of Civil Engineering, Indian Institute of Technology Bombay, India

ABSTRACT: The distress in the RE walls is attributed to either one multiple reasons, such as insufficient ground investigations, poor interpretations, inadequate designs, improper construction, and human errors. The current study examines failures of two recent Reinforced Earth wall in India, and identifies the likely causes of failure, through a systematic study of all stages of construction. Measures to avert such failures are also discussed. The investigation of the three case studies revealed that the drainage of RE Wall must be properly considered in RE walls, and highest quality control measures must be exercised in its construction. In view of the changes in the rainfall pattern, and increased probability of occurrence of high intensity of rainfall over several parts of India, it is suggested to cover the backfill material in order to avoid the water infiltration, if any, during the construction phase.

1 INTRODUCTION

Reinforced earth (RE) walls are common earth retaining structures. Space and economic constraints have made RE walls popular worldwide, notably in India. It is easy to place the reinforcement in the soil at the desired depths and compact a RE wall, making its construction cost-effective and straightforward. Road embankments and cuttings, and buildings used RE wall technology. Internal and external stability must be taken into consideration while designing RE walls.

RE walls provide many advantages over other earth-retaining structures. Insufficient drainage and compaction have led to certain RE wall failures. Koerner et al. (2005) highlighted the need of drainage control in RE walls and proposed the drainage behind the reinforcement zone when impermeable soils are utilized as the backfill material. Koerner & Koerner (2018) examined 302 case studies of RE wall failures and reported that insufficient compaction and the use of impermeable backfill materials led to 245 and 232 RE wall failures, respectively. Miszkowska et al. (2018) observed that clogging and retention have a substantial effect on the permeability of geotextiles. After 22 years of installation, the permeability of geotextile in an earthen dam had decreased by 2.6 times. Recently, Raghuram & Dasaka (2022) highlighted the importance of backfill compaction in the construction of RE wall.

The aforementioned studies demonstrate that drainage and compaction characteristics of reinforced fill material, as well as clogging and retention capacity of the geotextile filter, play a significant role on the stability of RE walls and should be taken into account. This study presents two case studies of a recently failed RE walls. The present study identified and discussed the most crucial factors behind failure of these RE walls.

2 CASE STUDY - 1

2.1 *Project details*

The Maharashtra government chose to expand and build a rail over bridge (ROB) in the city of Mumbai. The focus of the current study is on the two RE walls, RE wall-1 and RE wall-2,

DOI: 10.1201/9781003299127-333

which witnessed problems after construction. No geotechnical examination was performed on the foundation soil of the RE walls. An adjacent borehole shows clay in the upper 4 m to 5 m. RE wall-1 is 6.04 m high and RE wall-2 is 4.47 m high.

2.2 *Problem description*

After RE wall work began, the initial design was changed. Once the RE wall started, the public insisted on constructing a box culvert in the narrow zone. This caused an accessibility concern, because of which soil underlying the RE wall was unable to be compacted adequately once the box culvert was built. Before excavating the box culvert, sheet pile walls were erected on three sides to reach required depth for construction of box culvert. Moreover, water mains that bring water to Mumbai run beneath the surface of the ground near the RE wall. RE wall backfill and already compacted soil were excavated to create an excavation ramp for the box culvert. After installing the box culvert, the excavation was backfilled and compacted. Narrow area adjacent to the box culvert hindered proper compaction of the underground part and the refilled material. It resulted in the soil settlement at the culvert zone which in turn caused the settlement of RE wall facia and backfill, and pavement cracks.

The ROB was about to open to traffic. According to the Indian Meteorological Department, the area experienced 117 mm of rain immediately after the ROB was completed. A 5 mm crack and depressions were noted on the rigid pavement on 13 June 2021. Figure 1 shows that RE wall-1 fascia (modular blocks) settled 25 mm. Figure 2 shows that RE wall-2 fascia settled 65 mm.

Figure 1. Fascia settlement of RE wall-1 by 25 mm.

Figure 2. Fascia settlement of RE wall-2 by 65 mm.

Traditional boring from the rigid pavement could not be used due to the site constraints. One side of RE wall has large-diameter Mumbai water pipelines. On the opposite side of the RE wall, existing traffic lanes are present. In addition, a geogrid with very small aperture sizes (2 cm x 2 cm) was employed to reinforce the RE Wall backfill. Therefore, geophysical investigations, such as multichannel analysis of surface waves (MASW) and ground penetrating radar (GPR), were conducted at various locations to assess backfill and foundation soil and thereby to recognize the probable source of RE wall distress and cracks on the rigid pavement.

2.3 *Remedial measures*

Pressure grouting was considered the most effective preventive measure for this project due to the aforementioned site constraints. At the excavated ramp the inadequately compacted fill was pressure grouted. After grouting, galvanized iron grout pipes were left in the soil and filled with cement mortar. This could serve as additional reinforcement. The MASW test was

repeated post grouting, to assess the performance of improved ground. It was noted that shear wave velocities improved at the box culvert zone.

Moreover, pressure grouting is done to fill the PQC-DLC gap. As a precaution, a load test was performed on the treated pavement with a concrete block of size 1 m x 1 m. A vertical compressible load of 24 kPa, equivalent to typical traffic load (IRC:6 (2016), was given on the DLC layer to witness any further settlement of the DLC layer. The pavement was loaded in 10 kPa increments for 12 hours. Under the ultimate load, a 2 mm settling was recorded, which was deemed acceptable. The PQC was then reconstructed using M50 grade concrete. Additionally, a 10-cm test plate was also laid on DLC layer and a MS rod was mounted to test plate placed. This was done to observe DLC layer settlement under real traffic loads. After sixty days of traffic, there was no evidence of settling., demonstrating the good performance of the grouted ground and pavement.

3 CASE STUDY – 2

3.1 *Project details*

In the state of Maharashtra (near Nagpur), the public works department intended to construct a Road Over Bridge (ROB) as part of a state highway across a busy railroad line. Two RE walls were intended for the approaches on either side of the ROB for this reason. This study focuses on these RE walls and the flexible pavement that was constructed on top of the embankment.

The geotechnical investigation indicated the presence of clayey soil for 3 m below the surface of the ground. A ground improvement technique was implemented due to the existence of highly compressible clayey soil in the top layers in order to increase the strength of foundation soil. In addition, the groundwater table is located at 10 m below ground level.

3.2 *Problem description*

The maximum height of RE walls is 14.3 m and the approach length is approximately 1 km. As mentioned in the earlier sections, basal reinforcement and partial soil replacement was adopted as a ground improvement technique. The perforated drainpipe was encased in a non-woven geotextile. In addition, a geotextile layer was placed between the inverted filter and the RE wall's fascia. The backfill material was designed in accordance with IRC:SP:102 (2014) requirements. The RE wall was designed considering a backfill with unit weight of 20 kN/m^3 and an internal friction angle of 32°. The backfill cohesion is zero. Nonetheless, the proposed backfill material was not utilized during the actual construction of the RE wall. As a thermal power station is located in the close vicinity of the RE wall site, fly ash was used as backfill. It is acceptable to utilize any material in the reinforced zone, provided it is readily available near the construction site and meets the requirements indicated in IRC:SP:58 (2014). It was observed that 76% of the fly ash is composed of fines (silt and clay). However, the RE wall design and stability calculations were not modified when fly ash was employed as backfill. As the RE wall design and stability were not checked after considering the fly ash as backfill material, the same non-woven geotextile that was designed for the originally planned backfill was also used for fly ash. Therefore, the apparent aperture size of the geotextile was larger than the corresponding particle size of fly ash.

Due to time restrictions, work continued. This area received 174.8 mm of rainfall in August 2019 as per IMD records. Unfortunately, during the rains the backfill was not covered. Hence, the backfill was exposed to rainfall before the pavement was laid on the RE wall. A flexible pavement was laid over the RE wall without draining the pore water from the backfill. In September 2019, the project site received another heavy rain of 297 mm. In fact, perforated PVC pipes at a slope of 1 in 300 must be installed along the wall as per the design. During construction, horizontal drainage pipes with no slope were placed. Due to a faulty drainage system, rainwater and fly ash fines leaked through the fascia of the RE wall. As

illustrated in Figure 3, the fines were able to escape via the pore of the geotextile from the fascia of the RE wall, as the pore size of the geotextile is bigger than the size of the fines in the fly ash. As a result of the formation of loose soil pockets beneath the flexible pavement, a number of potholes appeared in various locations. The reinforcement was exposed at multiple locations, as shown in Figure 4.

Figure 3. Escape of the fly ash fines from the fascia of the RE wall.

Figure 4. Large potholes at various locations on the flexible pavement.

3.3 *Remedial measures*

All potholes on the flexible pavement were detected, loose soil pockets were eliminated, and gravity grouting was used as a preventative technique. By grouting the potholes, the stiffness of the ground would improve, reducing future settlements. In 2021, the pavement was exposed to rain fall throughout the months of July, August, and September. Now that the roadway is open to traffic, its performance is good and there are no signs of distress.

4 CONCLUSIONS

This study examined the potential causes of the failure of two RE walls in India. The key conclusions that can be drawn from this study are as follows.

➢ Case Study – 1
- Prior to the start of traffic on this freshly constructed ROB, localized depressions and surface cracks were observed in the pavement. In addition, the fascia of the RE walls 1 and 2 settled approximately 25 mm and 65 mm, respectively.
- At the edge of the box culvert, a wide gap was noticed between the PQC and DLC layers. Similar gaps were found in the subsequent two PQC panels.
- Evidence from visual damage and post-distress geotechnical investigations, indicates that the probable cause of the rigid pavement and RE wall collapse was inappropriate compaction of the re-fill underlying the RE wall adjacent to the box culvert.
- Pressure grouting was used as a preventive measure.
- Finally, a MS rod was mounted to the test plate and is placed on top of the DLC layer to monitor the DLC layer settlement, if any. No settlement was seen for 60 days of opening the highway for traffic.

➢ Case Study – 2
- A forensic analysis found that the drainage system was not properly installed as per design. Hence, excess pore water could not flow through the longitudinal drainage pipes placed along the facing.

- The design of the RE wall did not change when fly ash substituted granular backfill. Therefore, the apparent opening size of the geotextiles was greater than that of the fly ash particles.
- Due to heavy rainfall in August and September 2019, percolated water and fly ash fines escaped through the RE wall fascia joints.
- At several locations, loose pockets were observed under flexible pavement which caused severe potholes on the surface of the pavement.
- Grouting the potholes was chosen as a remedial measure.

Every site is distinct and requires a comprehensive site investigation before construction can commence. The above two case studies provide three important lessons. To begin, prior to construction of any structure, the geotechnical characteristics of the natural ground must be thoroughly examined. Second, the design and analysis must be updated to reflect any modifications in the type and quality of planned materials. Third, and perhaps most crucially, the backfill should be covered daily at the end of work to prevent the entry of rainwater. This protects the backfill material against any unanticipated rainfall infiltration. In order to enable periodic maintenance, it is recommended that the sub-surface drainage pipe within the filter/drainage layer be situated outside of the RE wall (i.e., in front of the fascia).

Hybrid monopile supported offshore wind turbine subjected to static and dynamic loads: A state-of-the-art review

Haroon Rashid
PhD PMRF Scholar, Department of Civil Engineering, Indian Institute of Technology Bombay, Mumbai, India

Deepankar Choudhury
Professor T. Kant Chair Professor and Head, Department of Civil Engineering, Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Currently, majority of OWT around the globe have monopiles as their foundation system. However, with increase in water depth, diameter of monopile required for such cases increases to a greater extent. To address this issue, a new cost-effective foundation system is needed. In this paper, hybrid monopile foundation has been reviewed that is a combination of monopile and gravity foundation. This new foundation structure fared exceptionally well in a number of centrifuge tests under both static and dynamic loading conditions. Hybrid monopiles have been found to be effective for reducing lateral deflection and improving bearing capacity. Hybrid monopiles have also been proven to minimize the susceptibility to liquefaction. In the paper various parametric studies have been reviewed pertaining to hybrid monopile foundation for both static and dynamic loads. The aim of this paper is to critically review and discuss the hybrid monopile foundation and identify its future scope.

Keywords: Centrifuge Modelling, Hybrid Monopile, Numerical Modelling, Offshore Wind Turbine

1 INTRODUCTION

Interest in the offshore wind energy has increased recently as people have shifted to renewable sources of energy because conventional fossil fuel cannot keep up with the expansion of the global economy. Offshore wind turbines (OWT) are lightweight structures that experience intense lateral loads caused by wind, ice, waves, etc. (Zhao *et al.* 2017). Offshore wind energy is preferred over onshore due to higher wind speed at sea, lesser disruption to human lives and more available area (Bhattacharya 2019). World's offshore wind capacity has reached 32.5GW reducing carbon emissions by 62.5 million tons (GWEC 2021). United Kingdom currently has the largest capacity of offshore farms followed by Germany and China. Typically, 20% to 40% of the overall capital expenditure goes for the design, transportation, and installation of the foundation (Mathern *et al.* 2021). Various foundation types currently exist for offshore wind turbines like monopile, jacket, tripod, floating foundation, gravity type etc. The most typical foundation for OWTs is a monopile due to various advantages (O'Kelly and Arshad 2016). Monopile is a very large diameter pile about 5-6 meters having slenderness ratio of about 6-7. For offshore conditions this diameter further increases compared to onshore as additional loads come into play due to wave loads. These wave loads depend primarily on water depths and also monopile diameter. Hence for deeper waters higher wave loads are expected. To reduce the wave loads in deeper waters monopile of lesser diameter has to be used while still satisfying design requirements but it is not possible using conventional

DOI: 10.1201/9781003299127-334

monopile. Hence majority of monopiles are constructed in waters upto 25 meters (Kuo *et al.* 2012). It has been found that if offshore wind farms with monopiles are installed in deeper waters, cost of energy will increase (Schwanitz & Wierling 2016). Hence an alternative cost effective foundation is required that can serve the purpose for using monopile of lesser diameter in deeper waters. The hybrid monopile foundation is a novel idea composed of gravity footing known as "wheel" and an embedded pile. Hybrid monopile is better suited to withstand the combined lateral and vertical loads brought on by the OWT while preserving the design's simplicity. In seismically active regions, several offshore wind farms are being constructed (Bhattacharya *et al.* 2021). In India, first offshore wind farm has been proposed in Gujarat that's a seismically active zone (Rashid and Sarkar 2022). Liquefaction is yet another problem that occurs in seismically active regions. Hybrid monopile foundation is known to reduce the liquefaction susceptibility and tilt caused due to earthquake (Wang *et al.* 2019b).

2 HYBRID MONOPILE FOUNDATION

Hybrid monopole foundation consists of conventional monopile and gravity wheel foundation added at the mudline. This friction wheel can be a frame filled with gravels or a solidly built circular foundation. The hybrid monopile is known to increase the lateral capacity of conventional monopile. Addition of wheel generates shear stress which resist lateral load and generate additional restoring moments. This addition of moments eventually adds to reduced pile rotations. It was asserted that hybrid footing was more beneficial if vertical translations were permitted between the wheel and the pile since the two components were working separately (Arshi 2016). When used with a wheel, the monopile is identical to a retaining wall with a stabilizing base. The base creates a bearing pressure that generates a resisting lateral load as well as moment (Carder *et al.* 1999). Hybrid monopile foundation is comparable to a pile having pile caps, and the benefits of pile caps have been extensively researched (Mokwa & Duncan 2001, Rollins & Cole 2006). Merits of pile cap has been attributed to significant contribution of passive resistance on the pile cap (Rollins & Cole 2006). Hence analogous to retaining wall and pile cap, hybrid monopile foundation is effective in resisting lateral loads. In general, two different arrangements have been proposed for hybrid monopile foundation i.e., coupled and decoupled.

2.1 *Coupled hybrid monopile foundation system*

In coupled hybrid monopile foundation system, the gravity circular footing is firmly connected to monopile. The pile and wheel in the coupled system share all vertical loading, and to achieve a contact pre-stress between the wheel and the soil, the loads applied must exceed the pile's axial capacity. This will prevent settlement and maintain the plate's contact with the underlying soil. This solution is fundamentally similar to a pile raft with a one pile and would give considerable savings in depth and diameter of monopile.

2.2 *Decoupled hybrid monopile foundation system*

In decoupled hybrid monopile foundation system, the gravity circular footing is not rigidly connected to monopile and is free to slide. The vertical loads applied are taken individually by the wheel and pile. The vertical load transfer occurs only due to frictional force at wheel-monopile connection. The wheel can resist significant vertical loads e.g., the loads coming from weight of wind turbine tower and small additional loads. Hence decoupled system can be used with little or no additional loads coming on pile.

2.3 *Various limit states for design of hybrid monopile*

The state beyond which the structure-foundation assembly will no longer meet the required performance standards is known as a limit state. For hybrid monopile foundation, four limit states are generally considered for design. These limit states are Ultimate limit state (ULS), Serviceability limit

State (SLS), Fatigue Limit state (FLS) and Accidental limit state (ALS). ULS is the maximum load-carrying capacity of a structure. It can be reached owing to various reasons like extreme buckling, loss in equilibrium of structure, extreme yielding and failure of component. For ULS load factors are taken as 1.35 and 1.0 for environmental loads and permanent loads respectively (DNV.GL 2016, Ma & Yang 2020). However, for cyclic loading condition ULS is not commonly experienced (Byrne & Houlsby 2003). Hence for cyclic conditions worst expected transient load is taken, which is calculated by dividing ultimate bearing capacity by 1.35. SLS is in accordance with tolerance requirements related to the usual and typical use of the wind turbine. The serviceability is generally lost due to very high deflections, excessive vibrations and differential settlements causing excessive tilt. Generally maximum allowable rotation is 0.25°. The Fatigue limit state (FLS) pertains to the cumulative effect brought on by repeated loads. To estimate fatigue, estimation of stiffness of foundation is necessary. The FLS depicts the likelihood of failure brought on by the accumulation of cyclic loadings, which may happen at 10^7 cycles. (Wang et al. 2019a). ALS takes into account potential unanticipated or inadvertent loads that could result in a loss of regional or local structural integrity.

In addition to the above mentioned states, there are various design considerations affecting limit states like scour, marine growth and corrosion. A significant design factor is scour, which can alter the structural integrity of foundations. With increase in scour depth, lateral capacity of hybrid monopoles can be reduced by around 15-20% for both SLS and ULS (Li *et al.* 2022).

3 STATIC RESPONSE OF HYBRID MONOPILE SUPPORTED OFFSHORE WIND TURBINE

Offshore wind turbines are slender structures that are subjected to lateral loads due to wind, wave and earthquakes. In this section, review of static response of hybrid monopile supported offshore wind turbine is presented.

Arshi (2016) performed experimental and numerical tests for hybrid monopile supported wind turbine. The effect of addition of wheel was examined for lateral loading conditions. Various parameters were varied and the effect on lateral bearing capacity was examined. Wang *et al.* (2018) performed various centrifuge tests for hybrid monopile foundations and increase in lateral capacity was noted more for loose sand than dense sand. Yang *et al.* (2019) studied lateral-moment loading using centrifuge and numerical modelling for saturated sand. Increase in lateral resistance of pile is found to be due to increase in bearing pressure in front part of the wheel. Wang & Li (2020) performed series of centrifuge tests for parametric studies of hybrid monopile and analytical method was proposed. Wang *et al.* (2022) performed centrifuge tests as well as developed numerical models to study the lateral response. Two different pile connection modes i.e., perfectly rough & perfectly smooth were studied. Different intensities of vertical loadings were also studied. The review of various studies pertaining to parametric variations is given below.

3.1 *The effect of vertical load*

The addition of vertical load enhances the bearing capacity of hybrid monopile considerably. However, this effect has been found to be dependent on position, intensity of vertical load as well as pile-wheel connection. For vertical load applied on wheel, the capacity increases to a greater extent. The enhancement in bearing capacity is because of better connection between wheel and soil due to applying loads directly on wheel (Arshi 2016). This effect of increase in bearing capacity when load applied directly on wheel is more pronounced in case of smooth connection between wheel and pile. It has been found with increase in vertical load, the stiffness decreases while as bearing capacity increases (Wang *et al.* 2022). Slight increase in capacity is also found when load is applied directly on pile. The increased stress in front of the pile is the cause of this increment. Moreover, it has been found that vertical bearing mechanism of hybrid rigidly joined monopile is similar initially to that of wheel only foundation implying more dominance of wheel during initial stages. Also vertical bearing capacity of hybrid monopile is smaller than that of pile and wheel individually. This decrease is due to overlapping stress zones (Brown *et al.* 1988, Ashour *et al.* 2004).

3.2 *The effect of connection type*

Three different connection types are possible between wheel and pile i.e., perfectly smooth, perfectly rough and frictional. Frictional coefficient has very less effect on lateral response of hybrid monopile (Wang *et al.* 2022). Hence perfectly rough and frictional connection are similar as far as lateral load response is considered. No increase in bearing capacity has been found for smooth connection type when vertical loads are applied directly on pile as there is no contact between wheel and pile. This increase is more pronounced in case of rough connection (Arshi 2016). This rigid connection eliminates the effect of position of vertical load. Further for higher loads the bearing capacity is high when loads are applied directly on wheel for smooth connection.

3.3 *The effect of wheel diameter*

Bearing capacity is found to be increased with increase in diameter of wheel. Centrifuge tests conducted have revealed that wheel rotates into the soil in addition to translation that results in soil heave right in front of wheel. Soil behind the wheel is found to be separated on application of lateral load (Yang *et al.* 2019). This embedment of wheel is found to be the reason of increase in lateral resistance (Pedram 2015). Hence with increase in diameter of wheel, the embedment will occur over large area resulting in increase in bearing capacity. The relationship between wheel diameter and ultimate bearing capacity was fitted by series of power curves (Wang & Li 2020)

3.4 *The effect of wheel thickness*

It has been established that as wheel thickness increase, so does lateral bearing capability (Yang *et al.* 2019). However, especially for wheels with very little thickness, the increase in stiffness is not as considerable as wheel diameter. The hybrid foundation system's lateral bearing capability increases linearly with wheel thickness (Wang & Li 2020).

4 DYNAMIC RESPONSE OF HYBRID MONOPILE SUPPORTED OFFSHORE WIND TURBINE

A few offshore wind turbines have already been built in seismically active areas, and some more are also planned (Bhattacharya *et al.* 2021). The soil becomes softer due to dynamic loads, which lowers the soil's bearing capacity. As a result, during the strong earthquake, significant structural settlements and tilts are observed (Liu & Dobry 1997). The soil liquefaction that occurs during an earthquake in an offshore area, in addition to the vibrations brought on by interactions with dynamic loadings and the vibrations of the blades, may seriously harm the entire structural system made up of the upper structure as well as foundation system.

4.1 *Liquefaction*

Liquefaction is one of biggest challenges in regions having high seismicity. Liquefaction of soil can cause serious damage to wind turbine. With highly seismic regions like Taiwan, India etc having plans of building wind turbine farms, the problem of liquefaction is inevitable (Kaynia 2019). Liquefaction could happen in the shallow deposits, which could cause the foundation structure to severely overturn and settle (Li *et al.* 2021). Few studies have been carried out to study liquefaction performance of OWT on monopile foundations (Esfeh & Kaynia 2020, Patra & Haldar 2021). Loss of support along monopile's depth occurs during liquefaction, significantly reducing the system's stiffness. Decrease of the fundamental frequency is observed and may cause resonance with high energy wave loads (Demirci *et al.* 2022). Hybrid monopiles have been found to reduce liquefaction both at the foundation edges and beneath the foundation close to the pile (Wang *et al.* 2020). Pore water pressure ratios near the pile where found to be reduced than free field response and hence chances of liquefaction were reduced. Review of various parametric studies are given below.

4.2 *The effect of wheel diameter*

For saturated as well as dry sand with increase in wheel diameter steep decrease in lateral displacement is seen. However, with increase in wheel diameter the settlements are increased due to dissipation of excess pore pressure requiring a longer pathway. Furthermore, for same weight, the hybrid settles with increase in diameter. Hence for settlement criteria, influence of wheel diameter has to been seen in conjugation with wheel weight. The large diameter pile is likely to attain lesser pore water pressure ratios though rate of dissipation has been found to be reduced. Hence with increase in wheel diameter, soil is found to be less susceptible to liquefaction (Wang *et al.* 2019b).

4.3 *The effect of wheel thickness*

Wheel thickness has considerable effect on response of OWT for both dry and saturated conditions. The lateral displacement tends to diminish as wheel thickness increases. However, the settlement increases with increase in diameter. Nonetheless, the rate of change is less severe than the lateral displacement. Also with increase in wheel thickness similar to wheel diameter, pore water pressure ratio is found to be reduced and hence chances of liquefaction are diminished by use of hybrid monopiles (Wang *et al.* 2019b)

5 CONCLUSIONS

This paper presents a comprehensive review of a novel hybrid monopile-supported offshore wind turbine. Sufficient experimental centrifuge studies and few numerical studies have been reviewed pertaining to hybrid monopile supported offshore wind turbine. Overall review of hybrid monopile along with its types have been presented in the paper. The review of numerous parameters for both static and dynamic conditions is also presented. Following important conclusions can be drawn.

1. It has been confirmed by various studies that hybrid monopiles are very effective for reducing lateral deflections, improving bearing capacity and also reduce liquefaction susceptibility.
2. With increase in wheel thickness and diameter, lateral deflections have been reduced for both static and dynamic tests. Lateral bearing capacity has been found to be increased.
3. Vertical load has improved the lateral bearing capacity as well as reduced lateral deflections and its effect is dependent on connection type as well as position of load.
4. Liquefaction susceptibility has also reduced by hybrid monopile. With increase in wheel thickness and diameter, susceptibility has been found to be reduced.
5. With many advantages in comparison to conventional monopile. There are few disadvantages of hybrid monopile. It has been found that hybrid monopile increases settlement in comparison to traditional monopile.
6. Though experimental and few numerical studies have been conducted in recent years for hybrid monopile still there are many aspects which have not been studied yet. In order to determine the foundation system's versatility, its performance should be examined for a variety of soil types. Wind turbine experience combined loading conditions. VMH failure envelopes can be developed for hybrid monopile foundation. All the experimental liquefaction studies conducted were not fully undrained tests, hence fully undrained centrifuge tests need to be conducted along with numerical studies to give a better picture of liquefaction of sand.

Difference in cyclic lateral loading behavior of a monopile on sandy and clayey grounds

K. Nakai
Nagoya University, Nagoya, Aichi, Japan

M. Ito & S. Sato
Obayashi corporation, Tokyo, Japan

ABSTRACT: As the market for renewable energy continues to expand, expectations for offshore wind power are growing. Monopiles, the most common type of offshore wind turbines foundation, are subjected to cyclic lateral loading due to wind and ocean waves during their service life. Therefore, it is desirable to accurately understand the cyclic loading characteristics of monopiles for design purposes. In this paper, we attempted to understand the difference in cyclic loading behavior of a monopile on sandy and clayey grounds through both model experiments and finite element analysis. As a result, it was confirmed that the lateral displacement of the sandy ground was gradually suppressed by the densification in front of the pile during cyclic loading. On the other hand, the clayey grounds showed rapid increase of displacement if the soil was disturbed by large cyclic loading.

1 INTRODUCTION

As the market for renewable energy continues to expand, expectations for wind power are growing. In Japan, there are few suitable sites for wind power generation on land, so offshore wind power generation is expected to become more popular. Monopiles, the most common type of offshore wind turbines foundation, are subjected to cyclic lateral loading from wind and ocean waves during their service life. Therefore, it is desirable to accurately understand the cyclic loading characteristics of monopiles for design purposes. Large-scale wind farms have been already constructed in Europe, and many studies have been accumulated. However, most of the studies on the behavior of monopiles subjected to cyclic loading have been conducted on sandy grounds (Long et al. 1994, Liao et al. 1999), and few studies have been conducted on soft clayey grounds which frequently exist around Japan. The purpose of this paper is to understand and compare the cyclic lateral loading behavior of a monopile on sandy and clayey grounds through model experiments and FEM analysis.

2 OUTLINE OF MODEL EXPERIMENTS AND NUMERICAL ANALYSIS

Schematic diagrams of the model experiment are shown in Figures 1a, b. The model pile was made of aluminum with an outer diameter of 130mm, a wall thickness of 3.0mm, and a length of 1,600mm, about 1/50th the scale of the real pile. The sandy ground was made of Nikko silica sand No. 6 in a rigid soil tank to achieve a relative density of 60%. The clayey ground was excavated from the surface soil at the outdoor test site to expose clay with N-values of 2 to 4. In both cases, a model pile was installed into the ground with a penetration depth of 800mm. Lateral loading was conducted by an electric jack 720mm above the ground surface.

DOI: 10.1201/9781003299127-335

The analysis code used was a soil-water coupled finite deformation analysis (Noda et al. 2008) employing elasto-plastic constitutive model; SYS Cam-Clay model (Asaoka et al. 2002), that can describe the mechanical behavior of various soils from sand to clay within a same theoretical framework. FEM mesh is shown in Figure 1c. The mesh was prepared with reference to the rigid soil tanks used in the model experiments, and a half-section model was used considering the symmetricity. The same mesh was used even for clayey ground. Here, the distance from the monopile to the boundary of the analysis domain is more than 3φ for a pile diameter of φ130mm, so the difference in boundary conditions was considered to have less effect. The material constants and initial conditions were determined from the results of laboratory tests (standard consolidation and triaxial compression tests) conducted under the same conditions as the model experiments. The monopile was assumed to be a linear elastic body using solid elements, and the elastic constants of aluminum were used to obtain the same conditions as in the model experiment.

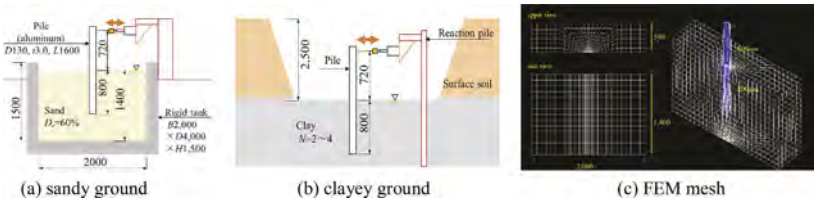

Figure 1. Schematic diagram of model experiments and FEM analysis.

3 MONOTONIC LATERAL LOADING BEHAVIOR

Figure 2 shows the reaction force-displacement relationship at the loading point for the monotonic lateral loading test conducted on sandy and clayey grounds. The analytical results for both grounds reproduce the experimental results well. Comparing the two grounds, the clayey ground had a clear ultimate bearing capacity *Pu*, while the sandy ground continued to increase lateral load. Based on the experimental results, *Pu* = 0.82kN for the sandy ground and *Pu* = 5.9kN for the clayey ground were determined.

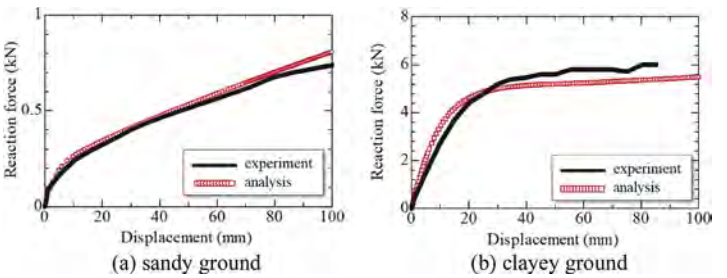

Figure 2. Monotonic loading behavior by model experiment and FEM analysis.

4 CYCLIC LATERAL LOADING BEHAVIOR

Cyclic lateral loading tests were conducted at amplitudes of 0.1*Pu*, 0.3*Pu* and 0.5*Pu* based on the ultimate load *Pu* obtained from the monotonic loading tests. The 0.1*Pu* assumes ocean waves at ordinary conditions, while the 0.3*Pu* and 0.5*Pu*, storm waves. The loading was given in the form of a one-sided triangular wave, and the periods are assumed to be 6, 11 and 16 seconds for 0.1*Pu*, 0.3*Pu* and 0.5*Pu*, respectively, as average values of the assumed external forces.

Figure 3 shows the relationship between the displacement increase rate at ground surface $\delta N/\delta N_1$ and the number of cycles N in the model experiments (where δN and δN_1 are the displacement at the Nth and 1st cycles, respectively). The lateral displacement increased with the

number of cycles for both grounds. For the sandy ground, the displacement tended to converge showing linear relation on the one-logarithmic graph. Moreover, the increase rate did not change significantly regardless of the amplitude. On the other hand, for clayey ground, the increase rate became large with the amplitude, and the lateral displacement increased rapidly during the cycles. In addition, the larger the amplitude, the more rapidly the displacement increased after a smaller number of cycles. The analytical results are shown in Figure 4. Although the number of cycles at which the displacement began to increase is slightly smaller for clay, the analytical results captured the trend of the experimental results well, as the increase rate was linear for the sandy ground and the displacement increased rapidly for the clayey ground.

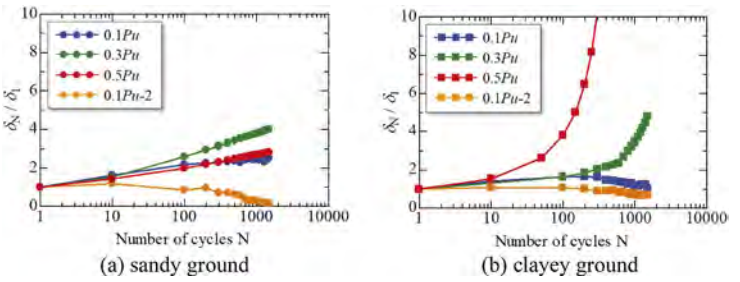

Figure 3. Relationship between displacement increase rate and number of cycles (model experiments).

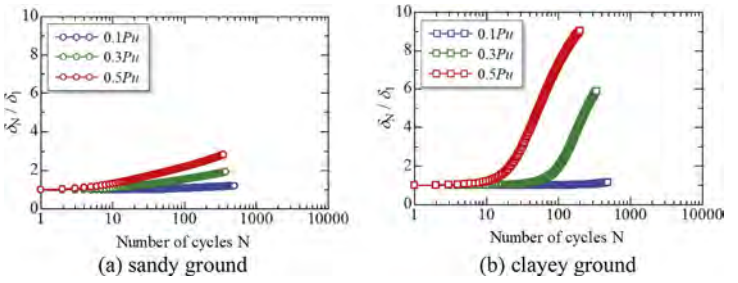

Figure 4. Relationship between displacement increase rate and number of cycles (FEM analysis).

The difference in cyclic loading characteristic between sandy and clayey grounds are discussed in detail. Figures 5 and 6 show the distribution of void ratio change, degree of structure and shear strain after 40 cycles at an amplitude of $0.5Pu$ in sandy and clayey ground, respectively. Here, structure stands for the bulkiness of the soil, which is widely observed in soft soils, and the higher the degree of structure, the more sensitive the behavior. Lowering/collapse of the structure can be regarded as soil disturbance, which causes volumetric compression and decrease in strength. The void ratio change shows that the sandy ground became denser in front of the monopile during cyclic loading. On the other hand, clay with low permeability showed little density change. This indicates that the displacement of the monopile in the sandy ground was gradually suppressed by the density increase during cyclic loading. The distribution of the structure indicates that clayey ground possessed higher degree compared with sandy ground at initial condition. In addition to that, the clayey ground was strongly disturbed during cyclic loading, and the structure around the monopile was lowered over a wide area. Especially in the case of large amplitude, the clay ground was significantly disturbed, and the displacement of the monopile increased rapidly during loading. The shear strain shows that the strain in the sandy ground was concentrated around the pile, whereas that in the clayey ground was spread over a wide area. This tendency was the same as the experimental results, although the details are omitted due to the limited pages.

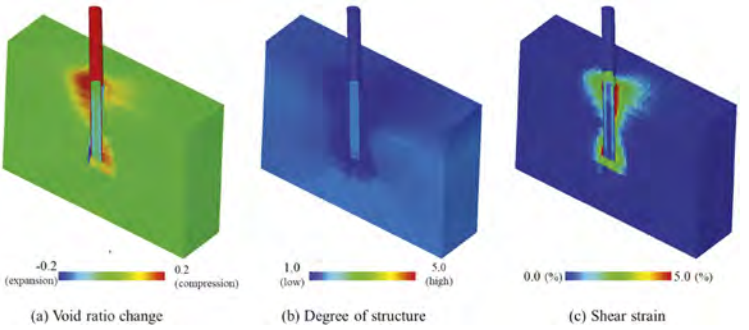

Figure 5. Contour distributions of sandy ground subjected to 40 cycles of cyclic loading with 0.5*Pu*.

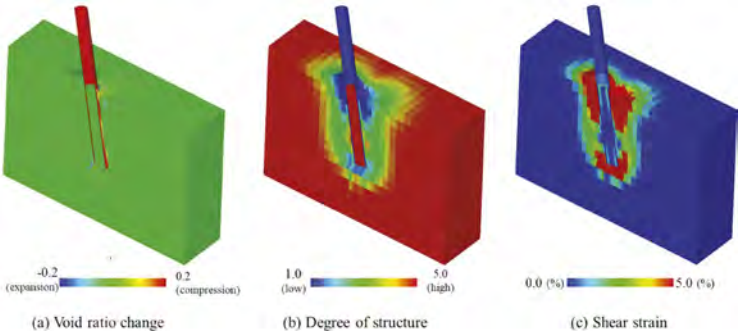

Figure 6. Contour distributions of clayey ground subjected to 40 cycles of cyclic loading with 0.5*Pu*.

5 CONCLUSIONS

We compared the cyclic lateral loading behavior of a monopile on sandy and clayey grounds through both model experiments and FEM analysis. In sandy ground, lateral displacement was gradually suppressed by density increase during cyclic loading. On the other hand, the clayey ground showed rapid increase of displacement if the soil was disturbed by large cyclic loading. In addition, the 0.1*Pu*-2 in Figure 3 was the result of cyclic loading at 0.1*Pu* after a cyclic history of 0.3*Pu*. This result also confirms experimentally that, if the load history is large beforehand, displacement hardly propagates under small amplitude loading.

Comparison between model experiments and FEM analysis has confirmed the validity of the analytical code. Therefore, in the future, this analysis code will be used to study complex stratification alternating clay and sand layers that cannot be reproduced by model experiments, as well as for full-scale studies.

Finally, we would like to thank Prof. Toshihiro Noda (Nagoya University) and Mr. Taku Kurimoto (Obayashi corporation) for valuable advice in the course of this research.

Enhancing load carrying performance of helical anchor with changes in load application point

J. Lee, Q. Abbas, J. Yoon, D. Nam & J. Lee
Yonsei University, Seoul, Korea

ABSTRACT: Helical anchor is effective to support offshore structures as the installation is relatively fast and simple. The installation requires mooring lines, which need to be introduced to carry floating upper structures. The mooring configuration for helical anchor usually shows an inclined loading condition. In this study, the effect of load application point (z_p/L) and inclined loading condition on the load carrying mechanism of helical anchor is presented. The pullout capacity of helical anchor for different load inclination conditions is described considering changes in load application point. Optimal load application point, which leads to the largest load carrying capacity, is shown for various helical-anchor configurations. The pullout load carrying capacity of helical anchor became different depending on the position of load application point, which was similar to the case of suction anchors. The location of optimal load application point that maximized the pullout load capacity was presented.

1 INTRODUCTION

For the past few decades, helical anchors have been used frequently for offshore foundation system. Helical anchors have various advantages including immediate mobilization of the load carrying capacity, fast installation, and flexibility in changing configurations. The helical anchor consists of a shaft and helically shaped plates welded along the shaft. Owing to the constitution of different structural components, helical anchors indicate a variety of configurations and can be effective to resist against both compressive and tensile loads. Furthermore, helical anchors can carry loads in various directions including axial, lateral, and inclined direction as the mooring system is introduced.

The load-carrying behavior of helical anchors has been widely studied (Rao et al. 1991,1993, Merifield 2011, Wang et al. 2013, Schiavon et al. 2016, Harnish & El Naggar 2017, Kwon et al. 2019). Merifield (2011) presented a design method for tensile load-carrying capacity of helical anchor installed with multiple plates for various anchor configurations. Wang et al. (2013) performed a large-deformation finite element (FE) analysis to characterize the tensile load-carrying capacity of helical anchors.

When helical anchors are installed for supporting an offshore floating structure, a mooring system with load-carrying lines is necessary to deliver loads from floating structure to the anchors. Cortes-Garcia et al. (2019) and Kwon et al. (2019) studied the load-carrying behavior of helical anchor subjected to inclined loading conditions and, and that for cyclic loading condition was investigated by Lee et al. (2019).

As the mooring system is introduced, the location of the load application point, given by pad-eye, also needs to be considered as a component that affects the load carrying behavior of the anchors. As reported in the literature (Aubeny et al. 2003, Tian et al. 2015, Kim & Hossain 2016), the location of the load application point on the shaft indicates certain effect on the load-carrying behavior of embedded types of anchor systems. The effect of the load application points for helical anchors was also investigated by Lee & Lee (2022).

DOI: 10.1201/9781003299127-336

In this study, the effect of the load application point on the load-carrying mechanism of helical anchors is presented. For this purpose, the results given by Lee & Lee (2022) were introduced and analyzed. 4 types of helical anchor with different failure types and number of plates were considered and the mooring location inducing the largest load-carrying capacity was proposed.

2 DESCREPTION OF ANALYSIS MODEL

2.1 *Model description*

The configuration of a helical anchor is illustrated in Figure 1. L, H, D, S, and d in the figure represent the depth of lowermost plate, the depth of uppermost plate, diameter of plates, spacing between plates, and the diameter of shaft, respectively. In this study, four different configurations of helical anchors were considered, and specifications are given in Table 1.

For the analyzing the effect of load application point on load-carrying capacity of helical anchors, the coupled Eulerian-Lagrangian (CEL) finite element (FE) analysis was adopted. Five load application points (z_p) of 0.0L, 0.25L, 0.5L, 0.625L, and 0.75L and four load inclination angles (θ) of 0°, 30°, 60°, and 90° were considered.

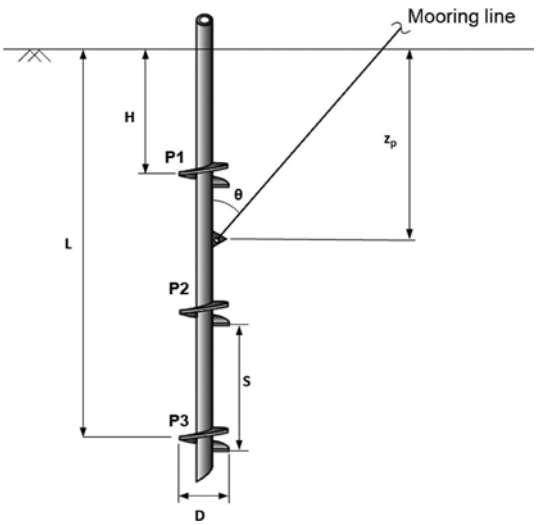

Figure 1. Configuration of helical anchor and mooring condition.

Table 1. Configurations of helical anchors.

Name	d (mm)	Plates	D (mm)	H (m)	L (m)	S (mm)	S/D
S2	160	P2, P3	300, 400	1.6	2.2	600	1.2
S3	160	P1, P2, P3	300, 400, 500	1.0	2.2	600	1.2
L2	160	P2, P3	300, 400	5.5	8.0	2,500	5
L3	160	P1, P2, P3	300, 400, 500	3.0	8.0	2,500	5

3 ANALYSIS RESULT

3.1 *Effect of load application point*

The value of load-carrying of helical anchor with each z_p (Q_u) obtained from the FE analyses were normalized with the value of the maximum load-carrying capacity of each θ condition

($Q_{u,max}$) in Figure 2. The normalized value ($Q_u/Q_{u,max}$) in the figure has showed similar shapes of changes. $Q_u/Q_{u,max}$ increased as z_p became greater, around to 0.5L or 0.625L. It decreased as z_p further increased. The case of $\theta = 90°$ in Figure 2(c) showed a consistent depth-profile shape with normalized load application point depth (z_p/L) for conditions.

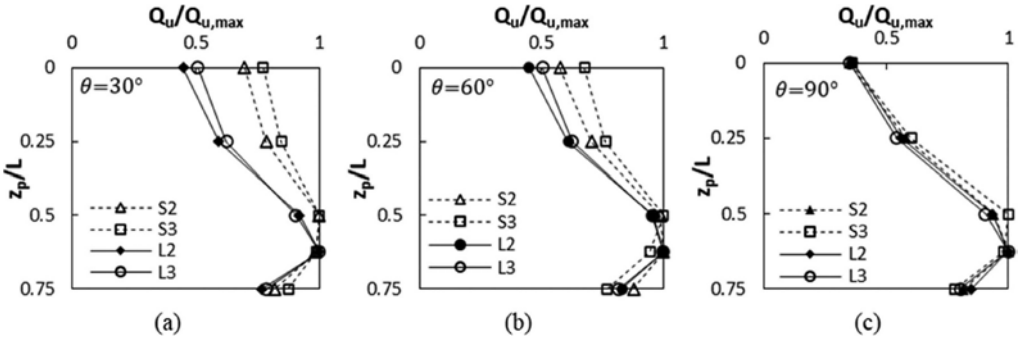

Figure 2. Values of $Q_u/Q_{u,max}$ for (a) $\theta = 30°$; (b) $\theta = 60°$; and (c) $\theta = 90°$.

3.2 *Design implication and optimum location of load application point*

It was shown that the load application point (z_p) affects the load-carrying capacity of helical anchors, and there is an optimal location of the load application point. The horizontal load-carrying mechanism indicated key role in the overall load capacity for helical anchors. For the optimum load application point, the vertical and horizontal load capacity components, given by Q_H and Q_V, were normalized with the maximum vertical and horizontal load capacity components of $Q_{H,M}$, and $Q_{V,M}$. These were plotted in Figure 3. For $Q_H/Q_{H,M}$, the results were unique while those for $Q_V/Q_{V,M}$ depended on the inclination angle as shown in Figure 3(a).

The correlation of $Q_V/Q_{V,M}$ to z_p/L and $Q_H/Q_{H,M}$ to z_p/L given in Figure 4 were:

$$Q_V/Q_{V,M} = 1 - 0.56(\theta \cdot z_p/L) \qquad (z_p/L \leq 0.625) \tag{1}$$

$$Q_H/Q_{H,M} = 1.1(z_p/L - 0.625) + 1 \qquad (for\ z_p/L \leq 0.625) \tag{2}$$

For Equation (1) and (2), the installation effect was considered for which the strength reduction factor of 0.6 was applied within the surrounding soil. Note that Equation 1 is valid for the condition $30° \leq \theta \leq 60°$.

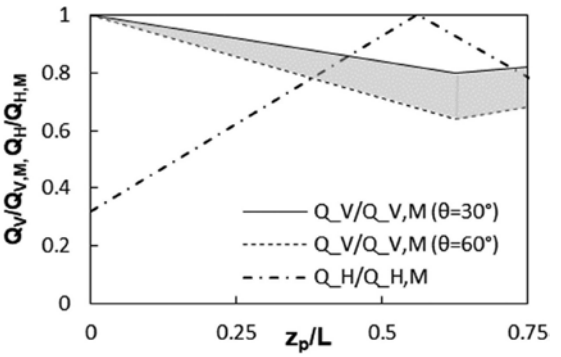

Figure 3. Normalized vertical and horizontal load capacities with z_p/L: (a) $Q_V/Q_{V,M}$; (b) $Q_H/Q_{H,M}$.

4 CONCLUSION

In this study, the effect load application point (z_p) on the load-carrying capacity of helical anchors under inclined loading condition was presented. Four configurations of helical anchors with different z_p and load inclined angles (θ) were considered. Unlike the conventional loading condition for helical anchor with loads applied at the top of the anchor, it was shown that adjusting z_p can further enhance the pullout load-carrying capacity of helical anchors. The load capacity of helical anchor increased for depths to the optimal load application point ($z_{p,opt}$), and decreased as z_p further increased to depths deeper than $z_{p,opt}$. The value of $z_{p,opt}$ equals to 0.625. Design equations for different loading conditions to quantify load-carrying capacity of helical anchor was presented.

Commentary on the art and science of hydraulic filling

O. Boumendjel-Game
University of Bristol, Bristol, UK
Arcadis Consulting, UK & Ireland

A. Diambra & P.J. Vardanega
University of Bristol, Bristol, UK

ABSTRACT: Hydraulic filling remains arguably a relatively new geotechnical engineering process, despite having been used for decades to construct mega projects around the globe. The publication of the Hydraulic Fill Manual has been an important initiative to standardize some key aspects of the hydraulic filling process. However, there are key aspects such as consideration of contractual arrangements that are aligned with current industry trends, characterization of the 'at source' and 'after deposition' properties of the hydraulic fill, and performance criteria of the fill mass for which further/revised guidance may be needed. This paper reviews the current state of hydraulic filling guidance documents and offers some suggestions for future developments.

1 INTRODUCTION

Hydraulic Filling (HF) is the process followed for excavation, transportation and deposition of fill, using a stream of water, to create new land and/or raise the elevation of existing low-lying land. HF has become synonymous with dredging and reclamation works, in particular for major infrastructure, civil and marine projects. This association is expected to continue, based on observed trends of reclamation contract volumes and the forecast for the demand for dredging services in the coming years (van 't Hoff & van Der Kolff 2012, Fmi 2022). Until the publication of the Hydraulic Fill Manual (HFM) (van 't Hoff & van Der Kolff 2012), guidance for reclamation projects using hydraulic fill was limited. Therefore, the HFM is considered a milestone in recognizing the complexity associated with the initiation, planning and construction of HF projects. This paper aims to highlight some areas that would benefit from further enhancement and future development of applicable codes of practice and standards specific to HF, while taking into consideration established local practices for reclamation works (e.g. Shen & Lee 1995, Shen et al. 1997, CEO 2002).

2 THE HYDRAULIC FILLING PROCESS

HF is the method/technique used to reclaim land and/or raise the elevation of low-lying land using a soil and water mixture to dredge, transport and deposit the hydraulic fill material in the designated development area (e.g. Kolman & van 't Hoff 2013) (see Figure 1 for a flowchart that depicts the key elements of the process).

3 PRACTICAL ENGINEERING CONSIDERATIONS

3.1 *Contractual aspects*

The HFM was developed around the interfacing among three contractual partners, namely Client-Consultant-Contractor (see HFM Sn. 1.3 & Fig. 1.3, p. 4). This suggests that HF project are planned, designed and constructed using a 'traditional contract' arrangement. However, as

DOI: 10.1201/9781003299127-337

'traditional contracts' have sometimes become the exception rather than the norm and considering the claims and disputes noted in recent years due to the use of other types of contracts (e.g. 'Design and Build' or 'Engineering Procurement and Construction'), it would be beneficial to adapt the manual to include other contractual arrangements. Such types of contracts are already apparent in the recommended example specification clauses in Chapter 12 of the HFM. In 2016, FIDIC published the FIDIC Blue Book, which is the second edition of the Form of Contract for Dredging and Reclamation Works (FIDIC 2016, Maddock & Vanderburghe 2016), was another milestone in recognizing the need of the marine industry for specialized guidance on contractual arrangements for HF projects.

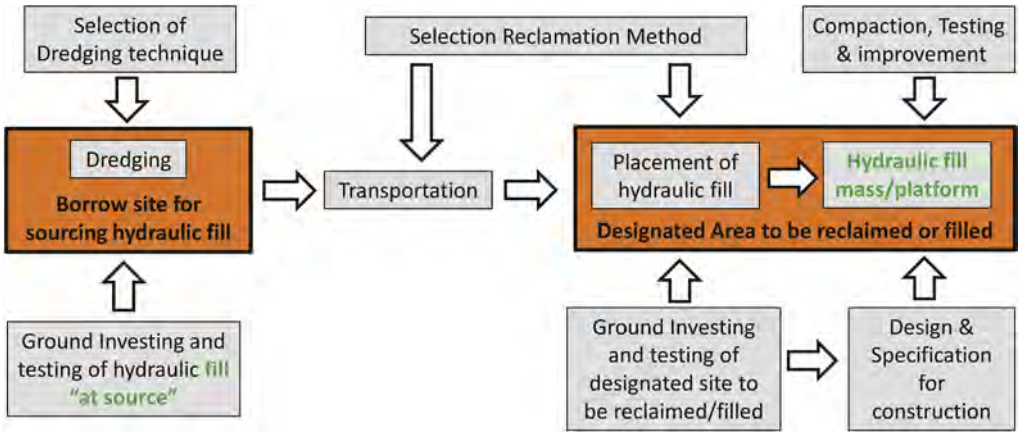

Figure 1. Key aspects of the HF process (based on van 't Hoff & van Der Kolff 2012, Kolman & van 't Hoff 2013).

3.2 *Ground investigation/Data collection*

For a HF project, there are two distinct areas/sites of interest, namely: (i) the borrow for sourcing the fill and (ii) the site receiving the hydraulic fill (see Figure 1). The borrow is usually located offshore up to several km away from the designated areas to be reclaimed and/or filled. The objectives and scope of ground investigation for each site are different, despite some elements of investigation and testing being similar for performance assessment. There is also the influence of the contractual arrangements discussed in Section 3.1 of this paper, regarding the scope and the stage of the project when gathering information for each area is required. To enable adequate interpretation of the hydraulic fill characteristics 'at source' and 'after deposition', the ground investigations for these two distinct sites/areas should be covered separately because of the influence of the latter on the design and construction of the intended development (e.g. Cao 2003, Lee et al. 1999, Mengé 2021).

3.3 *Design standards*

In this paper, the authors have endeavored to cite the most recent version of a British Standard Institution (BSI) standard when mentioned in this paper while noting that other cited publications may refer to earlier versions of these standards. Several standards are referred to in the HFM, notably the *Code of practice for earthworks* (BSI 2010a). Whilst it is accepted that the process involves earth moving activities, there are still several aspects that are distinctly different from a typical earthworks project. This has been recognized in the publication of the dedicated HF part (part 6) of BS EN 16907 (BSI 2018b). This could be applied to updates to other codes of practice such as *Eurocode 7: Geotechnical design* (BSI 2010b, 2014) to include specific guidance for characterization and testing of hydraulic fill, design of the hydraulic fill mass, and consideration of the serviceability of the intended constructions.

3.4 *Gradation of hydraulic fill*

The nature and characteristics of the in-situ soils forming the hydraulic fill 'at source' are not all equal due to varying local and regional geological settings and structures. As a result, change in gradation of the fill 'after deposition' is anticipated for some fill types (see Figure 1). The level of change is influenced by the composition of the in-situ sand fill, potential degradation during dredging, deposition and compaction at the designated site (e.g. van 't Hoff & van der Kolff 2012, Kolman & van 't Hoff 2013). Concentration of fines may also occur due to material segregation during transportation and compaction, which in turn, may lead to ponding of remnant water within the fill mass, all of which would affect the fill mass geotechnical characteristics and performance (e.g. Lee et al. 1999, Gens 2019, van Ginkel & Olsthoorn 2019). However, testing and modelling of the in-situ fill to mimic anticipated gradation and, therefore, potential properties 'after deposition' is generally not carried out, with reliance often being placed on investigation and testing of the fill mass 'after deposition' and compaction (e.g. Cao 2003, Mengé 2021). This is recognized in the manual (see HFM Sn. 5.2.1 p. 104 and Sn. 9.2.5.1 p. 357), subsequently recommending testing of fill samples having a range of different gradings (this is echoed in BSI 2018b).

3.5 *Drainage*

An overview has been provided in the HFM (see HFM, Sn 10.2 pp. 388–394) for the drainage aspects of the hydraulic fill mass. One of the highlighted issues relates to the formation of a fine-grained crust at the top of the fill mass during hydraulic placement (see HFM, Sn. 10.2.1, p. 390), thus, affecting permeability of the fill. Localized soft spots/bands can develop at any depth and extent of the fill mass during HF. There is also the issue of the remnant sea water after construction, which will affect both the dissipation rate of this remnant water within the fill mass and drainage of surface stormwater run-off during service (cf. van Ginkel & Olsthoorn 2019). The latter is usually addressed through design of appropriate surface storm water drainage systems (cf. van Ginkel & Olsthoorn 2019). The former, however, is influenced by the hydraulic conductivity of the newly formed fill mass, which in turn is governed by the gradation of the fill after deposition and compaction, vertical and lateral drainage paths within the fill mass, location and lateral distance of the ponded area from the discharge point of the same fill mass and the drainage system adopted to control phreatic levels (cf. van Ginkel & Olsthoorn 2019).

3.6 *Construction specifications*

One of the objectives of the manual is help avoid problems associated with stringent and conflicting specifications. As indicated in Section 3.1 of this paper, Chapter 12 of the HFM provides examples of typical specification clauses. As further enhancement, it is recommended that this overview is developed to include preparation of standard specifications for HF, thus, reduce uncertainties and potential mis-interpretations, and then, discontinue reliance on adapting technical specifications that were developed for previous dredging and reclamation projects or use of standard specifications that were developed for different earth moving practices (e.g. NH 2022). Such initiatives would complement the FIDIC Blue Book (FIDIC 2016) that was developed specifically for dredging and reclamation works, as discussed in Section 3.1 of this paper.

4 SUMMARY AND CONCLUSIONS

HF is commonly used in land reclamation and filling works. The publication of the HFM in 2012 (van't Hoff & van der Kolff 2012) and *Earthworks – Part 1: Principles and general rules* (BSI 2018a) and *Earthworks – Part 6: Land reclamation earthworks using dredged hydraulic fill* (BSI 2018b), are fundamental advances in specifications and guidelines for HF. This paper has highlighted some key aspects which would benefit from further consideration if updates of the manuals and/or preparation of new guidelines are considered. It is suggested that improvement of the practice in this manner combined with adopting the FIDIC Blue Book (FIDIC 2016) as a form of contract would reduce contractual disputes, claims and/or litigations through shared risks.

Increase in injection efficiency using surfactant for the geological carbon sequestration

Seok-Gu Gang, Jae-Eun Ryou & Jongwon Jung
Chungbuk National University, Cheong-ju, South Korea

ABSTRACT: Carbon dioxide is a greenhouse gas which cause the global warming. The geological carbon sequestration is one of ways to reduce the amount of atmospheric carbon dioxide. Among various sites such as hydrate-bearing sediments, coal seam etc., saline aquifer is one the possible sites for the geological carbon sequestration because saline aquifer has the larger volume capacity than others. Thus, it is important to store as much carbon dioxide as possible in aquifers with the limited volume space. In this study, we conducted micromodel experiments and PNM (pore network model) numerical analysis to increase the carbon dioxide injection efficiency using surfactants. Finally, the technique to enhance the carbon dioxide injection efficiency through surfactants was developed for the geological carbon sequestration

1 INTRODUCTION

1.1 *Global warming induced by carbon emission increasing*

With the development of mankind, carbon dioxide emissions are steadily increasing. Carbon dioxide emitted into the atmosphere induces global warming, and global warming threatens human living areas in the form of rising sea levels, floods, and explosions. Table 1 shows the main effects of global warming (1.5°C, 2°C). As a book to deal with such a climate crisis, the international community, through the IPCC (Intergovernmental Panel on Climate Change) and the Paris Climate Treaty, has derived scientific evidence and draft agreements for reducing carbon emissions by country (IPCC, 2018).

Table 1. Main effects of global temperature rise on 1.5°C vs 2°C (Government of Korea. 2020. 2050 Carbon...).

Impacts on earth & humans	1.5°C	2°C
Ecosystems and Humans	High risk	Very high risk
Mid-latitude heatwave temperature	3°C increase	4°C increase
High latitude cold wave temperature	4.5°C increase	6°C increase
Coral extinction	70~90%	≤99%
Population vulnerable to climate impact and poverty	Up to hundreds of millions more by 2050 at 2°C	
Water scarce population	Up to 50% increase at 2°C	
Risk of large-scale extreme events	Medium risk	Medium to high risk
Sea level rise	0.26~0.77m	0.3~0.93m
Frequency of complete extinction of arctic sea ice	Once in 100years	Once in 10 years

DOI: 10.1201/9781003299127-338

1.2 *Carbon neutral using geological carbon sequestration*

Countries around the world have established and implemented carbon neutral policies to reduce carbon emissions. Measures to achieve carbon neutrality are roughly divided into two categories, namely emission reduction and carbon dioxide capture and utilization storage in the fields of industry, construction and transportation. Carbon dioxide is stored in aquifers, dielectric waste gases, etc. In this study, experiments and numerical analyzes were performed with the aim of improving the injection efficiency of reservoirs using surfactants.

2 MATERIAL AND METHOD

2.1 *Material*

Surfactants are divided into positive, negative, non-ionic and amphipathic surfactants according to their hydrophilic charge state. Such a hydrophilic group charge state varies in characteristics depending on the ground soil particle surface charge. For example, the charge compatibility between the surfactant hydrophilic groups and the ground particle surface causes adsorption of the surfactant to the particle surface by attractive forces. This adsorption reduces surfactant loss and injection efficiency. Considering adsorption on particle surface, in this study use anionic surfactants. Because pore surface which use in this study consist of silica (represent anionic charge). So, two anionic sodium dodecyl sulfate (SDS) and sodium dodecylbenzene sulfonate (SDBS) surfactants were used in this study. Table 2 shows the properties and mechanisms of different types of surfactants in geotechnical applications The surfactant solution was diluted to wt% with deionized water (DI).

Table 2. Advantages and mechanism on surfactants ionic characteristic (Negin et al., 2017. most common. . .).

	Cationic	Anionic	Non-ionic	Amphoteric
Advantages*	Cationic and nonionic surfactants mixture is most effective agent for EOR (carbonate reservoir)	Effective for sandstone reservoir	Effective for surfactant flooding in high salinity water or hard water	Strong electrolyte tolerance, temperature resistance, thermos stability, better wetting and foaming
Electrical interaction of reservoir pore surface**	Carbonate surfaces have both cation and anion exchange sites	Sandstone surfaces have anion sites	Not effected by reservoir surface charge	-
Mechanism*	Reducing IFT and wettability alteration	Reducing IFT	Reducing IFT	Reducing IFT and wettability alteration

* Negin et al., 2017. Most common. . .
** Brady, P.V & Thyne, G. 2016. Functional wettability . . .

2.2 *Method*

The Micromodel (Micronit Micro Technologies, Netherlands) used a uniform network model with uniform voids, a pore-volume of 2.3μL, and a porosity of 0.58. Micromodel internal surfactant and carbon dioxide injections were injected via low pressure (New Era Pump Systems, NE-1010) and high pressure (Teledyne, Syriux 500x) syringe pumps, respectively. All injection processes were filmed with a micro lens camera.

2.3 *Experimental procedure*

Figure 1 shows a schematic of this experiment. The main equipment in conducting the experiment consists of a two-dimensional micromodel, low and high-pressure Teflon pumps, and

a micro lens for imaging the injection process. A micromodel connected to low- and high-pressure syringe pumps via high-pressure peak tubing is placed on the imaging bed. The surfactant solution is injected at a constant rate (0.5 ml/min) through a low-pressure syringe pump into the cavity until the air bubbles are completely removed. After 1 hour for Micromodel internal surfactant equilibration, inject carbon dioxide via a high-pressure syringe pump. All injection processes were recorded through a micro lens camera, and calculation of the replacement rate from the captured images utilized image j.

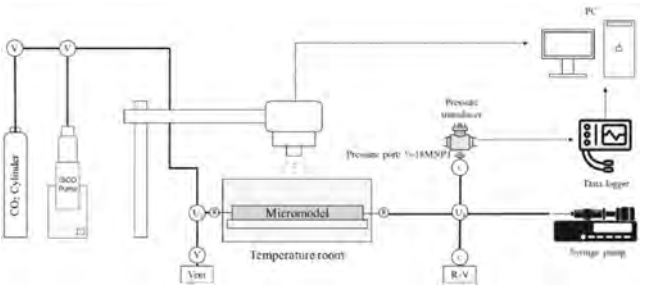

Figure 1. Experiment schematic and equipment.

2.4 *Pore network modeling (PNM)*

Through numerical analysis using MATLAB, we aim to develop micro model experimental verification and evaluation technology. For model validation, water or surfactant-carbon dioxide injection simulations were performed under normal temperature (20–25 °C) and low pressure (500 KPa) conditions. Interfacial tension, contact angle and viscosity in atmospheric condition are used as the fluid physical properties necessary for injection analysis by model, and the physical properties of water, carbon dioxide, SDS and SDBS are shown in Table 3.

Table 3. Physical properties of water, CO_2 and surfactant.

Property Material	Interfacial tension [mN/m]	Contact angle [°]	Viscosity [Pa·s]
Water	72	67.5	$1.002\ 10^{-3}$
Carbon dioxide (CO_2)	68.5*	29**	$1.3 \cdot 10^{-5}$
SDS (0.01 wt%)	55.57	33.3	0.9
SDS (0.02 wt%)	53.08	37.55	0.93
SDBS (0.01 wt%)	51.47	36.2	0.9

3 RESULT

3.1 *2D micromodel experiment*

Figure 2 shows the injection pattern over time and the results of image processing using image j. As a result of image processing, black areas indicate injected carbon dioxide, and similarity to images taken with a micro lens can be confirmed. In Figure 3, when the pore water was saturated with water, the replacement rate showed a tendency to converge after increasing with the carbon dioxide injection rate, and SDS did not show a tendency with concentration (0.01, 0.02 wt%) and injection rate. SDBS was 0.01 wt% and showed a slight increasing trend with increasing injection rate. The displacement ratio by the number of voids and the injection speed is shown in Table 4.

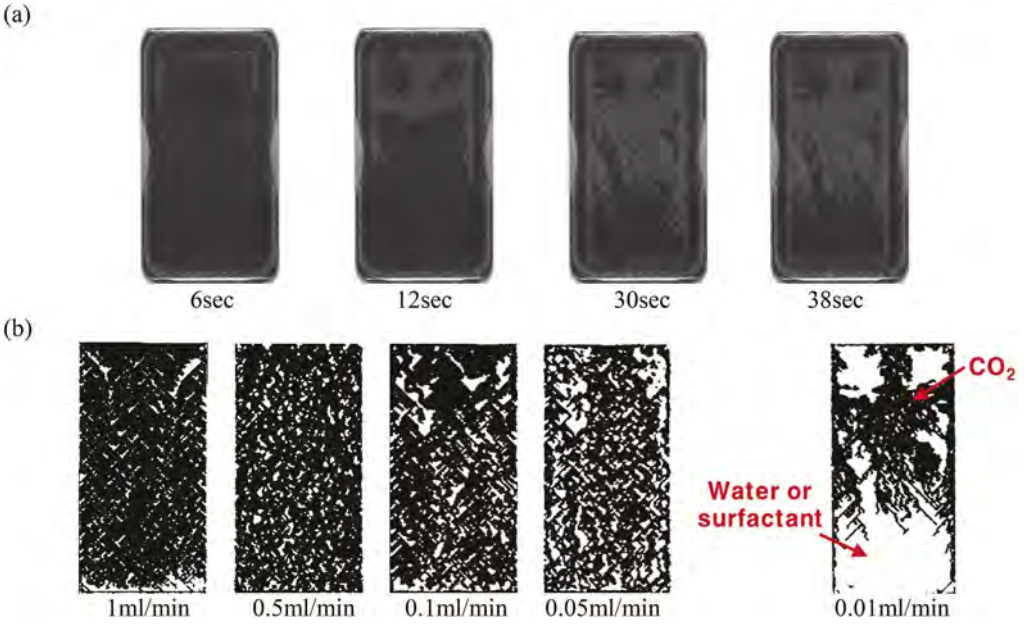

Figure 2. Result of water-CO2 displacement (a) displacement on time (b) image processing result.

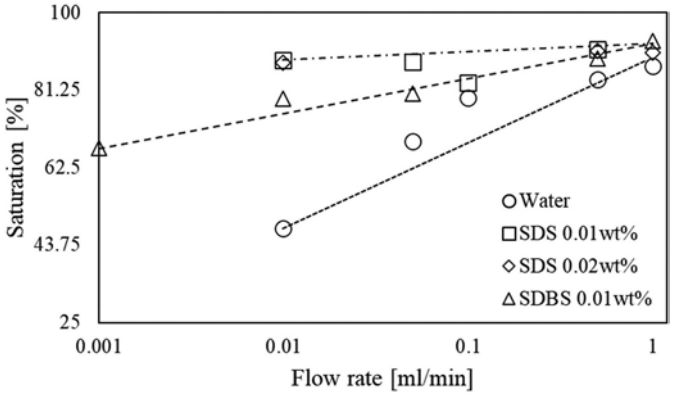

Figure 3. Displacement ratio of carbon dioxide on surfactant and flow rate.

Table 4. Displacement ratio of CO_2 on pore fluid.

Displacement ratio [%] Flow rate [ml/min]	Water	SDS [0.01wt%]	SDBS[0.01wt%]	SDS[0.02wt%]
1	87.035	-	93.204	90.408
0.5	83.815	91.053	88.854	90.694
0.1	79.475	83.06	-	-
0.05	68.948	88.097	80.485	-
0.01	47.723	88.578	79.12	87.912
0.001(1μl/min)	-	-	67.312	-

3.2 *2D pore network modeling*

Figure 4 shows the pnm simulation results with carbon dioxide injection into the water- and surfactant-saturated void under room temperature and low-pressure conditions. The carbon dioxide injection pressure was 500 KPa, and the distribution ratio according to the type of saturated pore fluid is shown in Table 5. Figure 5 shows the substitution rate according to concentration. Using a surfactant increased the distribution ratio. SDS also increased the displacement ratio as the concentration increased from 0.01wt% to 0.02wt%. At 0.01wt%, SDBS showed a higher displacement rate than SDS. These results showed the same trend as the results of the injection experiments using the micromodel.

Table 5. Displacement ratio of CO_2 on pore fluid using pnm.

Pore fluid Pressure [KPa]	Water	SDS [0.01wt%]	SDBS[0.01wt%]	SDS[0.02wt%]
500	37%	60.25%	66.45%	72.34%

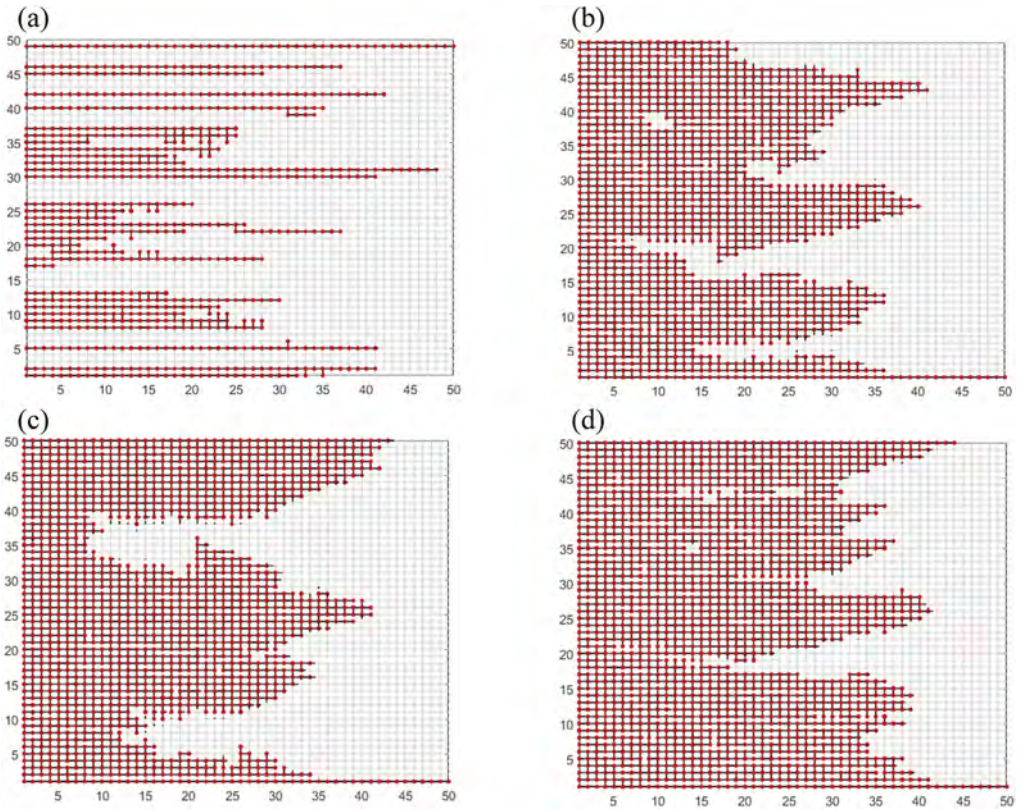

Figure 4. Displacement of carbon dioxide using pnm (a) water (b) SDS 0.01wt% (c) SDS 0.02 wt% (d) SDBS 0.01 wt%.

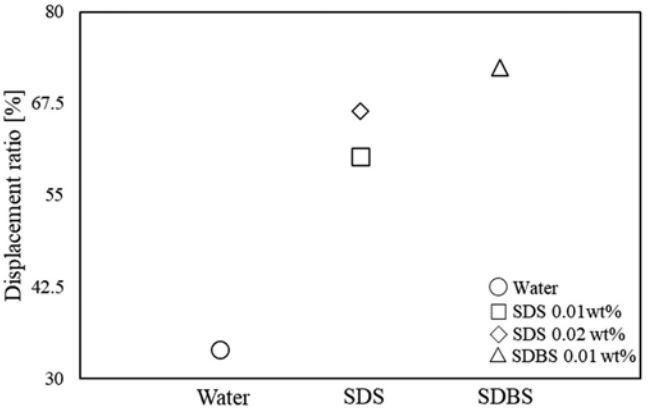

Figure 5. Displacement of carbon dioxide on concentration and surfactant.

4 CONCLUSION

In this study, injection experiments and pnm using a two-dimensional micromodel were performed. Water-carbon dioxide replacement results in a trend of increasing replacement rate with increasing injection rate. As a result of surfactant-carbon dioxide substitution, SDS showed no change in substitution rate with increasing injection rate and concentration, while SDBS showed a slight increasing trend of substitution rate with increasing injection rate. The results of water or surfactant-carbon dioxide injection simulations using PNM were confirmed to be like micromodel experiments. The construction of additional surfactant rheological property data and validation by pnm simulations is deemed necessary.

Unsymmetrical thermal loading effects on a 2×2 pile-group: 1g physical modeling approach

Fardin Jafarzadeh
Associate Professor, Sharif University of Technology & President of Iranian Geotechnical Society, Tehran, Iran

Sina Afzalsoltani
Ph. D. Candidate, Sharif University of Technology, Tehran, Iran

ABSTRACT: A 2×2 pile group with one of its piles acting as an energy pile is modeled using a 1g test setup. The model piles are closed-end aluminum pipes with 2cm diameter and 60cm length. The energy pile goes under several heating and cooling cycles which in return induces unsymmetrical loading on the pile group. A single steel U-tube through which water with a desired temperature is to be circulated is placed inside the initially water-filled energy pile to control its temperature during thermal cycling. A plastic tilt of the pile cap is observed with each thermal cycle having a gradually decreasing rate as the number of cycles increased. Readings from the horizontally oriented total pressure cells underneath the pile tips indicated changes in soil pressure during thermal cycling. Each of the heating and cooling phases had additive and subtractive effect on the soil pressure readings underneath the energy pile, respectively. Results showed that the use of unsymmetrical energy pile arrangement in a group should be approached with caution.

1 INTRODUCTION

The use of ground heat exchangers is not a new phenomenon. The concept was developed by Lord Kelvin in 1852 (Lund et al. 2004). The practice of fitting heat exchanger pipes inside the structural elements began from Austria and Switzerland: First inside base slabs (early in the 1980s), inside piles in 1984, inside diaphragm walls in 1996 and thermo-active tunnels in early 2000 (Brandl, 2006; Markiewicz and Adam, 2009; Katzenbach, 2015 and Sani et al. 2019).

During recent years many scholars have studied thermal efficiency and thermo-mechanical behavior of geothermal energy piles through field and laboratory scale experiments. Ng et al. (2015) studied effect of temperature on bearing capacity of energy pile in medium dense saturated sand using centrifuge tests. They concluded that piles at 37°C and 52°C have bearing capacities 13% and 30% greater than that at room temperature (22°C), respectively. Goode et al. (2015) carried out centrifuge tests on energy piles in medium dense dry sand and reported that bearing capacity of the pile is insensitive to temperature changes. McCartney et al. (2011) reported that bearing capacity of single energy piles in unsaturated silt increase by about 60% with 35°C increase in temperature. Senejani et al (2020) investigated thermo-mechanical behavior of a single energy pile using a small-scale physical model setup. They reported a reduction in elastic response of the soil during longer thermal cycles. Ng et al. (2021a) studied the Performance of elevated energy pile groups with different pile spacing in clay subjected to cyclic non-symmetrical thermal loading. They conducted a centrifuge modeling of pile spacing effects on thermo-mechanical interactions between piles within energy pile groups. Ng et al. (2021b) compared the behavior of non-symmetrical thermally loaded 2×2 elevated pile group with a piled raft. They stipulated that piled rafts undergo smaller tilts under unsymmetrical thermal loads.

The present study investigates the behavior of a 2×2 pile group behavior when on of its piles undergoes cyclic temperature changes with an amplitude of ±6°C. The results are briefly presented and discussed in the following sections.

DOI: 10.1201/9781003299127-339

2 TEST SETUP

The model contains a 2×2 pile group (each pile with outer diameter of D=2 cm) placed at a center-to-center distance of 6cm (3D). The soil container is a 100×100×80 cm (width × length × height) rigid steel box. The model ground is dry silty sand with relative density of 74%, placed in the container using dry tamping technique. Figure 1 shows the schematic of the model configuration and Figure 2 depicts the constructed model.

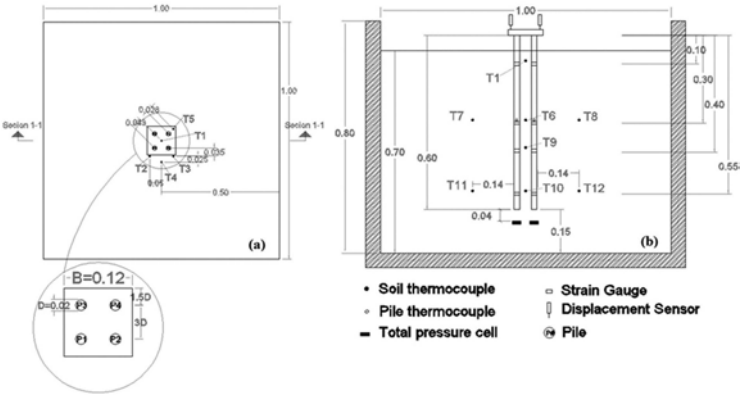

Figure 1. Schematic views of the model configuration; a) plan view and b) section 1-1.

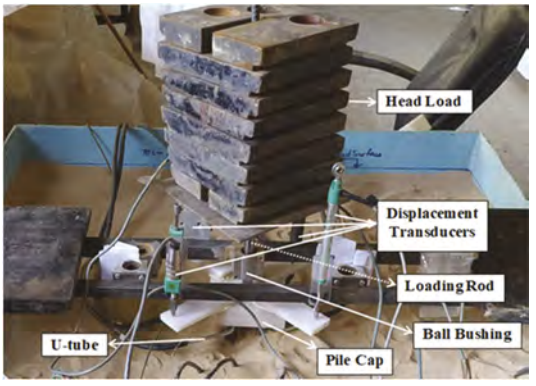

Figure 2. Pile cap and loading mechanism.

Pile temperature is controlled by circulating temperature-controlled water through steel U-tubes placed inside the piles. In order to provide sufficient thermal interaction between pile and U-tube, each pile is initially filled with water. The pile group was first mechanically loaded in 8 steps up to 400 N with resting time of 5 minutes for each step. Under constant mechanical surcharge, the energy pile has gone through 10 consecutive heating-cooling cycles with temperature amplitude of ±6˚C. Three tests were conducted. In test "Group1", Pile1 was energy pile and the other piles were non-energy piles. In test "Group2", Pile1 and Pile2 were energy piles and finally in test "Group3", Pile1, Pile2 and Pile3 were energy piles. After each test the whole model was reconstructed. Particle size distribution of the model ground is depicted in Figure 3. As can be seen the model ground is comprised of fine sand and 40% passing from #200 sieve. Results of Atterberg tests showed the part finer than #200 sieve is non-plastic silt. Hence the soil based on the Unified Soil Classification System is SM.

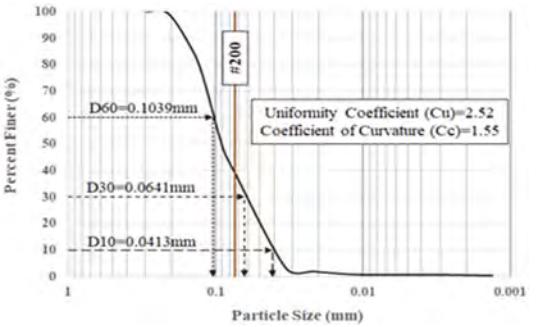

Figure 3. Particle size distribution analysis of the model ground.

3 RESULTS

Time histories of total pile head displacements during the test are presented in Figure 4. It can be seen that the energy pile has larger settlements than conventional piles of the group. During the first few heating phases, no upward displacement occurs in the energy pile until the third heating phase in day five of the test. In fact, during first and second heating phases, the upward thermal forces generated by the tendency of the energy pile for expansion, cannot overcome the downward reaction forces from the conventional piles of the group. As thermal cycling continues, settlement of the energy pile and the consequent redistribution of forces acting on the pile contribute to help the energy pile to slightly push the pile cap upwards which is recorded as small heaves during heating phases in Figure 4. The magnitude of total settlement of each pile remains smaller than the maximum allowable settlement, which is conventionally taken as 10% of the pile diameter (2mm). Figure 5 shows time histories tilt/rotation of the pile cap. The tilt can be calculated by dividing the relative vertical displacements of any two points on the cap, by the horizontal distance between them in the tilting direction. As can be seen, except for the first and second heating phase, the heating caused a decrease while cooling caused an increase in the tilt of the cap. The amplitude of oscillations in the tilt of the cap becomes smaller with an asymptotic trend. As indicated in Figure 5, tilt of the cap exceeds the allowable limit of 1/500 (0.2%) suggested by EN 1997-1 (2004) in the second cooling phase. Time histories of vertical soil pressure at depth of 4cm below the pile tip for different piles are recorded by four total pressure cells (for sensor locations refer to

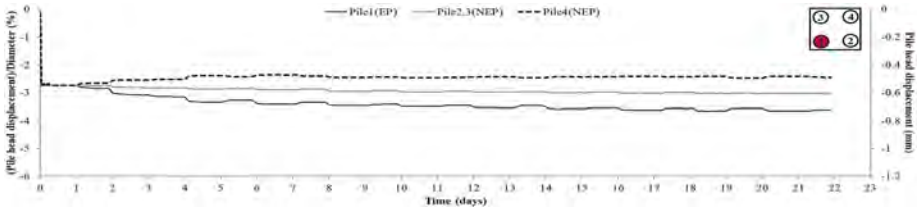

Figure 4. Time histories of pile head displacements presented as absolute values and also normalized with respect to pile diameter (positive values show heave and negative values show settlement).

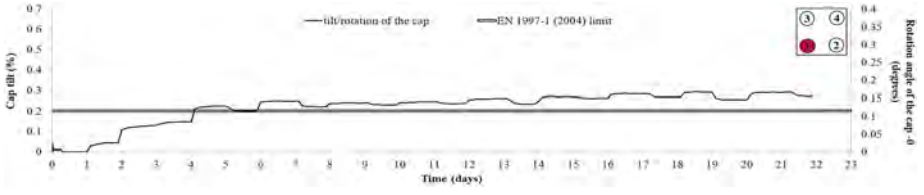

Figure 5. Tilt and rotation angle of pile group cap.

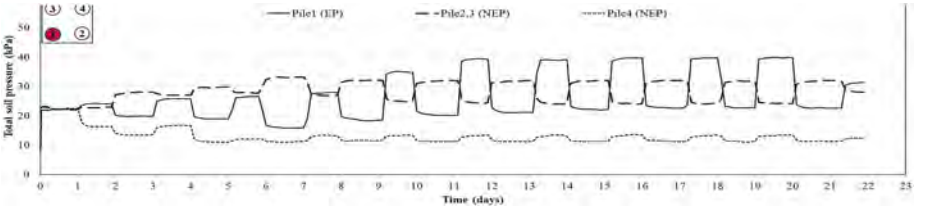

Figure 6. Time histories of total soil pressure under different piles.

Figure 1) and are plotted in Figure 6. It was observed that, with each heating/cooling phase the soil pressure under the energy pile has increased/decreased; respectively. The amplitude of soil pressure oscillations has increased gradually during the first few cycles until it remained almost constant after the fifth cycle.

4 CONCLUSION

A 1g physical modeling setup was developed to study the thermo-mechanical behavior of a 2×2 pile group when one energy pile is included. Results showed that even though displacements of each pile remain below the allowable limit of 2mm, the presence of energy pile may cause unallowable rotations of the pile cap. Results from the total pressure cells under the pile tip where also presented. It was observed that, with each heating/cooling phase the soil pressure under the energy pile has increased/decreased; respectively.

Application of hydraulic-thermal conductivity of steel slag based CLSM on the performance evaluation of horizontal GSHPs

Young-Sang Kim & Ba Huu Dinh
Chonnam National University, Gwangju, Republic of Korea

Gyeong-O Kang
Gwangju University, Gwangju, Republic of Korea

ABSTRACT: This study evaluated the feasibility of steel-making slag-based controlled low-strength materials (CLSM) as a heat transfer medium for horizontal ground source heat pump systems. Engineering properties of CLSM mixtures with different steel-making slag contents and steel-making slag types were evaluated. The in-door thermal response test was conducted to validate the numerical model and access the heat exchange rate of spiral-coil GHE backfilled with CLSM and natural sand. Finally, to access the beneficial use of the CLSM over the sand, economic analysis of 50 case studies for the horizontal GHE was performed. The results indicate that the ground type steel-making slag-based CLSM not only can replace the sand in the CLSM mixture but also can enhance the thermal conductivity up to 2.35 W/(mK). Another advantage of CLSM is a high air-entry value, which can limit the influence of the GWT drop. As expected, the GHE backfilled with the CLSM shows a better economic performance compared to that of the GHE backfilled with an ordinary soil owing to its high heat transfer performance.

1 INTRODUCTION

The ground-source heat pump (GSHP) system is a well-known environmentally clean and energy-efficient technology for the cooling and heating of buildings with ground energy sources. Among GSHPs, the horizontal GSHP system is expected to widely use in Korea since it is easy to install and has low construction cost compared to that of vertical GSHP system; however, its low heat transfer efficiency requires the larger installation area.

By-product-based controlled low-strength material (CLSM), with a relatively high thermal conductivity and good workability, is expected to utilize in the horizontal GSHP in order to increase the heat transfer efficiency of the system (Kim et al., 2020).

It should be noted that horizontal GHE is generally embedded at a shallow depth above the GWT, where unsaturated soil exists (Dinh et al., 2021). The change in the GWT strongly affects the thermal properties of the soil and therefore influences the heat transfer efficiency of the HGHEs. Thus, thermal conductivity of the proposed CLSM should be evaluated over the entire degree of saturation and effect of the GWT level drop on the heat transfer performances of HGHEs should be considered.

Besides increasing the thermal conductivity of backfill materials, another solution to increase the heat transfer performance of the horizontal GSHP system is using the new ground heat exchanger type to increase heat exchanger length (i.e., slinky, spiral coil types). Yoon et al. (2015) found that using spiral-coil and slinky-type pipes increased the total heat exchange nearly twice that of the conventional GHEs (U-type).

The results presented that suggested CLSM with spiral-coil type heat exchanger is a potential solution to enhance the performance of the horizontal GSHP system; however, it

DOI: 10.1201/9781003299127-340

may cause an increase in the initial investment cost (Kim et al., 2020; Yoon et al., 2015). The economic analysis is, therefore, necessary to answer the question: "Whether the high heat transfer performance of the spiral-coil GHE and CLSM can offset its high installation cost?".

2 EXPERIMENTAL PROGRAMS

2.1 *Evaluation of characteristics of controlled low-strength material*

The CLSM mixture in this study used different steel slag sizes (raw steel slag and ground steel-making slag) and content (10 %, 20 %, and 30 %) to replace the natural sand in the conventional control low strength material. The engineering properties of mixtures, such as flowability, unconfined compressive strength (UCS), and thermal conductivity, were tested in accordance with applicable ASTM Standards (2004): D 6103, D 4832, and D 5334, respectively.

2.2 *Numerical analysis for evaluating performance of horizontal GSHP system considering hydraulic-thermal characteristics of backfill material and groundwater table level drop*

The soil-water characteristic curves and unsaturated thermal properties of backfill materials (natural sand (NS), weathered granite soil (WGS), and controlled low-strength materials (CLSM)) were evaluated using modified 150-SWCC devices and a high-pressure membrane extractor, coupled with a thermal conductivity measurement system as shown in Figure 1. Subsequently, the influence of the GWT level change on the moisture content of the backfill materials was investigated using a seepage analysis (SEEP/W) (Dinh et al., 2021). Furthermore, the thermal performance analysis of the HGHEs with different backfill materials was conducted using a commercial finite element code program (COMSOL Multiphysics) (Figure 3).

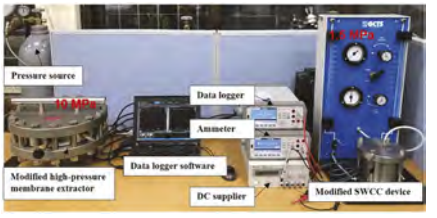

Figure 1. Modified SWCC device and modified high-pressure membrane extractor.

2.3 *In-door thermal response test and economic analysis*

The TRT test set-up is shown in Figure 2. A spiral-coil type heat exchanger was buried in a steel box (5 × 1 × 1 m) and backfilled with CLSM and sand. The inlet and outlet fluid temperature were measured by resistance temperature detector (RTD) sensors connected with a data logger program. Then, a finite element model using COMSOL Multiphysics was created and compared to validate the experiment model (Figure 3) (Dinh et al., 2022a, b).

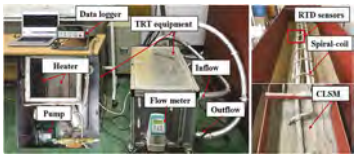

Figure 2. Thermal response test set-up.

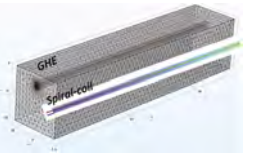

Figure 3. Full-size numerical model.

3 RESULTS AND DISCUSSION

3.1 *Thermal conductivities of proposed CLSMs*

The thermal conductivities of proposed CLSM mixtures are evaluated and compared with other grouts. Depending on the degree of saturation, the thermal conductivities of the CLSM mixtures in this study range from 1.21(dry) to 2.35(saturated) W/mK. The thermal conductivity of the CLSM proposed in this study is significantly higher than those of conventional grout materials as shown in Figure 4 (Kim et al., 2020).

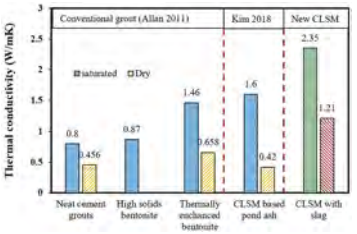

Figure 4. Comparison of thermal conductivity of different backfill materials.

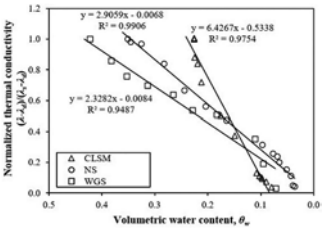

Figure 5. Normalized thermal conductivity and volumetric water content relationship.

3.2 *Water retention characteristics and thermal conductivity-water content relationship*

The water retention curves the backfill materials are measured using modified 150-SWCC devices and a high-pressure membrane extractor, coupled with a thermal conductivity measurement system (Dinh et al., 2022b). The air-entry value (AEV) of the proposed CLSM mixture, which represents the water retention ability, was significantly greater than that of the natural sand and weathered granite soil. The AEV of the CLSM was 1000 kPa, whereas the AEVs of natural sand and WGS were 4 kPa and 16 kPa, respectively. The relationships between the normalized thermal conductivity and volumetric water content of the backfill materials are shown in Figure 5. The thermal conductivity significantly decreases with the decrease in the volumetric water content. A linear relationship is observed for all backfill materials.

3.3 *TRT and economic analysis*

A very well agreement in the experimental (TRT) and numerical results (COMSOL) (Figure 6 (a) outlet fluid temperature, (b) soil temperature) demonstrated that the model proposed in Figure 3 and the parameters used for analysis are suitable to simulate the heat transfer in the horizontal GSHP system. With the same installation depth, the total construction cost of the Spiral-CLSM type is about 22 % higher than that of the Spiral-Soil (Figure 6(c)) since the CLSM costs about 40 USD/ m^3 while the soil is free to use (Kim et al., 2020). However, above the groundwater table level, where the horizontal GSHP system is located, the unsaturated thermal conductivity of CLSM is 1.68 W/(mK), which is about 52 % higher than that of the unsaturated soil (1.16 W/(mK)). As a result, the annual heat exchange rate of the Spiral-CLSM is significantly higher than that of the Spiral-Soil (39 % higher); thus, the net cash inflow of the Spiral-CLSM is considerably higher than the Spiral-Soil one. Consequently, the Spiral-CLSM has a lower simple payback period and higher IRR, compared to that of the Spiral-Soil one. Note that the annual heat exchange increases with an increase in the installation depth and fluid velocity (Figure 7(a)); however, it causes a significant increase in the total construction cost (Figure 6(c)) (i.e., excavation cost) and operation cost (i.e., the electrical power consumption of the pump). The Spiral-CLSM type with a buried depth of 2.5 m and a fluid velocity of 10 *l*/min has the lowest SPP and highest IRR (case 44); thus, it is the most beneficial use case from the standpoint of the economic analysis.

4 SUMMARY AND CONCULSIONS

This study comprehensively evaluated the feasibility of steel-making slag-based CLSM as a heat transfer medium for horizontal GSHP systems. The advantages of CLSM were found as follows: (1) CLSM has a high flowability; thus, it can fill the GHE without compaction; it is especially appropriate for spiral-coil GHE. (2) CLSM has a high thermal conductivity at both saturated and unsaturated conditions; thus, it can improve the heat transfer performance of the horizontal GHE. (3) CLSM has a UCS of 2.0 MPa (or higher); thus, it can protect the coil pipe from broken and shaped deformation. (4) The GWT level drop can give a negative effect on heat transfer performance of horizontal GHE, especially where the soil has a weak water storage ability (low AEV) (e.g., sand and sandy soil). However, CLSM with a strong water retention ability (AEV = 1000 kPa) can limit the influence of GWT level drop. (5) CLSM can incorporate many kinds of waste materials and by-products (i.e., pond ash, bottom ash, steel-making slag); therefore, the use of CLSM is not only economically beneficial but also has a good impact on waste treatment and environmental protection.

ABSTRACT: Understanding the geotechnical properties of Calcareous sand is essential to develop ocean engineering construction in South China sea. Therefore, a series of one-dimension compression tests were carried out on calcareous sand obtained from the South China sea to investigate its compressive property and particle breakage during compression. The results show that calcareous sand has normal consolidation line (NCL). Sample with relatively uniform gradation has smaller compressibility. The single particle strength plays an important role in compression properties, sample with larger particle size has smaller yield stress. Hardin's relative crushing theory was applied to quantitate the particle breakage during testing. It can be seen that particle breakage occurred at low stress region, and continues to occur to high pressure region with a nearly linear trend. The particle breakage is corresponding to particle size distribution. Under the same vertical stress, sample with uniform distribution and small particle size has less particle breakage.

1 INTRODUCTION

The Calcareous sand is widely distributed in the South China sea (Liu & Wang, 1998). In recent year, within the growing requirement of resource extraction and military construction on the South China sea, lots of large-scale engineering has been constructed, such as oil platform, military base, and so on. Due to the special component with biological debris and existence in the marine environment, calcareous sand is different from terrigenous soil. Therefore, it is essential to investigate the mechanical properties of calcareous sand.

Coop (1990) analyzed properties of calcareous sand of Dog's Bay, the results show that calcareous sand has a similar property to normal clay on compressibility. However, the influence of particle breakage dominates the calcareous sand compressive property gradually with stress increase to a high level. Catano & Pando (2010) investigated the differences between the uncemented calcareous sand and silica sand, results show that calcareous sand exhibits higher

DOI: 10.1201/9781003299127-341

tenacity, shrinkage, and peak friction angle, and yield axial stain, but lower shear modulus than silica sand. Salem et al. (2013) investigated the influence of relative density and confining pressure of calcareous sand by undrained triaxial tests. Shaqour (2007) conducted a series of CPT tests to detect penetration mechanism of calcareous sand. Sharma & Ismail (2006) found that the stress-strain relationship of calcareous sand in different location has a similar trend, although it shows great difference quantitatively. Also, some scholars have conducted many tests to research the effects of cementing materials and cementing content on the mechanical properties of calcareous sand (Ismail et al., 2002, Chai et al., 2021). Different from common sand, particle breakage plays an important part in mechanical properties of calcareous sand. Hence, many research on particle breakage had been carried on. Lee & Farhoomand (1967) indicated that the particle size distribution, particle size, particle shape, single particle strength may have effect on particle breakage. Hall and Gordon (1963) observed that particle size distribution has a significant influence on particle breakage, the more uniform the gradation, the less particle breakage. Luzzani & MR (2002) found that particle breakage of calcareous sand would appear until the strain come to a high level. Donohue et al. (2009) conducted a series of drained cyclic triaxial tests on Dog's Bay Sand, which showed that the increase of the number of cycles would aggravate particle breakage. Coop et al. (2004) found that particle breakage of calcareous sand would reach a limit under shear tests when the strain is large, and the final result of particle breakage correspond to the initial particle size distribution and normal stress. Shahnazari & Rezvani (2013) researched the influence of different parameters of calcareous sand on particle size with triaxial tests and revealed that axial strain has a significant influence on particle breakage. Zhang et al. (2005) conducted a series of compression tests on calcareous sands under lateral confinement, the results show that the particle breakage is considered the primary factor to explain the sample yield during compressing. Dehnavi et al. (2010) studied the mechanical properties of calcareous sands with isotropic compression tests and undrained triaxial compression tests, and found that peak deviator stress and particle breakage could be influenced with the change of confining pressure and compaction. Although many research has been conducted to study the mechanical properties of calcareous sand, the comprehensive analysis of calcareous sand on the aspect of microstructure and particle breakage is still elusive.

In this paper, a series of one-dimensional compression tests for calcareous sand in the South China sea with different particle size were carried out. Based on the analysis of the results of compression behavior and particle breakage on these tests, we studied the compression and crushable properties of calcareous sands obtained in the South China sea with the combination of single particle strength properties.

2 TEST MATERIALS AND TEST METHOD

2.1 *Test materials*

The calcareous sand used in this study was taken from island and reefs in the South China Sea. It is a loose and uncemented granular material. and is mainly composed of coral debris and some skeleton of marine debris. The X-ray diffraction (XRD) tests were conducted to determine the specific mineral composition of calcareous sample. It can be observed from the result of X-ray diffraction that the main composition of calcareous sand is aragonite ($CaCO_3$), calcium aluminate ($Ca_3Al_2O_6$) and magnesite ($MgCO_3$ $FeCO_3$).

The original particle size distribution of calcareous sand was measured by sieve method, and its curve is shown in Figure 1, while the indexes of original particle size distribution are shown in Table 1. It can be seen that the calcareous sand in this research has many coarse grains. It can be inferred that calcareous sand which is used in the tests has non-uniform grading. Figure 2 shows the scanning electron microscopic (SEM) image of calcareous sand particle (Jiang et al., 2017), it shows that the calcareous sand particles can be well divided into three inhomogeneous types: block, flake and strip, and it also shows that the surface of calcareous sand is dominated by tiny pore.

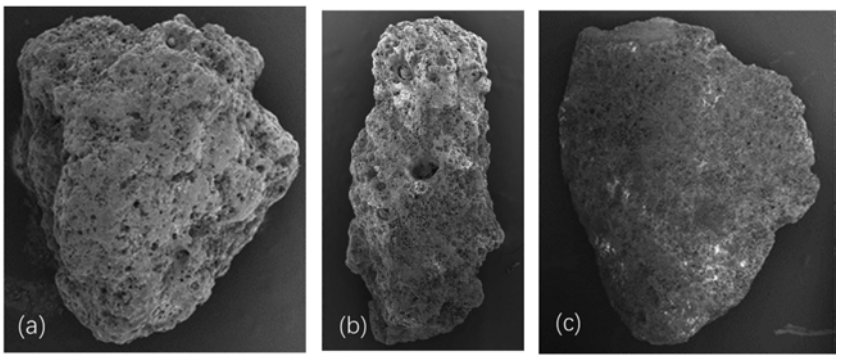

Figure 2. SEM photos of different shapes: (a) block, (b) strip, (c) flake.

Table 1. Basic parameters of original calcareous sand.

Sample	d_{10}(mm)	d_{30}(mm)	d_{60}(mm)	C_u	C_c
Original sand	0.26	0.79	11	42.31	0.22

2.2 *Test apparatus and method*

One-dimensional compression test, which is an uniaxial compression test under lateral restraint, was performed to investigate the geomechanical behavior of calcareous sand. Three types of gradation were selected, their curve is shown in the Figure 3. Samples with different particle size were prepared by sieve method, they include an overall gradation with maximum particle size of 2mm and single gradation of 1-2mm and 0.5-1mm respectively.

In the tests, loading was conducted by step, each step of compressive stress was 0.05, 0.1, 0.2, 0.4, 0.8, 1.6, 3.2, 6.4, 10, 15, 20, 25, 30 MPa respectively. The apparatus of test is shown on the Figure 4, the internal diameter and internal height of apparatus are 61.8 mm and 35 mm respectively. The calcareous sand samples were compressed to the default compaction degree by vibrating the compression tool. In each step of loading, the deformation data was recorded with an interval of an hour. The condition of sample could be seen as stable when the deformation data recorded in an interval is no bigger than 0.005mm. Test termination pressure was set to be 6.4, 10, 15, 20, 25, 30 MPa respectively, and the particle breakage of each termination can be researched by the change of grain gradation with sieve method.

Figure 4. Schematic diagram of compression test apparatus.

3 RESULTS AND ANALYSIS

3.1 *Compression behavior*

The results of the compression tests were shown in Figure 5, it is an e-lg P graph of sample with different particle size distribution. It described the relationship between pressure and compress deformation of calcareous sand. It can be seen that the curvature of e-lg P graph is increasing gradually with the increase of pressure under one-dimensional compression test. And then the e-lg P graph gets to be a straight line when the press increases to a higher level. This phenomenon shows that calcareous sand has a familiar one-dimension compression property with normal consolidated clay, which means that it exists normal consolidation line (NCL). It can be illustrated that rearrangement of particles make sample to reach a dense state with the increasing pressure and the particle breakage, which substitute the rearrangement of particles, take in charge of the procedure of compression gradually when the pressure continues to increase.

According to the e-lg P curves of different particle size distribution, it can be observed that the sample with particle size of 1-2mm has biggest void ratio and sample with particle size of <2mm has smallest void ratio. The sample with different gradation and void ratio has different compressive curve. However, compression curve of each sample has a trend to converge into a same line, it shows that the effect of initial void ratio on compressive property of calcareous sand will disappear with the increase of vertical pressure. Therefore, the compression of

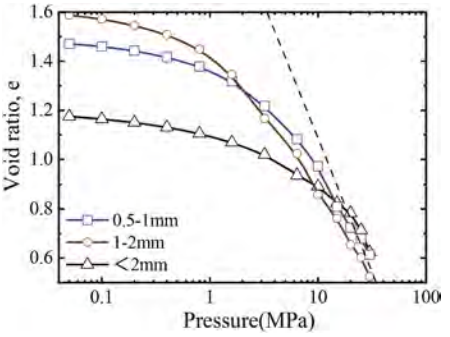

Figure 5. Compression curves of calcareous sand with different particle size distribution.

calcareous sand sample is stable in the final limiting condition, regardless of the initial conditions. It also can be observed that the sample with particle size of 1-2mm and 0.5-1mm have a relatively similar strain under compression, which is obviously larger than sample with particle size of not more than 2mm. The crushed particles in the sample with single gradation will fill the pore between particles, it induces the void ratio of sample decrease sharply. However, due to a more uniform distribution, the pore caused by larger particle in the sample with overall gradation has been filled by small particle, it makes the overall gradation sample has a relatively small change on void ratio when compressing. It shows that calcareous sand with relatively uniform particle size distribution has a better performance on compression property.

Generally, point with the maximum curvature is seen as the compression yield point of the sample. It can be seen that the overall gradation sample has higher yield strength than single gradation sample, it is because the relatively uniform particle size distribution lead to a uniform distribution of stress in the sample, and make it relatively hard to reach the yield point. For single gradation sample, it can be clearly observed that the sample with larger particle size has smaller yield strength.

Usually, we also describe the compression behavior by a bilinear model:

$$e = e_0 - \lambda \ln P \tag{1}$$

where e is void ratio, e_0 is initial void ratio, P is vertical pressure, λ is compression index. According to this model, we can get a relationship between compression index and pressure, and it is shown in the Figure 6. It can be found that compression index increases with the increase of pressure, while the λ of normal sand is a constant value under compression, it also shows a similar characteristics to clay and soil with component of calcium carbonate. The nonlinear curve of e-lg P and λ-lg P all shows that unique compression behavior caused by particle breakage is conspicuous.

3.2 *Relationship between compression behavior and single particle strength*

Generally, we believed that calcareous sand is elastic when the vertical stress is lower than yield point, the deformation of calcareous sand is mainly caused by compression and the rearrangement of particle. However, when the vertical stress reaches the yield point, calcareous sand starts to yield, it shows that a big scale of particle breakage starts to occur and the particle breakage has become the main reason to induce compression deformation, hence a parameter corresponding to the particle strength is supposed to use on the analyze of compression properties in aspect of micro-mechanical properties. Strength of single particle is believed to have a significant influence on the macroscopic mechanical properties (Jiang et al., 2018, Jiang et al., 2019). In order to research the relationship between particle strength and

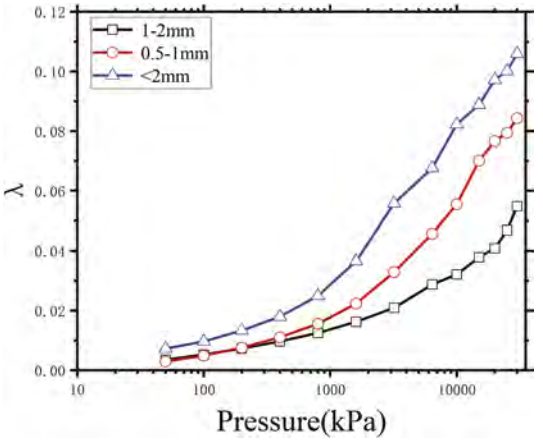

Figure 6. Compression curves of calcareous sand with different particle size distribution.

yield strength of compression, 320 groups single particle compression tests had been made to research the property of single particle strength on different size of calcareous sand particle used in this article before one-dimension compression tests (Jiang et al., 2018). The results are shown in Figure 7, it can be seen that the distribution of single particle strength with different particle size is discrete, and the strength of single calcareous sand decreases with the increasing particle size. Compare with single particle strength with different particle shape, we observed that block particles have a higher strength than flake particles when the particle size is same. Weibull distribution function is cited to make a further analysis statistically on the measured data, it shows that single particle strength follows Weibull distribution.

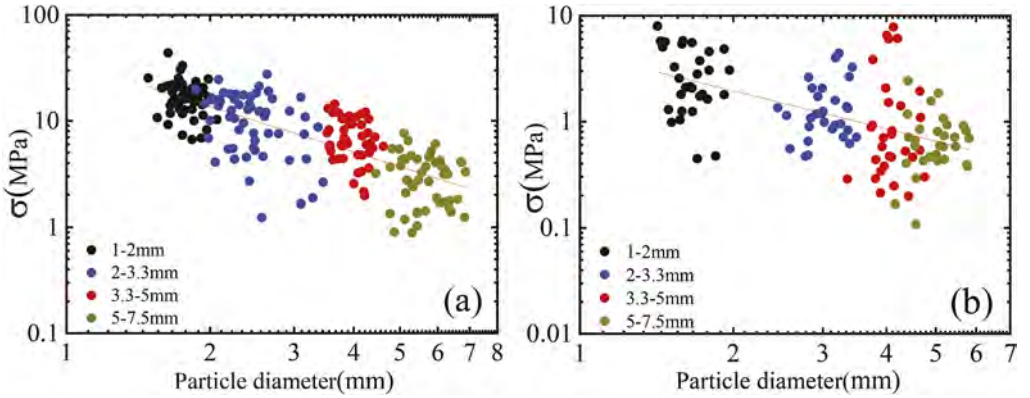

Figure 7. Strength distribution of single particle with different particle sizes: (a) Block particle, (b) Flake particle.

Based on the Weibull distribution function, we get the characteristic stress of each particle with different particle size when the probability of survival is 37%, each characteristic stress for the block particle is 19.4 MPa (1.5mm), 13.8 MPa (2.65mm), 7.7 MPa (4.15mm), 3.7 MPa (6.25mm) respectively and each characteristic stress for the flake particle is 3.1 MPa (1.5mm), 1.3 MPa (2.65mm), 0.9 MPa (4.15mm), 0.7 MPa (6.25mm) respectively. The results of characteristic stress are corresponding to the conclusion obtained in the above. After that, we use the characteristic stress of different particle to normalize the corresponded compression curves.

Figure 8 shows the normalized compression curves of calcareous sand, the characteristic stress chosen for sample with particle size of 0.5-1 mm is 19.4 MPa (block particle) and 3.1 MPa (flake particle), and the characteristic stress chosen for sample with particle size of 1-2 mm is 13.8 MPa (block particle) and 1.3 MPa (flake particle). It can be seen that normalized curves that corresponding to different particle size have extremely close yield points with each other, it shows that the single particle strength is a main reason to influence the yield point and the particle breakage of calcareous sand under compression. If the particle in the sample have a relatively higher single particle strength, it may have a relatively high yield point and more difficult to crush.

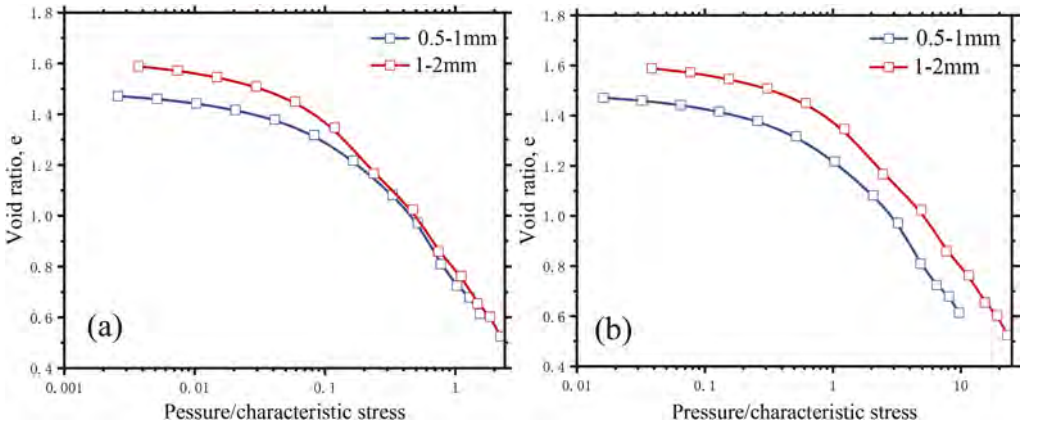

Figure 8. Normalized compression curves of calcareous sand with different particle size distribution: (a) Compression curves normalized by characteristic stress of block particle, (b) Compression curves normalized by characteristic stress of flake particle.

3.3 *Particle breakage*

The one-dimensional compression curves of calcareous sand show that particle breakage plays an important role in the compression process. The results of particle breakage of each sample on different termination of pressure are shown in Figure 9. It demonstrates that almost all part of particles has different level of particle breakage in the compression, and the particle size distribution become more uniform with the increase of pressure. The deduction of particle size on sample with single gradation (0.5-1mm and 1-2mm) is clearly larger than that on sample with overall gradation (<2mm). It shows that that the sample with relatively uniform particle size distribution has a minor particle breakage.

In order to analyze the results of particle breakage quantitatively, Hardin's relative crushing theory was applied (Hardin, 1985), Hardin believed that particle has a larger possibility to crush with the increase of its particle size, and the particle will not crush until its particle size is smaller than 0.074mm. According to this, Hardin define the potential of breakage and relative breakage.

In Hardin's relative crushing theory, the potential of breakage of a certain particle size (bp) was defined as:

$$b_p = \lg\left(\frac{d}{0.074}\right) \tag{2}$$

where d is particle diameter. According to the potential of breakage of a certain particle size (b_p), the potential of breakage (B_p) and total breakage (B_t) was given as:

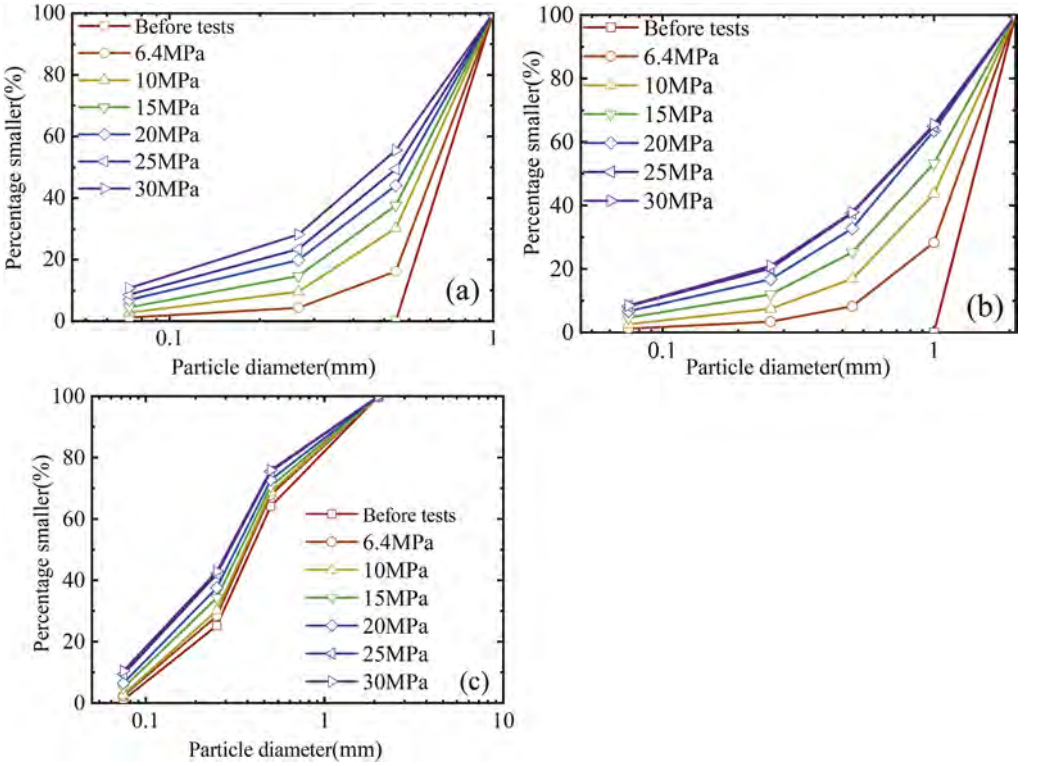

Figure 9. Particle size distribution of sand with different particle size distribution before and after compression tests: (a) 0.5-1mm, (b) 1-2mm, (c) <2mm.

$$B_p = \int_0^1 b_p df \tag{3}$$

$$B_t = \int_0^1 (b_{p0} - b_{p1}) df \tag{4}$$

where df is screening pass rates corresponding to the b_p, and b_{p0} and b_{p1} are the breakage potential of each grain gradation before and after tests respectively. Relative breakage (B_r) was calculated by B_r and B_t using the following equation:

$$B_r = \frac{B_t}{B_{p0}} \tag{5}$$

According to Hardin's relative crushing theory, relative breakage (B_r) is a value with a range from 0 to 1, it presents that particle have not any breakage when its value is 0 and all the particle size become smaller than 0.074mm through crush when its value is 1.

The relationship between pressure and relative breakage B_r on different particle size distribution is shown in Figure 10. From the graph, it can be found that relative particle breakage of calcareous sand is nearly lineal, it shows that particle breakage happens when stress is small and the particle breakage will continue to happen when stress reach a high level. It can be observed that the amount of particle breakage in single gradation sample (0.5-1mm and 1-2mm) is larger than overall gradation sample (<2mm) under the condition of same vertical pressure, it is because the filling of small grain size in the overall gradation sample reduces the

contact force of each grain. In the single gradation sample, the relative breakage of sample with larger particle size is larger than sample with smaller particle size, and the change of relative breakage on the sample with larger particle size is relatively faster than the sample with smaller particle size with the increase of pressure. It shows that sample with larger particle size has more amount of particle breakage, and the velocity of production of particle breakage of sample with larger particle size is faster than sample with smaller particle size. It can also be observed that the change of relative breakage decreases gradually for sample with particle size distribution of 1-2 mm and sample with particle size distribution of no more than 2mm. It might illustrate that particle breakage of sample will reach a limit if compression pressure reaches to a high value.

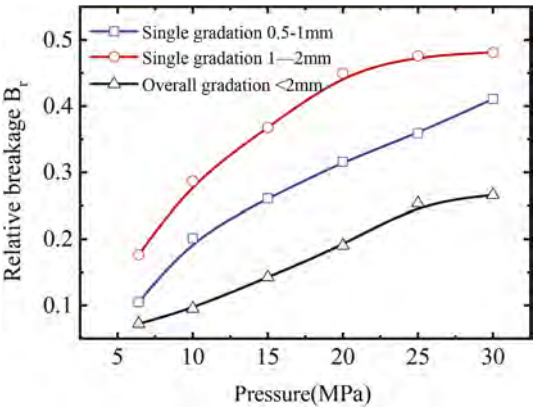

Figure 10. Relative breakage of calcareous sand sample with different particle size distribution.

4 CONCLUSION

In this paper, a series of one-dimensional compression tests were carried out to research the compression properties and particle breakage properties of calcareous sand obtained in the South China sea under compression. The main conclusions are summarized as follows:

(1) Calcareous sand has normal consolidation line (NCL). For samples with different initial condition, their differences on compression curves diminish with the increase of pressure, it can be seen as the particle breakage take in charge of procedure of compression when pressure level is high.
(2) Compare to the single gradation sample, overall gradation sample has a conspicuously better performance on compression properties because of its relatively uniform particle size distribution. For single gradation sample, sample with smaller particle size has a relatively better performance than sample with larger particle size because it has a relatively smaller initial void ratio.
(3) The vertical stress means an initial stress that a big scale of particle breakage starts to occur. The yield stress decreases with the increase of particle size, and the normalized results of one-dimension compression curves show that the divergence of yield stress is caused by difference of single particle strength of different particle size.
(4) Each sample of calcareous sand exhibit an obvious level of particle breakage, the sample with relatively uniform particle size distribution have less particle breakage. Relative breakage (B_r) was used to quantify the particle breakage, it can be found that the amount of particle breakage increases with increasing pressure, and particle breakage occurs from a small level of stress to a high level of stress. It can also be found that the larger the particle size, the larger the amount of particle breakage.

ABSTRACT: This paper presents the secant shear modulus (G_{max}) response of a normally consolidated undisturbed marine clay cyclically loaded during recompression to the past effective overburden pressure and swelling stages after consolidating to a new pre-consolidation pressure. The strain-controlled undrained dynamic cyclic simple shear tests were performed on undisturbed marine clay obtained from offshore Indonesia. The clay samples were consolidated to OCR of 2.3 and 4.6 during the loading stage up to in-situ past effective stress of 230kPa and allowed to swell to the same OCR values after consolidating to new past effective stress of 700kPa. The cyclic shear loading was applied with shear strains ranging from 0.025% to 0.5% at 0.5Hz. The results revealed that for the same effective axial stress and OCR, the G_{max} in the swelling stage is more than in the recompression stage.

Keywords: Marine clay, G_{max}, Cyclic simple shear, Recompression, Pre-consolidation pressure, Swelling, OCR

1 INTRODUCTION

The marine soils are often over-consolidated due to the geologic history of glaciation, erosion, etc. (Lad et al. 1980, 1981: Loken 1976; Mishu et al. 1982). Also, the normally consolidated soils may become over-consolidated because of stress release due to the decommissioning of offshore structures after their service life. The marine soils are subjected to dynamic installation loads from pile driving and environmental loads from waves, wind, and seismic activity. Undrained cyclic loading on cohesive soils causes a decrease in effective stress and breaks the soil structure leading to degradation of strength and stiffness (Thiers and Seed, 1969, Brown et al., 1975, Andersen et al., 1975, Yasuhara et al., 1983b, 1992, Yasuhara 1985). The foundation soil response to dynamic loading in terms of shear modulus (G_{max}) degradation and damping (ζ) may be influenced by the number of loading cycles (N), frequency (f), shear strain (γ_c), OCR, effective confining stress (p') and plasticity index (PI). The shear modulus degradation was not influenced significantly by f and N, whereas damping values increase with increasing f and decrease at large γ_c with increasing N (Darendeli, 2001). The shear modulus degradation parameter(t) increases rapidly when γ_c exceeds 1% and decreases with increasing OCR (Vucetic and Dobry, 1988; Takaki Kagawa, 1992).

DOI: 10.1201/9781003299127-342

It may happen that an over-consolidated soil due to previous stress history might be loaded to a normally consolidated state and upon stress release, it might go back to an over-consolidated state again. This study aims to understand the G_{max} behavior of an undisturbed, normally consolidated marine clay when cyclically sheared initially, during the recompression stage, and later during the swelling stage after it is consolidated to new pre-consolidation pressure.

2 MATERIALS AND TESTING PROGRAM

The marine clay obtained from offshore Indonesia was tested for Atterberg limits and specific gravity (Table 1). The natural moisture content and the bulk density are 60% and 16.2kN/m^{3,} respectively. The liquid limit and plasticity index are 110% and 65%, respectively. The soil is classified as clay of high plasticity (CH) as per ASTM D2487-17 (ASTM 2017a).

Table 1. Soil index properties.

Test particulars	value	Reference	
Natural Moisture Content, %	60	ASTM D 2216-19	(ASTM 2019)
Liquid Limit, %	110	ASTM D 4318-17	(ASTM 2017b)
Plastic Limit, %	45	ASTM D 4318-17	(ASTM 2017b)
Plasticity Index, %	65	ASTM D 4318-17	(ASTM 2017b)
Specific gravity, (-)	2.7	ASTM D 854-14	(ASTM 2014)
Bulk unit weight, kN/m^3	16.2	ASTM D 7263-09	(ASTM 2009)
Initial void ratio (-)	2.93	-	

The undisturbed soil specimens of size 70mm diameter and 20mm height were cut from the soil core. The soil specimens were saturated by applying a 10kPa back pressure through PV controller and collected the backwater from the specimen top. The saturation was considered 100% if the backwater collected was three times the soil pore volume.

The testing program included a) An oedometer test for the consolidation characteristics, b) A static simple shear test to determine undrained shear strength at pre-consolidation pressure of 230kPa obtained from the oedometer test, c) Undrained cyclic simple shear test (loading stage) on specimens consolidated to effective axial stresses of 50kPa (OCR = 4.6), 100kPa (OCR = 2.3) and 230kPa (OCR = 1.0), 500kPa (OCR = 1.0) and 700kPa (OCR = 1.0) d) Undrained cyclic simple shear test (unloading stage) on specimens consolidated to effective axial stresses of 150kPa (OCR = 4.6), 304kPa (OCR = 2.3). The loading frequency and the number of cycles for each test were 0.5Hz and 5, respectively. For each effective axial stress, the cyclic shear amplitude ranged from ±0.025% to ±0.5%. The test program for undrained cyclic simple shear tests is shown in Table 2.

Table 2. Test program for undrained cyclic simple shear tests.

Test particulars	p′	p′$_c$	OCR
Loading Stage	50	230	4.6
	100	230	2.3
	230	230	1.0
	500	500	1.0
	700	700	1.0
Unloading Stage	304	700	2.3
	150	700	4.6

3 RESULTS AND DISCUSSION

The oedometer test was conducted with effective axial stresses varying from 10kPa to 900kPa. The duration of each stress increment was 24hrs. The recompression, compression, and swell indices determined from void ratio – effective stress [e -log(p')] curve are 0.04, 0.84, and 0.23, respectively. The pre-consolidation pressure obtained using Casagrande's graphical method is 230kPa (Figure 1).

The static simple shear test was conducted with pre-consolidation pressure of 230kPa. The shear strain rate was 5% per hour up to a shear strain of 20% (ASTM D6528-17). The active height control method was used to maintain constant volume conditions so that the change in effective axial stress could be considered as excess pore-pressure mobilized during shear. As shown in Figure 2, the peak static undrained shear strength is 110 kPa.

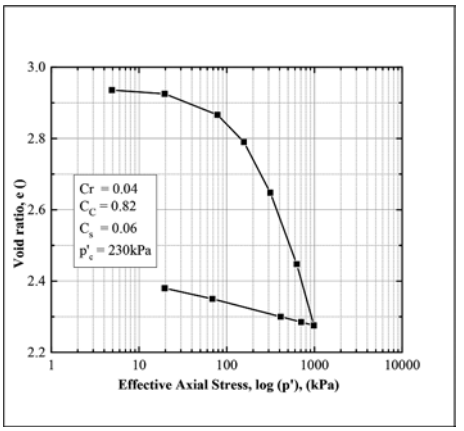

Figure 1. E-log (p′) curve.

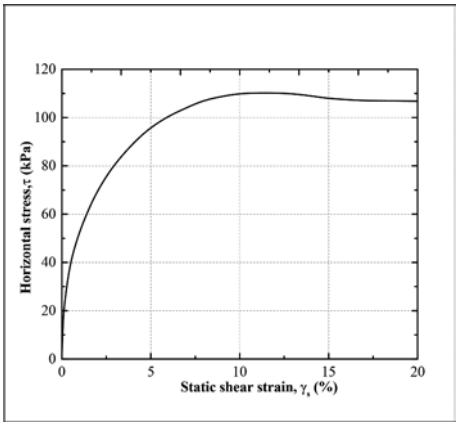

Figure 2. Horizontal stress, τ (kPa) vs static shear strain, γ_s (%).

The undrained cyclic simple shear tests were conducted as per the test program shown in Table 2 to determine the secant shear modulus of the first cycle (G_{max}) and its degradation with the increase in cyclic shear strain (γ_c) from ±0.025% to ±0.5% at a constant frequency of 5Hz and no. of cycles of 5. The cyclic shear stress vs. cyclic shear strain of the recompression stage from effective axial stress of 50 kPa to 230kPa, compression stage from 500kPa to 700 kPa, and swelling stage from 304 kPa to 50 kPa are shown in Figure 3. The G_{max}, at a very small shear strain of 0.025%, increased from 11.6MPa to 14.5MPa in recompression, 14.5MPa to 19.5MPa in compression, and 19.5MPa to 16.2MPa in swelling.

As shown in Figure 4, the G_{max} for the same effective axial stresses in recompression and swelling increased from 11.6MPa to 15.5MPa, 13.3MPa to 15.7MPa, and 14.5MPa to 16.2MPa, respectively, for 50kPa, 100kPa, and 230kPa. The increase in G_{max} in swelling compared to recompression can be attributed to the increase in soil stiffness due to the new pre-consolidation pressure of 700kPa. For any γc, the difference in G_{max} in the compression stage is more than in the swelling stage. At any $\gamma_c > 0.2\%$, the difference in G_{max} in the swelling stage is negligible.

As shown in Figure 5, the G_{max} for the same OCR of 2.3 increased from 13.3MPa in recompression to 16.5MPa in swelling and, for the same OCR of 4.6, increased from 11.6MPa to 15.9MPa. The increase in G_{max} in swelling compared to recompression could be due to the combined effect of new pre-consolidation pressure and effective axial stress to maintain the same OCR. The damping, ζ, in general, increased with the increase in γ_c for all P′. It varied from 1.7% at γ_c of 0.025% to 8.9% at γ_c of 0.5% in recompression and from 0.4% to 3.5% in swelling. The damping in swelling compared to recompression decreased by about 40%.

4 CONCLUSIONS

Dynamic cyclic simple shear tests were conducted to understand the G_{max} behavior during recompression, and swelling stages after the soil is consolidated to a new pre-consolidation pressure and stress release. The study's findings lead to the following conclusions.

1. The G_{max} increases in the recompression/compression stages and decreases in the swelling stage.
2. For the same effective axial stress, the G_{max} in the swelling stage is more than in the recompression stage due to the increase in soil stiffness when the soil is consolidated to a new pre-consolidation pressure. The difference in G_{max} in the compression stage, with the increase in P', is more than in the swelling stage. At any $\gamma_c > 0.2\%$, the difference in G_{max} in the swelling stage is negligible.
3. For the same OCR, the G_{max} in the swelling stage is more than in the recompression stage. This could be due to the combined effect of the new pre-consolidation pressure and the increase in effective axial stress in the swelling stage to maintain the same OCR.
4. The damping at a maximum γ_c of 0.5% examined in the current study decreased by 40% in the swelling compared to recompression.

Appraisal of barge-ladden oil drilling rig stability in the mangrove swamp of southern Nigeria

W.I. Beresibo
University of Port Harcourt, Nigeria

ABSTRACT: Accomplished in this paper is the stability appraisal of a 43,620kN barge-ladden oil rig platform in the mangrove swamp of southern Nigeria. The rig is to be deployed to a dredged slot and while in place it is meant to be ballasted prior to the oil drilling exercise. The appraisal of the rig-soil system was carried out using analytical methods and based on the operational requirements of the rig, soil condition and tidal information. The ratio of the bearing resistance to the rig load was found to be greater than 20; indicating that ultimate limit state is ensured. Serviceability limit state checks gave 207mm consolidation settlement which was estimated to occur over 18years period. Within the 10 months period over which the oil drilling exercise is planned, only about 25% degree of consolidation is expected. The results suggest that the operational minimum freeboard of 0.61m will be not exceeded.

1 INTRODUCTION

The southern part of Nigeria especially the Niger Delta region is known for oil and gas exploration activities. Several of these activities take place nearshore within the mangrove swamps. For such locations, a barge-ladden oil rig platform is usually mobilized. These rigs are made up of high ship and deck loads, founded on a barge with a large surface area. The barge helps in the movement of the oil drilling rigs to locations and acts as the platform that bears directly on the soils during the oil drilling operations. Contact pressure from the rig is exacted on the underlying soils through the barge.

The mangrove swamp is one of the morphological units of the coastal environment of the Niger Delta (Short & Stable 1967). The formation of soils across this sub environment are known to be stratified in structure (Whiteman 1982). They are mostly of weak strength with high compressibility characteristics and can hardly support high loads without significant settlements (Abam & George 1997). Hence for projects that involves heavy and sensitive structures, proper soil investigation program and analysis is required in order to avoid failures. This is particularly important for the mangrove swamp sub-environment of southern Nigeria where the soils are known to exhibit high variability and poor strength.

Failures of oil drilling rig platforms are usually fatal and with attendant economic consequences and litigations. Hence, the analysis of the rig-soil system is a necessary requirement prior to the deployment of the rig platform for any drilling operations. In this paper, the stability of a 43,620 kN barge-ladden oil drilling rig has been appraised. This rig is to be deployed to one of the mangrove swamps of southern Nigeria. In the analysis, the operations requirements of the rig, the prevailing soil condition of the site as well as the behaviour of the nearby river were taken into consideration. Analytical methods were employed in the calculations. Both ultimate and serviceability limit state checks were carried out in the analysis. Part of the brief for the analysis is to decide on ground improvement measures in the event that the minimum freeboard is exceeded by the downward movement of the barge. Another aspect of the decision

DOI: 10.1201/9781003299127-343

making involved the determination of the depth of dredge of the top soil layer. This depth has to be adequate for the haulage of the barge into the slot both at low and high-water conditions.

1.1 *Study area*

The study area is located within the Ogbotobo marginal field in the Niger Delta region of Nigeria. It lies within the mangrove swamp vegetation morphological units with network of rivers and creeks. The underlying sediments consist of sand deposits with alternating layers of clay and sand deposits.

2 INVESTIGATION PROGRAM

The investigation program included both field investigation and laboratory testing. Soil borings and sampling were accomplished to a depth of 20 m using percussion drilling rig The field operations were in accordance to requirements of Eurocode 7; part 2. Soil samples retrieved from the boreholes were subjected to laboratory tests to determine their index, strength and compressibility characteristics using relevant sections of the code.

2.1 *Ground condition*

Information obtained from the field and laboratory tests showed that the site consists of a layer of sand occupying the top horizon up to an average depth of 5.25 m. This sand deposit is medium to dense in compact state and overlies a thick layer of soft greyish clay that extended to a depth of 18 m. Beneath clay layer is another layer medium sand layer that extended to the limit of geotechnical exploration. The summary of the soil profile is given in Table 1. The water levels were measured at 0.52 m and 1.45 m below ground surface at high tide and low tide respectively.

The range of value for relevant soil parameters considered as inputs for the analysis is presented in Table 2. Characteristic soil parameters were determined from statistical approach defined by Schneider (1997). In the case of the coefficient of volume compressibility and coefficient of consolidation, their values are not constant but stress level depended. Hence their design values are based on the stress level that corresponds to the load from the oil drilling rig.

Table 1. Subsoil profile of the site.

Soil	Depth to both of stratum (m)	Thickness (m)	Consistency/ Density
Sand	0.00 – 5.25	5.25	Medium to dense
Clay	5.25 – 18.0	12.75	Soft
Sand	18.0 – 20.0	2.00	Medium dense

Table 2. Engineering properties of soils.

Soil	Soil properties	Units	Range of values	Design Value
Sand	Unit weight, γ	kN/m^3	19.9 ~ 20.1	19.9
	Friction angle ϕ	°	35 ~ 43	36
	Soil modulus, E	MPa	41 ~ 90	55
Clay	Unit weight, γ	kN/m^3	15.4 ~ 17.6	15.7
	Undrained cohesion	kPa	10 ~ 12	11
	Soil modulus, E	MPa	5 ~ 6	5
	Coeff. of vol. comp. Mv	m^2/MN	0.77 ~ 1.54	
	Coeff. of consol. Cv	m^2/yr	2.56 ~ 7.19	
Sand	Unit weight, γ	kN/m^3	19.0 ~ 20.2	19.2
	Friction angle ϕ	°	32 ~ 33	32
	Soil modulus, E	MPa	24 ~ 27	25

3 STABILITY ANALYSIS

3.1 *Design situation*

The stability of the rig-soil system was appraised in terms of shear failure and vertical movement of the soil. The following design situations were considered in the analysis.

- The overall rig loads taken as 43,620 kN.
- The dimension of the barge given as 63.9 m x 21.95 m x 4.27 m.
- The condition of soil underlying the site which comprised of sand deposits underlain by clay which in turn overlies sand beds at depths.
- The low and high-water levels of the adjourning river which was measured at 0.52 m and 1.45 m respectively.
- The nature of the rig facilities is such that is to be considered sensitive.
- Loading condition are static in nature
- Short term design was adopted noting the geotechnical and loading conditions of the site.
- The specification of the barge-ladden rig requires that the freeboard of not less than 0.61 m should be maintained during operations.

3.2 *Dredging requirement for the barge-ladden rig*

Based on the topography of the site, rivel level and transit draft of the barge, it is proposed that the top horizon of the soil profile be dredged to a depth of 3.09m in order for the rig to be tugged unhindered to the location. While in place at the drilling location, the compartments of the barge will be ballasted with water in order for the base to have a direct contact with the soil for commencement of the oil drilling operations. Given the elevation of the ground with the proposed depth of the dredge and the soil profile, the barge is expected to rest directly on a 2.16 m thick sand. Based on the high-water level of 0.52 m below ground surface, the freeboard when the barge is in contact with slot bed prior to any vertical movement is 1.7 m. Schematic drawing of the rig-soil system is presented in Figure 1.

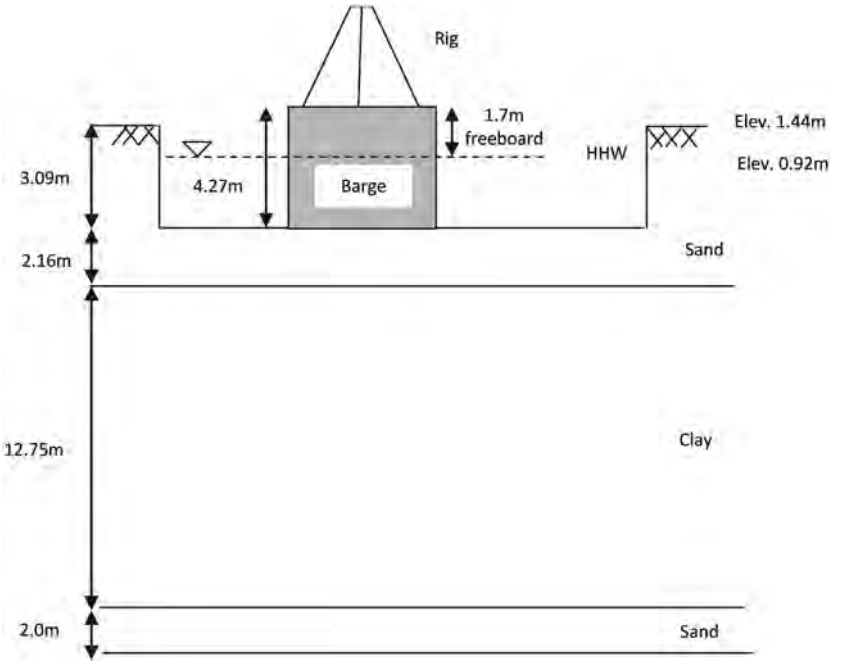

Figure 1. Schematic drawing of the soil-rig system.

3.3 *Analytical methods*

Stability of the barge-ladden rig was carried out with strict adherence to the provisions of relevant sections of part 1of Eurocode 7: Geotechnical Design - Part 1: General rules. Separate checks of ultimate limit states ULS and serviceability limit states SLS were conducted with well-established calculation procedures and reliable design models.

3.3.1 *Ultimate limit state check*

Given the profile of the site and the expected depth of excavation, it is expected that the rig will be resting directly on the medium to dense sand layers while in place. Hence, the effective stress parameters were considered for the stability analysis. The equation used is as given in Annex D, section 2.4 of the Eurocode 7. In the analysis, design approach 1; combination 2 was adopted. Appropriate partial factors were applied to the material properties, loads and bearing resistances. The analytical model used in the computation is expressed equation 1 below:

$$\frac{R}{A'} = C_u N_c S_c + q' N_q S_q + 0.5 B \gamma' N_\gamma S_\gamma \tag{1}$$

Where R = bearing resistance; A′ = effective area of the footing; C_u = undrained shear strength; q' = effective overburden pressure at the base level of the foundation; γ' = effective unit weight above the base level of foundation; N_γ N_q N_c = bearing capacity factors; and $S_c S_q$ S_γ = shape factors.

3.3.2 *Serviceability limit state check*

Serviceability was considered as the governing criteria for the stability appraisal of the rig-soil system. In the analysis, consolidation settlement was considered as the most critical given the condition of the soils at the site. Consolidation settlement analyses were performed using the equation given below:

$$S_c = \sum M_v \Delta_P H \tag{2}$$

Where Mv = coefficient of volume compressibility; H = thickness of the clay layer; and Δ_p is the increment in the vertical effective stress in the layer due to the net bearing pressure.

The rate of consolidation settlement was also estimated. The expression used to determine the time rate of settlement equation given below.

$$T_v = C_v \; t/H^2 \tag{3}$$

Where: Tv = time factor; Cv is coefficient of consolidation; and H is the thickness of the consolidating layer which is $H/2$ for double drainage situation. The characteristics values of the coefficient of consolidation used in the equation is based on the values obtained for the range of pressure that corresponds to the un-factored rig load.

4 DISCUSSION

Results from the ultimate limit state check returned bearing resistance values of 2271 kPa. The high value of the bearing resistance is attributed to the shearing resistance of the sand materials and the width of the barge. Given the 63.9 m x 21.95 m dimension of the barge, the rig is expected to exact a pressure 31 kPa on the soil. The ratio of the bearing resistance to the rig load is seen to be more than 20. This signifies that the ultimate limit state requirement is met. The serviceability limit state results indicated that the clay soils would undergo consolidation settlement of 207 mm when subjected to the rig load. The rate of consolidation of the clay layer is estimated at 18 years for 95 percent degree consolidation. It is planned that the entire oil drilling exercise would be concluded within 10 months period. In this case, only about 25%-degree consolidation would have been achieved. This would correspond to

a settlement of about 52 mm. The variation of the estimated consolidation settlement with time is shown in Figure 2. The freeboard that is achievable based on the estimated consolidation settlement and the observed high-high water level is 1.49 m; which is greater than the specified minimum value of 0.61 m. This shows that the serviceability limit state is also ensured and ground improvement is equally not necessary.

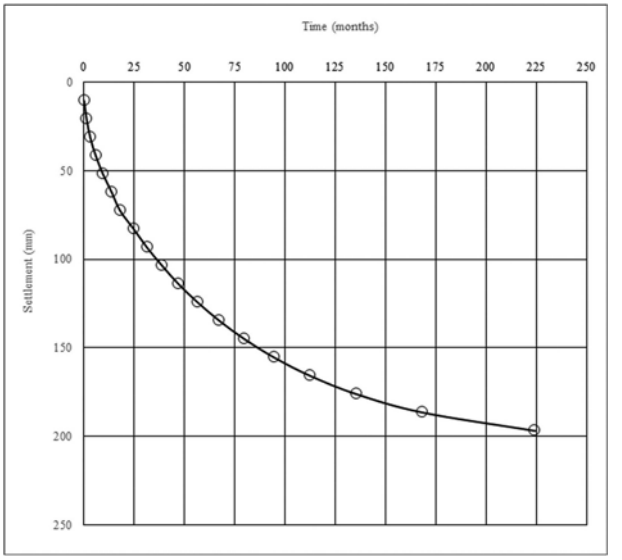

Figure 2. Variation of settlement with time.

5 CONCLUSION

The paper has been able to highlight some of the important geotechnical requirements in the determination of the stability of a barge-ladden oil drilling rig in mangrove swamps operations. The stability is accessed in terms of shear failure and vertical downward movement of the barge. For sites underlain by clay formations, consolidation settlement is considered the governing criteria. The limit of vertical movement is defined by the required minimum freeboard specified for the barge-ladden rig. The ballasting of the barge ought to be carried out in a manner that will ensure the entire barge base rest on the river bed at same time in order to avoid the occurrence of differential settlement.

Study of the resistance on the side surface of the underwater vehicle's soil base

A.A. Ananiev
Saint-Petersburg State University of Architecture and Civil Engineering, Saint-Petersburg, Russia

ABSTRACT: The object is the soil of the ocean floor. The goal is to predict the resistance of the underwater vehicle's soil base. Tools - laboratory methods for studying the physical and mechanical properties of soils, physical modeling of the work of the soil base, statistical processing of measurement results. The approach is verification of the viscous fluid model. The main results are experimental values of physical, strength and rheological parameters of the bottom soil, mathematical description of the experimental results, normative values of the strength of the ocean soil.

1 INTRODUCTION

The concept of technology for the development of deposits of ferromanganese nodules (FMN) of the World Ocean provides for the creation of a mining vehicle (MV) (Alexandrov 1992, Jungmeister, Smirnov, Verzhansky 2015, Tetsuo 2017). In operating mode, the MV must reliably move on weak soils of the ocean floor at depths of 4000-5000 m at a speed of 0.5- 1.5 m/s. Separation of FMN *1* from the soil *2* is carried out using a «knife-comb» *3*. The estimated depth of entry of the working body into the ground base is 100 mm and a width of 3-4 m (Figure 1) (Egorov, Kondratenko, Grigortsuk 2020).

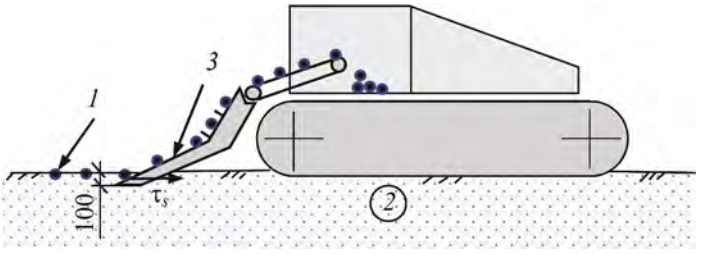

Figure 1. Scheme of separation of FMN: 1– FMN; 2 – ocean silt; 3 – knife-comb; τ_s – soil shear resistance.

To design the tractive forces of the MV, it is necessary to predict the resistance of the bottom soil on the side surface of the comb knives. To this end, experiments were conducted that made it possible to identify the features of the physical and mechanical properties of the bottom soil, and using the calculation model of the soil, a mathematical description of the results of the experiments was given.

DOI: 10.1201/9781003299127-344

2 PHYSICAL CHARACTERISTICS OF BOTTOM SOIL

Information on the characteristics of the physical properties of bottom soils in the ore province of Clarion-Clipperton of the Pacific Ocean was obtained by the Research Institute in the field of marine geology (VNIIOkeangeologia) together with the Saint Petersburg State University of Architecture and Civil Engineering (SPbGASU) (Neizvestnov, Kondratenko, Ananiev et al. 2004, Kondratenko 2012). Soils sampling of the ocean floor was carried out from the board of the research ship «Akademik Alexander Karpinsky» with the help of a grapple, a box-shaped sampler and a ground tube. The maximum stripped depth of the geological section was 4.15 m. The production of soil samples of undisturbed build was carried out by the cutting ring method. Samples were tested in laboratories on board and on land. The monoliths were isolated by the waxing method, the disturbed samples were placed in containers with hermetically sealed lids.

Physical characteristics – soil density ρ, water content w, solid particles density ρ_s, plasticity index I_P and liquidity index I_L were determined by standard methods of GOST 5180–2015 «Soils. Laboratory methods for determination of physical characteristics», by calculation method – dry soil density ρ_d, porosity n and void ratio e. All characteristics of water content were calculated with an adjustment for the mineralization of pore water. The areas of values of the physical characteristics of ocean soil are presented in Table 1.

Table 1. Physical characteristics of the ocean soil.

Soil characteristics	Indicators of soil characteristics
Soil density ρ, kg/m^3	(1.14–1.22)·10^3
Solid particles density ρ_s, kg/m^3	(2.41–2.42)·10^3
Dry soil density ρ_d, kg/m^3	(0.24–0.33)·10^3
Water content w, %	274–384
Porosity n, %	88–90
Void ratio e,	7.05–9.00
Plasticity index I_P, %	64–98
Liquidity index I_L	0,96–3,0

It has been established that in the active zone of interaction of the MV with the ground base, according to the classification of Neizvestnov, mainly weak clayey and siliceous-clayey bottom sediments of Holocene-Middle Miocene age lie. The mineral composition of the clay fraction is represented by hydromica, smectite and chlorite. The content of amorphous silica can reach 15-20%. Weakly compacted water sediments are characterized by a large aggregate structure, high dispersion. The most important distinctive features of the ocean soil are: high porosity, complete water saturation, absence of gases in free and dissolved form, fluid consistency. According to its state, the bottom soil can be considered as a solid-like viscoplastic medium.

3 MECHANICAL MODEL OF BOTTOM SOIL

Determination of the lateral resistance of the bottom soil was carried out at the stand for modeling the operation of soil bases (SMOB-1) (Dalmatov, Bronin, Ananiev et al. 1987). The closest analogue to the SMOB-1 design is a stand for studying the strength properties of ocean soils, developed at the University of San Diego (Noorany, Fuller 1982).

A sample of natural soil of ocean floor *1* with a total weight of 0.54 tons was loaded into tray *2* with overall dimensions: length – 6 m; width – 0,3 m; height – 0,3 m. The soil was mixed to a homogeneous state, the soil surface was leveled to a horizontal plane and covered with a layer of seawater 2-3 cm thick. Control of the uniformity of the bottom soil was carried out using an impeller. The tray was hermetically sealed with lids. The soil base prepared in this way was kept for 6 days before the start of the tests.

Models No. 1 and 2 were steel plates pointed from the end with a thickness of 2 mm with a height of 50 and 100 mm and a length of 200 and 400 mm, respectively, *3* buried in the ground vertically along the direction of movement. The models were moved in the ground base at constant speeds of 0.2 and 1.7 m/s using a drive mechanism. The pulling force was measured by a strain gauge rod *4* connecting the model to the trolley *5* and recorded on a paper recorder tape as the displacements of the model increased. A total of 20 experiments were performed: 6 with model No. 1; 5 and 3 with model No. 2 at shear speeds of 0.2 and 1.7 m/s, respectively. The number of experiments with the Model No. 2 was reduced to avoid the breakdown of the test machine due to its design flaws. The obtained data were processed in the form of graphs $T_i = f(U_i)$ (Figure 2).

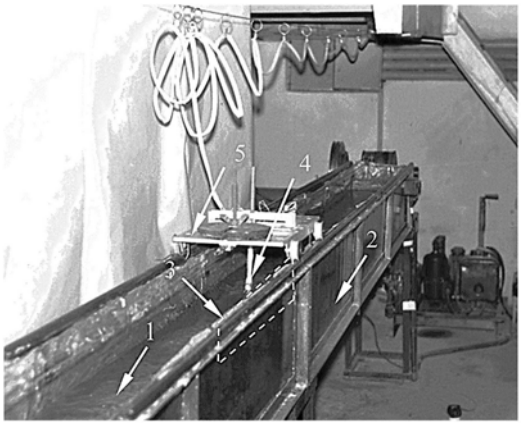

Figure 2. Testing machine SMBO-1: 1 – silt; 2 – tray; 3 – model; 4 – strain gauge; 5 – trolley.

During the experiments, T_i values were recorded on the paper tape of the recorder, depending on the horizontal movements U_i of the models. The characteristic graphs of the dependencies $T_i = f(U_i)$ are shown in Figure 3.

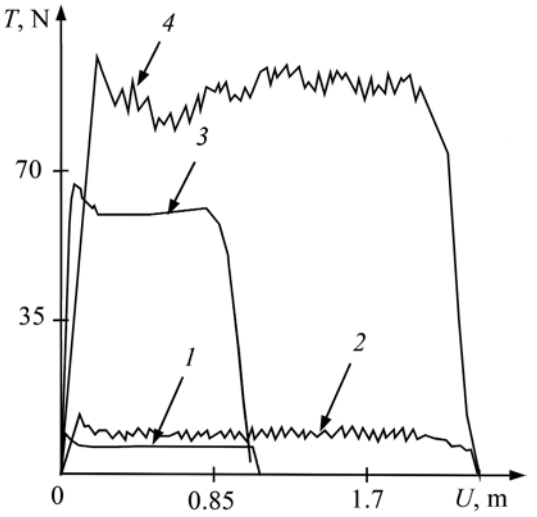

Figure 3. Graphs of the dependence of shear load T_i on horizontal deformation U_i: 1 – model No. 1, speed of movement V_1 = 0.2 m/s; 2 – the same V_2= 1.7 m/s; 3 – model No2, V_1=0,2 m/s; 4 – the same V_2 =1.7 m/s.

Graphs have a complex outline. Two characteristic criteria for the strength of the bottom soil, peak and residual shear resistance, were recorded. In the hardening section, the shear resistance increases linearly and reaches peak values, and in the softening section, the shear resistance decreases non-linearly to residual values. The process of reducing the strength of the bottom soil as the deformation increases can be explained by creep. Peak and residual strength increases with increasing deformation rate. The jagged sections of the graphs are explained by the vibration of the test machine at high shear speeds. During the experiments, a flow of the soil was recorded in a layer bordering with the models with a thickness of δ=20 (Figure 4).

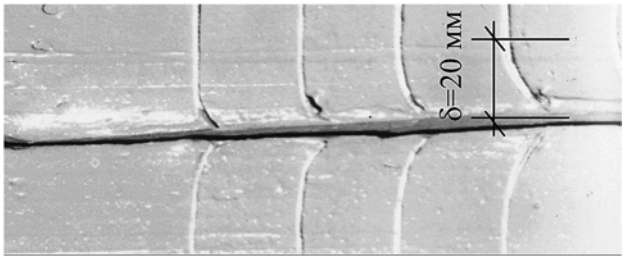

Figure 4. Boundary layer flow.

The values of peak and residual soil shear resistances were determined by the formula

$$\tau_i = T_i/A, \tag{1}$$

where T_i = the peak or residual shear load determined by the graphs $T_i = f(Ui)$; A = the side surface area of the model, $A = 0.02$ or 0.04 m^2.

Statistical verification of partial values of peak τ_i^{max} and residual τ_i^{min} of soil shear resistance showed the absence of possible erroneous values of characteristics (GOST 20522–2020 "Soils. Methods of statistical processing of test results"). As a result, the normative values of the parameters of the strength of the ocean soil are taken to be equal to their arithmetic means. (Table 2).

Table 2. Normative strength characteristics of ocean soil.

Model No1				Model No2			
Strain rate V m/s							
0.2		1.7		0.2		1.7	
Normative values of peak (max) and residual (min) shear resistances of the bottom soil, kPa							
τ_{n1}^{max}	τ_{n1}^{min}	τ_{n2}^{max}	τ_{n2}^{min}	τ_{n3}^{max}	τ_{n3}^{min}	τ_{n4}^{max}	τ_{n4}^{min}
0,59	0,42	0,67	0,51	1.48	1.35	2.5	2.2

Experiments have shown that with an increase in the size of the model object and a decrease in the time of exposure to the load, the strength of the ocean soil increases up to 80%.

The identified features of the deformation of ocean silt by mobile loads make it possible to choose a viscoplastic model, currently called the Bingham body, to describe the results of experiments. The flow equation of the Bingham body is written as follows:

$$\tau_i = \tau_l + \dot{\gamma}_i, \tag{2}$$

where τ_l = limiting shear stress; η = viscosity coefficient; $\dot{\gamma}_i$ = shear deformation rate.

Such a record of the equation of state of a solid means that at stresses less than the limit value τ_l of the soil is deformed elastic-plastically, and when this limit is reached, it begins to flow at a constant speed (Vyalov 1978).

The shear deformation rate $\dot{\gamma}_i$ let's define from the expressions:

$$\dot{\gamma}_1 = \gamma/t = U/(t \cdot \delta) = V_1/\delta = 0.2/0,02 = 101/\text{s}; \tag{3}$$

$$\dot{\gamma}_2 = V_2/\delta = 1.7/0,02 = 851/\text{s}. \tag{4}$$

4 RHEOLOGICAL CHARACTERISTICS OF BOTTOM SOIL

The rheological characteristics of the soil will be determined from the graph $\dot{\gamma} = (\tau_{ni}^{min})$: η_i – by the slope tangent of inclination of the straight line to the abscissa axis; τ_{li} – in scale, like a segment cut off by a straight line on the axis of the ordinate (Figure 5).

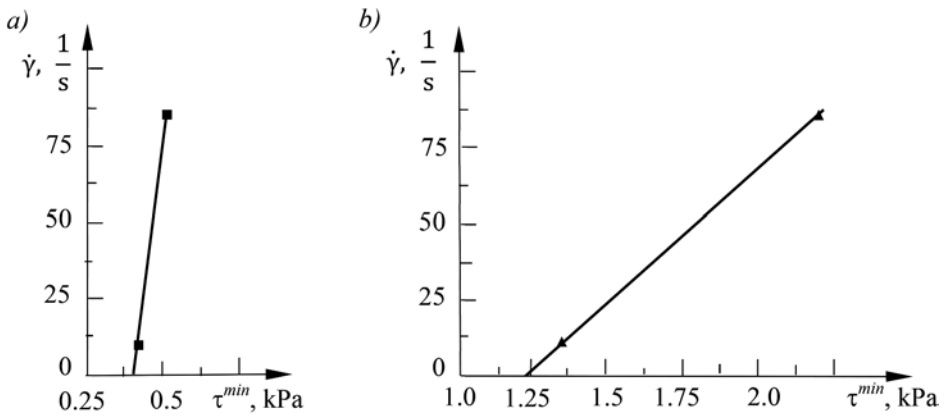

Figure 5. Rheological curves: *a)* – ocean silt creep in the boundary layer of Model No. 1; *b)* – same Model No. 2.

$$\eta_1 = (\tau_{n2}^{min} - \tau_{n1}^{min})/(\dot{\gamma}_2 - \dot{\gamma}_1) = (0.51 - 0.42)/(85 - 10) = 1.20 \cdot 10^{-3}\text{kPa} \cdot \text{s}; \tag{5}$$

$$\tau_{l1} = 0.25 + 6 \cdot 0.025 = 0.4\text{kPa}; \tag{6}$$

$$\eta_2 = (\tau_{n4}^{min} - \tau_{n3}^{min})/(\dot{\gamma}_2 - \dot{\gamma}_1) = (2.20 - 1.35)/(85 - 10) = 11.10^{-3}\text{kPa} \cdot \text{s}; \tag{7}$$

$$\tau_{l2} = 1.0 + 9 \cdot 0.025 = 1.23\ kPa. \tag{8}$$

The results of calculations according to the formulas (5) ÷ (8) show that with an increase in the lateral surface area of the model object by 4 times, the viscosity coefficient of the bottom soil increases by an order of magnitude, the liquidity strength increases by 3 times.

To compare the values of the rheological characteristics obtained during physical modeling, they were determined by the rotating cylinder method (Ananiev, Voznesenskaya 1988). Samples of bottom soils were tested on a rotational viscometer RV-4, Volarovich systems. The principle of operation of the device is based on the rotational shift relative to each other of the layers of a viscous body placed in the working space between the movable *1* and fixed *2* coaxial cylinders. Torque is created by a load mounted on thread suspensions 3 (Figure 6).

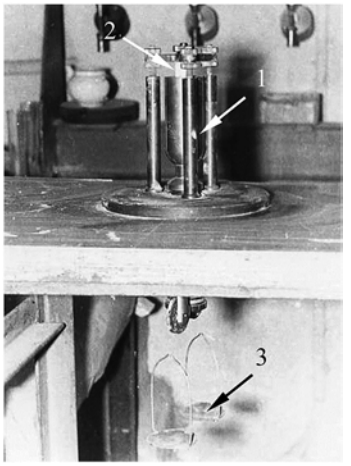

Figure 6. Viscometer RV-4: 1 – movable cylinder with silt; 2 – fixed cylinder; 3 – suspension for cargo.

Prior to the start of the experiments, the viscometer was calibrated for friction in the ball bearings. A soil sample was formed in the working space of the device using a rule. During the test, the load on the sample was transferred using a load of mass P_i, the angular velocity of the rotation cylinder N_i was measured using a stopwatch. A total of 5 soil samples with a multiplicity of 3 were tested.

Statistical verification of the partial values of the shear rate of the bottom soil N_i, performed in order to establish and exclude values sharply different from most values, showed the absence of possible erroneous measurements of the characteristic. A graphical representation of the test point polygon is shown in Figure 7.

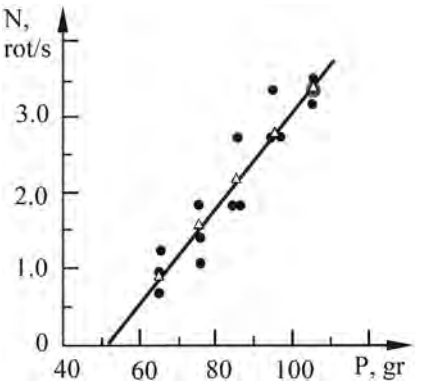

Figure 7. Graph $N=(fP)$.

Using the least squares method for a set of 15 pairs of experimental values of the parameters N_i and P_i, an approximating dependence was found

$$N_i = 61.2P_i - 3.08. \tag{9}$$

The normative angular velocity of the rotational shift N_{in}, calculated by the formula (9), are presented in Table 3.

Table 3. Results of determination of the viscosity coefficient of bottom soil.

Weight of the load rotating the cylinder with the ground adjusted for friction in bearings P, kg	Normative angular velocity of the rotational shift N_n, rot/s	Viscosity coefficient η, kPa ·s
0,066	0,959	$11{,}69\cdot10^{-3}$
0,076	1,57	$8{,}23\cdot10^{-3}$
0,086	2,183	$6{,}70\cdot10^{-3}$
0,096	2,795	$5{,}84\cdot10^{-3}$
0,106	3,4	$5{,}30\cdot10^{-3}$

The limiting shear stress τ_{sl} and the viscosity coefficient η of the bottom soil were calculated according to the formulas given in the instructions for the device PB-4:

$$\tau_{sl} = K_0 \cdot P_0 = 4191.01 \cdot 0.056 = 235\text{Pa} = 0.235\text{kPa}, \tag{10}$$

where K_0 is a constant, $K_0 = 4191.1$ 1/m·s^2; P_0 is the minimum weight of the load corresponding to the beginning of rotation of the cylinder with the ground adjusted for friction in the bearings, $P_0 = 0.056$ kg;

$$\eta = K \cdot \left(P_i - P_f\right)/N_{ni}, \tag{11}$$

where K is the constant, $K = 169.95$ 1/m·s^2; P_i is the mass of the load rotating the cylinder of the viscometer without adjusting for friction (Table 3); P_f is the friction of the bearings of the device, i.e. the minimum value of the load driving the empty cylinder, P_f = 9 g.

The results of determining the viscosity coefficient according to formula (11) are presented in Table 3. It is established that with an increase in the flow rate, the viscosity coefficient of the bottom soil decreases.

The viscosity coefficient defined as the tangent of the inclination angle of the graph $N = f(P)$ (Figure 6) turned out to be equal

$$\eta = K \cdot (P_5 - P_1)/(N_{n1} - N_{n5}) = 169.95 \cdot (0.106 - 0.066)/(3.4 - 0.959) = 2.785 \cdot 10^{-3}\text{kPa} \cdot \text{s}. \tag{12}$$

This viscosity value is close to the value $\eta_1 = 1.20 \cdot 10^{-3}$ kPa·s found in the conditions of testing the strength of ocean silt by Model No. 1.

5 CONCLUSION

Let's make a forecast of residual stresses τ_1^{min} and τ_2^{min} of bottom soil (see Table 2) on contact with Model No. 1. Rheological characteristics: τ_{sl} = 0,235 kPa (see Equation 10); $\eta_1 = 11{,}69\cdot10^{-3}$ kPa·s $\eta_2 = 5{,}30\cdot10^{-3}$ kPas (see Table 3) we will accept the results of their determination in a viscometer.

Using the Bingham body flow equation, we obtain:

$$\tau_1^{min} = \tau_{sl} + \eta_1 \dot{\gamma}_1 = 0.235 + 11.69 \cdot 10^{-3} \cdot 10 = 0.352\text{kPa}; \tag{13}$$

$$\tau_2^{min} = \tau_{sl} + \eta_{21} \dot{\gamma}_2 = 0.235 + 5.3 \cdot 10^{-3} \cdot 85 = 0.686\text{kPa}. \tag{14}$$

Comparison of the calculated values of shear stresses (see Equations 13 and 14) with the experimental ones $\tau_{n1}^{min} = 0.42$ kPa and $\tau_{n2}^{min} = 0.51$ kPa shows that their discrepancy is 16% and 26%, respectively. Since the discrepancy is less than 30%, the mathematical description of the

experimental results can be considered satisfactory. Experiments with Model No. 2 showed that a 4-fold increase in the lateral surface area of the model object caused a significant increase in shear resistance (see Table 2). The results obtained cannot be explained from the standpoint of the theory of viscous fluid, and, on the contrary, they may well be explained by the laws of solid-state mechanics. At the R&D stage, it is recommended to adopt the normative peak and residual shear resistance on the side surface of the comb knives respectively 2.5 and 2.2 kPa for the design of the MV mock-up sample (see Table 2). These strength values are in good agreement with the data of 12 measurements of rotational shear resistance, equal to 0.7-2.6 kPa, of samples of natural bottom soil containing nodules.

Information systems in geotechnics

G.G. Boldyrev
LTD NPP-Geotek, Penza, Russia

ABSTRACT: The article discusses the application of building information modeling (BIM) technology to build a 3D geotechnical model. The workflow for building a 3D geotechnical model includes surface relief data, field and laboratory test data, soil lithology, geometric characteristics of the foundation structure and load. Automated systems with processing and interpretation of test data are used to determine the characteristics of soils. Mathematical modeling of the behavior of the foundations of the foundations with various input data is performed using analytical solutions and numerical methods. The natural heterogeneity of soil properties and its impact on the behavior of buildings is estimated by the sensitivity indicator of the foundation-foundation system by introducing virtual workings between the existing normative ones and the subsequent calculation of the precipitation and roll of the foundation.

1 INTRODUCTION

The widespread use of information modeling in construction (BIM-Building Information Modeling) is mainly due to the advantages in terms of saving costs and time for the implementation of the project, due to the reduction of unforeseen problems and easier updating of the digital model. Thanks to technical research conducted by universities and industry, useful tools have been developed to optimize digital models and improve interaction between various specialists involved in the design process (Morin et al. 2014).

Building information modeling is widely used by civil engineers and architects for designing structures of buildings. At the same time, it may sound paradoxical, geological and geotechnical data are not used at all in the BIM design process, although most of the risks and uncertainties of construction arise from unknown or incorrectly estimated engineering and geological conditions. At the moment, BIM technologies are being developed for many sections of the design and construction, with the exception of engineering-geological and geotechnical surveys.

Unfortunately, not so many geotechnical projects have yet been implemented using the BIM approach, and in most cases, it still consists only in archiving, storing and updating geological and geotechnical data (Xikui et al. 2016, Migilinskas et al. 2013). However, in the last two years, the situation has changed and there have been works that consider the methodology of building information systems in geotechnics (Nappa et al. 2019, Pan et al. 2019).

This article demonstrates the applicability of the developed technology to the entire process of designing the foundations of construction objects, starting with engineering-geological, engineering-geotechnical surveys and ending with the calculation of the foundations of foundations using appropriate sets of rules or numerical methods. The advantage of automated testing methods and mathematical modeling of foundation bases based on known values of physical and mechanical properties of soils at normative and virtual workings is emphasized.

2 BASIC CONCEPTS AND DEFINITIONS

Basic definitions. The initial data for the construction of a digital information geotechnical model is an engineering-geological model, which is a schematic spatial representation of

DOI: 10.1201/9781003299127-345

engineering-geological elements (IGE), groundwater, hazardous geological and engineering-geological processes in the field of interaction of the object with the geological environment. This definition is given in SP 446.1325800.2019 "Engineering and geological surveys for construction. General rules for the production of works" and is incomplete, so it does not include the properties of soils in the IGE, despite the fact that the survey results include data on the physical and mechanical properties of soils. The proposed geotechnical information System (BIMG) has a more extended definition:

1. BIMG (Building Information Model Geotechnical) is a digital information model with a set of components that characterize stratigraphy and lithology, physical and mechanical properties of soils and the construction of the foundation in three-dimensional space.
2. BIMG-contains the information necessary for the design of the foundations of buildings and structures according to the limit states and is one of the information models that make up the BIM of a construction object.
3. The development and development of BIMG is carried out in a shared data environment, which means that all interested parties have constant access to a model filled with information from surveys at the construction site.
4. BIMG uses three approaches to modeling: geostatistical, explicit and numerical modeling. For all approaches, data is collected, quality-controlled, transformed (if necessary), harmonized, classified and interpreted. Modeling begins only after the input data has successfully passed the processing and quality control processes.

In order to eliminate confusion in the concepts of "geological model" and "geotechnical model", we will introduce additional explanations.

The 3D geotechnical model is created by geostatistical methods based on workings, surface maps and engineering-geological sections. It is important that the source data used is uniformly classified and consistent. The choice of the geostatistical method, scale, and other parameters of the model depends on various criteria, such as the parameter to be modeled, the scale of the model, the complexity of engineering and geological conditions, and the distribution of input data. To validate the implemented 3D models, various checks are carried out: visual checks, variogram analysis and cross-validation. Automation of data processing and interpretation processes ensures the relevance of models and the ability to track their development. That is why it is extremely important to automate as many stages of the workflow as possible.

The 3D geotechnical model is created on the basis of a 3D geological model by introducing additional information about the design of the projected foundation, external loads on the foundation, as well as the parameters of soil models necessary for calculating the foundations of foundations by numerical and analytical methods.

3 METHODOLOGY

The procedure for creating a geotechnical information system (BIMG) is a workflow consisting of the following main stages:

1) the surface relief of the construction site under consideration is determined using GIS systems.
2) a complex of laboratory and field tests of soils is carried out using automated complexes at standard workings. Here and further in the text, mining is understood as a geological well with the selection of monoliths or a point of static or dynamic sounding;
3) the stratigraphy and lithology, physical and mechanical characteristics of soils are determined. In the case of using numerical methods, the parameters of soil models are determined;
4) a 3D geological model is being built;
5) a geotechnical 3D model is formed by dividing the geological model into finite elements of a given scale and the coordinates of their nodes X,Y,Z are determined;
6) using the interpolation functions (for example, Shepard, Delaunay, Kriging, etc.) and the values of soil characteristics at standard workings, the soil characteristics (parameters of soil models) are found in finite elements;

7) the foundation structure and loads are introduced into the 3D model;
8) the foundation is calculated using analytical solutions of the corresponding sets of rules or numerical calculation methods;
9) virtual workings are introduced and the influence of heterogeneity of soil properties on the results of analytical or numerical solutions is evaluated;
10) To transfer information to the external environment, a 3D digital geotechnical model is produced in the IFC4 format, which allows it to be used in 3D programs such as Civil 3D, Revit, Allplan, Flac, Plaxis, etc.

3.1 *Geotechnical data*

Engineering-geological and geotechnical studies performed by geotechnical engineers or geologists are the main way to obtain geotechnical data that carry information about stratigraphy, lithology, physical and mechanical properties of soils and rocks at the survey site. Geotechnical data are of crucial importance in the design of the foundations of buildings and structures and the construction of transport infrastructure facilities.

Standard geotechnical data is collected from three main sources: (1) wells and pits; (2) in situ tests, including geophysical surveys, static (CPT) and dynamic sounding (SPT) tests, etc.; and (3) laboratory tests conducted on samples taken from wells. Some geotechnical data can be collected from pits or tests at the bottom of pits. However, they make up a small percentage of the data compared to well data and are usually processed in the same way.

For laboratory testing of soils, the automated ASIS Lab system (www.npp-geotek.com) has been developed, which includes various devices for static and dynamic testing of unfrozen and frozen dispersed soils, rocks. Field tests are carried out using various methods, such as cone penetration test, standart penetration test, dilatometer test, pressiometer test, etc. The interpretation of field test data is automated and is performed using the «Geotek Field» program.

3.2 *Data maps*

Data maps in the form of a situational plan of engineering-geological and geotechnical studies (Figure 1) describe the type of data (geophysical studies, field tests with stamps, static and dynamic penetration, etc.) available for each IGE in the model. Although these maps do not convey the reliability of the geological model, they give a very clear idea of what type of data contributed to each IGE and what is the data density in this area of the model. Based on the information obtained from the data maps, the user can quickly recognize areas studied by mathematical modeling (virtual workings) and areas based on measured data (standard workings). For example, in Figure 1, at object 4A-8, drilling wells and static penetration were performed at four points (standard workings, cone penetration tests) and 13 virtual workings (V1-V13) were constructed using the interpolation functions, in which the lithology and soil properties were determined.

The scale and detail with which a geotechnical model can be built are inherently related to the density and detail of data obtained from engineering-geological and geotechnical investigations. The amount of data depends on the stage of surveys and the category of complexity of engineering and geological conditions, which are determined by the regulatory requirements of SP 47.13330.2012 “Engineering surveys for construction. Main provisions”: the stage of choosing a construction site; the stage of preparing project documentation; the stage of construction and reconstruction of buildings and structures; and three categories of complexity of engineering and geological conditions. For example, for the stage of preparation of project documentation, the distance between the normative workings depends on the complexity category of engineering and geological conditions and varies from 25 to 100 m. The total number of mine workings within the contour of each building and structure for category I is 1-2 workings; for category II-at least 3-4, for category III – the number of mine workings is determined by the design of a specific foundation, loads on the base and engineering and geological conditions, but not less than 4-5, taking into account the geometric dimensions of the object. With such a meager density of workings, it is quite difficult to assess the heterogeneity of soil properties and their influence on the behavior of the projected building or structure.

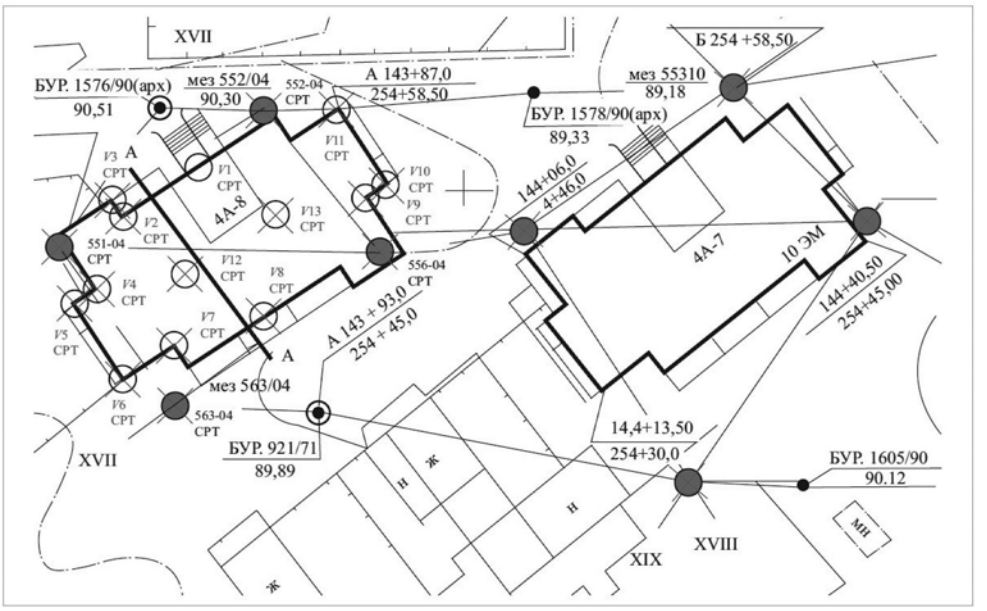

Figure 1. Survey data map with building plans.

3.3 *Data processing and interpretation*

The use of all available data from the workings involves the use of automated interpretation procedures due to the huge amount of available data. We have created a set of tools to provide a standard method for processing laboratory data, cone penetration test (CPT) and standard penetration test (SPT) data. With the help of this tool, we can interpret the lithology in the workings, using their position in the direction of the XY and Z coordinates of the three-dimensional soil array. The lithology inside the geotechnical model is determined by simple processing of CPT parameters (cone resistance, coefficient of friction, depth, see Figures 3 and 4) using P. Robertson diagrams (Lunne et al. 1997), and the physical and mechanical characteristics of soils are found from correlation equations connecting them with the parameters of static (CPT) and dynamic sounding (SPT). By applying automated procedures, we can use more data than ever before. This allows us to create more detailed geotechnical models.

Currently, BIMG includes data from laboratory tests, CPT, CPTU, SPT, DCPT in situ tests, performs a basic interpretation from the point of view of the behavior of the soil type (Lunne et al. 1997), determines the physical and mechanical characteristics of soils and calculates the foundations of buildings and structures in accordance with the requirements of the codes of regulations of the Russian Federation SP 47.13330-2012 "Engineering surveys for construction. Basic provisions", SP 24.13330.2011 "Pile foundations", SP 22.13330.2016 "Foundations of buildings and structures", SP 25.13330.2012 "Base and foundations on permafrost soils" or foreign regulatory technical documents EN 1997-1 "Eurocode 7-Geotechnical Design-Part 1: General rules", etc.

When determining the physical and mechanical characteristics of soils, correlation dependencies are used (for example, SP 446.1325800.2019) between the parameters measured during static and dynamic penetration and the data of laboratory tests of soils. Using the sounding parameters and correlation equations, the physical and mechanical characteristics of soils are determined.

The IFC4 format is used to transmit information to an external user. The IFC4 format was developed by building SMART in 2013 specifically for building information modeling, approved by the international standard ISO 16379 and recommended by GOST 10.0.02-2019 for use in the Russian Federation. The format file has a text structure corresponding to the STEP file (ISO 10303-21 international standard for CAD data exchange), which borrows a model of entity relationships from the EXPRESS data modeling language. Such entities are:

building elements, geometry, basic constructs. Entities form an object hierarchy with property inheritance. At the moment, there are more than 700 such entities. The format is extensible, if the required building element is not described, then it is possible to add your own.

No special entities have been created yet to create a digital geotechnical model. This is due to the lack of a format for the exchange of engineering and geological data in the Russian Federation at the moment. The authors use the entities IfcBuildingElementProxy and IfcPropertySet to build such a model. The first entity contains a geometric description of the surfaces, coordinates, color, and the name of the type of soil. The second one is responsible for storing the physical and mechanical characteristics of soils 2D and 3D visualization. An example of a three-dimensional visualization of a geological model is shown in Figure 2 (cross-section section A - A in Figure 1) together with the construction of a slab foundation. The 3D modeling and visualization provides a powerful tool for spatial analysis. The purpose of visualization is to use a 3D model that can receive different scales of information from different sides and in sections. Visualization includes standard and virtual workings, lithological columns, profiles of physical and mechanical characteristics of soils, the position of the groundwater level, the foundation structure.

Knowing the values of the soil characteristics in the standard workings, you can build virtual workings and then use the obtained values of the characteristics in calculations (for example, the calculation of the settlement and the tilt of the foundation according). You can build as many virtual workings as you want, and their impact can be estimated by the amount of the determined foundation precipitation. The main rule for choosing the number of virtual workings is determined by the rule for stabilizing the increment of the average foundation settlememnt as they are introduced. In Figure 3 shows an example of constructing a field of values of the deformation modulus for two standard workings and with the introduction of two virtual workings. In this example, the Kicking interpolation function is applied. As can be seen from the example considered, the use of the interpolation function allows you to build a digital array of the required soil characteristics.

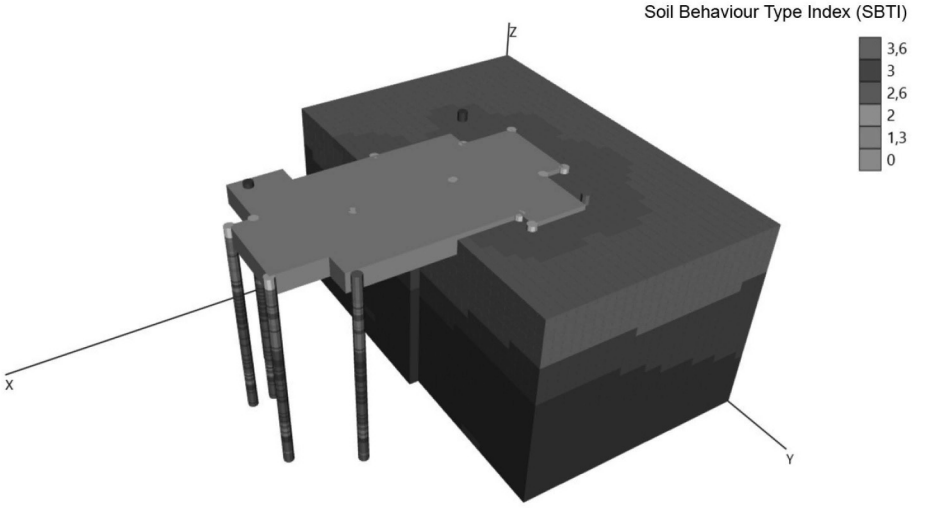

Figure 2. An example of 3D visualization of a geotechnical model with a foundation structure, virtual and standard workings.

It should be noted that the considered procedure is performed automatically, directly in the process of static sounding of soils, and since it is possible to perform sounding not in four, but in a larger number of points during a working shift, the accuracy of estimating the heterogeneity of engineering and geological conditions will be significantly higher.

Calculation of the foundation bases. Currently, the foundations of buildings and structures are designed using analytical and numerical solutions. Analytical solutions are simple, easily

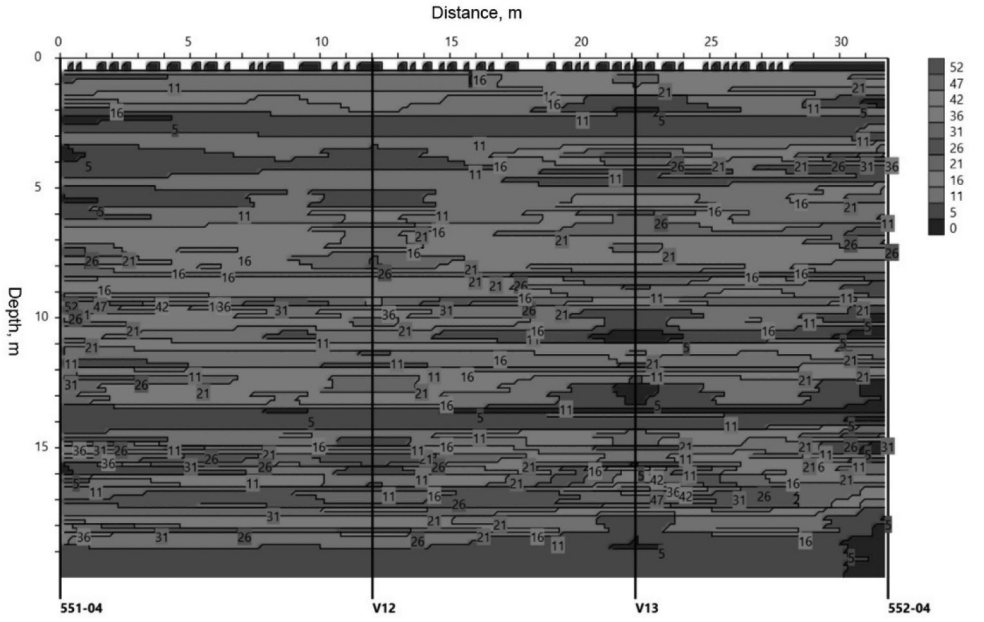

Figure 3. 2D distribution of the deformation modulus: 551-04, 552-04 - standard workings; V12, V13 - virtual workings.

programmable, require determining the minimum number of soil characteristics, and the long-term practice of their application testifies to the reliability of these solutions. Numerical methods for calculating the bases are much more complicated, in most cases it is necessary to determine a larger number of characteristics (model parameters) of soils during surveys, and often their reliability has to be checked using analytical solutions. Due to the fact that compliance with regulatory requirements is still mandatory in the Russian Federation, we suggest using the appropriate analytical solutions provided in regulatory documents to solve practical problems of designing buildings and structures. At the same time, the structure of the proposed information technology allows us to apply numerical methods of solutions implemented in various programs such as PLAXIS, FLAC, etc.

Thus, BIMG uses two procedures for calculating the foundations. Classical solutions given in the previously mentioned SP and the finite element method. These calculations allow us to model the behavior of the foundations using various defining equations (soil models), including elastic behavior (in the case of using SP) and nonlinear models in finite element calculations. The second modeling procedure was successfully tested for various engineering and geological conditions when solving problems of calculating the settlement of foundations, as well as the stability of the slopes. In both cases, the transition from the 3D model to the 2D model is used.

Estimation of the uncertainty of the properties of the 3D model. In geotechnical studies, it is generally accepted practice (or should be) to assess possible errors in determining the lithology, physical and mechanical properties of soils and the impact of these errors on a building or structure under construction. This is sometimes called a hazard and risk analysis (Shi 2014). Various methodologies, such as geostatic methods and probabilistic studies, are used to give a certain quantitative assessment of possible errors in the design of an engineering structure due to uncertainty about the properties of soils. However, two very important main points - the geological and geotechnical expertise used to create the model, and the division of the soil mass into IGE are considered in these analyses only very superficially or not at all.

In the existing estimates of the uncertainty of soil properties, the probability of distribution or innate error in estimating properties in a certain place of space is well determined if appropriate statistical procedures are used. However, much depends on the correctness of the data, which in itself is related to (1) the geology and (2) the variations allowed for each of the geotechnical characteristics of soils.

In the technology under consideration, it is proposed to evaluate the uncertainty of soil properties by modeling the behavior of the reference foundation for various input characteristics of soils (Barvashov & Boldyrev 2017). In this case, the sensitivity of the base-foundation-structure system (BFSS) is evaluated by introducing virtual workings between the existing standard ones and the subsequent calculation of settlement at the considered point of the foundation.

Such calculations can be performed on a variety of virtual workings with the determination of the average foundation settlement. If such variations lead to significant changes in the behavior of BFSS, then it is necessary to increase the volume of engineering and geological data due to additional workings, or to increase the reliability of the structure by increasing the strength of structures. This question is analyzed in the works (Barvashov & Boldyrev 2016, 2017) with the help of mathematical modeling and exact solutions for the standards (simplified models) of SOFS

Thus, the proposed approach of "sensitivity" analysis allows us to assess the degree of influence of each of the input parameters and the type of interpolation functions on the final result of the calculation. If traditional calculations gave only an average or pessimistic value, now you can find more information about possible variations in the results of calculations.

4 CONCLUSION

1. Digital processing of engineering-geological and geotechnical data leads to the fact that huge volumes of such data can be combined and analyzed, as well as imported and exported from databases and/or large spatial models in fractions of seconds. As a result, the assessment of the behavior of the designed buildings can be performed directly in the field during engineering and geological surveys.
2. Uniformity of data formats is important for the interoperability of data on various parameters and from various data sources. However, the use of large databases and the import of data sets into foundation calculation programs also require uniformity in the ways of structuring the description of geotechnical parameters and foundation structure
3. Time is almost never a parameter in 3D geotechnical models. If you enter time as a parameter of the model, then we are already talking about 4D modeling. This is fundamentally important when calculating the sediment of foundations in time and taking into account the creep of soils, as well as modeling the process of freezing and thawing of frozen and permafrost soils.

ABSTRACT: The paper presented a wooden frame house is one of the best inventions of human architectural thought. Wooden and half-timbered houses were widespread in medieval Western Europe. They create a unique flavor of small towns in Switzerland, Germany, Belgium, the Netherlands. To date, this branch of construction is actively developing - frame housing construction of low-rise buildings with the use of wooden composite I-beams and racks. The paper presented model of a beam with an OSB wall in program SCAD. The paper presented result of isofields of longitudinal stresses in the elements of the beam model and comparison of the test results of beams with a plywood wall.

Keywords: wooden composite I-beams, SCAD, OSB wall

1 INTRODUCTION

A wooden frame house is one of the best inventions of human architectural thought. Wooden and half-timbered houses were widespread in medieval Western Europe. They create a unique flavor of small towns in Switzerland, Germany, Belgium, the Netherlands. To date, this branch of construction is actively developing - frame housing construction of low-rise buildings with the use of wooden composite I-beams and racks in Figure 1. In such design solutions, you can easily embody any design fantasies. It is easy to pick up furniture made of FWF.

Figure 1. Wooden composite I-beams.

DOI: 10.1201/9781003299127-346

The experience of using glued wooden beams shows that their reliability depends on the quality of gluing and careful observance of the manufacturing process in special workshops with the necessary expensive equipment for high-quality drying of lumber. One of the ways to reduce labor and material costs is the widespread use in low-rise construction of composite wooden structures with a wall made of OSB plate (Oriented Strand Board) with a nagel connection with shelves. Unlike other plate materials, OSB has the ability to hold fasteners not with a binder, but with the nature of laying the board, with numerous thin chips oriented in a plane perpendicular to the axis of the fasteners.

Classification of beams:

Made of solid wood:

- solid wood;
- composite beams on malleable ties.

Made of glued wood:

- board-glued (consisting of packages of boards glued together mainly along the plast).

Glued plywood:

- plywood walls;
- LVL walls
- OSB walls.

To determine the VAT of the elements of a composite wooden beam with an OSB wall and a nagel connection with wooden shelves, an engineering calculation method has been developed and numerical and experimental studies have been carried out.

2 RESEARCH METHOD

2.1 *Creation of computer models of composite beams of the PC "SCAD"*

The theory of numerical methods is an extensive science and is widely used in the calculations of structures. The most widely used methods in the calculations of building structures of buildings and structures are the finite difference method (FDM), finite element method (FEM), variation-difference method (VDM), curved grid method (CGM), etc. The finite difference method makes it possible to solve very complex problems with known approximations, for which analytical methods are ineffective. FDM differs from many methods in its simplicity and algorithmicity. It is well implemented on a computer. The advantage of this method is its weak dependence on the geometry of the shell, the nature of the initial stress state. FDM makes it possible to successfully solve problems of stability and dynamics on a computer under boundary conditions, with the exception of a free edge, an inhomogeneous stress field and variable stiffness of thin-walled structures. The disadvantage of FDM is the need to specify a large number of grid steps to obtain good results, which leads to a high order of the system of algebraic equations. Among the numerous methods of calculating complex thin-walled and continuous systems in recent years, the finite element method has stood out sharply. The idea of the method is that a continuous medium (the structure as a whole) is modeled by dividing it into regions (finite elements), in each of which the behavior of the medium is described using a group of selected functions representing stresses and displacements in this area. The advantage of FEM is the convenience of forming equations and the possibility of representing irregular and complex structures and loading conditions. One of the numerical methods for studying the stress-strain state is the method of boundary integral equations (MBIE), otherwise - the method of boundary elements. When calculating homogeneous bodies, the number of variables can be significantly reduced by reducing boundary value problems for differential equations to integral equations at the boundary of the domain.

To calculate the composite beam, use the SCAD program.

The SCAD complex is used in the calculation and design of structures of various types and purposes. Having in its composition developed means of data preparation, calculation and

analysis of results, it does not impose practical restrictions on the size and shape of the projected structures. At the same time, for a design engineer, «simple» tasks are no less important, the solution of which takes him a significant part of the time. Checking the sections of elementary beams, collecting loads on structural elements, determining the geometric characteristics of composite sections - this is not a complete list of such routine design tasks. These circumstances stimulated the development of a series of «small» SCAD satellite programs focused on solving mass design problems. Together with the computing complex, they make up a single SCAD Office package.

The main stages of calculating the stress-strain state of building structures in SCAD. Here are the main stages of work on the linear calculation of the stress state of the rod system using the example of the SCAD program.

Stage 1. Launching the SCAD program and preparing to create a calculation scheme

Stage 2. Creation of the design scheme of the core system for the FEM

The geometric representation of the design schemes of flat trusses, frames and beams found in the tasks specified in the preface in the SCAD program can be performed in two ways:

a) using standard schemes of flat rod systems;
b) by sequentially entering first the nodes of the elements of the calculation scheme, and then the image of the elements themselves. A combination of these methods is also possible.

Stage 3. Loading the calculation scheme of the FEM. Loading in the SCAD program is called a system of simultaneously operating loads. The same core system can be calculated from several loading options. Therefore, their numbering is provided. The SCAD program allows you to immediately perform calculations from several loading options and from any combination of them. In accordance with the type of loads that occur in educational works, the following are given: the assignment of concentrated forces and moments acting at the nodes of the design scheme and at any point along the length of the type 2 element, and a uniformly distributed load applied along the length of the type 2 element. The program provides a procedure for crushing rods into sections to select points (intervals) load applications. In general, the procedure for loading the design scheme includes: Setting the nodal load. Setting the load on the element. Saving the upload. Print or save the calculation scheme with the created upload.

Stage 4. Performing a linear calculation and presenting its results:

a) Performing a linear calculation in which an algorithm for solving the FEM problem is implemented to determine the movements of nodes (in the coordinate system common to the rod structure) and forces in the sections of elements intended for calculation (in the local coordinate system);
b) Presentation of the obtained results of the calculation of the core system in the form of diagrams of the forces in its elements and a picture of the movements of the nodes. Saving and printing them;
c) Presentation of the obtained results of the calculation of the core system in the form of a table with the efforts in the planned sections of the elements and a table of displacements of the nodes of the design scheme. Saving and printing them.

Launching the SCAD program and preparing to create a calculation scheme. Window - Program Download, sections - Project, Options, Help. Window - Creating a new project. Project tree – Initial data, Calculation, Results, Construction. Types of finite elements in SCAD. The general and local coordinate system, the rule of signs. Filters for displaying and visualizing the calculation scheme. Numbering of nodes and elements in the diagram.

Creation of the design scheme of the core system for the FEM. Graphical representation of the design scheme in a common coordinate system. The geometric representation of the design schemes of flat trusses, frames and beams found in the tasks specified in the preface in the SCAD program can be performed in two ways:

– using standard schemes of flat rod systems;
– sequential input of the nodes of the elements of the calculation scheme first, and then the image of the elements themselves (input of elements). A combination of these methods is also possible.

Characteristics of procedures for entering nodes and elements, assigning the type and rigidity of elements. Features of the assignment of the stiffness of elements in the calculations of statically definable and statically indeterminate systems, depending on the purposes of calculation – determination of forces and displacements. The purpose of the support links, hinges in the nodes of the elements.

Loading the calculation scheme. Printing or saving the calculation scheme.

4) Procedures for calculating statically definable beam systems in SCAD. Implementation of the general calculation procedure: launch of the program - creation of the calculation scheme of the core system - loading of the calculation scheme - execution of linear calculation and presentation of its results for single-span and multi-span beam structures. Calculation of beams on a ground base according to the Winkler model.

5) Procedures for calculating statically definable truss and frame systems in SCAD. Implementation of the general calculation procedure: launch of the program - creation of the calculation scheme of the rod system - loading of the calculation scheme - performing linear calculation and presentation of its results for truss and frame structures. Example.

Procedures for calculating static undetectable frame structures in SCAD. Implementation of the general calculation procedure: launch of the program - creation of the calculation scheme of the core system - loading of the calculation scheme - execution of linear calculation and presentation of its results for statically indeterminate frame structures in the conditions of flat and spatial tasks. Illustration of an example.

Calculation of planar systems under conditions of plane stressed and deformed states. This category includes flat structures (for example, a wall panel, a stiffness diaphragm, a retaining wall, fragments of external and internal walls, slopes of pits and embankments, etc.). When calculating flat elements, the structure is divided into a set of finite elements (rectangular, triangular) in which a continuous displacement function is approximated on each element by a polynomial, which is determined by using the nodal values of this function. Calculations are made taking into account the features of the graphical representation of the design scheme, procedures for entering nodes and elements, assigning the type and stiffness of elements, assigning the stiffness of elements, assigning support links. Loading the calculation scheme. Printing or saving the calculation scheme. Conclusion and analysis of the results of the calculation of the stress-strain state of the structure under the conditions of a planar problem (components of stresses and deformations). Illustration of an example of calculating a rectangular beam-wall on the action of an external load.

The design model of a composite beam with belts of wooden bars connected to an OSB wall on glue was made up of plate elements with stiffness characteristics corresponding to the belts - pine tree of the 2nd grade for the wall - OSB plate in accordance with Figure 2. The dimensions of the elements of the design model are taken along the axes of the structural elements.

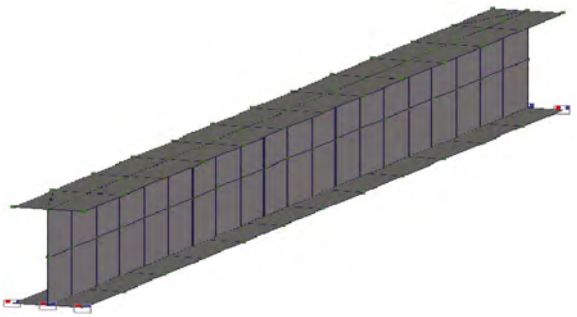

Figure 2. Model of a beam with an OSB wall.

2.2 *Creation of computer models of composite beams of the PC "SCAD"*

The design model of a composite beam with belts made of wooden bars connected to an OSB wall on glue, which is presented in accordance with Figure 1, was made up of plate elements with stiffness characteristics corresponding to the belts - a pine tree of the 2nd grade, for the wall – an OSB plate. The dimensions of the elements of the design model are taken along the axes of the structural elements.

The beam is fixed in three planes by a pivotally movable and pivotally fixed support located at the ends of the lower belt. The shelves are supposed to be glued. The beam is loaded with concentrated forces applied at the nodes of the upper tier. The beam elements are made of different materials (wood, plywood, OSB). The cross section of the beam is T-shaped.

For the proposed scheme of a loaded beam using the SCAD system, it is necessary to solve the problem: to form its plate finite element model.

Algorithm solution of the problem:

- Formation of the design scheme of structures;
- Creation of a calculation scheme;
- Setting the necessary parameters:
- Change the values of the units of measurement to m, mm, kN;
- Go to the calculation scheme Control tab, nodes and elements, node input, then enter the coordinates of the nodes along the x, y, z axes.

After entering the nodes, go to the nodes and elements tab adding plates, then go to the assignment tab, assign the stiffness of the plate. Since the SCAD PC library lacks these design characteristics, namely wood and other wood-based composites, we enter the characteristics of materials manually [21, p.4]. The process of entering design characteristics is presented in accordance with Figure 3.

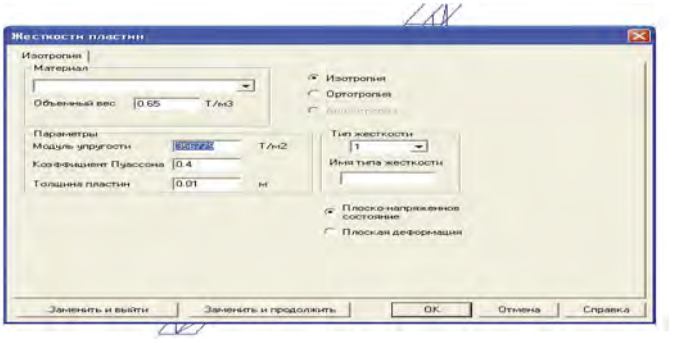

Figure 3. Plate stiffness assignments (OSB wall).

Next, go to the tab, the scheme is the generation of an arbitrary shape on the plane, the assignment of contours, automatic triangulation - stiffness, assign the stiffness of the materials of the shelves pine wood of the 2nd grade, since these materials are also not in the SCAD library, then assign them manually. Specify the triangulation step.

Next, we go into the nodes and elements of the crushing of 4 nodal plates, set the number of splits along the x-axis, along the y-axis.

The imposition of connections in the support nodes of the connection assignment beam, assign connections. After that, we set the loading of the beam.

All loads are applied in the global coordinate system of the calculation model. The following node movements are accepted as the main unknowns: X-linear on the X axis; Y-linear on the Y axis; Z-linear on the Z axis.

3 RESULT AND DISCUSSION

3.1 *Results of the calculation of the I-beam model*

The results of the numerical experiment are presented in the form of isofields of stress distribution in the elements and displacements of nodes of the calculated beam model in accordance with Figure 3.

According to the type of stress distribution in the beam elements, we can say the following:

– the level of longitudinal stresses in the wall elements has a maximum value of 1/3 of the span in the area of the transverse stiffeners and is close to the calculated tensile resistance-compression of the OSB plate with a thickness of 10 mm and further decreases in the middle of the beam span, and increases slightly to the supports;
– the level of transverse stresses in the wall elements is 4-5 times lower than the level of longitudinal stresses, and has a maximum value on supports and in places of load application;
– the level of displacement reaches an extreme in the middle of the span in the area of a clean bend.

As shown in Figure 4, the destruction of the beam is possible by the elements of the wall. At the same time, the greatest probability of destruction from tensile forces in 1/3 of the span in the area of the lower belt at the transverse ribs and further in the same sections from compressive forces at the upper belt.

The results of the numerical experiment are presented in the form of isofields of the stress distribution in the elements and displacements of the nodes of the calculated beam model.

According to the type of stress distribution in the beam elements, we can say the following:

– the level of longitudinal stresses has a maximum value in the girder belts in the middle compartment and is close to the calculated tensile resistance of the OSB plate with a thickness of 10 mm;
– the level of transverse stresses in the beam elements is an order of magnitude lower than the level of longitudinal stresses, and has a maximum value on supports and in places of load application.

Figure 4 shows the isofields of displacement, the maximum value at an external load of 1500 kg was 10 mm, which has sufficient similarity with the results of an experimental study, for a similar load – 8.56 mm. The discrepancy in the results was 14.4%.

Figure 5 shows the distribution of longitudinal stresses in the elements of a composite beam with belts of wooden bars connected to an OSB wall

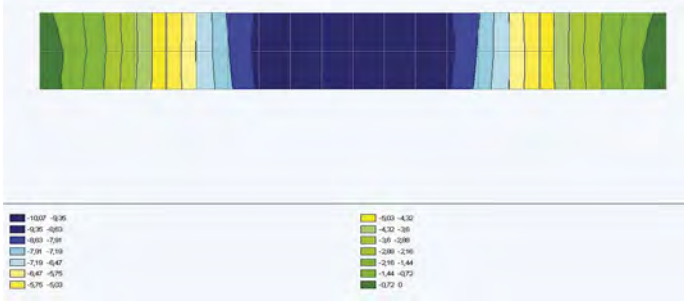

Figure 4. Isofields of longitudinal stresses in the elements of the beam model.

Comparison of the results of theoretical studies, experimental tests and modeling of the beams BDR-1, BDR-2, BDDSF-1 and BDDSF-2 in SCAD PC are presented in Figures 6 and 7.

Figure 7. Comparison of the test results of beams with a plywood wall.

4 CONCLUSION

Based on the results of the conducted research, the following conclusions can be drawn:

– Computer models of composite beams based on FEM have been developed, allowing to obtain the spatial distribution of stresses in the elements;

– Obtained isofields of stress distribution in the elements of beams, as well as pictures of possible destruction of beams in the nonlinear formulation of loading models;
– Comparisons of theoretical and experimental test results of wooden glued beams have been carried out, according to which the following inputs can be made when calculating according to the SNiP II-25-80 methodology, it is necessary to bring the materials of walls and shelves to the same material through elastic modules [22, 17 p.]. In the modeling of beams in the SCAD PC, this operation was not used, that is, the beams conditionally glued were not brought to the same material, and the shelves and the wall had their own characteristics. Simulations in the SCAD PC showed a discrepancy between the results and theoretical studies of 14.4% [23, 109 p.].

Belts of glued beams with a flat plywood wall should be made of vertically placed layers (boards). If the cross-section height of the belts exceeds 100 mm, horizontal cuts should be provided in them from the side of the walls. n. Plywood, LVL or OSB with a thickness of at least 8 mm should be used for the walls of the beams. In the plywood beams, it is advisable to place the plywood of the walls so that the fibers of the outer veneer sheets are directed along the axis of the beam, the connection of the plywood sheets is carried out «on the mustache». Flat-walled adhesive beams are recommended for spans up to 15 m. The height of the cross-section of such beams is taken from 1/5 to 1/12 of the span.

Calculation of board - glued beams . For a bent element provided against the loss of stability of a flat form of deformation, i.e. if there is no decrease in strength due to loss of stability in the transverse direction, the calculated strength will be determined by the strength of the material during bending. The loss of stability of an element bent relative to the y-y axis will occur if its compressed zone is not completely detached from the transverse displacement and the relative flexibility during bending relative to this axis is λ rel, $m > 0.75$.

Calculation of single-pitch glued beams. The calculation is based on the limiting states of the ability to determine:

– checking the carrier of the maximum values of shear stresses;
– maximum values of normal bending stresses.

When checking the limit states of operational suitability: deflections.

Instrumentation and monitoring for KVMRT Line 2 tunnelling works (Bandar Malaysia North Station to Chan Sow Lin Station) in Kuala Lumpur

Y.C. Tan, C.L. Low, C.L. Tei & K.L. Teh
G&P Geotechnics Sdn. Bhd., Malaysia

ABSTRACT: Underground construction works for KVMRT Line 2 in Kuala Lumpur includes tunnel boring works, excavation works for shafts and stations, and mine tunnel works for cross-passage and adits. This paper will present the instrumentation and monitoring for tunnelling works from Bandar Malaysia North Station to Chan Sow Lin Station which tunnelling in Alluvium and Limestone formation. Generally, all above ground and underground structures (e.g. SMART tunnel and SBK Line 1) that located within minimum monitoring zone are to be instrumented especially the sensitive structures located on top or nearby to the tunnel alignment. Manual observation/surface monitoring by manpower is also adopted during tunnelling works in order to take immediate action and provide first-hand information to the respective parties in the case of excessive settlement/ sinkhole formation (especially tunnelling in Limestone formation). This paper will share the instrumentation monitoring methods and concepts of the proposed instrumentation monitoring works. The instrumentation results for ground and buildings along this tunnel alignment will be presented and discussed.

1 INTRODUCTION

Sungai Buloh-Serdang-Putrajaya (SSP) Klang Valley Mass Rapid Transit Line 2 (herein referred to as KVMRT Line 2) in Kuala Lumpur has begun its construction works in 2016. The entire length of tunneling section is 13.5km connecting 11 nos. of underground station from Sentul West Station(SWS) to Desa Water Park Portal(DEWP). Overall tunnelling work is divided into eight tunnelling section namely Tunnel Drive 1 (TU1) to Tunnel Drive 8 (TU8). Case study is carried out based on the completed tunneling section TU7 (From Bandar Malaysia North Station (BMNS) to Chan Sow Lin Station (CSLS).

This paper will present the effectiveness of the instrumentation monitoring works plan in monitoring of the ground movement by comparing to predicted ground movement from the numerical analysis. This paper will provide some recommendation to improve instrumentation monitoring plan.

2 SITE BACKGROUND

TU7 was the first started tunnel drive for KVMRT Line 2 line which begun on March 2018 and completed on April 2019. The tunnelling length for TU7 is about 1.8km which launched in BMNS (CH37460) and breakout at CSLS (CH35620). Other than bored tunnel, there are also mined tunnel in TU7 for the construction of cross-passage. Along the TU7, the existing building structure above ground including The Royal Malaysian Air Force (TUDM), low rise building, ramps, monsoon drain, and etc. The sensitive structure along TU7 including MEX

DOI: 10.1201/9781003299127-347

highways, Besraya highway (Pier Structure), ongoing construction DUKE highway and LRT tracks (On Bridge deck) which is close to the breakout at CSLS.

2.1 *Site geology*

Geological formation for TU7 is in limestone formation overlaid by alluvium layer of thickness 5m to 30m. The entire tunnelling works along TU7 is in deep rock where rock head is generally more than 1D (i.e. tunnel diameter, D=6.35m) ranging from 5mbgl to 30mbgl.

2.2 *Predicted ground movement*

Predicted ground movement due to the effect of both bored and mined tunneling works is presented in the form of settlement trough to show estimated surface movement on top of the tunnel alignment. Since the tunneling works are expected to be carried out in deep rock, generally negligible movement is predicted based on the numerical analysis. Nonetheless, a conservative assumption of 5mm was made for tunnelling in rock where the minimum rock cover above the tunnel crown is one time the tunnel diameter with the extent of 10m from the centreline of each tunnel alignment with reference to the earlier similar tunneling experiences in KVMRT Line 1.

3 INSTRUMENTATION MONITORING PLAN

3.1 *Instruments*

Monitoring of ground movement due to tunneling works are carried out by the installation of instruments in the form of array which arranged in fixed interval along the tunnel alignment. The monitoring array adopted for ground movement monitoring along TU7 as shown in Figure 1.

Monitoring arrays are arranged at maximum 100m spacing for T1 array, 200m for T3 array, and 1km for T5 array. Monitoring array consist of instruments such as surface settlement marker, inclinometer, extensometer, and vibrating wire piezometer. Value engineering had been carried out during the implementation of the instrumentation works. For instances, instruments such as inclinometer and extensometer are assigned whenever necessary for sensitive structures only.

Monitoring works for most of the existing building structures (EBS) are carried out by tiltmeter and building settlement markers to detect the changes in building distortion and movement. Other instruments such as optical prisms are installed for sensitive structures (which located immediate on top of tunnel alignment) such as viaduct piers with real-time monitoring (RTM) (reading taken at every 30 mins.).

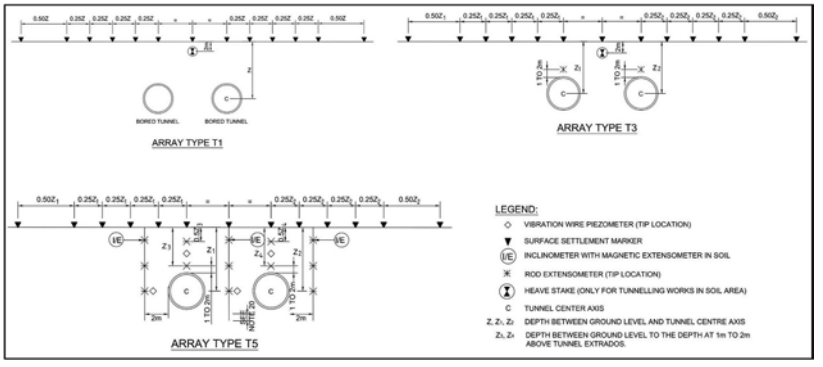

Figure 1. Instruments arrangement for Array Type 1, Type 3, and Type 5.

3.2 *Review level*

Review Level (Alert, Action, and Alarm) is established for the monitoring works based on respective predicted movement. Action is required to be taken when the monitoring results trigger the designed review level. Review level for different type of EBS were split into the 4 categories as shown in Table 1. Special category of review level will be provided for selected EBS based on building impact assessment or stakeholder's requirement.

Monitoring frequencies are based on tunnel activity and its relative distances to the EBS. Generally, monitoring frequencies increased when the distances from tunnel boring machine (TBM) to EBS is getting closer.

Table 1. Review levels.

		Alert Level		Action Level		Alarm Level	
Cat	Type of Structure/ Buildings	Building Settlement (mm)	Distortion Angle	Building Settlement (mm)	Distortion Angle	Building Settlement (mm)	Distortion Angle
1	Heritage Structure/ Building	7	1:1000	9	1:750	10	1:500
2A	Structure/Building on Deep Foundation Influenced by Tunnelling	11	1:750	13	1:500	15	1:300
2B	Structure/Building on Deep Foundation Influenced by Deep Excavation	11	1:750	13	1:500	15	1:300
3	Structures/Buildings on Shallow Foundation	18	1:750	21	1:500	25	1:300

3.3 *Case history for instrumentation monitoring and sinkholes – UG265 Sungai Besi Monsoon Drain*

GSMs monitoring nearby the Sungai Besi Monsoon Drain (UG-265-CH36920) showed first sudden drop on 18th July 2018 when NB TBM at about 5m away from the monsoon drain. GSMs were stable without showing any further movement until NB TBM passes the monsoon drain. Second sudden drop was observed on 25th August 2018 when SB TBM near to the monsoon drain as shown in Figure 2. The ground (2 to 3m) from monsoon drain was immediate found with sinkhole occurrence after the observation of sudden drop in GSMs.

For tiltmeter (TM) monitoring as shown in Figure 2, distortion of drain wall started to show increasing tilting trend and eventually breached Alert level (1.33mm/m) on 27th August 2018. It became stable when both north bound (NB) and south bound (SB) TBM passes for at least 300m away from the monsoon drain. Apart from instrumentation, whirlpool and air bubbles was observed when south bound (SB) TBM before reaching Sungai Besi Monsoon Drain (UG-265-CH36920). With all the monitoring results and observation, it is suspected sinkholes formed under the monsoon drain when NB TBM first arrive at this location. The sinkholes happened 2 to 3m away from the drain is suspected due to interconnected cavities which triggered by SB TBM (2nd TBM) when tunneling at this location.

Apart from instrumentation monitoring, the study on TBM parameters (i.e. the inlet and outlet slurry flow data), the slurry loss rate was found higher at about 150m^3/hour when south bound (SB) tunneling works was right below monsoon drain. Slurry was suspected to lose to the surrounding cavities which results in the monsoon drain movement.

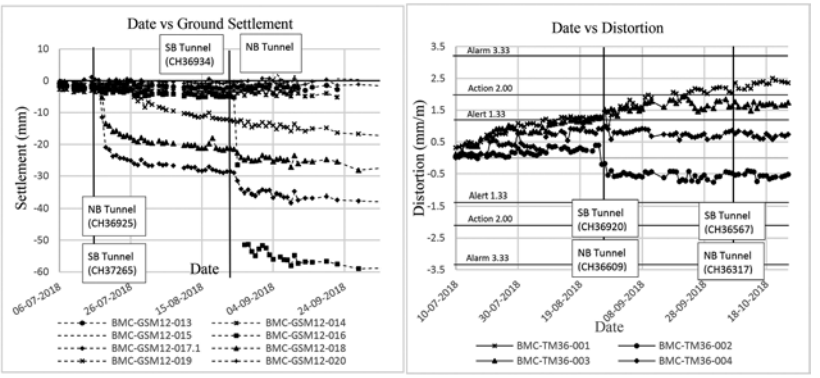

Figure 2. Ground settlements markers and tiltmeter monitoring results.

4 CONCLUSION AND RECOMMENDATION

4.1 *Conclusion*

Similar to the case history as discussed, ground settlement observed are mainly due ground depression caused by nearby sinkholes occurrences. Most of the monitoring results showed stable monitoring results during tunneling works in TU7. Exclude sinkholes, the findings from the instrumentation for ground movement is tally with the assumption that insignificant ground movement is expected for tunneling in deep rock area.

There was total 11 nos. different size sinkholes occurred along TU7 during tunneling works. 10 of out 11 nos. of the sinkholes were found located near to the tunnel alignment within 10m offset from tunnel centreline as mentioned in Section 2.2 predicted ground movement. As such, monitoring zone based on assumption of 5mm settlement contour for TBM impact zone is appropriated.

Instrumentation monitoring likely do not provide earlier warning for sinkhole occurrences when tunnelling at deep rock area. Nonetheless, the instrumentation monitoring is important to monitor the structure movements especially for sensitive structures.

4.2 *Recommendation*

TBM parameter is recommended to be reviewed as the changes in the parameter is good indication for possible ground movement/sinkholes occurrences caused during tunnelling works.

In order to minimize the occurrences of sinkholes or ground depression, pre-ground treatment such as grouting works is recommended to be carried out especially for tunnelling in high risk zone such as limestone formation or mixed soil condition.

Site team is recommended to provide close monitoring to standby for surface observation monitoring especially high risk activities such as unplanned cutterhead intervention.

X.S. Chen
College of Civil and Transportation Engineering, Shenzhen University, Shenzhen, China

ABSTRACT: This paper presents results of centrifuge tests investigating existing underground structures in a clay subjected to construction disturbance. A modelling technique was developed to simulate the failure of an excavation face in the ongoing construction. The effect of water was also simulated after the failure of the excavation. Deformations of the existing underground structures were measured by image analysis through tracing markers in the soil model. The centrifuge tests indicated that significant deformation developed in the soft clay resulted in great settlements of existing underground structures and bending of the existing tunnel. The maximum measured settlement of the existing tunnel was about 18% of tunnel diameter. The maximum settlements of the basement was 27.5% of tunnel diameter.

1 INTRODUCTION

Exploitation of the deep underground space results in a complex underground engineering system consisting of different functional structures. Soil–structure interaction design considerations are crucial for underground structures when subject to deep construction disturbance. The response behaviors of an underground system is influenced by the nonlinear soil/structure interaction, the failure pattern of the deep excavation, underground water, and the arrangement of the structures.

Numerous studies have been conducted using physical models to investigate the deformation and failure mechanism of structures due to excavation (e.g. Mair, 1979; Zhang et al., 2001; Ge, 2002; Son and Cording 2005; Zhang et al., 2007; Farrell and Mair 2010; Ng and Wong 2013; Sabagh and Ghalandarzadeh, 2020; Weng et al., 2020; Ritter et al. 2020; Xu et al., 2021).

In the present study, centrifuge model test was carried out to investigate the deformation mechanism of existing underground structures subjected to deep excavation failure in a clay. Effects of water discharge are also discussed.

2 CENTRIFUGE MODEL SETUP AND TESTING

Figure 1 shows the centrifuge model setup. A strong box accommodated existing underground structures in a clay of a building basement, a tunnel, two storage houses (Storage L and Storage R) and a sewer line (Sewer) above an ongoing deep construction. The model structures were boxes made from transparent acrylic plate. The deep construction was modeled by a rigid steel box at the bottom of the strong box, having an excavation face. A hydraulic actuator was connected to a steel plate simulating the excavation face. The actuator initially

DOI: 10.1201/9781003299127-348

supported the excavation face and later pushed the face at the centrifugal acceleration of 80 g to simulate excavation failure.

The centrifuge model test was carried out in the geotechnical centrifuge at Tsinghua University (Zhang et al., 2015). Soil models are scaled down to satisfy the principles of mechanical similitude between a model and its prototype (Taylor, 1995). The soil model, which was subjected to a centrifugal acceleration of 80 g, had internal dimensions 0.6 m long × 0.2 m wide × 0.5 m high, equivalent to 48 × 16 × 40 m in the prototype. A transparent side wall on one side of the strong box enabled the model to be monitored visually during the test.

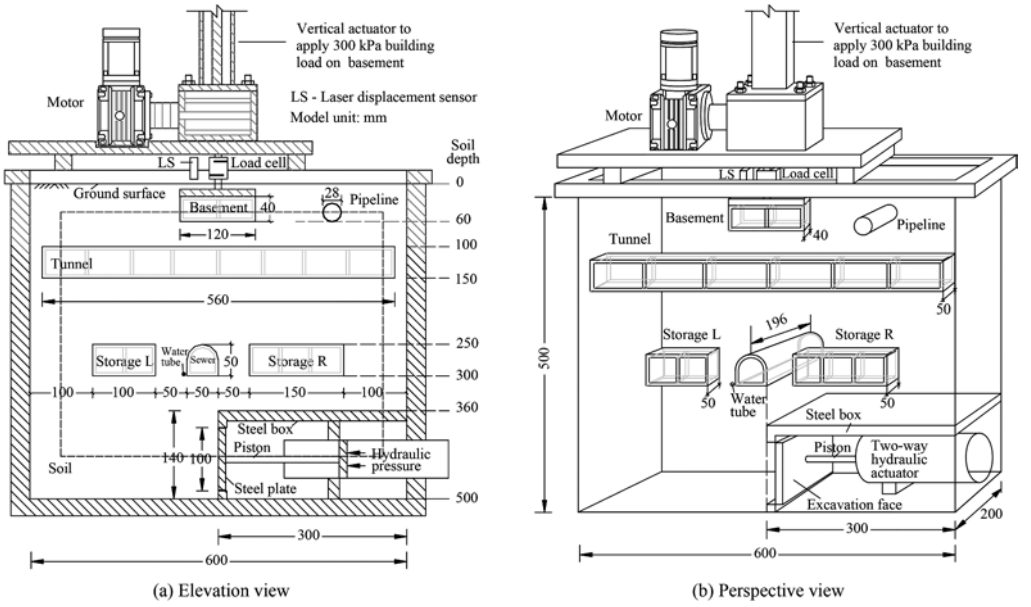

Figure 1. Centrifuge model setup in model scale: (a) elevation view, (b) perspective view.

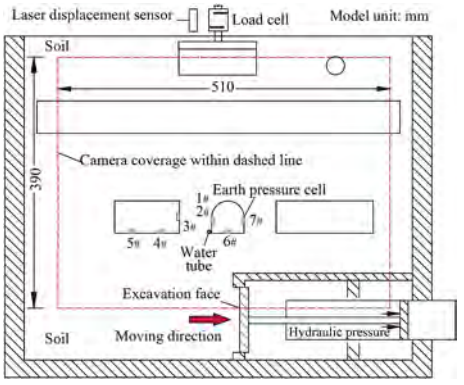

Figure 2. Instrument used in centrifuge model.

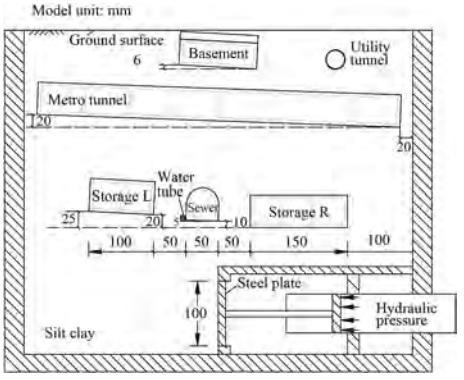

Figure 3. Positions of structures during preparation.

The clay had a plasticity index of 15.8, with a maximum dry density of 2287 kg/m^3 at a water content of 15% (ASTM D698). It was compacted into the strong box with a water content of 17% and a dry density of 1600 kg/m^3. The clay exhibited high plasticity and high compressibility. To compensate for significant deformation during consolidation, the model

structures were placed initially inclined as described in Figure 3. Markers of small white pebbles were placed on the side of the model to trace the deformations of the soil.

A surcharge loading of 300 kPa was applied by a vertical actuator on the basement to simulate the weight of the tall building. To measure the settlement of the ground surface, a non-contact laser displacement sensor was installed above the basement. Seven tiny earth pressure cells were used to monitor the change of earth pressures with time. A digital video camera was placed in front of the transparent side wall, covering an area as indicated by the dashed lines in Figure 2. A photo-imaging technique was used to accurately measure the displacements of the soil and the structures (Zhao and Zhang 2020). The soil model was consolidated at 80 g under self-weight and then consolidated again under the surcharge load. The excavation face then was pushed laterally to trigger soil and structure movement.

3 RESULTS AND DISCUSSIONS

Figure 4a shows the ground surface settled down 2.6 m due to consolidation. The positions of the structures after consolidation were taken as the initial positions for calculating the structure movement subject to excavation face displacement. Figure 4b presents displacement vectors of the clay toward the excavation face when it had moved 1.8 m. The maximum displacement of the clay of up to 0.9 m occurred ahead of the excavation face. A water discharge (0.84 kg in model scale) induced a crack and a muddy flow ahead of the excavation face (Figure 4c) and softened the clay. It thus resulted in more settlements of the structures with the increasing excavation face displacement from 3.0 m to 5.8 m (Figure 4d). The second water discharge (3.34 kg in model scale) was brought into the soil. It scoured the soil and widened the crack (Figure 4e). Eight minutes later after the water discharge was stopped, the settlements of the building basement, the metro tunnel, the left-hand storage and the sewer line were 1.1 m, 0.75 m, 0.97 m and 1.0 m, respectively (Figure 4f).

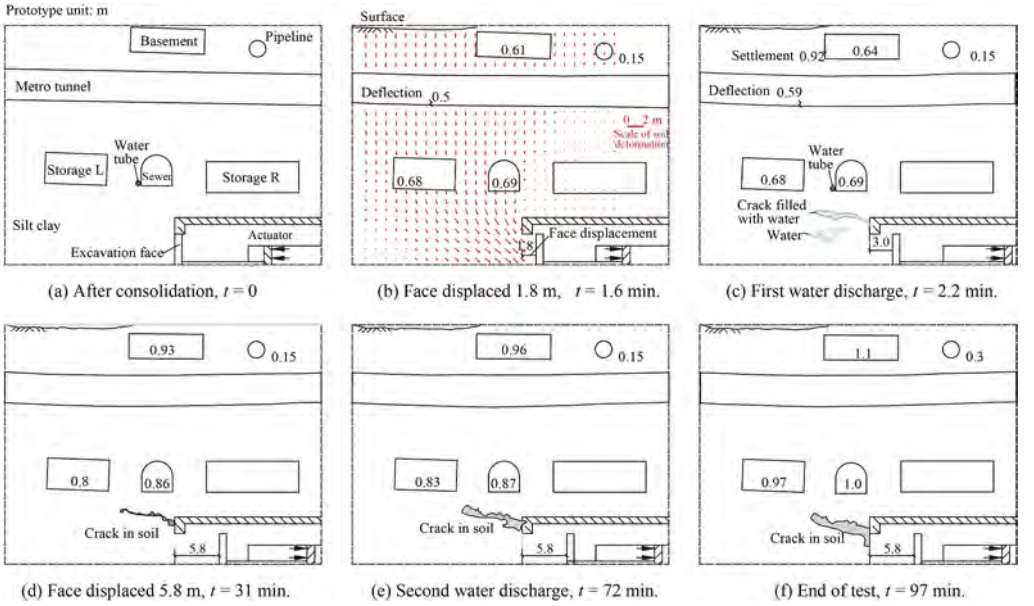

Figure 4. Deformation mechanism of underground structures in clay developed with excavation face displacement, underground water changes and time (model scale). Values in the figure indicate prototype settlements of the existing structures.

Figure 5 compares the settlements of the existing underground structures developed with time. The time is in model scale, originating from the point of when the tunnel face began to move. At about 2.2 minute, all the structures settled significantly consistent with the initial excavation face displacement of 0 – 3.0 m and the first water discharge. The basement experienced the most significant settlement. The maximum settlements of the basement was 1.1 m, 27.5% of tunnel diameter. Figure 6 shows deformations of the metro tunnel in the process of construction disturbance. The tunnel significantly bended at the middle part and lifted at the right side. The maximum measured settlement of the metro tunnel induced by soil-structure interactions was about 18% of tunnel diameter.

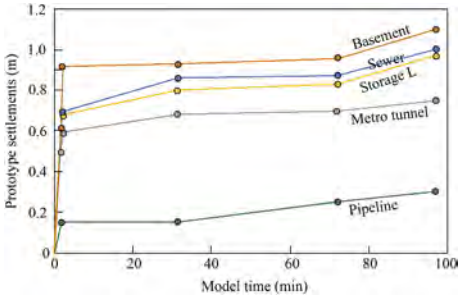

Figure 5. Structure settlements versus time.

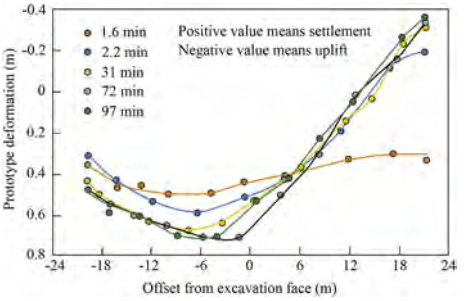

Figure 6. Deformations of tunnel versus time.

4 CONCLUSIONS

This paper presents results of centrifuge tests simulating existing underground structures in a clay subjected to deep construction disturbances. The results of centrifuge model tests indicated that significant deformation of the clay and existing underground structures developed when subject to the deep excavation failure. The maximum measured settlement of the existing tunnel induced by soil-structure interactions was about 18% of tunnel diameter. The maximum settlements of the basement was 27.5% of tunnel diameter.

ABSTRACT: A comparative analysis of the results of field tests and numerical modeling to determine the bearing capacity and settlement of a driven piles at medical facilitie at Astana are presented. The aim of the study was to carry out a comparative analysis of the results of numerical modeling and static tests in order to identify the difference in settlement of test pile under the design load. The results of settlement of the pile, determined by numerical modeling, is slightly lower than from static tests, with a difference in results being in 7%.

1 INTRODUCTION

An 800-bed Astana Medical University Hospital is being constructed on the right bank of the Esil River in the city of Astana, Kazakhstan. The total area of the hospital will be 140 thousand square meters. It will house a consultative and diagnostic center, round-the-clock and day facilities with 800 and 110 beds, respectively. Figure 1 shows an architectural rendering of the hospital complex.

Figure 1. Architectural rendering of hospital complex in Astana, Kazakhstan.

DOI: 10.1201/9781003299127-349

2 GEOLOGICAL AND GROUND CONDITION OF CONSTRUCTION SITE

At the time of the geologic survey, the building site was free of any previous development. A total of 22 exploratory borings were made at the site.

In all of the borings, the topmost soil layer was found to consist of dark brown top soil. The thickness of this layer ranged from 0.5 to 3.6 m.

In all 22 borings, the top soil was underlain by a layer of saturated, light brown loam with clay seams up to 20 cm in thickness. The consistency of the loam varied between hard to soft-plastic. The thickness of this layer ranged from 0.0 to 7.5 m.

In 5 borings, a layer of saturated, brown sandy loam of medium density was next encountered. The thickness of this later ranged from 2.9 to 4.6 m.

In 13 of the borings, a layer of saturated, grey fine sand was next encountered. The thickness of this layer ranged from 1.0 to 12.0 m.

In 19 of the borings, a layer of saturated, light brown gravelly sand was next detected at a depth of approximately 9.8 m. the thickness of this layer ranged from 0.6 to 5.2 m.

In 12 of the borings, the gravelly sand was underlain by a layer of saturated clayet loam that was violet in color. The thickness of this layer ranged from 9.5 to 18.0 m.

Table 1 summarizes the values of geotechnical parameters that were determined from the results of laboratory tests performed on undisturbed samples taken from the boreholes in conjunction with statistical analysis of test results.

Table 1. Summary of parameter values for soils at astana medical facility site.

Soil type	C (kPa)	φ (degrees)	E (MPa)
(EGE-1) Topsoil	–	–	–
(EGE-2) Loam	17.0	13.0	5.0
(EGE-3) Sandy loam	19.0	27.0	6.5
(EGE-4) Fine sand	1.0	33.0	27.0
(EGE-5) Gravelly sand	1.0	38.0	35.0
(EGE-6) Loam	38.0	11.7	12.2

Figure 2 shows an idealized soil profile at the site of the Astana medical facility.

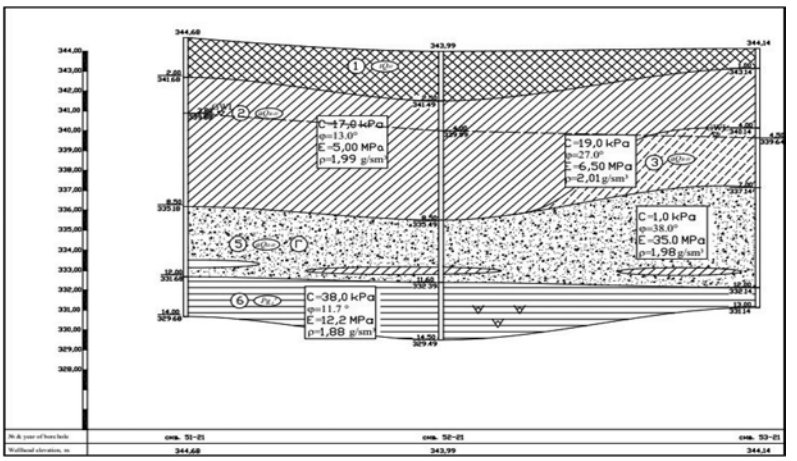

Figure 2. Soil profile at site of Astana medical facility.

3 NUMERICAL MODELING OF DRIVING PILE IN THE PLAXIS 3D

We will calculate the drilling pile using the solutions of the theory of the limit state of a granular medium (numerical methods). When using the numerical method - the finite element method and using the Plaxis application program.

According to the report of Engineering and geological surveys at the facility "800-bed Astana Medical University Hospital" was collected the calculation scheme of the engineering-geological well column No.53–21. Physical and mechanical properties of soils are presented in introduction. The Calculation model of driven test pile 10C-30 was showing in the picture.

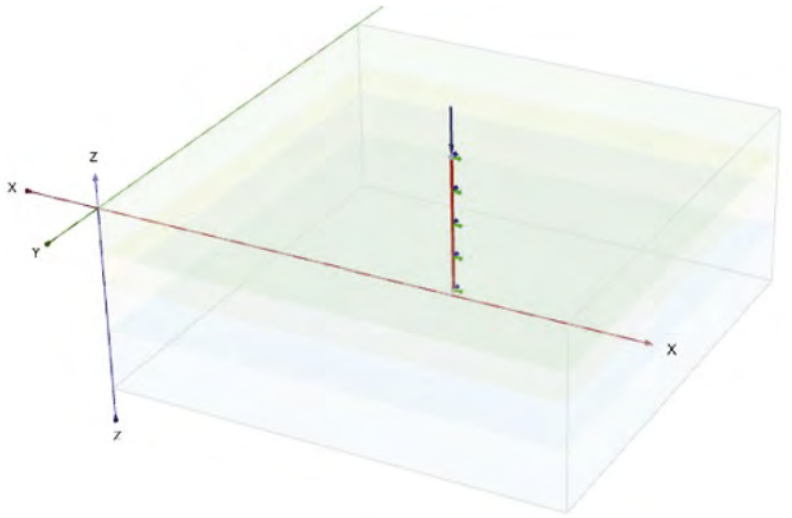

Figure 3. Calculation model of driven pile for Astana site.

To calculate pile, the Linear Elastic model and the Elastic-Plastic model with the Mohr-Coulomb strength criterion were used.

The analysis of the calculation results was performed according to:

- displacement of the pile are showing in the Figures 4–5;

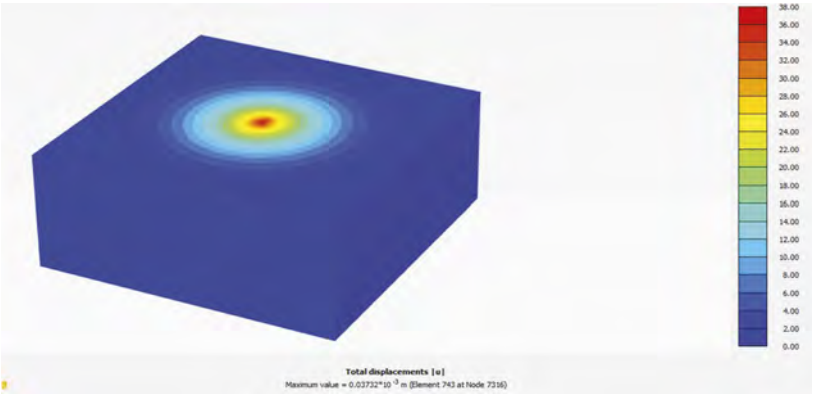

Figure 4. Total displacement of the pile.

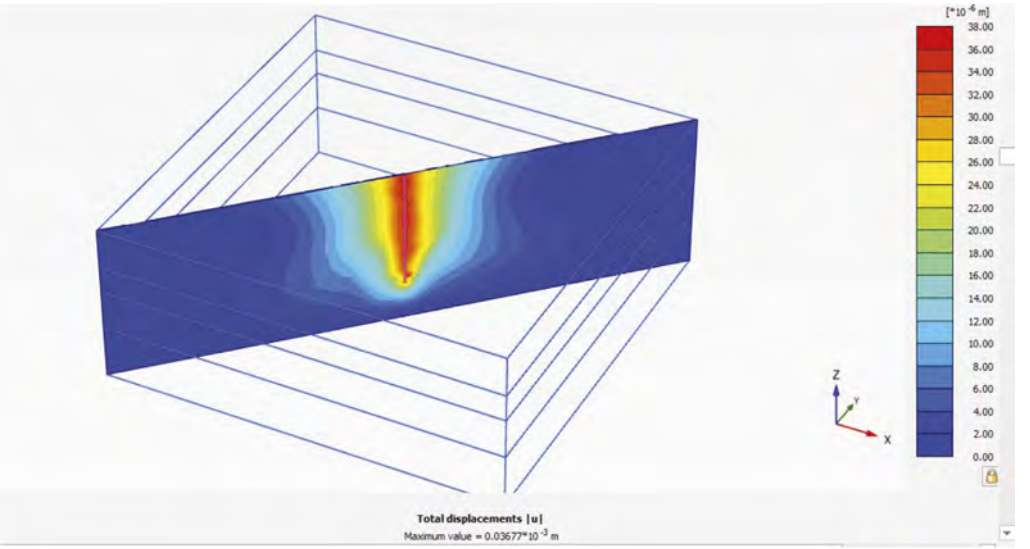

Figure 5. Total displacement of the pile.

The result of the numerical simulation of pile settlement with a design load of 940 kN in the Plaxis 3D software package is:

the settling of the driving pile C10-30 was 38 mm, which is within the normal range according to SP RK 5.01-103-2013. Pile foundations, 2015

4 STATIC PILE TESTS

Field tests of S10-30 driven piles with static, vertical-indentation loads were carried out from December 02, 2020 to January 08, 2021 at the construction site of the Main Building and the Parking lot of the Astana Medical University Hospital in Astana.

The tests were carried out on four driven test piles C10-30 numbered 29, 40 (Main building) and 62, 66 (Parking lot), as shown in Figure 6. The piles were driven to a depth of 9.5 m. Field

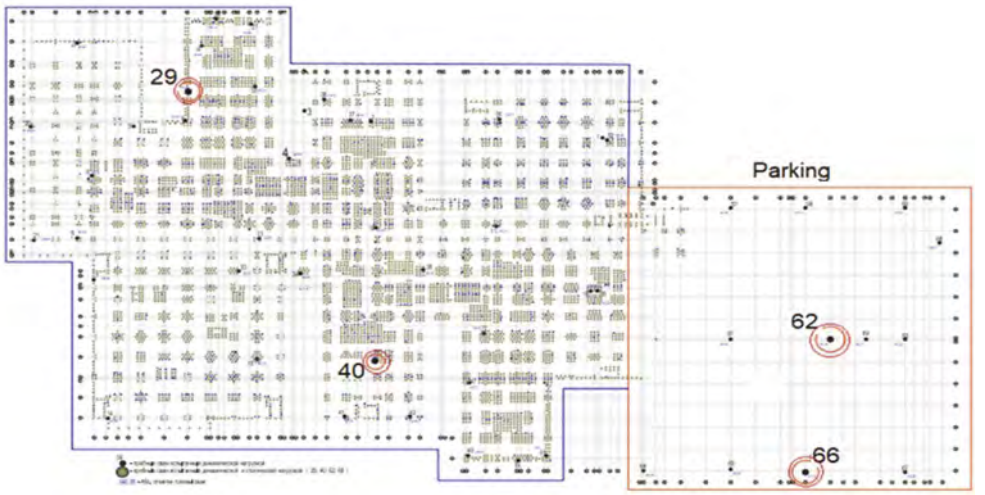

Figure 6. Plan view of static pile test layout at Astana site.

tests were carried out after a period of pile "rest" equal of 30 to 60 days after driving. The load on the pile was created using a 100-ton hydraulic jack "Enerpred DU100P150" with a pumping station "Enerpac P462", abutting against a test and loading stand, weighing 120.0 tons (Tulebekova, et al. 2012), (Zhussupbekov, et al. 2015).

The process is described in detail in the articles previously published. (Turashev, 2015, Yenkebayev, 2012, Tulebekova, 2021). Pile settlement curves are shown in Figure 7.

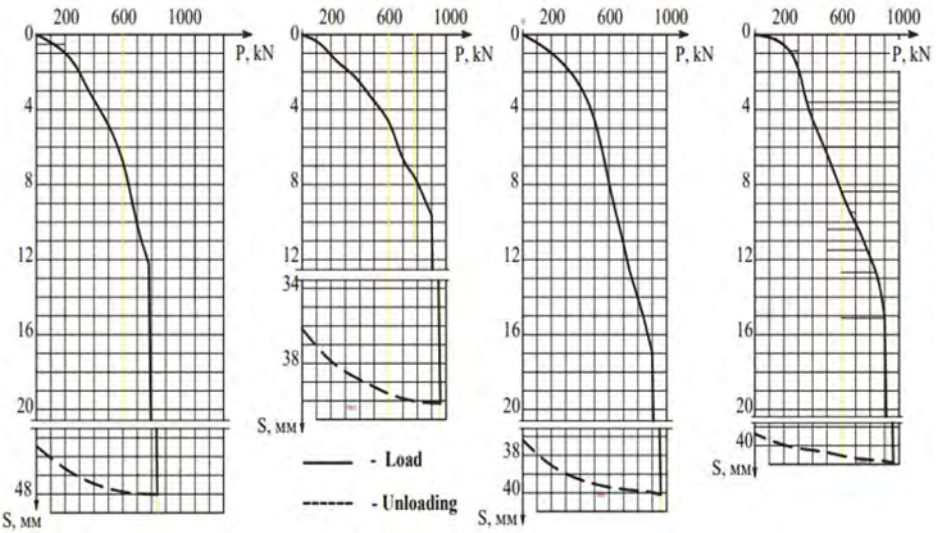

Figure 7. Pile settlement curves for Astana site.

The results of the static pile tests are summarized in Table 2. Some important points regarding the static pile tests at the Astana site are as follows: The bearing capacity of the pile tests at the locations of the main hospital building and the parking structure were 990 kN and 780 kN, respectively. The permissible pile load, taking into account the safety factor $\gamma_k = 1.2$ in accordance with clause 4.4.1.11. SP RK 5.01-103-2013 ("Pile foundations"), is equal to 750 kN and 650 kN for the main hospital building and parking structure locations, respectively.

Table 2. Summary of static test results for Astana site.

Pile №	Depth of immersion of piles in the ground, m	Maximum applied load, kN	Displacement at the highest applied load, mm	Partial value of ultimate resistance, kN	Bearing capacity of piles, kN
№ 62	9.5	840	48.01	780	780
№ 66	9.5	960	40.14	900	
№ 29	9.5	960	40.12	900	900
№ 40	9.5	960	40.91	900	

5 CONCLUSIONS

1. The result of the numerical simulation of pile settlement with a design load of 940 kN in the PLAXIS 3D software package is: the settling of the driving pile C10-30 was 38 mm
2. Static indentation test results must be considered when determining the correct pile length.
3. The results of settlement of the pile, determined by numerical modeling, is slightly lower than from static tests, with a difference in results being in 7%.

Digitalization and BIM in geotechnics – opportunities and challenges

C. Boley
Institute for Soil Mechanics and Geotechnical Engineering, Bundeswehr University Munich, Germany

L. Wilfing
Boley Geotechnik GmbH, Munich, Germany

ABSTRACT: The topic of BIM is also gaining enormous importance due to public requirements for current and future tenders for infrastructure projects. So far, the specifications, requirements and software programs are mainly based on the subject of structural engineering and infrastructure. But also in the field of geotechnics it is necessary to keep up with the progress and to transfer the ground structure from 2D sections into a 3D ground model.

For this purpose, the borehole profiles have to be implemented and the subsoil layers have to be connected to form a spatial 3D layer model. A multitude of attributes can be assigned to these solids (geotechnical parameters, homogeneous areas, etc.). In the article, several software programs available on the market were tested and the advantages and disadvantages of each were compiled. The 3D ground model can be integrated into the overall BIM model via the open data exchange format IFC, so that 4D or even 5D planning of large projects is possible.

Finally, the opportunities and challenges of BIM in geotechnics are explained and discussed using project examples from practice.

1 INTRODUCTION

For some years now, the BIM method has to be implemented for new construction projects. The core of the BIM method is the creation of three-dimensional building models, which contain predefined components and structural elements. Such predefined models do not exist in geotechnical modeling. In principle, a building structure model can be used at any location on earth, whereas a ground model is site-specific and, due to its natural formation, not generally reproducible and geometrically heterogeneous in nature.

So far, the requirements for the BIM model have been based on the fields of structural engineering and infrastructure planning. Thus, the "subject model ground" differs significantly from the other subject models (e.g. structural engineering, signal technology, buildings, etc.) in terms of its content structure.

On the one hand, the article is intended to show which challenges have to be met by the geotechnical sector due to the introduction of digital construction and, above all, due to the "subject model ground" with 3D ground modeling. On the other hand, the possibilities of the BIM methodology will also be explained on the basis of project examples.

2 SUBJECT MODEL GROUND – STATE OF THE ART

The ground model is an attributed and parameterized 3D soil model. The integration of the "subject model ground" into the overall BIM model is necessary in order to take the properties of the soil into account in the other trades during the planning phase and to evaluate the information for processes and cost forecasts.

The model contains all the information describing the ground (Figure 1). This includes, above all, terrain models, suspected contaminated sites and explosive ordnance, geological and hydrogeological fundamentals as well as the findings from project-specific ground investigations (e.g. thickness and composition of the ground layers, groundwater levels, homogeneous areas, etc.).

DOI: 10.1201/9781003299127-350

However, the specialized model is only valid in connection with the geotechnical report and is to be seen as a supplement to it. With completion of the geotechnical report the "subject model ground" has to be handed over and should consist of the following 3D sub-models:

- Sub-model "Outcrop"
- Sub-model "Ground layers"
- Sub-model "Homogeneous areas"
- Sub-model "Groundwater"

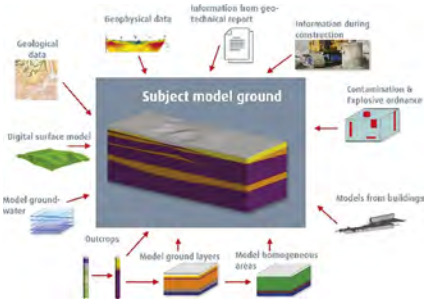

Figure 1. Information needed to build a 3D ground model.

3 APPLICATION EXAMPLES

There are many software packages available on the market, some with very different workflows and capabilities for basic 3D ground modeling. In the context of this article, application examples will be shown with two software solutions that differ significantly from each other in terms of their basic structure.

3.1 *3D ground model with Autodesk Civil 3D*

Autodesk programs have already been used for a long time to create plans, so the program is already available in many engineering companies and the step of acquisition or the decision for the Civil 3D add-on is made much easier.

Due to the individual programming of Dynamo scripts, importing and further editing of the specialist data in Civil 3D is very convenient. For example, investigation data can be automatically imported as 3D cylinders from a CSV or XLSX file. In principle, there are many possibilities for automated processing. However, the creation of dynamo scripts requires a significant amount of prior knowledge in programming as well as a high time requirement - especially for the first projects in which a 3D ground model is to be created.

The creation of solids or ground layers, on the other hand, is quite complicated and requires time-consuming post-processing (Figure 2). Attributes can be attached to the individual solids by creating individual property sets and exported to the IFC file format (openBIM) together with the geometry.

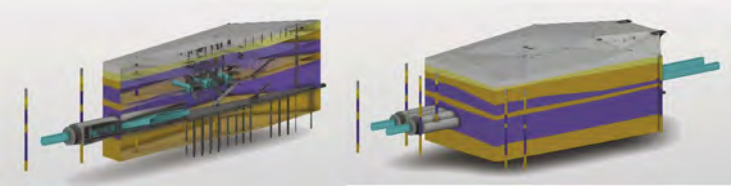

Figure 2. 3D ground model of a deep construction pit with Civil 3D.

A major advantage of Civil 3D is the possibility of automated coordinate transformation. Here, all the different basic and project data can be transferred into a uniform coordinate system specified by the employer. This enables the spatial representation of the ground-structure interaction as well as the early detection of possible collisions. The import of structures such as tunnels, station structures or bridges is easily possible using standard Autodesk formats (Figure 2). This aspect is a big plus especially with regard to public relations and the early involvement of the population in large projects.

Civil 3D is designed for the planning of infrastructure projects and is not specialized for the creation of 3D ground models. However, the software complements special ground modeling programs very well due to its additional functions (e.g. coordinate transformation).

It has been shown that Civil 3D is a good software alternative for spatially limited project areas. For larger projects with more complex layered structure (faults, geological lenses, etc.) and large project sections, it is advisable to work with a special software solutions for 3D ground modeling.

3.2 *3D ground model with Leapfrog*

Leapfrog Works is a software specialized in the construction of 3D ground models. With Leapfrog, complex and very large 3D ground models can be created. The software is probably not one of the standard programs used in medium-sized engineering companies. The field of application of the software is limited to the creation of 3D ground models, so that the economic efficiency must also be weighed up when purchasing the software.

The software is clearly and logically structured due to the project tree, so that the program can be used without much previous experience. The automatic modeling of individual bore profiles to form connecting ground layers is much easier than with Civil 3D, and the attribution of the solids is also intuitive (Figure 3). However, the flexibility in importing and attributing outcrop data is more limited than with Civil 3D and automatic coordinate transformation is not possible.

However, even this program has reached its limits in the case of complex geological conditions. If there are long tracks with a strong tectonic desintegration (e.g. up- & downdip, horst- & trench structures), the automated modeling of the ground layers works only conditionally. Here, for example, each individual tectonic plateau must be represented as a separate submodel, which ultimately significantly increases the amount of work involved in modeling but especially in attributing each individual layer (Figure 3). To minimize this effort, again the import of the ground layer model can be done in Civil 3D or Revit, in which the further steps like attribution and data export can be done in a more automated way.

Similar to Civil 3D, the 3D models of the planned structures can be integrated in the program in order to obtain a clear visualization at an early stage of the project and, if necessary, to identify critical collisions.

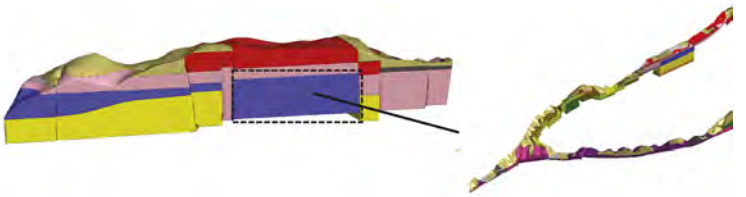

Figure 3. 3D ground model of a tunnel track with Leapfrog.

3.3 *Conclusion software programs (Advantages & Disadvantages)*

Basically, the programs mentioned are both suitable for the creation of a 3D ground model, whereby each software has its strengths in different areas. Which software is used most sensibly also depends to a large extent on the project conditions. Here, the size of the project area to be modeled and the complexity of the subsurface conditions are the most important factors.

In the case of long tracks, such as in large-scale infrastructure projects, the use of Leapfrog is the best option. If the ground model must include a large number of geological layers as well as tectonic structures, the use of software specially developed for ground modeling is recommended. This is often the case, for example, in tunnel construction projects, where the tunnel gradient is well below the ground surface and the complete layer structure from the ground level to the gradient must therefore be represented in the model.

The strengths of 3D construction modeling with Civil 3D lie in its high flexibility due to the programming of dynamo scripts for the automated import of technical data and the attribution of layers. It has been shown that especially complex construction projects with a limited project size, such as deep excavations, can be modeled optimally.

4 CONCLUSION AND OUTLOOK

The majority of projects that have to implement the BIM method and the 3D ground model in accordance with the requirements of the state, are in the preliminary planning stage or in an early phase of planning. In many cases, the planner has not yet been named, so that the continuous coordination process between the geotechnical expert and the planner cannot take place with regard to the required specialist data and, above all, their depth of detail and data format. Thus, the "subject model ground" is often created so far without knowing exactly whether the planner can continue to use the model in this form or which aspects should be worked on more intensively or less intensively. The issue of subsequent data exchange is also still unclear.

In addition, the requirements for BIM-supported planning are still strongly influenced by the areas of structural engineering and, in some cases, simply cannot be implemented, since the ground or ground layers cannot be predefined but are geometrically extremely heterogeneous volume elements.

The development of recommendations for 3D ground modeling within the framework of the BIM method and thus a standardization of the processing is decisive for the successful implementation of the BIM method.

The creation of the "subject model ground" can be accomplished in many ways and with a wide variety of software. There is a wide range of different software solutions, whereby each program still has its application limits and no model solution is available. Especially for medium-sized engineering companies, the aspect of economic efficiency must also be taken into account when using specialized software. Here, it must be weighed up whether sufficient BIM projects with the requirement of a 3D ground model can be acquired in the future to compensate for the partly very cost-intensive software.

Nevertheless, digitalization in geotechnical engineering offers many advantages that can simplify many processes. Anyone who does not want to loose the connection in the construction industry will inevitably have to deal with the topic of BIM and 3D ground modeling in the future.

Laboratory study on soil properties of natural Iraqi clay

Rula Fuad Ibrahim, Mohammed Y. Fattah & Nahla M. Salim
Civil Engineering Department, University of Technology, Baghdad, Iraq

ABSTRACT: The aim of this research is to gain a more thorough understanding of how soft clays can be modeled and predicted more accurately with respect to primary consolidation settlements by using finite element analysis, and how to cope with uncertainties that follow the selection of soil parameters drawn from standard soil investigation reports. The natural soil used in this study is a brown soft clay soil brought from Al- Sadder site east of Baghdad city. Standard tests were performed to determine the physical and chemical properties of the soil. The grain size distribution of the soil used is which reveals that the soil is composed of (7%) sand, (38%) silt and (55 %) clay. The consistency limit tests include liquid limit and plastic limit tests of soil by using the Casagrande apparatus in accordance with ASTM D 4318 standard procedure. Soil classification was (CL) according to plasticity chart.

Keywords: Soft soil, properties, laboratory, material parameters

1 INTRODUCTION

Soft clays are defined as cohesive soils whose water content is higher than its liquid limit. Soft clays are well known for their low strength and high compressibility. Usually, due to sedimentary process on different environment, both physical and engineering properties of the clays (namely void ratio, water content, grain size distribution, compressibility, permeability and strength have been calculated. Furthermore, they exhibit high compressibility (including an important secondary consolidation), reduced strength, low permeability and compactness, and consequently low quality for construction. Terzaghi and Peck (1967), stated that clay is considered as very soft if its unconfined compressive strength is less than 25 kPa and as soft when the strength is in the range of 25 to 50 kPa.Brand and Brenner (1981), specified that the identification and classification of a soft clay should be based on the following type of information:

1. The geological history of the deposit.
2. The water content and the Atterberg limits.
3. A description based on a visual study of the fabric of clay in a wet and a partly dried out condition.
4. The results of one or several in-situ vane tests.
5. The results of consolidation tests for evaluation the shape of the e-log p curve.

The determination of soil properties of soft soils requires undisturbed samples of high quality. The quality of the samples depends on the sampling, storage and preparation techniques. All the apparatus so far developed for sampling from the surface are based on the same principle, which is to push a tube in the soft soil layer. When a soil is exposed to a certain amount of load, it tends deform in the direction of the application of the load. The type and value of deformation differ from one soil type to another. For instance, soft soil tends to deform in a different manner when compared to stiff soil

DOI: 10.1201/9781003299127-351

through application of the same amount of load. The deformation property of soil is dependent on the origin of the soil, the structure of the soil particles, the bond between particles, water content and so on. (Gustafsson, 2011). A field and laboratory evaluation of a soft clay southern Iraq was presented by Fattah et al. (2006). The study described the geotechnical properties of normally consolidated Garmat Ali clay located at the meeting of the Tigris and Euphrates rivers southern Iraq, to form Shatt Al–Arab River which flows southward entering the Arabian Gulf. They presented the data developed from the field investigations performed at the Garmat Ali site of the water injection project in Rumaila. Namely, the data of boring explorations which include the results of field tests such as Dutch cone tests, standard penetration tests, vane shear tests and field density tests, in addition to the results of laboratory tests on samples taken from the site. The subsurface conditions in this area indicated the presence of a deep layer 15 m of soft clay. Several correlations were obtained from the field and laboratory properties of the soil.. From these relationships, several correlations were obtained from which prediction for geotechnical properties of soft clays can be made.The engineering properties of surface layer on very soft clay of the south coast in Korea presented by Jung et al., (2006). They evaluated the undrained shear strength of very soft clay layer in the south coast area to investigate engineering characteristics of in situ clay and dredged-reclaimed clay by various test methods. Results obtained by standard penetration test, field vane test, piezocone penetration test and dynamic cone penetrometer test were compared.It was concluded that when undrained shear strengths depth are analyzed compared with penetration depth, in case of very soft grounds composed of cohesive soil, the strength of the upper surface layer was verified to be higher than that of the lower part. The strength of lower part is greater than that of upper part in the very soft grounds (Site D) composed of loose sandy soil.A Comparison between behavior of undisturbed and reconstituted Tunis soft clay was presented by Klai and Bouassida, (2009). A laboratory investigation was carried out on undisturbed specimens and remoulded specimens of Tunis soft clay preceded by initial consolidation under vertical stress of 50 kPa. Recorded laboratory data were collected from oedometric and triaxial tests. A comparison between characteristics of undisturbed and remoulded Tunis soft clay specimens was presented by Klai and Bouassida, (2009). A laboratory investigation was carried out on undisturbed specimens and remoulded specimens of Tunis soft clat preceded by intial consolidation under vertical stress of 50 kPa. Recorded laboratory data were collected from oedometric and triaxial tests. A comparision between characteristics of undisturbed and remoulded Tunis soft clay specimens was then discussed. Also the verification of well-known correlation between physical parameters and mechanical characteristics has been investigated. Back analysis of soft clay behavior under highway embankments was presented by Rémai, (2012), who discussed the most important goals of Hungary to develop high quality transportation links between different parts of the country, and (with special respect to the goals the European Union) between the surrounding countries. As early as the design phase the subsoil conditions must be taken into consideration (in some cases soil improvement techniques may be necessary), because proper embankment base is required to find a durable, safe, high quality, economical and environmentally friendly solution for highway embankment construction. Remai (2012) investidated the strength parameter determination of saturated, soft cohesive soils based on moder in situ test results. Investigation of recently used methods' reliability; proposal of new empirical relationship for soft clays in Hungary. Calculation possibilities of embankment settlements (i.e. the compression of the underlying soft clay layer) using analytical and finite element methods were also studied the objectives of the present paper is to determine the material properties for a sophisticated soil model called "Soft Soil Model" which is widely used in the software PLAXIS and other programs . A clayey soil from Baghdad city was selected. the objective of the present study to understand the geotechnical properties of clayey soil which are required to characterize the general relations among soil parameters.

2 EXPERIMENTAL WORK

The testing program includes determination of water content, specific gravity, particle size distribution by sieve analysis and hydrometer and Atterberg limits. The program also includes compaction test on soil samples, unconfined compression test, consolidation test and triaxial compression test on samples prepared at different water contents. The natural soil used in this study is a brown soft clay soil brought from Al-Sadder site east of Baghdad city. Standard tests were performed to determine the physical and chemical properties of the soil. The grain size distribution of the soil used is shown in Figure 1 which reveals that the soil is composed of (7%) sand, (38%) silt and (55 %) clay. The soils used in the study were classified in accordance with the AASHTO soil classification and the Unified Soil Classification System (USCS). These classifications are based on the consistency limits and the particle-size analysis. The consistency limit tests include liquid limit and plastic limit tests of soil by using the Casagrande apparatus in accordance with ASTM D 4318 standard procedure. Soil classification was (CL) according to plasticity chart. The classification according to the AASHTO system is A-7-5. Table 1 shows the results of these tests with physical properties of the soil used.The soil is classified as CL according to (USCS).

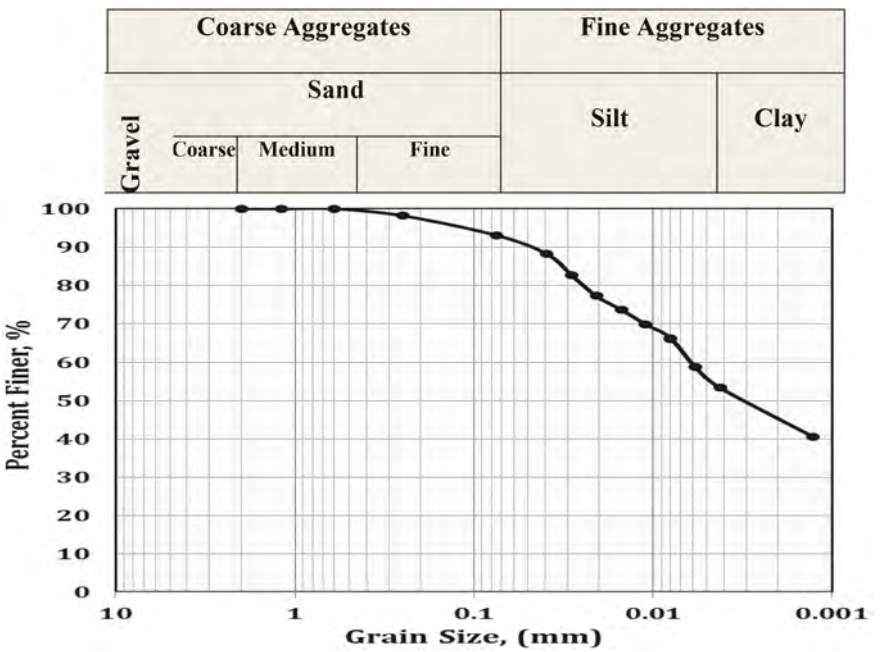

Figure 1. Grain size distribution of the soil tested.

Table 1. Physical properties of the soil used.

Physical properties	Index properties	Index values
Atterberg limits	Liquid limit, L.L (%)	33
	Plastic limit, P.L (%)	21
	Plasticity index P.I (%)	8
Grain size analysis	% sand (0.075-4.75) mm	6.9
	% silt (0.005-0.075) mm	38.1
	% clay (< 0.005) mm	55
Specific gravity G_s	----	2.723
Compaction test	Optimum moisture content	20 %
	Max γdry, kN/m^3	16.67

Regarding the standard Proctor test, the soil is compacted according to (ASTM D 698-00) in a mold of 4 in (101.6 mm) diameter and 4.584 in (116.43 mm) height in three layers with a hammer mass of 5.5 Ib (2.5 kg) dropped from a height of 12 in (305 mm) and the number of hammer blows for each layer is 25. The dry unit weight-moisture content relationship for the soil used is determined. Consolidation test was carried out on four samples with different water contents (15%, 20%, 25% and 33%) which represent dry side, optimum and wet side, respectirely. The last water contents 33% illustrates the layer of soil which is fully saturated. Consolidation test is very essential in soil mechanics for acquiring parameters in the calculation of consolidation settlements and evaluating stress history. The samples were performed at three water contents (dry, optimum and wet). According to NGI for equipment and procedure guidelines, it is possible to get reliable and credible parameters for very soft clays and other difficult parameters. The test was carried out according to ASTM D 2435 - Standard Test Method for One-Dimensional Consolidation properties of soils. Triaxial tests with the device have been one of the special equipment which is used to estimate reliable soil parameters to the maximum possible for an extensive range of geotechnical difficulties and soil types mainly for soft and quick clays, ASTM D2850:Standard Test Method for Unconsolidated Undrained Triaxial. Compression test on cohesive soils. When the deformation analysis of soil is performed by an advanced soil model in PLAXIS program, there is a need to a triaxial test. This is because advanced models require more input of material data, for instance hardening soil model requires input of three modules, such as Eoed obtained from consolidation test, E50 and Eur, which are obtained by performing a triaxial test. The triaxial test is a common test performed to determine the deformation properties, in this case compression modulus. In the test method, a cylindrical soil sample is placed into the test equipment, which is filled with water.Unconfined compressive strength tests (UCS) were performed according to (ASTM D 2166) on the raw soils at different moisture contents to draw the soil strength versus moisture content to evaluate the threshold moisture content at which soil strength treatment is required in the finite element model. All the samples for UCS tests were compacted in 3 layers with 25 number of blows/layer to achieve approximately uniform energy that is equivalent to standard Proctor test (12.4 ft.lb/ft^3). The number of blows per layer was determined by equating the compacting energy from 3 layers and 25 number of blows/layer of standard Proctor test with the energy produced by three layers of soils in 2.8 inch (71.12 mm) diameter and 5.6 inch (142.24 mm) high mold while keeping the hammer weight as well as drop height constant.

3 RESULTS AND DISCUSSION

The soil has predominately clay particles with mineralogy test indicating primarily kaolinite and halloysite. The moisture-dry unit weight relation showed high values for maximum dry unit weight in accordance to energy applied on the sample. The results can be shown in Table 2. The shape of compaction curves for standard Proctor compaction showed a single peak curve, Figure 2. The decrease in dry unit weight with increase in moisture content (at about 5%) can be attributed to the capillary tension effect. At lower moisture contents, the capillary tension in the pore water inhibits the tendency of the soil particles to move around and be densely compacted, (Das, 2002).

Table 2. Summary of compaction test results at water contents of 15%, 20%, 25% and 33%.

Water content, %	15%	20%	25%	33%
Maximum dry unit weight, (kN/m^3)	15.93	16.67	16.01	14.67

The maximum dry unit weight was found equal to 16.67 kN/m^3 at water content 20%. This method could be more accurate to determine the unit weight for soft soils with some fines.

Figure 3 and Table 3 present a summary of the results of consolidation test on samples prepared at different water contents. The coefficient of consolidation C_v was determined by Casagrandi method at a pressure of 200 kN/m^2.

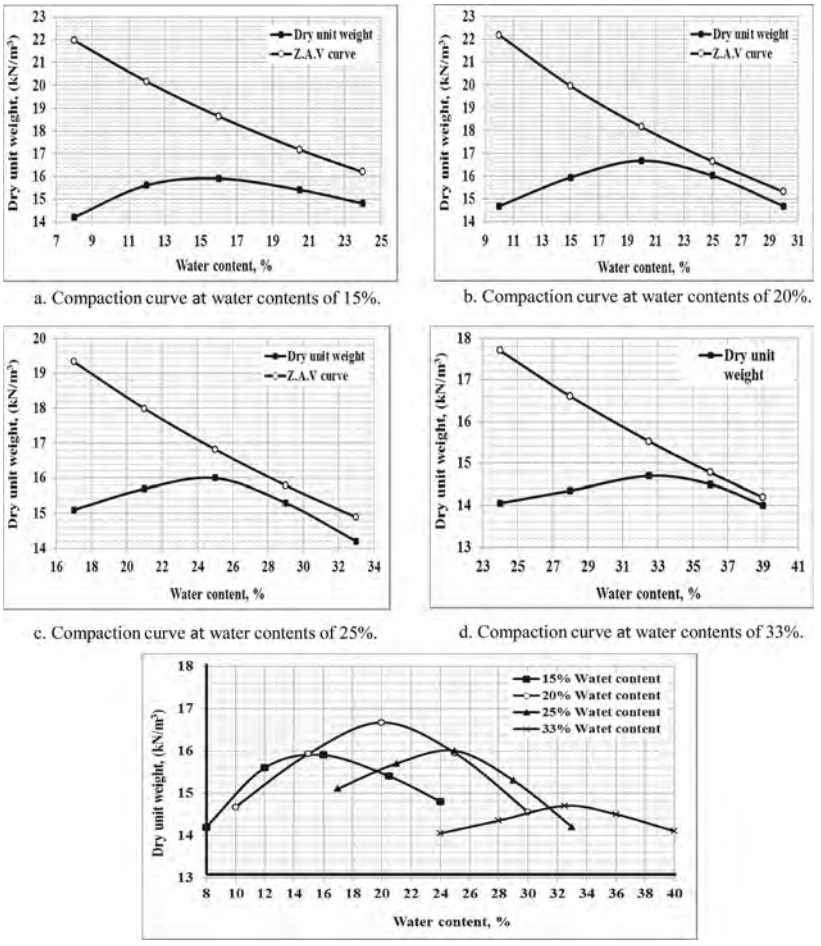

Figure 2. Compaction curves for all samples.

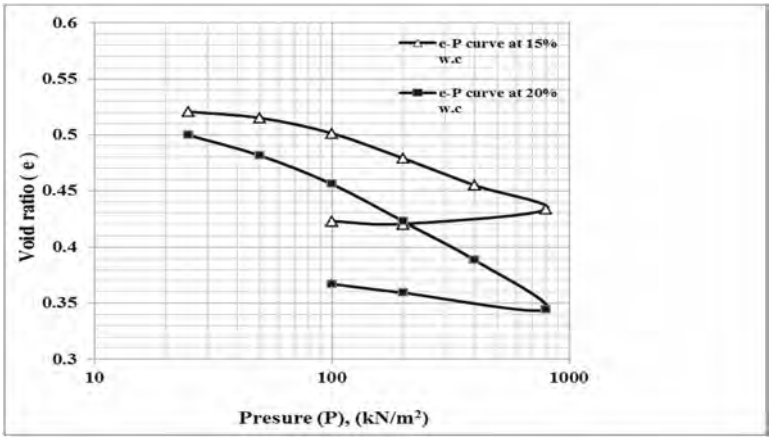

Figure 3. Void ratio versus effective stress curves from the consolidation test on samples prepared at different water contents.

Table 3. Summary of consolidation test results on samples at different initial water contents.

Properties	Water content, %			
	15%	20%	25%	33%
av, (m^2/kN)	0.0002	0.00023	0.0005	0.0003

κ*	0.0456	0.015	0.021	0.018
E_{oed}, (kPa)	18462	13750	8718	1000

Figures below from (4) to (7) present relationships between the dail reading and time at deffernt water contents:

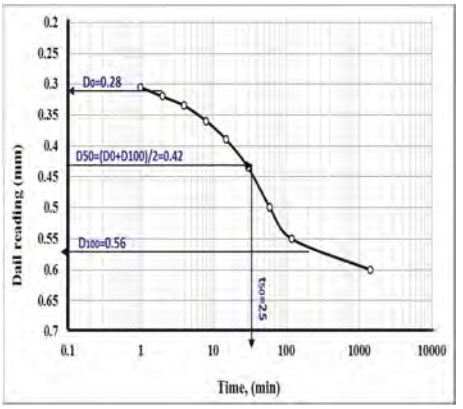

Figure 4. Dial reading versus time curve from the consolidation test at 15% initial water content.

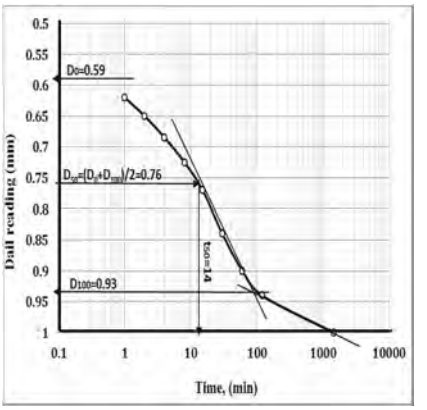

Figure 5. Dial reading versus time curve from the consolidation test at 20% initial water content.

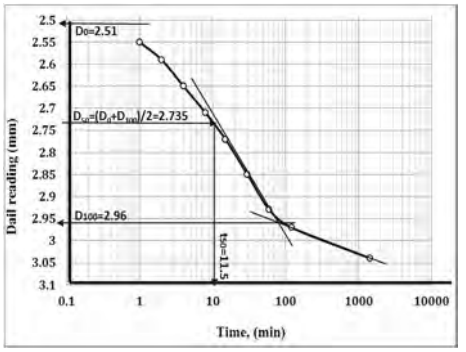

Figure 6. Dial reading versus time curve from the consolidation test at 25% initial water content.

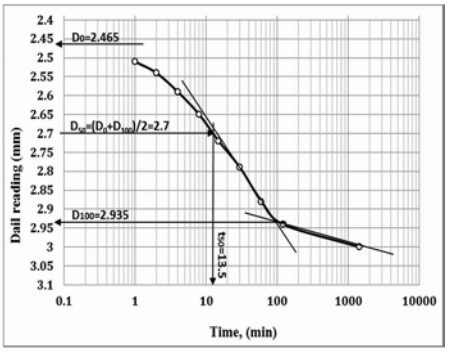

Figure 7. Dial reading versus time curve from the consolidation test at 33% initial water content.

Table 4 summarizes the results of unconfined compressive strength (UC test) at different water contents. The sample with an initial water content of 15% showed a maximum deviator stress value of 89 kN/m^2. The sample with 20% of water content failed at 64.6 kN/m^2. The sample with 25% of water content failed at 28.6 kN/m^2. These unconfined compressive strength values (28.6 and 89.0) kN/m^2 correspond to a soil soft consistency.

Table 4. Summary of unconfined compression strength test results for samples prepared at water contents of 15%, 20% and 25%.

	properties	
Water content	Qu (kpa)	Cu = Qu/2
15%	89	44.5
20%	64.6	32.3
25%	28.6	14.3

The Mohr-Coulomb failure criterion was used to establish the relation between shear strength parameters, as illustrated in Figures 10 to 12 at different water contents. From these values, higher strength can be achieved at water content is 15% (C_u = 88 kPa), and there was no change on angle of internal friction (ϕ_u = 0). Table 5 presents a summary of the results.

Figures 12 to 14 present the deviator stress – axial strain relationships for these samples, from these figures, the tangent elastic modulus is obtaine.

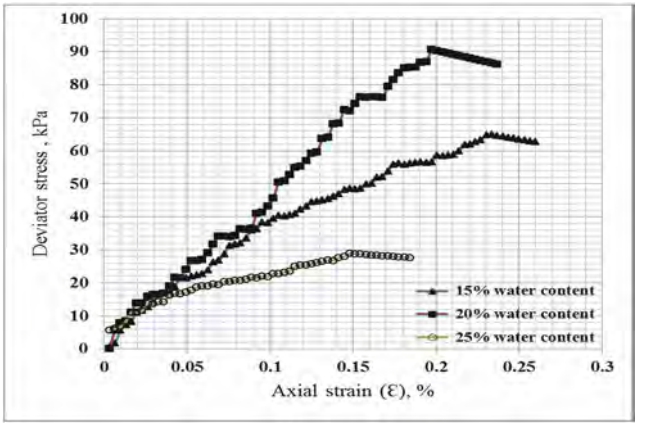

Figure 8. Present the deviator stress - strain relationships.

Table 5. Summary of traixial test results for samples prepared at initial water contents are 15%, 20% and 25%.

water content, %	C_u, kPa	ϕ_u
15%	88	0°
20%	63	0°
25%	43	0°

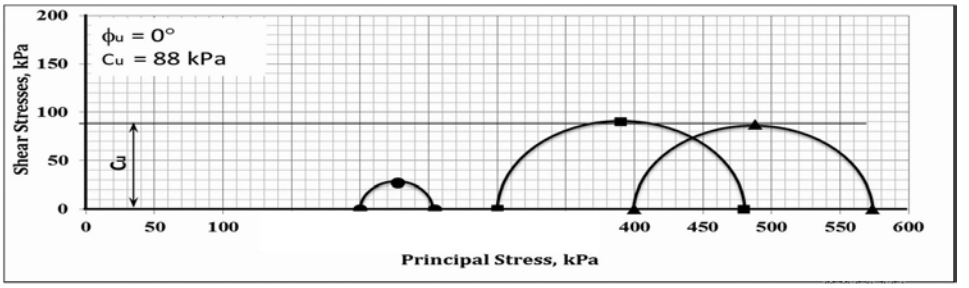

Figure 9. Total stress Mohr's circle and failure envelope ($\phi = 0$) obtained from triaxial UU test on soil prepared at water content of 15%.

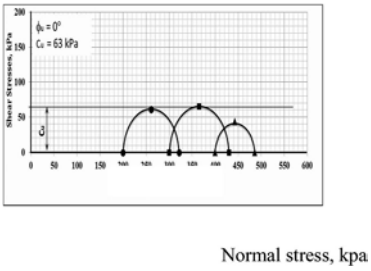

Figure 10. Total stress Mohr's circle and failure Envelope(ϕ=0) obtained from triaxial UU test On soil prepared at W.C of 20%.

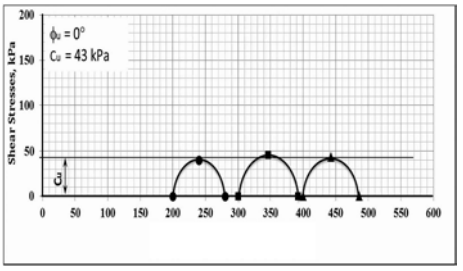

Figure 11. Total stress Mohr's circle Envelope (ϕ=0) obtained from triaxial test on soil prepared at W.C of 25%.

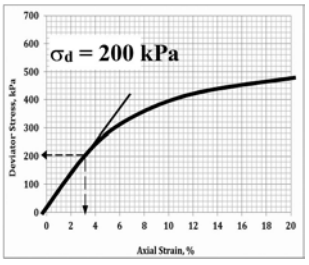

Figure 12. Deviator stress versus axial strain obtained from triaxial UU test on soil at water content of 20%.

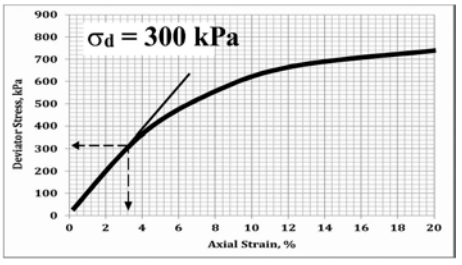

Figure 13. Deviator stress versus axial strain obtained from triaxial UU test on soil at water content of 15%.

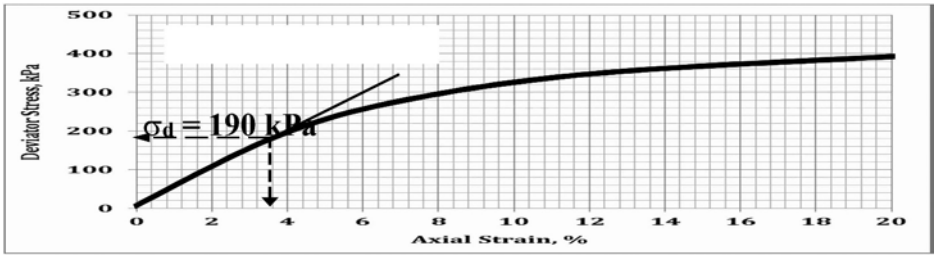

Figure 14. Deviator stress versus axial strain obtained from triaxial UU test on soil at water content of 25%.

4 CONCLUSIONS

1. Design parameters adopted by two failure criteria; Mohr-Coulomb and Soft Soil model were determined experimental for a soil from Baghdad city.
2. Initial water content of soil samples play controlling role in determination of soil strength and compressibility. As the water content is increased from 15% to 25%, the undrained cohesion is halved. On the other hand, the initial tanget modulus increases five times for same change in water content.

Technology of geodetic works during modernization operating construction

M.Zh. Sagyndyk, Zh.M. Aukazhiyeva, M.Sh. Ishankulov & A.M. Sharapiev
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The issues of application of laser scanning technology, tacheometry, satellite methods for obtaining information about underground and above-ground engineering structures on the example of operating oil producing enterprises are considered.

Keywords: Modernization of existing facilities, laser scanning, tacheometry, satellite methods

1 INTRODUCTION

It was planned to start the technical re-equipment of existing enterprises of the oil industry in Kazakhstan with a set of measures, ranging from the re-equipment of existing workshops in order to install new equipment necessary for the modernization of production to the modernization of existing facilities for launching information platforms that integrate the production and service sectors, while maintaining the existing functional purpose of the enterprise. At the same time, the technologies of geodetic works of are no small consequence.

2 METHODS

The area of the research object is about 2.5 km^2. As a result of the technical survey, the technically and technologically complex facilities of the enterprise were divided into three levels - low, medium and high complexity. The objects of low complexity included roads, trees, signposts, etc. Office and residential buildings, construction sites, etc. attributed to objects of medium complexity, and to objects of high complexity - various installations, pipes, valves, etc.

Geodetic monitoring of these objects, located in a remote and dangerous place for human life, consisted in the use of modern measuring instruments and in obtaining real-time information about the state of the entire object and its individual parts.

One of the important stages of geodetic monitoring in the study area was the reconstruction of the network. The network reconstruction was carried out not only to improve the accuracy of the network, the reliability of determining the parameters of the transformation between the global geocentric coordinate system, the state and local geodetic coordinate systems, but also to preserve the local coordinate system in which large-scale surveys were previously performed (Sysoeva, 2005).

Geodetic monitoring using modern measuring instruments to safely obtain information about an object located in a hard-to-reach place and dangerous to human life is currently widely used not only in the reconstruction of structures, but also in the modernization of production. Modern technologies have radically changed the conditions for conducting field and cameral.

DOI: 10.1201/9781003299127-352

At the same time, the density and conditions for fixing the points of the geodetic base, the error in the mutual position of the points in plan and in height ensure the subsequent thickening and development of the network to provide topographic surveys and solve other engineering and geodetic problems. And the use of satellite technologies and electronic total stations must correspond in accuracy to the terms of reference submitted by the customer.

The next important task is to identify areas of possible obstacles, distortions and radio interference. As a result of the reconnaissance, the position of the points planned earlier in the design process was clarified. Taking into account the clarifications, and also taking into account that geodetic observations will be carried out on the territory of the enterprise with objects of varying technical complexity, a rational method was chosen to create a geodetic base in the form of polygonometry moves. The constructed polygonometry passages will serve as a planned basis for the production of topographic and ground-based laser surveys.

Practical experience has shown that in places where the passage of radio signals from satellites is difficult, it is necessary to use the Leica TS10 total station. Points are fixed with temporary signs taking into account their safety at the time of filming. Satellite determinations were made by two (base and rover) GPS receivers Leica GPS1200. The measurement results are processed using the Credo software, which includes preprocessing, adjustment and correction of measurement errors.

Topographic and ground-based laser surveys based on the developed project were carried out to survey all above-ground and underground structures, marks, identification marks, installations and others. The result of the laser scanning process is shown in Figure 1.

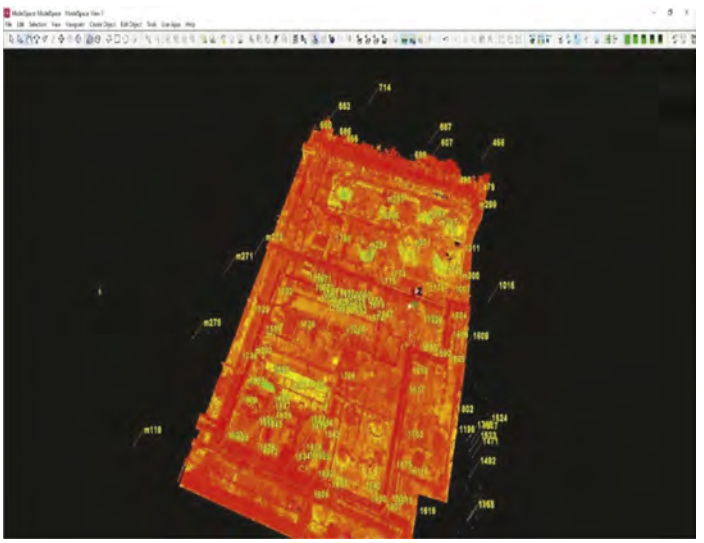

Figure 1. The result of the laser scanning process in intensity.

An electronic tacheometer is installed at the shooting point and, in sequence, special poles with reflectors are installed at the picket points. The measured data are processed using a special program to obtain the data necessary to build a digital terrain model or a topographic plan (Marfenko, 2004).

Scanning was performed by two scanners located close to each other, given that the scanning range of the RTC 360 (Figure 2) of 130 m is the maximum for equipment of this class.

One scanner was intended for scanning indoors, and the second for scanning outdoor installations. The location of the stations during scanning is shown in Figure 3.

Based on the developed technique, scanning inside the premises was carried out at medium density, and for scanning outdoor installations at high density. The measurement results were processed using the Leica Cyclone software package.

Figure 2. RTC 360 laser scanner.

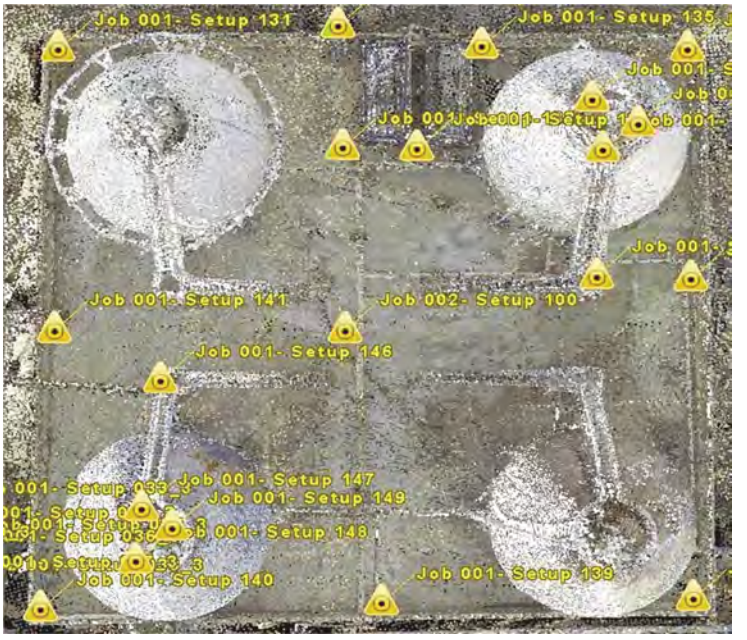

Figure 3. Location of scanner stations.

Control, stitching and binding of scans was carried out by marks, the centers of which were determined by the tacheometer.

3 RESULTS

The first stage of office work is data loading. The import is done via the Import RTC 360 data function. One of the main criteria for brand selection is brand display in the Leica Cyclone software. The brand display error occurs during the process of brand recognition by the program. Sometimes crosshairs in brick buildings can be recognized as a mark.

The next stage of in-office processing is cleaning the scans from noise and checking them for ghosting. Scans are cleaned in Model Space. Noise is a cloud of points that occur in various places. Noises also arise from hot fumes released by industrial facilities. Frequently encountered noises include noises located on power cables. Noise points are shown in Figure 4.

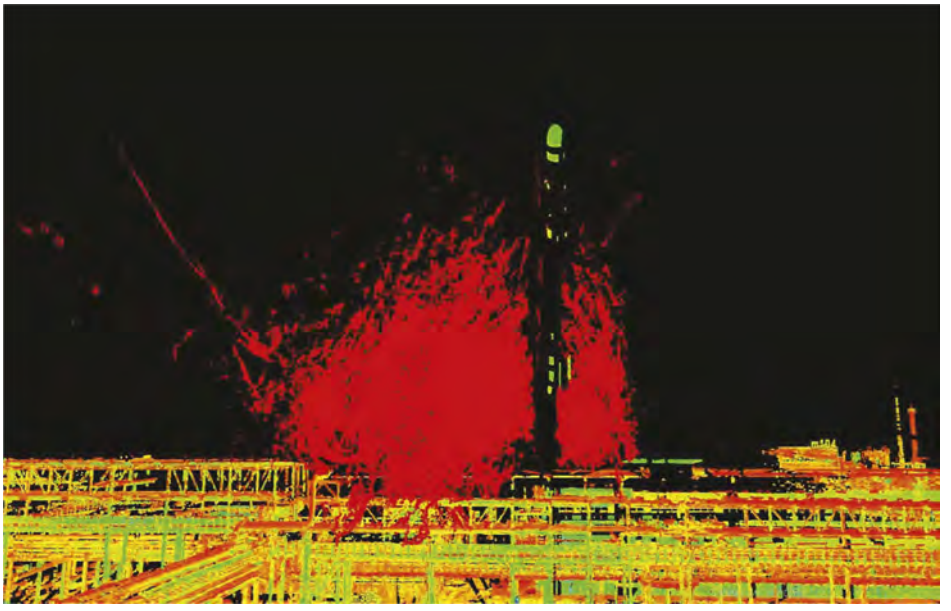

Figure 4. Noise points.

4 DISCUSSION

The shooting process depends on various external conditions that must be taken into account in the process of work. When conducting ground-based laser surveys in an industrial area, it is necessary to pay attention to three main factors that affect the final result of the survey.

4.1 *The content of vapors and dust in the air*

In industrial facilities, fumes and dust are often present in the air. When scanning, errors occur, the so-called noise, due to the fact that these particles have a density. Noise occurs, as a rule, when the scanner beams collide with particles of steam or dust. This is a big hindrance, because sometimes these particles do not allow you to get data about the object behind them. Therefore, there is a need to clarify the operating time of the structure, and minimize this factor.

4.2 *Inhomogeneous surfaces*

The presence of heterogeneous surfaces in the industrial zone is one of the main factors. An inhomogeneous surface is a surface that has the ability to reflect. Heterogeneous surfaces also occur after precipitation. They are most often represented on scans as noise covering objects or below the scanner horizon.

4.3 *Scanner stability and vibration*

The location of the scanner on the surface plays a huge role in the shooting process. At the slightest vibration, a systematic shift can occur, which will lead to errors in the overall system. This problem can be averaged during data processing, or duplicate scans can be eliminated.

It is possible to indicate in advance the areas where a large amount of noise and various errors may occur, taking into account these factors.

The most common type of noise occurs due to a weak signal when reflected from various metal structures. Usually, these noises appear at the edges of various objects, cables, pipes. These errors will appear on every scan. Elimination is done manually in the Leica Cyclone software, or by removing it by finding the noise intensity factor limit. In the course of the work, it was proved in a practical way that points in the intensity limit of 0.001 are noise points. This technique of eliminating noise within the one-hundredth limit is not correct when cleaning inside buildings, since the correct point clouds may be in this limit. Therefore, this method is used when cleaning the outside of buildings and on the street (Seredovich, 2009).

At an industrial facility, during the process of functioning of various structures, various pairs are emitted, which will be reflected on the scans as noise. This problem is solved by manually deleting a portion of the point cloud. In some cases, pairs can show the real location of the object, which should not be removed.

The considered noises arise due to a weak signal and the functioning of an industrial facility. Ambient type noise may also occur during the ground laser survey process. Noise can be a person caught in the frame, birds and other moving objects. This type of noise is removed manually by selecting them.

The next main work process is the stitching of scans. This operation is done through registration. Registration is a project that includes the functions of stitching, adding marks, and adjustment.

Stitching can be done using stamps, manual and automatic methods. Cross-linking can also be done using a visual method. These methods can be applied in different ways. At the beginning of work with registration and loading data into it, the stitching is performed by an automatic method. This method can be applied once for stitching a general contour. However, some scans may not be stitched together. To solve this problem, the manual stitching method is used. Thus, the main stitching of the network occurs when using two methods. At the same time, stitching using the visual method works much better inside buildings and structures.

The bonds obtained are evaluated by the quality of the crosslinking. The Error Vector indicator is responsible for this. It evaluates a single link between scans. Empirically, we decided to re-link all connections with an accuracy of more than 20 mm. These values allow you to say with what accuracy the scans were filed. The automatic stitching process ends after all inaccurate links have been corrected. Then the registration process starts. The registration process involves the adjustment and general stitching of the Model Space. Often, due to errors in scanning, there is a lack of links. The problem is solved by creating a single network of scans, which includes a serial network system. Further stitching is done using a manual method.

Manual stitching of scans is performed by finding scans with the same overlap. In this mode, 4 common points on two scans are selected, due to which the stitching is performed. In this case, the accuracy depends only on the performer.

The links created are passed through the optimization and registration operation. Links are created until registration is made. If the registration is successful, there is no need to add links. The performed registration stitches all scans and determines the mean square error of each connection relative to the total stitching by the least squares method. The error should be no more than 10 mm.

The network of scans must be adjusted if errors greater than 10 mm occur. Error reduction is achieved by creating additional links to the link that gives the error. The cause of the error may be double scans, or poor-quality communication. Thus, error reduction is achieved and equalization is performed

One effective method to control and verify links is to add tags. The marks serve as a control of the accuracy of the stitching, the accuracy of 10 mm, in case of exceeding, an error is searched for, and the erroneous connection is corrected. The next step is to create a general model that includes all the scans included in the registration. This process merges all Model Spaces into a single space. Thus, this model represents the result of the entire registration (Simonyan et al, 2019).

After obtaining the general model, it is landed on the coordinates. The coordinates are obtained by surveying marks located in different areas.

The final process for processing ground-based laser survey data in Leica Cyclone is the unification of the entire common point cloud. Unification is a process designed to average point clouds into a single one since there can be more than 7- or 8-point clouds per design. Unification averages all these clouds into one model. This results in one finished model for modeling.

5 CONCLUSION

The end result of the data was submitted for further modeling of the digital twin in the AVEVAEverything 3D program, the formation of a common plant database and the registration of obsolete equipment. The model is a single cloud of points of the entire plant, planted by coordinates in natural colors without errors and doubling. The resulting model will allow the integration of a digital twin system with PDM systems for full control of the plant, which will help simplify most of the work, as well as increase work efficiency and improve the quality of products.

Dynamic and spectral characteristics of the Kapchagay HPP dam

Vladimir Lapin, Yerken Aldachov, Nurakhmet Makish, Seric Aldachov & Alimzhan Ali
Kazakh Scientific Research and Design Institute of Civil Engineering and Architecture JSC, Almaty, Kazakhstan

ABSTRACT: For the first time, the instrumental records of accelerations at the Kapchagay HPP facilities (soil, HPP building and channel dam) are provided at two 5-magnitude earthquakes, the foci of which are located at different distances from these facilities. The task was set to study spectral characteristics of these earthquakes in the points of instrumental recordings and to determine the period of the dam channel vibrations. The β spectral curves have been constructed. It was found that the spectral curves are the least different for the case of the channel dam, the most– for the registration point on the soil. Dominant periods of soil vibrations under the influence of 2 earthquakes vary within the range of 0.15-0.55 sec.

The period of the spectrum maximum, approximately equal to the period of vibration of the dam -0.59-0.67 sec. Recommendations are provided for increasing the number of registration points.

Keywords: instrumental records, antiseismic construction, accelerograms, embankment dams, vibration period

1 INTRODUCTION

Ensuring the reliability of critical structures such as dams is an important and complex task. Especially it concerns the issues of seismic stability of dams of hydraulic structures made of earthen materials. Such structures can be erected from available and cheap local materials in almost any alignment and on any grounds. They can be of significant height up to 300 m and more, have good technical and economic indicators, high enough seismic stability and therefore are very common.

There is a sufficient number of works devoted to different aspects of investigation of dams of different types Biondi (2021), Wang (2018), Gu, (2015), Gu, (2021), Alibertia (2016), Valamenesh (2011), Zhong (2013), Cascone (2021), Bayraktar (2009). For example, Biondi (2021)] studies existing earth dams that were designed and constructed before the introduction of the seismic code, so it is of considerable interest to assess their seismic performance and operation conditions after seismic impacts. Probabilistic methods are used in Wang (2018) to estimate seismic stability of a 285.5 m high dam in China. Non-linear models and finite element schemes for calculating the dam in Italy are provided in Alibertia (2016) Topical issues of studying the effects of antiseismic strengthening with Fiber-Reinforced Poly/mer Material (FRP) attached to the surface of the dam in the design of dams are considered in Zhong (2013).

There are many HPP dams located in earthquake-prone areas in Kazakhstan. In East Kazakhstan, these are the Bukhtarma and Ust-Kamenogorsk HPPs, built in an area that was not previously considered earthquake-prone.

In Almaty region, the Kapchagay HPP with a capacity of 100 MW is located in the area of a seismicity of 7 MSK, supplying the entire region with cheap electricity. This Power Plant is an important element of Almaty's infrastructure, supplying it with electricity. The height of the channel dam is 49.0 m. It is the only Plant in the Republic of Kazakhstan that is equipped with a seismic engineering service station. The Plant was installed in 1977.

DOI: 10.1201/9781003299127-353

The Shardara HPP is located in an earthquake-prone area in the south of Kazakhstan.

The mud dam in Medeo mountain area near the city of Almaty is located in the 10-magnitude area.

Therefore, the field studies of the behavior of dams during earthquakes become important Krasnikov (1981).

A new Seismic Zoning Map has been introduced in the Republic of Kazakhstan, in which each territory corresponds to a seismic magnitude or peak acceleration value. These are the predicted amplitude characteristics in the territory of Hydroelectric Power Plants.

The actual task is to determine the spectral characteristics of seismic impacts on the territory of the Kapchagay HPP and dynamic characteristics of the 49 m high channel dam on the basis of the analysis of instrumental records of earthquakes. Such tasks were not solved earlier.

2 MATERIALS AND METHODS

The 49-meter-high Kapchagay Dam was built on the Ili River near the city of Kapshagay. In the area with a seismicity of 7 MSK. This Dam is the first dam in the world to be made of homogeneous fine-grained eolian sands (fractions less than 0.1 mm make up 80%). The upstream and downstream slopes base was determined by calculating their stability at constant accelerations along the height of the structure equal to $1.5K_{C7}$, where $K_{C7} = 0.025$ coefficient of seismicity, which characterizes the RMS of acceleration in fractions from the acceleration of free fall.

Laboratory and field (using explosions) studies of the stability of the structure of water-saturated eolian sands have shown that they are dynamically stable at vibration accelerations corresponding to a 7-magnitude earthquake Mikhailova (2013). However, this conclusion, due to lack of the critical acceleration method certainly needed to be clarified. Therefore, the instruments of the seismic engineering service station were installed to observe the dam.

Kazakh Scientific Research and Design Institute of Civil Engineering and Architecture JSC has the only engineering seismic service station in the Republic of Kazakhstan, which has 12 stations. Kapshagay Plant 15 was established in 1975 and is equipped with analog instruments.

In 2011, the well-known Kapshagay earthquake occurred, but due to specific location of the earthquake focus on the territory of the HPP the seismic vibrations were practically not felt. The earthquake has been registered on May 1, 2011 at 08 hours 31 minutes local time. Residents of Almaty felt the earthquake, the intensity of which was 4 - 5 MSK in the city. The earthquake magnitude is $m_b = 5.6$ and the focus depth is 20-23 km. Parameters of strong movements on the territory of Almaty according to the Geophysical Research Institute of the National Nuclear Center of the Republic of Kazakhstan demonstrated predominantly high-frequency seismic impacts with dominant periods of 0.13s. The intensity of impacts at the level of 8.4 cm/s^2 (KNDC plant was at a distance of 79 km from the epicenter) Mikhailova (2013).

Therefore, instrumental records of seismic Kapchagay HPP recorded in 1978 and 1979 were re-digitized for analysis.

On March 25, 1978 there was a strong Zhalanashtyup earthquake, which was felt on a large territory of Almaty region and Tyup district of Kyrgyzstan. Its epicenter was at a distance of 140 km from Almaty. This earthquake (magnitude about 6.5, the focues depth is 30-35 km) is the strongest for the last 40 years on the territory of Almaty region. In Kazakhstan it was strongest in Kegen (7-8 MSK), Narynkol (6-7 MSK) districts of Almaty Region. On the territory of Kyrgyzstan, the maximum intensity of the earthquake was observed in the Santash Collective Farm, Taldy-Su Settlement, etc. (about 7 MSK). (about 7 MSK) with gradual decrease to Tyup (about 6 MSK) and Przhevalsk (about 5 MSK) Zhunussov (1982).

A very strong earthquake on the territory of Kazakhstan occurred on September 25, 1979, 198 km north of Almaty (magnitude 5.6; intensity about 7 MSK; focus depth is 30-40 km), which was registered on the territory of the city of Almaty with a force of 4 MSK Zhunussov (1079). According to the results of MSK-64 scale macroseismic survey of damages of different building types the intensity of earthquake effect in Bakanas settlement (60 km from epicenter, the nearest settlement to the earthquake epicenter) made up 6-7 MSK. In Kapchagay city (120 km from the epicenter) the intensity of the earthquake according to the results of

macroseismic survey and instrumental data recorded at the Kapchagay seismic engineering service station reached 5 MSK. The Bakanas earthquake is peculiar in the location of the focues, which was located in a non-seismic area.

By the way, in Almaty and the surrounding areas, the Bakanas earthquake was recorded simultaneously by a large number of seismic engineering service stations installed on buildings of various design solutions and storeys erected on different soils.

3 RESULTS

Table 1 provides the maximum acceleration values for each of the components of the instrumental records for the case of the Zhalanashtyup earthquake, and– Bakanas in Table 2 (the accelerograms sample interval in Tables h). The soil registration points (fissured rocky soil), the HPP building (steel frame, second floor) and the channel dam crest (mark 49 m).

Instrumental recordings (accelerograms) were recorded on the soil, the HPP building and the channel dam.

Table 1. The maximum values of accelerations and parameters of accelerograms during an earthquake on March 23, 1978 (h=0.027 s).

	Acceleration	Effective duration		Spectrum maximum period
Component	cm/s^2	s	Spectral Coefficient	s
Soil-y	19	7.83	3.16	0.15
HPP	20	5.35	3.61	0.25
DAM	48	4.40	3.75	0.59

Table 2. The maximum values of accelerations and parameters of accelerograms during an earthquake on September 25, 1979 (h=0.028s).

	Acceleration	Effective duration		Spectrum maximum period
Component	cm/s^2	s	Spectral Coefficient	s
Soil-y	28.27	12.99	3.02	0.55
HPP	30.70	11.79	3.21	0.42
DAM	0.95	13.38	3.55	0.67

According to the current MSK-64(K) scale, a 5-magnitude earthquake corresponds to an acceleration interval of 16-35 cm/s^2 with a median value of 25 cm/s^2. Tables 1-2 show that the acceleration value on the soil falls within the specified interval. The same can be said about the registration point on the HPP building. The accelerations are very different on the dam crest. This is due to the fact that the dam is a structure with a rather complex spectrum. It should also be noted that the effective duration of the accelerogram of the Bakanas earthquake is 2-2.5 times higher than the similar characteristic of the Zhalanashtyup earthquake (the effective duration here is a period of time during which the acceleration amplitude is not less than half of the maximum value).

Attention should be paid to significant fluctuations of accelerations at the channel dam crest. At the same time, the foci are 120-135 km away from the Kapchagay HPP for both earthquakes. The acceleration maxima differ up to one and a half times for the other two registration points.

Figures 1 and 2 show the spectral curves of seismic events for three registration points (Figure 1 shows – Zhalanashtyup earthquake on March 23, 1978, Figure 2 shows– Bakanas earthquake on September 25, 1979). Spectral curves were determined for the magnitude of the vibration decrement equal to 0.3. The Figures 3-5 show spectral curves in pairs for each registration point for the convenience of comparison.

The smallest differences in the values of the spectral coefficient occur for the channel dam. The most spectral curves differ for the case of the registration point on the soil (Figure 3).

For the registration point on the channel dam, the values of the maximum period of the spectrum of 0.59-0.67 seconds are apparently close to the period of vibrations in the fundamental tone. The result was obtained for the first time.

The registration point in the HPP building is installed on a steel column of the 2nd floor, so the spread of the maximum values of the spectrum does not cause surprise (Figure 4).

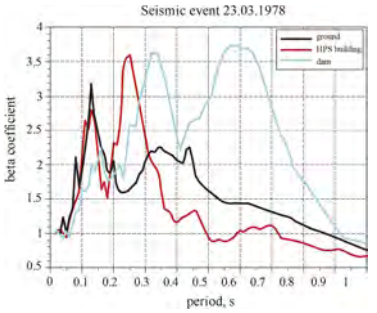

Figure 1. Zhalanashtyup earthquakeon March 23, 1978.

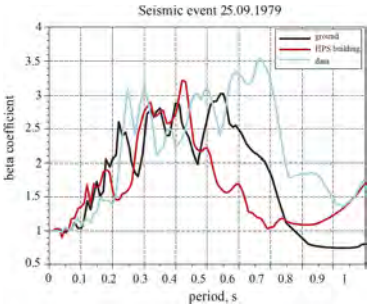

Figure 2. Bakanas earthquake on September 25, 1979.

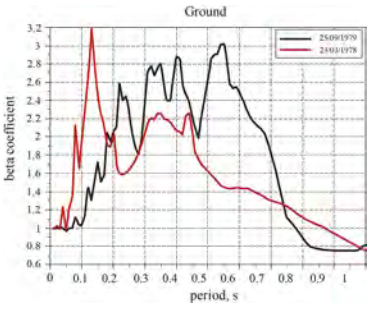

Figure 3. Spectral curves of seismic events, March 23, 1978 and September 25, 1979 (soil).

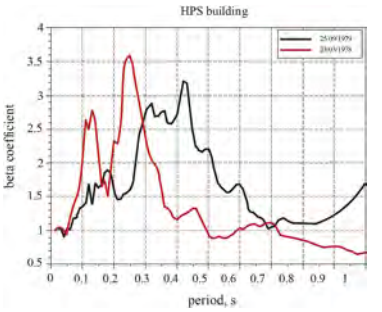

Figure 4. Spectral curves of seismic events, March 23, 1978 and September 25, 1979 (HPP building).

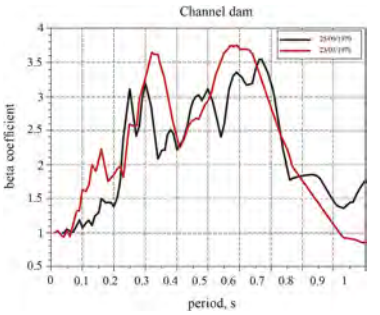

Figure 5. Spectral curves of seismic events, March 23, 1978 and September 25, 1979, (channel dam).

The maximum values of spectral curves for the registration point on the channel dam are the most stable. The same can be said about the maximum period of the spectrum. It is notable that the spectral curves for the two earthquakes here are generally similar in nature (Figure 5), although the maximum acceleration values differ by two orders of magnitude.

The spectrum of the recording on the soil for the case of the Bakanas earthquake are strongly indented (Figure 3). Instrumental recordings are quite different in spectral composition.

The greatest width of the spectrum occurs for accelerograms of the Bakanas and Zhalanashtyup earthquakes recorded on the channel dam crest.

According to accelerograms, it is hard to judge the influence of the water body on the amplitude and frequency composition of the impact. It is possible that the significant indentation of the spectrum is a consequence of the presence and impact of the water body.

Interesting results can also be obtained by decomposing instrumental records into Fourier series or by using classical correlation and spectral analysis.

4 DISCUSSION

It is interesting to assess the reliability of the estimation of the period of channel dam vibration. Lyamzina (1973) shows the results of experimental studies of the Orthokay rock-earth dam with a height of 54 meters. According to the results of the analysis of instrumental records of earthquakes, the vibration period was 0.45 seconds. Taking into account that at approximately the same height, a rock-earth dam is tougher than an embankment dam, the vibration period of an embankment dam of 0.59-0.67 seconds seems very reliable.

The results of the study can be used to perform calculations of this dam based on the application of a new regulatory framework in construction - according to Eurocode 8. At the same time, the peak acceleration value, taking into account the data of the Seismic Zoning Map of the Republic of Kazakhstan should be taken with a repeatability of 1 earthquake in 475 years – 0.15g, in 2475 years - 0.32g (g is the free fall acceleration).

5 CONCLUSIONS

1. For the first time the vibration periods of 0.59-0.67 sec were defined using instrumental records of seismic engineering service for the Kapchagay HPP channel dam.
2. The dominant periods of soil vibrations during the impact of 2 earthquakes vary within the range of 015-0.55 sec.
3. The seismic events of March 23, 1978 and September 25, 1979 represent 5-magnitude earthquakes in terms of acceleration on the soil.
4. The least spectral curves differ for the channel dam, the most - for the soil. Apparently, this is determined by spectral features of earthquakes.
5. For such a structure as the Kapchagay HPP the number of registration points should be doubled. It is necessary to add registration point on the middle of channel dam. It is necessary to set the registration point on the middle of the logging dam, where the hydraulic shock during seismic impact will be less noticeable. In addition, it is desirable to install recording devices on the water pipe – the underground tunnel.
6. In order to equip Hydroelectric Power Plants with seismic engineering service stations, it is advisable to develop a special normative and technical document (regulations) regulating the arrangement of devices (displacement, velocity and acceleration sensors) at such facilities.

Geomonitoring of the foundation of a high-rise building applied fiber optics

A. Buranbayeva, A. Sarsembayeva & S.T. Mussakhanova
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: New technologies in building and high-rise monitoring make it possible to track damage and defects in existing structures and infrastructures. The need for timely detection of defects in building structures using fiber optic sensors is increasingly prompting planners, builders and facility managers to use the capabilities of a powerful system such as DFOSS. In addition to the well-known advantages, they are the most reliable in conveying the stress-strain state of the structure in the long term. The main objective of any construction project is safety for people, which can only be ensured by proper monitoring of the condition of the building, where the presentation and management of the resulting information on changes in the system and structure can be ensured with DFOSS.

1 INTRODUCTION

The condition may deteriorate over time, resulting in a serious and ongoing issue for the operating company. Evaluating the genuine state of crumbled structures is important for opportune distinguishing proof of deformities and settling on conclusions about suitable fixes.

Because of the enormous number of maturing frameworks, including noteworthy designs, observing the state of designs has started to assume a powerful part during the activity and upkeep period of the primary life cycle the board interaction.

SHM works with the observing and assessment of primary properties, which streamlines underlying upkeep costs and further develops underlying wellbeing [Buranbayeva, 2022].

Structures have various responses under various burdens during their life cycle, which can be estimated by utilizing SHM frameworks and sensors to acquire data about the changed boundaries and components. Observation and measurement of design, condition assessment, information management, planning and decision-making, repair execution, and evaluation of repair and maintenance performance are the primary stages of condition monitoring [Agdas, 2016], [Huston, 2016].

Utilizing a distributed fiber optic monitoring system will make structural condition assessment in sanitary monitoring more efficient and accurate. The construction sector can benefit greatly from DFOSS's use.

The limitation of a structure's deformations and/or stresses is frequently the foundation for engineering design standards. This is significant because deformation indicates the potential degree of damage that has occurred and is a measure of how close the construction material is to its strength capacity. This is significant on the grounds that disfigurement is a proportion of how close the material of development is to its solidarity limit, and hence shows the likely level of harm that has happened.

There is a long history of applying solid checking strategies to take care of structural designing issues. For instance, vibrating wire or metal foil strain checks are notable devices for estimating resist individual focuses in a construction. Because the strain distribution is a function of the end conditions and the applied load, they are typically suitable for determining the

DOI: 10.1201/9781003299127-354

complete strain profile within structural components like beams or columns. However, foundations, tunnels, and pipelines—all of which interact with the ground—are exempt from this.

Since the soil loads are dispersed in these situations, it is impossible to fully comprehend the structure's state without knowing the entire site strain profile [Soga, 2015]. Problems caused by soil heterogeneity, such as deformations, rotations, and unevenly distributed soil and structural force interaction forces, can be identified with the assistance of knowledge of the continuous deformation profile. Conventional pinpoint strain measurements can miss such problematic areas [Soga, 2014]. FO distributed strain sensing became a tool to provide continuous strain profiling and, as a result, enhance our comprehension of civil structures around the middle of the 2000s.

For more than a decade, DFOSS has been used to measure the strain in civil engineering structures. It is now used worldwide to monitor a variety of structures, including diaphragm walls, tunnels, bridges, piles, dams, embankments, and bridges.

DFOSS depends after backscattering when lights communicated along an optical fiber. One standard ticular part of the backscattered light is created by Brillouin dissipating. Anytime along a fiber, the recurrence of Brillouin backscattered light relies on the strain and temperature by then. Considering the impact of temperature thusly, the strain anyplace along a fiber can be reasoned by communicating beats of light down the fiber and dissecting the recurrence of backscattered light.

DFOSS presents a novel approach to strain measurement in comparison to the utilization of isolated strain gauges in that:

1. The continuous strain profile along a structural element is returned by DFOSS. It is possible for strain gauges to miss vital strain variations between gauges because they can only provide discrete pointwise readings.
2. Electromagnetic interference does not affect optical fiber backscattering.
3. Pure, inert and extremely stable silica forms the core of optical fibers. The filaments in this manner oppose consumption, don't taint the neighborhood climate and have a design life estimated regarding many years.

Optical filaments can work over a lot more extensive scope of temperatures than most electronic gadgets.

Because of their small size and lack of intrusion, optical fibers are simple to incorporate into both new and existing structures.

The total strain profile can be recuperated for a fiber extending a few kilometers, potentially supplanting a huge number of discrete sensors. Installation is greatly simplified by using a single cable.

Because of the continuous improvement of DFOSS read-out units, a DFOSS framework inslowed down presently can profit from potential upgraded estimation capacities later on.

2 ENGINEERING-GEOLOGICAL INVESTIGATION OF THE CONSTRUCTION SITE

The site of the experiment was in Astana city, in the basement of the tallest building complex in Central Asia - Abu Dhabi Plaza, 320 meters high. Abu Dhabi Plaza is a complex high-rise building with a retail and leisure podium and a hotel cluster at the base that rises to form a series of office and residential towers to the north – a creation of the famous British architect Norman Foster (Figure 1).

The raft construction process is shown in Figure 2, the complex consists of several buildings, where fiber optic cable monitoring was carried out in 3 of them, blocks R, Z, Y. Block R is the tallest building in the complex and is a 75-storey residential building with a 4-storey underground parking at the base. The foundation structure of the building consists of a pile raft including Auger Cast Piles 1,125 m and boring piles with a diameter of 1.2 to 1.5 meters (Figure 2).

The length of the piles varies depending on the height of blocks from 13 to 25 m from high-strength concrete with an exposure durability of 40 MPa. The raft is built form the C28/35 concrete. The maximum design excavation level for the construction of a raft for block R was 19.30 m. The basement floors consist of 4 levels from B1 to B4 of the lowest.

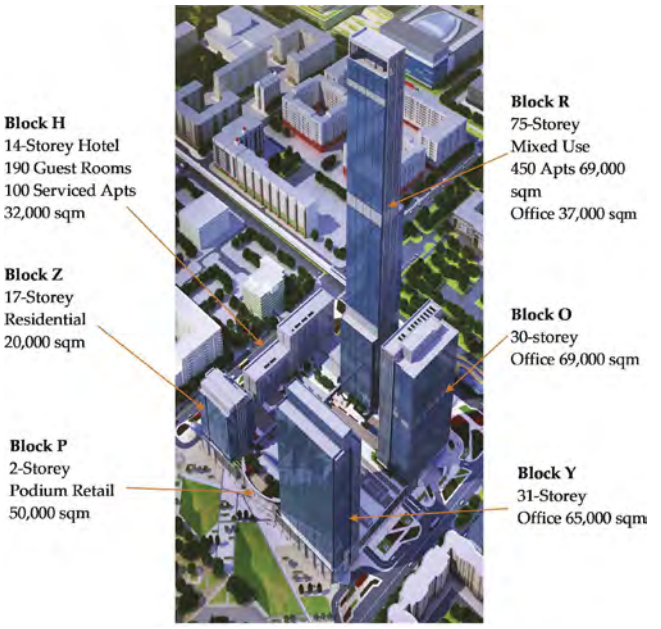

Figure 1. Abu Dhabi plaza building complex.

Figure 2. Construction site.

3 FIBER OPTIC MONITORING SYSTEM

3.1 *Design of distributed fiber optic strain sensing system (DFOSS)*

The proposed DFOSS system comprises a grid of fiber optic cable bonded to the B4 slab linked to an analyzer located in a temperature- and humidity-controlled room at B1 level.

On the B1 level, there is an analyzer of the monitoring system for temperature and strain data collected via distributed fiber optic strain sensing system (DFOSS) from B4 level (Figure 3). The applied DFOSS system transmits the signal via a grid of fiber optic cable to the B4 raft linked to an analyzer located in a temperature- and humidity-controlled room at B1 level.

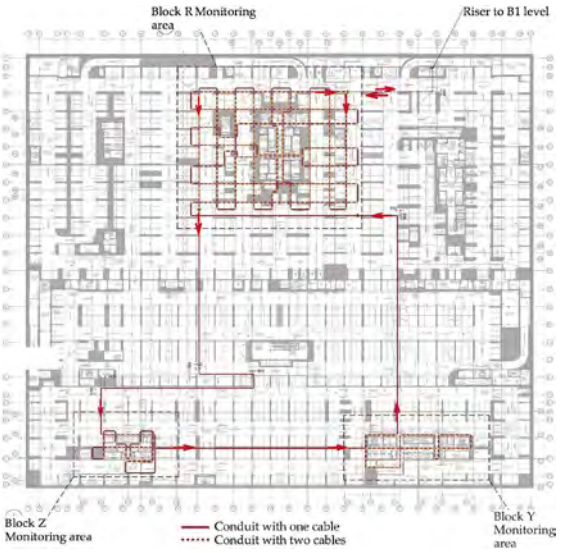

Figure 3. Part plan of cable routing in block R monitoring area on B4 raft.

3.2 *Analyzer and analyzer room*

The analyzer must operate within specified environmental conditions and so must be located inside a room whose temperature and humidity are controlled. The analyzer room will also accommodate the logging system and computer required to interface with the Internet and as such the room must be supplied with uninterrupted electrical power and a high-bandwidth Internet connection and must be sufficiently spacious for two operatives to work comfortably inside. A summary of the analyzer specification is presented in Table 1.

Table 1. Specification for analyser.

Parameter	Value
Spatial resolution	≤ 1.5 m
Optical budget	≥ 11 dB
Measurement resolution	≤ 22με
Distance range	≥ 2.09 km
Gauge length	≥ 2 m
Measurement range	≥ 1.5 %
Measurement interval	≤ 3hrs
Operational period	≥ 70 yrs
Data acquisition	Remote control and transmission via internet

Note – Optical budget includes both strain and temperature measurements cables configured in a loop

Particular consideration must be given to the routing of the fiber optic cables into the analyzer room from the riser used to route the cables to B4 level. The cables may be routed in channels cut into the B1 slab in a manner similar to the channels in the B4 slab. Running the channels through doorways instead of under walls would remove the need to demolish portions of blockwork wall to enable cable installation. Alternatively, the cables may be routed overhead via cable trays into the analyzer room (Figure 4); in this case blockwork at ceiling level will need to be removed for the cable to pass through any walls. Regardless of the routing method it is essential that the allowable curvature of the cable is not exceeded.

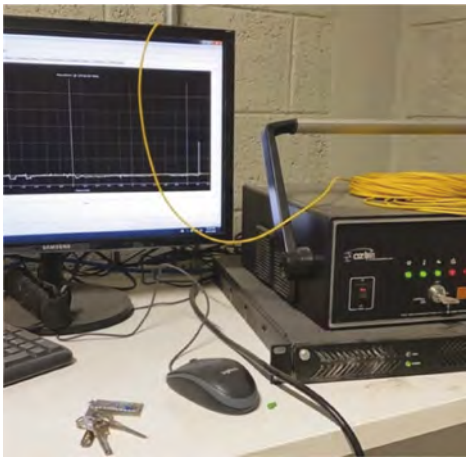

Figure 4. Monitoring room with typical analyser.

3.3 *Field results*

Emphasis in obtaining the results of the fiber optics was given to high-rise blocks, namely block R, where, as expected, the highest strain values of the fiber optic cable were obtained. C_T was found as 1.113MHz/°C, and Cε was equal to 0.054MHz/με. At the time of the measurements, the temperature field distribution was relatively stable and varied within + 4 +8°C over the entire area of the B4 level of block R (Figure 5). The location of areas with lower temperatures in the center of the building along the load-bearing walls of the core is explained by the greater thermal conductivity of reinforced concrete structures. Considering the depth of the raft -19 m and the allocation of the block R in the middle of the complex of buildings the ambient temperature did not affect to the results of the FO strain measurements during recording. Considering that the measurements were taken in February 2021, as well as the cold climate of Astana.

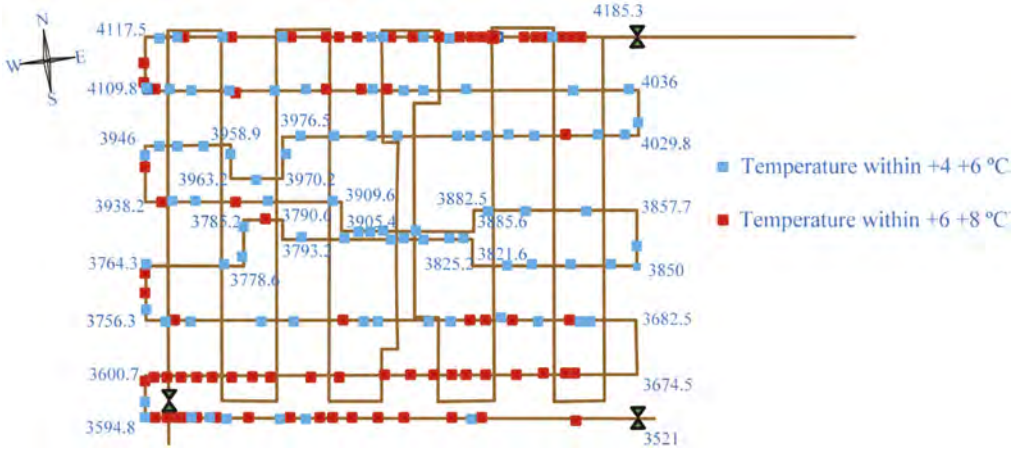

Figure 5. Temperature field distribution in block R.

As can be seen in Figure 6, the fiber optic results show alternating strain signs along the length of the fiber optic cable embedded in the raft of the lowest level B4 of block R. Compression deformations prevail in the central part of the building core, in the zone of

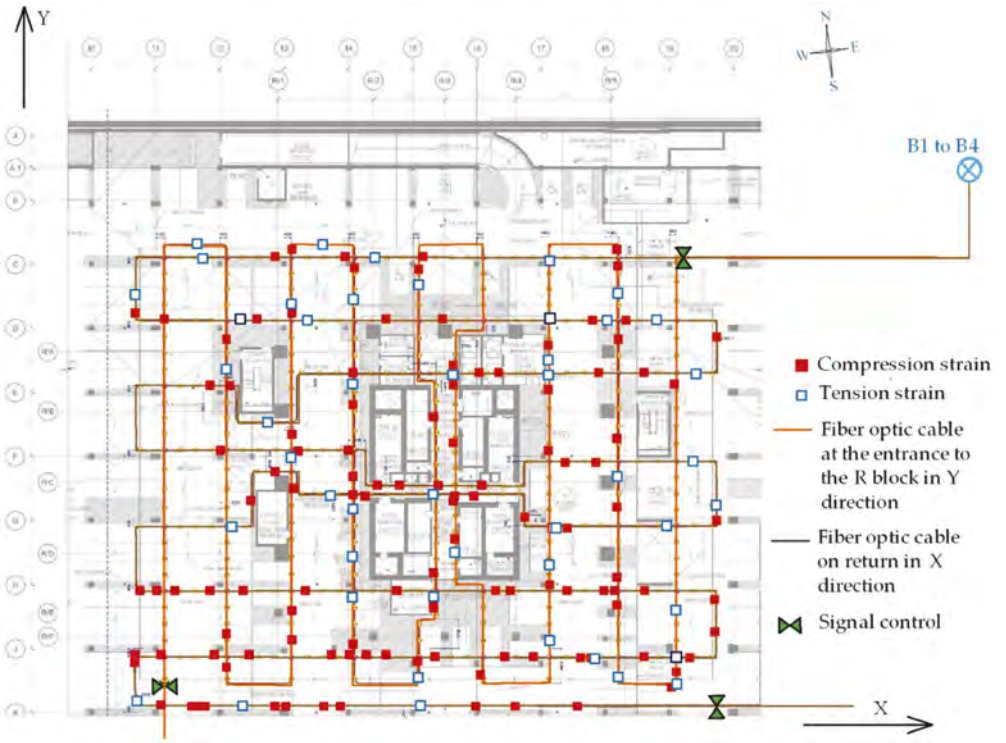

Figure 6. Fiber optic strain along the cable layout in the block R, level B4.

increased load from reinforced concrete load-bearing walls. Tensile deformations are most focused on the extreme axes, as well as near the joints of the columns. The interpretation of compression zones by values is shown in Figure 7 and tensile zones in Figure 8.

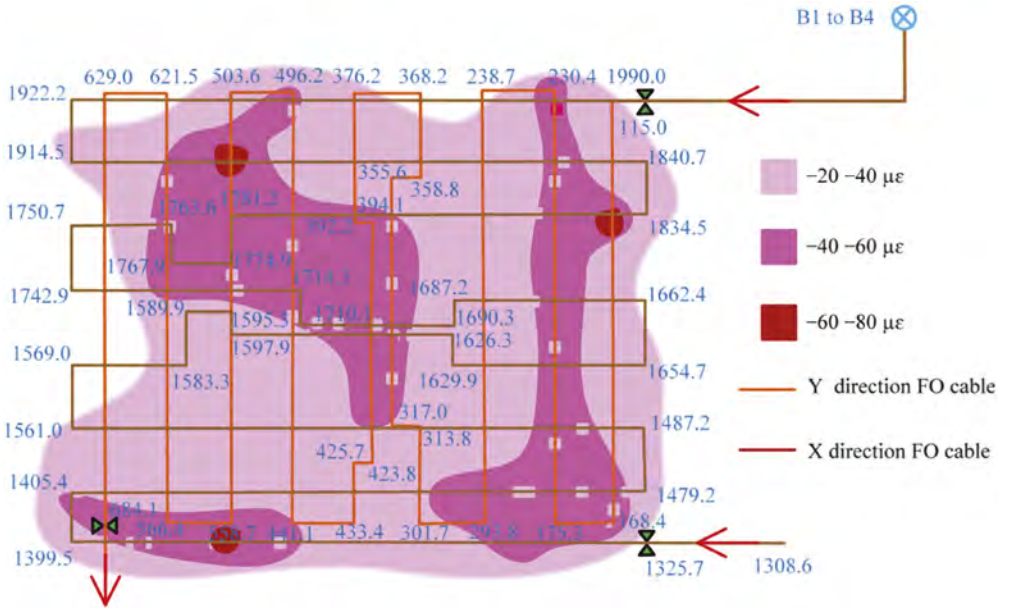

Figure 7. Zones subjected to compression strains.

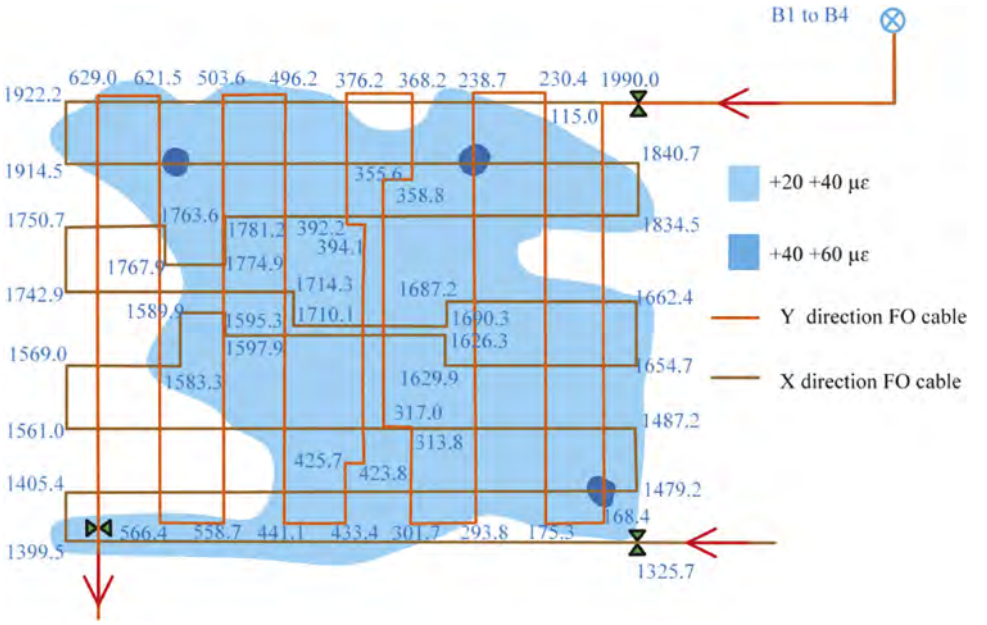

Figure 8. Zones subjected to tension strains.

Tension zones as indicated by Figure 8 are uniformly disseminated over values from −20 to −40 με, with a slight transcendence on the right (east) side of the structure. Individual spots of −40 to −60 με are once in a while situated along the external shape of the structure. Tensile stresses accumulate in more stable patterns in the building's center, north, and east [Buranbayeva, 2022].

4 CONCLUSION

The authors considered whether the distributed fiber optic strain sensing system technology could be used to monitor structures, using the Abu Dhabi Plaza complex's underground parking lot as an example in Astana's soil conditions. The technology enables you to evaluate the outcomes of geomonitoring in real time, ensuring the safe operation of underground buildings in the challenging engineering and geological conditions of Kazakhstan's capital.

The following conclusions were drawn as a result of the evaluation of the data used for structural health monitoring that was embedded in the raft plane of pile-raft foundations of a high-rise building at the beginning of its operation:

1. Fiber optic's monitoring made it possible to provide actual results of strains in the upper layer of the raft at the lowest level B4 of the high-rise 75-storey block of the Abu Dhabi Plaza building on multilayer soils of Astana city.
2. The compression strains were observed over the entire area of the building with values -20-40 με. A greater values of compression strain, -40-60 με, were registered in the center in the Y direction and along the eastern facade of the block R in the building core with some points up to - 60-80 με.
3. The tension strains are concentrated along the extreme axes of the building, with a predominance in the southern part of the R block, as well as in the immediate vicinity of the columns, in a range of + 20+40 με, with separate spots +40+60 με.
4. Individual patches of tension strains near the columns have been explained by the increased deflection of the raft under the application of a concentrated load (columns).

5. When a strain above 1000 με (1%) occurs, a basic structural analysis is recommended, above 1500 με (1.5%) a detailed structural analysis is required.
6. Fiber optic monitoring results at the time of testing did not exceed the permitted values for high-rise building operation; however, they characterized the general picture of the strain in the raft plane and make it possible to determine the initiation of cracks in concrete at an early stage.

ACKNOWLEDGEMENT

This work was funded by the Science Committee of the Ministry of Science and Higher Education of the Republic of Kazakhstan (Grant No. AP13268861).

BIM technologies - New design options in architecture

O.N. Semenyuk, U.D. Dyisebayev & V.S. Semenyuk
Gumilyov Eurasian National University, Kazakhstan

ABSTRACT: The difficulty and complexity of the problems solved in architectural design, the change in construction technologies, the development of new materials, require constant improvement of the methods of training in shaping, the widespread use of innovative systems for modeling buildings and structures, techniques and technical means in architectural creativity. The shaping of the future structure is of fundamental importance for the design. BIM is a comprehensive program that uses a common three-dimensional base for the model and tools, replenished and improved during the design process. BIM based on a parametric building model that combines 3D model and external data. Due to the interdependence of all elements, the model is correctly updated and allows you to automatically generate updated project documentation.

1 INTRODUCTION

Building Information Modeling (BIM) is a process that generates an information model of a building (structure), and for each stage there is a certain model that displays the amount of information processed (architectural, design, technological, economic) about a building or structure, to which all interested parties have access.

The conceptual model is a 3D sketch of the future building, which allows in the early stages of design to provide customers (investors, buyers) with a visually understandable concept of the future object (plans, facades, sections, bypasses).

This model quickly created and easily edited, which allows you quickly make changes at the initial stage of approval. BIM based on a parametric building model that combines 3D model and external data.

The ability to import the model into software packages (3ds Max and Lumion) allows you to quickly create high-quality photorealistic renders and animations.

The shaping of the future structure is of fundamental importance for the design. Traditional methods of solving this issue include the widest range of technical tools: manual sketch - clause, working layout, model in various 3D packages successfully imported into Revit.

In Revit Architecture, when searching for the shape of a building, you can immediately calculate very important characteristics for the project as areas and volumes, and their values will automatically change depending on the course of the simulation (Figure 1).

Mass elements allow you to perform tasks such as creating in-place or family-based instances of mass elements specific to individual project parameters, creating mass element families associated with commonly used building volumes.

You can change the materials, shapes, and relationships between the mass elements that represent the main components of a building, and design options.

Examine zoning mapping, both visually and numerically, by correlating the building's intended shape with its volume and floor area, and by composing complex mass elements from a library of standard families.

DOI: 10.1201/9781003299127-355

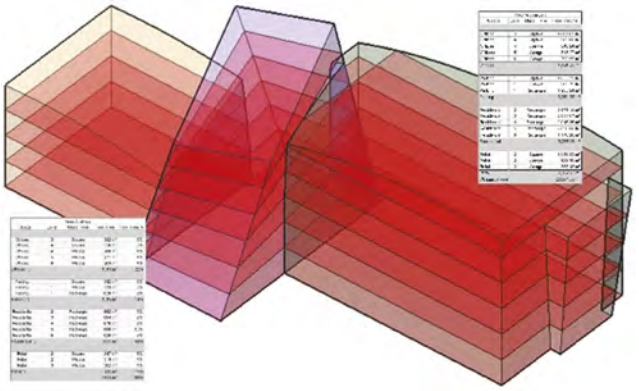

Figure 1. Model in Revit Architecture.

Creates floors, roofs, stained glass systems, and walls from mass instances when managing categories, types, and parameter values. When a mass element changes, the update of these elements is completely controlled [1]. BIM Technology helps to create a building project in a shorter time.

2 HISTORY OF BIM TECHNOLOGIES

The concept of computer modeling in construction began to develop back in the late 20th century. At that time, CAD technologies actively used, but the capabilities of technology did not yet allow us to move to a qualitatively new level.

The idea of BIM modeling takes its roots from the 1970s. In 1975, AIA (American Institute of Architects) published the work of Technology Institute professor Chuck Eastman, which first mentioned an information model of a building called the Building Description System. In parallel, similar work carried out in Europe. For example, in Finland in the early 1980s, the term Product Information Model came into use, and in the USA - Building Product Model. Both systems not focused on the design process, but on its object. Later, the general concept of Building Information Modeling formed.

In 1986, the creator of the RUCAPS program, English engineer Robert Aish, formulated the basic principles of the information approach to design:

- Automatic drawing;
- Creating 3D objects;
- Intelligent parameterization of buildings;
- Database rollup;
- Distribution of construction stages over time, etc.

The practical application of the technology demonstrated during the reconstruction of the third terminal of Heathrow Airport.

Since the early 2000s, the history of BIM technology has moved to a new round. The term has become one of the key in the global construction industry.

The concept of "building information model" was first mentioned in the current meaning in the article "Modeling multiple views on buildings" by G. A. van Nederwin and F. P. Tolman. This term came into wide use only in 2002 and began to use to name the digital representation of the construction process. The founders of modern BIM programs were the applications RUCAPS, Sonata and Reflex, ArchiCAD. Today, the key players in the global building information modeling market are Autodesk, Bentley Systems, Dassault Systemes, AECOM, Asite Solutions, Beck Technology, Nemetschek, Pentagon Solutions, Trimble Navigation, and Synchro Software [2].

In fact, the purpose of using information modeling technology is to embody numerical information in a form that is convenient for perception and analysis. The input data in the finished model is coordinated, coordinated and linked to each other. Each digit has a specific physical reference. It is can analyzed and calculated. Simplifies the procedure for making adjustments, updates.

3 OVERVIEW, APPLICATION

Preparation of architectural and construction projects in the BIM environment - a set of interconnected processes for creating an information model based on the customer's requirements. The technology of design, erection and operation of the object in BIM considered in the section of the life cycle (from the English product life cycle, PLM) of the product, in this case, the object of construction. The information model (IM), being a digital analogue, also experiences all stages of the LC: from the idea of creating an object to its reconstruction/dismantling (Figure 2).

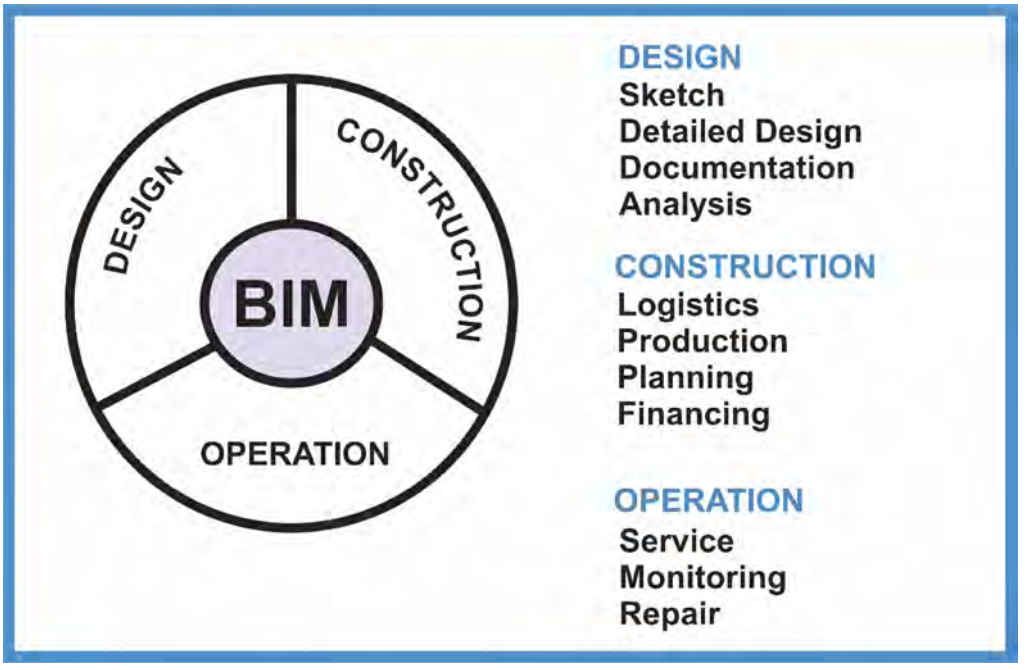

Figure 2. Preparation of architectural and construction projects in BIM environment.

BIM can considered both the process of building a model itself, and the finite model itself, saturated with information. An information model (IM) is information suitable for computer processing about a designed or existing construction site, while:

- Properly coordinated, coordinated and interconnected;
- Having a geometric reference;
- Suitable for calculations and analysis;
- Allowing the necessary updates;
- Interoperable [3].

BIM based on object-oriented design. This means that all programs working in this technology assume modeling based on a large number of pre-created objects, called families, the main design operations carried out with elements such as indivisible blocks, a kind of components. Each model element carries geometric and attribute information (Figure 3).

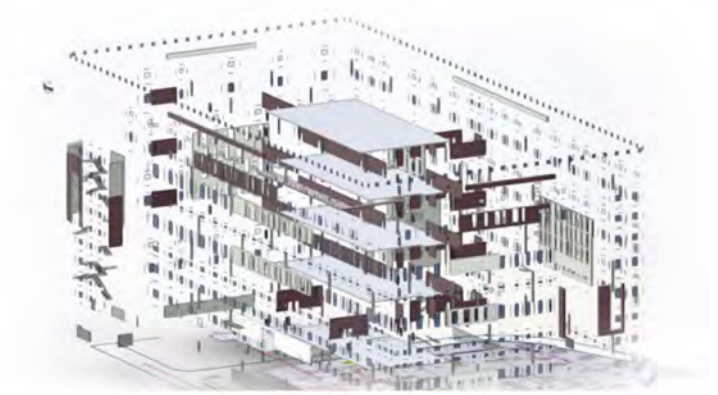

Figure 3. Each model element carries geometric and attribute information.

The unified information model involves collective work that brings together specialists from all design areas: technologists, architects, designers, engineers of internal and external networks, etc. Teamwork carried out in a single design environment, a pig (general data pig environment) and must comply with certain rules and interaction between the participants in the BIM modeling process, which are reflect in the BEP document.

The use of BIM technology in construction has many advantages:

- Visually inform contractors, investors, customers, controlling authorities about the state of the object using 3D visualization. Models can be demonstrated using special glasses;
- Centralized storage of the full range of data on the object under construction. When making changes to any one section, the designer can immediately follow the results and consequences in interconnected projections;
- Shortening project development time;
- Reducing the risk of errors, detecting inconsistencies at the design stage, and not during implementation;
- Quick and visual calculation of the main building structures. For the development of engineering complexes, already created bases of typical nodes and elements used;
- Real-time management. BIM design allows you to control the key indicators of the facility and the timing of the work;
- Automation of working equipment control processes;
- Quick unloading of information on the results of tests, surveys, data from design documentation, other information on request;
- Possibility of changing the financial parameters of the building, labor costs in individual specifications to adjust the total cost of construction;
- Centralized management of accounting, procurement, development programs;
- Easier and more efficient operation of buildings;
- Construction of a facility that meets the customer's requirements and desired characteristics as much as possible.

4 BIM MODEL CREATION PROCESS

The following algorithm can schematically display the process of creating a BIM model:

Creation Request (Sold-to Party)

- Formation of terms of reference, EIR;
- Development of the project implementation plan by the Contractor BEP;
- Pre-project, equipment layout;

– Design works;
– Approval;
– Development of detailed design documentation;
– Transferring the model to construction;
– Updating the model during LC;
– Archiving.

The information supplied to the BIM model stored and processed in this model and obtained from it for further use shown in (Figure 4).

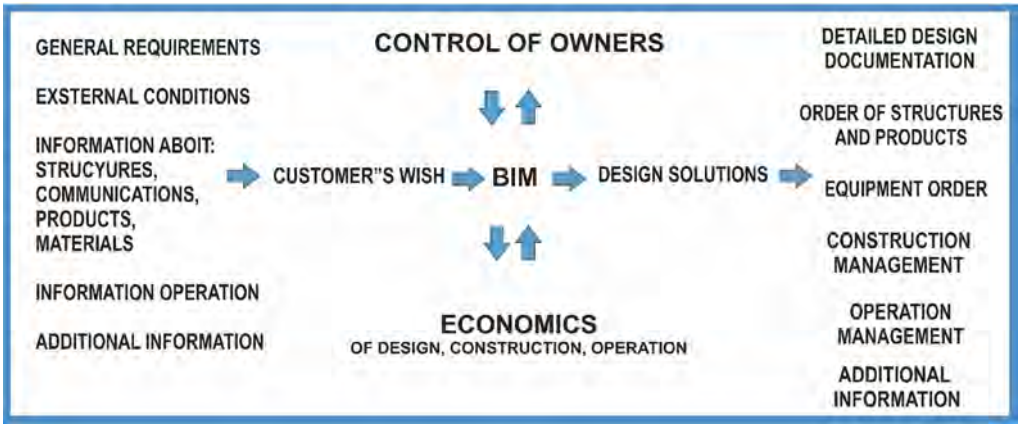

Figure 4. Information to and from the BIM model stored and processed in this model for further use.

The development and development of the model carried out in a common data environment (CDE), which means that all interested parties have constant access to the model filled with useful and up-to-date information: engineering, chronological, financial, and so on.

The delegation of access levels for a different circle of persons involved in the interaction process when creating an object ensures the clarity and relevance of the received data for each task. Thus, BIM covers all stages of the life cycle of a building or structure, continuously filling it with valuable information, which, in turn, significantly reduces the cost of its maintenance (OPEX), reduces the speed of construction, minimizes design errors, and allows all interested parties to have prompt access to information (Figure 5).

5 BIM DESIGN PHASES

The use of BIM technologies in design can conditionally divided into several stages.

Creates a 3D architectural model of the building. Visualize all sections, plans. The data required for the Architectural Solutions section is automatically loaded.

Calculation of parameters of the main elements of the building. The specialist enters the received model into a program that provides characteristics and simultaneously uploads drawings, specifications, lists, details of determining the estimated cost of construction.

Introduction of information about engineering networks. The 3D model determines the natural illumination level of areas, heat losses, and other important characteristics.

Development of WEP (Method Statement) and Construction Management Plan (Construction Management Plan). This step performed after the calculation of the scope of work obtained. The program automatically prepares the planning table.

Logistics. Enter information about the types of materials and the timing of their delivery to the object into the model.

Figure 5. Delegation of access levels for different groups of people involved in the interaction process when creating an object.

The process is as follows.

The program develops blocks that will manufactured outside the construction site and are not subject to division into parts, but are important components of the building: windows, doors, lighting and heating equipment, ventilation, floor slabs, etc.

They model the parts of the building that will erected directly on the site: walls, foundation, roof, facade system, etc.

At any stage, you can change one type of heating equipment to another, with different characteristics and costs, for example. The volumetric model is very flexible - this is one of the key advantages of BIM technology. You can change the modeling stages without performing large-scale additional work to adjust the project documentation.

When finished, the finished 3D model can used to operate the building. For this, a sensor system is used. The program monitors emergencies, operating modes of engineering communications, etc. The 3D model will automatically change its configuration and content according to the initial data throughout the life cycle of the building.

Information modeling of objects under construction does not replace traditional design, but is only one of the next stages of its development. It should understood that fundamental decisions still depend on the person, and the program only performs the work of finding, storing and analyzing the information provided. The difference lies in the quality and volume of processed data, which simply cannot handled manually and which brilliantly operated by the computer.

6 APPLYING BIM TO PROJECT PARTICIPANTS

Traditionally, building design involves working with separate two-dimensional projections: plans, drawings, technical documents. The BIM design technology allows you to collect and process data on all the main characteristics of the object in a single information field. The specialist gets the opportunity simultaneously analyze structural, architectural and planning, technological, economic, operational solutions in conjunction. The information rendered on a 3D virtual model with real physical properties.

However, the volumetric representation of the design data of the structure is not all the possibilities of BIM. The technology adds variables: cost, plans, timing. The parameters of the

building construction process can calculated even before the start of work. 3D Model Management enables you to find the best solutions to shorten project life and extend design life [4].

Using BIM for the customer allows you to solve the following problems:

- Visualization of the facility before the start of construction;
- Risk management in the implementation of the investment project;
- The ability to monitor the progress of design and construction based on the BIM model in real time with cloud services;
- Optimal technical solutions;
- Maximum accuracy of ICP cost calculation (according to AACEI);
- Control of compliance of design solutions and construction results;
- Obtaining a digital twin based on the results of construction (AS BUILD model for maintenance, reconstruction, dismantling).

Using BIM for the designer allows you to solve the following problems:

- Implementation of design with selection of options;
- Automation of routine operations;
- Reduction of time for making changes to the detailed design documentation;
- Reduce design errors with visualization;
- Interdisciplinary collaboration: collaboration of various specialists in 3D;
- Centralized document management on your server or in the cloud;
- Checking the project for collisions (intersection of engineering equipment with other elements) before the start of construction;
- Check for compliance with SP, GOST and SNiP in specialized software;
- Facilitating communication with the customer, expertise, builders;
- Protection of the process of transferring the design results to the customer.

Using BIM for builders allows you to solve the following problems:

- Clarity of technical solutions and the result of construction due to the presence of a BIM model;
- Visualization of the object erection in conjunction with the schedule;
- Setting tasks and deadlines for its execution with reference to the 2D- or BIM model;
- Introduction of electronic technical documentation of equipment and materials into the BIM model;
- Design documentation does not contain collisions, and therefore "surprises" at the construction site;
- Unloading of materials for PTD into one "click";
- Facilitated communication with project organizations due to the possibility of prompt introduction of changes and comments into the same BIM model;
- Introduction and approval of adjustments to the project directly at the construction site;
- The builder always has the latest version of the project documentation;
- Centralized document management on your server or in the cloud;
- Marking and notification of problems and/or changes clearly, with reference to the 2D- or BIM model;
- Unloading of as-built documentation from the BIM model.

BIM in operation:

- The BIM model corresponds to the constructed object;
- BIM-model building elements contain the necessary technical documentation;
- The presence of a BIM model allows you to quickly find and fix problems, carry out current maintenance of the object;
- Reception of text, audio and video applications about problems with reference to a specific location on the area and/or zone.

Market Compliance Challenge.

In-depth and comprehensive TEO analysis based on the LOD 200 BIM model variants; development of marketing materials.

– Resource and Risk Assessment Challenge.

Formation of primary requirements for equipment; assessment of technical specifications for connection to communications; options for the optimal location of the object on the ground.

– Database consistency Challenge.

All project participants have operational access to feedback information; modeling of calendar and network schedules of work performance based on IM.

– Deadline problem.

Modeling of calendar and network schedules based on IM.

– Budget savings.

Modeling of financial flows based on MI 4D.

– Reduction initial scope of work.

Through a clearly formulated budget, deadlines, compliance of the scope of work with the project.

– Project deviations.

Comprehensive analysis and approval of technical solutions during design check for collisions.

– Construction quality.

The materials and equipment used known in advance; the scope of work precisely defined; author's control based on MI.

– Labor protection.

By optimal arrangement and control of elements (fences, scaffolding, fire hydrants...) ensuring safety.

– The problem of operation.

Electronic passport of the facility, including all up-to-date information on equipment, materials, service life, monitoring and maintenance systems.

– The problem of transparency of the work process.

Data on the object and the progress of its implementation are available in the cloud (closed server);

Roles and responsibilities regulated by the requirements of EIR, BEP, etc...;

All changes promptly made to the model with the possibility of feedback;

Speed of decision-making and prompt monitoring of design/construction progress are available to all interested parties

VDC - we immediately predict based on the optimal decisions of them construction time, financial flows, minimized deviations, make operational management decisions.

8 DIGITALIZATION OF CONSTRUCTION IN KAZAKHSTAN

The size of the construction market of Kazakhstan in 2021 was estimated at $20.3 billion. The market was projected to grow at an AAGR of more than 5% between 2023-2026 [5].

Digitalization of construction in Kazakhstan is in full swing - thanks to an active state program - and this can called a feature of this market, which allocates Kazakhstan from many countries. Since the state program "Digital Kazakhstan" has been launched in Kazakhstan since 2018: now there are digital projects in the construction segment that are aimed at maximizing the digitization of many bureaucratic issues in construction and simplifying a number of procedures, contributing to the transparency of interaction between government agencies and end consumers. These include several innovative digital initiatives developed with government support.

Digital Construction Systems of Kazakhstan.

The E-Kurylys system is a single information system that is one of the digital tools for improving quality control and transparency of construction in the country. They are trying to lead with it state architectural and construction control in the Republic of Kazakhstan. All reports for each of the construction facilities are contained; the stages of acceptance and commissioning of the facilities recorded. There are more than 25,000 objects in the database.

E-PSD is a system for interaction between experts and customers. It stores all data on projects - from technical and economic indicators of the project and estimates, to standard projects.

Also in Kazakhstan, there is a single geoportal of infrastructure data (EGID). It designed to regulate urban planning and development of territories - it contains data on all general plans, planning and engineering nodes and infrastructure, as well as analytics of urban development. The database contains 63.7% of information about the engineering networks of the built-up area; the number of users in the system is about 2000.

E-SHANYRAQ. This system focused on the needs of housing and communal services. With its help, the effectiveness of the work of utilities monitored and analyzed - to ensure their transparency and productivity. This includes a water and heat metering instrumentation system, accounting and control of the operation of elevators, etc. The system helps quickly track the state of the communal infrastructure in order to make effective decisions.

As we can see, in fact, these systems took as a basis individual components of the information model, where the entire information on the project is located in one three-dimensional information model of a particular object.

With the introduction of BIM technology in Kazakhstan, things are also not bad - large construction companies-developers and private architectural bureaus offer design using BIM (more precisely, in Kazakhstan they prefer the abbreviation TIMSO- technology of information modeling of construction facilities).

That is, the maturity of BIM technology in Kazakhstan can defined as level 0, but the state is in every possible way interested in its development. In particular, Almaty General Plan has developed national standards for the use of BIM technologies taking into account international standards, in particular, the regulatory and technical framework for BIM: general provisions, design and construction, operation and information security).

Technologically complex facilities in the Republic of Kazakhstan used by TIMSO and experts at various specialized seminars and business conferences repeatedly voice support and the need to develop this technology.

The need for digitalization of construction and technology confirmed by such figures: in 2017-2019, it was spent on information and communication technologies (ICT) by 31% more than in 2014-2016. In 2020, 13.2 billion tenge was spent on ICT. In addition, in general, investments in technologies for construction demonstrate positive dynamics in the Republic of Kazakhstan. There is also a system "State Bank of Information Models," the purpose of which is to collect and provide all data on TIMSO facilities and for making decisions when implementing investment projects. 2023 is called the year when it is planned that the construction sector of Kazakhstan will switch to the widespread use of BIM technologies.

9 CONCLUSIONS

BIM is at the intersection of different disciplines. Using this modeling method in one project, you can combine comprehensive data on architecture, design, engineering, economic solutions and much more, which together allows you to avoid errors, increase the payback and efficiency of the project.

The data entered in accordance with the established standards, are accurate and updated regularly. One of the main advantages of the model is the reduction of time and costs on the part of the customer, as well as the ability to correct and improve the project at the first stages of its formation. Information modeling technology makes the customer a full participant in construction. It can visualize what the object will be like and make adjustments along the way. No 2D drawing will provide such a realistic picture of the future building as is possible with BIM modeling. It happens that the idea of an architect, designer or customer is not always feasible in practice, and only in the BIM model can this seen at the initial stages of design. With this type of design, a building that has not yet been built "comes to life" on the screen, making any shortcomings and possible problems noticeable.

For the model to work effectively, you need to create a single information environment that can provide instant access to the data of all project participants. A huge amount of data is tied to the digital BIM model, including work schedule, geolocation, and financial statements. Modern mobile applications are capable of reproducing virtual reality, which allows you to recreate a construction facility in real conditions and assess the progress of construction, while being anywhere in the world.

ABSTRACT: Geotechnics is an essential component of construction and engineering that involves studying how rock and soil interact with structures. Borehole drilling and sample collections are traditional methods used to collect subsurface data, but they are time-consuming, expensive, and only cover a small area. Information modeling technology can address these challenges by building intricate digital models of subsurface conditions that are more accurately and effectively used to design and analyze structures such as buildings, bridges, tunnels, and dams. This article discusses the main stages of creating an information model of a geotechnical object, including preparatory work, preliminary tests and work volume determination, field tests, and laboratory tests. The resulting digital engineering-geological model should include the geometric dimensions of the investigated soil mass and the physical and mechanical characteristics of the soils in the IFC data format.

1 INTRODUCTION

Any building or structure is built on a soil foundation or is located directly in the thickness of the soil. Its strength, stability and normal operation are determined not only by the structural features of the structure, but also by the properties of the soil, the conditions of interaction between the structure and the foundation (Talapov, 2021 & Talapo, 2015).

The cost of foundations is on average 12% of the cost of the structure, labor costs often reach 15% or more of the total labor costs, and the duration of the construction of foundations reaches 20% of the total construction time of the structure. In difficult soil conditions, these figures increase significantly. Therefore, the improvement of design and technological solutions in the field of foundation engineering will lead to large savings in material and labor resources, and a reduction in the construction time for buildings and structures (*https://www.planradar.com/ru/bim-tekhnologii-v-stroitelstve*).

With the assignment to the city of Astana of the honorary title - the capital of the Republic of Kazakhstan, the development of its territory is being carried out at an accelerated pace. Under these conditions, the analysis and optimization of one or more factors that are repeatedly repeated in production can provide a significant economic effect, as well as significantly improve and increase the efficiency of this type of work.

The territory of Astana is due to rather complex engineering and geological conditions, which is confirmed by a large variety of stratification of relatively weak soils in the upper part of the base, but at the same time, the bearing layers of the soil turn out to be quite reliable (*https://www.planradar.com/ru/bim-tekhnologii-v-stroitelstve*).

Designers in these conditions, when choosing foundations, often use pile foundations, the bearing capacity of which is not fully used in projects, and in some cases its underutilization reaches 40%. This leads to unjustified expenditure of funds, material and labor resources, due to the incomplete use of the bearing capacity of piles in terms of soil and material.

DOI: 10.1201/9781003299127-356

The design and construction of economic structures of pile foundations is possible if there is sufficiently representative and reliable information about the conditions of occurrence and properties of soils at construction sites, which are obtained as a result of soil studies during engineering and geological studies.

The presence in the projects of excessive reserves of the bearing capacity of piles can be explained by the following reasons:

- inferior engineering and geological surveys.
- manifestation by designers of excessive caution due to the fact that the structures of pile foundations are assumed by them to be insufficiently reliable;
- the experience of previous construction, in similar soil conditions, is not taken into account.

Geotechnics is a crucial aspect of construction and engineering. It entails examining and comprehending how rock and soil behave and interact with structures. Construction projects might suffer from costly and deadly mistakes if subsurface conditions are not accurately or sufficiently disclosed. Borehole drilling and sample collection are two common traditional techniques for getting subsurface data, but they can be time-consuming, expensive, and only cover a small area.

These issues can be resolved using information modeling technology, which builds intricate digital models of subsurface conditions. These models can be used more accurately and effectively to build and analyze structures. This article examines the use of information modeling technology in geotechnics.

2 GEOTECHNICAL ENVIRONMENT OF ASTANA CITY

The mechanical composition of floodplain deposits is more or less uniform. This is unsorted gravel, sandy-clay and loamy material. The heaviest precipitation is observed in the floodplain of the Nura and in the narrowed sections of the Ishim valley. Floodplain deposits of Kulanutpes are usually sandy-loamy. The formation of spits and shoals is currently taking place. Deposit thickness up to 4m. In terms of studying the geological features of the territory of Astana, the results of studies obtained in the course of his work by Popov V. N. are also of particular interest (Zhussupbekov et al. 2023 & Zhussupbekov et al. 2021 & Zhussupbekov et al. 2019a & Zhussupbekov et al. 2019b & Zhussupbekov et al. 2020) and Alibekova N.T. (Alibekova et al. 2020 & Zhussupbekov and Alibekova. 2013).

Popov V.N. in his work (Zhussupbekov et al. 2023 & Zhussupbekov et al. 2021 & Zhussupbekov et al. 2019a & Zhussupbekov et al. 2019b & Zhussupbekov et al. 2020), conducted research to assess the geotechnical conditions of the territory of Astana, the results of which include:

- description of geomorphological characteristics, within the boundaries of the city, on the basis of which a geomorphological map was compiled at a scale of 1: 100,000;
- hydrological conditions were described and a hydrological map was drawn up at a scale of 1:100,000;
- the geological conditions were studied taking into account the influence of geotechnical loads and a geotechnical map of the scale 1:100000 was compiled, with an explanatory table to it;
- an assessment of the physical and mechanical properties of soils was made by conducting a complex of field and laboratory studies;
- an assessment of the geo-ecological state of the territory was given.

The predominant geomorphological type of terrain in the region of Astana and the adjacent territory is the watershed plain. The southwestern part of the territory is characterized by two types: high and low floodplains.

The floodplain terrace separates the high floodplain from the watershed plain, which can be classified as a river terrace (Figure 1).

In addition, on the basis of the geomorphological map, a geotechnical map (Figure 2) of the territory of Astana was compiled.

On the basis of the geophysical surveys and reference drilling with a depth of up to 40 m, Popov V.N. indicated that along the Astana-Rozhdestvenka highway there is a zone of a sharp

drop in the depth of the roof of sedimentary rock, extending in the meridional direction (Figure 1), which should be addressed attention when designing high-rise buildings in the area.

Alibekova N.T. (Zhussupbekov et al. 2023 & Zhussupbekov et al. 2021 & Zhussupbekov et al. 2019a & Zhussupbekov et al. 2019b & Zhussupbekov et al. 2020 & Alibekova et al. 2020 & Zhussupbekov and Alibekova. 2013), together with Japanese geotechnicians, for the first time created the Geoinformation Database program based on the materials of engineering and geological surveys to assess the engineering and geological conditions of the built-up area of the city.

This program, at the time of its creation, included data from 1200 boreholes, 402 static sounding points and 125 dynamic sounding points and static and dynamic load pile tests, which made it possible to analyze the regional soil conditions before a detailed study (Figure 2) (Buranbayeva et al. 2023 & Zhussupbekov et al. 2022 & Buranbayeva et al. 2021 & Omarov et al. 2021 & Zhussupbekov et al. 2021 & Zhussupbekov et al. 2020a & Zhussupbekov and Omarov 2020 & Zhussupbekov et al. 2020b & Zhussupbekov et al. 2019a & Zhussupbekov et al. 2019b & Zhussupbekov et al. 2019c & Zhussupbekov et al. 2018 & Zhussupbekov et al. 2015 & Zhussupbekov et al. 2016a & Zhussupbekov et al. 2016b).

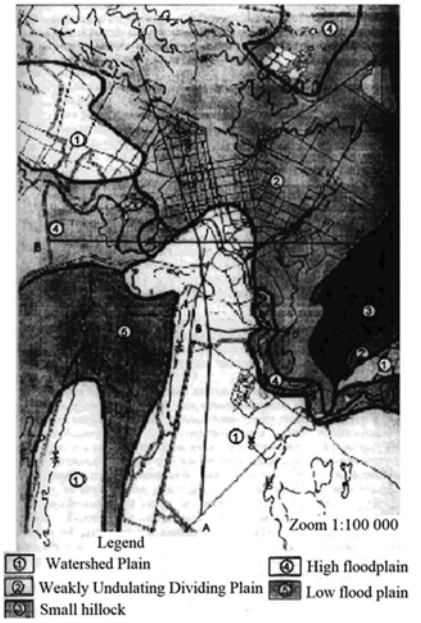

Figure 1. Geomorphological map. (Popov).

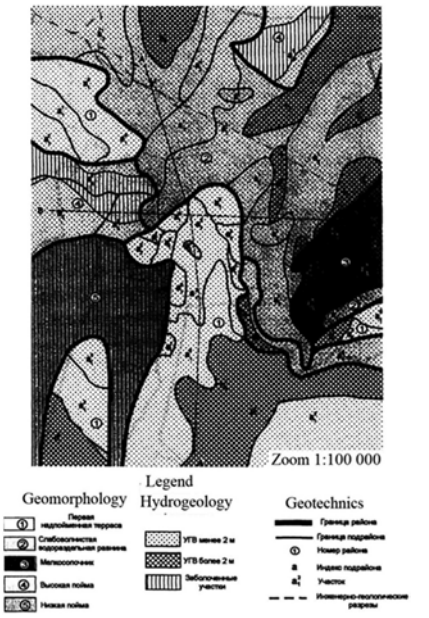

Figure 2. Geotechnical map of Astana.

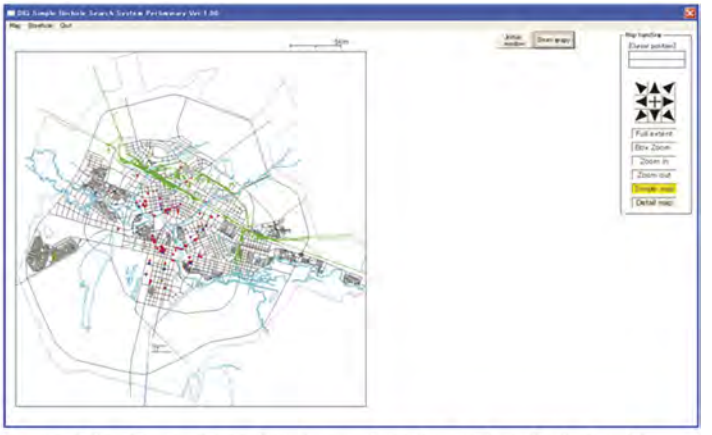
With the help of the "Geoinformation Database" program, six main engineering-geological elements (EGE) of various origin and age were identified, and maps were built for them by thickness [9]:

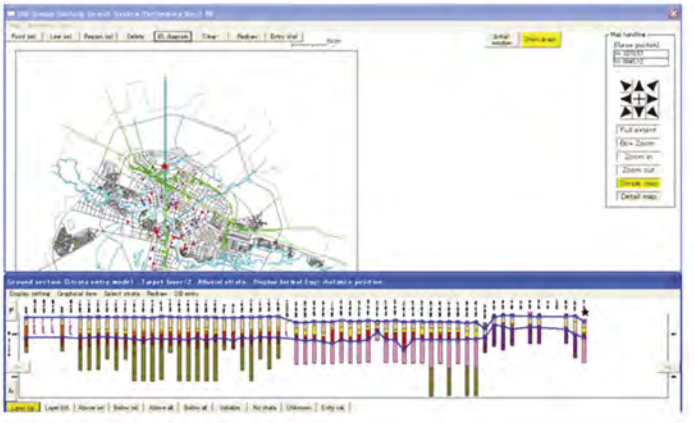
- EGE-1 - technogenic deposits (tIV) are represented by a soil-vegetation layer (EGE-1a) and bulk soil (EGE-1b). The loamy soil-vegetation layer has a thickness of 0.2 to 0.5 m. Bulk soils are composed of Quaternary loams, construction and household waste, the thickness varies from 0.2 to 2.0 m.
- EGE-2 - alluvial mid-Quaternary modern deposits a (QII-IV) are represented by clayey soils, consisting mainly of loams (EGE-2a) with intercalation of sandy loams (IGE-2b), clays (IGE-2c) and silt (IGE-2g), throughout their thickness they have lenses and interlayers of sands of various sizes up to 1-3 cm, sometimes up to 10 cm. The thickness of these soils varies from 0.9 to 10.0 m.
- EGE-3 - alluvial mid-quaternary sand and gravel formations a (QII-IV) consist of sands of various sizes (EGE-3a), gravel sands (EGE-3b) and gravel soils (IGE-3c). The thickness of

sands of various sizes varies from 0.4 to 8.3 m, gravelly sands from 0.5 to 6.5 m, gravel soils from 1.0 to 9.2 m.

– EGE-4 - eluvial formations of the weathering crust e(C1) are presented in the form of loams and clays with lenses and interlayers of sandy loams and inclusions of gruss-rubble soils occurring at depths of 6.0-10.0 m.
– EGE-5 - eluvial formations in the form of gruss-rubble soils e(C1) are widespread in the study area and they were found at depths from 7.0 to 23.0 m.
– EGE-6 - sedimentary rocks of the Lower Carboniferous (C1) are represented mainly by sandstones, which are interbedded with siltstones and mudstones of the same age throughout their thickness. They occur at depths from 11.6 to 26.2 m.



a) a map of the city territory showing engineering and geological wells



b) geological and lithological section South-West

Figure 3. General view of the program "Geoinformation database" (Alibekova et al. 2020).

In addition, with the help of the Geoinformation Database program, engineering-geological sections were built, which made it possible to assess the conditions of soil occurrence, on the basis of which it was revealed that these elements form about eight types of foundations up to bedrock (Figure 4).

The engineering-geological, geomorphological and hydrological description of the territory of Astana considered above by various authors in their works V.I. Dmitrovsky, Popov V.N. and Alibekova N.T. (Figure 4) provide a cartographic display of the construction characteristics of the geological environment and make visual results of engineering and geological surveys, and

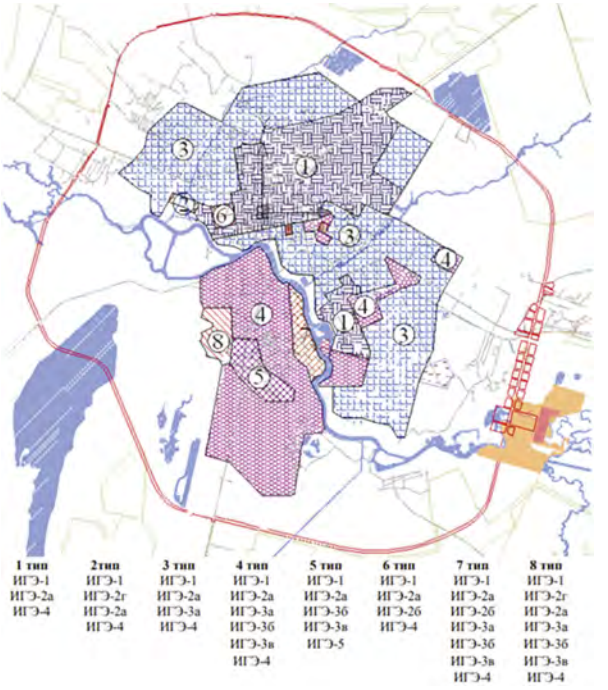


Figure 4. Zoning of the territory of the city of Astana by types of grounds (Zhussupbekov and Alibekova 2013).

can also serve as the basis for the analysis of the geological environment in order to optimize the length of the piles.

3 GEOTECHNICAL USE OF INFORMATION MODELING TECHNOLOGY

The creation of digital models of subsurface conditions is a step in the application of information modeling technology in geotechnics. The process includes collecting data on soil and rock layers, groundwater, and other geological features, and creating a three-dimensional digital model using specialized software. The digital model can then be used to design and analyze structures, such as buildings, bridges, tunnels, and dams.

The step of data collection entails boring holes, gathering samples, and performing laboratory tests. A three-dimensional model of the subsurface conditions, including soil and rock layers, groundwater, and other geological elements, can be made using the data gathered. To build a more complete model, this digital model might also include additional data, such as topographical and environmental data.

The digital model can be used to design and examine structures once it has been constructed (Liam et al. 2016). The behavior of the rock and soil layers and their interactions with the structure can be simulated by the software. This can assist identify potential problems before construction and offer insightful information on the structure's performance.

Let's consider the main stages of creating an information model of a geotechnical object:

1. Preparatory work.
   Create a project. Enter the site plan of the survey area. Enter the technical characteristics of the object. Enter the locations of the boreholes and field tests. Choose a method of field testing and enter equipment parameters. Choose the type of correlation equations.
2. Preliminary tests and determination of work volumes.
   Perform preliminary static penetration tests at four points at the corners of the survey area,

determine the type of soils (engineering-geological element), physical and mechanical properties of soils, and the depth of compressible strata. Refine the number of boreholes and field test locations, the volume of field and laboratory soil tests. Make changes to the site plan.

3. Field tests.
   Static probing. Dynamic probing. Testing with a flat or helical stamp.
4. Laboratory tests.
   Using the data from field and laboratory tests, develop a digital engineering-geological model (DEGM) of the survey area (in IFC data format). The model should include the geometric dimensions of the investigated soil mass and the physical and mechanical characteristics of the soils. An example of such a model created in the Geotek Field program is shown in Figure 5.

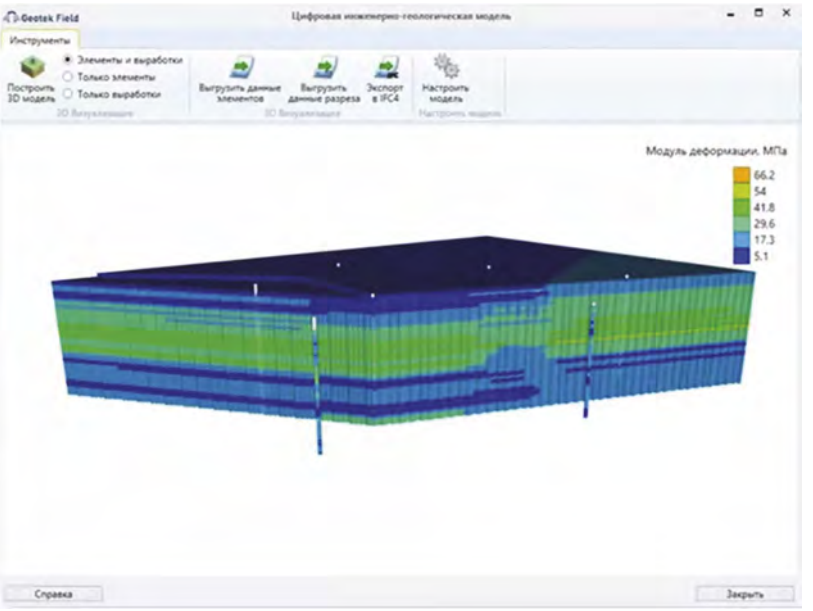

Figure 5. Digital engineering-geological model of the base of the building.

The file with the IFC extension contains an information model of a building or structure and is used to exchange model data between different computer-aided design systems that support the Building Information Modeling (BIM) standard. The file includes data on spatial elements, materials, and forms of the construction object model. Programs such as Graphisoft ArchiCAD, Autodesk AutoCAD, FreeCAD, and others support working with IFC files.

From the point of view of the authors of the article, which explores the potential use and benefits of BIM technologies in the construction sector (Bryde et al. 2013), a BIM model should include at least the following geotechnical information:

1. Information on geological workings.
2. Rules for constructing engineering-geological sections between wells.
3. A table of the main indicators of physical and mechanical properties of soils, determined in accordance with the current normative literature.

The following information may also be present:

1. Results of static probing performed directly at the construction site.
2. Results of soil testing with screw stamps or pressiometric tests.
3. Protocols for conducting soil tests, including triaxial tests.
4. Results of determining additional characteristics (RQD, OCR, data from dynamic probing, data from geophysical studies, etc.).

5. Data from hydrogeological studies.
6. Alternative data on the main indicators of physical and mechanical properties of foundation soils as a result of additional surveys.
7. Data on work performance (including ground freezing, excavation of the pit, discrepancies in the actual geological structure compared to the results of engineering-geological surveys, deviations of piles from design positions, presence of a sludge layer, defects in piles, results of concreting, lack of contact between the foundation and the base, defects in waterproofing, etc.).
8. Information about communications.

Note that the engineering digital terrain model usually includes information about communications that are located close to the surface. However, part of the communications on it cannot be shown for various reasons.

When constructing foundations, the possible number of adjustments to the design documentation is significantly higher than when constructing aboveground structures. This is due to the difference in the actual geological structure of the site from the results of surveys, the presence of hidden voids in the soil, and the impossibility of accessing all areas of the constructed structures (primarily this applies to piles and structures constructed using the "wall in the ground" method). From this perspective, the implementation of information technologies in the production of work on the construction of all types of foundations is a relevant task.

3.1 *Conclusions*

The analysis of the engineering-geological conditions of the territory of the city of Astana and the experience of building pile foundations in the territory of Astana in the conditions of a variety of building complexes and soil stratification made it possible to establish that the engineering-geological conditions of the construction area and the characteristic features of buildings and structures are not sufficiently taken into account when forming the development of quarters, choice of foundation designs and technology of their construction. These circumstances lead to a significant rise in the cost of foundations and lengthening the construction of buildings and structures.

The application of BIM technology in geotechnical engineering provides a collaborative platform for collaboration among all stakeholders, from the geotechnical engineer to the architect, contractor and owner. It provides a 3D model that can collect and visualize geotechnical data, including soil profiles, well logs, and geophysical surveys. This data can be used to make informed decisions during the design phase, such as choosing the best type of foundation or slope stabilization measures. Geotechnical engineers can model soil and structure behavior, analyze the effects of various loads, and optimize the structure accordingly. During the construction phase, BIM technologies can be used to create a virtual construction site that allows contractors to plan construction sequences, visualize earthworks and identify potential hazards. The use of BIM technology allows you to increase efficiency, as well as reduce the number of errors and rework. In conclusion, the use of information modeling in geotechnical engineering has revolutionized the industry by providing a collaborative platform for all stakeholders from the design phase to construction, maintenance and management. By incorporating geotechnical data into the BIM model, engineers can design more efficiently, reduce errors, and optimize designs for safety and sustainability.

Modeling of geogrids in the analysis of the stability of reinforced soil structures with the finite element method

A.V. Kuznetsova
Tensar Innovative Solutions, Russia

ABSTRACT: Finite elements models (FEM) programs have become an integral part of geotechnical analysis. However, the inclusion of geosynthetics in the model often gives results that differ from the actual behavior of the structure. The classic way is the modeling of a geogrid in the form of a membrane with specified strength parameters. The list of these parameters and methods for their determination are not spelled out clearly enough in the design and test standards. The author proposes to investigate both the finite element and analytical models and estimate their cohesion with the monitoring results and ability to fully consider the effect of geogrids.

1 INTRODUCTION

Reinforced soil was used for retaining systems since ancient times. Ziggurat in Mesopotamia, Roman marinas, the Great Wall of China and a lot of other structures were built using this technology. But today's methodology of design and construction has started its development in 1960s by Henri Vidal. Until the two last decades of technology development mainly analytical design methods have been used by engineers. But today finite elements models (FEM) serve to check the validity of the design for complex geometry, geology or loading. The classic way is the modeling of a geogrid in the form of a membrane with specified strength parameters. The list of these parameters and methods for their determination are not spelled out clearly enough in the design and test standards. In this study author defines time and load dependent parameters for both analytical and FEM methods, provides comparison of results of both approaches and makes propositions for the further development of the model.

2 REINFORCED SOIL MODELING

2.1 *Analytical methods*

A number of analytical design methods have been developed since 1960s. All of them analyze the balance of forces and mainly differ in terms or partial factors and a degree of conservatism.

Reinforcing elements are described by their design strength calculated as short-term tensile strength reduced by a row of durability parameters including creep, installation damage and environmental influence. The purpose of the analysis is to check the balance between acting and resisting forces as shown in Figure 1.

Analytical methods have been widely used during the last three decades and are showing good correspondence with the actual structure behavior.

DOI: 10.1201/9781003299127-357

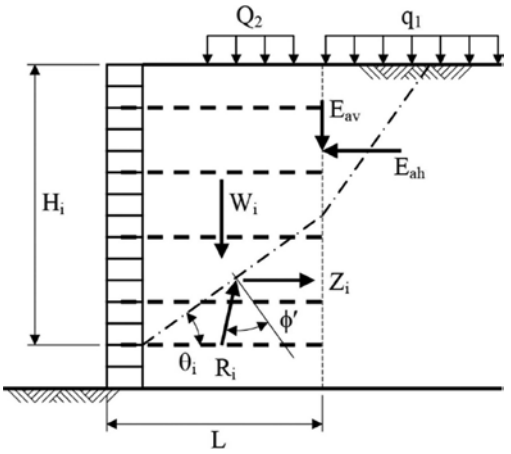

Figure 1. Scheme for calculating the internal stability of a reinforced soil retaining wall.

H – total height; H_i – distance from the top to the wedge base; L – length of geosynthetic material; φ' – fill angle of friction; θ – angle from horizontal to the failure surface; Q_2 and q_1 – surcharge; E_{ah} and E_{av} – horizontal and vertical components of active force and surcharge; W_i – failing wedge weight; Z_i - required resistance force; R_i – base resistance force.

2.2 *Finite element analysis (FEM)*

Firstly used for homogeneous soil structures, FEM now covers all types of reinforced soil applications, including retaining walls. Geogrids are implemented as membrane elements with given stiffness or modulus. Soil models are well calibrated with actual soil behavior, but geogrid models are far from that point. For that purpose, a number of real laboratory tests have been modeled with the use of FEM, like tensile strength test or pull-out test, shown in Figure 2 and others. But the behavior of a full structure still cannot be predicted accurately.

Figure 2. Geogrid model used for correlation.

FEM highly overestimates facing deformation due to the inability to model the actual grid influence on the fill material.

3 DESIGN STRENGTH AND STRAIN OF A GEOSINTETIC ELEMENT

3.1 *Design strength*

Design strength is described in a number of national standards and manuals for reinforcement soil design (BS8006, EBGEO and etc.) as a strength, guaranteed on the last year of service

after material was affected by creep, installation, aggressive environment, microbiology and UV. For polymer geogrids and geotextiles creep is the main reduction parameter and it could drop the strength to 30 – 60 % of quality control short-term strength. Figure 3 shows the difference in creep behavior of HDPE geogrid depending on the load applied. For this particular material creep test the long-term creep strength for 120 years is set as 24kN/m.

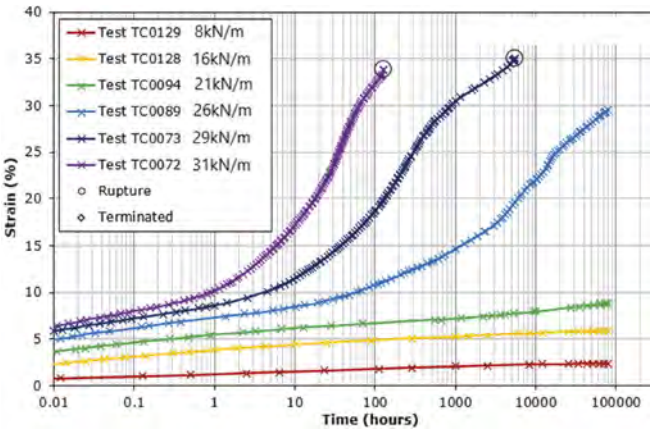

Figure 3. A series of creep test.

This number is used for ultimate limit state (ULS) analysis, that models a case where geogrid is ruptured. But for the serviceability limit state (SLS) that investigates geomaterial strain during the post-construction period, allowable load for geogrid should be limited even stricter. For reinforced soil retaining wall geogrid strain during the service life is limited by 1% only. Due to this design strength for the material above is set as 10kN/m for SLS analysis.

3.2 *Creep related stiffness*

FEA uses the stiffness of material that is generally obtained as load (strength) divided by strain. From geometry point of view stiffness could be compared looking at the degree of lines in Figure 3. First, it differs dramatically depending on the load applied, but Figure 4 indicates that even for the single load it changes during the test.

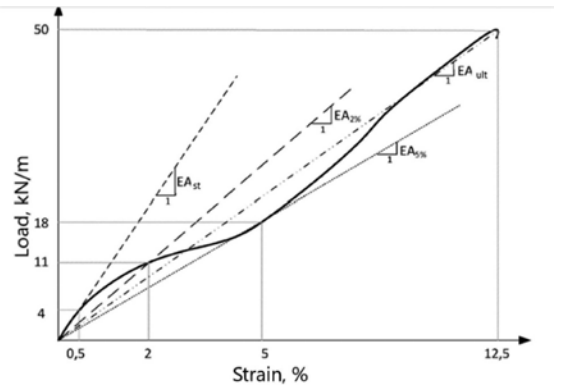

Figure 4. Stiffness deviation during the test.

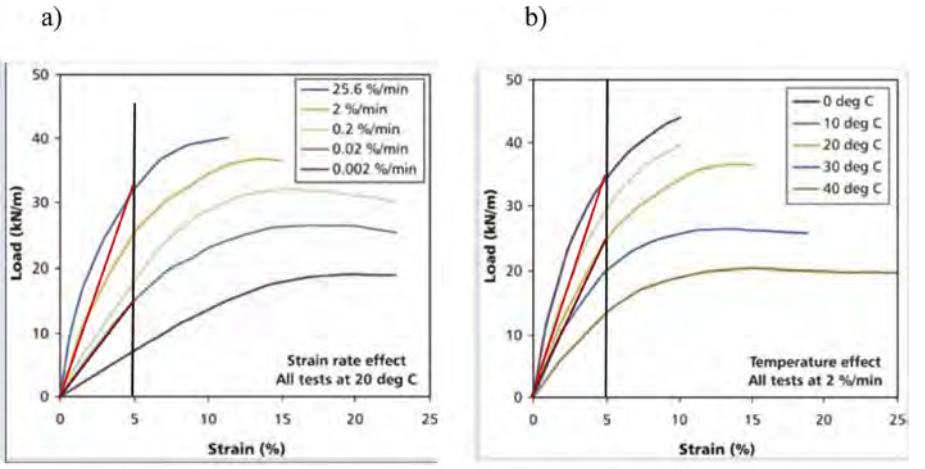
In Russian design manual for geosynthetic materials FEM ODM 218.3.120-2020 short-term stiffness at 2 or 5% load is recommended as a performance related parameter. During the service life HDPE geogrid is subject to permanent load equal to 5 – 45% of its short-term strength. It could hardly be correlated with short-term 2% strain load recommended in ODM. For example, 50kN/m strong HDPE grid shows a short-term stiffness at 2% equals to 500kN/m but the 120 years creep test isochrone provides 262 kN/m for 2% strain.

Apart from loading speed and type there is one more significant factor for polymer geogrids – design temperature in the soil massive. ISO/TR 20432:2007 proposes to define it as the temperature which is halfway between the average yearly air temperature and the normal daily air temperature for the hottest month at the site. Creep behavior related to test speed and temperature is shown in Figure 5.



a) short- and long-term stiffness comparison; b) stiffness at various temperatures

Figure 5. Stiffness deviation due to loading speed and temperature.

Summarizing the above, the list of input data is the following:

- design life;
- design temperature;
- durability parameters;
- actual load in reinforcing element as partial from short-term strength.

To provide this data, geogrid should have been tested for creep at all range of loads from 5% to maximum creep related strength that differs from 40 to 70% depending on polymer type.

During a finite element analysis operator or software defines the actual load in reinforced element and uses the corresponded stiffness. For example, Plaxis includes Elastoplastic (N-e) geogrid model that requires stiffnesses at all load proportions and chooses the proper one automatically.

4 FINITE ELEMENT MODEL

4.1 *Soil slope model*

To highlight the difference between soil and reinforced soil models two structures are shown. First one is a Mohr-Coulomb simple soil 6m high embankment with no geosynthetic material. Main design properties are shown in Table 1.

Table 1. Design properties for soil slope.

Parameter	Fill	Foundation
Cohesion, kPa	1	-
Angle of friction, °	36	-
Su, kPa	-	125
Unit weight, kN/m3	19	18

Stability analysis shown in Figure 6 provides a factor of safety equal to 1,22.

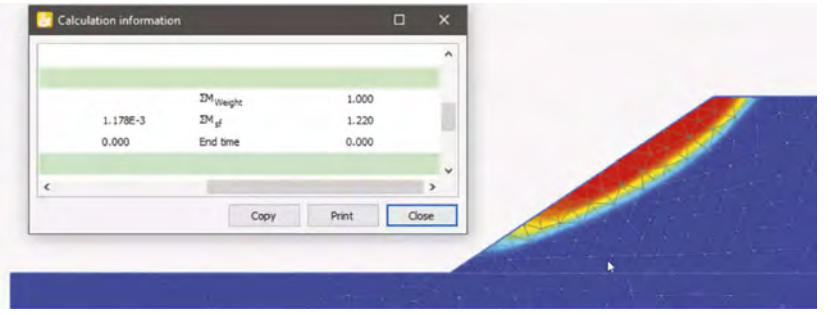


Figure 6. Simple slope FEM analysis.

The same slope modeled by analytical method shows a non-circular slip surface with quiet close nature and safety factor of 1,206 as per Figure 7.

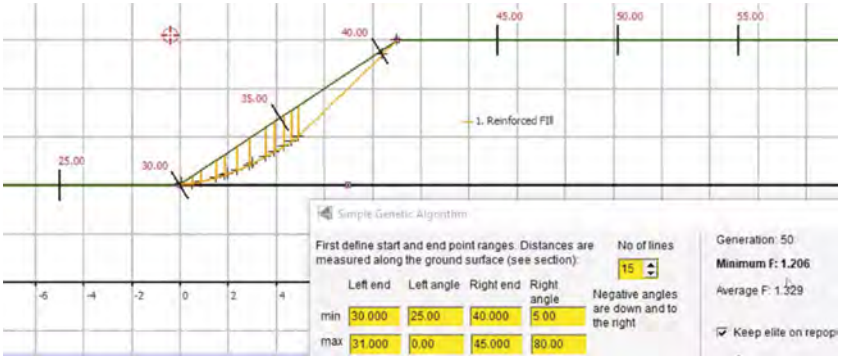

Figure 7. Simple slope analytical analysis.

Based on this, we can assert a high convergence of finite element and analytical modeling the results.

4.2 *Reinforced soil model*

Second model represents a 6m high reinforced soil structure with facing wrapped around sandbags. Main design properties are shown in Table 2, section is shown in Figure 8.

Table 2. Design properties for soil slope.

Parameter	Reinforced soil	Retained fill	Foundation	Soilbags
Material model	H-S (Drained)	H-S (Drained)	M-C	M-C
E_{50}^{ref}	25.000	20.000	-	-
E_{oed}^{ref}	25.000	20.000	-	-
E_{ur}^{ref}	75.000	60.000	-	-
m	0.5	0.5	-	-
E, kN/m^2	-	-	37.500	30.000
v	-	-	0.35	0.30
λ*	-	-	-	-
k*	-	-	-	-
c', kPa	1	0.1	-	10
s_u,kPa	-	-	125	-
Angle of friction, °	36	30	-	30
ψ, °	0	0	-	-
Unit weight sat, kN/m3	19	19	18	19
Unit weight sat, kN/m3	19	19	18	19

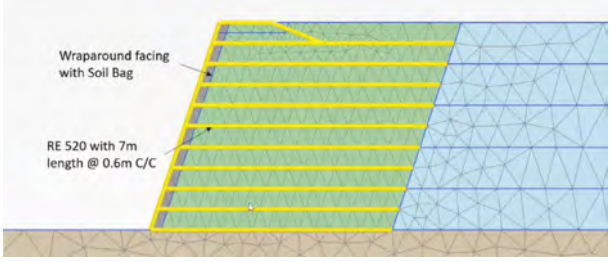

Figure 8. Reinforced soil structure FEM model.

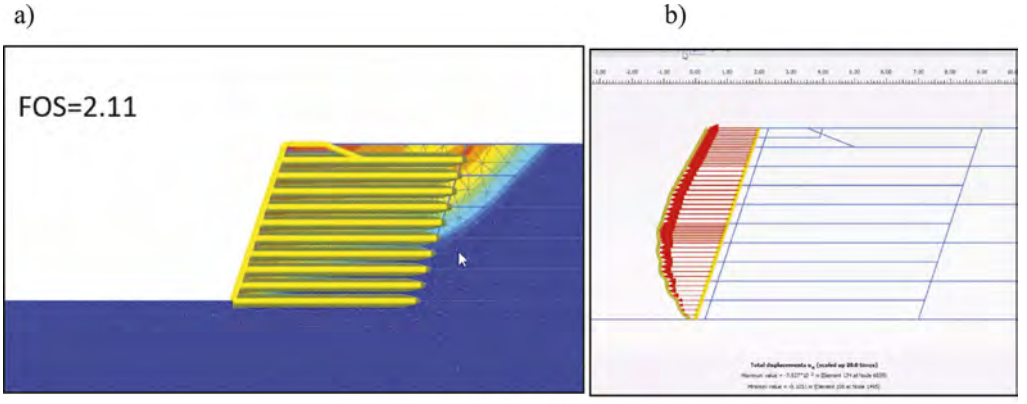
For geogrid an elastoplastic model was obtained with secant stiffness EA_1 = 262kN/m and design strength $N_{p,1}$=23.5 kN/m that came from a set of creep tests under loads from 5 to 65% of short-term strength. No surcharge was used. Stability analysis shows factor of safety 2,11 and 10,5cm surface deformation as per Figure 9.



a) failure surfaces; b) deformations

Figure 9. Reinforced soil structure FEM stability and deformation analysis.

The same structure modeled in analytical software shows a different way of failure with much lower factor of safety (1,657) as per Figure 10. Grid strain is lower than 0,25% or 1,5cm.

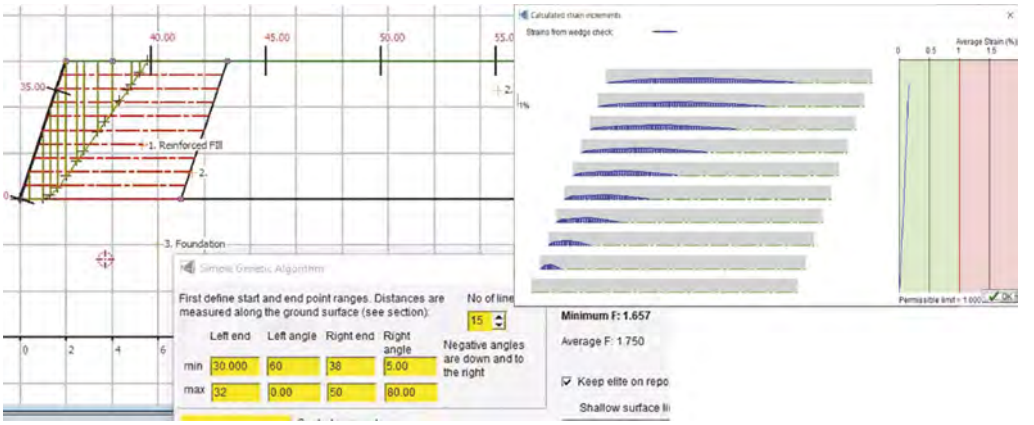


Figure 10. Reinforced soil structure stability and deformation analysis in analytical software.

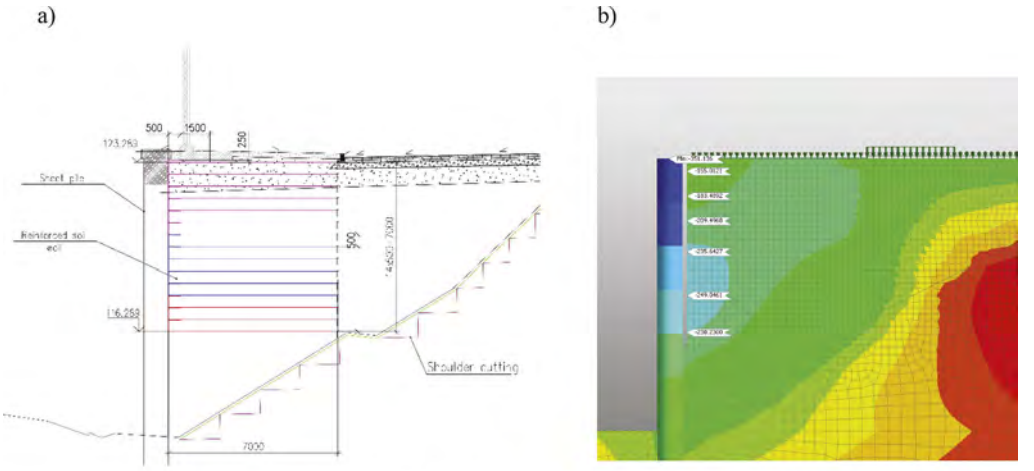
Modeling a real reinforced soil structure on the automobile road "Perm - Berezniki" in Perm region of Russia under in-service load resulted in 25cm movement shown in Figure 11.



a) design section; b) FEA DX displacement result

Figure 11. Reinforced soil wall at "Perm - Berezniki".

Construction is going to start in the beginning of 2023 with accompanying monitoring. Further scientific work is being carried out to compare the results of modeling and monitoring.

5 ALTERNATIVE APPROACH

Lees & Dobie (2021) propose to include stabilisation effect of geogrid into the analysis. This effect was measured during biaxial testing in a unit cell as an ability to reduce the horizontal

stress and strain once loaded vertically. The biaxial test was then simulated by FEA using Plaxis 3D software followed by a back-calculation of existing trial wall behavior. It was recommended to add stabilisation effect as an additional 9° to an angle of friction for reinforced soil areas with σ_3 < 20kPa or 14kPa cohesion for reinforced soil areas with σ_3 > 20kPa.

This approach was proved to follow the actual reinforced wall behavior way more accurate than classic FEM modeling of a membrane elements. But stabilisation effect must be defined for each individual grid + fill combination during the specific and not standardized test.

6 DISCUSSIONS

This is an important finding in the understanding of the long-term creep related stiffness being the key design parameter together with classic service life design strength. The present study confirmed the findings about insufficiency of current FEM models. Previously this fact was not so evident because of wide usage of short-term stiffness.

7 CONCLUSION

At this moment, analytical modeling methods better correspond to the real life behavior of reinforced soil structures. Numerical modeling is used for complex geometry cases and is able to include reinforcement effect. To do this, a full range of creep tests is required for specifying long-term stiffness at design tension level in reinforcement. Secant stiffness EA_1 is obtained from a creep test isochrone for required service life and not from a short-term tensile test. Long-term stiffness is 50-100% lower than short-term one and this reveals a problem of FEM overestimating structure deformations when compared to either analytical designs or actual soil structure behavior. Discovering of stabilisation effect that geosynthetics provides to a fill material moves FEM models closer to actual monitored structure deformation but requires a series of specific and not standardized tests.

ACKNOWLEDGEMENT

The author would like to acknowledge Lau Joe Jiunn of Tensar International - Malaysia for providing a sensitivity FEM analysis and Mikhail Strapchuk of the JSC "Stroyproekt Institute" for project support.

Modeling simultaneous transfer of soil water and heat in the evaporation process in unsaturated shallow ground

M. Sawada
Tokyo Institute of Technology, Tokyo, Japan

M. Mimura & K. Yoshikawa
Kyoto University, Kyoto, Japan

ABSTRACT: The accurate prediction of complex mechanical and hydrothermal soil behavior in shallow zones is necessary to mitigate geo-disasters. This study aimed to develop a numerical model for predicting soil water transfer in both liquid and vapor forms, involving heat transfer in the evaporation process in shallow zones. Parametric studies demonstrated that intensive surface desiccation occurs in soils with a low coefficient of permeability or low water retention. The numerical model was validated by comparing the numerical and experimental results of the evaporation tests, which showed that the evaporation rate can be predicted quantitatively. However, some modifications are required for both calculations and experiments to confirm the validity of local soil water transfer and temperature variation.

1 INTRODUCTION

Soil behavior in shallow zones is significantly affected by climate, which occasionally results in slope failure, collapse, desiccation cracks, and salinization. The occurrence of these phenomena affecting our lives can increase because of future extreme climates, such as heavy rainfall and drought. However, to predict these phenomena, the mechanical and hydraulic behavior unique to shallow zones must be considered. Tensile failure is prone to occur in shallow zones under unsaturated and low-confining-pressure conditions. Additionally, pore water transfers both in liquid and vapor forms, and the phase change involves heat transfer. Such complex behavior in shallow zones is not completely covered by conventional geotechnical engineering.

We aimed to develop a numerical model for predicting deformation and hydrothermal transfer in shallow zones. This paper discusses the numerical modeling of the simultaneous transfer of water and heat during evaporation. Predicting the evaporation process is difficult compared with the seepage process in terms of the boundary conditions between the atmosphere and ground surface, where the time-varying evaporation rate is governed by both atmospheric conditions and the hydraulic properties of soils. The temperature decrease due to the latent heat consumed during the phase change from liquid to vapor also contributes to the evaporation rate. We created a one-dimensional analysis code to predict the evaporation process and performed parametric studies to elucidate the effects of the soil permeability and water retention. Furthermore, the numerical model was validated by comparing the numerical and experimental results of evaporation tests.

2 METHODOLOGY

We used the governing equations proposed by Wilson et al. (1994) for the evaporation analysis. The equations for the water and heat transfer are expressed as follows:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z}\left\{k_w \cdot \frac{\partial(\psi + z)}{\partial z}\right\} + \frac{1}{\rho_w} \cdot \frac{\partial}{\partial z}\left(D_v \cdot \frac{\partial P_v}{\partial z}\right) \quad (1)$$

DOI: 10.1201/9781003299127-358

$$C_h \cdot \frac{\partial T}{\partial t} = \frac{\partial}{\partial z}\left(\lambda \cdot \frac{\partial T}{\partial z}\right) + L_v \cdot \left(\frac{P + P_v}{P}\right) \cdot \frac{\partial}{\partial z}\left(D_v \cdot \frac{\partial P_v}{\partial z}\right) \quad (2)$$

where θ is the volumetric water content, k_w is the coefficient of permeability [m/s], ψ is the pressure head [m], ρ_w is the water density [kg/m^3], D_v is the diffusion coefficient of water vapor [kg•m/kN•s], P_v is the pore air vapor pressure [kPa], P is the atmospheric pressure (101.325 kPa), C_h is the volumetric heat capacity [kJ/m^3•K], T is the temperature [K], λ is the thermal conductivity [W/m•K], and L_v is the latent heat (2557 kJ/kg). The functions referred to as the van Genuchten—Mualem model (van Genuchten 1980) were used to express the relationships between θ and ψ (i.e. SWCC) and $k_w - \psi$. A semi-empirical model (Wilson et al. 1994) was used to determine D_v, which is a function of the soil cross-sectional area occupied by pore air. The moisture dependency of λ was considered by applying an approximation formula given by Equation 3 to an experimentally obtained relationship between the degree of saturation, S_r, and λ (Sawada & Mimura 2017);

$$\lambda = \frac{\lambda_{max}}{1 + C_1 exp(-C_2 S_r)} \quad (3)$$

where λ_{max} [W/m•K], C_1, and C_2 are the fitting parameters. The evaporation rate E [m/s] at the ground surface was estimated using the Dalton-type equation:

$$E = f(u)(e_s - e_a) \quad (4)$$

where $f(u)$ is the turbulent exchange function [m/s•kPa], e_s is the vapor pressure at the ground surface [kPa], and e_a is the vapor pressure in the atmosphere [kPa]. In this study, $f(u)$ under hydrothermal conditions (i.e. 20 °C, 60%RH) was determined to be 6.489×10^{-7} m/s•kPa by measuring the evaporation rate from the free water surface (i.e. e_s=saturated vapor pressure). The heat transfer at the ground surface results from latent heat being proportional to E, and sensible heat q_u [W/m^3], which is estimated as follows (Hokoi et al. 2002):

$$q_u = \alpha_h \cdot (T_\infty - T_s) \quad (5)$$

where α_h is the heat transfer coefficient considering convection and radiation (23.0 W/m^3•K), T_∞ is the ambient temperature at a location well away from the ground surface [K], and T_s is the ground surface temperature [K]. Subsequently, the calculation results were obtained using the forward finite difference method.

3 PARAMETRIC STUDIES

Evaporation from a sandy soil column (sand: 58%, silt: 17.3%, clay: 24.8%) with a height of 0.45 m placed under a constant climatic condition of 20 °C and 60%RH was calculated. The bottom of the soil column was assumed to be impermeable to both water and heat. The parameters are listed in Table 1. Several additional experiments were performed to analyze the influence of the coefficient of permeability and SWCC on evaporation. In this study, two additional cases were compared with the original case (i.e. Case 1): Case 2, where the saturated coefficient of permeability, k_{sat} [m/s], was 1/10 of Case 1, and Case 3, where S_r at an arbitrary suction was lower than that of Case 1.

Figure 1a compares the evaporation rate and total evaporation for the three cases. The evaporation rate rapidly decreased after the start because the vapor pressure at the soil surface decreased with a decrease in temperature owing to latent heat, and then it was almost constant for several days. This potential evaporation rate in the first stage was governed only by atmospheric conditions. The decrease in the evaporation rate in the subsequent second stage was affected by the hydraulic properties of the soil. Figure 1 shows that in the additional cases, the transition to the second stage was early, which lowered the total evaporation. This was because of the clear difference in the water content profiles in the vertical direction between Case 1 and the other cases. A comparison between Cases 1 and 2 (Figure 1b) indicated that upward water transfer in the soil column lagged the potential evaporation rate as a demand from the atmosphere when the coefficient of permeability was

Table 1. Parameters used in Case 1.

Properties			Properties		Properties	
SWCC	θ_s	0.481	λ_{max}	1.258	void ratio	0.927
	θ_r	0.000	C_1	2.470	dry density [g/cm^3]	1.370
	α [1/m]	1.435*	C_2	0.026	initial water content [%]	29.0
	n	0.187	k_{sat}	1.04×10^{-5}**		

* α=5.000 in Case 3. ** k_{sat}=1.04×10^{-6} in Case 2.

low, which resulted in an early transition to the second stage and intensive surface desiccation with the remaining wet deep zone. Intensive surface desiccation was also observed in Case 3, although the water content and coefficient of permeability in Case 3 were initially equal to those in Case 1 (Figure 1c). In the evaporation process, the water transfer in the liquid phase in the upward and downward directions was caused by the pressure head gradient and gravity, respectively, as described in Equation 1. In Case 3, assuming a soil with low water retention, the intensive surface desiccation was caused by these opposite flow directions. The downward flow in Case 3 was significant compared with that in Case 1 because the initial suction was small and the suction gradient corresponding to the water content gradient was small.

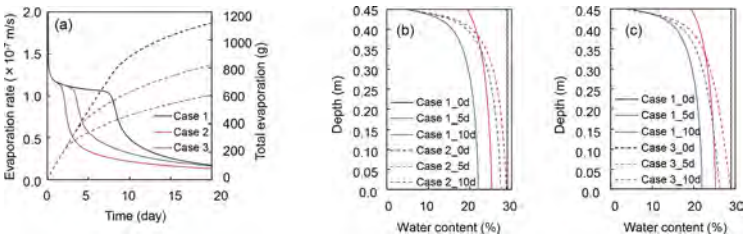

Figure 1. Results of parametric studies.

4 MODEL VALIDATION

Evaporation tests were conducted in a constant climate chamber in which the temperature and relative humidity were kept constant at 20 °C and 60%RH, respectively, using a rectangular soil column (0.10 m × 0.15 m × 0.45 m). The soil column with initial water content and dry density are listed in Table 1 was prepared by compacting sandy soil in an acrylic mold. The sides of the soil column were covered with a Rockwool sheet to cut off heat inflow from the atmosphere. The weight of the soil column was measured to determine the evaporation rate. Moisture sensors (TEROS 10, METER, Inc.) and potential sensors (TEROS 21, METER, Inc.) were installed at depths of 0.05, 0.15, 0.25, and 0.35 m. The potential sensors measured suction within a range of 9–2000 kPa and temperature.

The SWCCs obtained in the evaporation test were almost consistent with the results of the water retention tests during the drying process, although the suction near the surface reached the measurement upper limit during the test. The best-fit curve estimated using the least-squares method had fitting parameters of θ_s =0.481, θ_r =0.000, α = 3.167, and n = 1.184. The evaporation test was numerically simulated using the SWCC. The other parameters used for the simulation were the same as those listed in Table 1. Figure 2a compares the measured and calculated evaporation rates and total evaporation. The measured and calculated evaporation rates agreed well throughout the first and second stages until five days after the start, although a slight discrepancy was observed in the subsequent third stage with a constant evaporation rate. Figure 2b compares the measured and calculated time series of water content. The calculated water content was lower than the measured value throughout the test at the two lower measurement points. This tendency was observed at the upper two measurement points a few days after the start, and the calculated water content subsequently exceeded the measured value. These results indicated that the numerical model can quantitatively predict evaporation over the entire soil column; however, the actual local water transfer in the soil column differed from the numerically

predicted one. This discrepancy may have been due to the discontinuities in the non-homogeneously compacted soil column. Sandy soil with a high fine fracture content was difficult to compact homogeneously because it was aggregated at the initial water content. Fissures or voids above the two lower measurement points in the soil column may have restrained the upward liquid water flow from the lower zone and accelerated evaporation in the upper zone. To confirm the validity of local water transfer, evaporation tests should be modified to use homogenous soil columns of sandy soil prepared at lower water contents or other soils with lower fine fraction content.

Figure 2c compares the measured and calculated time series of the temperature. Temperature significantly decreased a few days after the start owing to latent heat and then gradually recovered with a decrease in the evaporation rate and heat inflow from the atmosphere through the soil surface. The calculated temperature qualitatively agreed with the measured temperature. However, the calculated temperature decrease was significant compared with the measured decrease, although the evaporation rate was underestimated. These conflicting results were owing to the heat inflow through the sides of the actual soil column, which was not considered in the one-dimensional analysis. This was supported by additional evaporation tests without the side Rockwool sheet, which measured a smaller decrease in temperature. It was impossible to completely cut off the heat inflow from the sides in the experiments. Thus, a three-dimensional analysis is necessary to confirm the validity of temperature variation.

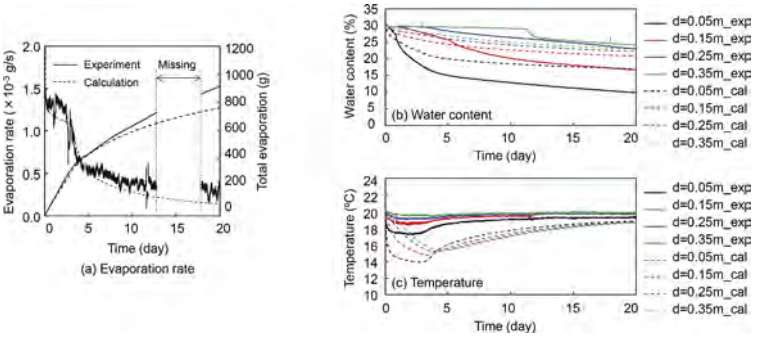

Figure 2. Comparison between calculated and measured results.

5 CONCLUSIONS

This paper presents a numerical analysis of the simultaneous transfer of soil water and heat during evaporation in shallow zones. Parametric studies showed that intensive surface desiccation occurs in soils with a low coefficient of permeability or low water retentivity. A comparison between the numerical and experimental results of evaporation tests showed that the numerical model is valid for predicting the evaporation rate; however, some modifications are required for both calculation and experiment to confirm the validity of local soil water transfer and temperature variation.

Comprehensive engineering protection of the territory on the example of the sochi mountain cluster

I.S. Bogdanov
GEOIZOL Project LLC, St. Petersburg, Russia

ABSTRACT: Hosting the Winter Olympics 2014 became an incentive for an active development of the Sochi mountain cluster (Krasnodar Region, Russia). A set of engineering protection measures against dangerous geological phenomena and processes was taken on the territory where sports and recreational infrastructural facilities were to be constructed. The Sochi mountain cluster became a real testing ground for implementing advanced technical solutions in the area of engineering protection in really specific conditions when developing facilities in the national park on a steeply sloping terrain under the risk of high seismic activity (9 points). The article provides review of the measures taken. They include constructing flexible mudflow-retaining and snow-retaining barriers, ensuring the stability of slopes by soil nailing using the GEOIZOL-MP multifunctional geotechnical system, constructing retaining structures (retaining walls) of various designs: piled, corner monolithic on a piled base, reinforced soil, gabions.

Keywords: Engineering protection of the territory, Landslide, Mudflow, Snow avalanche, Rockfall, Erosion, Ground anchor, GEOIZOL-MP

1 GENERAL DESCRIPTION OF THE DESIGN OBJECT

The 2014 Winter Olympics became the starting point for creating one of the largest conglomerates of mountain climate resorts in Eastern Europe in the mountain cluster of Sochi (Krasnodar Region, Russia). Implementation of the large-scale construction project began in the national park, which required to minimize environmental impact and preserve the existing ecosystems. The construction sites of the recreational and sports infrastructural facilities were located in the hard-to-reach areas on steep slopes. There was a risk for the facilities to be exposed to the dangerous geological phenomena and processes such as soil erosion, landslide processes, mudflows, snow avalanches, and rockfalls. Another complicating condition is a high seismic activity of the region (9 points).

Under the given conditions, traditional methods of engineering protection of the territory with massive reinforced concrete structures, dirt fills, and dams were inapplicable. GEOIZOL Project analyzed the best international practices in engineering protection of the territory and introduced a wide range of advanced technical solutions to ensure the possibility of construction and subsequent safe operation of the facilities.

It is especially worth noting a comprehensive approach to engineering protection of the territory and facilities that included a use of combinations of various structures to improve reliability of structures and optimize financial costs. The mountain cluster of Sochi became a testing ground for implementing new methods of engineering protection of the territory. One of the outcomes of this work is development of the regulatory and technical base as well as adding new technologies and solutions to the standards.

2 MEASURES FOR COMPREHENSIVE ENGINEERING PROTECTION OF THE TERRITORY

2.1 *Drainage and protection against erosion*

Water is one of the main destructive factors in the mountains. When flowing downhill, running water accumulate significant energy, destroying ground cover and having a negative impact on engineering structures. Water soaks soil bodies, activating landslide processes. In this regard, during a design stage it should be given a priority to measures for draining water away from the facilities under construction: building drainages, intercepting and slope ditches, and capture chambers.

During construction work, an integrity of the soil cover is inevitably disturbed. Without additional protection, opened ground is subject to erosion – intensive destruction by wind and precipitation.

Cover systems of various designs are generally used for erosion control. Geosynthetic erosion control mats are installed to provide soil reinforcement and subsequent revegetation. A high-strength steel mesh fixed with ground anchors is additionally arranged on steep slopes.

Anti-erosion measures fully offset a negative effect of anthropogenic impact on soil and prevent the development of creep processes.

2.2 *Landslide protection without changing the relief*

When implementing the projects in the mountain cluster of Sochi, soil nailing of slopes was widely used as a landslide protection. The essence of the technology is to spatially reinforce a soil body with such geotechnical elements as injection-bored soil nails. Ground nails extend beyond the slope sliding surface, holding a soil body (landslide body), and they are fixed in the deeper stable layers. The cover system (high-strength steel mesh with anti-erosion mats) prevents displacements on the surface, it does not allow soil to fall out in the inter-nail space and protects against erosion.

The solution is used to ensure stability of natural and artificial slopes when there is a high risk of triggering landslide processes. It allows performing the work without vegetation destruction while maintaining the original relief. Soil nailing is also justified when locating facilities on a slope, for example, cableway supports.

The principle of such reinforcement is similar to how anchors fix concrete pressure plates. It is a proprietary design of GEOIZOL Project. The solution is a compact alternative to a counterweight berm. Plates fixed with anchors create additional pressure (counterweight) on the soil in the lower area of the landslide body and increase the holding forces, thus increasing stability of a potential landslide slope.

The multifunctional GOIZOL-MP system is used as ground anchors and nails (as well as bored micropiles). The GEOIZOL Group solution has better characteristics than the best European analogues. The production of GOIZOL-MP was deployed at the Pushkin Machine-Building Plant in St. Petersburg.

2.3 *Landslide protection with changing the relief*

Locating objects on steep mountain slopes inevitably leads to changing the relief for leveling construction sites or laying roads. It often requires installation of restraining structures of various designs. When cutting slopes, sheetpile or pile retaining walls are used. A pile retaining wall consists of one or more rows of bored piles, united along the top with a grillage. An additional stability of the structure is usually achieved by ground anchors. They are arranged in one or more horizontal rows through the distribution beams as the soil is excavated. At the final stage, a monolithic pressure wall is made on the front side.

When forming the relief by backfilling of the territory, it is possible to use various structures. They include corner walls on a natural or pile foundation, different reinforced ground embankments lined with gabions, prefabricated concrete elements, the Green Terramesh system or their combinations. To ensure even greater stability, the restraint structures may be supplemented with an uphill and downhill soil nailing.

2.4 *Mudflow protection*

Engineering protection measures against mudflows are chosen depending on the specifics of the protected facility. GEOIZOL Project applied various technical solutions and their combinations at the sites in Sochi. First of all, measures are provided to exclude mudflow triggering factors: stabilization of watercourses, installation of erosion protection in the mudflow basin, nailing of certain potentially unstable soil bodies.

A traditional solution to eliminate an impact of mudflows on the protected facility is constructing mudflow trapping reservoirs along with retaining dams and special drainage structures.

Traditional massive anti-mudflow dams were replaced with flexible mudflow-retaining barriers in the mountain cluster of Sochi. They are installed across the foreseeable mudflow bed to retain the solid part of the flow, which poses the greatest threat to the protected facilities. The barrier consists of a high-strength steel mesh stretched between posts and reinforced with steel ropes and buffers. The GEOIZOL-MP injection-bored ground anchors are used to fix the posts and guy ropes. The construction and operation of such structures is possible using compact vehicles, even in the hard-to-reach areas where laying access roads is impossible.

Only a section of the ski slope had to be protected at one of the facilities. A closed-type structure was built for this purpose. A box-shaped tunnel was built under the protected ski slope for the estimated volume of mudflow to go through. It ensures a normal regime of stream between mudflows.

2.5 *Avalanche protection*

Engineering protection methods are chosen depending on the avalanche type. Preventive measures should be taken in the areas with a high avalanche risk. One the most common measures is artificial triggering snow flows. To reduce the snow mass, it is possible to set up snow blowing structures or GAZEX avalanche-control systems in places where snow is accumulated.

When constructing facilities in the area characterized with high risk of channeled avalanches, it is possible to erect local protective structures. High reinforced soil embankment with gabion lining was made to provide avalanche protection for the Yunost ropeway station, located on the slope of the Aibga Ridge. The nearby cableway supports are protected by massive reinforced concrete avalanche breakers.

A natural method of controlling snow slides is forest restoration. Another effective control method is erecting flexible snow-retaining barriers. The barrier structures are installed across the slope in places where snow is accumulated. The barriers keep the snow mass in a static state, reducing the risks of snow slides. The structures are fixed with the GEOIZOL-MP ground anchors. In summer, the structures can function as rock barriers.First line of text or heading.

2.6 *Rockfall protection*

Before choosing rockfall protection solutions, it is necessary to determine dangerous areas and a type of the rock mass destruction. If the area where rocks can fall off is relatively small, it is fully covered with a high-strength steel mesh while large rock formations are reinforced. In some cases, an optimal solution to prevent landslide phenomena can be nailing. To protect the facilities against falling debris, including those having high energy of up to 10,000 kJ, installation of rock barriers is applicable. Such mesh structures can also be used to protect against associated risks such as avalanches and mudflows.

2.7 *Repair of emergency retaining structures*

Sometimes the company has to deal with cases where a customer needs to restore existing retaining walls. Increasing rigidity of such structures is one of the most difficult engineering tasks in the field of protection against landslide processes. When designing such measures, it is necessary to take into account an actual rigidity of emergency structures and how their functionality will be changed after reinforcement. An actual state of the structures is also taken into account, including a decrease or partial loss of the bearing capacity of the structural elements.

There are several approaches to reinforcing emergency retaining walls. The first one is improving stability of retaining structures by arranging rows of the GOIZOL-MP ground anchors inserted through the body of existing structures. Another one is installation of backup retaining walls to relieve additional load under special effects.

It should be noted that a comprehensive approach is required when designing repair of emergency structures. First of all, it is necessary to identify the reasons for reduced performance of the structures. This may be a change of the hydrogeological conditions. The essential parts of the design should be elimination of these causes and elimination of consequences of man-made impact during the repair: taking anti-erosion protection measures and providing drainage.

3 CONCLUSION

After having designed the engineering protection of the territory for the Olympic venues in Sochi, GEOIZOL Project Company gained a unique experience. This work demonstrated the obvious need for an integrated approach when designing safety engineering measures for the territory. Considering all the risk groups on the whole allows us to interconnect and optimize protective measures, which positively affects both the effectiveness of the measures adopted in the framework of the project, as well as the terms and cost of their implementation. An integrated approach to designing the engineering protection of the territory has become the standard for the Company.

In the Sochi mountain cluster, GEOIZOL Project Company has put into practice the methods for safety engineering for the territory proven their effectiveness, which allow ensuring the required level of safety with a minimal impact on the environment. Many of these technologies have never been used in Russia before. These include flexible barriers used to protect against mudflows, avalanches and rockfalls. Also in Sochi, the soil nailing of landslide hazard slopes is widely used.

The experience gained in the construction of Olympic venues has had a positive impact on the construction industry in Russia as a whole. The GEOIZOL Project Company has become one of the pioneers of the engineering protection of the territory as an independent trend in the construction industry of the country.

ABSTRACT: The work determines the stress intensity factor (SIF) at the crack tip in bending reinforced concrete beams. The problem has been solved in a three-dimensional formulation using special elements that take into account peculiarities of the stress field at the crack tip.

Calculations have been carried out for beams of rectangular cross-section with pure bending to obtain analytical calculated dependences on variable factors. To obtain analytically calculated dependences on variable factors, a matrix of rational planning a multifactorial computer experiment has been compiled to determine the SIF and stress state parameters in bending rectangular reinforced concrete beams with a crack. Regression dependences for the SIF and the stress in the armature on the parameters of the beam and loading are obtained. The numerical calculation method is general and applies to beams of an arbitrary section under arbitrary loading. The obtained dependencies make it possible to evaluate the crack resistance of reinforced concrete beams according to the force criterion of fracture mechanics without the use of computer technology and expensive software complexes. In this paper, there is considered determining the SIF in bending reinforced concrete beams by the finite element method. The calculation results are presented in the form of the SIF regression dependences on the varied parameters.

1 INTRODUCTION

Cracks are a very common type of defect in reinforced concrete structures [1, 2]. They can appear both at the manufacturing stage and the stage of mounting and operation. Operational cracks appear in the tensile zone of concrete when the maximum stress exceeds the ultimate strength of concrete. Since concrete is a brittle material and has lower tensile strength than compressive strength, cracks appear even before the bearing capacity of the reinforced concrete element is exhausted.

It is necessary to determine the stress state in the section with a crack to assess the bearing capacity of a reinforced concrete element. To assess crack resistance, it is necessary to determine the parameters of fracture mechanics that correspond to the accepted fracture criterion. The brittle fracture force criterion is applied for concrete, expressed through the stress intensity factor (SIF). When bending, it is necessary to determine the SIF of the first type (a separation crack). It is necessary to know the nominal stresses at the crack tip to determine it.

In the general case, the calculation of the SIF is performed by the finite element method (FEM) in a linear formulation. Such a calculation for bending reinforced concrete elements is

DOI: 10.1201/9781003299127-360

rarely performed. The one is due to the complexity of the calculations associated with the above-mentioned character of crack development and the need for a volumetric formulation of the problem.

Since cracks exist in any reinforced concrete elements, determining the stress state in the section with a crack and calculating the SIF are very important for assessing the real state of the structure in operation.

In this paper, there is considered determining the SIF in bending reinforced concrete beams by the finite element method. The calculation results are presented in the form of the SIF regression dependences on the varied parameters.

2 METHODS

The finite element method is the main method of determining the parameters of fracture mechanics in metal structures. Because of the complexity of implementing the algorithm of determining the SIF in reinforced concrete structures, it is rarely used and has its characteristics. This calculation is carried out in a linear setting based on a three-dimensional model. The SIF is determined by the field of displacements or stresses at the crack tip. In the ANSYS software package, all the stages of calculations are automated, especially in the Workbench interactive mode.

A common disadvantage of numerical calculation methods is the difficulty of analyzing the final results to control the calculated value. It is not clear from the solution, which input parameters, in which direction, and how much is better to be changed to get the desired result. It is necessary to carry out multiple calculations with step-by-step changes in many variable parameters to catch the change trends. In addition, the results obtained cannot be used with a quantitative change in the properties of materials, structural parameters or loading.

For reasonable selecting of the parameters of reinforced concrete elements and controlling the loading parameters, it is necessary to have analytical dependences of the SIF on the varied parameters. A multifactorial computer experiment must be planned and performed to obtain these dependencies. By processing the results of such an experiment, the desired regression dependencies can be obtained.

3 RESULTS

The SIF in a flexible reinforced concrete beam was calculated by the finite element method in a linear formulation based on a three-dimensional model. The SIF was determined from the displacement or stress field at the crack tip. ANSYS (Ansys, Inc., Canonsburg, PA, USA) was used in Interactive Workbench mode. The main stages of solving the problem were as follows.

According to the above algorithm, there has been calculated a reinforced concrete beam of rectangular cross-section with the size of (15x30) cm of concrete grade B25 (Rbt=1.6 MPa, Rb=14.5 MPa, Eb=24000 MPa) with reinforcement made of AIII steel (Rs=370 MPa, E=200000 MPa). Figure 1 shows the scheme of fastening and loading the beam. In the middle section of the beam, a pure bending occurs with the moment M=Fa.

The beam has an initial crack l0=6 cm in the pure bending and reinforcement zone with the area of As=6.75 cm2 in the tension zone at a distance of 3 cm from the edge of this zone. The calculation of the beam has been carried out under the action of the torque of 8 kN·m. As a result of the calculation, there has been obtained KI=0.41 MN/m3/2.

4 PLANNING A COMPUTER EXPERIMENT

The purpose of the experiment is to obtain an analytical dependence of the SIF on the varied parameters. To assess the bearing capacity of a beam, one can simultaneously determine such dependences for the stress in the reinforcement and for the maximum compression stress in concrete. The analysis of numerous calculations to determine the stress state in reinforced

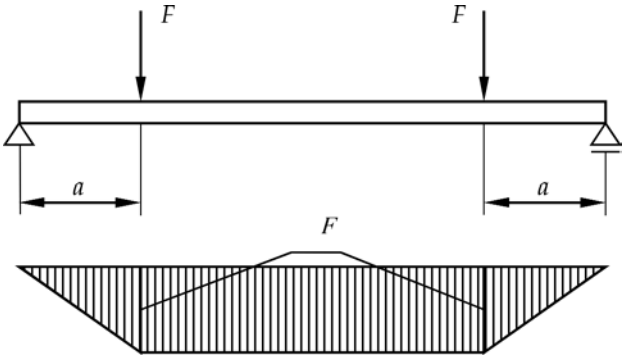

Figure 1. The calculation scheme with a moment diagram.

concrete beams with a bending crack shows that the stress in the reinforcement reaches standard resistance earlier than the stress in concrete. Therefore, alongside the SIF, regression dependences for the stress in the reinforcement σ_s are determined.

To obtain these dependencies, one first needs to select the parameters that significantly impact the output function. Then it is necessary to determine the real limits of changes in these parameters. Each argument's levels should be set so that they meet the requirements of the arithmetic progression (have the same intervals). These actions make it possible to plan the experiment properly and can reduce the required volume significantly.

When planning experiments, selecting the factor levels is important. It is made taking into account two conflicting requirements: the levels of factors should cover the entire possible range of its change, the total number of levels for all the factors should not lead to an excessive volume of tests.

For testing, we take a rectangular beam with reinforcement in the tension zone at a distance of 3 cm from the edge of this zone.

The main factors influencing the output values are the section dimensions h, b, the crack length l, the percentage of reinforcement μ, the elastic moduli of concrete E_b and reinforcement E_s, and the bending moment M. Since the calculation is performed in a linear formulation, the output values will vary linearly to the moment. Therefore, it can be excluded from the number of variable factors and taken fixed in the experiment. The performed test calculations and the analysis of analytical solutions [3, 4] show that the impact of the elastic moduli of materials can be taken into account by one parameter equal to their ratio $\alpha=E_s/E_b$. This leaves five variable factors: h, b, $z=l/h$, μ, α.

We will take the limits of changing these factors to most fully cover the entire range of their changes in real conditions:

$$h = (10 \ldots 50)\text{cm}, b = (5 \ldots 40)\text{cm}, z = 0.1 \ldots 0.7, \mu = (0, 5 \ldots 3)\%, \alpha = 6 \ldots 11.$$

There are no interrelationships between the factors of the model. Therefore, we will use rational planning of the experiment. Since there are five variable factors, we will change them at five equal levels. Table 1 shows the values of the varied parameters at different levels.

Table 1. Varied parameters values.

	Variable values				
Levels	h, cm	b, cm	z	μ, %	A
1	10	5	0.1	0.5	6
2	20	14	0.25	1.1	7.2
3	30	23	0.4	1.7	8.4
4	40	32	0.55	2.3	9.6
5	50	41	0.7	2.9	10.8

With few numbers of factors ($k > 4$) for obtaining an experiment plan, it is more rational to use numerical matrices. The number of rows in the matrix is equal to the number of experiments, and the number of columns is equal to the number of influencing factors. The combination of numbers in each line is a combination of the factor levels in the corresponding experiment. Such plans are based on Latin squares. Only orthogonal Latin squares are suitable to obtain an optimal plan [5]. The technique of constructing mutually orthogonal squares is described in detail in [6].

According to the planning matrix, the full experiment will consist of 25 experiments divided into five orthogonal squares. The first three squares are shown below:

1	1 2 3 4 5	6	1 3 5 2 4	11	1 4 2 5 3
2	2 3 4 5 1	7	2 4 1 3 5	12	2 5 3 1 4
3	3 4 5 1 2	8	3 5 2 4 1	13	3 1 4 2 5
4	4 5 1 2 3	9	4 1 3 5 2	14	4 2 5 3 1
5	5 1 2 3 4	10	5 2 4 1 3	15	5 3 1 4 2

Each row of the matrix represents one experiment, the number of which is indicated by the first digit, and the subsequent digits indicate the levels of the corresponding factor. These levels correspond to the values of the varied parameters shown in Table 1. The first row of the planning matrix shows all the levels in ascending order. The rest of the rows are obtained by incrementing the level number by one in the matrix column with the order from the last to the first number. The first line of the next square consists of the diagonal of the previous square.

5 NUMERICAL CALCULATION

To carry out a computer experiment, we use the structural design shown in Figure 1. The bending moment at pure bending is set equal to 10 kN·m.

The calculation of the SIF in the beam is performed using the ANSYS Software with the rational planning matrix. In each experiment, as a result of the calculation, the SIF (K_I) and the stress in the reinforcement σ_s have been displayed for viewing. A fragment of the experimental results is shown in Table 2.

Table 2. A fragment of the experiment results.

No.	h, cm	b, cm	z	μ	α	K_I, MN/m$^{3/2}$	σ_s, MPa
1	10	14	0.4	2.3	10.8	0.433	229
2	20	23	0.55	2.9	6	0.266	27
3	30	32	0.7	0.5	7.2	0.195	98
4	40	41	0.1	1.1	8.4	0.13	15.3
5	50	5	0.25	1.7	9.6	0.6	57

Based on the results of the computer experiment, regression dependences are constructed for the output parameters. To do this, we will use an unconventional regression analysis method, which is implemented in the ANETR program created at Karaganda Technical University.

The program first arranges the factors in order of decreasing the impact on the output parameter value. For each factor, it selects the corresponding equation from 15 types of equations included in the program. At the same time, to identify the impact of some factors, it may be necessary to neutralize the impact of potent factors. The program ends with selecting a certain combination of partial equations to form the general model. The dependences obtained in this way are valid in the range of variation of the variable parameters.

The adequacy of the general model is assessed by the standard deviation (SD) of the calculated and experimental values of the output quantity and the multiple correlation coefficient of the model. Note that the program developers evaluate the resulting regression model as "excellent" if the standard deviation is lower than 25% and "good" if the standard deviation is lower than 40%.

The initial data of each experiment are entered into the ANETR program in the form of a 25x5 matrix and the value of the analyzed output parameter (response function) in the form of a 25x1 column vector to obtain regression dependences.

Let us present the finally formed multidimensional models for the stress intensity factor:

$$K_I = (M/10)[1.415 \cdot 10^{-3}h^2 - 0.125h + 7.09/b - 1.086\lg z + \\ +0.537\mu^2 - 1.804\mu - 0.117\alpha + 4.209]\left(\mathrm{MN/m^{3/2}}\right). \quad (1)$$

In this expression, the variables must be substituted in the units in which they are indicated in Table 1. The results will also be in the units in which the output values are given in Table 2. The standard deviation of the model is 38.2 %, and the multiple correlation coefficient is $R = 0.82$.

Regression dependences for stress in reinforcement:

$$\sigma_s = (M/10)[25460/h^{1.718} + 1202.5/b + 1697z^2 - 1290z - 85.5\mu + \\ +310.9/\alpha + 185.7](\mathrm{MPa}). \quad (2)$$

The SD of the model makes 25.4%, and the coefficient of multiple correlation R=0.924.

To reduce the standard deviation, you can increase the number of levels of changing the factors, but this will increase the number of experiments. For example, for seven levels, there are needed 49 experiments

The SIF is a parameter of linear fracture mechanics. Therefore, its FEM calculation is carried out in a linear setting. With increasing the bending moment, there should be expected increasing the error in determining the SIF. This is due to the growing influence of physical nonlinearity at high stresses. Under these conditions, it is recommended to calculate the SIF only by the analytical method [4].

6 CONCLUSIONS

The technique and algorithm of determining the stress intensity factor in bending reinforced concrete beams with a crack by the finite element method are described. A matrix of rational planning of the multifactorial computer experiment to determine the SIF in bending rectangular reinforced concrete beams with a crack has been compiled. Based on this planning matrix, using the ANSYS software, machine experiments have been carried out for pure bending beams. By processing the experiment results using the program of unconventional regression analysis ANETR, dependencies have been obtained for determining the SIF and stress in reinforcement in reinforced concrete beams with cracks. The impact of the operational crack length on the SIF has been analyzed. It has been found that in a reinforced concrete beam, the SIF decreases with increasing the crack length. At the critical crack length, the SIF becomes zero and the effective moment is equal to the breaking moment. In reinforced concrete beams, unstable crack development does not lead to the rapid destruction of the beam. However, it reduces its bearing capacity due to increasing the crack length and increasing stresses in concrete and reinforcement. The obtained dependences make it possible to evaluate the crack resistance of reinforced concrete beams according to the force criterion of fracture mechanics without the use of computer technology and expensive software systems. They also make it possible to assess the real state of the beam depending on the reinforcement stress.

ABSTRACT: In this paper, a theoretical study of the problems of reliability of building structures of buildings and structures is carried out. The deterministic (classical) and probably-statistical approach is considered; at the same time, it is established that the probabilistic calculation method with a small increase in material consumption (compared with the deterministic calculation method) gives higher reliability indicators. A methodology for determining the residual resource of buildings and structures based on the results of a technical survey (with an example of calculation) is also proposed.

1 INTRODUCTION

When designing new and operating existing construction structures of buildings and structures, along with deterministic methods of calculation and their bearing capacity (strength, rigidity, stability), probabilistic methods are also used, which take into account the statistical variability of the properties of materials and the magnitude of external influences, etc [1-3].

For practical calculations in building codes and regulations, such variability is indirectly (indirectly) taken into account through appropriate safety coefficients (for materials, for loads), which are based on a statistical, but deterministic essence. In these conditions, the reliability approaches of load-bearing capacity calculations are of actual importance, directly (directly) taking into account statistical variations of the entire complex of initial parameters, represented as random variables or random processes [4-6].

With such a dual approach (deterministic and probabilistic), a logical question arises - to what extent the obtained results of deterministic and probabilistic calculation methods differ, i.e. whether there is a similar difference in the margin of safety (reliability or safety), and also what kind of savings or overspending of construction materials designed during the operation of existing ones building structures of buildings and structures [7].

Since the method of deterministic calculation of building structures is well known, then we will consider in more detail the method of probabilistic calculation.

2 METHODOLOGY

The reliability of "H" structures (in the absence of failures) is determined by the following formula

$$H = P(R < S) \tag{1}$$

DOI: 10.1201/9781003299127-361

where P – probability of an event, R – random limit voltages, S – random design voltages.

To conduct a comparative analysis of the results of deterministic and probabilistic calculation of building structures, we calculated a single-span metal beam for transverse plane bending in two variants: the first - based on the probability approach; the second - based on the deterministic approach.

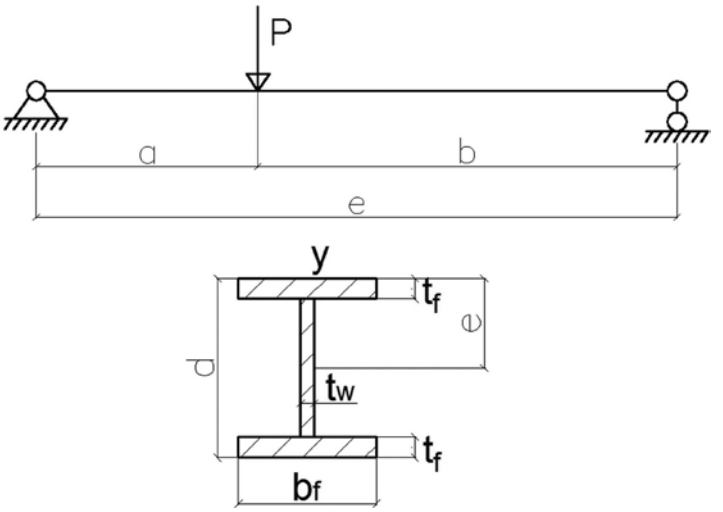

Figure.1. Calculation of a single-span beam for bending: a- girder geometry, b- cross-section.

Determine the dimensions of the cross section in a probabilistic and deterministic way.

Random variables:

a) dimensions a, b, l;
b) strength characteristics of "R";
c) the load value "P".

Comparison of the results (obtained):
(d=62.2 mm) – by the probabilistic method,
(d=59 mm) – by the deterministic method.

3 RESULTS

Thus, the probabilistic method of calculating the beam in comparison with the deterministic one leads to a slight increase in the consumption of materials (steel), but at the same time the reliability of its operation (or safety) increases in some way.

Next, we will consider the relationship between the stock ratio (laid down in building codes) and the reliability of structures:

The strength condition (in general) has the form:

$$S \leq R \tag{2}$$

where S- actual voltage; R- limit voltage; m_s- average mathematical expectations «S»; m_r- also for «R».

According to the probabilistic scheme, expression (2) can be written as follows:

$$S_p \leq R_p \tag{3}$$

S_p- quite rarely (probably) a possible occurring high value of the load parameter; R_p- also, but a low value of the carrying capacity; $S_н$, $R_н$ – normative values; S_p, R_p – calculated values; S_K, R_K – quantiles of the corresponding distributions f(S) and f(R).

Quantile is the value of the corresponding given probability, at which its distribution function is equal to the given probability.

Probability distribution parameters:

m_s, m_R – mathematical expectations

σ_s, σ_R – the same standards (or sko.-standard deviations)

$R_s = \sigma_s/m_s$; $K_R = \sigma_R/m_R$ – coefficients of variation.

a) For the average regulatory resistance, you can write:

$$1_R = 1 - \gamma_R K_R \tag{4}$$

probabilistic interpretation of the material reliability coefficient ($l_R = R_p/R_H$)

б) With some difference in the normative resistance from the average value, we have:

$$R_H = m_R(1 - \sigma_R{}^* K_R) \tag{5}$$

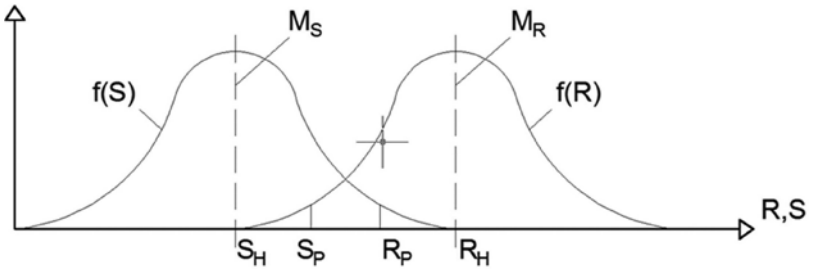

Figure.2. Ratio between (S) and (Rp).

Then (taking into account 5) expression (4) has the form:

$$1_R = \frac{1 - \gamma_R{}^* K_R}{1 - \gamma_R{}^* K_R} \tag{6}$$

With a normal distribution of ɤr=3 (3 sigma rule), n(ɤR=3) the probability of finding a smaller value of "R" will be 0.00135 (P=0.00135).

Similarly to (6), we can write an expression for the load reliability coefficient

$$1_s = \frac{1 + \gamma_s * K_s}{1 + \eta_s * K_s} \tag{7}$$

Thus, using the formulas (3,4,6), it is possible to express the value of the margin coefficient in terms of the probabilistic characteristics of loads and resistances:

$$n = \frac{1 + \gamma_s{}^* K_s}{1 + \eta_s{}^* K_s} * \frac{1 - \eta_R{}^* K_R}{1 + \gamma_R{}^* K_R} \tag{8}$$

that is, the relationship of the reserve coefficient "n" with the load reliability coefficient has a statistical nature.

Let 's introduce the notation:

(Ψ= R – S) – the function of indestructibility (reliability). Then the reliability of the "H" structures is defined as the ratio:

$$H = p(\Psi > 0) = \int_{-\infty}^{\infty} f(\Psi) d\Psi \tag{9}$$

where p=(Ψ>0)- probability; f(Ψ) – probability density of the magnitude distribution «Ψ»;

With a normal distribution law (for 9):

$m_\Psi = m_R - m_s$ - mathematical expectation

$$\sigma^2{}_\Psi = \sigma^2{}_R + \sigma^2{}_s \tag{10}$$

Then (by "9") (taking into account "10") we have:

$$H = \frac{1}{\sigma_\Psi \sqrt{2\pi}} \int_0^\infty \exp\left[-(\Psi - m_\Psi)^2/(2\sigma_\sigma)^2\right] d\Psi \tag{11}$$

Let's replace the variables:

$$t = (\Psi - m_\Psi)/\sigma_\Psi \tag{12}$$

Then, taking into account expression (12), expression (11) will take a different form:

$$H = \frac{1}{2\pi} \int_{-t_0}^{\infty} \ell^{-t^{2/2}} dt \tag{13}$$

$$t_0 = (m_R - m_s)/\sqrt{\Psi_R^2 + \Psi_s^2} \tag{14}$$

In this case, we have a special case: if the limiting voltage "R" is a deterministic value, then instead of expression (8) we have:

$$n = 1 + t_0 \, K_s \tag{15}$$

Consider the case when the probabilistic distribution of stress and strength is unknown, but the first two moments of these distributions are known. In this case, probabilistic reliability is determined by the formula:

$$H \geq 1 - \frac{n_c^2 \left(K_R^2 + K_s^2\right)}{n_c^2 \left(K_R^2 + K_s^2\right) + \left[n_c\left(1 + K_s^2\right) - 1\right]} 2 \tag{16}$$

The lower limit of reliability at the known two moments of stress distribution and strength

$$n_c \geq \left[1 + K_s^2 - \frac{\sqrt{\left(K_R^2 + K_s^2\right)} H}{1 - H}\right]^{-1} \tag{17}$$

$$K_n = \sqrt{K_R^2} + K_s^2 \,/\, \left(1 + K_s^2\right) \tag{18}$$

The calculation of the remaining resource is performed according to one or more criteria:

1) Calculation of the residual resource depending on physical wear and tear

$$\varepsilon = \frac{a_1 \, \varepsilon_1 + a_2 \varepsilon_2 + \ldots + a_i + \varepsilon_i}{a_1 + a_2 + \ldots a_i} \tag{19}$$

where, ε_1, ε_2, ε_i, – maximum damage to individual structures; a_1, a_2 … a_i – coefficient of significance of individual structures. a) Relative assessment of damage to the structure [8]

$$\lambda = 1 - \varepsilon \tag{20}$$

The constant of "wear" is determined by the results of surveys

$$\lambda = \frac{-\ell \, \mathrm{n}\, y}{t_{cp}} \tag{21}$$

where t_0 – service life in years at the time of the survey.

The service life of the first operation in years before the start of repair [9]

$$T = \frac{0.16}{\lambda} \tag{22}$$

2) Calculation of the residual resource with statistical strength. Residual life according to permissible voltages

$$\mathrm{T_R(T_Э)} = \frac{\sigma_{\varepsilon(t)} - [\sigma]}{\alpha_0} \tag{23}$$

where $\sigma_{\varepsilon(t)}$ - tensile strength at the time of examination; [σ] – tensile strength by calculation; α_0 – the rate of reduction of mechanical properties.

$$\alpha_0 = \frac{\sigma_\varepsilon - \sigma_{\varepsilon\,(t)}}{\mathrm{t}} \tag{24}$$

σ_ε- normal tensile strength; t– time from the start of operation to the moment of inspection; 3) Calculation of residual corrosion life (for metal)

$$\mathrm{T_K} = \frac{\mathrm{S_ф} - S_\mathrm{p}}{\lambda} \tag{25}$$

$\mathrm{S_ф}$– actual minimum thickness in mm; $\mathrm{S_p}$ – the calculated value of the degree, in mm; α – uniform corrosion rate, mm/year

$$\alpha = \frac{\mathrm{S_u} - \mathrm{S_ф}}{\mathrm{t}} \tag{26}$$

where $\mathrm{S_u}$- executive wall thickness of the element, mm; t- the time of the start of operation until the time of the survey, years.

4) Calculation of the residual resource for structural fatigue:

$$\mathrm{T_Ц} = \frac{\mathrm{T_Э} - [\mathrm{N}]}{\mathrm{N_Э}} \tag{27}$$

Тэ-operating time from the moment of operation, years; [N] – additional number of loading cycles; Nэ- the number of loading cycles during the period of operation; Next, we calculate the resource of residual performance:

$$\mathrm{T_{ОСТ(Ц)}} = T_ц - T_Э \tag{28}$$

4 CONCLUSIONS

In the process of analysis, it was established:

1. The results of deterministic and probabilistic calculation methods are quite close; at the same time, probabilistic calculation, compared with deterministic, leads to a small increase in material consumption with a simultaneous increase in the degree of reliability (safety).

The reliability coefficient of the structures "nc" statistically depends on the coefficients of variation in load and strength, which in turn statistically affects the probabilistic reliability of the structures "H".

2. The value of the residual life (in years) of the operated structure depends on the rate of change in mechanical properties and the rate of corrosion of materials and the number of loading cycles.
3. The probability of the presence of defective plates in the general population depends on the number of such plates in the corresponding sample, on the distribution laws of the probability function (the paper presents comparative results of two distribution laws: standard normal and Poisson distribution); In this case, the calculation according to the normal distribution law will give a lower probability.

Developing a two-dimensional nonlinear vertical spring model for mat foundation in clays using hyperbolic function

D.W. Chang & T.M. Chou
Tamkang University, New Taipei City, Taiwan

ABSTRACT: A two-dimensional nonlinear soil spring model for mat foundation in clays is introduced in this paper. Hyperbolic function was used to model the nonlinear load-displacement relationships of the mat. The solutions from three-dimensional finite element analysis were analyzed to find the model parameters of the soil springs underneath the slab. Using the normalized functions of the model parameters across the mat, the two-dimensional modelling of the soil springs was suggested. The solutions from the proposed model with the finite difference analysis were found agreeable to the three-dimensional finite element analysis.

1 INTRODUCTION

The serviceability performance of the foundation has become more important in modern foundation design. It requires the structural deformation analysis to predict the load-displacement relations of the foundation. For nonlinear responses of mat foundation, three-dimensional finite element analysis can provide the most rigorous solution, and the approximate analyses have been often used in design practice with appropriate nonlinear soil springs. The former requires the explorations of the material Laws while the latter simply needs a few model parameters in applications. It should be noted that the soil springs are not the same due to the flexibility of the mat. Recently a two-dimensional soil spring model based on linearly elastic soils has been suggested by Chang et al (2021). The principles of the mat (raft) foundation analysis and design can be found in Bowles (1997) and Fellenius (2014).

The hyperbolic function used in geotechnical engineering can be found by Kondner (1963) in modeling the stress and strain behaviors of cohesive soils. Alternate form of such modeling for clays from the Tri-axial test was known as the Hyperbolic soil model (Duncan & Chang 1970). Until now, the hyperbolic soil model has been discussed frequently with the hardening soil model (Schanz et al 1999). It can be used as three-dimensional constitutive laws for the clays in both drained and undrained conditions. On the other hand, the application of the hyperbolic function in modeling the Plate Load test on gravels has been reported by Wrench (1984). The hyperbolic function of the soil reactions, q and foundation displacements, s can be expressed in Equation (1) with two parameters k and q_{ult}. The value k is defined as the initial tangent modulus of the curve, and q_{ult} is the ultimate strength revealed.

$$q = s/(1/k + s/q_{ult}) \tag{1}$$

The hyperbolic function shown in Equation (1) is adopted in this study. Through a number of numerical studies on the loaded mat foundations, the soil reactions and the foundation displacements from the three-dimensional finite element analysis were analyzed to obtain the parameters k and q_{ult} for each nonlinear soil spring. They are varying across the mat and dependent of soil stiffness and foundation width. The proposed modeling is discussed as follows.

DOI: 10.1201/9781003299127-362

2 NUMERICAL MODELLING

A square mat foundation with width varying at 16, 26 and 36 meters was assumed. The thickness of the mat was 1m. Homogeneous clays were assumed as the ground soil. The corresponding shear wave velocity, V_s of the soil was varying at 120, 140, 160, and 180 m/s, respectively. The study neglected the ground water table, and the Poisson's ratio of the soil was assumed at 0.4. The Young's modulus of the soil, E_s can be thus obtained. Empirical relations suggested by Hsieh et al (2003) between the Young's modulus E_s and the undrained shear strength of the clays, S_u in Taipei was used to obtain the value of the undrained shear strength. The Mohr-Coulomb soil model was adopted. The uniform load, p was applied until the foundation failure. It was decomposed into a series of load increments at 10kPa. Iterative procedure was carried out to ensure the equilibriums of the system. Table 1 summarizes the material properties and engineering parameters used in the analysis.

Table 1. Foundation geometries, material properties and parameters of the study.

Foundation dimensions and load	FE zone: 200m×200m×60m for Mat width (B): 16m, 26m FE zone: 300m×300m×60m for Mat width (B): 36m Thickness of mat: 1m Maximum load (p): 220kPa, 310kPa, 410kPa, 530kPa varied w/ soil stiffness
Concrete	γ_c =24 kN/m^3, E_c =30 GPa, ν_c = 0.15
Soil	γ_s=20 kN/m^3, ν_s= 0.4, V_s = 120m/s, 140ms, 160m/s, 180m/s E_s = 82Mpa, 112Mpa, 146Mpa, 184Mpa; S_u= 41kPa, 56kPa, 73kPa, 92kPa Note E_s/S_u =2000 is assumed for different clays

The 3D FE analysis was made using Midas GTX NX package (Midas, 2014). Three dimensional 8-node solid elements were used to model the concrete structure and the soils. The interface elements were implemented between the concrete and the soils. Normal and tangent stiffness of the interface elements, k_n and k_t were assigned as $10E_s$ and E_s, respectively. Ultimate adhesion of the interface elements was assumed as 2/3 of the undrained shear strength of the clay. The stability of the foundation displacements was ensured with the FE dimensions varied (see Figure 1). Essential boundaries such as the rollers were placed. Two- and three-dimensional hinges were resulted at the interfaces of these boundaries. Since the structural system and load symmetry, only 1/4 of the structural system was analyzed. The computation time required for the FE analysis approximates 0.5~2.5 hrs using PC with CPU: AMD Ryzen 7 3800X 8-Core Processor, GPU: NVIDIA GeForce GTX 1060 3GB, and RAM: 64GB.

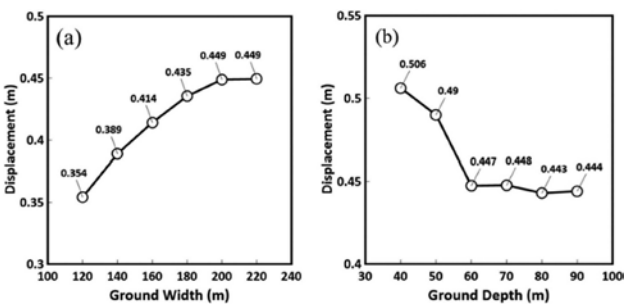

Figure 1. Stability of the solutions from 3D FE analysis (a) ground width (b) ground depth.

3 HYPERBOLIC MODEL PARAMETERS AND THEIR FUNCTIONS

The FE analysis was first conducted to obtain the load-displacement relationships of all the cases. The soil reactions, q obtained at the nodes across the central section of the mat foundation were plotted against the nodal displacements, s of the foundation. By doing so, the hyperbolic function can be used to model the curves found by q vs. s. Figure 2 reveals the modeling where the value of q_{max} was the maximum load pressure that can be applied before reaching the ultimate load, q_{ult}. The ratio of q_{ult}/q_{max} was assumed to obtain q_{ult} for the appropriate modeling. In the study, the ratios at 1.1~1.4 were suggested to yield rational predictions from the hyperbolic functions with those obtained from FE analysis. Figure 3 illustrates the matching results for mats with width at 26m on soils with shear wave velocity of 140m/s using q_{max} and q_{ult}. It can be observed that the modification of q_{max} is rather important. The values of k and q_{ult} for nodes at the center of the mat foundations studied can be found in the range of 1.2~10.8MN/m^3 (for k) and 264~681kPa (for q_{ult}). Detailed values can be found in Chou (2022).

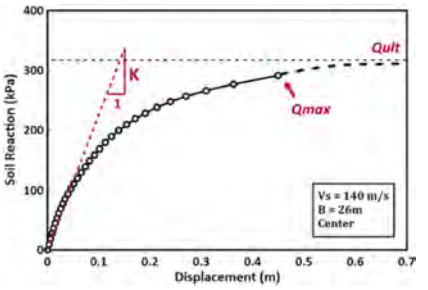

Figure 2. The relationships of soil reactions and foundation displacements.

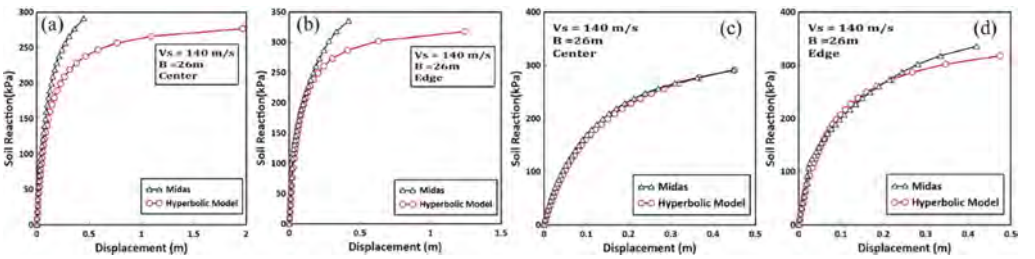

Figure 3. Hyperbolic modeling of soil reactions and foundation displacements (a) & (b) using q_{max} (c) & (d) using q_{ult}.

Plotting the values of k and q_{ult} obtained at the nodes across the central section of the foundation, the normalized functions of k and q_{ult} can be both achieved with respect to their values exerted at the center of the foundation. Figure 4 depict the variations of the normalized data for k and $q_{ult,}$. The normalized functions $f_k(x)$ for k and $f_q(x)$ for q_{ult} have been reported by Chou (2022) using the regression analysis. They are dependent of the soil stiffness and the mat width. As the results, the two-dimensional nonlinear soil model can be suggested by following equations in association with the use of Equation (1). Note that k_c and q_{ultc} are the parameters found at center of the foundation.

$$k = k_c \times f_k(x) \times g_k(y), \text{ where } g_k = f_k \tag{2}$$

$$q_{ult} = q_{ultc} \times f_q(x) \times g_q(y), \text{ where } g_q = f_q \tag{3}$$

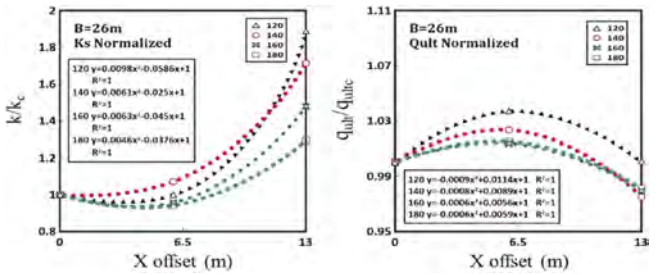

Figure 4. Variations of the normalized k and q_{ult} for mat with width of 26m.

4 VALIDATIONS

In order to verify the proposed model of the nonlinear soil springs, the finite difference analysis WERAFT (Chang et al 2018) for the mat foundation following the Thin-Plate theory was adopted. The soil springs underneath the mat foundations in WERAFT analysis were replaced by the newly proposed model. It is important to point out that the secant modulus of the sub-grade reactions at the nodes of the mat must be computed first in order to form the structural stiffness matrix for solving the foundation displacements. Thus the secant modulus of the sub-grade reactions is dependent of the foundation displacements. Therefore the equilibriums of the applied load with respect to the foundation displacements must be ensured by the iterative procedures. The solutions from the WERAFT analysis using the two-dimensional nonlinear soil springs suggested in this study were found agreeable with those obtained from 3D FE analysis. Figure 5 reveals their comparisons. They are applicable to mat foundation with thickness of 1m~2m (Chou, 2022). Note that the computational time required for the WERAFT analysis is much less than those found in the Midas analysis.

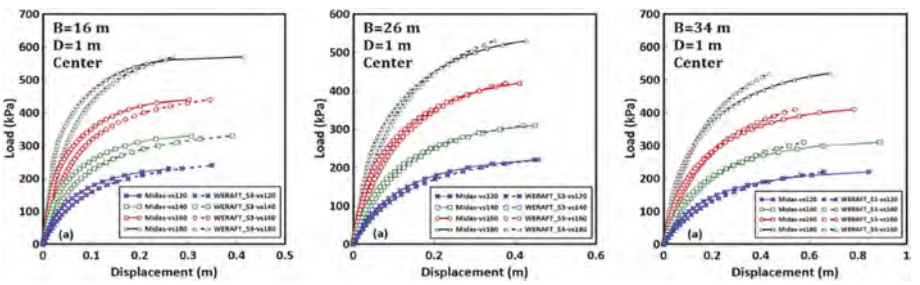

Figure 5. Comparison of the solutions from FD w/ the proposed soil springs and FE analyses.

5 CONCLUDING REMARKS

A two-dimensional nonlinear soil spring model is suggested in this study for vertically loaded mat foundation located in clays. Hyperbolic function is adopted to model the nonlinear relationships between soil reactions and foundation displacements. Model parameters k and Q_{ult} were back-analyzed from the solutions of 3D FE analysis. The variations of these parameters across the mat were calibrated with the normalized functions. The proposed modeling can be applied to the finite difference analysis of the mat foundation, and the results were found comparable with the 3D FE analysis.

ACKNOWLEDGEMENT

This paper presents a partial result of the research project sponsored by Ministry of Science and Technology (MOST) in Taiwan. Sincere gratitude is expressed towards the finance supports through research grant MOST109-2221-E-032-010-MY2.

Dimensionless modulus of subgrade reaction for embedded mat foundation in soft clay under vertical load

D.W. Chang & J.H. Lin
Tamkang University, New Taipei City, Taiwan

Y.K. Lin, F.C. Lu & C.J. Kuo
Ground Master Construction Co., Ltd., Taipei, Taiwan

ABSTRACT: The dimensionless modulus of the subgrade reaction for embedded mat foundation in soft clays under the vertical load is suggested in this paper using 3D FEM analysis and the Mohr-Coulomb soil model. Besides the soil stiffness, the embedded depth and width of the raft, the depth of diaphragm wall, and the total structural loads were considered as influence factors. For applications to routine designs, foundation displacement, soil reaction, and modulus of subgrade reaction were examined by their non-dimensional measures. The optimized correlations with the foundation geometries are suggested based on various soil stiffness and structural load.

1 INTRODUCTION

1.1 *Analysis of mat foundation*

The serviceability performance of the foundation has become more important in modern foundation design. It requires the structural deformation analysis besides the conventional ultimate capacity analysis of the foundation. For mat foundation, the deformation analysis can be simply made by treating the foundation as a one-dimensional beam or two-dimensional mat resting on a series of soil springs. For more rigorous analysis, the foundation and its surrounding soils can be modeled as a continuum discretizing by two- or three-dimensional finite elements. Despite that the finite element (FE) analysis has been widely used in modern foundation designs, the approximate numerical analyses are still adopted in many foundation designs due to its simplicity. The principles of the mat (raft) foundation analysis and design were discussed by Bowles (1997) and Fellenius (2014).

1.2 *Modulus of subgrade reactions*

If a simplified numerical tool was used to analyze a mat foundation, the modulus of subgrade reaction of the soils is important for engineers to know. The modulus of subgrade reaction for soils underneath the raft deforming vertically is denoted as k_v (units in F/L^3). It is defined as the ratio of the soil reactions to the foundation displacement. For foundation vibrations, the soil spring constant of a rigid disc foundation has been suggested by Lysmer & Richart (1966). Alternate spring models of the soils can be found either with the effects of foundation geometry and finite thickness of subgrade or with the embedment of foundation (Novak & Beredugo 1972, Kausel et al 1978, Gazetas 1991). By taking the load frequency as zero, static displacement of the foundation can be achieved. The modulus of subgrade reaction in above models is able to obtain by dividing the soil spring constant with the area of foundation. In addition, many researchers focused on analyzing the foundation settlements due to large static

DOI: 10.1201/9781003299127-363

loads following the Theory of Elasticity and/or consolidation hypothesis. In such case, the modulus of subgrade reaction, k_v of the foundation can be determined by dividing the load pressure with the calculated foundation settlement. Poulos (2018) has discussed the modulus of subgrade reaction for foundation analysis. It should be pointed out that the resulting strain level of the soil is important in different engineering problems. Engineers must use appropriate soil modulus to obtain rational predictions. In recent years, research studies conducted by advanced analytical and/or numerical analyses (Lee et al 2015, Chang et al 2019) had shown that the foundation settlements under vertical load are varying across the foundation, and affected by soil stiffness, foundation size, and the load applied to the foundation. Therefore, the soil spring constants underneath the mat should be dependent of these design factors. Chang et al (2021) have suggested a two-dimensional soil spring model for the surface mat foundation in soft clay. This study intends to discuss the modulus of subgrade reaction for mat foundation embedded in soft clays due to the vertical load. The modulus of subgrade reaction was calibrated to dimensionless measure, and their correlation with the dimensionless quantities representing the foundation geometry was suggested.

2 NUMERICAL MODELS

2.1 *Foundation modelling*

The numerical model of the embedded mat foundation is illustrated in Figure 1. A square mat foundation with the width varying at 16, 26 and 36 meters was assumed. The thickness of the mat was 1m. Embedded depth of the mat was varying at 8 and 12m. For more realistic modelling, the concrete diaphragm wall was around the mat. The depth of the diaphragm wall was kept as 2 and 2.5 times of the depth for foundation embedment. Homogeneous soft clay was assumed for the ground soil. The corresponding shear wave velocity, V_s of the soil was varying at 100, 120 and 140 m/s, respectively. Ground water table was not included whereas the Poisson's ratio of the soil was 0.4.

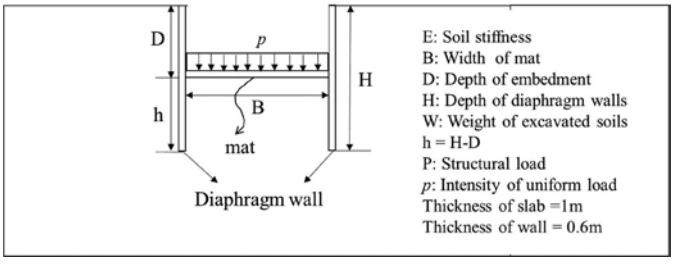

Figure 1. Foundation model of this study.

The Young's modulus of the soil, E_s can be thus obtained. Empirical relations suggested by Hsieh et al (2003) between the Young's modulus E_s and the undrained shear strength of the clays, S_u in Taipei was used to obtain the value of the undrained shear strength. The Mohr-Coulomb soil model was adopted. Notice that the structural load, P was taken approximately as 1 and 1.5 times the weight of excavated soils. In some studies, the total load was fixed and independent of embedment depth and size of the slab. The applied uniform load, p was decomposed into a series of incremental loads of 10kPa. Iterative procedure was carried out to ensure the equilibriums of the system. Table 1 summarizes the material properties and engineering parameters used in the analysis. Totally 72 numerical cases were analyzed.

Table 1. Foundation geometries, material properties and parameters of the study.

Foundation dimensions and load	FE zone: 200m×200m×60m, Mat width (B): 16m, 26m, 36m, Depth of embedment (D): 8m, 12m Depth of diaphragm (H): 2.D and 2.5D Thickness of mat: 1m, Thickness of wall: 0.6m Structural load (P): 1.0W, 1.5W, Weight of soils excavated (W): $\gamma_s \times B^2 \times D$
Concrete	γ_c =24 kN/m^3, E_c =30 GPa, ν_c = 0.15 γ_s=20 kN/m^3, ν_s= 0.4, V_s = 100m/s, 120ms, 140m/s,
Soil	E_s =57 MPa, 82Mpa, 112Mpa, S_u= 28.5kPa, 41kPa, 56kPa (E_s/S_u =2000) for soils denoted as E1, E2 and E3

2.2 *Discrete mesh and boundaries*

The 3D FE analysis was made using Midas GTX NX package (Midas, 2014). Three dimensional 8-node solid elements were used to model the concrete structure and the soils. The interface elements were implemented between the concrete and the soils. Normal and tangent stiffness of the interface elements, k_n and k_t were assigned as $10E_s$ and E_s, respectively. Ultimate adhesion of the interface elements was assumed as 2/3 of the undrained shear strength of the clay. Stage-construction feature available in Midas analysis was used. The stability of the foundation displacements was ensured with the FE dimensions at 200m×200m×60m. Essential boundaries such as the rollers were placed. Two- and three-dimensional hinges were resulted at the interfaces of these boundaries. The computation time required for the analysis are around 4~24 hours using PC with Processor 11th Gen Intel® Core™ i7-11700 @2.5 GHz.

3 FOUNDATION BEHAVIORS

3.1 *Foundation displacements*

The largest displacements of the foundations were found appeared at the center in the range of 15~310mm. They were mainly affected by soils stiffness. Large structural loads would increase the settlements. Nonlinear load-displacement relationship was able to find. For similar structural loads, increasing the depth of embedment and the size of the mat foundation will reduce the foundation settlements. The depth of diaphragm wall could slightly reduce the foundation settlements especially for the mat in very soft soil. Figure 2 presents the influences

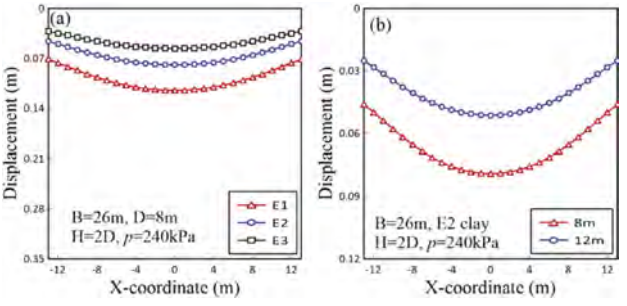

Figure 2. Foundation displacements affected by (a) soil stiffness (b) depth of embedment.

of soil stiffness and depth of embedment of the mat with width at 26m. The maximum foundation displacements occurred at different locations of the cases were reported by Lin (2022).

3.2 *Soil reactions*

The soil reactions underneath the mat foundation are generally distributed like the settlements. Nevertheless, in some cases where the structural load is equal to the weight of the excavated soils, i.e. compensated foundation, when the soil stiffness increased, the soil reactions at the foundation center became less than the soil reactions occurred near to the edge. The oscillations of the soil reactions were found in such cases. The largest soil reaction of the foundations were found in the range of 190~385 kPa. They will be affected by soil stiffness, depth of foundation embedment, and total structure load. Figure 3 indicates the corresponding soil reactions for those shown in Figure 2. Again, the largest soil reactions recorded in the study was discussed in Lin (2022).

3.3 *Modulus of subgrade reaction*

The modulus of subgrade reactions, k_s of the soils underneath the mat can be obtained as in the range of 3~26 MN/m^3 for compensated foundation (i.e. P=1W), and 1.5~12 MN/m^3 for the cases where the structural load is 1.5 times the weight of excavated soils. These moduli were found to be smaller for softer soils and larger structural loads. The distributions of the soil reactions along the foundation showed that the smaller k_s were found in the center.

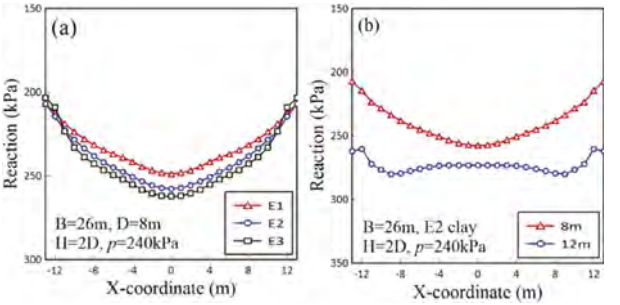

Figure 3. Soil reactions affected by (a) soil stiffness (b) depth of embedment.

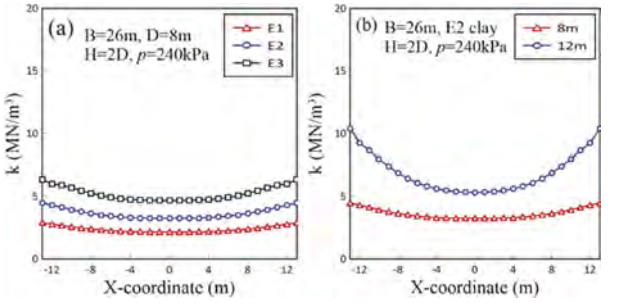

Figure 4. Modulus of subgrade reaction affected by (a) soil stiffness (b) depth of embedment.

Figure 4 reveals the corresponding results. The depths of the foundation embedment and the diaphragm wall would help to increase the modulus of subgrade reactions. For more information, please refer to Lin (2022).

4 DIMENSIONLESS MEASURES

4.1 *Foundation displacements*

In order to apply the study results, dimensionless measures of the maximum foundation displacements, s were defined as $\gamma_s s/E_s$, s/B, and $\gamma_s s/p$, whereas γ_s, E_s, B and p are the unit weight of the soil, Young's modulus of the soil, width of the mat, and the loading pressures applied to the mat, respectively. The dimensionless values representing for the foundation geometry were defined as 2D/B and 2h/B, whereas D is the embedded depth of foundation, h is defined as the length of the diaphragm wall underneath the embedment, which is equal to H-D. The relationships of the dimensionless foundation displacement with respect to the dimensionless values of the foundation geometries was evaluated respectively by plotting the data in x-y plane formed by non-dimensional displacements as the ordinate and the geometric values as the abscissa. Regression analysis was applied to examine the corresponding statistic efficiency of the correlations. The optimized correlations between the dimensionless foundation displacement and the dimensionless values of the foundation geometry was found to be $\gamma_s s/p$ vs. 2D/B. Figure 5 depicts their correlations with the dependence of soil stiffness and structural load applied at the foundation. Note that P1 is equal to the weight of excavated soil, W whereas P2 is equal to 1.5W.

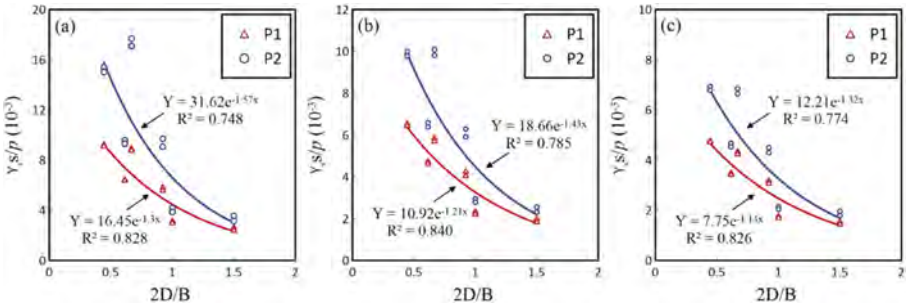

Figure 5. Optimized correlations of dimensionless foundation displacements versus 2D/B of mat (a) E1 clay (b) E2 clay (c) E3 clay.

4.2 *Soil reactions*

Similarly, dimensionless soil reactions in association with the above dimensionless foundation displacements were defined as q/E_s, $q/\gamma_s B$, q/p (where q is the soil reactions recorded at the center of foundation), respectively. These values were plotted against the values of dimensionless foundation geometry to verify their efficiency. Again, the optimized correlations formed by q/p and 2D/B can be shown in Figure 6.

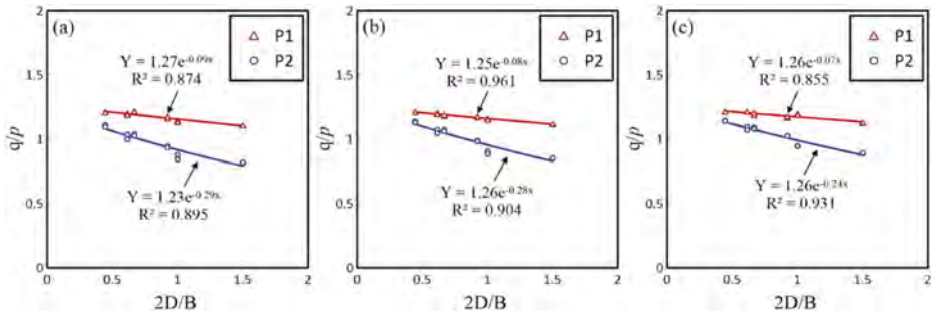

Figure 6. Optimized correlations of dimensionless soil reactions versus 2D/B of mat (a) E1 clay (b) E2 clay (c) E3 clay.

4.3 *Modulus of subgrade reaction*

The dimensionless modulus of subgrade reactions in association with all the dimensionless foundation displacements and their corresponding soil reactions was found as $q/\gamma_s s$. Their values were plotted against the values of dimensionless foundation geometry to determine the optimized correlation. As the results, the optimized correlations between $q/\gamma_s s$ and 2D/B can be shown in Figure 7. Notice that to obtain the value of k_s, one must compute the foundation settlement, s first from Figure 5. Then use Figure 7 or Figure 6 to obtain q. k_s is computed as q/s.

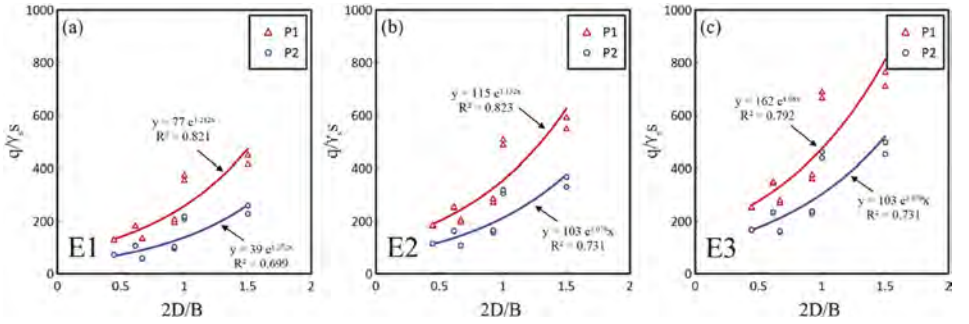

Figure 7. Optimized correlations of dimensionless modulus of subgrade reaction versus 2D/B of mat (a) E1 clay (b) E2 clay (c) E3 clay.

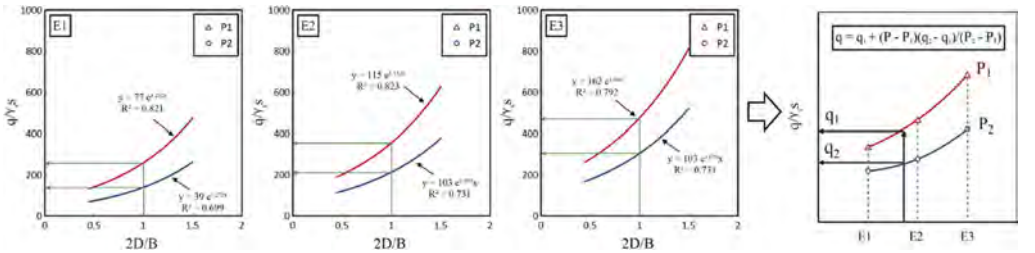

Figure 8. Soil reaction to be calculated from the interpolations.

4.4 *Applications*

The engineers can use the regression curves shown in Figures 5–7 to estimate the foundation displacement, the soil reactions and the modulus of subgrade reactions if the site soils and the structural loads are similar to the case studied. For soil stiffness and structural load different to the suggested quantities, interpolations should be used to obtain the approximated values. For example, the soil reaction, q can be found as the procedures shown in Figure 8. Foundation displacement can be found using the similar procedure. Once the foundation settlement, s and soil reactions, q are obtained, the modulus of subgrade reaction, k_s can be thus calculated.

5 CONCLUDING REMARKS

The foundation displacements, soil reactions, and the modulus of subgrade reactions of the embedded mat foundation located in soft clays subjected to vertical loads have been analyzed by 3D FE analysis. The influences of the soil stiffness, the foundation size, the depth of embedment, the depth of diaphragm wall, and the structural loads were studied by seventy-two cases. In order to use them in routine design, their values were first transformed to dimensionless quantities, and then correlated to dimensionless values of the foundation geometry. The correlations of $\gamma_s s/p$, q/p, and $q/\gamma_s s$ versus 2D/B was found to be the optimized one. They are suggested as a preliminary

design tool for mat foundations in soft clays. Further examination with the field measurements is encouraged.

ACKNOWLEDGEMENT

This paper presents a partial result of the technical project supported by Ground Master Construction Co. Ltd. In Taiwan. Sincere gratitude is expressed. The thankfulness is extended to Prof. C.H. Chen (NTU), Dr. C.D. Ou (SEAGS & AGSSEA) and R&D Director Mr. C.C. Ko (MAA) for their valuable comments/suggestions in reviewing the project.

Evolution of the foundation design methods for multi-storey and high-rise buildings in seismic regions

A.I. Polishchuk, M.B. Marinichev & I.G. Tkachev
Kuban State Agrarian University named after I.T. Trubilin, Krasnodar, Russian Federation

ABSTRACT: Methods for the construction of foundations for multi-storey and high-rise buildings in seismic areas are proposed, taking into account compound conditions, such as: slopes of the relief, heterogeneity of subsoil layers, the risk of landslide processes and others. A point system for assessing areas of territory by the convenience of its development for the construction of multi-storey and high-rise buildings (structures) has been developed. Effective solutions of the foundations for the projects in difficult soil conditions have been patented. Methods of calculation and design of foundations were developed and implemented during the construction and reconstruction of multi-storey and high-rise buildings in Krasnodar, Sochi, Novorossiysk, Anapa.

1 INTRODUCTION

Over the past decade, new methods of design for raft-pile foundations in particularly difficult soil conditions have been developed and implemented. Methods are divided into the following three groups: the implementation of foundations with a given initial settlement of the slab part; implementation of piles with different lengths and consequential inclusion in joint work with the slab part; technical solutions with the possibility of foundation settlements regulation during construction stages (Shadunts K.Sh. et al, 2007, 2008, 2010, 2012).

The proposed methods are the development of well-known methods of calculation and construction of pile and pile-raft foundations taking large vertical and horizontal loads (Mangushev and Osokin, 2010; Ilyichev et al., 2021; Katzenbach et al., 2020a; Katzenbach et al., 2020b; Gotman and Gotman, 2018; Mangushev et al., 2023; Zhussupbekov et al., 2022; Ter-Martirosyan and Ter-Martirosyan, 2020; Ter-Martirosyan et al., 2021). The main point of the studied methods is to find ways to greaterly include the foundation slab in joint work with piles, which is expressed in the ratio of the corresponding shares. When the desired result is achieved, the share of the load transferred to the foundation slab can be up to 40-50% of the total value.

A perspective direction in the use of the developed foundation design methods for the pile and raft-pile foundations is their consideration during preparations the master plans of territories with the presence of complex soil conditions. For this purpose, a classification of methods for calculating and constructing the foundations of multi-storey and high-rise buildings in particularly difficult ground conditions is proposed, which allows to avoid mistakes at the stage of choosing design solutions and, thereby, reduce the risks of investments in construction.

2 METHODS

2.1 *The implementation of raft-pile foundations with a given initial settlement of the slab part*

The method of execution of the foundation proposed in Figure 1 (RU patent No. 2379425) includes the execution of a pile field and a slab, where the piles are made along the perimeter of the foundation, and the slab is made of two parts - the external, which has ledges upwards, immediately resting on the piles, and the internal one - with ledges downwards, which rests on the outer

DOI: 10.1201/9781003299127-364

part of the slab. At the same time, after reaching the calculated settlement, the outer and inner parts of the slab are rigidly combined, ensuring the joint operation of the pile-slab foundation.

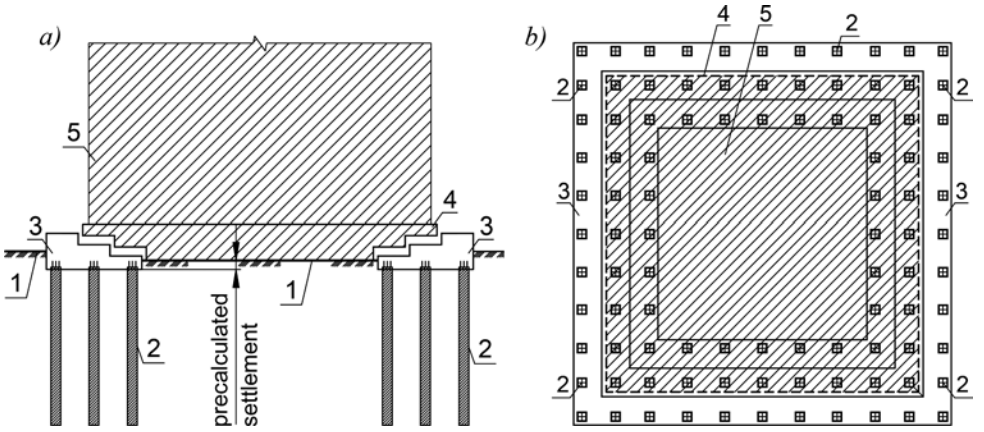

Figure 1. Scheme of construction of a raft-pile foundation: *1* – prepared soil surface; *2* – perimetral piles, united by a grillage; *3*; *4* – foundation slab with designed configuration; *5* – high-rise building (RU patent No 2379425).

The first group of methods also includes: construction method for a raft-pile foundation (RU patent No. 2378454); pile-slab foundation (RU patent No. 2331738).

2.2 *Implementation of piles with different lengths and consequential inclusion in joint work with the slab part*

A brief description of the methods included in the group is given below.

The method presented in Figure 2 (RU Patent No. 2300604) assumes that in order to increase the proportion of the load on the slab, it is necessary to make the slab with the opportunity to obtain a large amount of displacement at the initial stage of settlement development. This is possible if the interaction of the slab and the piles begins after the slab has undergone a certain predetermined initial settlement. The result is achieved if piles forming the raft-pile foundation have different lengths: the main ones - long piles - are located directly under the load-bearing elements of the building and are included in the joint work after the foundation slab receives a certain proportion of settlement, i.e., at a given (controlled) stage of including the piles in joint work with the slab part.

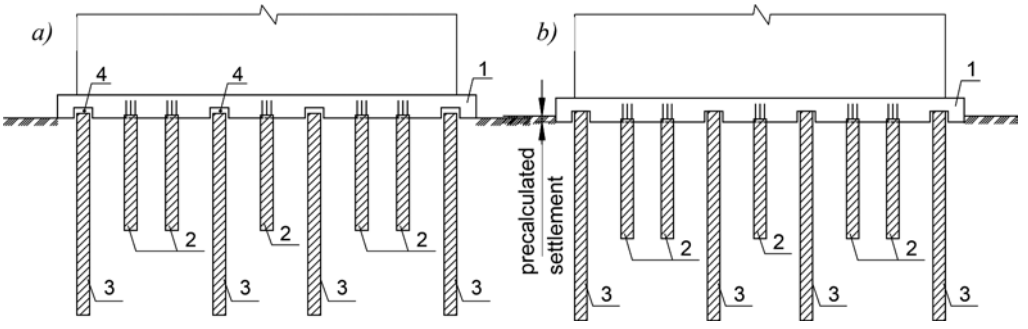

Figure 2. Method of construction of raft-pile foundations in seismic areas: *а)* the initial stage of deformation increment – the settlement of the slab rigidly combined with short piles: *1* – foundation slab; *2* –short piles rigidly joined with the slab; *3* – long piles separated from the slab by a design clearance *4*; *б)* the final stage of deformation development is the involvement of long piles in the work of the raft-pile foundation (RU patent No. 2300604).

The second group of methods also includes: method of a bored pile installation with increased bearing capacity for construction in seismic areas (RU patent No. 2761795); improved raft-pile foundation (RU patent No. 2320820).

2.3 *Technical solutions with the possibility of foundation settlements regulation during construction stages*

The methods included in the group are listed below.

The developed method of erecting a raft-pile foundation (Figure 3) allows to achieve the greatest efficiency due to the consequential inclusion of foundation elements in the joint work (RU patent No. 2513050). Often, in the construction of high-rise objects, cross-wall structural schemes are used due to their high spatial rigidity and bearing capacity. In particular, such a scheme allows within the framework of existing regulatory documents to provide for the largest number of storeys for seismic areas.

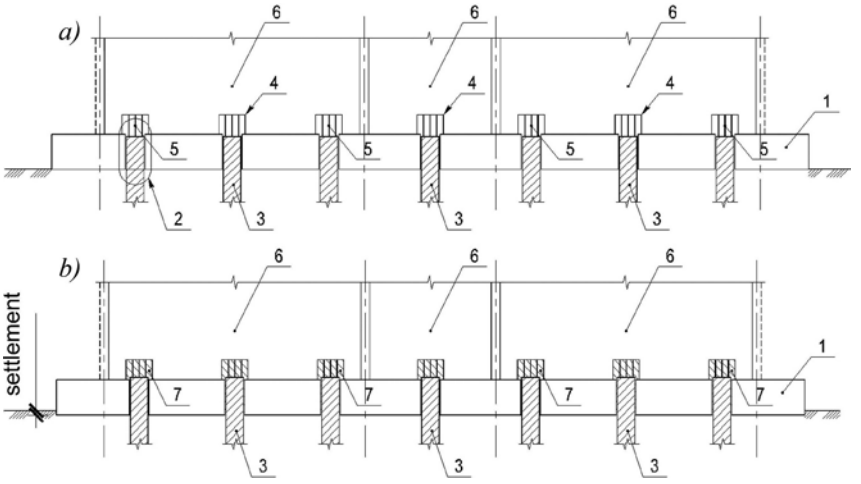

Figure 3. Method of construction of pile-slab foundation: *1* – foundation slab; *2* – through hole in the slab; *3* – projected piles; *4* – niches above pile heads in load-bearing walls; *5* – upper parts of pile reinforcment for the formation of rigid joints; *6* – load-bearing walls; *7* – concrete to fill niches in the walls when the specified value of the slab settlement is reached (RU patent No. 2513050).

The third group of methods also includes: a method for regulating the inclinations of the pile-slab foundation in seismic areas on unevenly compressible soils (RU patent No. 2734750); slab foundation on an unevenly compressible base with the possibility of regulation the inclinations (RU patent No. 2731969).

Based on the research and taking into account new methods of construction of pile and raft-pile foundations recommendations were prepared for the design and construction of foundations in particularly difficult soil conditions, taking into account the given stages of construction.

2.4 *Calculation and construction methods of foundations of multi-storey and high-rise buildings in particularly difficult soil conditions*

The developed methods for calculating and constructing the foundations of multi-storey and high-rise buildings in particularly difficult ground conditions include:

- The method of calculation and construction of foundations based on the studieded parameters of interaction between single pile and soil and between the pile group and soil
- The method of calculation and construction of pile foundations using an intermediate transfer layer
- The method for regulating uneven foundation settlements by increasing the spatial stiffness of the foundation structure

– The method of foundations design using adaptation of its form to the surface of steep relief
– The method of construction of foundations with constant and temporary deformation joints
– The method of construction of foundations with the consequential inclusion of foundation elements in the joint work

The implementation of the developed methods of calculation and construction of foundations in particularly difficult ground conditions was carried out at more than 50 objects of multi-storey and high-rise buildings (Figures 4-7).

3 RESULTS

3.1 *A complex of multi-storey residential buildings on a steep terrain on yesaulenko street in Sochi*

One of the objects in the implementation of the method of foundations design using adaptation of its form to the surface of steep relief is a complex of multi-storey residential buildings located on a slope steepness of up to 35 ° in Sochi (Figure 4).

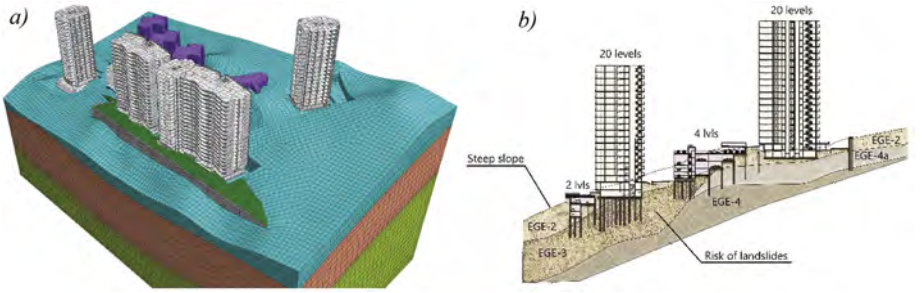

Figure 4. Multi-storey residential buildings located on a steep slope with a risk of landslides: *a* – spatial FEM model; *b* – geological section of the construction site, combined with the designed multy-storey buildings.

The construction was carried out in the conditions of adjoining new buildings to existing residential buildings located at a distance of 5 meters or more from the structures being built. The adjoining of the loaded foundations of existing buildings determined strict requirements for maintaining a minimum impact on existing facilities, so the deep excavation for the construction site was initially excluded. The solution was found by adapting the raft-pile foundation to the variable surface of the relief, which made it possible to minimally affect the slope and avoid

Figure 5. Stages of construction of multi-storey buildings on a landslide slope: *a* – general view of the construction site; *b* – the final stage of construction of section No. 1.

landslides. As a result of the application of a reasonable consequence the construction of the foundation became possible to achieve compliance with all the required parameters (Figure 5).

3.2 *Multi-storey multifunctional residential complex on a landslide slope in the Khosta district of Sochi*

In the process of implementing the method of construction of foundations with constant and temporary deformation joints, analyses were carried out to assess the forces arising in the completed piles of overlying blocks at each stage of the construction of the foundations of the complex, up to the moment of unification of the adjacent sections in the places of temporary deformation joints (Figure 6). After that the horizontal forces and bending moments in the piles were significantly reduced due to the inclusion in the joint work of the underlying structural block and its foundations.

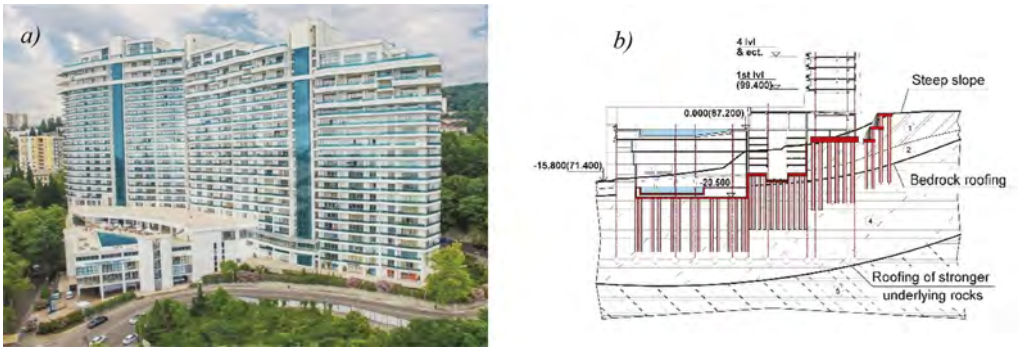

Figure 6. Multi-storey residential complex on a landslide slope in an area with 9-point seismicity: *a* – completed construction; *b* – scheme of a terraced foundation combined with the geological section.

The final scheme of the foundations, terraced from top to bottom, also let to achieve the required spatial stability of the landslide slope, which became possible due to the formed spatial stiffness of the completed foundations and upper structures, sequentially combined into a single scheme by modification of temporary deformation joints. The pile layout for each block (Figure 7) was determined by analyzing the worst combination of forces.

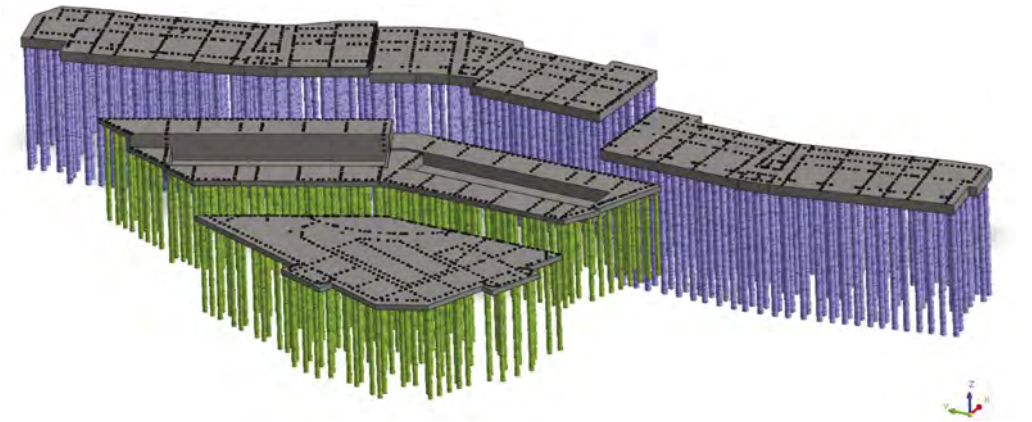

Figure 7. 3D scheme of the terraced raft-pile foundation of the neighboring high-rise blocks.

In general, more than 20 geotechnical and structural design stages were calculated and implemented, the most important were the stages of combining horizontal forces and displacements of adjacent foundations using temporary deformation joints.

Blocks work separately from each other when taking external influences. However, a solution to reduce the loads on the foundation of the high-rise part can be found by involving adjacent stylobate parts in the work of the foundation. Joints between adjacent blocks designed hinged - only for the transmission of horizontal forces. In combination with this, the terracing of adjacent foundations, taking into account the natural shape of the slope, allows to significantly reduce the amount of soil excavation. The overall stability of the entire scheme can be ensured after the properly integrated upper structures and the foundations of the underlying blocks in the joint work with the overlying blocks by combining them through horizontal temporary deformation joints.

4 DISCUSSION

The efficiency after the application of the developed methods is the greatest in conditions of dynamic and seismic influences, as it leads to a decrease of horizontal loads on piles. The reduction of moment loads and horizontal forces ensures the stability of the soil around the lateral surface of the upper part of the piles. That was confirmed in the series of numerical studies in a volumetric approach, taking into account the seismic intensity of 7, 8 and 9 points, described by accelerograms of real earthquakes of different years. With an intensity of seismic impact of 7-9 points, the maximum horizontal forces in the upper part of the piles, consequently included in joint work with the slab, are reduced by 2.5-3.0 times in comparison to standard schemes.

When constructing such foundations, attention should be paid to the rational layout of piles within the plot of the foundation: the distance between piles, it's length, diameter and total volume of the material, taking into account the shape and spatial stiffness of the aboveground structure (Marinichev, 2022).

As a result of the implementation of the developed methods, the reduction of vertical and horizontal loads on piles reasonably leads to a decrease in the volume of material for construction, a decrease in overall costs and a reduction in the time of construction stage.

5 CONCLUSION

New methods of design and construction of pile and raft-pile foundations in seismic areas are proposed: the implementation of foundations with a given initial settlement of the slab part; implementation of piles with different lengths and consequential inclusion in joint work with the slab part; technical solutions with the possibility of foundation settlements regulation during construction stages. The developed classification of methods for calculating and constructing the foundations of multi-storey and high-rise buildings in particularly difficult ground conditions helps to avoid mistakes at the stage of choosing design solutions and allows to ensure the safety of objects during the construction period and further operation, reduces the risks of investments.

Ground modelling by MPS-CAE simulation under different influencing parameters

S. Shakya & S. Inazumi
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: This study focuses on the application of the MPS (moving particle semi-implicit) - CAE (computer-aided engineering) method to simulate the unconfined compression test, from the planning and design stages, in an attempt to model the ground parameters under various influencing parameters. The best fitting ground model was designed for the primary parameters and is compared with the known soil data to justify the claim. Furthermore, the authors endeavored to find the secondary governing factors that will affect the accuracy of the ground modelling. The results show that the values of the primary parameters are influenced by the values of the secondary parameters, resulting in a different model. The influence of the secondary parameters is studied and the best fitting ground model is designed by incorporating both primary and secondary parameters. The resultant ground model is expected to provide more accurate results if firstly applied in various construction simulations.

1 INTRODUCTION

Research based on simulations has become popular for the study of soil-improvement methods and for the visualization of construction phenomena and evaluation methods. These studies are generally carried out from the design phase of the ground model. The accuracy of the studies mostly depends on the accuracy of the ground model. Unlike other participating materials, the governing parameters for the soil are difficult to measure; therefore, the ground modelling is carried out by conducting an unconfined compression test simulation to derive the values of the ground parameters. Inazumi et al. (2021) used an unconfined compression test simulation to check the validity of the ground parameters employed in the visualization and evaluation of jet grouting technology. Since the MPS-CAE method (Inazumi et al. 2020) is preferrable for the present study, the major governing parameters that define the ground models are the plastic viscosity, yield value, and yield parameter.

2 OUTLINE OF BINGHAM FLUID

A Bingham fluid is a fluid that flows when the shear stress exceeds a specified value. The model employed for this fluid is a bi-viscosity model (Nakao et al. 2021). It treats the fluid as a viscoplastic fluid in the fluid state, and as a highly-viscous fluid in a rigid state.

The apparent viscosity in the fluid state is reflected in Eq. 1.

$$\eta = \left(\eta_p + \frac{\tau_y}{\dot{\gamma}}\right) \quad \dot{\gamma} \geq \dot{\gamma}_c \tag{1}$$

The apparent viscosity in the rigid state is reflected in Eq. 2.

$$\eta = \left(\eta_p + \frac{\tau_y}{\dot{\gamma}}\right) \quad \dot{\gamma} < \dot{\gamma}_c \tag{2}$$

DOI: 10.1201/9781003299127-365

where τ_y is the yield value, η_p is the plastic viscosity, $\dot{\gamma}$ is the average shear velocity, and γ_c is the yield criterion of the fluid and rigid states, given by Eq. 3.

$$\dot{\gamma}_c = \frac{2C_y\tau_y}{\eta_p} \tag{3}$$

where C_y is the yield parameter.

During the design stage, the yield value (τ_y), plastic viscosity (η_p), and yield parameter (C_y) are presented as the model parameters.

3 ANALYSIS CONDITIONS

3.1 *Modelling and simulation specifications of sample*

A cylindrical soil sample, 50×100 mm, and an unconfined compression test simulation setup were modeled. The top plate was lowered such that the soil would deform at the uniform strain ratio of 1% per minute. It was simulated for a total time of 1200 seconds during which the soil was expected to exceed the yield value.

The effects of the yield value, plastic viscosity, and yield parameters were studied for soil with a strength level of 60 kPa and subjected to numerous trial-and-error simulations. In this way, the best fitting ground model was designed. It was observed that yield parameter values greater than 1/1000 resulted in the collapse of the structural composition during the simulation, leading to failure. The yield value was inputted as 60 kPa and the values of the other parameters, at which the input yield value became equal to the output yield value, were determined.

3.2 *Material parameters*

Table 1 shows the final values of the materials employed in the unconfined compression test that produced the best fitting ground model after incorporating the influence of the primary parameters. The values for these parameters were selected after the successful simulation of the unconfined compression test.

Table 1. Material parameters.

Material	Density (kg/m^3)	w/c	Yield value (Pa)	Plastic viscosity (Pa.s)	Yield parameter (-)	Surface tension (N/m)	Fluid model
Water	1000	-	-	-	-	0.10	Newtonian fluid
Ground	1600	-	60000	17000	0.0001	0.002	Bingham fluid

4 MPS-CAE SIMULATION RESULTS

4.1 *Comparison of results with known data*

Figure 1 shows the results of the simulated stress-strain curve for the Table 1 data compared with the known data. The soil yielded at the compressive strength of 61.24 kN/m^2 and strain value of 12.59%. The Aomori soil sample was silty soil with an avg. diameter of 0.0036 mm. It yielded at a compressive strength of 64.69 kN/m^2 and strain value of 4.73%. The Yamagata soil sample was sandy soil with an avg. soil diameter of 0.034 mm. It yielded at a compressive strength of 61.55 kN/m^2 and strain value of 0.55%. Although the simulation results and known data are approximately equal in terms of their peak strength, they all yielded at different strain values. In order to determine the cause of this discrepancy, further study is conducted with the intention of determining the secondary parameters.

4.2 *Studying the influence of density and soil particle size*

In this simulation, the water content of the test sample could not be defined clearly, but the input value for density was changed for different simulations, while all the other parameters

were kept constant. The results showed that the values for the output compressive strength and exerted strain were almost the same, implying that for samples with the same yield value, yield parameter, surface tension, and plastic viscosity, a change in density has no effect on the design of the ground model. Table 2 summarizes the overall simulation results for the changing density.

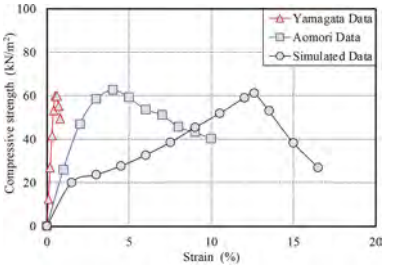

Figure 1. Simulation results compared to known data.

Table 2. Influence of density of ground modelling.

Yield value = 60 kPa, Plastic viscosity = 17000 Pa·s,	Density (kg/m^3)	Compressive strength (kN/m^2)	Strain (%)
Particle size = 3 mm,	1600	61.299	12.59
Yield parameter = 0.0001,	1172	61.559	12.49
Surface tension = 0.002 N/m	793	61.702	12.4

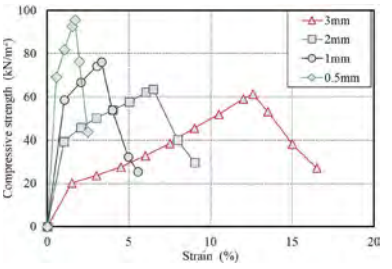

Figure 2. Comparison of simulated results for particles of various sizes.

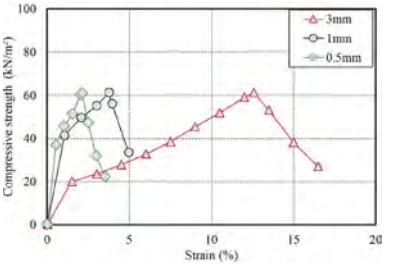

Figure 3. Correct output model for 0.5-mm and 1-mm soil particles.

As the known data have different particle sizes and different strain values, the study was conducted to find the influence of the particle size. Figure 2 shows the changes in the output yield value when the particle size in the simulation was changed to 2, 1, and 0.5 mm and was compared to that of 3-mm soil particles. All the other parameters were kept the same, but the results

Table 3. New material parameters and output results for each soil particle size.

Soil size (mm)	Input yield value (Pa)	Plastic viscosity (Pa·s)	Yield parameter (-)	Output yield value (kPa)	Strain (%)	Fluid model
3	60000	17000	0.0001	61.30	1.26	Bingham fluid
1	60000	10000	0.0001	61.30	0.38	Bingham fluid
0.5	60000	5500	0.0001	61.07	0.21	Bingham fluid

showed drastic changes in the output yield value and strain. The soil samples yielded at 63.43, 76.03, and 95.54 kN/m^2, respectively, and strain values of 6.48, 3.34, and 1.69%, respectively.

4.3 *Remodeling the ground for different soil particle sizes*

As the influence of the secondary parameters has been quantified, a correct model must be designed for each soil particle size. The process includes trial-and-error simulations to determine accurate values for the primary parameters that are similar to those of the initial phase.

Figure 3 shows the correct stress-strain relationship for soil particles of sizes 0.5 mm and 1 mm compared to the 3-mm soil particles. Since the results for the 2-mm soil particles did not largely deviate from those for the 3-mm soil particles, it was not remodeled in this study. However, if the situation demands, it can be remodeled too. For this study, the interest lies in remodeling for the minute particles which showed more deviation from the original 3-mm soil particles.

Table 3 shows the details of the new ground parameters and output values for each soil particle size. For the 0.5-mm soil particles, the output compressive strength of 61.07 kN/m^2 and strain value of 2.11% were obtained for the input plastic viscosity of 5500 Pa.s. For the 1-mm soil particles, the output yield value was recorded to be 61.30 kN/m^2 and it yielded at the strain value of 3.76%. These results were obtained for the plastic viscosity of 10000 Pa·s.

5 DISCUSSION

It was observed that the plastic viscosity and strain value for finer soil particles decreases if the yield value is kept constant. One probable reason is that the composition characteristics of the soil sample correspond to its yield value. And, since the bi-viscosity model was assumed, the value for the plastic viscosity itself is likely to be high. However, one can only speculate by the empirical method based on the simulation results. The influence of the surface tension, when simulated, was found to be low. Thus, its value was assumed to be approximately zero in order to reduce the calculation load. Moreover, since changes in density were seen to have a negligible influence, the soil samples were assumed to be in a dry state such that the value for the surface tension could be disregarded.

Simulations for finer soil particles involve an astronomical calculation load and may even fail to produce the results of the unconfined compression test simulation depending upon the calculation load. The objective should be to create as accurate a ground model as possible and it should be easily adoptable for future studies. The results of this study have suggested that soil particles of a smaller size provide the best fitting stress-strain curve characteristics when compared to the known data. However, due to the increased calculation load, the simulation might also fail. Thus, the optimum choice should be made regarding the adoption of a soil particle size.

6 CONCLUSIONS

In this study, the importance of the soil particle size during the simulation of the unconfined compression test under different parameters was confirmed. In addition, the model suitable for each soil particle size was successfully recreated. It was observed that the simulation tended to fail due to the heavy calculation load if the soil particles were very small. It was also found that the ground modelling had almost no relation to the density of the soil.

In conclusion, this study will be a helpful reference for future studies related to ground simulations and for creating more accurate ground models.

ABSTRACT: The study of a new construction of a micropile are presented. The proposed vertical micropiles of a new construction has a large surface area due to the spiral shape and a bigger bearing capacity compared to the usual micropile. As a result, numerical modeling, the influence of the number of a pile spiral turn and the relative "elongation" of a spiral turn on the change in load capacity, as well as the features of its compressibility. Analysis of the results of the numerical modeling shows area of the effective constructive combinations of the spiral turns number along the length of pile and the "elongation" (width) of the turn. This area arranges the biggest load capacity of the spiral pile compared to the usual micropile. Additionally, restrictions on compressibility have been imposed to confine torsional tensions. At conclusion, the authors for-mulate the problems for continuation research.

1 INTRODUCTION

One of the areas of geotechnics, the development of which is most active, is pile foundations. This is promoted by the development of construction on areas with difficult unfavorable soils and the increasing in the technological level of execution the work.

The common goal in the development of all pile technologies is to maximize the bearing capacity of the piles. At the same time the pile must have a high technological effectiveness of the pile installation, a low unit cost and minimum settlements. Many new installation technologies for various types of piles have appeared in recent decades to solve this goal (Mangushev et al., 2015). The goal achievement is particular important during construction on soft soil, where the pile cannot be based upon hard or rock soil. Such soil conditions imply the using of friction piles only. These soils are common in Sedimentary and Residual Soils areas.

2 STATE OF THE RESEARCH

Many scientists have worked on the problem of increasing the bearing capacity of friction piles in soft soil (Xu et al., 2020). Studies were conducted on various ways to increase friction forces on the side surface of piles(Teixeira et al., 2012, Dai et al., 2007), determinate and clarify friction coefficients between soil and pile (Ivanova et al., 2016), clarify calculation assumptions and models (Basack et al., 2022), develop new pile designs (Vertynskii and Emel'yanova, 2013). Many studies have found application in civil engineering (Hajrullin et al., 2015).

One way to increase the bearing capacity of a friction pile is to increase the side surface area. Until now, this could be achieved in two ways: by increasing the cross-section of the pile or by increasing its length. However, there is another way, suggested by the authors, that does

DOI: 10.1201/9781003299127-366

not affect the cross-section and length of the pile. In this case pile length will be understood as the depth of the pile tip position.

In order to describe this method, it is first necessary to explain the stages that preceded its creation. The authors encountered a problem of ensuring the verticality of the borehole at depths greater than 10 meters - the borehole axis began to deflect. The first stage included this observation about the borehole, that was made for soil investigation or the micropile installation. The maximum deflection angle of the borehole or micropile axis reached 10 degrees during vertical drilling. This led to the conclusion that the probability of borehole deviation from the vertical increases with depth. The next step was a study based on previous findings: if random deviation from vertical is possible for a vertical micropile, how will it affect on the bearing capacity of the pile? Authors found out during a series of numerical modeling experiments that a small deviation of the micropile from the vertical has no effect on its bearing capacity. Then the angles of deviation from the vertical were larger, than the bearing capacity decreased.

Analyzing the conclusions at each of the steps, the author's team decided to apply the idea of "Conversion of harm into benefit" for the method of increasing the bearing capacity of the pile. The use of this idea is expressed in the following: 1 - there is always a probability of micropile deviation from the vertical during installation; 2 - the probability of micropile deviation increases through depth; 3 - minor deviations do not affect on the bearing capacity of micropile; 4 - deviation of micropile from the vertical reduces the depth of the pile tip position.

Therefore, if the micropile axis is bent, it is possible to increase the lateral surface area, compared to the vertical micropile, which have the same tip depth. If the micropile axis is not randomly bent, but rather, it is possible to obtain a micropile of a new design. All this can have a favorable effect on the bearing capacity of the pile.

3 MATERIALS AND METHODS

A new design of spiral micropile (SMP) is proposed. A spiral shape of micropile is described by equations (1). SMP can be created with different shapes. The study was conducted with different design solutions of SMP in order to identify the general laws of the shape influence on SMP behavior in the soil. The design dimensions are shown in Figure 1: D_1 is the overall diameter of SMP, D is the diameter of the spiral, d is the cross-sectional diameter of the micropile shaft, L is the overall height of SMP, l is the pitch of the spiral. The top of the SMP has a vertical section for coaxial accommodation of the vertical load.

$$\{x = (u)\ (cos\ cos\ (v) + B)\ y = A \cdot sin(u)(cos(v) + B)\ z = sin(v) + C \cdot u \tag{1}$$

if $u \in [-D{\cdot}\pi;\ D{\cdot}\ \pi]$ $v \in [-D{\cdot}\ \pi; D{\cdot}\pi]$

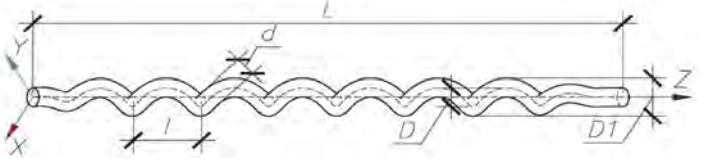

Figure 1. General design of the spiral micropile (SMP).

Taking into account different design types of SMP to study their behavior in the soil, it is necessary to introduce additional properties of SMP, allowing them to classify. Such properties will be: the relative elongation of the pitch of the spiral l/D (Figure 2) and the number of the pitch of the spiral L/l (Figure 3).

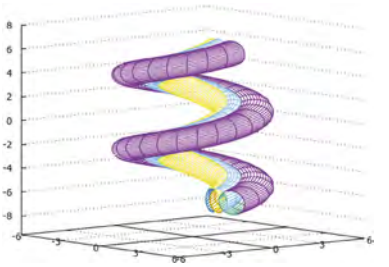

Figure 2. Influence of the relative elongation of the pitch of the spiral *l*/*D* at a constant value of *l*.

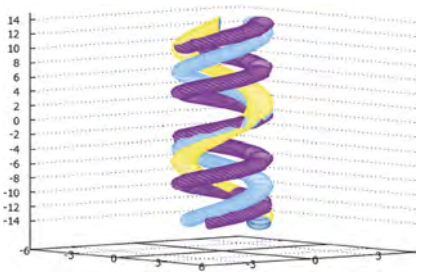

Figure 3. Influence of the number of the pitch of the spiral *L*/*l* at a constant value of *D*.

Using parameters *l*/*D* and *L*/*l*, it is possible to perform a simultaneous analysis of SMP of different shapes to identificate of trends of changes in bearing capacity and compressibility. Unfortunately, different mathematical forms of SMP cannot be reflected in reality. This is hindered by technological limitations and principles of reasonableness.

The design of the spiral micropile is new and implies many directions for its research. Given that the advantage of such piles has not yet been identified, the least time-consuming study would be numerical modeling.

4 NUMERICAL MODELING

To identify the influence of the SMP shape on its behavior in the soil, a numerical study was performed using Midas FEA NX 2022.1.1. Various SMP shapes with intersectional parameters *l*/*D* and *L*/*l* (Table 1, columns 1-7) with a constant cross-sectional diameter of the micropile shaft *d* were considered.

Table 1. Dimensions of the studied SMP.

№	*d*, m	*D*, m	*L*, m	*l*, m	*L*/*l*	*l*/*D*	IF_d, kN	$IF_{d,min}$, kN	IF_d	ε_i, %
1	2	3	4	5	6	7	8	9	10	11
1		0.45	4			2.67	547		1.31	0.022
2		0.6			3.33	2.00	617	419	1.47	0.068
3		0.9				1.33	607		1.45	0.263
4		0.45	7			2.67	846		1.36	0.038
5	0.3	0.6		1.2	5.83	2.00	895	622	1.44	0.090
6		0.9				1.33	641		1.03	0.214
7		0.45	10			2.67	1091		1.30	0.042
8		0.6			8.33	2.00	1020	841	1.21	0.097
9		0.9				1.33	646		0.77	0.171

The general view of the computational model is shown in Figure 4. The computational model has dimensions of 26,0x21,2x20,0 m. The structure is a pile cap measuring 6,0x1,2 m and two identical spiral micropiles (Table 1, columns 2-7) with a spacing of 4,0 m. A uniformly distributed load was applied to the pile cap to determine the bearing capacity of the piles. Transmission of pressure from the pile cap to the soil was prohibited.

Additionally, vertical micropile simulations were performed with the same tip depth to determine the effectiveness of SMP (Figure 5).

Mohr-Coulomb model was used to define soil behavior, Elastic model was used to define contruction behavior (Mirnyj and Ter-Martirosyan, 2017). The parameter values are presented in Table 2. Based on the geometric model, a finite element mesh was created (Karaulov et al., 2022). The size of the finite elements increased as they moved away from the study area. The interface elements were used for modeling SMP in the soil.

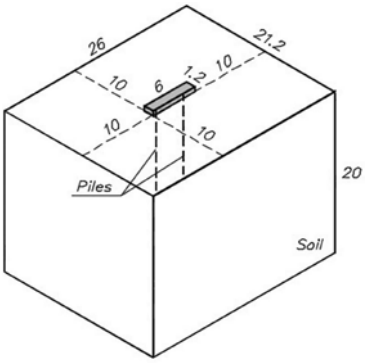

Figure 4. The general view of the computational model.

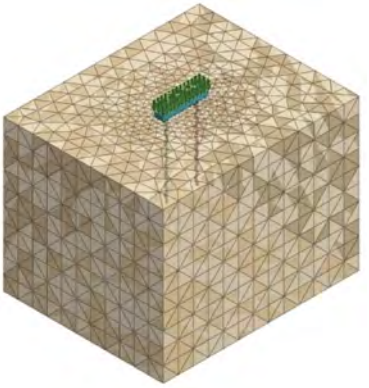

Figure 5. The computational model.

Table 2. Material models and their parameters.

Symbol	Parameter	Unit	Material model	
			Mohr-Coulomb	Elastic
E'	Young's modulus	MPa	15.2	38000
v	Poisson's ratio	-	0.39	0.2
c	Intercept cohesion	kPa	33	–
φ	Angle of internal friction	degree	17.5	–
ψ	Angle of dilatancy	degree	0	–
γ	Unit weigh	kN/m^3	18.7	25

5 ANALYSIS AND RESULTS

A series of numerical calculations with SMP of different shapes made it possible to determine their bearing capacity (Table 1, column 8). It was found that the increase of parameter *l*/*D* decreases the bearing capacity of the pile. The bearing capacity values of vertical micropiles were also obtained (Table 1, column 9). An the bearing capacity increase index $\boldsymbol{IF_d}$ for SMP was additionally determined to evaluate the obtained data (Table 1, column 10). It was defined as the ratio between the bearing capacity of the SMP of the selected shape and he bearing capacity of the vertical micropile at equal pile length *L* and pile cross-section *d*. This index allows us to evaluate the effectiveness of the SMP form, considering only the criterion of bearing capacity increase.

A polygonal surface was constructed to analyze the effectiveness of multiple SMP shapes simultaneously. Nodes of the surface were the values of the bearing capacity increase index IF_d (Figure 6), the relative elongation of the pitch of the spiral *l*/*D* and the number of the pitch of the spiral *L*/*l* of each investigated SMP shape. The polygonal surface has a delineated maximum $IF_d = 1.44$ (Figure 6, point 5), and a delineated minimum $IF_d = 0.77$ (Figure 6, point 9). This allows us to conclude that the shape of the SMP significantly affects on the bearing capacity.

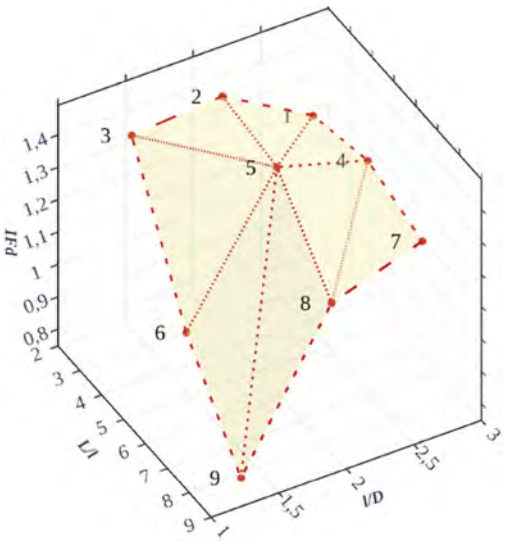

Figure 6. Polygonal surface IF_d for SMP.

For further analysis of the results, the complexity of the SMP shape compared to the vertical micropile should be considered. A reasonable application of the SMP should provide a significant increase in the bearing capacity compared to the vertical micropile (i.e., a significant increase in IF_d). In author's opinion, this would be a reasonable "price" for the increased complexity of the SMP shape. The condition $IF_d \geq 1.4$ is assigned as an area of reasonable SMP appliance. A horizontal cutting plane was drawn across the polygonal surface (Figure 6) at $IF_d \geq 1.4$ (Figure 7) to determine the many different SMP shapes that possess the accepted condition. A projection on the plane of the polygonal surface represents the outer boundaries of the effectiveness SMP forms area satisfying the condition $IF_d \geq 1.4$.

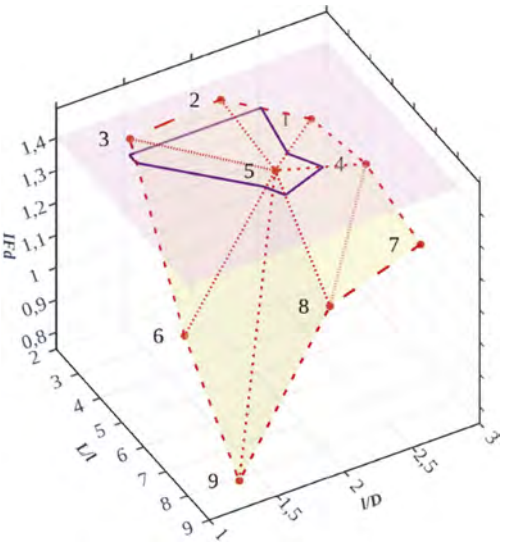

Figure 7. Polygonal surface IF_d for SMP and horizontal cutting plane.

The identified area (Figure 7) determines the effective shape of the SMP, based only on the accepted its bearing capacity increasing. At the same time, it should be taken into account that the shape of SMP is more susceptible to compression than vertical micropile due to helicity. Therefore, the SMP behavior in the soil should be evaluated by the compression of the pile shaft additionally.

The fulfilled series of SMP numerical calculations made it possible to determine the relative compression of the pile shaft ε under the load equal to the bearing capacity of the pile (Table 1, column 11). It was found that the SMP length has an insignificant effect on the compressibility of the pile (less than 15%). The greatest influence on the compressibility of the SMP shaft has the relative elongation of the pitch of the spiral l/D. The increasing of D at constant l increases the relative compressibility of the SMP particularly (Figure 8). For example, for a 7 m long SMP with $l/D = 2.67$, the relative compressibility of the pile shaft is $\varepsilon = 0.038\%$, and with $l/D = 1.33$ $\varepsilon = 0.214\%$, higher by 463%. Relative compressibility of the pile shaft ε decreases as the parameter l/D increases.

It is necessary to establish limit values to evaluate the relative compressibility of the pile shaft ε. If parameter ε is in excess of limit values the SMP material mode of operation changes significantly. In other words, the limit value of ε should indicate the elastic limit or the beginning of the cracking process. The actual value of the limit parameter ε should depend on the SMP material and the technology of its installation. Authors specified the value of the limit of the relative compressibility of the pile shaft ε as 0.1% (horizontal red dashed line in Figure 8). It intersects with the envelope functions of compressibility development for SMP with different length. The projection of the intersection point on the X-axis indicates the minimum allowable value of the parameter $l/D = 1.95$ that meets the compressibility criterion. Thus, the area of SMP design solutions according to the criterion of relative compressibility admissibility is highlighted (the green area in Figure 8).

Effective SMP shapes must meet the joint requirements of higher bearing capacity and low compressibility. Thus, it is necessary to combine the surface projection IF_d (effective SMP shapes) satisfying the condition $IF_d \geq 1.4$ (Figure 7) and the minimum allowable value of parameter $l/D = 1.95$ (Figure 8), assigned by the compressibility criterion $\varepsilon \leq 0.1\%$. The result is the highlighted area of the effective SMP shape, shown in Figure 9.

The coordinates of the point (l/D and L/l) inside the selected area describe the design solution of the SMP that simultaneously meets two conditions: $IF_d \geq 1.4$ and $\varepsilon \leq 0.1\%$.

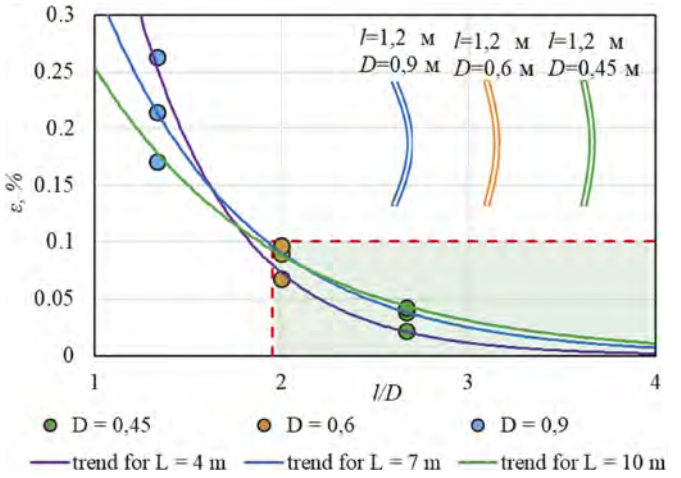

Figure 8. Analysis of change ε for SMP.

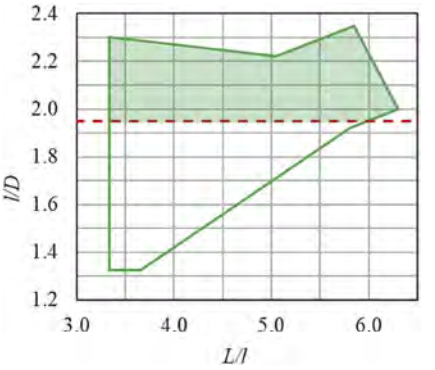

Figure 9. Surface projection IF_d for SMP that are limited by compressibility criteria.

6 CONCLUSIONS

It should be introduced a significant clarification that the spiral micropile (SMP), at the moment, is only an idea. Completed numerical simulation of its behavior with the soil is an effort to reveal the reasonableness of its more targeted research in future. The conditions adopted in the work $IF_d \geq 1.4$(and $\varepsilon \leq 0.1\%$) reflect only the way of such search and do not yet have the necessary justification. Nevertheless, taking all this into account, it is possible to draw general conclusions:

1. The spiral shape of micropile is the result to solve the problem of the verticality of boreholes at depths greater than 10 m. The way to find such a solution was to adopt one of the **TIPS** ideas "Conversion of harm into benefit". It allows to reinforce the main defect of micropile - random deviation from verticality.
2. Giving the micropile a regular spiral shape affects its bearing capacity. The bearing capacity of some SMP structural forms exceeds the vertical micropile bearing capacity with the same length by more than 40%. The bearing capacity of the SMP depends to a greater extent on the elongation of the pitch of the spiral.
3. The regular spiral shape of the micropile significantly effects on its compressibility. The elongation of the pitch of the spiral is more significant than the number of the pitch of the

spiral along its length. The compressibility of the SMP exceeds the compressibility of the vertical micropile. Therefore, the structural shape of SMP should be based on the condition of its ultimate compressibility.

The idea of the SMP is inherently revolutionary. The pile shaft was traditionally perceived only as straight, and its deviation (curvature) was considered as a defect. That was the inertia of thinking. SMP appeared by looking at this problem from a different angle and turning the disadvantage to the advantage. A wine corkscrew can be considered as the prototype of SMP in normal life. The bearing capacity of such "anchor pile" is very high. Research of the SMP behavior as an anchor will be conducted.

The material of SMP and the technology of its installation into the soil are a fair question. At this stage the authors see the implementation of SMP from metal or reinforced concrete. SMP can be screwed into the soil or arranged in the soil by directional drilling. Be that as it may, the questions of SMP material and technology have not been answered.

The authors are convinced that the idea of SMP should be protected. That is why a patent application has been filed for future research.

Mathematical equations for modelling soil-water characteristic curve

Nura Bello, Alfrendo Satyanaga*, Gerarldo Davin Aventian, Sung-Woo Moon & Jong Kim
Department of Civil and Environmental Engineering, Nazarbayev University, Kazakhstan

ABSTRACT: Climate change is continuously becoming a vivid global problem that needs to be tackled from every angle for the survival of our planet. Landslide is one of the fore-front phenomena attributed to climate change, claiming lives, and destroying the environment across the globe. To prevent the occurrences of those slides, a good understanding of unsaturated soil is necessary. Soil-water characteristic curve (SWCC) which describes the amount of water retained by a particular soil is an important hydraulic property of the soil, especially related to the soil's pores sizes and spaces connection within it. Modeling water distribution and flow in unsaturated soils requires knowledge of the SWCC which plays a critical role in water management and in prediction of its transport within the soil. There are many attempts to model SWCC mathematically, with the likes of the Satyanaga, Zhai, Fredlund and Xing, Van Genutchen, Brooks and Corey, and several other models for soils with unimodal and bimodal characteristics. Each equation has its own advantage and disadvantage which can model certain type of soil due to the variability of soil properties. It is however important to analyze the available models, study their best applicable scenario and limitations. This paper will therefore study and review several available mathematical equations for modelling SWCC.

1 INTRODUCTION

Soil slopes constitutes an inclined earth face that are either naturally occurring as in hills and cliffs, or artificially made, usually to carry transportation infrastructure such as in road and rail embankments. Those slopes are continuously facing a danger of slides in form of partial or total collapse, and when the slopes fail, it usually involves damage to such infrastructures they supported, deters daily economic activities and often even leads to loss of lives (Bello et al., 2019, Gariano and Guzzetti, 2016). Climate change is the fore-front phenomenon contributing to landslides and slope failures. It causes an escalation of rainfall, and the increases in the rainfall intensity yield a significant impact on groundwater changes and alter those parameters responsible for soil strength, such as suction, thereby causing various geotechnical problems such as excessive soil settlement and slope failures (Satyanaga et al., 2022a, Tamm et al., 2008, Jakob, 2022). As such, the need to quantify effects of climate variables on geohydrogical hazards is therefore becoming more necessary (Gariano and Guzzetti, 2016).

With the incorporation of the unsaturated soil mechanics principles, many of the geotechnical problems including slope instability could be attenuated. This is achieved by proper understanding of the soil's mechanisms and making appropriate designs using actual soil's condition and its variability. Whilst soils suction is highly dependent on soil types and its infiltration settings, understanding its mechanism plays a vital role in stabilising geotechnical structures, as it is a common knowledge that changes in soil's pore-water pressure is the top variable influencing a slope performance or failure (Satyanaga et al., 2022a, Griffiths and Lu, 2005). In fact, the variation in negative pore-water pressure (suction) and water content hugely influences the

*Corresponding author: Alfrendo.satyanaga@nu.edu.kz

DOI: 10.1201/9781003299127-367

unsaturated soil's shear strength as observed by (Rahardjo, 2009), and the two most distinct hydraulic properties related to unsaturated soil are its water-characteristic curve (SWCC) and permeability function (Satyanaga et al., 2022b).

SWCC signifies a relationship between soil suction (ψ) and its pore water content (either in gravitational or volumetric form). It is believed to be one of the most important soil parameters for geotechnical engineering operation involving unsaturated soil mechanics. Various important soil behaviour such as its shear strength, water volume storage, change in volume, thermal conductivity and specific heat could all be deduced using SWCC (Sillers, 1997, Sillers et al., 2001, Pan et al., 2021). SWCC could be measured directly in the laboratory, but the procedure is highly time consuming, coupled with high cost and results variability, due to its importance, various empirical equations were developed to calculate SWCC. Therefore, in doing that, a suitable mathematical equation that will clearly provide physical definitions of the SWCC variables must be sought and used (Ellithy, 2017, Pan et al., 2021, Satyanaga et al., 2017). The main objective of this paper is therefore to understand some important available mathematical equations for modelling SWCC and provide an informed review accordingly.

2 UNIMODAL SWCC

Plotting SWCC in respect of water content (θ_w) against soil suction (u_a-u_w) was first proposed by Fredlund (2006), the curve always having a sigmoidal shape have four main elements: the saturated volumetric water content (θ_s) residual volumetric water content (θ_r,) air entry value (ψ_a) and water-entry value (ψ_w). The curve are generally plotted on a logarithmic scale for whole abscissa range (Satyanaga et al., 2017).

There are a variety of fitting equations developed to model the relationship between quantity of water retained by a soil and its matric suction (Zhai and Rahardjo, 2013), the following are some of the best fit equations used for unimodal SWCC.

2.1 *Brooks and Corey, (1964)*

Brooks and Corey (1964) provided one of the earliest fitting models for drying SWCC at a suction lager than air entry value of the soil, in the form of equation (1) (Tinjum et al., 1997, Fredlund, 2006, Wang et al., 2021).

$$\Theta_n = \left[\frac{\psi}{\psi_{aeb}}\right]^{\lambda} for\ \psi > \psi_{aeb} \tag{1}$$

Where, Θ_n is dimensionless normalized volumetric water content, and it is equal to $\left[\frac{(\theta-\theta_r)}{(\theta_s-\theta_r)}\right]$

θ *and* θ_r are saturated and volumetric water contents respectively

ψ is soil suction at a point and ψ_{aeb} is air entry value of the soil

λ is a fitting parameter called pore size distribution index

Degree of Saturation (S) could replace the normalised water content Θ_n in the equation, while residual water content θ_r could be established on semi log plot of straight line by trial and error (Fredlund and Xing, 1994).

Brooks and Corey equation has been widely used by many researchers, but its main shortfall is it only describes SWCC between air entry value (AEV) and residual condition. In order to solve this, McKee and Bumb (1987) and Bumb (1987) presents a more fitting model for SWCC approximation in the area before AEV but unfortunately not useful in the high suction range (Gardner et al., 1970, Rogowski, 1971, Williams et al., 1983, Bumb, 1987, McKee and Bumb, 1987).

The McKee and Bumb equation is given by;

$$\Theta_n = \frac{1}{1 + exp[\frac{\psi - a_m}{n_m}]} \tag{2}$$

where a and n are fitting parameters.

2.2 *Van Genuchten (1980)*

Van Genuchten model is another popular relationship between water content and suction that was widely used among researchers.

$$\Theta = \left[\frac{1}{1+(p\psi)^n}\right]^m \tag{3}$$

p, n and m are soil parameters. The equation provides additional flexibility compared to Brooks and Corey, (1964) (Ellithy, 2017, Pan et al., 2021). However, as noted by Fredlund and Xing, 1994, "in trying to get a closed-form solution for hydraulic conductivity, Van Genuchten (1980) related m and n through the equation m = (1-1/n), and therefore reduced the added flexibility" and as shown by best fit analysis, identical quality fit could be equally be possible by simply taking the variable (m) as 1. (Fredlund and Xing, 1994, Fredlund, 2006).

2.3 *Gardner, (1958)*

Gardner (1958) presents permeability function equation that mirrored SWCC and could be seen as an extension of Van Genuchten model.

$$\Theta = \frac{1}{1+q\psi^n} \tag{4}$$

q and n are curve fitting parameters related to soil's AEV and the inflection point's slope of the SWCC, respectively.

2.4 *Fredlund and Xing, (1994)*

Fredlund and Xing, (1994) proposed a fitting model relating volumetric water content (θ) and soil suction (ψ) which complements the limitations of the previous fitting equations (i.e., this equation is valid for the entire suction range up to 10^6 kPa). The proposed equation was in the form of;

$$\theta = \theta_s\left[\frac{1}{In(e+\psi/a)^n}\right]^m \tag{5}$$

Equation (5) have three fitting parameters a, m and n, such that if m and n are fixed then a will have a value so close to the soil air entry value for albeit for a small value of m, otherwise the a is generally greater than aev.

$$a = \psi i,\ m = 3.6\ In(\theta_s/\theta_r),\ and\ n = \frac{1.31^{m+n}}{m\theta_s} 3.72s\ \psi i$$

and the slope to the tangent line of the curve (s) could be calculated using $s = \frac{\theta_i}{\psi p - \psi i}$ where ψp is an intercept of the tangent to the suction.

The equation (5) clearly indicated that (θ) equals (θ_s) when (ψ) is zero; as such it will be valid at the lower suction range, but it can be noted that θ becomes (0) when suction approach infinity, therefore still needing modification for fitting the upper limit of suction. As indicated in experimental data by (Croney and Coleman, 1961), that soil suction attains its peak value of 10^6 kPa when $\theta = 0$, thus the upper limit of the suction range needs to be taken care by the equation. In doing so, a correction factor C(ψ) was introduced into the equation (5).

$$\theta(\Psi, a, m, n) = C(\psi)\left[\frac{\theta_s}{In(e+\psi/a)^n}\right]^m \tag{6}$$

$$\text{Where } C(\psi) = \left[-\frac{In(1+\psi/\psi_r}{In(1+10^6/\psi_r)}\right] + 1$$

It could be seen that at the limiting value of $\psi = 10^6$ kPa, the C will be equals to 0, clearly indicating at that limiting value the corresponding water content (θ) calculated using equation (6) will now be equals to (0) (Fredlund and Xing, 1994). The equation (6) provided by Fredlund and Xing 1994, could safely be used for whole suction range (i.e., 0kPa -10^6 kPa) and has successfully taken care of the limitations of the previous fitting equations.

2.5 *Satyanaga Et Al., (2017)*

Although equation (6) could be used to fit SWCC for the entire suction range, it has one important disadvantage, in the sense that most of its parameters lacked a clear physical meaning, which refers to as "an ability of the equation parameters to clearly represents the variables in the SWCC" (Satyanaga et al., 2017).

So, for the fact that a convenient mathematical equation containing parameters that are able to represents the exact variables in the SWCC is needed, Satyanaga (2017) presents an efficient best fitting model for that;

$$\theta_w = C(\psi)\left[\theta_r + \left\{\theta_s - \theta_r\left(1 - (\beta)efrc\left(\frac{In\left(\frac{\psi_a - \psi}{\psi_a - \psi_m}\right)}{s}\right)\right)\right\}\right] \tag{7}$$

Where;
β is 0 at the suction range at or before aev, and 1 at any suction beyond aev
θ_w is calculated volumetric water content
θ_s is saturated volumetric water content
ψ is matric suction in view (kPa)
ψ_a is soil's air entry value (kPa)
ψ_m is the matric suction at inflection point of the SWCC (kPa)
S is representing standard deviation of the SWCC
θ_r soil's residual volumetric water content
ψ_r is matric suction corresponding to θ_r on the SWCC (kPa)

The good thing about equation (7) is, while it is valid for the entire suction range, its parameters equally have a clear physical meaning to represents the variables of soil water characteristics curve.

3 BIMODAL SWCC

Debris of weathered rocks found in an unsaturated zone are called residual soils, and in most cases, those residuals and colluvial soils are widely gap graded, exhibiting bimodal grain-size distribution (GSD). And usually, colluvial soils with bimodal characteristics GSD brings about bimodal characteristics of SWCC, the bimodal SWCC happens as a result of the soil containing two pore series (Kutílek, 2004, Rahardjo et al., 2004, Zhang and Chen, 2005, Satyanaga et al., 2013).

GSD and SWCC modelling using continuous function is very important, as the SWCC predicted using GSD could be used to establish various soil properties in very short duration, as compared to the time-consuming laboratory SWCC tests. Among many GSD equations developed Fredlund et al., is commonly used for fitting bimodal GSD, although the equation's parameters are unrelated to the soil's physical properties (Satyanaga et al., 2013).

3.1 *Zhang and Cheng (2005)*

Zhang and Cheng (2005) developed a method of predicting bimodal soil water characteristics curve for bimodal soil. They utilized the theoretical basis of estimating SWCC from a pore distribution as provided by Fredlund and Xing, 1994. The SWCC for the bimodal soil was

established as the sum of the two components of the soil with large pore series and small pore series. And the bimodal SWCC could be described using either Van Genuchten, 1980 function or Fredlund and Xing, (1994) function as follows.

$$\Theta(\psi) = p_i n_{p1}\left[\frac{1}{1+(a_i\psi)^{ni}}\right]^{mi} + p_s n_{ps}\left[\frac{1}{1+(a_s\psi)^{n}s}\right]^{m_s} \tag{8}$$

where,

a_l, n_l, and m_l are fitting parameters for the large-pore series component, and a_s, n_s, and m_s are fitting parameters for the small-pore series component.

p_l and p_s are respectively the volumetric percentages of the components with the large-pore series and the small-pore series in the soil mass and could be calculated easily based on the density values and the percentages by dry weight of the soil components.

n_{pl} and n_{ps} are porosities of the components with the large-pore series and the small-pore series when they are considered individually

and;

$$\begin{aligned}\theta(\psi) =& \mathrm{p_i n_{p1}}\left[\left[1-\frac{\mathrm{In}(1+\psi/\psi_\mathrm{r}}{\mathrm{In}(1+10^6/\psi_\mathrm{r}}\right]\right]\left\{\frac{1}{\mathrm{In}(\mathrm{e}+\psi/\mathrm{a_1})^{\mathrm{n1}}}\right\}^{\mathrm{m_l}} \\ &+\mathrm{p_s n_{ps}}\left[\left[1-\frac{\mathrm{In}(1+\psi/\psi_\mathrm{r}}{\mathrm{In}(1+10^6/\psi_\mathrm{r})}\right]\right]\left\{\frac{1}{\mathrm{In}(\mathrm{e}+\psi/\mathrm{a_s})^{\mathrm{n_s}}}\right\}^{\mathrm{m_s}}\end{aligned} \tag{9}$$

where,

e is the base of natural logarithm; and all other parameters as explained.

3.2 *Satyanaga Et Al., (2013)*

Although Zhang and Cheng (2005) present a model that could predicts a bimodal soil water characteristics curve for a bimodal soil, the equations where developed based on Van Genuchten 1980 and Fredlund and Xing (1994), whose some of the variables having no physical meaning in relation to the SWCC's parameters. Therefore Satyanaga et al. (2013) provide an equation to mitigate limitation of the Zhang and Cheng (2005) model.

"The equation was developed considering five important factors.

i. The equation parameters could be related to the soil's physical meaning
ii. The soil water content is set to zero as the soil's suction reached 10^6 and the Fredlund and Xing's correction function (C) is utilized
iii. The shape of SWCC is like lognormal distribution. Therefore, Kosugi (1994) equation is used as a basis for the development of the proposed equations.
iv. Water content when soil is fully saturated (saturated water content, w_{sat}) is known.
v. Since the bimodal characteristic of SWCC occurs if the percentage of coarse-grained soil is high, the total volume of soil is assumed to be constant during the SWCC tests (Satyanaga et al., 2013, Kosugi, 1994)."

$$\begin{aligned}\theta_w = \left(1-\frac{In(1+\psi/\psi_r)}{In(1+10^6/\psi_r)}\right)\Bigg[\theta_r + (\theta_{s_1}-\theta_{s_2})\left(1-efrc\left(\frac{In\left(\frac{\psi_{a_1}-\psi}{\psi_{a_1}-\psi_{m_1}}\right)}{s_1}\right)\right)+ \\ (\theta_{s_2}-\theta_r)\left(1-efrc\left(\frac{In\left(\frac{\psi_{a_2}-\psi}{\psi_{a_2}-\psi_{m_2}}\right)}{s_2}\right)\right)\Bigg]\end{aligned} \tag{10}$$

where,

θ_w is the calculated volumetric water content, θ_s the saturated volumetric water content (measured in the laboratory), ψ is the matric suction under consideration, ψ_a represents the air-entry value of soil, and ψ_m represents the matric suction at the inflection point of SWCC and S represents the geometric standard deviation of SWCC (Satyanaga et al., 2013).

4 CONCLUSION

Many SWCC equations were reviewed in this work, such as Brooked and Corey, (1964), Van Genuchten, (1980), Gardener, (1958), Fredlund and Xing, (1994) and Satyanaga et al., (2017) for unimodal SWCC, while Zhang and Cheng, (2015) and Satyanaga et al., (2013) were used for bimodal SWCC. And it could be concluded that Satyanaga, (2017) for unimodal SWCC (equation 7) and Satyanaga et al., (2013) for bimodal SWCC (equation 10) are best fit for the said purpose. This is for their unique ability of been valid for the entire soil suction range (up to 10^6kPa), also containing parameters that have physical meanings that best describe the soil variables.

Assessing shallow landslide susceptibility using the random forest algorithm

M.L. Lin & P.H. Huang
Department of Civil Engineering, National Taiwan University, Taipei, Taiwan

ABSTRACT: Typhoon Morakot induced significant shallow landslide failures that spread widely in southern Taiwan causing severe property and infrastructure damages. This study adopted a Random Forest Algorithm to construct a shallow landslide susceptibility map for the Namasia study area in southern Taiwan. The landslide inventory was compiled using data from existing landslide inventory by Central Geological Survey in 2009, satellite images, and field investigations. Nine causal factors, namely: slope angle, lithology, aspect, terrain ruggedness index, curvature, distance to fault, distance to road, and distance to stream were examined in the analysis. The scale effect was studied using four different grid resolutions to generate landslide susceptibility map. The resulting susceptibility map was validated with satisfactory accuracy. Thus, the susceptibility map could provide vital references supporting hazard mitigation strategy.

1 INTRODUCTION

Being situated in the convergence zone of tectonic plates, Taiwan is prone to fragile geological conditions, and typhoons often carry heavy rainfall causing landslide hazard. Typhoon Morakot brought more than 3000 mm accumulated rainfall in 2009, and induced widely spread shallow landslides in southern Taiwan. The shallow landslides caused by Typhoon Morakot in the Namashia area, Kaoshiung City, south Taiwan, were identified by Soil and Water Conservation Bureau (Lin et al. 2013), and susceptibility assessment of the area was conducted in this study. The machine learning method has a good ability of event classifications, and can be used to discriminate landslide versus non-landslide units. We adopted Random Forest Algorithm for its capability of treating nonlinear multi-variates relation, and the susceptibility assessment model was constructed. The environment causal factors were selected and tested for independency and significancy. The model was then constructed and validated, and the regional susceptibility map of the study area was developed accordingly.

2 STUDY AREA AND MATERIALS

2.1 *Study area*

The study area is the Namashia area in Kaoshiung City, south Taiwan, which locates in the upstream area of the Chishan River Watershed with elevation ranging from 217 to 2480 m a.s.l. as shown in Figure 1. The Namashia study area locates in the Western Foothill Geological Zone and is composed mainly of sedimentary rock formations. The lithology of the area is unmetamorphic rock formations of the Miocene with sandstone, siltstone, shale, and sandstone/shale interlayer formations, that include mainly Changchihkeng Formation, which is a sandstone/shale interlayer, Hunghuatzu Formation, which is mainly a silty sandstone, and Sanmin Shale. A small area of Lushan formation was identified in the north part of the area, which is composed

DOI: 10.1201/9781003299127-368

of slate. The geological map of the study area modified from 1:50000 watershed geological map published by the Central Geological Survey (CGS) in 2000 is as shown in Figure 2.

2.2 *Inventory of shallow landslides and data*

The Central Geological Survey conducted mapping of debris avalanche of the southern Taiwan affected by Typhoon Morakot in 2009. The CGS defines the debris avalanche as the sliding of weathered top soil, rock fragment and debris, and colluvium, which can be considered as shallow landslide. Mapping was conducted using aerial photos taken after Typhoon Morakot for the slope area with slope angle smaller than 55°. The mapped results were verified using FORMOSAT-2 satellite images, and field investigation was conducted. The mapped shallow landslides were then compared to the deep-seated landslide inventory by National Science and Technology Center for Disaster Reduction. The mapped shallow landslide scars coincided with the deep-seated landslide scars were eliminated to avoid the possible errors (Lin & Chen 2016). A total of 1710 shallow landslides were identified after verification and data modification. Figure 3 shows the distribution of the mapped landslides.

Digital terrain model (DTM) with a 5m resolution produced by the Ministry of Interior in 2003 was adopted for derivation of topographic related causal factors in the Geographic Information System (GIS). The geological map in Figure 2 was used for derivation of the geology related causal factors.

3 RESEARCH METHOD

3.1 *Environmental causal factors*

A grid-based analysis was conducted, and grids enclosed in the landslide scars were considered as landslide units, while other grids were considered as non-landslide units. The environmental causal factors typically include geomorphology related factors, geology related factors, and hydrology related factors. Referring to factors adopted by previous researches (Dai & Lee 2002, Guzzetti et al. 1999), the slope angle, lithology, aspect, terrain roughness index, curvature, distance to fault, distance to road, and distance to stream were selected for this study. The geomorphological factors were derived from the DTM data, and geological factors were obtained from the digital geological map, while the hydrological factors werer derived by generating watershed and stream based on DTM in GIS. The factors for both landslide and non-landslide units were generated in the analysis. All factors were tested for independency and significancy.

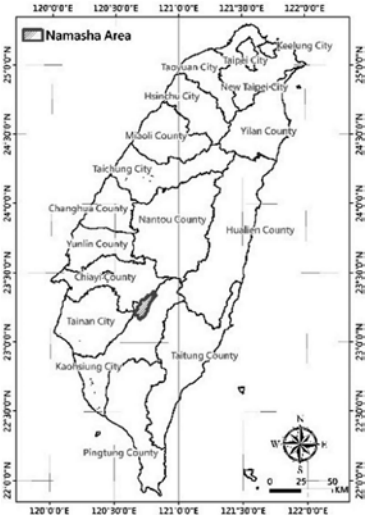

Figure 1. Location of study area.

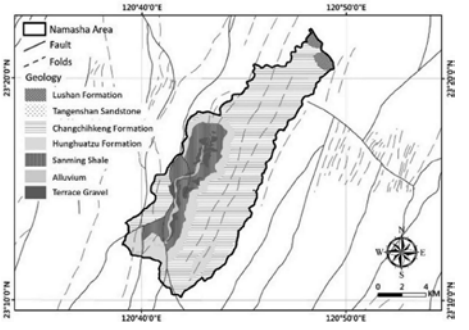

Figure 2. Geological map of the study area.

Figure 3. Distribution of mapped landslides in the study area.

3.2 *Random forest algorithm*

The random forest algorithm is a supervised machine learning method that has been used for classification. In this study, the random forest algorithm is used to identify landslide from non-landslide grids. The supervised learning process is conducted by input sets of factors and expected output values for training and thus a prediction model is constructed. The random forest is an ensemble of decision trees that can consider both the numerical and categorical factors without pre-process of unit or scale of factor. The tree randomly samples a subset training data to build the model through bootstrapping techniques, and data not included are referred to as out-of-bag, which account for about 30 % of the original sample subset (Breiman 2001). Each tree randomly selects variables to split each node to minimize classification errors. The error can be estimated through prediction errors of the out-of-bag data of each tree (Liaw &Wiener 2002). An overall error estimation can be presented as the average error of the out-of-bag errors of all the trees.

3.3 *Model test and verification*

To set up the over-all model of the random forest, the number of trees, settings of nodes of each tree, and the number of runs need to be determined. A series of tests were conducted to examine variations of the out-of-bag errors versus each variable set. The prediction model is expected to provide consistent and stable results from the causal factors with selected random components. The over-all accuracy of the prediction model is evaluated using the confusion matrix. For the confusion matrix, the accurately predicted instances are the sum of true positive and true negative classes, and the accuracy rate is represented by the ratio of the sum over the total number of instances. The receiver operating characteristic curve (ROC) is plotted as the true positive ratio versus the false positive ratio, and the area under the curve (AUC) was calculated to assess the performance of the prediction model. The AUC value of 0.5 suggests no prediction capability, and the larger the AUC value, the better the prediction performance.

4 RESULTS AND DISCUSSIONS

A series of test was conducted starting with 10 trees and gradually increased to 1500 trees, and the out-of-bag error decreased rapidly with increasing number of trees. The variations of out-of-bag error becomes stable with 500 trees. The number of nodes of each tree and number of runs were tested using the similar process, and 200 nodes and 100 runs were used to construct a stable prediction model. Due to the factors used in the model were derived on a grid-based analysis, the sensitivity of the factors and results could be significantly affected by the size of the grid, which has been discussed by several researchers (Catani et al. 2013). The effects were evaluated in this study by using grid sizes of 5m, 10m, 20m, 25m, and 40m resolution respectively, by combining the 5m resolution DEM into larger grids. In addition, the number of landslide data was much smaller than the number of non-landslide data as shown in Figure 3, which might induce sample bias problem. To avoid bias of sample sizes, two different measures were adopted. The first measure was to resample (up-sample) the landslide data, and the second measure was down-scale

sampling (down-sample) of non-landslide data to ensure an equivalent size of landslide and non-landslide data.

Comparing the results of up-sample to the down-sample sets, it was found that the up-sample set yields more stable results of ROC curve and higher AUC values. Figure 4 shows the ROC curves for different grid sizes using up-sampling data. It appears that the curves and AUC values for grid sizes of 5m, 10m, and 20m are about the same, however, the set with grid size of 5m has the best average accuracy rate of 75.65% from the confusion matrices. Thus, the landslide susceptibility map of the study area was developed according to the threshold on the ROC curve as shown in Figure 5. Close examination of the susceptibility map shows that most mapped landslides locate in the area with medium to high potential, and the prediction model provides satisfactory results.

Figure 5. Susceptibility map of the study area.

5 CONCLUSIONS

This study adopted a Random Forest Algorithm to construct a shallow landslide susceptibility map for the Namasia study area in southern Taiwan. The landslides caused by Typhoon Morakot were compiled and nine causal factors were adopted in the analysis. The model settings and scale effect were tested using four different grid resolutions. Equivalent sample sizes were warranted adopting up-sampling of landslide data. The resulting susceptibility map from 5m grid up-sampling data was validated with satisfactory accuracy. The susceptibility map could provide vital references supporting hazard mitigation strategy.

Global warming impact of drilled shafts

M. Lee & D. Basu
University of Waterloo, Waterloo, Canada

ABSTRACT: Incorporating sustainability considerations as early as in the design of pile foundations can help in reducing excessive use of construction materials, thereby reducing environmental impacts. This paper uses drilled shafts as an example to illustrate the importance of environmental impact assessment in the design phase of foundations. Life cycle assessment (LCA), a standardized method for quantifying environmental impacts, is applied to drilled shafts in this study. The global warming impact of drilled shaft, quantified using LCA, is compared with two reference values – global warming impact caused by a person annually and a passenger car throughout its entire twelve-year life cycle. The comparisons help in understanding how severe the global warming impact of drilled shaft is in relation to commonly perceived polluters. Plots are developed that may be used for quick estimation of global warming impact of drilled shafts without the use of specialized LCA software programs.

1 INTRODUCTION

Drilled shafts are one of the widely used deep foundations that provide support to bridges, high-rise buildings, excavations, retaining structures, and slopes (FHWA, 2010). Concrete and steel, known to be energy and carbon intensive materials, are the main materials used in constructing drilled shafts. These materials together are responsible for 16% of global carbon dioxide emissions that contribute significantly to global warming and climate change (Watts, 2019; World Steel Association, 2021). As the use of drilled shafts continually increases, it is important to understand their environmental impacts through quantitative methods.

Studies quantifying the environmental impacts of geotechnical structures are rather limited and mostly performed using life cycle-based tools. Life cycle assessment (LCA) has been particularly used for quantifying the environmental impacts of various geotechnical applications including pile foundations (Giri and Reddy, 2014; Luo et al., 2019; Misra, 2010). Although drilled shafts have been widely used for various applications, there is a lack of knowledge regarding their environmental impacts. There is no easy-to-use guideline available using which a designer can relate a particular design to its environmental impact without the use of specialized LCA software packages. In this study, the global warming impact of typical single drilled shafts are quantified using LCA considering different subsurface and loading conditions.

2 DRILLED SHAFT DESIGN

The drilled shafts in this study are designed by satisfying the ultimate limit state criterion of ultimate pile capacity corresponding to 10% relative settlement and the serviceability limit state criterion of allowable pile settlement. The ultimate capacity of drilled shafts is calculated as the summation of capacities developed at the base and along the shaft:

$$Q_{ult} = q_{b,ult}A_b + \sum_i q_{sL,i}A_{s,i} \quad (1)$$

where Q_{ult} is the total ultimate capacity (kN), $q_{b,ult}$ is the ultimate unit base resistance (kPa), A_b is the cross-sectional area of the pile base (m^2), $q_{sL,i}$ is the limit unit shaft resistance of the i^{th} soil

DOI: 10.1201/9781003299127-369

layer (kPa), and $A_{s,i}$ is the surface area of the pile in contact with the i^{th} layer (m^2). According to Salgado (2008), the ultimate unit base capacity of drilled shafts in sand is given by

$$q_{b,ult} = 0.38 p_A \exp(-0.0066 D_R) \exp[0.1041\phi_c + (0.0264 - 0.0002\phi_c) D_R] \left(\frac{\sigma'_h}{p_A}\right)^{0.841 - 0.0047 D_R} \quad (2)$$

where D_R is the relative density of sand (%), p_A is the atmospheric pressure (= 100 kPa), ϕ_c is the angle of friction at the critical state, and σ'_h is the effective horizontal stress (kPa) at the pile base. The limit unit shaft capacity of drilled shafts in sand is given by (Salgado 2008):

$$q_{sL} = \sigma'_z \left[0.7 K_0 \exp\left\{\left[0.0114 - 0.0022 \ln\left(\frac{\sigma'_z}{p_A}\right)\right] D_R\right\}\right] \tan\delta \quad (3)$$

where σ'_z is the effective vertical stress at a depth where q_{sL} is determined, K_0 is the coefficient of lateral earth pressure at rest, and δ is the friction angle at the interface of the pile and soil (= ϕ_c).

The total settlement of drilled shafts ΔH_p is calculated following the method by Bowles (1997):

$$\Delta H_p = \frac{P L_p}{A_b E_p} + \Delta q B_p \frac{1 - \mu_s^2}{E_s} m I_s I_F F_1 \quad (4)$$

where P is the axial force (kN), L_p is the length of pile (m), E_p is the Young's modulus of pile (kPa) (= 34,077,000 kPa in this study), Δq is the bearing pressure at the pile base (kN/m^2), B_p is the drilled shaft diameter (m), μ_s is Poisson's ratio of soil (= 0.35), E_s is the Young's modulus of soil below the pile base (kPa), mI_s is the shape factor (= 1.0), I_F is the Fox embedment factor = 0.55 if $L_p/B_p \le 5$ and = 0.50 if $L_p/B_p > 5$, and F_1 is the reduction factor (= 0.50 in this study).

The working stress design method is used to obtain the drilled shaft dimensions with a factor of safety (FS) ranging over 2-3. Hence, the allowable pile capacity Q_{all} is obtained by reducing Q_{ult} with a factor of safety (FS) — $Q_{all} = Q_{ult}$/FS. The allowable settlement of drilled shaft is assumed to be 30 mm, as recommended by Salgado (2008). The volume of steel reinforcement in the drilled shaft is assumed to be 2.5% of the volume of concrete shaft (FHWA, 2010).

Two sandy soil profiles are considered in this study, as described in Figures 1(a)-(b). For an applied load, the drilled shafts are designed assuming either (i) a fixed diameter or (ii) a fixed length. For example, if a fixed diameter of, say, 600 mm is assumed, the pile length that satisfies the ultimate limit capacity with a factor of safety is determined, and if a fixed length of, say, 10 m is assumed, the pile diameter is determined. In this study, the pile length L_p is varied from 5 m to 30 m, and pile diameter B_p is varied from 0. 3 m to 1.5 m.

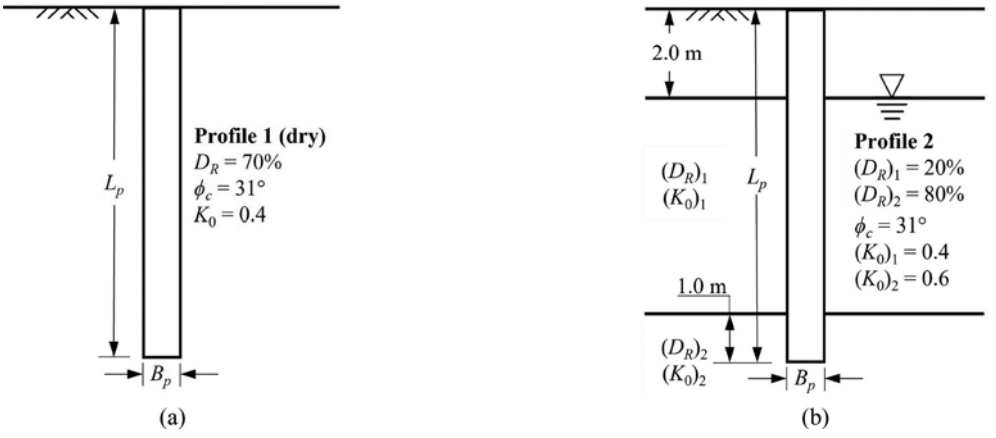

Figure 1. Soil profiles considered in this study.

For a given profile and applied load, the drilled shaft dimensions are determined as part of design. After the dimensions of the drilled shafts are finalized, the total volumes of concrete and

steel are computed and converted into their corresponding masses using the respective densities of 2400 kg/m^3 (Vieira, 2015) and 7850 kg/m3 (CEN, 2002), respectively. For example, for a single drilled shaft with 0.8 m diameter, 15 m length, and 2.5% steel reinforcement, the total masses of concrete and steel are 18096 kg and 1480 kg, respectively. These values are used as inputs to the LCA.

3 LIFE CYCLE ASSESSMENT OF DRILLED SHAFTS

LCA is a tool for quantifying the environmental impacts (e.g., global warming) that are caused throughout the life cycle of a product (drilled shaft in this case). Figure 2 shows the life cycle of typical drilled shafts based on which the LCA is performed in this study. LCA comprises four parts: (1) goal and scope definition, (2) life cycle inventory analysis (LCI), (3) life cycle impact assessment (LCIA), and (4) interpretation, as described in Figure 3. ISO 14040 and 14044 standards are followed and GaBi software program is used to conduct the LCA (ISO, 2006a; 2006b).

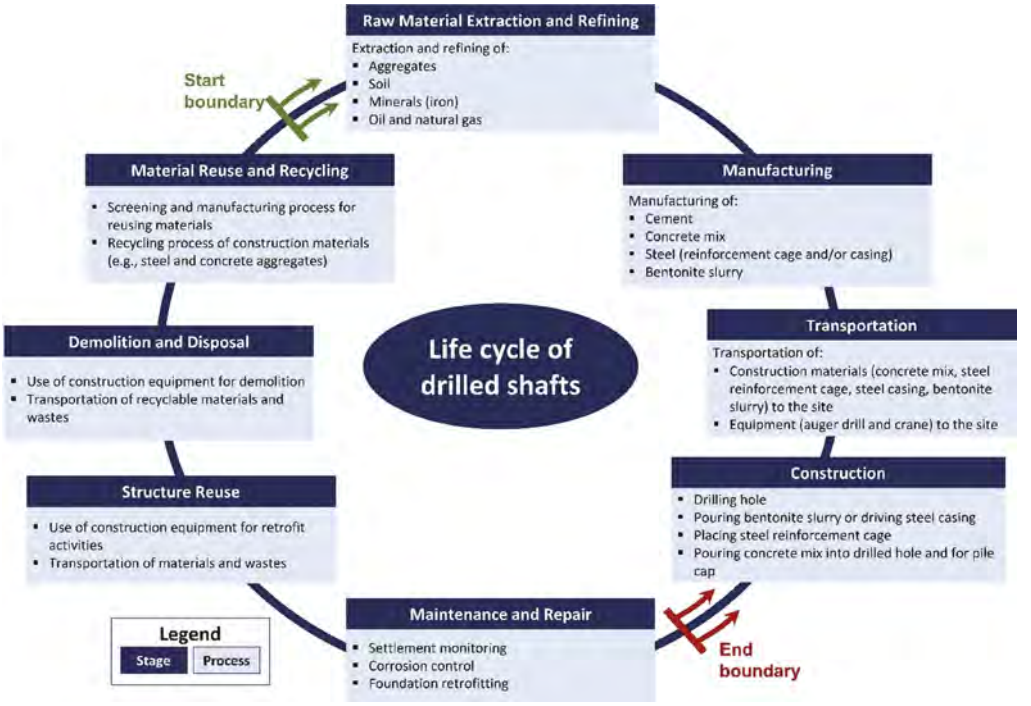

Figure 2. Typical life cycle of drilled shafts.

In this study, the system boundary starts from the extraction and refining of raw materials and ends with the completion of the construction stage, as shown in Figure 2. The functional unit is "the mass (in kg) of drilled shaft required to support the applied load in a given subsurface profile without bearing capacity failure (assuming FS = 2-3) and settlement exceeding 30 mm". Table 1 lists the assumptions used in conducting the LCA.

In LCI, the inputs (e.g., raw materials and energy) and outputs (e.g., emissions) for a product are compiled and quantified considering all the processes in its defined life cycle (ISO, 2006a). In this study, inventory databases by Thinkstep (Gabi, 2021), World Steel Association (Gabi, 2021), and National Renewable Energy Laboratory (NREL, 2012) are used to conduct the LCI. The LCIA characterizes the emissions (computed from the LCI) as global environmental impacts. LCIA is capable of quantifying various environmental impacts as shown in Figure 3. However, only global warming impact of drilled shaft is discussed in this paper because of space constraints. In this study, the ReciPe method by Goedkoop et al. (2013) is followed to conduct the LCIA.

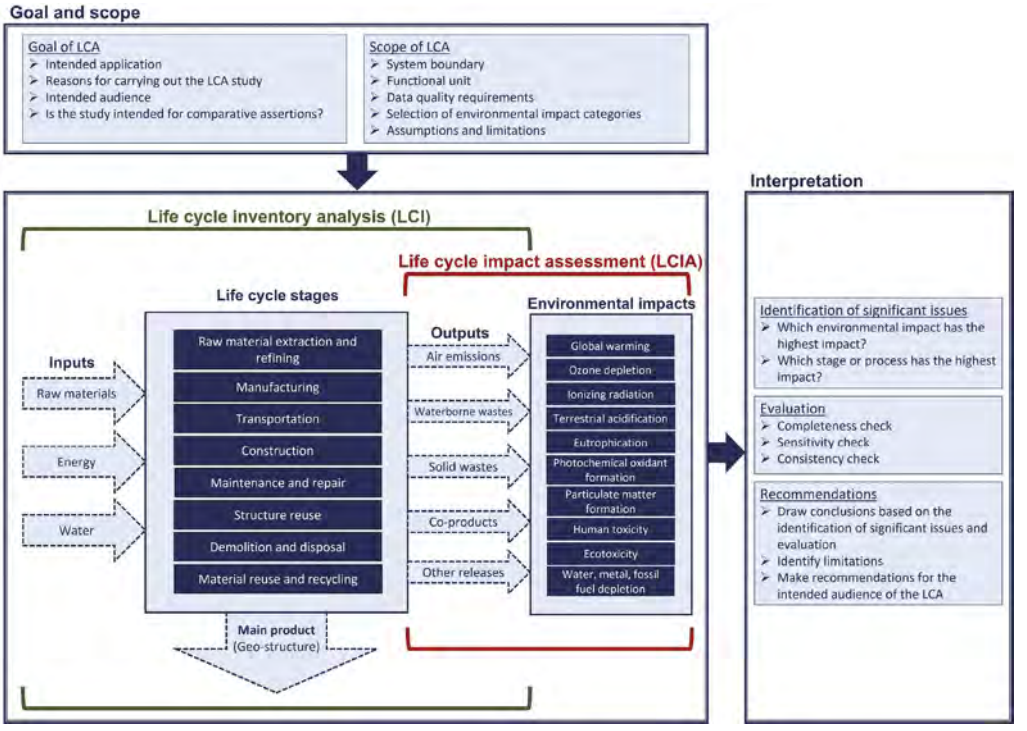

Figure 3. Framework of life cycle assessment.

Table 1. Assumptions used in LCA of drilled shaft.

LCA stage	Characteristics of materials or assumptions	
From raw material extraction to manufacturing	Strength class of concrete	C35/45 according to Eurocode 2 (CEN, 2004)
	Type of steel	Steel reinforcing bar rolled on a hot rolling mill
Transportation	Weight of the construction machinery	Auger drilling machine: 43000 kg (Bauer Maschinen GmbH, 2021) Hydraulic cane:12340 kg (Tadano, 2018)
	Hauling distance	From concrete manufacturing plant to site: 10 km From steel manufacturing plant to site: 50 km From machinery rental location to site: 50 km
	Type and payload capacity of hauling trucks	Diesel-driven 27-tonne capacity trucks
Construction	Operation time of the construction machinery	Calculated based on Zayed and Halpin (2005)
	Fuel consumption rate of the construction machinery	Auger drilling machine: 21.4 L/hr (Bauer Maschinen GmbH, 2021) Concrete mixer truck: 11.1 L/hr (Zagula et al., 2012) Hydraulic crane: 11.6 L/hr (Tadano, 2018)

4 GLOBAL WARMING IMPACT OF DRILLED SHAFTS

Table 2 summarizes a sample result of LCA for a drilled shaft (L_p = 15 m, B_p = 0.8 m, P = 1000 kN, and Profile 1). The actual values of global warming impact are compared with (i) the annual world impact per person in year 2010, obtained from Huijbregts et al. (2016) and (ii) a complete life cycle of a typical passenger vehicle with a lifespan of 12 years, obtained from European Commission (2008), as shown in Table 2. A typical drilled shaft with L_p = 15 m and B_p = 0.8 m, for

example, generates 4.2 tonnes of global warming potential (GWP), which is equivalent to 7.6% and 39% of the GWP of a typical passenger car and GWP of annual world impact per person, respectively. GWP is a measure of global warming impact that combines the contributions from different greenhouse gases such as carbon dioxide, methane, and nitrous oxide.

In order to investigate the relationship between GWP and pile dimensions for different applied loads, GWPs of drilled shaft designs with fixed pile length with L_p = 5-30 m and correspondingly B_p = 0.4-2.2 m are calculated for P = 1000, 2000, and 3000 kN in Profiles 1 and 2. Figure 4 shows designed pile length and diameter corresponding to the different applied loads. The GWP for each design is calculated and plotted on the same figure, and curves joining these points generate the GWP contours. For example, for a drilled shaft with L_p = 15 m and B_p = 0.8 m under P = 1000 kN in Profile 1, its GWP is slightly less than 5000 kg CO_2 equivalent according to Figure 4(a), which is consistent with the results in Table 2.

Table 2. Environmental impacts of a drilled shaft (L_p = 15 m, B_p = 0.8 m, P = 1000 kN, and Profile 1).

Global warming (kg of CO_2)	Drilled shaft impacts	Typical passenger vehicle impacts	Proportional drilled shaft impact with respect to passenger vehicle (%)	Annual world impact per person	Proportional drilled shaft impact with respect to annual world impact (%)
	4244	56200	7.6	10757	39

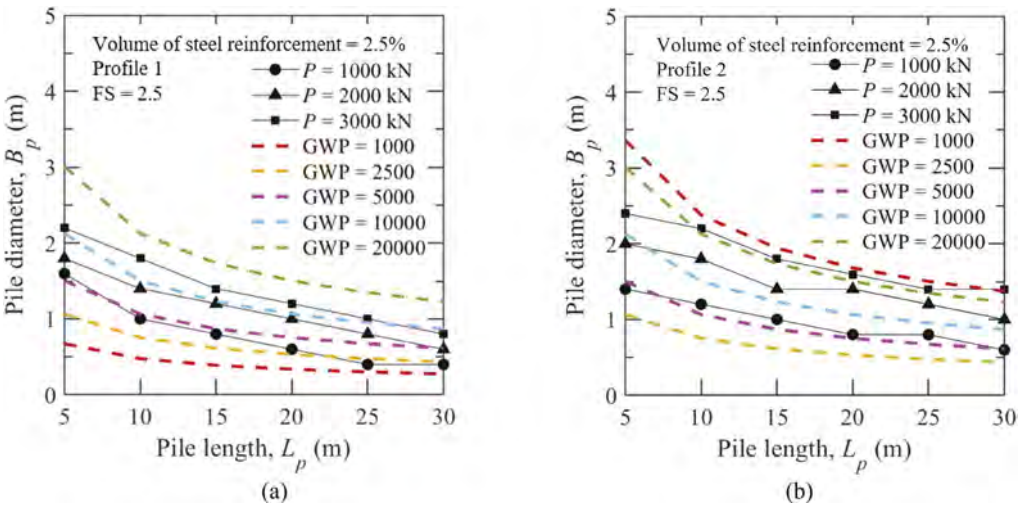

Figure 4. Relationship between dimensions of drilled shafts for different applied loads along with GWP contours (GWP in kg of CO_2 equivalent) for (a) soil profile 1 and (b) soil profile 2.

5 CONCLUSIONS

Concrete and steel – the two most used materials in geotechnical constructions – require large amount of fossil fuel in the production phase. Hence, minimizing the use of these materials is crucial in reducing global warming impact, and it can be practiced as early as in the design phase.

In this paper, life cycle assessment (LCA) is used to quantify the global warming impact of drilled shafts installed in two different sandy soil profiles. The relationship between pile diameter and length for different applied axial loads are plotted for two sandy soil profiles along with the contours of global warming potential (GWP). These figures can be used for quick initial estimate of GWPs by the designers without the use of sophisticated LCA software packages. Similar project-specific figures can be developed for ready reference of the designers in important projects. The GWPs of a typical drilled shaft are compared with the global warming impact caused by a typical passenger vehicle over its life span and the annual world impact per person. Global warming impact of a typical single drilled shaft is equivalent to

7.6% of impacts by a typical passenger vehicle and 39% of the annual world impact per person. Considering the large number of drilled shafts constructed all over the world, the global impact of drilled shaft constructions is significant.

The LCA results in this paper provide a sound basis for understanding the importance of environmental considerations in geotechnical designs. LCA can be applied to other types of foundations and geo-structures with appropriate considerations of life cycle processes, functional units, LCA databases, and other site-specific data.

Off-fault displacement distribution of dip-slip fault by analog experiment

N. Inoue & N. Kitada

Pasco Corporation, Tokyo, Japan

ABSTRACT: The ranges of distribution of off-fault displacement occurring apart from the main fault are very important threshold values for city planning, mitigating hazards, etc. Analog experiments using wheat flour examined the evolutions and distributions of dip-slip off-fault displacements (fault dip angles of 30° and 60°). The experiments have conducted repetitions of up or down movement of the basal fault, and surface displacements have been measured with a 3D scanner on every incremental displacement. Some off-faults show no displacement with the incremental main fault displacement. Most of the off-fault displacements occurred on the hanging-wall side. The off-fault distributions of analog experiments indicated a similar distribution compared with the off-fault displacement attenuation relation, which has been constructed from field observations compiled from reverse faulting earthquakes.

1 INTRODUCTION

Surface ruptures caused by an earthquake occur not only on previously mapped faults but also on unknown traces. Most of the former are main faults (principal faults), while some of the latter are off-faults (secondary or distributed faults). The off-fault may occur at a location distant from the principal fault. Recently detailed distributions of off-faults can be obtained through the progress of aerial photograph surveys and satellite data (e.g., Fujiwara et al., 2016; Omata et al., 2017). The displacement of the principal fault can be estimated from geological, geomorphological, and paleoseismological surveys. On the contrary, predicting off-fault displacements is difficult, because of previously unavailable mapping capability due to the small amount of displacement and discontinuity before an earthquake.

Ranges of distribution and displacement of off-faults are important threshold values considering fault displacement hazards of nuclear facilities and important structures and have been examined in many previous studies (e.g. Youngs et al., 2003; Petersen et al., 2011; Valentini et al., 2021). The range of distribution and displacement of off-faults of dip-slip faults were investigated by analog experiments with wheat flour.

2 METHOD

The analog model, which was enabled to simulate both reverse and normal faults, consists of a wheat flour layer deposited with a total thickness of about 2.5cm in an acrylic-sided experimental device (Figure 1). The height of the surface was measured with a high-resolution 3D scanner when the displacements of the basal fault were 0.5, 1, 2, 3, 5 and 8mm. The vertical and horizontal direction accuracies and measurement range are 5μm, 0.1mm, and

DOI: 10.1201/9781003299127-370

10cm×15cm, respectively. Wheat flour was densely packed pressing by a trowel. The final displacement of the basal fault was set to 8mm in the 30° experiments and up to 5mm in the 60° experiments. The final vertical displacement of both models was about 4mm.

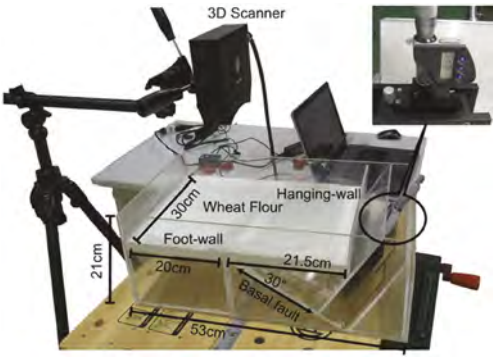

Figure 1. Experimental equipment (the dip angle of the basal fault is 30°).

3 RESULTS

In order to interpret the faults that occurred in the analog experiments, corresponding to the extension from the basal fault were treated as the principal fault and the other faults were classified as off-faults.

3.1 *Reverse fault experiment*

The principal fault propagated from the basal fault with a convex shape occurred around 40mm on the y-axis in Figures 2(a) and 2(b). In the cross section (Figure 2(c)), until 0.5mm of displacement of the basal fault, the fault occurred between 40mm and 45mm on the horizontal axis. After 1mm of displacement on the basal fault, the fault displacement was increased near 50mm on the horizontal axis, and the displacement of the previously formed fault did not seem to increase. In other words, the principal fault displacement that previously occurred shifted to the foot-wall side and was activated. The short fault, which was the principal fault at the initial stage, showed no displacement after the principal fault shifted to the foot-wall side. A fault is also formed on the hanging-wall side, which was considered to correspond to the back thrust (e.g. Lin et al., 2006).

In the result with the fault dip angle of 60°, the principal fault occurred 40 to 70mm away from the basal fault. An off-fault above the basal fault showed an opening displacement. There was no off-fault far from the basal fault on the hanging-wall side like in the results with 30° (Figure 2). In numerical simulations based on a Finite Element Method, the back thrust was formed on the hanging-wall side under low-angle reverse faults with strong ground strength (Lin et al., 2006).

3.2 *Normal fault experiment*

In the result with the fault dip angle of 30°, the principal fault propagated from the basal fault and occurred near 0mm on the y-axis as shown in Figures 3(a) and 3(b). The fault displacement was increased at 20mm away from the initial fault on the foot-wall side during the small basal fault displacements as shown in Figure 3(c). After 5mm displacement of the basal fault, much larger fault displacements were observed around 0mm on the y-axis. The fault that occurred on the foot-wall side seemed to be displaced as the principal fault at the initial stage. In the result with the fault dip angle of 60°, the principal fault occurred above the basal fault similar to the result of 30° normal fault experiments. The off-fault appeared around 30mm away from the principal fault on the hanging-wall side and showed wider distributions at the higher fault dip angle.

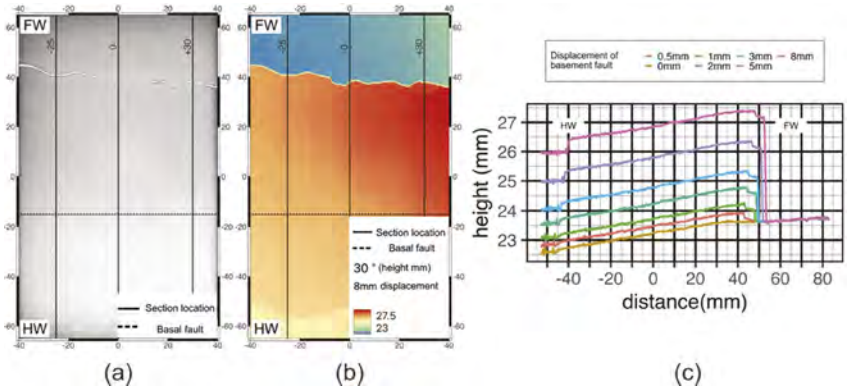

Figure 2. Experiment results of reverse fault (fault dip angle of 30°). (a) and (b) are the image and height of the wheat flour surface obtained by the 3D scanner, respectively when the displacement of the basal fault is 8mm. (c) Cross sections along 30mm on the x-axis of Figures 2(a) and 2(b). HW and FW are hanging-wall and foot-wall sides, respectively. The horizontal axis is shifted in the location of the basal fault to 0mm on the horizontal axis compared to Figures 2 (a) and 2 (b).

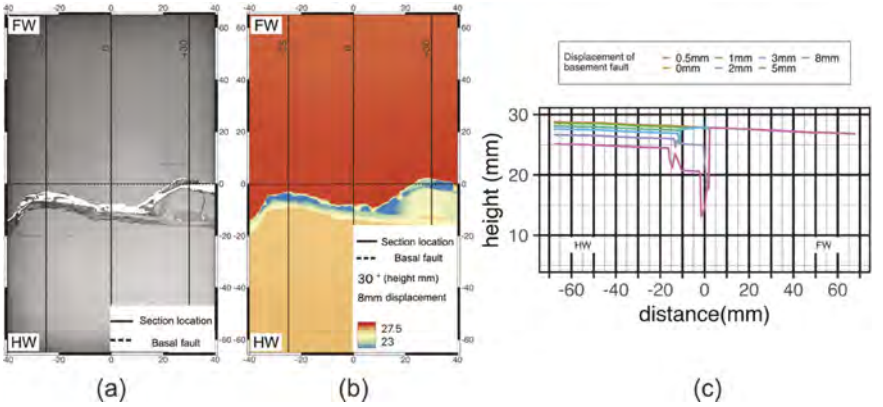

Figure 3. Experiment results of normal fault (fault dip angle of 30°). (a) and (b) are the image and height of the wheat flour surface obtained by the 3D scanner, respectively when the displacement of the basal fault is 8mm. (c) Cross sections along 30mm on the x-axis of Figures 3(a) and 3(b). HW and FW are hanging-wall and foot-wall sides, respectively. The basal fault is located at 0mm on the horizontal axis.

4 DISCUSSION

Previous Probabilistic Fault Displacement Hazard Analysis (PFDHA) studies provide off-fault displacement attenuation relations of various faulting types (e.g. Youngs et al., 2003; Petersen et al., 2011). Figure 4 indicates the off-fault displacement attenuation relation compiled by reverse faulting earthquakes with the experiment results considering the length scaling 1.7×10^{-4} (natural sedimentary rock, cohesion=50MPa and density=2.8g/cm^3; the dense deposited wheat flour, cohesion=2.5kPa and density=0.80 g/cm^3 derived from strength measurement). The attenuation relation of the analog experiments was in good agreement with the field observations.

The numerical simulation of the analog experiment was conducted using a discrete element method, to simulate the wheat flour layer. The simulation results indicated a similar fault distribution to that of the analog experiment.

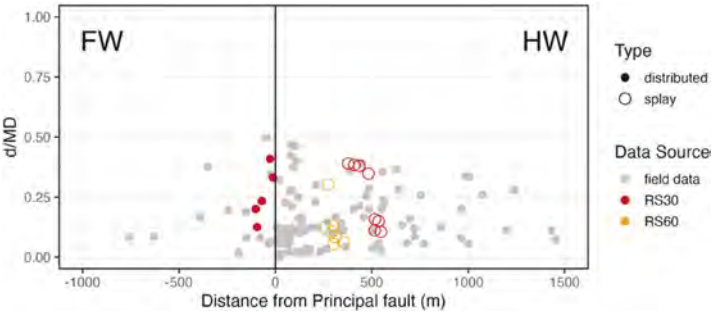

Figure 4. Comparison off-fault displacements between the field observation and the analog experiment for the results of reverse faulting. The vertical axis was normalized off-fault displacements (d) by the maximum displacement (MD).

5 CONCLUDING REMARKS

Analog experiments with wheat flour were conducted using pieces of equipment capable of simulating reverse faults and normal faults with high (60°) and low (30°) fault dips. In the case of reverse faults, the distribution range of off-faults tended to be wider in the low-angle experimental results. On the other hand, for normal faults, the principal fault tended to occur above the basement fault, regardless of the fault dip angle of the basal fault. In addition, the distribution of off-faults tended to be wider at higher angles in the case of the normal fault. Some off-faults show no displacement with the incremental basal fault displacement. Most of the off-fault displacements occurred on the hanging-wall side. The attenuation relation of the analog experiments was in good agreement with the field observations constructed from reverse faulting earthquakes.

ACKNOWLEDGEMENTS

Part of this study is due to the 2018 research project 'Acquisition of knowledge on fault displacement evaluation' and the 2021 research project 'Research on fault displacement evaluation' by the Secretariat of Nuclear Regulation Authority (NRA), Japan.

Comparison of small bridges and box culverts

Akira Hasegawa
Emeritus Professor, Hachinohe Institute of Technology, Hachinohe, Japan

Shinya Sukegawa
Technical Section Chief, GIKEN, Aomori, Japan

ABSTRACT: Aging of bridges is a common issue in the world. Bridges are one of important social infrastructures that is indispensable for living and industry, it is necessary for us to solve the problem of aging of Bridges. About 720,000 road bridges have been constructed in Japan, many of which are managed by local governments. Bridges managed by them are almost small bridges with narrow widths and short lengths. As structures for short bridges, two types are used: bridge type and box culvert type. Box culvert without the joints is effective in easing deterioration and simplifying inspection work. In addition, the precast box culvert, which is manufactured in advance at the factory, is excellent in that the material quality can be ensured and the construction period can be shortened. It is suitable for constructions with limited traffic restrictions and in winter of cold regions. In this paper, the comparison and discussion for two types are described.

1 INTRODUCTION

Aging of bridges is a common issue in the world. In Japan, the aging of bridges that have been constructed so far has become a major issue. Since bridges are important social infrastructures that are indispensable for living and industry, it is necessary for us to solve the problem of aging. About 720,000 road bridges have been constructed in Japan, many of which are managed by local governments. The bridges managed by the government are constructed for wide area transportation and include many large-scale bridges. On the other hand, the bridges managed by local governments are mainly constructed for the local transportation of the local governments, and many of them are small bridges with narrow widths and short lengths.

There are two types for small span bridges: bridge types such as slab bridges and girder bridges, and box culverts. The bridge type consists of abutments, bearings, girders and slabs, and the box culvert is an integrated structure as a rigid flame. Moisture and salt are the main causes of aging, and deterioration of member joints such as member ends is conspicuous. Box culvert with the joints removed is effective in mitigating deterioration and simplifying inspection work. In addition, the precast box culvert, which is manufactured in advance at the factory and joined at the site, is excellent in that the material quality can be ensured and the construction period can be shortened. It is suitable for erections with limited traffic restrictions and winter erections in cold regions. In this paper, we will consider the small-scale bridges used for road bridges in comparison with box culverts. In particular, the comparison will be made in consideration of the aging of bridges in cold regions that are damaged by frost and salt.

2 TWO TYPES: BRIDGE TYPE AND BOX CULVERT TYPE

Figures 1 and 2 show examples of two structures used to straddle the span. Different types of structures are used for similar short span lengths. Figure 1 is a girder bridge and Figure 2 is a box culvert. Here, the former type is called a bridge type and the latter is called a box culvert type.

DOI: 10.1201/9781003299127-371

Figure 1. Example of a bridge type.

Figure 2. Example of a box culvert type.

2.1 *Bridge type*

It is a structure in which a bearing is placed on the abutment, several bridge girders are hung on it, and a floor slab is placed on it. I girders, T girders, and box girders are used for bridge girders depending on the span length and materials used. If the span length is short, there is a slab bridge that omits the girder and puts it directly on the bearing. Both girder bridges and slab bridges are composed of abutments, bearings, bridge girders and decks, and joints of members are generated. If the span length is short, the road load is received only by the floor slab without installing a bridge girder.

2.2 *Box culvert type*

Box culvert is a structure integrated with reinforced concrete members which are called a top end, side wall, bottom slab, etc. depending on the position of the member. However, after the reinforced concrete is placed, it is an integrated structure. In the case of precast box culvert manufactured in advance at the factory, due to restrictions on the transportation dimensions from the factory to the erection position, it is divided into several parts,transported to the site, and united there. Lastly, the members become an integrated structure.

3 USING OF TWO TYPES

Figure 3 shows the completed years of the bridges managed by Aomori Prefecture (1418 bridges, excluding 827 bridges which completed year is unknown) among the bridges (2,245 bridges with a bridge length of 2 m or more) by every 10 years. Since World War II, new bridges have been constructed, with the largest number being in the 1970s. After 1970s, new construction has been carried out, however with the improvement of road maintenance, human resources and expenses have been shifting to the maintenance of bridges.

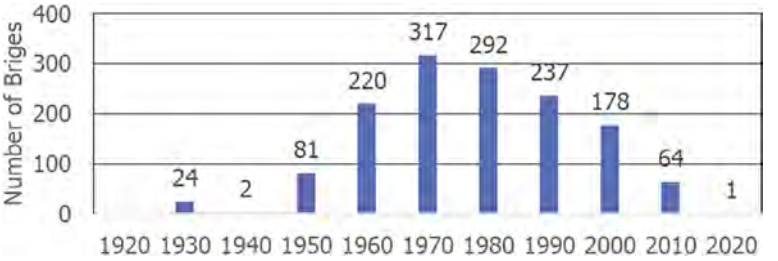

Figure 3. The completed year and the number of bridges managed by Aomori Prefecture.

A comparison was made by classifying bridges before 1979 and after 1980, with the 1970s, when the completed year was at its peak. The target bridges were 1406 bridges excluding 827 bridges of unknown construction year and 12 bridges of unknown type, 639 bridges before 1979, and 767 bridges after 1980. In Figure 4a, the number of bridges in which box culvert is used is shown every 5m in the average span lengths. Before 1979, box culvert was used to be less

than about 5 m, but since 1980 it has expanded to about 10 m. Figure 4b shows the number of bridges by average span length of bridges that also use slab bridges as the bridge type. Before 1979, it was often used under 5m, but since 1980, the range of use has expanded to around 15m.

A similar spread of the span length is seen in the girder bridge, and before 1979, the peak was 5-10 m and the use decreased as the span length became longer, but after 1980, it has been widely used around 30 m. The truss, arch, rigid frame bridge, and cable-stayed bridge were not compared because the number of bridges is small.

The fact that the range of span lengths adopted by various bridge types is expanding indicates that the technology of each bridge type has been developed and it has become possible to provide span lengths with a wide range.

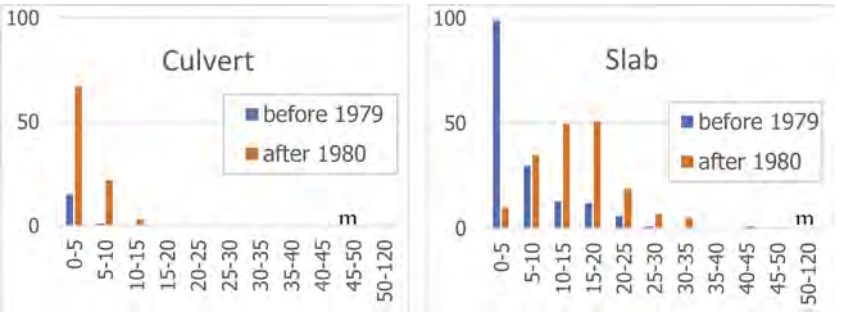

Figure 4. The number of bridges and average span length (left 4a: box culvert, right 4b slab).

4 DIFFERRENCES OF TWO TYPES

4.1 *Differences in construction*

In the girder bridge type, starting from the construction of the abutment with foundation work, after the abutment is prepared, the bearing is installed on it, and the bridge girder is erected on it. The bridge girder is pre-made in the factory or around the site, moved and installed in place.

On the other hand, in culvert box, especially in the precast box culvert, the parts are divided into parts in advance at the factory and manufactured, and then joined at the site to form an integrated structure. Depending on the size of the culvert cross section, it is divided into two or four parts. The maximum internal cross section is 13m wide and 9m high. In addition, by providing a partition wall in the middle, it is possible to connect two or three boxes. The appeal of precast box culvert is quality and construction period. Since the parts are manufactured under factory management, the quality of reinforced concrete is high, and the construction period can be shortened by about 70% compared to the culvert box constructed on site.

Figure 5. Construction site of girder bridge (left) and box-culvert (right).

4.2 *Differences in aging*

It can be said that the issue of aging bridges is worldwide. In Japan, various efforts have begun since the accident caused by aging in the tunnel in 2012. The concept of maintenance has changed

from the conventional post-maintenance that repairs after breaking to preventive maintenance that is inspected and repaired in advance. It is also obligatory to visually inspect every five years.

According to the observation results up to now, it is known that the deterioration at the member joint of the bridge is remarkable. Especially in cold regions, frost damage caused by hydration and salt damage caused by the salt content of the snow melting agent sprayed on the pavement surface occur. In addition, it may take time to inspect the bearings due to sediment accumulation and overgrowth of vegetation. In the case of bridges, efforts are being made to facilitate maintenance. For example, efforts are being made to reduce the number of girders that support the deck and reduce the number of member elements.

Comparing the two bridge types from the viewpoint of dealing with aging, it can be said that the box culvert, which is an integrated structure, is more advantageous than the bridge type having member joints such as bearings.

5 CONCLUSIONS

In this paper, we have compared and studied two types of small-scale bridges, the bridge girder type and the culvert. These two types are often used for short span bridges. As a result of comparing the features of both in consideration of cold regions and aging, the following conclusions were obtained.

(1) There are two types of bridges between small spans: deck type and culvert. The bridge type consists of abutments, bearings, and decks, and the box culvert is an integrated structure. Box culvert with few structural elements can simplify the work from manufacturing to inspection.
(2) Moisture and salt are the main causes of deterioration of aging, and most of them occur at the member ends and decks of member joints in girder bridges. Therefore, it can be said that removing the joint portion alleviates deterioration and is effective as a countermeasure against aging, and box culvert is excellent as a countermeasure against aging.
(3) In addition, the precast box culvert, which is manufactured in advance at the factory and united at the site, is excellent in that the material quality can be ensured and the construction period can be shortened. It is suitable for construction with limited traffic restrictions and winter erections in cold regions.
(4) However, there is a limit to the span length that can properly use box culvert. Therefore, it is expected that it will be applied to various span lengths by studying the structure of other chambers using partition walls.

Structural simplification simplifies work from construction to maintenance. Looking at the member force generated in the member, it changes smoothly as compared with the structure in which many members are combined. The fact that abrupt changes in stress do not occur is also excellent in terms of mechanical strength. However, we need inspection methods for deterioration of back surface faced to soil. Though we use the method such as tapping sound inspection, it is expected to develop a simple inspection method for a damage of back surface.

ACKNOWLEDGMENTS

In this paper, we referred to the documents of the Ministry of Land, Infrastructure, Transport and Tourism in Japan and Aomori Prefecture. In particular, we referred to Aomori Prefecture Longevity Repair Plan formulated by the Road Division of Department of Land and Infrastructure in Aomori Prefecture. we would like to express deep thanks everyone involved. And, we thank Prof. Takase (Associate Professor of HIT) and Mr. Goto (Senior Managing Director of GIKEN in Aomori) for their kind support.

ABSTRACT: Significant compressive and tensile forces due to both ordinary and earthquake loads act on the foundations of ultrahigh-rise buildings with large aspect ratios, which are increasing in urban areas of Japan. A diaphragm wall foundation with an enlarged part has been developed to handle this issue; this is a diaphragm wall foundation with an increased width at a section of the foundation near the wall tip. It is important for the trench of diaphragm wall foundation to be stable in the construction process. The purpose of this study is to evaluate the trench stability for the diaphragm wall foundation with an enlarged part. The following studies were carried out to grasp this. 1) Centrifuge model tests to evaluate the trench stability of the diaphragm wall foundation with an enlarged part. 2) Numerical simulation using a shear strength reduction FEM to simulate the centrifuge model tests.

1 INTRODUCTION

Significant compressive and tensile forces due to both ordinary and earthquake loads act on the foundations of ultrahigh-rise buildings with large aspect ratios, which are increasing in urban areas of Japan. A diaphragm wall foundation with an enlarged part shown in Figure 1 has been developed to handle this issue; this is a diaphragm wall foundation with an increased width at a section of the foundation near the wall tip. It is important for the trench of diaphragm wall foundation to be stable in the construction process from the excavation to the concrete placing stage.

The trench stability of diaphragm wall has been studied previously in several researches, in which experimental and numerical approaches have been attempted. A concept that the diaphragm wall is generally stable is summarized in JGS(1988), since the fluid pressure such as the slurry in the trench supports the earth-pressure of ground around the trench. Katagiri et al. (2000) carried out centrifuge model tests to examine the trench stability of diaphragm wall. An analytical study of trench stability was performed by Ishii et al. (2001). They conducted an elasto-plastic FEM combined with a shear strength reduction method to estimate the global safety factor.

It is therefore necessary to evaluate the trench stability on the diaphragm wall foundation with an enlarged part because the failure mechanism and the applicability of analysis are still uncertain.

Thus, the purpose of this study is to evaluate the trench stability on the diaphragm wall foundation with an enlarged part. The following studies were carried out to grasp this:

2) Numerical simulation using a shear strength reduction FEM to evaluate the centrifuge model tests.

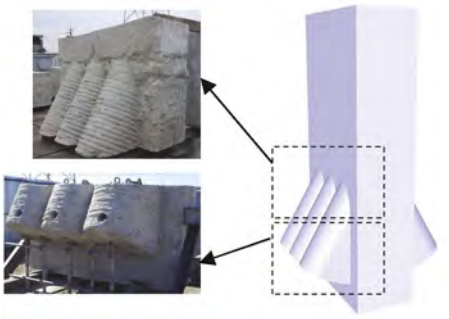

Figure 1. Diaphragm wall foundation with an enlarged part.

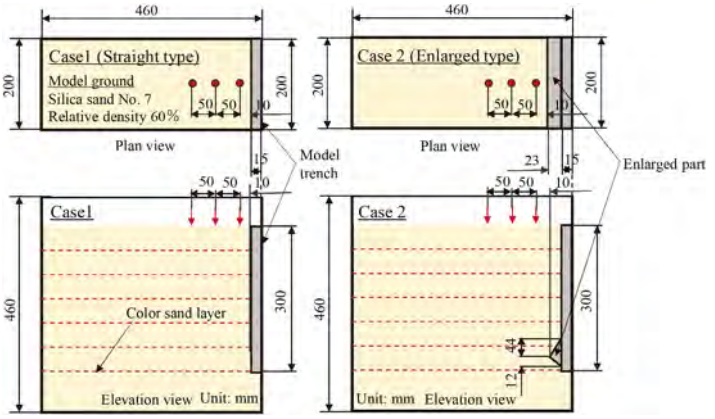

Figure 2. Schematic view of centrifuge model test apparatus.

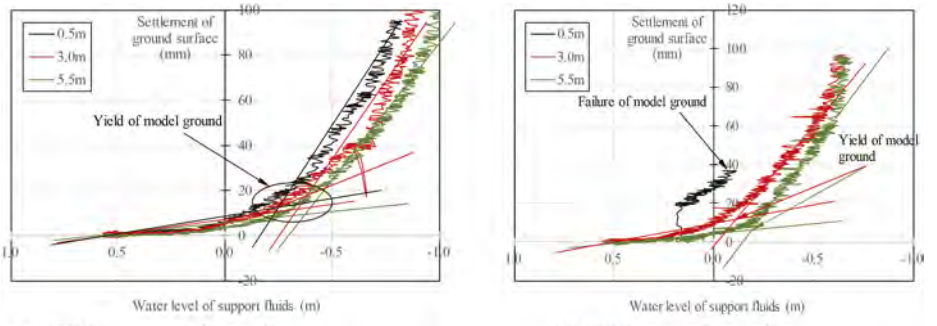

Figure 3. Relationships between settlement of model ground and water level of support fluid.

2 CENTRIFUGE MODEL TESTS

2.1 *Experimental condition*

The Aichi Institute of Technology Centrifuge (AIT Centrifuge) was used in the model test described in this paper. This centrifuge is a beam type with a pair of parallel arms that hold platforms on which the model container and a counterbalance weight are mounted. Effective radius of rotation is 1.36m, which is the distance from the rotating shaft to the platform base.

A schematic view of the test apparatus is shown in Figure 2. The dimensions of the steel container are width B=460mm, height h=460mm and length l=200mm. The model ground was prepared by air-pluviation method using Silica sand No. 7 which has the physical properties of $\rho_s = 2.645\text{g/cm}^3$, e_{max}=1.158 and e_{min}=0.692 to achieve a relative density of D_r=60%. The model ground is saturated after preparing the dry sand ground. All the tests were conducted in saturated sand conditions under 50G. The model diaphragm wall foundations are assumed in a two-dimensional condition considering symmetry of the prototype diaphragm wall foundation in the planar shape. The shape of model diaphragm wall is simulated by a thin plastic (thickness t=0.1mm). This thin plastic represents mud membrane inside the trench in the actual construction process.

The experiments progress in such a way that the support fluid in the model trench decreases when a target centrifuge acceleration of 50G is reached. Here, the support fluid used is

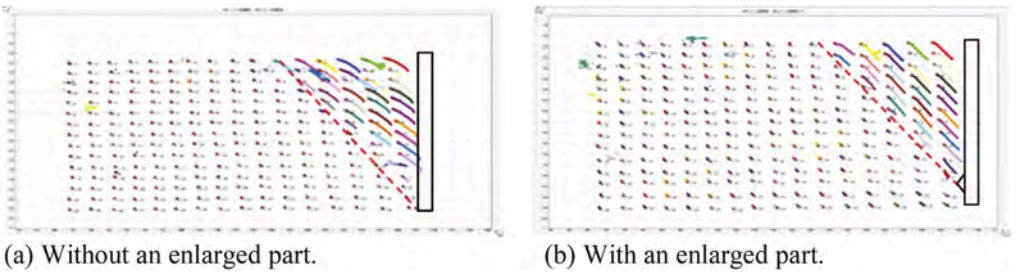

Figure 4. Results of image analysis.

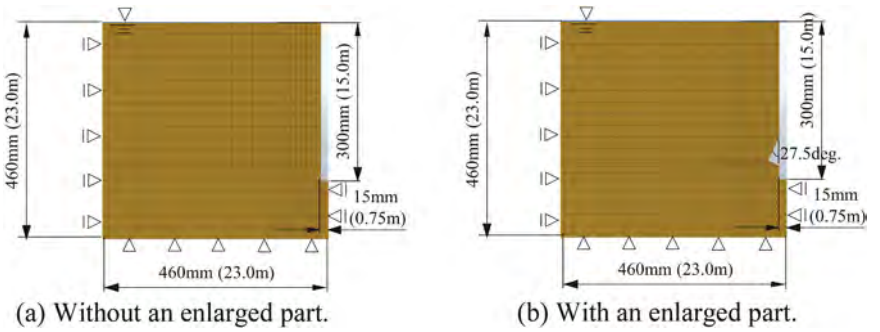

Figure 5. Schematic view of FEM analysis model.

a saline water (Specific gravity, 1.05) which is equivalent to actual support fluid such as bentonite and polymer fluid. The initial water level before the support fluid drainage is set 0.5m above the ground surface in the prototype scale. A low-flow type solenoid valve is used to drain the support fluid in the model trench of the diaphragm wall foundation.

2.2 *Results of centrifuge model tests*

Figure 3 indicates the relationships between settlement of model ground and water level of support fluid. The settlement of model ground increases as the water level of support fluid decreases. The model ground yields when the water level of support fluid is 0~-0.25m.

The failure modes obtained from the image analysis of the centrifuge model tests are shown in Figure 4. The deformation of the model ground progresses as the support fluid in the model trench decreases. It is seen in Figure 4 that a slip line occurs when the trench and the model ground fail. The shape of the slip lines is a straight line in both cases. The angle of slip line is 64 deg. for diaphragm wall foundation with and without an enlarged part. Here, the active failure angle is calculated as 63.4 deg. if an internal friction angle obtained from the triaxial compression test for silica sand No. 7 is used. It is said that the failure (*i.e,* slip line) occurs at a deeper depth for diaphragm wall foundation without an enlarged part (Figure 4 (a)). On the other hand, as shown in Figure 4(b),the failure progresses near the enlarged part for diaphragm wall foundation with an enlarged part.

3 SIMULATION OF CENTRIFUGE MODEL TESTS

3.1 *Numerical analysis method*

Shear Strength Reduction-FEM (SSR-FEM) is an elasto-plastic FEM simulation scheme including the shear strength reduction method and can evaluate the global safety factor that is defined by limit equilibrium methods without assuming a slip surface. In addition, when deformation problems have to be considered in elasto-plastic FEM simulations, it can deal with complicated conditions, taking into account the confining pressure which acts on a sliding earth mass.

The purpose of this analysis is to simulate the results of centrifuge model tests described in Section 2. The model trench is a quadrant of the prototype scale considering symmetry. It is assumed that the failure of soil is defined by the Mohr-Coulomb's failure criterion. The iteration process is based on the modified Newton Raphson method.

Figure 5 indicates a schematic view of the FEM analysis model. The model is divided into the model ground and the model trench. The parameters of ground and the support fluid used in the

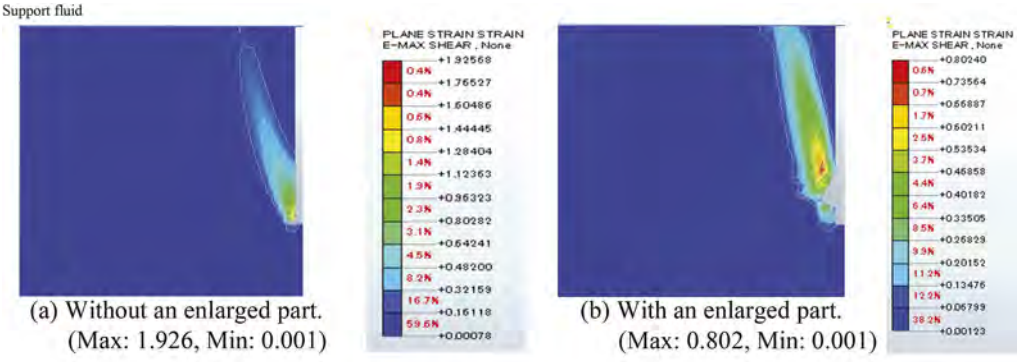

Figure 6. Distributions of maximum shear strain (Water level of support fluid: 0m).

analysis are shown in Table 1. The material parameters of cohesion c', internal friction angle φ' and deformation modules E_{50} are determined based on the results of triaxial compression tests. The Poisson's ratio is obtained from the result of K_0 consolidation test. As for the boundary

Table 1. Parameters of FEM analysis model.

Model ground	Saturated unit weight γ_{sat}	18.3	kN/m^3
	Deformation modulus E_{50}	4470	kN/m^3
	Poisson's ratio ν	0.28	
	Cohesion c	6.5	kN/m^2
	Internal friction angle ϕ	37.3	°
	Dilatancy angle Ψ	37.3	°
Support fluids	Unit weight γ_s	10.3	kN/m^3

conditions, the displacement on the bottom surface is fixed in all directions, while back and right-side surfaces are laterally confined.

3.2 *Results of numerical analysis*

Figure 6 presents the contour of maximum shear strain when the difference in water level ΔH is -0m. This means the support fluid level is equal to the ground water level at the ground surface. The figure shows the deformation immediately after the failure. According to the contour of maximum shear strain, deformation toward the ground surface was confirmed from the model diaphragm wall foundation. In addition, it is seen that the shape of indicated slip line is a straight line. This trend is consistent with the results of centrifuge model test shown in Figure 4. In case of diaphragm wall foundation with an enlarged part, it is observed that the maximum shear strain becomes large near the enlarged part. It is therefore clear that the deformation behavior for the centrifuged model test can be simulated by the SSR-FEM described in this section.

4 CONCLUSIONS

The purpose of this study is to evaluate the trench stability on the diaphragm wall foundation with an enlarged part. The following findings were obtained from this study.

1. The failure mode of diaphragm wall foundation with or without an enlarged part was exam- ined by the centrifuge model tests. It is suggested that the failure mode is in a straight slip line close to the active failure line.
2. The failure mode of FEM simulation is consistent with the centrifuge model test results, suggesting that can be simulated by the SSR-FEM.

ABSTRACT: The results of experimental studies of the stress-strain state of reinforced concrete three-dimensional blocks under the action of vertical loads are presented. Information is given on the distribution of deformations, the formation and opening of cracks, horizontal displacements, strength and nature of destruction, and the influence of the type of concrete. Proposals are given for calculating the bearing capacity, taking into account damage.

Keywords: reinforced concrete volume blocks, strength, deformations, cracks and displacements, failure patterns.

1 INTRODUCTION

The ideas of volume-block construction originated in the USSR and abroad at the beginning of the 20th century. At the end of the fifties, the design of structural systems and the construction of residential buildings from reinforced concrete three-dimensional blocks began in the Soviet Union. Currently, in various cities of the CIS (Khabarovsk, Krasnodar, Gulkevichi, Volzhsk, Minsk, Voronezh, Moscow and Astana) there are factories for the manufacture of volumetric blocks and the construction of volumetric-block buildings up to 16 floors high. The most widely used volumetric blocks such as "cap" and "lying glass". In recent years, several countries have built a significant number of multi-storey buildings from reinforced concrete three-dimensional blocks (Weisman 1967, Drozdov 1969, Berezovsky 1973).

The advantages of volumetric-block construction are the transfer of the main construction processes to the factory, which makes it possible to improve the quality of construction (Toleubayeva 2020), automate production, use effective building materials, reduce the impact of seasonal work, drastically reduce construction time, and significantly reduce construction costs (Kirkorov 1975, Ilyenko 1979). The main features of a three-dimensional block building are associated with increased flexibility of wall elements, which leads to premature loss of wall stability (Zhussupbekov 2020). In addition, the extremely limited amount of experimental and theoretical studies of such constructive systems should be attributed to the disadvantages of using volume-block housing construction (Utepov 2022).

DOI: 10.1201/9781003299127-373

In the city of Astana (Kazakhstan), a house-building plant "ModeX Astana" was built, which manufactures reinforced concrete volumetric blocks of the "lying glass" type of enlarged sizes. The building is mounted from pillars of volumetric modules, leaning against each other through a layer of mortar. In the process of mastering the technology at the plant, control tests were carried out on the main load-bearing structures of volume-block multi-story buildings, which made it possible to improve their manufacturing technology and design solution, taking into account the use of modern materials.

2 EXPERIMENTAL STUDIES

This article presents the results of testing full-scale volumetric blocks that differ in the type and strength of concrete, as well as reinforcement. Volumetric blocks have two side walls of a ribbed design with a wall thickness of 50 mm and ribs 100 high, as well as a flat end wall 100 mm thick. The floor slab of the volumetric unit is ribbed with a shelf 80 mm thick and ribs 170 mm high. The ceiling slab of the volumetric unit is flat with a run-out, 80-97 mm thick. Volumetric blocks are reinforced with spatial frames and reinforcing meshes made of cold-drawn wire Ø4-Ø5 mm Y500C class, combined into a single spatial block, as well as additional bar reinforcement Ø12 S500. External insert wall panels are multi-layered with a bearing layer of concrete, effective insulation and a facing layer, installed as a facade system.

Three-dimensional blocks were tested on a test bench, which is a rigid rod system of adjustable vertical and horizontal frames (Guidelines 1977, Guidlens 1983). The loading of volumetric blocks was carried out using hydraulic jacks with a capacity of 200 tf through a distribution reinforced concrete slab. During the tests, the compressive deformations of concrete were measured using vertical strain gauges with a base of 50 mm, horizontal and vertical displacements of walls and ceilings - using digital deflection gages PA0-6, and the crack opening width - using an MPB-3 microscope (CP 501.1325800.2021).

Volumetric block No. 1 is made of concrete of axial compressive strength class LC20/22 and density grade D1800 using crushed expanded clay. At a vertical load of N = 728.4 tf, cracks were observed at the corners of the volumetric block, vertical cracks in the lintel above the window in the wall panel and in the lintel above the doorway in the end wall. At the same time, the opening width of existing technological cracks increased by 0.05 mm (CP RK EN 2011).

Figure 1 shows a plot of longitudinal deformations of concrete along the perimeter of the walls of a volumetric block with a vertical load N = 829.86 tf. The value of vertical deformations along the length of the longitudinal walls was within -(26-61) 10-5 relative units and averaged -(42-53)10-5 relative units. The concrete deformations in the end wall and wall panel were almost 20% less. Under this load, the crack opening width in the lintels reached 0.05-0.10 mm, and the crack opening width in the longitudinal walls was in the range of 0.10-0.25 mm.

The destruction of the volumetric block occurred at a vertical load N = 1083.88 tf and was caused by fragmentation of the upper part of the longitudinal wall in the area of adjacency to the wall panel with the continuous growth of horizontal deformations of the walls from the plane and the formation of new cracks. The crack opening width in the lintels reached cracks of 0.15-0.2 mm, and the crack opening width in the longitudinal walls was within 0.20-0.25 mm (Figure 2).

Figure 3 shows diagrams of horizontal displacements of walls from the plane of the volumetric block. The largest movements of the top of the longitudinal walls reached 2.1-2.45 mm, the movements of the end wall were 3.08 mm, and the wall panel - 4.24 mm. The increase in displacements almost linearly depended on the vertical load, and only at the last stage of loading was a sharp increase in horizontal displacements (deplanation) of the walls observed. (Figure 5). The average compressive stresses of concrete in the longitudinal walls were equal to 8.74 MPa, that is, they amounted to 43.7% of the concrete strength. The average compressive stresses in the concrete of the longitudinal walls were equal to 8.33 MPa, that is, they amounted to 41.7% of the concrete strength. The experimental breaking load exceeds the control breaking load for 16-storey buildings in Astana by 4%.

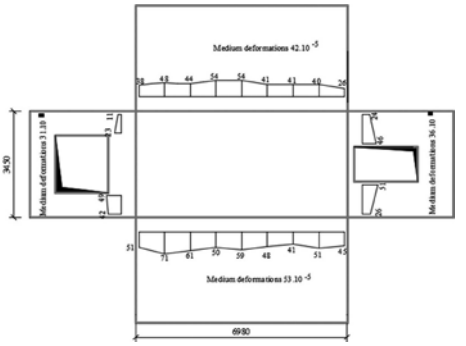

Figure 1. Distribution of concrete compression strains along the perimeter of the walls of block No. 1 at 76% of the breaking load.

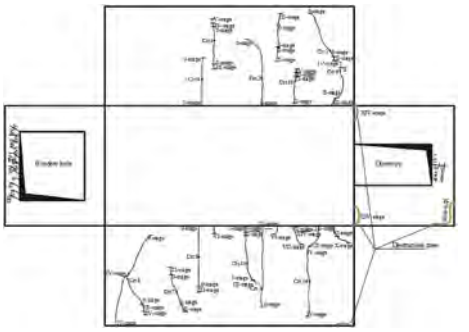

Figure 2. Scheme of the location of cracks on the development of the walls of block No. 1.

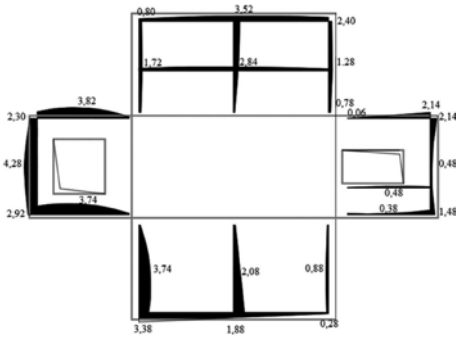

Figure 3. Horizontal displacements of walls under breaking load.

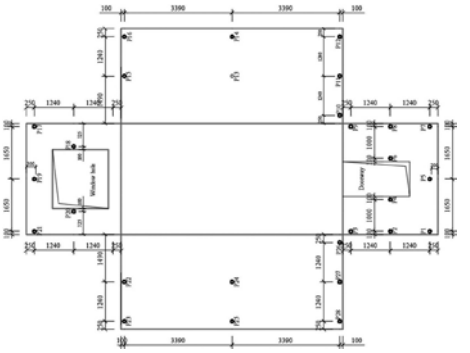

Figure 4. Scheme of the location of deflectometers.

Figure 5. Damage to the interface between walls and ceiling slabs.

Volumetric block No. 2 is similar in geometrical dimensions to block No. 1, however, it had less reinforcement of walls and floors, and was also made on crushed expanded clay from concrete of class LC16/18, density grade D1800. When loading the sample with a vertical load up to N = 652.4 tf, cracks formed at the corners of the volumetric block, vertical cracks in the lintel above the window in the wall panel and the lintel above the doorway in the end wall. With a vertical load N = 815.5 tf, the crack opening width in the lintels reached 0.05-0.10 mm, and the crack opening width in the longitudinal walls was in the range of 0.10-0.25 mm. The value of

vertical deformations of concrete along the length of the longitudinal walls was within -(22 - 49) 10-5 relative units, concrete deformations in the end wall were about 72% of the average deformations of the longitudinal walls, concrete deformations in the wall panel were about 52 % of these deformations. In this case, the largest displacements of the top of the longitudinal walls were 2.63 and 2.84 mm, deformations of the end wall - 3.29 mm, and the wall panel - 2.07 mm.

The destruction of the volume block occurred at a vertical load of N = 1002.33 tf (Figure 6) and was accompanied by the destruction of the concrete of the upper part of the longitudinal walls in the area of interface with the roof slab and the outer wall panel, the splitting of the roof slab and the end wall, as well as the continuous increase in the horizontal deformations of walls from the plane. The average compressive stresses in the longitudinal walls were equal to 7.93 MPa, that is, they amounted to 49.56% of the concrete strength. The experimental breaking load exceeds the control vertical load for 13-storey buildings in Astana by 30%.

Figure 6. Splitting of the block floor slab No. 2.

Block No. 3 was similar in terms of reinforcement and geometrical dimensions to block No. 1, but was made of heavy concrete of class C20/22. The first vertical cracks appeared in the lintel of the wall panel under a vertical load of N=850 tf, then vertical cracks appeared in the lintel of the doorway and vertical cracks in the window sill of the wall panel. During the stage before the destruction of the volume block, the largest crack opening width did not exceed 0.20-0.25 mm, the horizontal displacements of the walls from the plane of the volume block did not exceed 1.2 mm, and in the middle part of the window opening of the wall panel was 5.03 mm. The compressive deformations of concrete in the longitudinal walls were in the range of -(19 - 31)10-5, and in the area of adjacency to the wall panel they increased sharply, approaching the ultimate compressibility of concrete in axial compression. The deformations of concrete in the end wall and wall panel were two times less than the deformations of concrete in the longitudinal walls.

The destruction of the volumetric block occurred at a vertical load N = 1482.21 tf and was accompanied by the destruction of the upper part of the longitudinal walls in the area of interface with the floor slab, the opening of vertical seams between the wall panels, the formation of cracks in the lintels of the wall panel and the end wall, the formation of longitudinal cracks in the ceiling slab with an opening width of 0.10-0.15 mm. The average compressive stresses in the longitudinal walls were equal to 12.03 MPa, that is, they amounted to 57.8% of the concrete strength. The experimental breaking load exceeded the control breaking load for 16-storey buildings in Astana by 4%.

3 ANALYSIS OF RESEARCH RESULTS

The performed studies of the bearing capacity of three-dimensional blocks revealed their complex stress state under vertical loads, established the sequence of formation and width of cracks in walls and ceilings, the magnitude of the ultimate deformations of walls from the plane, the distribution of longitudinal deformations of concrete in the walls and the causes of destruction of

three-dimensional blocks. The main features of the behavior of volumetric blocks under vertical loads are associated with a small wall thickness compared to that required for buildings with load-bearing reinforced concrete walls, which, according to [18], should be at least 200 mm.

Increased flexibility of the walls of volumetric blocks at initial loads, an increase in the free length of walls in the process of significant damage to walls and ceilings, as well as significant displacements of walls from the plane of the building under high vertical loads, lead to premature destruction of volumetric blocks.

The destruction of the walls of expanded clay concrete volumetric blocks for the destructive stage of the work of the walls occurs at compressive stresses in the walls equal to 44.7-49.6% of the concrete strength. Thus, the strength of reinforced concrete walls should be determined by introducing the coefficient of reduction in the bearing capacity of flexible compressed elements φ=0.44-0.5. When designing the walls of the volume blocks of the lower tiers of buildings, damage to the volume blocks should be taken into account. Changes in the flexibility of walls in the calculation of serviceability limit states (SLS) can be ignored, and for critical states in terms of bearing capacity (ULS), the design length of the walls should be increased by 50-56%.

The rigidity and crack resistance of volumetric blocks made of heavy concrete is much higher than that of volumetric blocks made of expanded clay concrete. Therefore, when designing walls of bulk blocks made of heavy concrete for the action of vertical loads, taking into account damage to bulk blocks, the change in the flexibility of walls when calculating serviceability limit states (SLS) can also be ignored, and for critical states in terms of bearing capacity (ULS), the calculated length walls should be increased by 43%.

Landscape science potentiality for the construction of buildings on megafans

M.Sh. Ishankulov, Zh. M. Aukazhiyeva & M.Z. Sagyndyk
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The possibility of using the potential of landscape science for the construction of buildings is considered on the example of two unique natural formations of Kazakhstan - megafans of the Talass and Kon rivers. Landscape science as a synthetic natural science discipline can contribute to the design of foundations for buildings and structures. The presented materials testify to the variety of variants of megafans, their dissimilarity, which entails the need for an individual approach to their assessment. The megafans considered by us are complex and diverse in their structure and do not always correspond to traditional ideas about alluvial fans and inland deltas. Separate cone-shaped formations included in their composition are facultatively closed; they correspond to the time stages of mudflow or, in the case of inland deltas, flood process. The approach outlined in the article is considered by us as an addition to engineering and geological surveys, which are mandatory when designing the foundations of buildings and structures. It gives a systematic vision of the subject of research. The approach is applicable in the development of a strategy for large-scale design of the construction of buildings and structures in the volumes of the country's regions.

Synthetic physical-geographical discipline - The Science of Landscape - has been developing in Kazakhstan since the early 60s of the last centuries. Its foundations were laid in the 19th century by the outstanding Russian naturalist V.V. Dokuchaev. The subject of study of landscape science are natural formations of different hierarchical levels.

Landscape cartography serves as a source of new information about natural formations, the basis for creating thematic maps for various scientific purposes and theoretical generalizations. Two giant (more than 10^5 km^2) fan formations - alluvial fans and inland deltas in the basin of the Talass and Kon rivers were chosen by us for a closer acquaintance with the possibilities of landscape maps for the construction of buildings. These natural formations are the main arena for the life of the population in arid conditions and the objects of the construction boom that has unfolded in the country.

1 TALASS COMPOUND MEGAFAN

1.1 *Landscape map of the Talass river alluvial fans*

The landscape map of the Talass river megafan is shown in Figures 1 and 2).

a – Current lines of former water-ground flows drawn along watersheds (solid, dotted and dotted lines correspond to alluvial fans of landscape rank (Solntsev, 1948); b- corresponding to the tops of alluvial fans; c - branching nodes of current lines of former water-ground flows, corresponding to the tops of alluvial fans in the rank of morphological units of the landscape (tracts, facies) d – numbers of alluvial fans landscapes; e - the border of the Talass and Assa of alluvial fans systems; f – boundary of the Assa alluvial fans system of with fans superimposed on the Talass fans; g - boundary of the alluvial fans of the Ichkeletau mountains and the Talass system

DOI: 10.1201/9781003299127-374

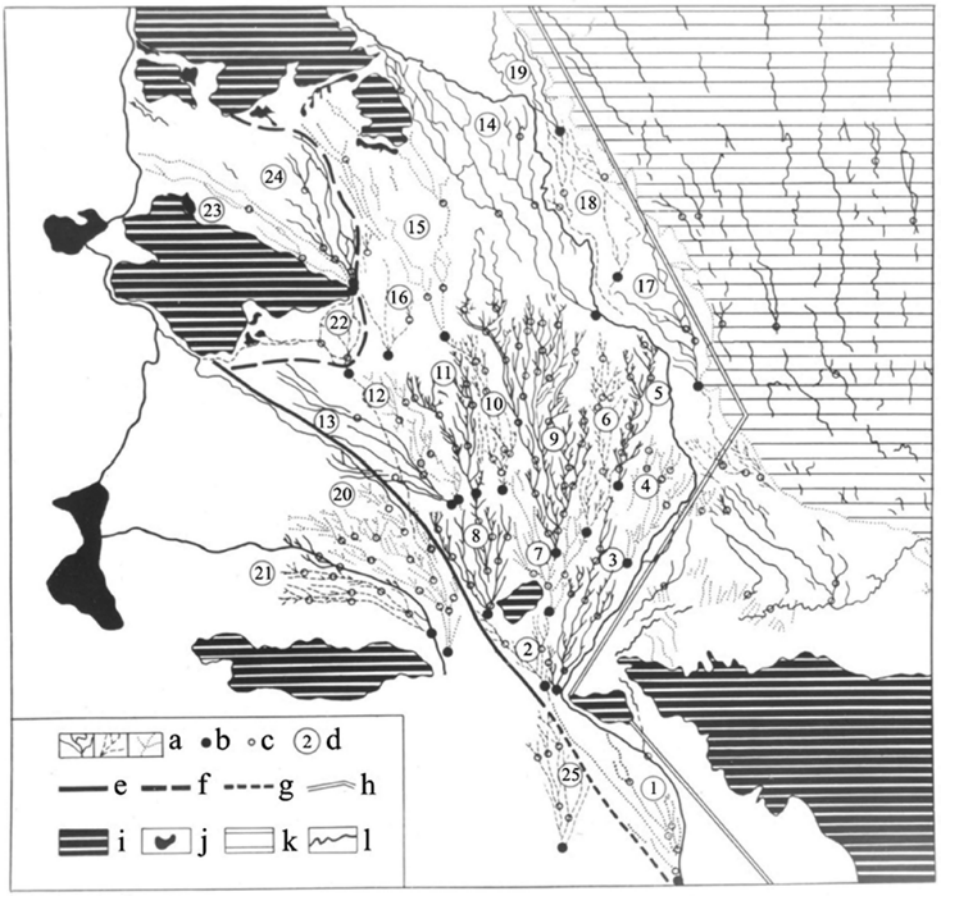

Figure 1. Talass system of alluvial fans landscapes (Ishankulov, Ropot, 1978, p.33).

of alluvial fans; h – boundary of the dead system of Talass alluvial fans, buried under eolian sediments of the Moyinkum and partially involved in the mountain uplift in the process of orogenization of the territory (restored by interpretation of aerial photographs); i - low mountains, remnant low mountain massifs and plateaus within the territory of the development of alluvial fans; j - lakes; k- sands; l – rivers-bed.

Talass alluvial fans landscapes system:

Active fans: 1 - Pokrovka, 2 - Dzhambul, 3 - Rovnoe, 4 - Karasu, 5 - Zylikha, 6 - Kosheni, 7 - Karatobekol, 8 - Zhanasaz.

Dying fans (transitional state from active to dead): 9 - Karashingil, 10 - Eshkilikbay, 11 – Kolkaynar, 12 – Shiyozek, 13 – Torangy.

Dead fans: 14 – Karabakyr, 15 – Dalazhailau, 16 – Kudeli, 17 – Upper Kokozek, 18 – Middle Kokozek, 19 – Lower Kokozek.

Assa river alluvial fans system: 20 – Karakemir, 21 – Kyrshandy.

Assa alluvial fans landscapes system superimposed on landscapes of alluvial fans of the Talass system: 22 – Karabuget, 23 – New Tasaryk, 24 – Old Tasaryk (Figure 2).

1.2 *Landscape map of the Talass river alluvial fans*

Tracts and their combinations:

1 – Delta streams, mostly sandy with a thin layer of silt, deposited during flood periods by undeveloped alluvial-meadow soils with succession changes of herbaceous communities.

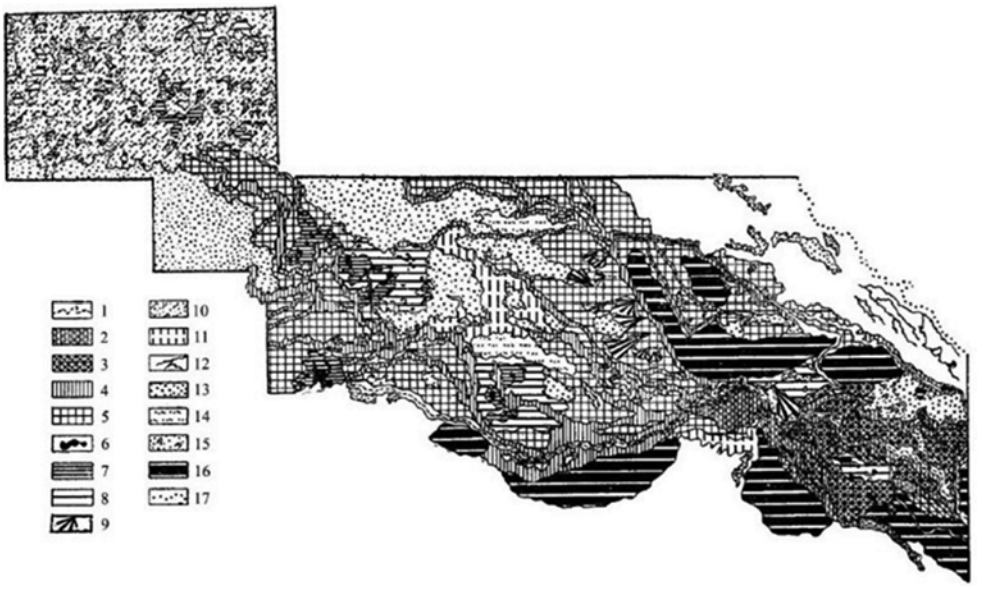

Figure 2. Landscape map of the Talass river inland deltas (Bogachev, Ishankulov, 1986, p. 22-23).
The map of inland deltas is a continuation in runoff of the map of Talass alluvial fans, presented in Figure 1.

2 – Embryonic levee, composed mainly of sands and sandy loams, washed out during floods with a multi-year periodicity; alluvial-meadow-tugai and alluvial-meadow soils under Salsola chingils.

3 – Embryonic interchannel depressions composed of medium and heavy loams during flooding for 10-40 days a year and groundwater at a depth of up to 2.5 m with meadow-bog and bog-meadow soils under reed-forb-reed, Climacopter-reed, Comba communities.

4 – Mature levee composed mainly of sandy loam and light loam when washed out during floods with annual or long-term periodicity with alluvial-meadow-tugai and alluvial-meadow soils under Elaeagnus angustifolia and Chingil tugai; in the absence of floods - with alluvial-meadow desertifying soils under Saltwort chingils, Aeluropus–limonium-Saltwort with Alhagi communis.

5-8 – Mature interchannel depressions composed of medium and heavy loams and clays (5) with year-round stagnation of waters entering the flood – deltaic lakes (6); with flooding 160-190 days a year and groundwater at a depth of up to 1 m with swamp soil under Typha angustifolia, Typha angustifolia-Phragmites communis, Aeluropus and Bolboschoenus communities (7); with flooding 100-110 days a year and groundwater at a depth of up to 2.5 m – with meadow boggy soils under Forb-read, Reed grass-Forb-Reed communities (8); with flooding 30-40 days a year and groundwater up to 5 m – with swampy-meadow and meadow-swampy decertifying soils under Elytrigia repens, Puccinellia, Tamarix and Halostachys communitis; in the absence of floods and occurrence of groundwater at depth of 5-10 m and deeper – with takyr-like soils under Artemisia-Anabasis salsa with Haloxylon aphyllum communities.

9 – Alluvial fans formed by temporary flows originating from the remnants surrounding land deltas, composed mainly of saline red-colored clays with gray-brown desert soils under Gramínea-Saltwort communities in the upper part and solonchaks along the periphery of alluvial fans.

10 – Eolian hilly-ridged sands processed by floods; with flooding 160-190 days a year and groundwater at a depth of 2.5 m with meadow boggy and swampy meadow soils under Forb-reed communities; with flooding 30-40 days a year and groundwater at a deep of 2.5-5.0 m – with alluvial-meadow soils under Forb grass-Calamagrostis communities.

11 – Runoff hollows filled with silty sands with alluvial-meadow soils under Artemisia- Puccinellia communities.

12 – Gully.
13 – Hilly-ridged sands with Agropyron fragile-Hordeum communities.
14 – Ridge sands with Artemisia-Agropyron repens-Eurotia ceratoides communities.
15 – Dune-hummocky sands with Artemisia-Agropyron repens communities.
16 – Monoclinal remnant ridges - local anticlines composed of red-colored clays, gray-brown desert soils under Artemisia pauciflora.
17 – The boundary of the sand massif Moyinkum.

2 KON COMPOUND MEGAFAN

2.1 *Proluvium of the North Kazakh Plain*

Five rivers of the basins of the Ob watershed of the Kazakh hills (Kon, Nura, Ishim, Olenty and Shiderty) created the North Kazakh plain. In the geographical literature, it is also called the Ishim plain, and sometimes the Ishim steppe. Each of the watercourses, upon exiting the drainage basin to the North Kazakh Plain, forms alluvial fans and inland deltas created by deposits of proluvial genesis (Figure 3).

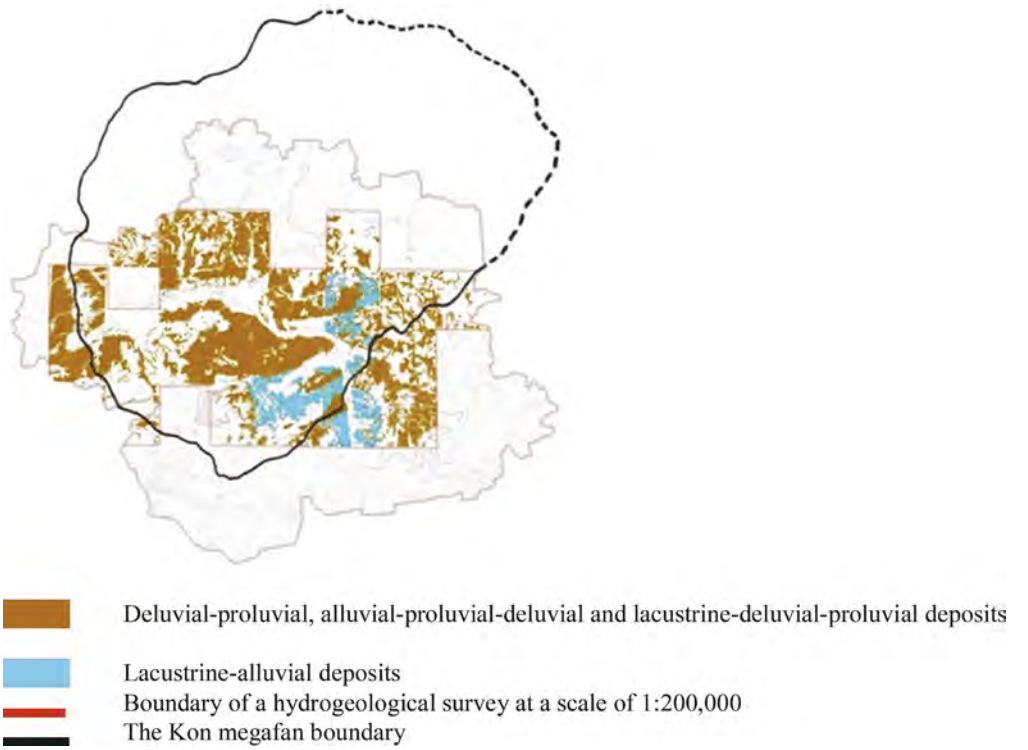

Figure 3. Proluvium of the North Kazakh Plain within the boundaries of the Akmola and Nurinsky districts of the Karaganda region (compiled by M.Sh. Ishankulov according to the hydrogeological maps of the USSR, m 1:200,000, surveyed in 1955-1979).

The alluvial fan of the Kon River stands out with gigantic dimensions against the background of all 5 alluvial fans of Kazakhstani rivers of the Ob watershed of the Kazakh hummocky terrain (Figure 4). Its area is estimated at 240,368 km^2; length from north to south – 586 km; from west to east – 587 km (Figure 4).

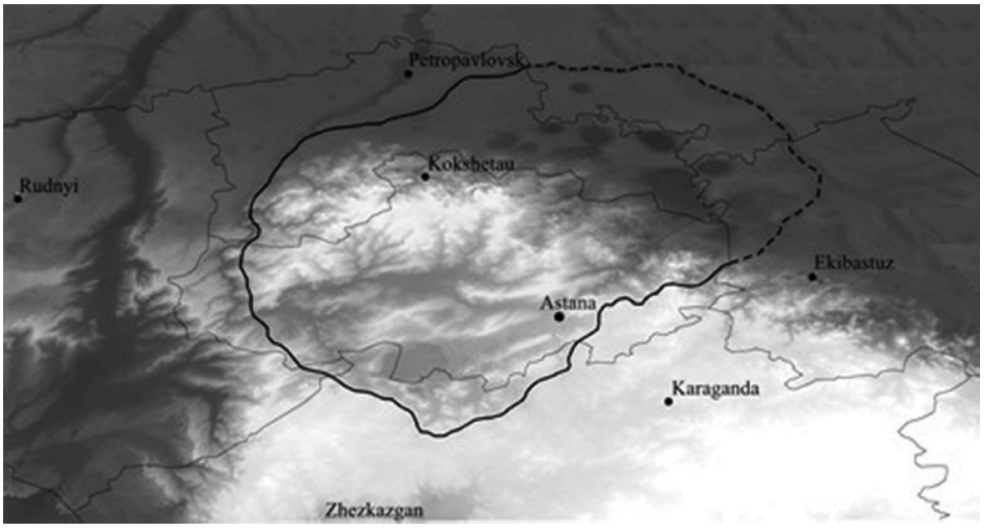

Figure 4. Proluvium of the North Kazakh Plain within the boundaries of the North-Kazakhstan, Akmola and Nura districts of the Karaganda region (compiled by M.Sh. Ishankulov according to the hydrogeological maps of the USSR, m 1:200,000, surveyed in 1955-1979). (The dotted line shows the proposed segment of the border. Thin lines inside the object of study are the boundaries of administrative regions).

The reason for such gigantism lies in the specifics of its origin and in the properties of the rocks of the catchment. The megafans arose due to the ultra-mud flow. Such flows are rare and represent one of the groups of mudflows and mudflows of the Earth, characterized by a grandiose scale of the process (Perov, 1996). As for the properties of rocks, it was found that the drainage basin of the Kon river is the only active river catchment area on the Ob watershed of the Kazakh hummocky terrain that can supply material with plastically viscous properties for in other watersheds mudflows - fatty Miocene clays. in other watersheds, such clays are absent or limited (Figure 5).

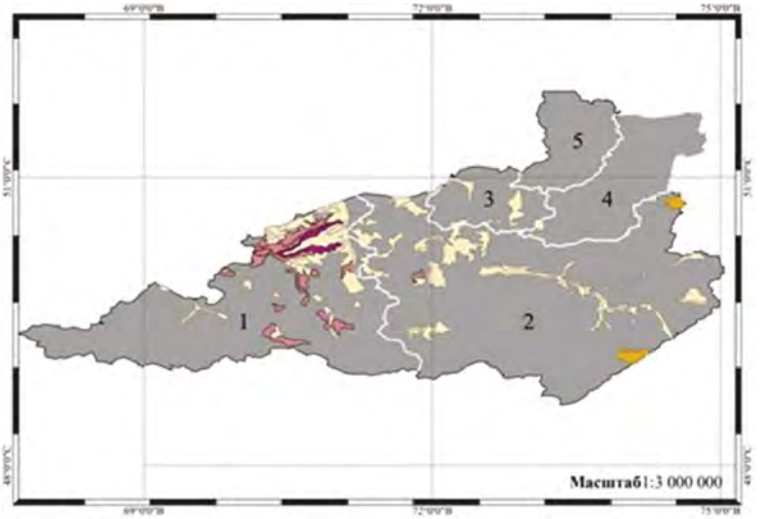

Figure 5. Resilience of rocks composing watersheds to displacement under conditions of extreme climatic situations. Drainage basins of the rivers: 1 – Kon, 2 – Nura, 3 – Ishim, 4 – Selety, 5 – Shiderty.

The object discovered in 2007 has not yet been studied with the same detail as the Talass compound megafan. However, the first results of the research say that the object is original and does not look like the Talass megafan at all. Its drainage basin is located not in the mountains, but in the hills of the Kazakh hummocky terrain.

Its top is composed not of coarse clastic material, but of red-colored saline clays, which led to the formation of saline deep-lying groundwater and soils of the saline series (Figure 6).

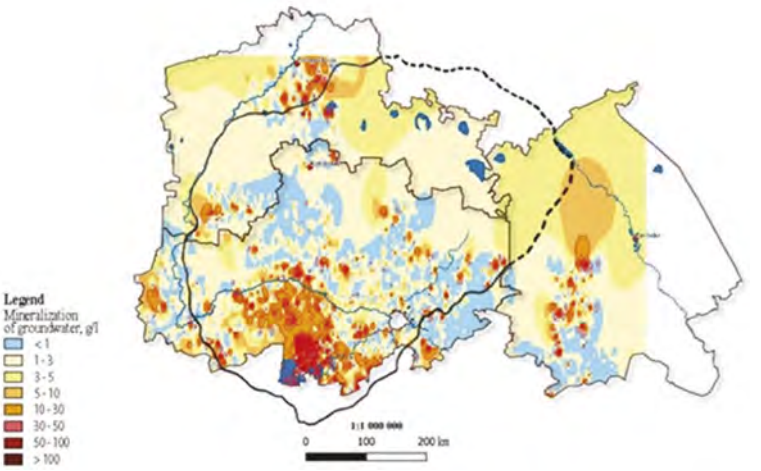

Figure 6. Mineralization of underground waters of the Kon megafan.

The issue of choosing a foundation for the construction of buildings is a key one and needs to be thoroughly considered. Construction objects in the cartographic material presented in the article are considered against a wide systemic natural background instead of the practiced point local consideration of specific objects that have little to do with the natural environment. The content of landscape maps testifies to the existence of a variety of options for megafans, their dissimilarity, optional isolation and the need for an individual approach to their assessment for construction purposes. They also contain specific detailed factual material in terms of soil characteristics, which is necessary when designing shallow foundations.

Practitioners-builders are little aware of the potential inherent in landscape maps and they are not used and for landscape specialists, familiarity with the subject of building construction can become a new area for the practical application of acquired knowledge.

ABSTRACT: The results of experimental studies of the strength of inclined sections of bent reinforced concrete elements with fiber-reinforced plastics are presented. Comparative data have been obtained on the use of new types of fiber-reinforced plastics for reinforcing reinforced concrete structures. Experimental studies have been obtained on the value taken into account in the calculations of the limiting deformations of fiber-reinforced plastics under various types of loads.

Keywords: Bending reinforced concrete elements, Beams, Strength of inclined sections, Deformations and cracks, Reinforcements, Fiber-reinforced plastics, Prototypes, Deflections, Tests

1 INTRODUCTION

The need to strengthen reinforced concrete structures during operation arises due to the long-term effect of operational loads or corrosive wear, when errors are eliminated in the design, manufacture, and transportation when the operating conditions become more complicated or not envisaged by the project, the scheme of action and magnitude of loads, the occurrence of various damages, as well as when reconstruction and renovation of the enterprise (EN 2004). An alternative to traditional methods of reinforcing reinforced concrete structures is the use of fiber-reinforced plastics (FRP) - polymers reinforced with fiberglass. Unlike traditional reinforcement methods using steel reinforcement, these methods have high reinforcement efficiency, and do not require overburden and welding, concreting of reinforced elements, they are distinguished by durability, corrosion resistance, low labor intensity, and economic feasibility.

The following types of fibers are commonly used as FRP reinforcement: basalt (B), carbon (C), aramid (A), glass (G), and polyester (Teng et al., 2002).

Reinforcement of reinforced concrete structures with fiber-reinforced plastics (FRP) can be used in the following cases:

– to reinforce undamaged reinforced concrete structures due to increasing loads during the reconstruction of the object (Shilin 2004);
– to strengthen reinforced concrete structures damaged during operation ("shooting off" of the protective layer of concrete, corrosion of reinforcement and concrete, formation and

DOI: 10.1201/9781003299127-375

development of cracks, excessive deflections, etc.) in order to restore the performance of the elements (Mander et al., 1988);
- to protect against corrosion, increase water resistance, and increase the durability of structures (Mochizuki 2020);
- fiber reinforcement (FAP) is produced by the following methods;
- by impregnation of concrete;
- external reinforcement with fiber-reinforced plastics (FRP)

Reinforcement systems for reinforced concrete structures are made in the form of unidirectional braided sheet coverings or woven unidirectional or bidirectional fibers produced on looms. The most widespread are the following types of fibrous fibers; carbon, aramid and glass. The most common method of reinforcement is external reinforcement with fiber-reinforced plastics (FRP), which is used for longitudinal and transverse reinforcement, as well as for creating reinforcing clips in compressed concrete elements, which prevent the transverse expansion of concrete, creating a triaxial stress state in concrete and can increase the strength of the latter in repeatedly (Samaan 1988, Awwad et al., 2019).

Wrapping reinforced concrete structures with polymer fiber fabrics (FFA) can increase the strength of compressed elements several times by limiting the transverse expansions of concrete and thereby creating a triaxial stress state. Sticking high-strength polymer-fiber tapes (laminate) with unidirectional fibers can significantly increase the strength of tensile reinforcement, and reduce the width of normal cracks (Saafi et al., 1999).

Sticking high-strength polymer-fiber tapes (laminate) with bilaterally directed fibers can significantly increase the strength of the transverse force, reduce the width of the opening of inclined cracks, or significantly increase the bearing capacity of reinforced concrete slabs supported along the contour.

However, comprehensive data on the operation of reinforced concrete structures reinforced in such ways under various operating conditions and the variety of influences of force, temperature, aggression and other factors have not yet been obtained (Miyauchi et al., 2000, Miyauchi et al., 2005).

The purpose of this work is to obtain experimental data on the strength of inclined sections of bent reinforced concrete structures reinforced with fiber-reinforced plastics (Katsumata et al., 1988) under static loading, as well as information on the stress-strain state, strength, stiffness and crack resistance of inclined sections of bent reinforced concrete elements reinforced with high-strength fiber-reinforced plastis.

The implementation of the proposed project will radically improve the technical support and implementation of the strengthening and restoration of building structures, increase the qualifications and potential of workers, reduce noise and environmental pollution due to the rejection of overburden, welding and labor-intensive work, increase the durability and aesthetic appearance of reinforced structures, reduce the time and cost of implementation works.

2 EXPERIMENTAL STUDIES

The strength of inclined sections in terms of the transverse force of bent reinforced concrete elements was tested on 3 batches of prototypes of reinforced concrete beams reinforced in the support zone with fiber-reinforced meshes. The batches of samples differed in the type of fiber-reinforced materials used for reinforcement. The prototypes were tested according to the scheme of a hinged beam with a span of 2.0 m, loaded in the span by two equal concentrated forces at a distance of 1.2 m. At the same time, the ratio between the size of the cut span and the height of the section was providedequallyl to lcp/h = 2.0.

The study of the work of inclined sections of bent reinforced concrete elements, reinforced in the support zone with fiber-reinforced mesh tapes, was carried out on experimental reinforced concrete beams of three batches, tested according to the scheme of a hinged beam with a span of 2.0 m, loaded in the span by two equal concentrated forces at a distance of 1.2 m. In this case, the ratio between the span of the cut and the height of the section lcp/h = 2 was provided.

Three batches of reinforced concrete beams were tested, and the reinforcement of the support zones of which differed in the type of reinforcing material:

- samples of the 1st batch were reinforced with meshes of the S&P C Sheet 240 series 50 mm wide (BASF, Germany);
- samples of the 2nd batch were reinforced with meshes of the FibArm Tape 530/300 series 300 mm wide (HK Composite, Russia);
- samples of batch III were strengthened with meshes of the MBRACE FIB CF 230/4900/530 g/5.100 m series (BASF, Germany).

The prototypes of the 1st batch in the support zone at one end of the beams were reinforced with bent double-shear clamps from Ø6 A-1, installed with a step of 100 mm, and the other end was reinforced in the support zone with vertical or inclined tapes from unidirectional meshes of the S & P C Sheet 240 series 50 mm wide. In addition, the stretched zone was reinforced with S&H Laminate CFR 150/200 50 x 1.2 mm.

Table 1 presents the following experimental data for testing beams of the BI series:

- bending moment at which normal cracks appeared;
- transverse force at which oblique cracks were formed;
- shear force that caused the destruction of the beam;
- bending moment at which the beam failed.

Table 1. Forces at which cracks were formed and the destruction of beams of the BQ-I series occurred.

Beam brand	Transverse reinforcement	$M_{crc,s}$ kNm	$Q_{crc,w}$ kN	M_u kNm	Q_u kN
BQ1-1c	Without clamps	6,38	36,79	15,94	45,53
BQ1-2c		6,87	36,70	18,67	53,44
BQ1-3c	Vertical hair mesh	5,15	31,88	31,76	90,74
BQ1-4c		5,15	41,69	38,63	110,36
BQ1-5c	Inclined mesh strips	5,15	39,24	35,19	100,55
BQ1-6c		6,87	39,24	28,33	80,93

Table 2 presents the following experimental data for testing beams of the BQ-I series:

- the greatest deformations in tension reinforcement;
- the greatest deformations in the compressed reinforcement;
- the greatest deformations in steel collars;
- the greatest deformations in fiber-reinforced meshes;
- the greatest width of opening of normal cracks;
- the largest width of the opening of inclined cracks in the zone of reinforcement with steel clamps;
- the largest crack opening width in the reinforcement zone with fiber-reinforced meshes;
- vertical deflections in the middle of the span of the beam.

Table 2. Deformation parameters of the operation of inclined sections of beams of the BQ-I series.

№	Transverse reinforcement	ε_s ‰	$\varepsilon_{s.1}$ ‰	$\varepsilon_{f,w}$ ‰	$w_{k,s}$ mm	$w_{k,w}$ mm	$w_{k,p}$ mm	a_k mm
1	Without clamps	1,4	0,4	–	0,2	3,5	–	5,82
2		0,96	0,5	1,1	0,16	3,4	–	6,66
3	Vertical stripes made of fiber-reinforced mesh	1,75	0,7	–	0,3	0,6	1,55	14,03
4		1,95	1,4	3,8	0,35	0,9	0,95	15,25
5	Inclined strips of fiber-reinforced mesh	2,0	0,7	2,3	0,3	0,65	0,95	11,12
6		1,9	0,7	2,6	0,25	0,4	1,5	11,14

Let us consider the features of the work of inclined sections in terms of transverse force with their various reinforcement. In beams that do not have transverse reinforcement at the support end, in the process of increasing the vertical load with a bending moment of about 15% of the breaking load, the formation of normal cracks in the zone of pure bending was observed, with an increase in the load by almost 5 times, oblique cracks formed in the support zones. With a further increase in the vertical load, accelerated opening of inclined cracks was observed, and after reaching a crack width of more than 3-3.5 mm, the concrete was destroyed along the inclined zone in the supporting unreinforced zone of the beam. The vertical deflections were about 6 mm, the deformations of the tensile longitudinal reinforcement were about 0,15%, the deformations of the compressed reinforcement were 0,05%, and the opening width of normal cracks was about 0.2 mm. At the opposite end of the beam, reinforced with clamps Ø6 A-1 with a pitch of 100 mm, the width of the opening of inclined cracks did not exceed 0.1 mm, and the deformations in the clamps were about 0,1%.

In beams reinforced in the supporting zone with strips of fiberglass mesh, the strength of inclined sections in terms of transverse force almost doubled. After the formation of normal cracks, which also appeared at a bending moment of about 15% of the breaking load, oblique cracks were formed at a transverse force of about 35-40% of the breaking load. The destruction of the beams was caused by the breaking off of the concrete layer under the glued mesh strips, the switching off of the transverse reinforcement, was accompanied by a loud sound and had a fragile character. At the stage before destruction, inclined cracks reached a value of 1.0–1.5 mm; clamps were about 0.2. The values of vertical deflections were about 11-15 mm, the deformations of the tensile longitudinal reinforcement were about 0.2% of the compressed reinforcement - 0.7-1.0, the opening width of normal cracks was about 0.35 mm.

Prototypes of the BQ-II series of the batch in the form of beams 2.2 m long, had a cross section of 120 × 200 mm and were reinforced with double reinforcement: in the lower zone 2Ø18 A-III and in the upper zone - 2Ø10 A-III. In the support zone, one end of the beams was reinforced with bent double-shear clamps made of Ø6 A-1, installed with a step of 100 mm, and the opposite end did not have transverse reinforcement.

The support zones of the beams of the BQ-II series were reinforced with a sticker of vertical unidirectional meshes of the FibArm Tape 530/300 series 300 mm wide, and the tension zone was reinforced with a FibArm Lamel 12/100 lamella.

The beams were loaded in stages not exceeding 5-8% of the breaking load.

Table 3 presents the following experimental test data for beams of the first batch:

- bending moment at which normal cracks appeared;
- transverse force at which oblique cracks were formed;
- shear force that caused the destruction of the beam;
- bending moment at which the beam failed.

Table 3. Results of testing beams of the second batch BQ-II.

Beam brand	$M_{crc,s}$ kNm	$Q_{crc,w}$ kN	M_u kNm	Q_u kN
BQII-1	13.3	73,3	48.0	120.0
BQII-2	12.0	80	58,0	145,0
BQI1-3	12,0	70	48,0	120,0

With an increase in the transverse load, normal cracks formed in the zone of pure bending, then oblique cracks appeared, after which the destruction of the support zone occurred, accompanied by separation of the concrete protective layer.

Table 4 presents the following experimental data for testing beams of the first batch:

- the greatest deformations in tension reinforcement;
- the greatest deformations in the compressed reinforcement;
- the greatest deformations in fiber-reinforced meshes;

– the greatest width of opening of normal cracks;
– the largest width of the opening of inclined cracks;
– vertical deflections in the middle of the span of the beam;
– vertical deflections under loads.

Table 4. Deformation parameters of inclined sections.

Beam brand	ε_s ‰	$\varepsilon_{s.1}$ ‰	$\varepsilon_{f,w}$ ‰	$w_{k,s}$ mm	$w_{k,w}$ mm	f_{max} mm	f_o mm
BQI1-1	1,76	–1,44	3,36	0,1	0,30	13,8	7,4
BQI1-1	2,4	–1,52	3,84	0,25	0,30	15,0	9,6
BQI1-1	1,76	–1,6	2,72	0,20	0,30	12,0	8,5

The distribution of tensile strains of fiber fibers along the length of the cut occurs along a convex curve, while the largest strains of mesh fibers reached values of 0,2-0,38%.

Prototypes of beams of the BQ-III series, 2.2 m long, had a cross section of 120 × 200 mm and were reinforced with double reinforcement: in the lower zone 2Ø18 A-III and in the upper zone - 2Ø10 A-III. The stretched area of the beams was reinforced with a sticker of MBRACE LAM CF 165/3000 100x1,4.100m laminate, and the support areas of the beams were reinforced with a sticker of vertical unidirectional meshes of the MBRACE FIB CF 230/ 4900.530g/5.100m series.

Table 3.10 presents the strength test data for BQ-III series beams:

– bending moment at which normal cracks appeared (Mcrc,s);
– bending moment at which the beam failed (Mu);
– shear force that caused the destruction of the beam (Qu).

Table 5. Forces at which normal cracks were formed and the destruction of BQIII series beams occurred.

Beam brand	$M_{crc,s}$ kNm	M_u kNm	Q_u kN
BQIII-1	5,53	38,2	95,5
BQIII-2	11,1	31,6	78,9
BQIII-3	11,1	34,3	85,8

With an increase in the transverse load, normal cracks were formed in the zone of pure bending, then the delamination of the upper corner of the grids near the zone of application of the transverse force and the separation of the protective layer of concrete began, after which the destruction of the support zone of the beam occurred, accompanied by crushing of the concrete along the inclined strip.

Table 6 presents the following deformation data based on the test results of BQIII series beams:

– the greatest deformations in tension reinforcement (εs);
– the greatest deformations in the compressed reinforcement (εs.1);
– the greatest deformations in the strips of the laminate (εf, lam);
– the largest deformations in the reinforcement grids (εf,w);
– maximum width of normal cracks (ak,s);
– vertical deflections in the middle of the span of the beam (fmax);
– vertical movements under loads (fo).

Thus, the experimental strength in terms of the transverse force of inclined sections of reinforced concrete beams, reinforced in the support zones with fiber-reinforced meshes, exceeds the design strength by an average of 16%.

3 CONCLUSIONS

1. The results of tests on the transverse force of inclined sections of bent reinforced concrete structures reinforced by gluing in the support zone by surface gluing of various types using carbon fiber plastics showed that reinforcement of beams increases strength by 1.4-2.3 times.
2. The calculated strength of inclined sections of bent reinforced concrete structures reinforced with fiber-reinforced plastics showed a fairly close agreement with the experimental data.

ABSTRACT: There are presented the results of an experimental study of the strength of compressed reinforced concrete elements with polymer-reinforced plastics FIBARM TAPE 530/300. Reinforcement of compressed reinforced concrete elements with cages made of fiber-reinforced plastics causes triaxial compression in concrete, in which the strength of the elements can increase several times. Gluing clips of unidirectional vertical grids led to an increase in the strength of the compressed elements of a circular cross-section.

Keywords: Amplification, Fiber reinforced plastic, Carbon fiber, Composite, Static loading, Deformation

1 INTRODUCTION

In the process of operation, buildings and structures change their purpose, undergo reconstruction and renovation, they increase the requirements for reliability and comfort, they are subject to physical wear and tear and damage. Under these conditions, the need to strengthen building structures is becoming increasingly important. A special place is given to the strengthening and restoration of buildings and structures in seismic areas of construction (Zhussupbekov et al., 2020, Tulebekova et al., 2022), in areas of natural disasters, and after accidents and terrorist attacks.

Most of the load-bearing structures of buildings and structures of our time are made of concrete and reinforced concrete, so the problems of developing methods for strengthening reinforced concrete structures are becoming increasingly relevant. Traditional methods (SNIP 1991) of reinforcing reinforced concrete structures are very laborious, require overburden, welded and concrete work, and require considerable time to ensure the required strength. New, modern methods of reinforcing reinforced concrete structures are focused on the use of composite fiber-reinforced plastic materials for reinforcing, which are characterized by high strength, corrosion resistance and durability.

An alternative to traditional methods of reinforcing reinforced concrete structures is the use of fiber-reinforced plastics (FRP) - polymers reinforced with fiber fibers (Bakis et al., 2002). Unlike traditional reinforcement methods using steel reinforcement, these methods have high reinforcement efficiency, and do not require overburden and welding, or concreting of reinforced elements, they are distinguished by durability, corrosion resistance, low labor intensity, and economic

DOI: 10.1201/9781003299127-376

feasibility. The following types of fibers are commonly used as FRP reinforcement: carbon (C), aramid (A), glass (G), polyester.

2 METHODOLOGY

The study of the operation of compressed elements reinforced with fiber-reinforced plastics was carried out on samples of concrete cylinders and prisms of various sizes, differing in the number of layers of reinforcement meshes.

Some of the samples were tested under the axial action of quasi-static compression on hydraulic presses IPS-200 and ALPHA 3-3000S. To do this, the samples were subjected to axial compression with a gradual increase in the magnitude of the longitudinal compressive force at a rate of 0.3 MPa/s, up to the destruction of the sample. The magnitude of the stage of load increase did not exceed 5–8% of the breaking load.

During static loading, the longitudinal and transverse deformations of the prototypes were measured using strain gauges with a base of 50 mm, glued to all side faces of the samples, and an automatic strain gauge AID-4M (Figure 1).

Figure 1. General view of the test of reinforced samples for axial compression on hydraulic presses ALPHA 3-3000S and IPS-200.

3 RESULTS

JSC Kazakh Scientific Research Institute of Civil Engineering and Architecture conducted research on the behavior of reinforced concrete elements under static effects of compression, reinforced with layers of fiber-reinforced meshes FibArm Tape 530/300 (Modern Composite Materials of the Composite Holding Company), limiting transverse deformations of concrete and thereby creating triaxial compression of concrete.

Concrete cylinders of three sizes were used as prototypes: with a diameter of 100 mm and a height of 200 mm (K10), a diameter of 150 mm and a height of 300 mm (K15) and a diameter of 200 mm and a height of 400 mm (K20), made from one batch of concrete of natural hardening class B27.5. The prototypes were pasted over with layers of carbon unidirectional meshes (FibArm Tape 530/300), which had unidirectional fibers, a width of 300 mm, a surface density of 530 g/m2, a design thickness of 2.45 mm, with an elastic modulus Ef = 245 GPA and tensile strength fu =3.6 GPa.

Static tests of concrete cylinders were carried out under axial action of quasi-static compression on hydraulic presses IPS-200 and ALPHA 3-3000S. The samples were subjected to axial compression with a gradual increase in the magnitude of the longitudinal compressive force at a rate of 0.3 MPa/s, up to the destruction of the sample.

Tables 1-3 present data on the strength under static loading of concrete cylinders with a different number of reinforcement layers with FibArm Tape polymer meshes, the strength ratio of the series, ultimate longitudinal and transverse deformations.

The destruction of samples reinforced with FibArm Tape carbon fiber meshes occurred gradually (Khayutin et al., 2002). At first, a crack appeared, caused by the rupture of individual fibers, with an increase in the load, the crack increased and a section of the mesh broke and the concrete was brittle crushed in this zone, accompanied by a sharp sound.

4 DISCUSSION

Analysis of the data shows that the strengthening of the samples by wrapping (pasting) with FibArm Tape 530/300 material led to a significant increase in the strength of the compressed samples, while the strengthening value almost linearly depended on the number of mesh layers. So, single-layer meshes caused an increase in strength by an average of 200% for samples (K10 series), by 162% for samples (K15 series), by 41% for samples (K20 series), two-layer meshes led to an increase in strength by 224% for samples (K10 series), by 275% for samples (K15 series), by 143% for samples (K20 series), and three-layer meshes - by 453% for samples (K10 series), by 422% for samples (K15 series), by 161% for samples (K20 series).

The presence of cages made of FibArm Tape meshes leads to a significant increase in the longitudinal deformations of concrete, which reach 4‰, as well as an increase in the transverse deformations of concrete, which can increase almost 10 times, reaching a value of 0.3-0.4%. In addition, there is an increase in the initial modulus of elasticity, which increased by 30%, 52% and 61% with one, two and three layers of reinforcement meshes.

In general, the effect of reinforcement with FibArm Tape meshes for 200x400 (bxh) mm samples is much less than for 100x200 mm and 150x300 (bxh) mm samples.

5 CONCLUSION

The destruction of concrete samples reinforced with carbon fibers of the FibArm Tape series occurs gradually under axial compression. First, a crack appears, caused by the rupture of individual fibers. With an increase in the load, the crack increases and then there is a brittle crushing of the concrete in the area of the mesh rupture, accompanied by a sharp sound. The more layers of reinforcement, the earlier the process of breaking the fibers of the grids begins.

Strengthening concrete samples by wrapping (pasting) FRP under axial compression led to a significant increase in the strength of the elements, while with an increase in the cross-sectional dimensions of the sample and the number of layers of reinforcement grids, the efficiency of using FRP decreases. So, for samples with dimensions of 100×200 (b×h) mm and 150×300 (b×h) mm, single-layer meshes caused an increase in strength on average by 200% and 162%, respectively, two-layer meshes led to an increase in strength by 224% and 275%. % and three-layer mesh increased strength by 443% and 422%. At the same time, for larger specimens (200×400 (b×h) mm), the corresponding increase in strength was much smaller.

The presence of meshes leads to a significant increase in the longitudinal deformations of concrete, however, with an increase in the number of layers of meshes, the intensity of strain growth decreases and, with three layers of meshes, the deformations of concrete differ little from the deformations of specimens with two layers of meshes. The ultimate compressibility of concrete is about 0.3%. The presence of meshes also causes an increase in transverse deformations of concrete. They increase from 30-40×10-5 to 300-400×10-5 relative units, i.e. in magnitude approach the limiting value of longitudinal deformations.

Increasing the cross-sectional dimensions of the compressed members reduces the effect of increasing the strength of the compressed members. An increase in the cross sections of compressed specimens from 100 × 200 (b×h) mm and 150 × 300 (b×h) mm to 200 × 400 (b×h) mm led to a decrease in relative strength by almost a factor of two.

Slope slip surface prediction using machine learning algorithms

Jeehoon Ma & Tae Sup Yun
Yonsei University, Seodaemun-gu, Seoul, Republic of Korea

ABSTRACT: In this study, the slip surface of the slope was predicted using several machine learning algorithms multilayer perceptron (MLP), XGBoost, and support vector machine (SVM). The slope used for the study is in the form of a simple finite slope, and the soil constituting the slope is sandy soil containing fine content. In performing the slope stability analysis, groundwater conditions were considered, and the influence of matric suction in unsaturated soils was also considered. The results of slope stability analysis using the limit equilibrium method were derived by applying the results of analysis on groundwater conditions using FEM. Using the Morgenstern-Price method, which can consider both force and moment equilibrium, a total of 42,000 data were produced and used for model training. In order to quantify the performance of the model in predicting the slip surface, the factor of safety of the slip surface obtained using the limit equilibrium method and the machine learning algorithm was compared.

1 INTRODUCTION

Slopes are widely distributed structures, including artificial and natural slopes. Since slope failure often occurs on a large scale, and cases of slope failure and its damage are also reported continuously, slope stability analysis has been a very important geotechnical design problem (Singh 2008; Wang 2013; Bünz 2005; Oh 2008; Song 2006). Therefore, the slope stability analysis started with the traditional method of slice, and then the strength reduction method through the finite element analysis (Dawson 1999; Matsui 1992; Kim 2004), numerical analysis considering rainfall infiltration (Cai 1998; Cai 2004; Duong 2019; Wei 2019; Cho 2019; Park & Ahn 2019), and slope stability analysis in earthquakes considering groundwater (Lu 2015) has also been developed. In the case of the conventional method using the finite element method, there is a disadvantage in that it is difficult to configure the domain conditions and mesh for analysis.

For this reason, recent attempts to apply a simple form of artificial intelligence to slope stability analysis and use it as an auxiliary means are steadily being made (Ma & Yun 2022). However, many attempts are limited to simply predicting the factor of safety of the slope, so information on the slip surface cannot be obtained, or the distribution of the groundwater level within the slope and the matric suction of the unsaturated soil are not considered by simply considering the groundwater level as the pore water pressure ratio.

Although it is known that the destruction of the slope is mainly affected by groundwater (Brönnimann 2011; Zhang 2012), the groundwater on the slope increases the shear strength through matric suction in the unsaturated soil. (Ng & Shi 1998). In fact, most of the ground in the natural state exists as unsaturated soil rather than completely dry or saturated, so the results of the stability analysis of the slope considering the mechanical characteristics of the unsaturated soil are highly applicable to the field.

Therefore, in this study, we trained to perform slope stability analysis using simple artificial intelligences multilayer perceptron (MLP), XGBoost, and support vector machine (SVM). A model for predicting the failure arc was trained, and to compare the results of the three models, a methodology to evaluate the performance of the model was presented. In order to

DOI: 10.1201/9781003299127-377

consider the matric suction of unsaturated soil due to the presence of groundwater in the modeling of the slope used for training, data were generated by analyzing both the dry slope and the slope in which the groundwater level was considered.

2 MATERIALS AND METHODS

2.1 *Finite element method*

In order to consider the groundwater condition of the slope, the seepage analysis using the commonly used finite element method was applied. In numerical analysis, the structure is actually divided into elements of finite size, and the structure is analyzed as an aggregate of these elements. In this study, the SEEP/W program of Geostudio 2012 software was used to analyze the steady-state seepage of groundwater. The soil composing the slope to be analyzed was assumed to be sandy soil containing fine particles widely distributed in the natural world by referring to the results of ground surveys in various regions of Korea (Park 2017; Jung 2014). The volumetric water content function was calculated and used in the program so that the matric suction has a maximum of 1,000 kPa and a minimum of 0.01 kPa in the range of the volumetric water content that the soil constituting the slope can have. Based on this volumetric water content function, the hydraulic conductivity function representing the relationship between the head (h) and the hydraulic conductivity ($K_r(h)$) was estimated by the van Ganuchten method (van Genuchten 1980). The form of the hydraulic conductivity function is expressed by Equation (1), where, *m, n,* and α are the van Genuchten model parameters.

$$K_r(h) = \frac{1 - (\alpha h)^{n-2}\left[1 + (\alpha h)^n\right]^{-m}}{\left[1 + (\alpha h)^n\right]^{2m}},\ (m = 1 - 1/n,\ 0 < m < 1) \tag{1}$$

2.2 *Limit equilibrium method*

To obtain the factor of safety of the slope, a slope stability analysis was performed using the limit equilibrium method. Using the SLOPE/W program of Geostudio 2012 software, the factor of safety and slip surface of the slope were obtained through the Morgenstern-Price method, which can consider both the force and moment equilibrium between the slices (Morgenstern & Price 1965). In this process, the groundwater conditions were analyzed using the analysis results of SEEP/W, considering the effect of matric suction on the effective stress of unsaturated soil. In addition, for comparison with the case where there is no groundwater, analysis was performed on the dry slope under the same conditions.

2.3 *Constitution of slope domain*

The geometry of slope used in slope stability analysis is a condition of 6 slope height (H: 10, 12, 14, 16, 18, 20 m) and 5 slope inclination conditions (β: 1:1.0, 1:1.2, 1:1.5, 1:1.8, 1:2.0) were combined. The normalized value of the groundwater level in each slope geometry to the slope height (H_w*: -1.0, 0, 0.2, 0.4, 0.6, 0.8, 1.0) were set for 7 groundwater level conditions. To set the soil conditions for the analysis section, the soil constant of sandy soil mixed with fine particles was given. In general, the porosity of sandy soil with fine particles is distributed between 0.145 and 0.495, and accordingly, the specific gravity (G_s) of the solid is considered as 2.65 and the dry unit weight (γ_d) range is set to 13.0 ~ 22.35 kN/m^3, friction angle (ϕ) and cohesion (c) were set to be uniformly distributed within the indicated range (Swiss Standard SN 670 010b, 1999) (Table 1).

2.4 *Training machine learning models*

In this paper, MLP, XGBoost, and SVM were used to predict the failure arc of the slope by using the slope geometry, soil properties, and groundwater level conditions as input

Table 1. Range and distribution of input parameters used in seepage and slope stability analysis.

	H (m)	β (-)	γ_d (kN/m^3)	c (kN/m^2)	ϕ (°)	H_w* (-)
Min	10	1	13.00	2	30	-1
Max	20	2	22.35	22	40	1
Mean	15	1.5	17.64	12.03	34.96	0.286
St. dev.	3.42	0.369	2.67	5.75	2.87	0.613

parameters. In order to predict the failure arc of the slope through regression model, it was expressed as the length of the radius of failure arc (R) and the abscissa on both sides of the point where the failure arc and the slope meet (x_{in}, x_{out}) (Figure 1).

In the case of the MLP model, it consists of one input layer with 6 nodes, four hidden layers with 800 nodes, and one output layer with 3 nodes. The training schedule of the MLP model consisted of learning rates of 0.00001 and 500,000 epochs, and the SGD optimizer was used as the optimizer. In the case of XGBoost, the learning rate was set to 0.05 and the maximum depth was set to 500. In the case of SVM, the order of the polynomial kernel function was set to 3 and the tolerance of the stopping criterion was set to 0.001.

Figure 2 Shows the training data configuration of the MLP model. A total of 42,000 data consisting of 6,000 slope domains and 7 groundwater conditions for each domain were randomly separated at a ratio of 6:1:3 for training, validation, and testing. In the training of the 3 models used in this study, a separate dataset was applied at the same rate. The validation data is to confirm that the model overfits the training data during the training process.

Figure 3 Describes the overall sequence of this study. In [Step A], seepage analysis was performed by inputting the slope height (H), slope inclination (β), groundwater level (H_w), and dry unit weight (γ_d) of the slope shape factors into SEEP/W. In [Step B], the SEEP/W analysis result obtained in [Step A] and the previously set friction angle (ϕ) and adhesive force (c) conditions were used as initial conditions, and these were entered into the SLOPE/W program. After that, slope stability analysis was performed. Failure arc parameters (Arc_{Geo}: x_{in}, x_{out}, R) calculated through slope stability analysis were obtained. In [Step C], three models (MLP, XGBoost,

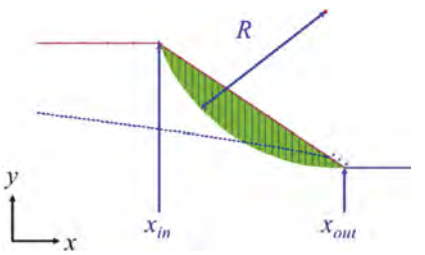

Figure 1. Expression of the slip surface with abscissa of both ends (x_{in}, x_{out}) and radius of the failure arc (R).

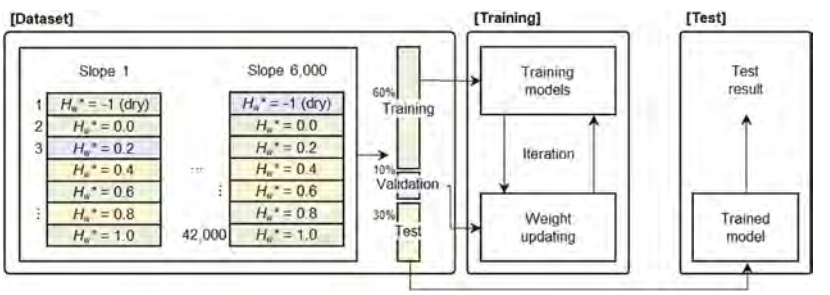

Figure 2. Data set configuration and MLP model training, validation, and test process.

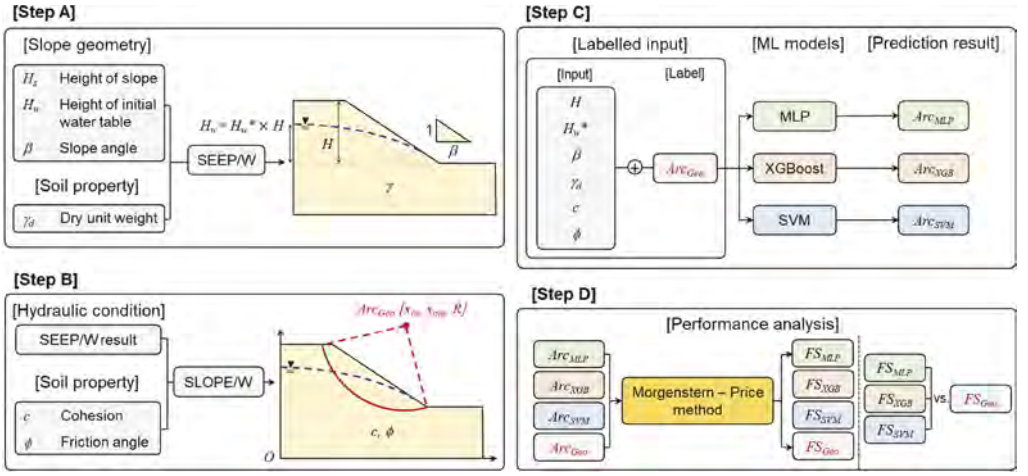

Figure 3. Overall sequence of data generation, MLP model training, and analysis.

SVM) were trained to predict the failure arc of the slope, respectively. Training is performed so that the failure arc predicted by the models for the input H, β, γ_d, c, ϕ, H_w* are approximated to the labels Arc_{Geo} (x_{in}, x_{out}, R) prepared in [Step B], respectively. Finally, in [Step D], the performances of the models were quantitatively evaluated by comparing the results of the slope stability analysis using SLOPE/W with the prediction results of the trained models. The FS_{Geo} was calculated by the Morgenstern-Price method from the failure arc Arc_{Geo} (x_{in}, x_{out}, R) obtained from the SLOPE/W analysis and FS_{MLP}, FS_{XGB}, and FS_{SVM} were calculated by failure arc Arc_{MLP}, Arc_{XGB}, and Arc_{SVM} (x_{in}, x_{out}, R) predicted by the three models, respectively. The performance of the model was evaluated by comparing FS_{MLP}, FS_{XGB}, FS_{SVM} and FS_{Geo}.

3 RESULT

To evaluate the performance of the model, the factor of safety of the failure arc predicted by the MLP, XGBoost, and SVM model was obtained using the method of slice and the values were compared. When performing the limit equilibrium analysis using the program the effective stress increase due to the matric suction in the unsaturated soil is considered, it is difficult to obtain the factor of safety by simply using the intercept method in the case of the groundwater exist. Therefore, using the Morgenstern-Price method for the analysis results of the dry slope among the test data, the factor of safety calculated by the failure arc predicted by models were compared with the factor of safety calculated by SLOPE/W in the same method.

Figure 4 Is the result of comparing the factor of safety (FS_{MLP}, FS_{XGB}, and FS_{SVM}) of the failure arc predicted by the trained model with the factor of safety (FS_{Geo}) of the failure arc calculated by SLOPE/W. Among the test data, 1,829 data on dry slopes were compared, and both safety factors were calculated from the failure arc. The coefficients of determination (R^2) were 0.999, 0.999, and 0.994 at MLP, XGBoost, SVM model respectively. Overall, the prediction performance was high, and the MLP and XGBoost models showed similar performance, but the performance of the SVM was slightly lower.

4 CONCLUSION

In this study, slope stability analysis was performed using simple machine learning algorithms such as MLP, XGBoost, and SVM. In training the model, a total of 42,000 data were generated using SEEP/W and SLOPE/W from various slope inclinations, distribution of groundwater, and soil properties. The slope used for data generation is a simple slope composed of

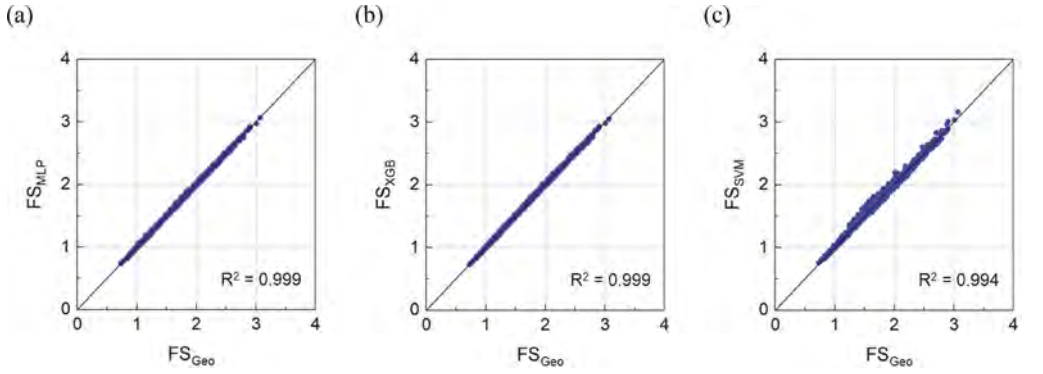

Figure 4. Failure arc prediction performance of (a) MLP, (b) XGBoost, and (c) SVM model through comparison of the factor of safety calculated from Arc_{Geo} and Arc_{MLP}, Arc_{XGB}, and Arc_{SVM}.

one layer, and the ground condition of the slope is assumed to be sandy soil containing fine particles, and the corresponding physical properties are given.

(1) In order to evaluate the performance of predicting the failure arc, the Morgenstern-Price method is used to calculate and compare the safety factor of the failure arc predicted by the machine learning model (FS_{MLP}, FS_{XGB}, and FS_{SVM}) and the safety factor of the failure arc derived from SLOPE/W (FS_{Geo}). Through this evaluation method, the performance of the model predicting the failure arc was good, and the coefficients of determination were 0.999, 0.999, and 0.994 in MLP, XGBoost, and SVM model respectively. This training method has a wider scope of application in that it can even obtain information on the failure arc than the result of training by simply targeting the factor of safety.
(2) The performance of the SVM model was the worst. It is considered that this is because multiple regression is not possible due to the characteristics of SVM regression analysis, so the predictions for x_{in}, x_{out}, and R are individually evaluated. Training took more than 2 hours for MLP model, tens of seconds for SVM, and several seconds for XGBoost. The MLP model has the advantage of having excellent performance and being able to easily change the structure of the model, but it has the disadvantage of taking a long time to train. XGBoost, which takes less time and has excellent performance, is concerned to be suitable for extending and applying to other later problems of slope stability.
(3) As a result of analyzing the results on the factor of safety and failure pattern, most of the fractures occurred were toe failure, and there were a few cases of base failure, and almost no case of slope failure. For the general application of the training model on the failure pattern, it is concerned that training based on the analysis results in a slope made of several layers of soil or in more diverse soil conditions is necessary.

In this study, slope stability analysis was trained using a machine learning algorithm. Due to the nature of machine learning, which requires a lot of learning data, a large number of data is required, and it is unreasonable to compose data with the physical properties of actual slopes through literature research and satisfy the number. Therefore, all the data used in the study are virtual slope data composed by arbitrarily inputting physical properties suitable for the conditions of the soil constituting the slope. In a follow-up study, these limitations can be compensated for by verifying the actual slope data using the test set of the machine learning algorithm.

ABSTRACT: In the arid and semi-arid zones, where about eighty of the area of Algeria is covered, the difficulties linked to the supply of water for watering these workings make it necessary to examine the solution of compaction with low water content. The proposed communication will be an experimental contribution on low water compaction of fill soils, in order to optimize the reuse of excavated soils and to minimize the amount of water needed to achieve optimum compaction. Its main objective is to better appreciate the role of water in compaction when the water content varies from the dry state to water content close to the Proctor optimum water content. In a first phase, three Algerian soils with different granular classes are investigated in laboratory to analyse the impact of soil nature and compaction energy on the soil's California Bearing Ratio value. The results show that a soil compacted at 56 blows at a water content of 2% had a higher bearing capacity than a soil compacted at the same speed under optimal water content. It concluded that compaction with low water content is possible on soils with well-graded grain size and high compaction energies. In the second phase, two section tests are performed on a local material enabled us to release that it is possible to compact materials with low water content if the aim is to obtain adequate properties for the construction embankments and subgrades. The compactness obtained varies between 86 and 93%.This experimental study on site lead to the conclusion that dry compaction does not make it possible to obtain the expected compactness for the upper layer of the earthworks and the foundation layer. Compaction to fifty percent of the optimum water content of the upper layer of the earthworks is achievable.

1 INTRODUCTION

Arid regions represent about eighty percent of the surface area of Algeria. The development of these regions, which contain oil and gas resources, requires the construction of a large number of road, rail and airport infrastructures. However, the construction of pavements in deserted areas is handicapped by the unavailability of water necessary for the compaction of materials. The scarcity of water makes compaction in these regions costly and difficult. Since the water points are very far away (about 100 to 300 km), the compaction operations (drilling wells, pumping water, spreading and mixing) require a sometimes constraining worksite organization, in particular to limit the rapid evaporation of water. Experience has shown that the cost of the water needed to compact materials can represent up to a third of the cost price of road infrastructure. Under these conditions, it is clear that the compaction of materials in their hydric state can represent a definite socio-economic potential for arid regions. Interest in the compaction of soils with low water content began with the Trans-Saharan project in the seventies. Due to socio-economic conditions the project was stopped. In recent years, as part of the implementation of the principles of sustainable development, efforts to promote local materials and the preservation of rare resources have revived the interest of researchers in redefining more efficient compaction methods that

DOI: 10.1201/9781003299127-378

allow achieve water savings. During the construction of earthworks, the compaction of soils and materials is traditionally carried out at an optimum water content defined in the laboratory by the Proctor test which should correspond to the best densification of the material. The choice of this water content, which saves compaction energy, is amply justified in temperate countries in which soils and materials are naturally in states of humidity close to optimal values. However, in sunny countries like Algeria, which suffer from severe water deficits, especially in arid areas, the soils have an almost dry water state and require considerable quantities of water to reach the optimum water content. This operation is all the more complicated as the hot and drying environment of these areas prevents the maintenance of this humidity until compaction is carried out due to evaporation during transport and the watering of the soil.

Many scientists have investigated compaction energy's impact on the engineering characteristics of both unstabilized and stabilized soils. Attom (1997) studied the effect of increasing compaction energy on shear strength, swelling pressure and permeability of compacted cohesive soils. Bahar et al. (2004) and Kenai et al. (2006) investigated the performance of three compaction methods (dynamic, static and vibro-static) on unstabilized and cement stabilized soil characteristics. Çokça et al. (2004) researched the influence of compaction with low water content on the shear strength of clay soils. Drew and White (2005) analysed the impact of compaction energy level on optimal moisture content, maximum dry and unconfined compression strength of soils. Ampadu (2007) and Vinod et al. (2015) investigated the effect of water content and compaction energy on the California Bearing Ratio (CBR) of local soils. Yusoff et al. (2017) analysed the effect of different compaction energy on geotechnical properties of Kaolin and Laterite soil. Loualbia et al. (2022) assessed the impact of the compaction water content on the mechanical behaviour of a lime-stone tuff under static loading. Sadek et al. (2022) investigated the impact of the combination (cement/energy) on soil behavior for pavement construction in arid areas. All authors agree that a higher compaction effort increases the dry density and, consequently, the stiffness and strength of the material.

The paper contributes to research efforts aimed at developing a practical method for compacting materials with low water content in arid areas. The compaction of soils with low water content and the impact of the nature of the soil and the energy of compaction on the value of the California Bearing Ratio (CBR) of the soil are analyzed in the laboratory. Three Algerian soils are studied.

2 MATERIALS AND TESTS

Three Algerian soils are studied. The first soil was extracted from the Chlef region, located in the north center of Algeria, characterized by a semi-arid climate. The second soil is from Oued-Souf and the third is from Bousaada, these two last soils are dune sand, located in the north of the Algerian desert. The two sand soils are very used in civil engineering buildings. The soils are subjected physical, standard Proctor and CBR tests following geotechnical French standards (NF P94-AFNOR). The previous materials are subsequently subjected to more intense compaction to increase their maximum density using the proctor normal/modified test. After having fixed the water content at 2% (climate arid condition), CBR tests are carried out on several samples in order to vary the energy of compaction. The compaction energies are calculated according to the height of fall, the mass and the number of blows. For this work, the increasing energies (E) correspond to 10 (E1), 25 (E2), 56 (E3) and 80 (E4) blows.

3 RESULTS AND DISCUSSION

3.1 *Soil characterisation and Proctor tests*

Figure 1 presents the grain size distribution curves of the three soils. Table 1 presents the results of the specific gravity, sieve analysis test, methylene blue test (VBS), Atterberg limits.

Figure 2 presents the conventional compaction curves obtained on the three soils for two different compaction energy level, normal (E1) and modified compaction test (E2). The maximum dry unit weight and the optimum moisture content are presented in Table 2.

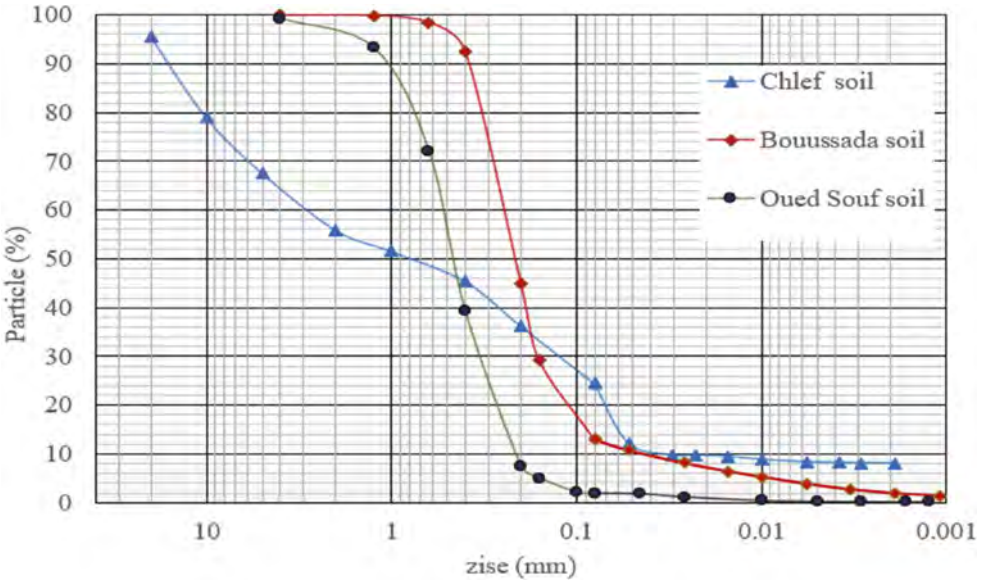

Figure 1. Particle size distribution curves.

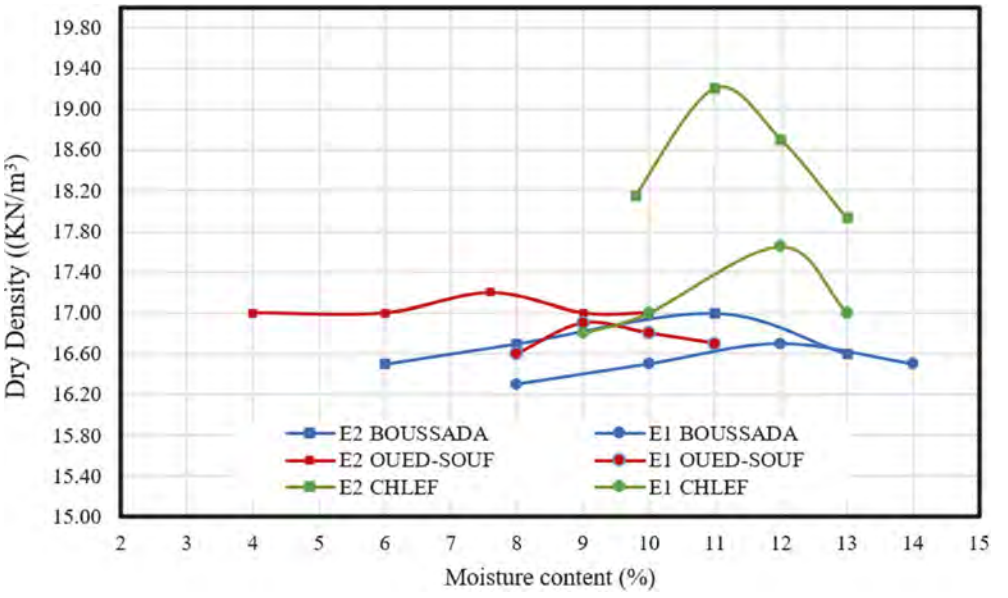

Figure 2. Normal and modified compaction test curves.

From the results of Table 1 and Figure 1, the used soils are classified as below: the Chlef soil is a well-graded silty sandy gravel soil with a spread particle size and low plasticity. By referring to the French Roadworks Guide (GTR) and LCPC classification, Chlef soil is classified silty sandy gravel (B5) and silty sand (SL) respectively. The Oued-Souf sand is poorly graded soil (94% of sand), tight particle size and it is not sensitive to water, classified (SM). The Bousaada

Table 1. Soil properties.

Parameter	Chlef Soil	Oued-Souf sand	Bousaada sand
Specific gravity	2.70	2.6	2.6
Gravel (%)	45	3	0
Sand (%)	31	94	87

Soils	Chlef	Oued-Souf	Bousaada
Normal Proctor			
MDD (kN/m^3)	17.7	17.0	16.77
w_{OPT} (%)	11.9	9	12
Modified Proctor			
MDD (kN/m^3)	19.2	17.3	17
w_{OPT} (%)	11.2	7.5	11
CBR	50	13	13

soil is poorly graded silty sand (87 % of sand) tight particle size and not sensitive to water. It is classified (SL). By referring to the French GTR, The two sands are classified (B1).

Figure 2 indicates clearly the effect of soil nature on the compaction results. The high maximum dry density (MDD) obtained for the silty sandy gravel of Chlef soil are 17.7 kN/m^3 and 19.2 kN/m^3 for normal proctor energy (E1) and modified proctor energy (E2) respectively. Their optimal moisture content are 12.2 % and 11.3% respectively. The lower dry density is obtained for Bousaada soil (γ_d=16.7 KN/m^3) for normal and modified Proctor energy. The compaction curve of Oued-Souf soil is almost flat and the change in optimal moisture content doesn't affect the MDD because this soil is not sensitive to water. The increase of level compaction energy doesn't affect the state of soil compaction because of the grains size of the soil; the soil has a uniform grain size (0.1 ≤ sand diameter (mm) ≤1). The Boussaada soil almost behaves in the same way as the Oued-Souf. Despite the presence of silt in addition to sand, increasing compaction energy had no effect on maximum dry density. Contrary to the Boussaada and Oued-Souf soils the compaction curve of Chlef soil is well graded, and the effect of the compaction energy is well observed. This soil is silty sandy gravel with a presence of 8% of clay. Its composition gives the tested soil the lowest water sensitivity (low plastic) and also the ability to improve compactness when the compaction energy is increased. According to the CBR values obtained from the tested soil compacted with modified Proctor standard (Table 2), Chlef soil has a good bearing (CBR= 50). The other two sand soils have the same value of CBR around 13; this value is more than 10 indicating a good bearing.

3.2 *Compaction at low moisture content*

Since the compaction energy has no effect on the soils of Oued-souf and Boussaada, the study of the evolution of the maximum dry density as a function of the increase in the compaction energy level will be carried out only on the Chlef soil. The results of modified Proctor tests performed at different level of energy compaction and at the low moisture content (w=2%) are shown in Figure 3. The MDD increases with the increasing of number of blows; for ten (10) 84 blows the MDD is equal to 16.1 KN/m^3 and 18.6 kN/m^3 respectively. In the dry part of the compaction curve, the moisture contents are very low to saturate the soil. Therefore, the

reduction in void ratio volume can always be achieved by increasing the compaction energy. Figure 3 shows that the increase in maximum dry density as a function of compaction energy is non-linear and tends towards a limit value beyond 55 blows. Figures 4 and 5 show the results of CBR tests carried out on samples compacted at a water content of 2% with different compaction energies. The CBR value increases with the compaction energy and confirm the behavior observed with the modified Proctor tests. These results were observed by many researchers (Attom, 1997; Vinod et al., 2015; Masoud et al., 2015; Yusoff et al., 2017; Basack et al., 2021). They reported an increase in maximum density and a decrease in optimal moisture content when the compaction energy increased. It was also found that the higher CBR values were recorded with increase in compaction energy.

Soils compacted with 56 and 84 blows require high penetration energy to reach a depth of 2.5 mm, the compaction energy required to reach this depth is 497 and 746 kN.m/m^3 respectively (Table 3). For samples compacted with lower values, 10 to 25, the same penetration (2.5 mm) does not require great energy, it is 89 and 182 kN.m/m3 respectively. This result is consistent with that found by Ampadu (2007).

Soils compacted with low water content (2%) have a very high bearing capacity and a low density (MDD=18.6 kN/m^3) compared to that obtained at the optimum water content (MDD=19.2 kN/m^3). The CBR value obtained at optimal water content (w_{opt}= 11.2%) is 50 and that obtained for water content of 2 % under the same number of blows (56 blows) is about 91 (Figure 5). In the dry part of the compaction curve, the soil does not resist by its compactness but probably by the mobilization of friction forces between the grains which are not sufficiently lubricated, which justifies the increase in the CBR values.

Table 3. Energy of compaction value.

3.3 *Application*

As part of the construction of a road in the Algerian Sahara, a local material is subjected to laboratory tests and experiments on site. Two sections 250 m long, 10 m wide and 0.20 m thick, compacted dry or with low water content are carried out. The compaction of the first board is mixed, and the second is compacted with a vibrating compactor. The results of laboratory tests carried out on the material extracted from a site located approximately 0.50 km from the test sections are given in Table 4. The first section is compacted with a water content of 50% of the optimum Proctor (OPM), or 3%. The layer are leveled and moistened by a water tank after scarification of the surface of the platform, and compacted with 13 tons vibrating roller, and the finish is carried out with 27 tons heavy roller-tyred roller. The number of passes at any point is 6 passes for the vibrating compactor and 8 passes for the pneumatic compactor. the compactness ($\gamma_{d(lab)}/\gamma_{d(site)}$) reached at different points for maximum compaction energy of more than 2 t.m3/km varies between 93 and 97%. The dry compaction is assigned exclusively to the with 13 tons vibrating roller. The compactness measurements are performed every 3 passes on each measured point. the compactness obtained varies between 86 and 93%. The analysis of all the results obtained lead to the conclusion that dry compaction does not make it possible to obtain the expected compactness for the upper layer of the earthworks and the foundation

layer. Compaction to 50% of the optimal water content is achievable for the upper layer of earthworks and is possible for the foundation layer provided that the water content is well homogenized by effective mixing of the material and that compactnesses are accepted in the vicinity by 96% for the foundation layer which represents sufficient resistance (bearing capacity). These results are in agreement with the results of the researches carried out by Cisse (1982) and Ellis (1980). The two studies deals with the dry compaction of embankments and roadbases and subbases. Cisse (1982) conducted trials in Niger, two materials underwent laboratory testing and field experiments: a dune sand and ungraded gravel desert material. Ellis (1980) carried out trials in Sudan on black silty clay for use on a road embankment and subgrade. Tests in Morocco (Kabbaj 1979) using natural well graded gravels as fill material were reported to be successful but problems were experienced with dry sands.

Table 4. Soil properties.

Properties	Values	Compactness (%)
% passing 2 mm	32	-
% passing 0,08 mm	10	-
Plasticity Index PI	6,3	-
Maximum Dry Densiy (kN/m^3)	22,3	-

Immediate CBR (55 blows)	108	100
Immediate CBR (25 blows)	66	96
Immediate CBR (10 blows)	31	92
Compression strength (MPa)	2,02	-

4 CONCLUSION

An experimental study was carried out in the laboratory on three types of soil with different granular classes to evaluate the feasibility of compaction at low water content and to identify the factors that influence compaction. It concluded that compaction with low water content is possible on soils with well-graded grain size and high compaction energies. Increasing the compaction energy offers the possibility of reducing the volume of voids and it will have no effect once saturation is reached. Soils with approximately uniform grain size are more difficult to compact. The results showed us that a soil compacted at 56 blows at a water content of 2% had a higher bearing capacity than a soil compacted at the same speed under optimal water content. The section tests carried out on a local material enabled us to release that it is possible to compact materials with low water content if the aim is to obtain adequate properties for the construction embankments. For the foundations, it is necessary to moisten the surface and couple two compactors, a vibrating roller and a heavy roller-tyred roller. The experimental study on site lead to the conclusion that dry compaction does not make it possible to obtain the expected compactness for the upper layer of the earthworks and the foundation layer. Compaction to 50% of the optimum water content of the upper layer of the earthworks is achievable. It is also possible for the foundation layer provided that the water content is well homogenized by effective mixing of the material, and that compactnesses around 96% are accepted. With these conditions, the foundation layer has sufficient bearing capacity. We propose to extend this research to other materials and other types of equipment.

Strength-ductility behavior of earthen block reinforced with vetiver shoot

M.S. Islam, S. Paul & S.M. Iqbal
Department of Civil Engineering, Bangladesh University of Engineering and Technology (BUET), Dhaka, Bangladesh

ABSTRACT: Buildings made of earthen blocks have gained popularity in recent years from the viewpoint of sustainability. But due to their brittleness and low tensile strength, earthen buildings are very prone to earthquakes. Recent studies have focused on improving the strength-ductility behavior of earthen blocks by incorporating natural and synthetic fibers. Vetiver grass is utilized to safeguard embankment slopes and riverbanks worldwide. But its effectiveness in reinforcing earthen blocks is missing in the literature. Work herein focuses on evaluating the strength and ductility characteristics of vetiver shoot reinforced earthen blocks through unconfined compression tests. Vetiver shoots in 1%, 2%, and 3% proportions are mixed with clay soil for the preparation of earthen blocks. Improvements of up to 38% in compressive strength and 202% in ductility index are obtained in reinforced samples compared to unreinforced samples. Microstructural investigation shows that clay particles sticking to the fiber surface contributed to such improvements.

1 INTRODUCTION

Many civilizations have employed earthen building materials for ages. About 30% of the world's population still resides in earthen houses, with that number rising to 50% in developing nations (Minke, 2013). But due to stability problems brought on by insufficient strength, ductility, and susceptibility to earthquakes, new building materials like concrete, steel, fired clay bricks, etc. have emerged (Islam & Iwashita, 2006; Paul et al., 2022). These new building materials are not considered sustainable, particularly for developing nations, due to their high cost and energy-intensive production processes (Sujatha & Selsia Devi, 2018). Stabilization of earthen structures can ensure sustainable earthen construction by improving the strength and ductility properties of raw earth. In earlier research, different natural and synthetic fibers were used to reinforce earthen blocks to increase their strength and ductility. Fibers like sugarcane bagasse, banana, jute, coconut, steel, plastic, polypropylene, etc. have been widely used in previous studies for reinforcing earthen blocks (Danso et al., 2015; Eko et al., 2012; Islam & Iwashita, 2010; Jiang et al., 2010; Kumar & Barbato, 2022; Prasad et al., 2012; Sujatha & Selsia Devi, 2018). Here, fibers can make the soil more resilient and ductile by preventing the cracks at the shear band from spreading and enlarging. Vetiver grass (*Chrysopogon zizanioides*) has a lengthy and bushy root system (Badhon, 2021). Its shoots have a height range of 0.5 to 1.5 meters and are heavily branched on stems that cluster together in big clumps. The usefulness of vetiver roots in increasing soil shear strength and lowering slope erosion potential has been widely studied in recent research (Aziz & Islam, 2022; Badhon, 2021). However, the effectiveness of vetiver shoots as earth reinforcement has not been studied previously. The current study focuses on investigating the suitability of vetiver shoots in enhancing the strength-ductility characteristics of earthen blocks. Unconfined compressive strength tests were conducted on un-reinforced and vetiver shoot-reinforced specimens to discern the strength and

DOI: 10.1201/9781003299127-379

ductility properties of earthen blocks. Moreover, microstructural analysis has been conducted to analyze the effectiveness of vetiver shoots in controlling the development and propagation of cracks and to understand the reinforcement mechanism.

2 MATERIALS: SOIL AND VETIVER SHOOT

The soil sample for the present study was collected from Gazipur, Dhaka. The grain size distribution of the soil was obtained by conducting a hydrometer analysis (as the soil particles were smaller than 0.075 mm) as per ASTM D 7928. For further characterization of soil, specific gravity tests, Atterberg limit tests, and standard proctor compaction tests were conducted as per ASTM D 4318, ASTM D 698, and ASTM D 854 respectively. The physical properties of soil are shown in Table 1. The soil is classified as lean clay (CL) according to the Unified Soil Classification System. Dry vetiver shoots were cut at 50 mm lengths, and the width of the shoots varied from 4-5 mm.

Table 1. Physical characteristics of the soil considered in this study.

Soil Property	Value
Specific gravity, G_S	2.72
Silt (%)	72
Clay (%)	28
Liquid Limit, LL (%)	30
Plastic Limit, PL (%)	18
Plasticity Index, PI (%)	12
Optimum moisture content (%)	11.3
Maximum dry density (kNm^{-3})	17.2
Soil classification (USCS)	CL

3 METHODS

3.1 *Production of earthen blocks*

Earthen blocks were manufactured by using the selected vetiver shoot content of 0%, 1%, 2%, and 3% by weight of dry soil. The size of the earthen blocks molded for this research is 241 mm × 114 mm × 70 mm. Firstly, the soil sample and fibers were mixed homogenously under dry conditions. Then the proper amount of water which is the optimum moisture content determined from the standard proctor test previously was added to the soil-fiber mixture. The mixture was kneaded again under wet conditions to prepare a homogenous mix. The mixture was then poured into the mold and compacted in three layers using the standard proctor hammer. Here, the compaction energy was kept equal to the standard proctor compaction energy (593.7 kJ/m^3). After preparing samples, the mold was kept undisturbed for 24 hours, and thereafter, the sample was taken out of the mold. The samples were dried in the shade for 7, 14 and 28 days.

3.2 *Experimental investigation*

Unconfined compression tests were performed on the prepared reinforced and unreinforced samples to assess the compressive strength and ductility behavior of earthen blocks as per ASTM D 5102.The samples were tested after 7, 14, and 28 days of drying. The loading device was set so that the upper platen just touched the prepared specimen after it had been centered on the bottom platen and loaded into it. Axial force and deformation readings were taken. The loading was continued up to the failure point. An axial deformation rate of 1%

per minute was maintained. For conducting scanning electron microscopy (SEM) tests on vetiver shoot-reinforced earthen blocks, some small portions measuring 2 cubic inches were cut from each sample using a sharp wire, which were mounted on a stud and placed in the chamber of a machine with SEM capabilities.

4 RESULTS AND DISCUSSIONS

Figure 1 Shows the axial stress-strain behavior of unreinforced clay and clay reinforced with various contents of vetiver shoots (0%, 1%, 2%, and 3% by weight of dry soil), over periods of 7 days, 14 days, and 28 days. The results reveal that there is a significant improvement in ductility (up to 202%) of earthen blocks when vetiver shoots are incorporated. Thus, vetiver shoot reinforcement improves the post-peak behavior by distributing the loads across the cracks. Moreover, the presence of shoots in the soil matrix prevents the propagation and widening of cracks. The SEM micrograph of vetiver shoot stabilized earthen blocks is depicted in Figure 2(a), which reveals that soil particles are strongly adhered to the surface of the vetiver shoot. This makes the soil matrix more homogenous and interconnected, which leads to better strength-ductility behavior of vetiver shoot reinforced earthen blocks. On the other hand, Figure 2(b) reveals the heterogeneity of the unreinforced specimen having a higher number of voids and fissures.

Table 2. Summary of unconfined compressive strength (UCS) test results.

Sample ID	Shoot Content (%)	Density (kNm^{-3})	UCS (MPa)	% Increase in UCS	Failure Strain (%)	Elastic Strain (%)	Ductility Index (D)	% Increase in Ductility

V2D28	2	14.4	1.337	7.9	11.43	2.699	4.234	57.2
V3D28	3	12.6	0.965	-22.1	21.59	2.655	8.133	201.9

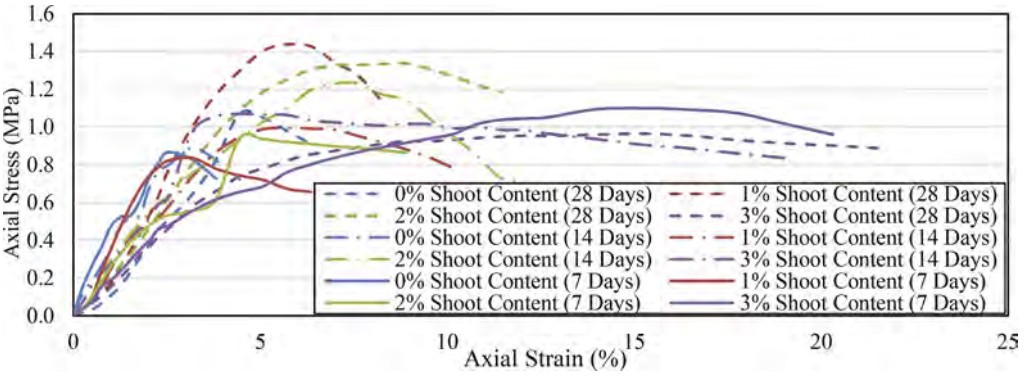

Figure 1. Axial stress-strain behavior of unreinforced and fiber reinforced earthen blocks.

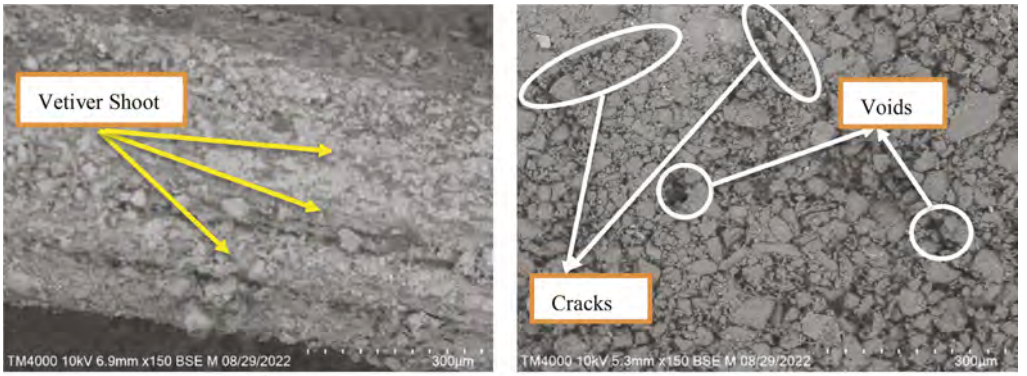

Figure 2. SEM micrographs of (a) fiber reinforced and (b) unreinforced earthen blocks.

Table 2 lists the unconfined compressive strength (q_u) and ductility index (D) of unreinforced and reinforced soil blocks. The specimens are designated as VxDy, where x denotes the vetiver shoot contents and y denotes the sample age in days. Here, the ratio of total elastoplastic response strain (failure strain) to strain at the elastic limit (strain at $q_u/2$) is known as the ductility index (Islam & Iwashita, 2010). The unconfined compressive strength of reinforced earthen blocks is increased with respect to the unreinforced ones, except for the V1D7 and V3D28 specimens. The increase in unconfined compressive strength is due to the creation of an isotropic matrix between the soil and the vetiver shoot, which prevents the movement of the soil particles. Considering both strength and ductility perspectives, a vetiver shoot content of 2% is recommended.

5 CONCLUSIONS

Unfired earthen blocks have significant economic and environmental advantages over fired clay bricks. Therefore, it is necessary to improve the mechanical properties of earthen blocks to overcome the limitations of raw earth. Based on the findings of this study, vetiver shoot reinforcement can effectively improve the strength-ductility behavior of earthen blocks. At 2% vetiver shoot content, significant increase in ductility was found with no reduction in compressive strength. Therefore, the optimum shoot content is recommended to be 2%.

Deformation analysis of the reclaimed submarine foundations with dredged materials in Osaka Bay by utilizing the geoinformatic database

M. Mimura, Y. Iseki & M. Imiya
Kyoto University, Kyoto, Japan

ABSTRACT: A series of elasto-viscoplastic finite element analyses is conducted to assess the long-term deformation of this reclaimed island with dredged materials at Yumeshima reclaimed island in Osaka Bay, Japan. The geoinformatic database has been utilized to develop the initial subsurface ground model together with the setting the geotechnical parameters for the individual Holocene and Pleistocene soils. The generation and dissipation process of excess pore water pressure as well as the related compression performance of the natural and reclaimed dredged materials are discussed. The calculated performance shows the remarkable long-term settlement even after the completion of reclamation, which can affect the superstructures on the reclaimed island.

1 INTRODUCTION

Osaka Bay is a heart of Kansai economy along which the urban business cities such as Osaka and Kobe are located. Urbanization has been progressed in Japan associated with the development of coastal area as well as offshore-reclaimed lands. Yumeshima Island is one of the largest reclaimed islands in Osaka Port. The world exposition will be held in 2025 followed by the development of the integrated resort facilities on this reclaimed island. A large and long-term settlement is generally expected to occur in such offshore reclaimed island on the marine soft ground. Because the Yumeshima Island is reclaimed with dredged clayey materials from the seabed, the superstructures constructed on this island will suffer from soft soil induced serious geotechnical problems such as a large and long-term settlement. Compared to general offshore islands, which are reclaimed with low-compressibility high-quality soils, Yumeshima has the serious problem that tremendous compression is expected to occur in the reclaimed soil itself.

In the present paper, a series of elasto-viscoplastic finite element analyses is conducted to assess the long-term deformation of this reclaimed island with dredged materials at Yumeshima reclaimed island in Osaka Bay, Japan. The Kansai Geoinformatics Database has been utilized to develop the subsoil ground model as well as setting the necessary material parameters that are required by the elasto-viscoplastic constitutive model. The construction sequence is modeled based on the Yumeshima construction reports. Stress and deformation of the reclaimed dredged layers together with the natural foundation ground in Osaka Bay is discussed on the basis of the calculated performance. Attention is focused on the long-term settlement of the deep Pleistocene clay layers that affects the stability of the superstructures constructed on the Yumeshima Reclaimed Island.

2 SUBSURFACE MODELING BASED ON THE GEOINFORMATIC DATABASE

Geometrical modeling of the foundation ground is indispensable to conduct the deformation analyses due to reclamation. Soil boring logs are the essential information of the subsoil structures. Usually, prior to construction work, a boring survey is carried out in the target area, and the profile of the soil classification from the ground surface to the required depth is shown in

DOI: 10.1201/9781003299127-380

the form of a soil boring log describing what kind of soil is deposited with depth. It is true the individual soil boring log has the advantage of showing the correct information of the subsurface structure of the site, but that they have the problem that the individual boring information does not give the spread of strata. Then it is effective to utilize a database that integrates soil boring information to know what kind of sedimentary structure the target area has, and the information such as lateral continuity and change in thickness of the individual layers. In the present paper, the Kansai Geoinformatics Database of Kansai Geoinformatics Network (KG-NET) is applied to construct the subsoil model of Yumeshima Reclaimed Island.

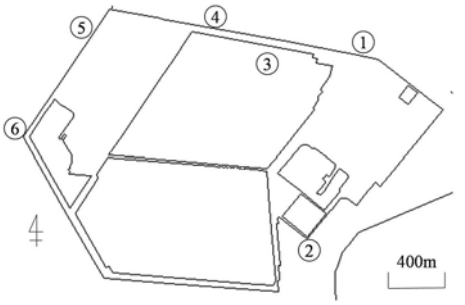

Figure 1. Location of the boreholes before construction at Yumeshima Reclaimed Island.

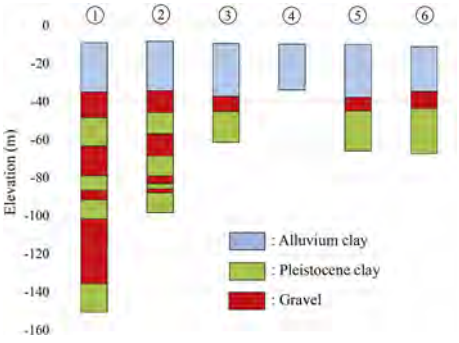

Figure 2. Stratigraphy of the 6 boreholes.

About 130 boring data for Yumeshima have been registered in the Kansai Geoinformatics database. Attention should however be paid to the fact that boring data before reclamation is necessary to develop the initial ground model without the effect of compression of clay layers due to reclamation. Screening under these conditions limits the number of borings that can be used to six as shown in Figure 1. The almost all borings were located near the border of Yumeshima Reclaimed Island because the soil investigation from the sea was conducted for the design of seawall of the reclaimed island. The selected 6 soil boring logs are shown in Figure 2. As shown in Figure 2, the survey depths of the six boreholes are different, but the overall stratigraphy is the same. The Holocene clay layer is underlain by the alternating Pleistocene gravel and clay layers. The representative soil profile model was developed based on those six boring data and the lower Pleistocene deposits were modeled by introducing the existing information from the adjacent reclamation islands in Osaka Bay. Then, Figure 3 shows the setup initial foundation ground model

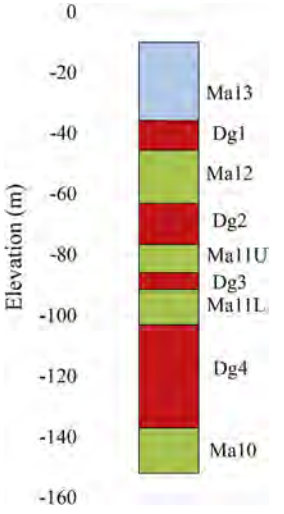

Figure 3. Representative sub soil ground model for the Yumeshima Reclaimed Island.

that is regarded as the representative one for Yumeshima Reclaimed Island. Based on the soil classification and clay content of the individual boring data, the boundary between the clay layer and the gravel layer is determined. As for the thickness of each layer, the average value of them was adopted. For example, the thickness of the Holocene clay, Ma13 was determined by averaging the data from six borehole data. The thickness of the gravel layer, Dg2 was determined with boring 1 and 2 that contain Dg2 in them. The deep Pleistocene layers were determined based on the information of boring 1. As shown in Figure 3, the elevation of the seabed is -10m and the bottom of the representative model is the Pleistocene clay called Ma10 because of the limitation of the deep deposits information.

3 ELAST-VISCOPLASTIC FINITE ELEMENT ANALYSIS

3.1 *Constitutive model and formulation*

The elasto-viscoplastic constitutive model used in this paper was proposed by Sekiguchi (1977). Sekiguchi (1982) et al. modified the model to a plane-strain version. The viscoplastic flow rule for the model is generally expressed as follows:

$$\dot{\varepsilon}_{ij}^{p} = \Lambda \frac{\partial F}{\partial \sigma'_{ij}} \tag{1}$$

in which F is the viscoplastic potential and Λ is the proportional constant. Viscoplastic potential F is defined as follows:

$$F = \alpha \cdot \ln\left[1 + \frac{\dot{v}_0 \cdot t}{\alpha} \exp\left(\frac{f}{\alpha}\right)\right] = v^{p} \tag{2}$$

in which α is a secondary compression index, $\dot{v}_0$ is the reference volumetric strain rate, f is the function in terms of the effective stress and v^{p} is the viscoplastic volumetric strain. The concrete form of the model is shown in the reference (Mimura and Sekiguchi, 1986). The resulting constitutive relations are implemented into the finite element analysis procedure through the following incremental form:

$$\{\Delta\sigma'\} = [C_{\mathrm{ep}}]\{\Delta\varepsilon\} - \{\Delta\sigma^{\mathrm{R}}\} \tag{3}$$

Where $\{\Delta\sigma'\}$ and $\{\Delta\varepsilon\}$ are the associated sets of the effective stress increments and the strain increments respectively, and $[C_{\mathrm{ep}}]$ stands for the elasto-viscoplastic coefficient matrix. The term $\{\sigma^{\mathrm{R}}\}$ represents a set of 'relaxation stress', which increases with time when the strain is held constant. The pore water flow is assumed to obey isotropic Darcy's law. In relation to this, it is further assumed that the coefficient of permeability, k, depends on the void ratio, e, in the following form:

$$k = k_0 \cdot \exp\left(\frac{e - e_0}{\lambda_k}\right) \tag{4}$$

in which k_0 is the initial value of k at e=e_0 and λ_{k} is a material constant governing the rate of change in permeability subjected to a change in the void ratio. Note that each quadrilateral element consists of four constant strain triangles and the nodal displacement increments and the element pore water pressure is taken as the primary unknowns of the problem. The finite element equations governing those unknowns are established on the basis of Biot's formulation (Christian, 1968, Akai and Tamura, 1976) and are solved numerically by using the semi-band method of Gaussian elimination.

3.2 *Determination of material parameters*

The soil parameters required for the input to the finite element code are determined rationally based on the prescribed procedure (Mimura et al., 1990). The necessary parameters for clays

are "compression index; λ", "swelling index; κ", "critical stress ratio; M", "initial void ratio; e_0", "elastic shear modulus; G", "secondary compression index: α" and "reference volumetric strain rate; $\dot{v}_0$". A due attention should be paid to the fact that the Pleistocene clays in Osaka Bay exhibit lightly overconsolidated performance although they are normally consolidated without any mechanical overconsolidated history (Mimura et al., 2003). In the present paper, the concept of quasi-overcosolidated clay reported by Mimura and Jang (2004) is applied to the Pleistocene clays in Osaka Bay. The compression less than p_c is assumed to be elasto-viscoplastic with the compression index, λ_{QOC} that is equivalent to κ. Time dependent behavior is also assumed to occur in the compression less than p_c with the secondary compression index α_{QOC}. See reference (Mimura and Jan, 2004) for more detail of the modeling concept of the quasi-overconsolidated Pleistocene clays in Osaka Bay. The material parameters are shown in Table 1.

Table 1. Material parameters for Holocene and Pleistocene clays.

	C_c	C_s	M	e_0	α	$\dot{v}0$ (/day)	k_0 (m/day)

3.3 *Loading sequence*

Unplanned damping was carried out from the sea before the start of development from the sea, followed by the official construction of the Yumeshima Reclaimed Island that was started in 1985 with the construction of seawalls. The official construction was conducted by dumping the channel dredged soils from the Osaka Port (Osaka Port Authority, 2016, 2017). Then, filling was carried out with good quality gravelly soils for the surface ground of the Yumeshima Reclaimed Island. Based on the unit weight of the corresponding materials, the stress increment Δp in terms of the reclamation loading is modeled with the elapsed time as shown in Figure 4.

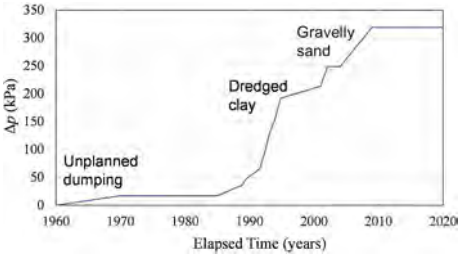

Figure 4. Loading stress history reflecting the reclamation work of Yumeshima.

4 RESUTS AND DISCUSSIONS

4.1 *Excess pore-water pressure generation and dissipation*

Reclamation stress loaded on the seabed causes the generation of excess pore water pressure particularly in the clay layers together with the dredged soil layer. The profile of excess pore water pressure with depth is shown in Figure 5. Here, Vertical drains are installed in the dredged soil layer and the alluvial clay layer sandwiching the sand mat. The macro-element method (Sekiguchi et al., 1986) is introduced to model the radial collection and drainage function in 1-D analysis. At the completion of reclamation in 2008, large amount of excess pore water pressure generated and remained in all dredged and natural clay layers. Because of the vertical drain effect, excess pore water pressure in the dredged soil and Ma13 layers, excess pore water pressure partly dissipated even during the loading period. At present in 2022, consolidation of these layers almost terminated whereas the excess pore water pressure still remains in the Pleistocene clay layers. It means that the long-term consolidation induced settlement will occur mainly in the Pleistocene clay layers in future. Almost all clay layers except Ma10, excess pore water pressure will dissipate in 2070. The relatively large amount of excess pore water pressure remains in Ma10 because Ma10 has a large thickness and high plasticity with low permeability. Vertical drains cannot be adopted for such deeply situated clay deposit. As is already pointed out, long-term settlement will occur not in the shallow Holocene and dredged soil layer but deep Pleistocene clay layers.

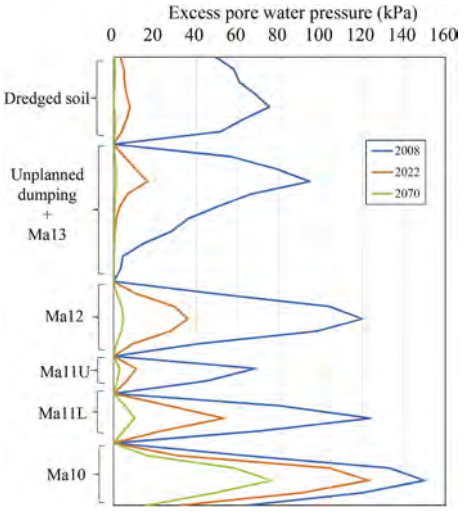

Figure 5. Calculated profile of excess pore water pressure with depth.

4.2 *Settlement*

Calculated compression with time for the individual clay layers is shown in Figure 6. The main reclamation was started in 1985. Drastic compression of the alluvial clay layer is attributed to the loading by the sand mat and drainage promotion effect of the vertical drain driven at the time. Compression of the reclaimed dredged soil is also tremendous because of its high water content and compressibility. Rapid progress in compression from 1989 to 2002 is attributed to the accumulation of dumped dredged soils with vertical drains. As for the Pleistocene clay layers, the progress in compression is milder compared to Ma13 and dredged soil layer and a larger settlement is found to occur in the upper Pleistocene clay layers. In 2022, the settlement of Ma13 and dredged soil layer is 6.5m and 5m respectively whereas .the one of Ma12 is about 1.85m. Long-term settlement is found to take place in all Pleistocene clay layers with time.

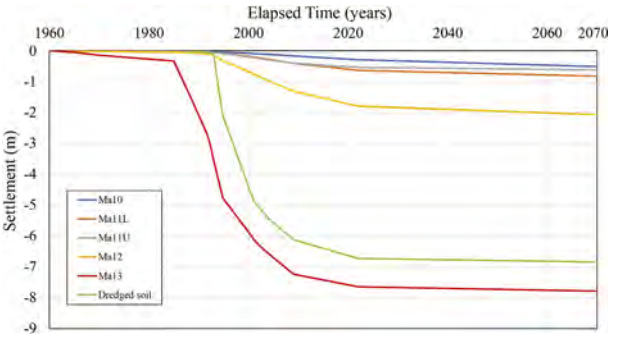

Figure 6. Time~settlement relations for the individual clay layers.

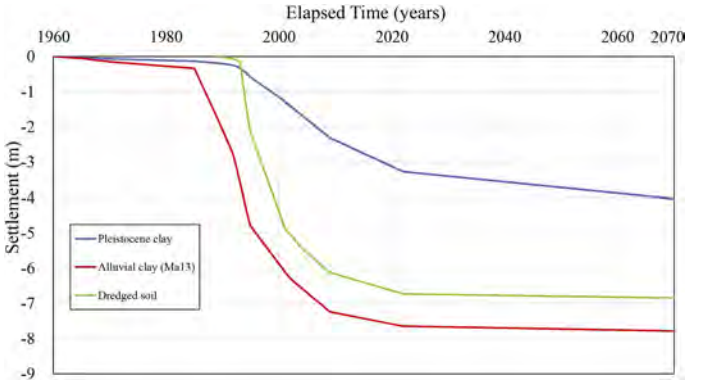

Figure 7. Contribution to the settlement for the dredged soil, alluvial and Pleistocene clay layers.

Contribution to the total settlement for the dredged soil, the alluvial clay (Ma13) and the Pleistocene clay layers is shown in Figure 7. Although the amount of settlement is occupied by the compression of alluvial clay and dredged soil, the long-term settlement such as the one after 2022 is found to occur mainly in the Pleistocene clays. This behavior is very consistent with the dissipation result of excess pore water pressure shown in Figure 5. The long-term compression of both Ma13 and dredged soil is regarded as a secondary consolidation without dissipation of excess pore water pressure and the amount of settlement of these layers remains limited. In contrast, the settlement of the Pleistocene clay layers is about 1m for the coming 50 years. A due consideration is necessary to the harmful effect on the stability of the pile foundations that will install to the bearing stratum in the Pleistocene deposits.

5 CONCLUSIONS

A series of one-dimensional elasto-viscoplastic finite element analyses was conducted to assess the stress and deformation of the reclaimed marine foundations at the Yumeshima Reclaimed Island in Osaka Bay, Japan. The sophisticated geoinformatic database was utilized to setup the subsoil geometrical model together with the determination of the required material parameters. The calculated performance showed that the steady excess pore water pressure dissipation due to the effect of the vertical drains both in the alluvial and dredged soil layers while the excess pore water pressure remains.in the Pleistocene clay layers for a long time and it may cause the long-term settlement of the reclaimed foundations. It is also found that the rapid and large settlement took place in the alluvial and dredged soil layers in the short period due to the effect of vertical drains. On the other hand, serious long-term settlement will occur in

the Pleistocene clay layers. After completion of reclamation, the high rise buildings and facilities for meeting, incentive travel, convention and exhibition/event (MICE) are planned to be constructed on the subsiding foundations. We have to pay attention to the effect of the long-term settlement on the stability of pile foundations driven into the Pleistocene bearing stratum to support those superstructures.

Architectural and historical value - The heritage of the people

K.K. Arynov, E.K. Duisebay, S.Sh. Sadykova, L.A. Zhakhsylykova & E.N. Khvan
Department of Architecture of the Faculty of Architecture and Construction, L.N.Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The article adresses the results of staged restoration of architectural and historical monuments of educational building of Kazakh Humanitarian Law Innovative University located at Abay street 94, in Semey city and the current state of other valuable historical monuments with spiritual values and historical significance to future generations of the country.

Keywords: monuments of architectural and historical value, restoration, major repairs, facade, building built in the style of Russian classicism

1 INTRODUCTION

The main focus of the article is devoted to the academic building of the university, which has architectural and historical significance and is distinguished by its cultural and spiritual values, located at Abay Street 94, in Semey city.

This building is notable for its uniqueness and historical value not only in the city of Semey, but also at the national level. (Figure 1).

Figure 1. The building of the Kazakh Humanitarian Law Innovative University, before restoration.

The building was built in 1872 and is a national historical and architectural monument. From 1894 to 1919the building was the educational building of the Pedagogical Institute of the Kazakh SSR (former male gymnasium), from 1919 to 1934 the Siberian district headquarters of the 11th White Guard Regiment. Since 1934 the facility served various educational institutions, and now the building is the educational building of the Kazakh Humanitarian Law Innovative

DOI: 10.1201/9781003299127-381

University. As it can be seen, over the existence of the mentioned building hid many mysterious twists and turns of fate [1,3,5].

The general plan of the building is a 2-storey U-shaped house, made in the style of Russian classics, decorated in a component of white and white-pink colors. The length of the main facade, located on the side of Abay Street, is 40,000 mm (40 m) (Fig. External surface of the building is plastered with a traditional lime-sand mortar. Technically, the building consists of three floors - the 1st and 2nd floors and basement. Height of 1st and 2nd floors from floor to ceiling is 3,90 m, basement's - 2,85 m. (its upper side above the ground level of 1.25 m, the lower side of 1.60 m from ground level).

The load-bearing structure of the building, i.e., the bearing walls are built of burnt red brick, wall thickness is 950 mm (3 bricks), the thickness of the walls in the basement is 1150 mm.

2 MATERIALS AND METHODS

The research method is based on a systematic analysis of research objects, compositional analysis of graphic measurements and scientific generalizations.

The work is based on the description of the material collected by the authors as a result of studying materials on architectural objects and an analytical review of scientific literature.

3 RESULTS AND DISCUSSION

The building has been in continuous use since its construction to the present day, that is, almost a century and a half of use. Up until yesterday no comprehensive research capital repair and restoration work was carried out.

Restoration is not an easy task that can be done in a short time, so research work and restoration work go hand in hand here. Because in reconstruction, namely in the modernization of historic buildings, other additional types of work of varying degrees of complexity is involved. Much of the work is done by hand, with great patience and precision, and requires not only professional skill, but also deep knowledge of history and architecture [1,3]. (Figure 2).

Figure 2. The building of the Kazakh Humanitarian Law Innovative University, after restoration.

As of today, with the support of the university administration, the overhaul and renovation work on the building has been successfully completed on schedule. Before proceeding to such a very important work, we had to step by step and systematically solve many problems. Especially these few concerns had to be addressed:

– conducting an overall integrated historical and architectural study of the building;
– review and analysis of extant archives and other historical sources;
– determining the suitability of the building's foundation, the basement fence and the load-bearing walls (resulting in a positive conclusion);
– the phased implementation of a series of rehabilitation measures to prevent further deterioration and deterioration of the building's roofing and covering structures such as beams, rafters and batten (due to the potential excessive drying out of wooden beams and rotting of rafters from moisture);
– testing the quality of the brick, which is the main building material, to determine the degree of deformation due to various external natural influences (resulting in a positive conclusion). (Figure 3);
– carrying out an inspection and corresponding comprehensive survey on the suitability of the building's exterior plaster layers to date.

As a result of site-specific investigations, it was found that the external surface of the facade plaster and paint layer has significant damage (abrasions, cracks) at various levels as a result of various external natural influences and long-term use.

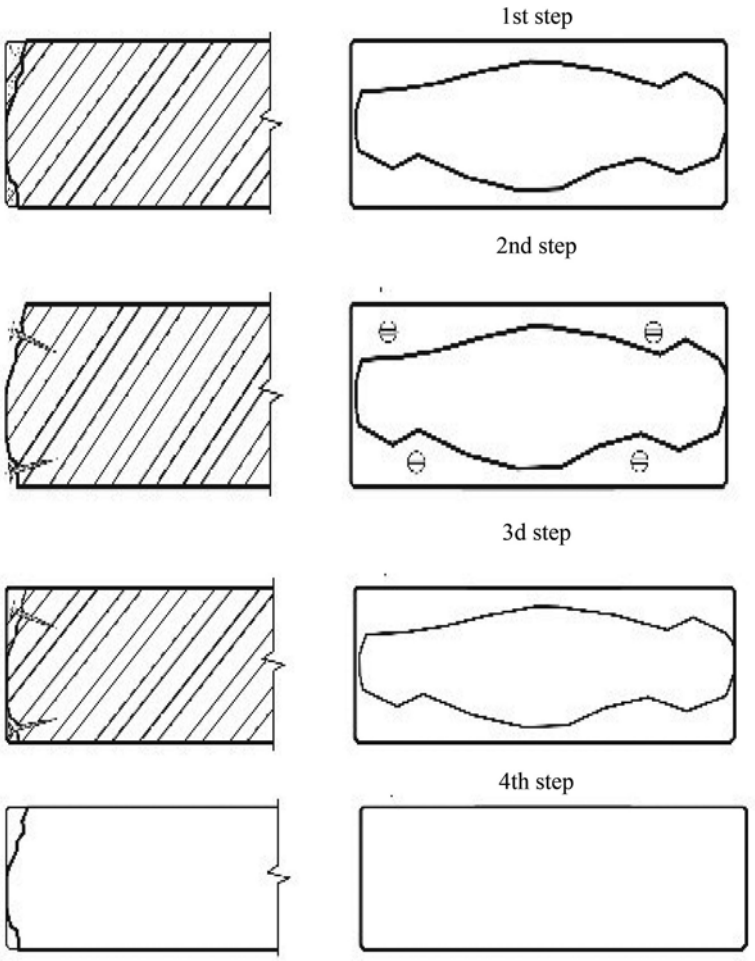

Figure 3. Steps of restoration of deformed parts of building bricks due to various external natural influences (in section and front view).

Subsequently, external plaster layers and brick surfaces deemed unsuitable are routinely removed (dismantled) and replaced with new plaster (4,5-drawings);

When the building was reconstructed, tiles of various shapes were made and used on the basis of previous architectural elements in order to preserve the artistic and stylistic features of its facade.(Figure 6) In spite of the long period of use, the building has survived to this day in reasonably good condition [1,5].

Figure 4. The building of the Kazakh Humanitarian Law Innovative University, after restoration (fragment).

Figure 5. The building of the Kazakh Humanitarian Law Innovative University, after restoration (fragment)

During the renovation and restoration work, the university administration fully understood the importance of the project, took great responsibility for it and contributed actively to the successful completion of the work.

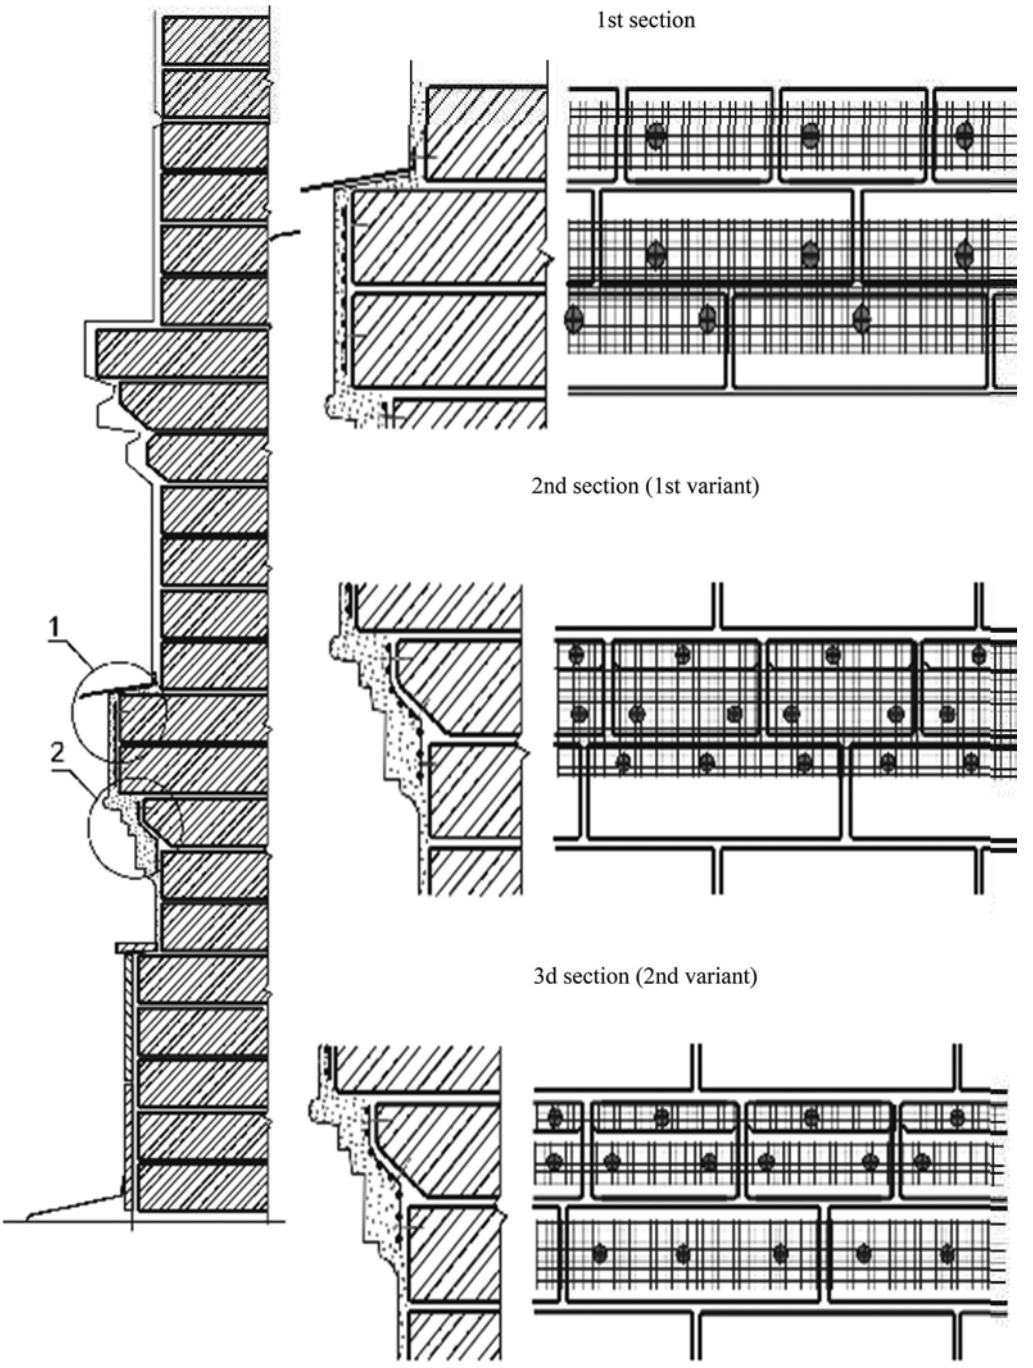

Figure 6. Measures to preserve artistic and stylistic features and external architectural elements of the exterior of buildings.

In the near future, in addition to continuing the exterior restoration of the building, there are plans to restore its interior historic finish, improve the quality of the wooden roof structures, and study and, if possible, run the interior natural ventilation, air purification and heating systems. This means going beyond the exterior architectural restoration of a building and trying to restore it to its original interior working condition in a comprehensive way [2].

On the basis of the research and restoration work carried out to date and the results of future work, there are plans to write digital catalogues and monographs on the restoration and reconstruction of architectural monuments in Semey.

It is worth noting that this is the first time such a positive initiative has been launched in Semey from a building belonging to this university. We hope that such activities will continue at the city level and Semey could, with its rich architectural and historical gems of the 18th-19th centuries, be counted among the number of cities such as Turkestan, Taraz, Sayram, having architectural and historical value of the world level. We believe that the restoration and preservation of such architectural and historical treasures should be one of the most pressing problems facing the citizens [3].

Currently, the state of architectural monuments with historical values in the city of Semey is critical. Suffice it to mention as an example the fate of the former Semey Veterinary Institute. This building is unique with its architectural and stylistic features and obviously a very valuable architectural object, that does not have got any analogues not only in Kazakhstan but also in other neighboring countries, including Russia [4,5].

Figure 7. Current view of the former Semey Veterinary Institute building.

The building, built before the revolution (at that time a female gymnasium) burned down for the first time in the assembly hall in the evening of December 10, 1917, and for the second time on December 9, 1986, 69 years later. Since then, 36 years have passed; now the walls of the magnificent building gradually crumble with each year, it is impossible to pass by such a deplorable appearance of buildings without sympathy. (Figure 7).

4 CONCLUSIONS

The fact that such buildings over the years are severely affected by nature and neglect by society is deeply troubling and saddening, another spiritual value «disappearing before our very eyes»!

High spiritual values, such as the architectural and historical heritage of the people, have always been and will remain one of the important aspects of the country's development. We want to believe that the preservation of architectural monuments will become one of the priority tasks of our republic.

Geotechnical properties of combustion waste and its suitability for embankment constructions

A. Dąbska, P. Pytlak, B. Bednarz & Z. Bereda
Faculty of Building Services, Hydro and Environmental Engineering, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: This paper presents research results on the geotechnical properties of the combustion by-products (fly ashes) from wet waste landfills "Jelnia" in Stalowa Wola. The fly ash's physical, mechanical, and permeability properties were determined in laboratory conditions. The possibility of using combustion waste to construct road and water engineering embankments was assessed regarding the applicable European standards and guidelines. Examples of fly ash usage in embankments construction are also presented.

1 INTRODUCTION

In recent years, there has been an intensive development of expressway and freeway networks as well as large-scale construction and modernization of flood banks in Poland. These activities require a high demand for soil materials necessary for the construction of transport and flood embankments. Limited resources of natural materials, more and more difficult to obtain concessions for the opening of new mines and high costs of transport of these materials are the reasons for looking for alternative materials of anthropogenic origin for the embankment constructions. Types of anthropogenic soils allowed for embankment construction are specified in the Regulation of the Minister of the Environment from the 11th of May 2015 (Dz. U. 2015 poz. 796).

Ashes and slags from coal combustion in power and heating plants, classified as Combustion By-products (CBs) are one of the anthropogenic materials (Szczygielski 2015). Various chemical and phase compositions as well as physical and mechanical properties of fly ashes force to analyze their parameters each time to select the most effective method of their transformation or utilization (Zabielska-Adamska 2019). Recycling ashes is also a part of the idea of sustainable development and a circular economy, implemented successfully in Poland (Kledyński et al. 2020). CPs storage generates significant financial and ecological problems and their rational use in the economy, especially in the construction industry, is more frequently recommended (Roszczynialski et al. 2012). The ash reuse reduces the amount of ash in landfills, limits the exploitation of natural resources and indirectly lowers carbon dioxide emissions, e.g. by partially replacing fly ash with Portland clinker, as it requires thermal treatment involving the emission of CO_2.

The paper presents the results of geotechnical properties tests of ashes deposited on the combustion waste landfill "Jelnia" and an analysis of the possibility of using these ashes for the transport and flood embankment bodies.

2 TESTED MATERIAL – FLY ASH

Investigated combustion waste was taken from the combustion waste landfill "Jelnia" in Stalowa Wola (Poland).

The tests were performed on four samples of combustion waste taken from quarters no. 4S-E (Figure 1), from about 2.0 m below the level of accumulated wastes. Two of them were taken

DOI: 10.1201/9781003299127-382

from the discharge zone (Z1, Z2) and two from the inlet zone, at the overflow well on the western side (U1) and on the eastern side (U2). The samples were characterized by a disturbing texture and were protected from moisture content and graining changes during transport and storage.

Figure 1. The combustion waste landfill "Jelnia"- view of the waste-filled quarters No. 4S-E (September 2018).

3 PROPERTIES OF COMBUSTION WASTE FROM "JELNIA"

3.1 *Test method*

Soil description by macroscopic analysis, grain size composition, moisture content, specific density of solids, compactibility, capillarity rise, permeability coefficient, swelling, compressibility and shear strength tests were performed at the Laboratory of Soil Mechanics and Geotechnics of the Department of Building Services, Hydro and Environmental Engineering at Warsaw University of Technology. Testing of specific density of solids was performed in accordance with PN EN 1097-7 standard, however other tests were carried out according to the PN-B-04481:1988 standard and the guidelines in the book (Pisarczyk & Rymsza 2003). Capillarity rise, permeability coefficient, swelling, compressibility and shear strength were determined at compaction with optimum water content assessed by the standard method I Proctor test.

Table 1. Properties of tested fly ash.

Parameter				Sample no.			
Name		Symbol	Unit	Z1	Z2	U1	U2
Fraction content	gravel	f_z	%	0.6	0.1	0.2	0.1
	sand	f_p	%	93.6	81.5	83.0	84.2
	silt	f_π	%	5.7	18.0	16.4	15.4
	clay	f_i	%	0.1	0.4	0.4	0.4
Uniformity coefficient		C_U	-	3.42	2.57	2.82	2.39
Natural moisture content		w_n	%	17.8	53.5	62.1	61.4
Specific density of solids		ρ_s	kg/m^3	2480	2150	2210	2160
Capillarity rise		H_{kc}	m	1.19	> 2.00	> 2.00	> 2.00
Permeability coefficient		k_{10}	m/s	$8.0*10^{-7}$	$4.3*10^{-10}$	$2.0*10^{-10}$	$5.6*10^{-10}$
Expansion index / swelling index		I_{hc}	%	0.9	13.4	12.8	12.2
Compactibility (I normal Proctor method)	optimum water content/optimal moisture content	w_{opt}	%	21.6	33.2	36.1	38.0
	maximum dry density	ρ_{ds}	kg/m^3	1430	1130	1130	1060
Oedometric modulus (primary consolidation) (0-0.2 MPa)		M_0	MPa	8.9	3.1	2.3	4.2
Shear strength (direct shear apparatus)	cohesion	c_u	kPa	13.6	50.2	42.5	50.4
	internal friction angle	φ_u	°	48.6	36.9	38.6	41.0

3.2 *Test results*

The results of fly ash laboratory tests are shown in Table 1. More detailed test results are included in the engineering thesis (Pytlak 2020).

4 ANALYSIS OF TEST RESULTS

4.1 *Assessment of combustion waste properties*

Wastes disposed in one section of the landfill are not homogeneous materials, and their properties change depending on the material storage zone. The grain size composition of the discharge zone waste corresponds to uniformly-grained fine sand and silty sand, whereas that of the waste from the intake zone corresponds only to silty sand (PN-B-02480:1986). The specific density of combustion waste is lower than the density in soils of natural origin. Considering physical properties, compactability, permeability and mechanical properties tested ashes do not correspond to natural soils of similar grain size (PN-B-03020:1981). Significant differences are noticed in the strength and compactibility parameter values. The combustion waste is characterized by lower maximum bulk densities of the skeleton at lower optimum moisture contents, higher cohesion and internal friction angles. The properties of the studied ashes do not differ from other hard coal ashes (Pisarczyk 2015).

4.2 *Assessment of applicability of ash for construction of embankments*

4.2.1 *Road embankments*

The soil for the construction of road embankments in Poland should be selected in accordance with the PN-S-02205:1998 standard which allows the usage of anthropogenic materials to construct road embankments, including fly ash and ash-slag mixtures. Tested ashes can be used in

Table 2. Properties of the tested ash according to the requirements for ash-slag mixtures for construction of road embankments based on the PN-S-02205:1998 standard.

Parameter	Value required for embankment body construction	Sample no.			
		Z1	Z2	U1	U2
Main conditions					
Grain size composition	≥ 35 %	94.2 %	81.6 %	83.2 %	84.3 %
- sand-gravel friction content	≤ 75 %	12.0 %	30.0 %	30.0 %	25.0 %
- grain smaller than 0.075 mm content					
Organic matter content (unburned carbon)	≤ 10 %	6.7 % (Dąbska et al. 2019)			
Maximum dry density after compaction according to Proctor (I or II method)	≥ 1 kg/m^3	1430 kg/m^3	1130 kg/m^3	1130 kg/m^3	1060 kg/m^3
California bearing ratio (CBR), after 4 days of soaking in water	≥ 10 %	n.d.	n.d.	n.d.	n.d.
Linear swelling					
- without load	≤ 2 %	0.9 %	13.4 %	12.8 %	12.2 %
- under 3 kN/m2 load	≤ 0,5 %	b.d.	b.d.	b.d.	b.d.
Additional conditions					
Internal friction angle φ	≥ 20°	48.6°	36.9°	38.6°	41.0°
Passive capillarity H_{kb}	≤ 2 m	n.d.	n.d.	n.d.	n.d.
Sulphate content (as SO_3)	< 3 %	0.07 % (Dąbska et al. 2019)			

n.d. – no data

lower layers of road embankments, below the frost zone, in dry or water-isolated areas, and after improvement with binders such as cement, lime, and active ash in upper layers of embankments in the frozen zone (Dabska et al. 2022). Requirements for ash-slag mixture application into road embankments according to the PN-S-02205:1998 and the comparison of tested ash properties are presented in Table 2.

Analysis of data presented in Table 2. shows that the tested wastes follow the requirements for ash-slag mixtures for road embankment construction, except for the linear swelling requirement for combustion waste with a grain size that corresponds to the grain size of silty sand. The combustion waste can be used in lower layers of road embankments below the frozen zone, under conditions of isolation from water, and in upper layers of embankments in the frozen zone, after improving it with binders. Combustion waste with a silty sand grain size requires previous mixing with coarser fractions in order to reduce their swelling properties.

The road embankments of the S19 expressway in Poland constructed with tested combustion waste are presented in Figures 2-3.

Figure 2. Forming a slope from ashes on the section Janów Lubelski – Łążek of the S19 expressway in Poland (May 2020) (GDDKiA).

Figure 3. View from above on the S19 expressway embankment, made of ashes from the combustion waste landfill "Jelnia" (May 2020) (GDDKiA).

4.2.2 *Flood embankments*

Ash-slag mixtures are not recommended for use in the earth dams in riverbeds and flood embankments. Ashes and slags are commonly used to construct subsequent phases of wet landfill embankments, functioning as water engineering structures (DGWiM 1973, Dąbska et al. 2019). Tested ash was used for the construction of the second, third and fourth phases of the embankment at the combustion waste landfill in Stalowa Wola (Figure 4).

Figure 4. Embankment of the combustion waste landfill "Jelnia" in Stalowa Wola (Poland) constructed from ashes (November 2020).

5 SUMMARY

According to the preliminary assessment, the tests of combustion waste properties and analysis of their results indicate that this material can be built-in in the bodies of transport embankments and used for the construction of embankments of combustion waste landfills under some restrictions. The main limitation of using ashes with finer grains is their swelling in direct contact with water. For this reason, ashes cannot be applied in layers where there is a possibility of contact with water in most water engineering constructions and transport embankments.

The presented results should be supplemented by testing the California bearing ratio CBR, soil swelling under load, and passive capillarity to fully evaluate the suitability of tested ashes from the wet landfill "Jelnia" for constructing the bodies of transport and flood embankments. These tests can significantly affect the preliminary assessment of their use as embankment soils.

Construction of the S19 expressway, the ring road of Stalowa Wola and Nisko towns with the use of ashes from the wet landfill "Jelnia", indicate that properly built waste can be a material for building the body of road embankments, and effectively limit the exploitation of local mines of natural resources. It is estimated that about 1.1 million tons of combustion waste from the "Jelnia" landfill have been applied to the road embankments, which effectively increased the storage capacity of the landfill. This investment is an excellent example of the idea of a circular economy implementation, bringing real economic benefits and a positive impact on the environment.

Geotechnical forecast of the construction of structures in conditions of degrading permafrost soils

S.A. Kudryavtsev, T.Yu. Valtseva, A.V. Kazharsky, I.I. Gavrilov, I.I. Sakharov & V.N. Paramonov
Far Eastern State Transport University, Khabarovsk, Russia

ABSTRACT: The article summarizes the results of the operation of the roadbed for more than fifty years of operating experience on degraded permafrost soils. The modern technique of numerical modeling of the forecast of the process of degradation of frozen soils is considered, which allows the development of modern structures that reduce or exclude deformations of structures. The construction and operation of structures in permafrost conditions is associated with the degradation of the temperature state of the soil of structures due to the effects of solar radiation. Global climate change plays a crucial role in ensuring the reliability of railway infrastructure facilities. To prevent thawing of permafrost soils of the base, thermostabilizers are used - seasonal cooling devices and stone cooling sketches. The article considers predictive thermal engineering studies of permafrost foundations of railway bridges and pipes in order to substantiate regulatory design solutions. Numerical studies were carried out by the finite element method using a non-stationary and physically nonlinear thermophysical model of soils

Keywords: permafrost, degradation, soils, temperature, thawing

1 INTRODUCTION

The purpose of this work is to consider the methodology of numerical modeling of structures taking into account insolation and the use of modern devices that exclude deformation of the roadbed on permafrost soils. The embankment with a permafrost subgrade on swampy areas has undergone substantial processes of freezing, thawing and heaving during its 40-year exploitation period. The major defrosting factor for a permafrost subgrade is a water impact. In case the water runoff is absent, a consequent thawing of the permafrost subgrade takes place that results in thawing basin. To avoid this effect, it is reasonable to make drainage soil fills, rocky cooling structures and take other analytically proved effective measures [1,2].

Construction and operation in permafrost conditions is associated with many problems, the most urgent of which is the degradation of the frozen state of soils due to the effects of solar radiation on the process of thawing of permafrost foundations of buildings and structures.

Currently, considerable attention is being paid to the negative impact of natural impacts on railway infrastructure facilities and the level of train safety. It is noted that the greatest natural risks are directly or indirectly related to climate change in recent decades.

According to the materials of the Russian Hydrometeorological Service, the average rate of warming of permafrost soils in Russia is three times higher than the average for the globe and is 0.51 ° C/10 years. In 2020, the average annual air temperature anomaly left +3.22°C - more than 1 degree higher than the previous maximum in 2007 at a rate of 2.2% of the ten–year norm.

DOI: 10.1201/9781003299127-383

According to the data of the international program CALM (Circum Polar Active Layer Monitoring) for the period 2005-2020 in the zone of permafrost soils of Russia, the thickness of the seasonally thawed layer increased by an average of 5-15 cm [3–6].

The increase in air temperatures in recent decades in the Baikal-Amur Mainline zone strongly affects the temperature regime of the soil of the roadbed and its foundations. It was found that during the period 2010-2020, in areas without cooling structures, the permafrost roof at the base of the roadbed decreased to 0.5 m with an increase in soil temperatures of undisturbed landscapes and a decrease in the permafrost roof to 1.8 m on the southern slopes of positive relief forms, as well as in areas stacked with well-draining soils. The degradation of permafrost is accompanied by the disappearance of "ice-cement", which binds loose soils into a single, previously stable mass.

2 DESIGN-BASIS JUSTIFICATION

Design-basis justification is necessary for a variable development of the designing solutions for railway structures that keep the roadbed and its base at a less than maximum permissible values or even zero deformability.

In 2005 we developed for construction engineering organizations a unique software that makes numerical modeling by the method of finite elements. It simulates freezing, heaving and thawing processes in seasonally frozen and permafrost soils in a 3-dimentional perspective. This is the only programming product calculating not only temperature fields but also deformations in the embankment and the base. This complex uses the Cloud technologies. A wide circle of users enjoys a monograph that contains practical examples of thermo-physical and stress-strain calculations of the embankment, the roadbed, bridges pipes, waterworks, seasonally cooling structures for permafrost preserving and other structures.

In this research first of all a thermo-physical task should be solved as a basis for the study of a stress strain behavior of the railway embankment taking into account its perspective life-span on permafrost.

2.1 *The numerical modeling of thermo-physical design calculations*

The numerical modeling was carried out in the program complex FEM-models developed by the "Geoconstruction" Design Institute, St.Petersburg, Russia. As a part of this program complex, the "Termoground" program allows a 3D research of freezing, frost heaving and thawing processes in an annual cycle by the finite elements numerical modeling [7–11]. The calculation was performed for a fifty-year forecast period and, due to a universal solver, is performed with multimillion operations of unknowns with a finite element dimension of tens of centimeters within one hour. For the study, it is necessary to determine the thermophysical, physical and climatic properties.

The program calculations assume the researched area including the design is divided into the finite elements of the same temperature and soil characteristics. The design model is defined first by the initial and the boundary conditions, then the thermotechnical task is solved resulting in calculation of temperature and moisture areas for every time-period.

The initial conditions include the soil temperature defined by depth, while the boundary conditions include the surface temperature (under the rock fill) defined by time. The upper boundary is affected by a time-variant heat flow determined by the defined air temperatures and the heat-transfer coefficients.

General equation describing the freezing and thawing processes for a transient thermal regime in a three dimensional soil space can be expressed as following:

$$C_{th(f)}\rho\frac{\partial T}{\partial t} = \lambda_{th(f)}\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) + q_V \tag{1}$$

where $C_{th(f)}$ - specific heat of soils (frozen or thawed), J/kgK; ρ - soil consistency, kg/m³; T – temperature, K; t – time, c; $\lambda_{th(f)}$ - thermal conductivity of soil (frozen and thawed), W/mK; x, y, z – coordinates, m; qv- internal heat source capacity, W/m³.

The core of a mathematical modeling of thermophysical processes in "Termoground" program is the model of high ice, thawed and frozen soils offered by N.A. Tsytovich, Y.A. Kronik and V.F. Kiselev.

The major factors determining the defined surface temperatures on the embankment elements and the adjacent territory are the atmospheric air temperature and the heat exchange conditions between the air and the structure surface that depend on the wind conditions, solar radiation, vaporation, and others.

The calculation value of the defined average monthly air temperature is determined from the formula:

$$T_{np.} = T_b + \Delta t_r - \Delta t_e \tag{2}$$

where T_b is average monthly air temperature; Δt_r and $\Delta t_e$are corrections to average monthly air temperatures due to solar radiation and evaporation, °C.

The correction to air temperature due to solar radiation (Δt) is calculated according to formula:

$$t_r = \frac{R}{0.073\alpha}, \tag{3}$$

where R is monthly sum of radiation balance for the considered element of the surface, kkal/см2 ×months; α is surface heat exchange coefficient, kkal/м2 ×h×°C, and its empirical-formula dependence is:

$$\alpha = 10\sqrt{V}, \tag{4}$$

where V is wind velocity.

The monthly sums of radiation balance for horizontal surfaces are determined from the formula:

$$R_o = Q_o \times k - 0.42, \tag{5}$$

where Q_o is average monthly sum of total solar radiation striking the horizontal surface, kkal/см2 ×months; k – empirical coefficient in terms of the surface reflecting capacity (albedo).

The monthly sums of radiation balance for bevel faces (subgrade embankments) are determined from the formula:

$$R_\beta = \left(m_\beta I_o + P_\beta D_o\right) \times k - 0.42, \tag{6}$$

where I_o and D_o – average monthly sums of direct and diffuse radiations striking the horizontal surface, kkal/см2 ×months, the values being taken from the climatological guide; m_β non-dimensional coefficient in terms of the bevel face angle to horizon and spatiolization of the face for beam radiation intake; P_β – coefficient in terms of the bevel face angle to the horizon and spatialization of the face for a sky radiation intake that is determined from the formula:

$$P_\beta = \cos^2\frac{\beta}{2}, \tag{7}$$

where β– angle of the bevel face to the horizon, degrees.

The thermophysiscal characteristics of the roadway and roadbed soils in thawed and frozen states are taken in accordance with the СП 25.13330.2012 – Permafrost Foundation Engineering Standards.

2.2 *The numerical modeling of the embankment stress strain behavior for the targeted time-period*

The relative thawing strains of permafrost are determined according to the results of the standard laboratory tests. In this case the relative stresses are calculated according to the formula:

$$\varepsilon_{th} = A_{th} + \delta_{ith} \tag{8}$$

where $A_{th}$is the relative strain of thaw thermal subsidence; $\delta_{ith}$is the relative strain of thaw loading subsidence.

$$\delta_{ith} = \mathrm{m_{0th}} \cdot \mathrm{p}_i, \tag{9}$$

where m_{0th} is the coefficient of compressibility of thaw soil (MPa-1); p_i is the compacting vertical stress (MPa).

3 DEVELOPING A RATIONAL DESIGN

Administratively, the work site is located in the Amur region of the Baikal-Amur Mainline in Russia. The embankment is built up to 9.0 m high. Part of the railway track runs along the swampy above-floodplain terrace of the river, composed of peat, sandy loam, sand and gravel-pebble deposits lying on the weathering crust of granite rocks of the early Archean. The distribution of permafrost soils and taliks is reflected in the normative geocryological data. According to engineering-geological and geocryological conditions, the railway track is laid on a section of the III (complex) category.

The climate of the area of the site location is of a sharply continental type, with monsoon features and is characterized by a harsh long winter and a short hot summer. Specific soils are widespread along the highway: peat, eluvial deposits, permafrost and technogenic soils. Of the unfavorable geological processes and phenomena in this area, it is possible to distinguish: the presence of permafrost soils; frost heaving, deformation of the roadbed.

Thermal engineering calculations were performed for various variants of cooling structures. The experience of operating the existing track, the latest achievements of research and development work were taken. The article presents the construction of the roadbed with measures to prevent further thawing of permafrost soils.

The article presents the results of the performed forecast calculation at the time of maximum thawing of soils - october of the calculated year. The calculation was made for the third, fifth, tenth year of operation of the roadbed. The results are presented for the tenth year of operation.

The stabilization of the roadbed in the areas of permafrost degradation will occur between the fifth and tenth years. The design of the cooling rock outline was selected individually, depending on the type of foundation, the established temperature field, engineering and geological features, etc. The article presents an optimal cooling stone structure that allows to raise the permafrost by more than one meter in ten years (Figures 1–2).In the studies, boundary conditions of the first kind were accepted, the essence of which is that the temperature is set at all points on the surface of the body for a given time.

Designs that did not provide the required reliability parameters were excluded from further consideration. The results of thermophysical calculations showed that under the existing embankments of the site, the temperature of permafrost soils increases with the formation of a thawing bowl, and the degradation of permafrost is observed.

When using cooling measures in the form of a rock outline, the permafrost boundary rises into the body of the embankment, ensuring reliable operation. Geometric dimensions (width, height) were selected individually taking into account the operation of the existing railway.

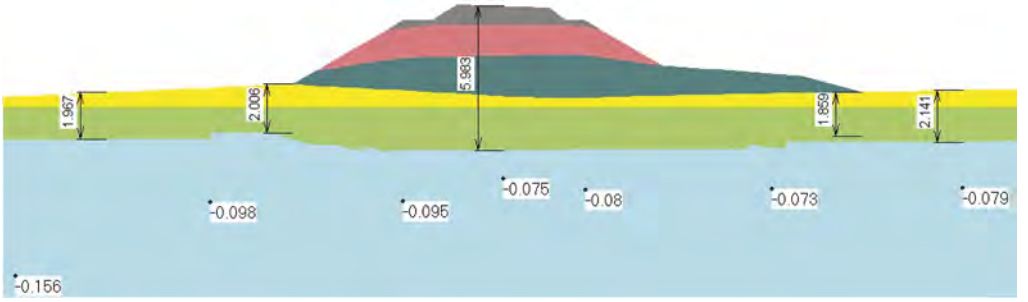

Figure 1. The results of determining the boundary of permafrost soils at the initial time. The blue color shows the ground in a frozen state.

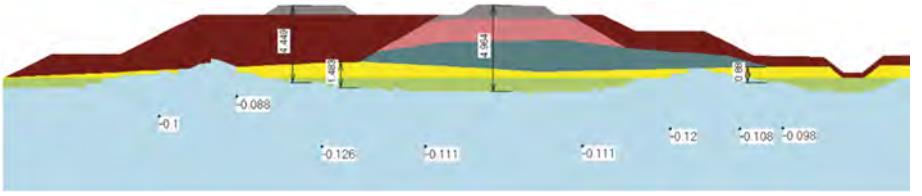

Figure 2. The results of determining the boundary of permafrost soils at the estimated time. The blue color shows the ground in a frozen state.

In Figures 3–4, a variant of the device of a cooling stone outline on the cones of the bridge abutment was considered. Thawing for ten is about five meters. The columnar foundation is located on frozen soils with sufficient bearing capacity and, accordingly, load capacity.

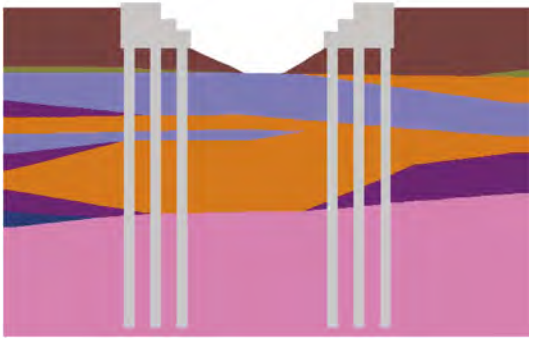

Figure 3. Design scheme of the bridge section.

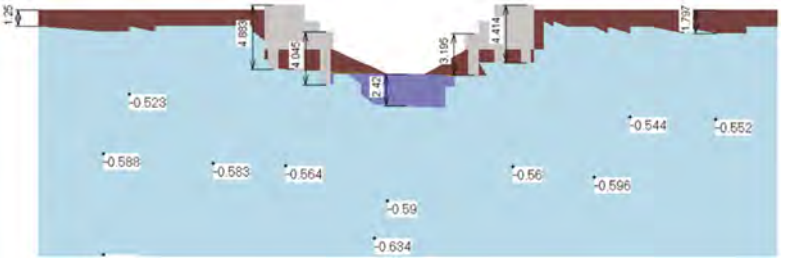

Figure 4. The results of determining the boundary of permafrost soils at the calculated time. The blue color shows the ground in a frozen state.

4 CONCLUSIONS

1. The detailed information of the study includes a set of measures that allow to give an objective forecast of the preservation of the permafrost base from the degradation process as a result of an increase in air and soil temperatures. The research was carried out on a section of the Baikal-Amur railway in Russia. Using the survey and the numerical modeling method for the calculation of quantitative and qualitative assessment of the railway structures on permafrost makes it possible to carry out thermo-technical designs of constructing and projected buildings and structures with the perspective to know their behavior in decades. This allows to assess stress and strain state of "base-embankment" system and provide a reliability of the projected structures when considering all the variants. The obtained forecast results of numerical modeling are in good agreement with the data of observations of the temperature and the processes of thawing of permafrost soils of the base of the railway embankment.
2. The program complex "FEM-models" having the "Termoground", a module for non-stationary heat flow calculation, allows to make calculations of freezing, thawing and frost heaving for seasonally freezing and permafrost soils.
3. If the lateral seepage through the embankment roadway and the subgrade takes place, the permafrost eventually gets thawed, and a thawing basin is formed under the embankment.
4. If the lateral seepage is not stopped, some cooling methods such as rock fills or ditches are not effective for keeping the permafrost in the subgrade.
5. When a geomembrane is installed along the rock fill toe, the infiltration of water due to warm precipitation and ground waters through gravel soils of the roadway and turf soils of the subgrade get reduced or disappear. This method provides a longer exploitation period of rock fill structures as well as lifts the permafrost line into the roadway and lessens deformations of the embankment to the accepted values.

ABSTRACT: The authors propose a combined approach for a cylindrical geomechanical model of piles by numerical determination of shear rigidity of a multilayer soil cut by a pile. The rigidity of the subsoil under the tip of the pile is calculated analytically as for a stamp on an elastoplastic base. This approach is more visual in the analysis of the stress-strain state of piles and near pile soils. The finite element method simplifies the consideration of the non-linear properties of materials and the additional swelling or frost effects Dynamic impacts always affect the foundation, which is already experiencing deformations from dead loads. The approach proposed by the authors makes it possible to take into account the conditions of the formation of the stress-strain state of the pile foundation within universal model of the pile cell. After the perception of horizontal static horizontal loads by piles in the form of a beam on an elastic base, proceed to the integral dynamic rigidity of the large pile field.

1 SINGLE PILE MODELS

1.1 *Analytical cylindrical two-layer model of a pile*

A mathematical shear two-layer cylindrical model of a single pile or a group of up to 25 piles was introduced in 2010 in the Russian Code Design SP 24.13330.2011 "Pile foundations" (clause 7.4.2) instead of the method of «conditional foundation». The model is based on a significant amount of experimental data generalized by the research team of the NIIOSP (Fedorovsky et.al. 1972, 2003). However, a mathematical presentation with an excessive number of intermediate coefficients makes it difficult to perceive the physical meaning of the technique.

The authors would describe in the Fedorovsky model the condition that there is an influence of neighboring piles loads introducing the limiting radius a_{lim} (Formula 1). The limiting radius parameter of mutual piles influence is the radius of a cylindrical geomechanical model, with a height equal to the length of the pile L and with an underlying layer depth of $0.5L$ (Figure 1a). The exclusion of deformability of the concrete pile and the introduction of the radius of influence simplifies the formulas of SP 24.13330 for a homogeneous subsoil (Formulas 2, 3, 4).

$$a_{lim} = k_\nu \frac{G_1 L}{2G_2} = \left(2.82 - 3.78\nu + 2.18\nu^2\right)\frac{G_1 L}{2G_2} \tag{1}$$

$$S_i = 0.17\ln\left(\frac{a_{lim}}{2d}\right)\frac{N_i}{G_1 L} \tag{2}$$

DOI: 10.1201/9781003299127-384

$$S_{ad.ij} = 0.17 \ln\left(\frac{a_{lim}}{a_j}\right) \frac{N_j}{G_1 L} \tag{3}$$

$$S_{i.gr} = S_i + \sum\nolimits_{j \neq i} S_{ad.ij} \tag{4}$$

The obvious advantage of the single pile analytical shear model is the simplicity of application for automation of FEM numerical calculations (Shapiro 2016, Edigarov 2015, Nuzhdin & Mikhaylov 2018a). The two-layer concept was proposed for the first time in 1953 (Ter-Ovanesov 1956). Excluding the small compressibility of the pile body in comparison with the soil, the total settlement of the pile S is easily decomposed into the settlement of the subsoil along the lateral surface S_τ (Figure 1b), always equal to the settlement of the underlying soil S_0 from the pushing of the pile bottom (Figure 1c). Based on this concept the research team of the MSUCE developed alternative analytical geomechanical model of the pile taking into account rheological and elastoplastic processes in the soils (Ter-Martirosyan & Dinh, 2006).

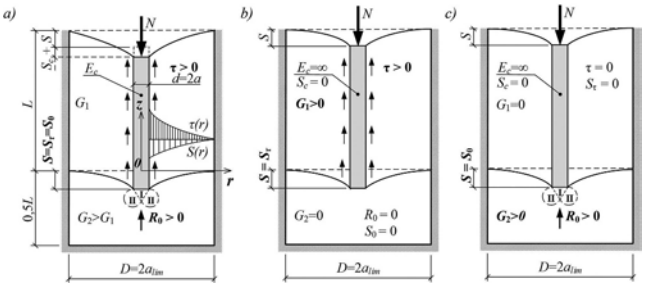

Figure 1. Diagram of a two-layer analytic cylindrical geomechanical pile model.

1.2 *Numerical cylindrical multilayer model of a pile*

The authors propose further development of the cylindrical model by replacing the analytical description for the area of shear linear deformations along the length of the pile with a multilayer axisymmetric numerical FEM solution. The method was verified in the Mathcad software (see Figure 2) with a spatial (see Figure 3a) and an axisymmetric (see Figure 3c) finite element models of a pile in SCAD software, considering a fragment of a cell with a height of 0.4 m and a radius of 0.57 m, and the pile of concrete B20 and 0.34 m in diameter is surrounded by loam with a deformation modulus of 10 MPa. A fragment of the numerical finite element method (FEM) solution in SCAD software with the definition of nodal displacements in the finite elements of an axisymmetric body and in spatial FEM model are presented below (see Figure 3b and d).

The settlement of a single pile of the 12 m length (L) in an elastic axisymmetric model in SCAD software is shown below (see Figure 4). Settlement with a depth of the underlying layer of $0.5L$ (see Figure 4a) is 24% less than the analytical solution (see Equation 1–4). An increase in the thickness of the elastic underlying layer to the depth of the compressible thickness of the conditional foundation H_c = 11.4 m is insufficient (see Figure 4b). The complete exclusion of the underlying layer leaves only the shear rigidity along the lateral surface with an excess of settlement S_τ = 6.41 mm by 4.8% over the analytical solution (see Figure 4c). Only at a double depth of $2xH_c$ = 22.8 m, the settlement corresponds to the analytical solution. This is due to the fact that nonlinear zones of compacted core and limit equilibrium are formed under the pile fifth (see Figure 4d) and should be found in elastoplastic or by the analytic solutions (Schleicher, 1928).

The numerical solution corresponding to the analytical method can be achieved by replacing the underlying layer with a spring with the rigidity of the base under a round stamp (see Figure 4d). The parameter of the spring under the fifth of the pile can be calculated by the analytic solution either from the inverse ratio G_2d/G_1L, indicating what proportion of the rigidity under the fifth is of the rigidity on the lateral surface, equal to 3.4% in the example under consideration.

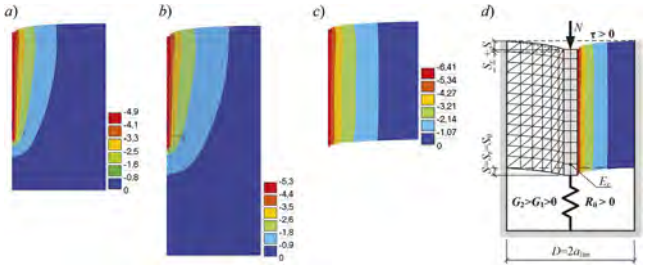

Figure 4. Deformations in axisymmetric single pile model (a, b, c) and diagram of the complex model (b).

2 LARGE PILE FOUNDATION MODELS

2.1 *Numerical model of a large pile foundation under impact of dynamic loads*

In the Figure 5 presented an example of a pile field foundation numerical model accounting on the effect of vertical and horizontal loads, which was considered in detail in the authors' previous publications (Nuzhdin & Mikhaylov 2018b, 2020). The given example of calculating piles in a group in accordance with analytical methods can be implemented by a single algorithm for foundations in the form of a single pile, a group of piles or a pile field with equivalent stiffness at various stages of the formation of the stress-strain state of structures.

At the first step of static numerical modelling in SCAD FEM software, bed coefficients are assigned along the lateral surface of the piles to set their horizontal stiffness, which increases in depth as soil weight increases. Taking into account the horizontal influence of piles in the group (Fedorovsky et.al. 1972, 2003), algorithm begins with the calculation of the reducing coefficient

α. Then the values of the coefficients of the bed C_z on the side faces of the pile are calculated in accordance with the table of stiffness for different types of soils (Zavriev et.al. 1970):

$$C_z = K \cdot z \cdot \frac{\alpha}{\gamma_c}. \tag{5}$$

At the second step of numerical calculation in SCAD, the initial boundary conditions are assigned vertically without taking into account the mutual influence of piles in the group. The calculation of the preliminary vertical rigidity of piles is carried out in accordance with analytical cylindrical two-layer model of a pile (see Equation 2). The shear modulus G_1 of the soil layers cut through by the pile is calculated on the basis of the averaged deformation modulus E_1 and the dimensionless Poisson's ratio ν_1 for the i layers cut through by the pile. Similarly, the shear modulus G_2 is calculated for the soil layers located under the lower ends of the piles. The modulus of deformation of the soil layers located under the pile, E_2, is taken averaged within a depth equal to half the length of the pile $0.5L$ or equal to $10d$ of the reduced pile diameters from the lower ends of the piles. The Poisson's ratio ν_2 is set directly on the layer below the pile tips.

Figure 5 shows a fragment of the algorithm for taking into account the mutual influence of piles in the pile field. The problem is solved using linear programming. An array with imported coordinates of pile nodes is converted into two numerical series with X and Y coordinates. The next step is to form a general matrix a_2 of the relative position of piles in the pile field in the form of calculated distances between piles.

Based on the matrix of mutual arrangement of piles, the δ_2 matrix of vertical mutual influence of piles in the pile field is calculated according to the theory of elastic half-space in the form of additional efforts or in the form of coefficients of reduction of the initial stiffness. This is ensured by performing multiple calculations of each member of the matrix in accordance with the analytical formulas (see Equations 1–4), which provides for zeroing the coefficient of mutual influence of one pile on another when a certain distance between them is exceeded. The limiting radius of influence a_{lim} (see Equation 1), is the radius beyond which there is no mutual influence between piles.

The last step is the calculation of the additional forces ΔN_h, which are the sum of the initial vertical reactions N_h in closely spaced piles, taking into account the coefficient of mutual influence δ. These efforts are necessary for the occurrence in the design scheme of additional deformations in the lower node of each pile and the formation of a common settlement funnel.

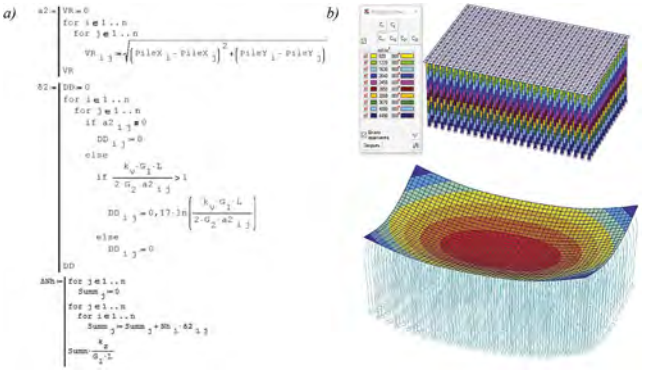

Figure 5. Algorithm of mutual influence of piles in the field (a) and resulting FEM model in SCAD (b).

2.2 *Numerical model of a large pile foundation under impact of static loads*

When performing dynamic calculations, the discrete model of a pile field is the most researched. The reduction in the bearing loads of piles for vertical loads is carried out by

reducing coefficients and by introducing the zone of partial loss of contact with the ground in the upper area of the pile along its side surface in accordance with (Ilyichev et.al. 1983).

For taking into account the horizontal dynamic rigidity of a wide pile field in conditions of seismic impacts the authors recommend methods, used in specialized software as SASSI. Difficulties in developing such a technique are associated with a number of features of the pile foundation (Tyapin A.G. 2000). The increased rigidity of the pile group in comparison with the initial soil in its natural state, as well as the possibility of loss of contact with the soil along the lateral surface of the piles, does not allow us to consider the pile field as a layered half-space with anisotropic properties. The dimensions of the pile sections are so small, and their number is so large that the applicability of discrete models is not feasible in practice.

A new approach is considered by the authors, which adapts the methodology for an impedance numerical-analytical model in the SASSI software for use in direct physical models of pile foundations, which can be implemented in the environment of the widespread FEM programs.

The method is based on the use of dynamic characteristics of soils (modulus of elasticity, shear modulus, Poisson's ratio), studied by seismic and microseismical methods before and after the completion of the pile field. The results of the seismic method on the velocities of elastic waves make it possible to identify soil layers with characteristic of dynamic stiffness, as well as to check their damping properties. If strong seismic movements of the soil are possible on the site, then further data processing for a given intensity of seismicity of the construction site is performed. The experimental data are applied to a foundation direct physical numerical model.

In accordance with (Ilyichev et.al. 1983), only the integral shear stiffness of concrete piles without soil stiffness is taken into account for the calculated depth to which the resistance of the soil on the side surface is not taken into account. The shear stiffness of this layer is defined as the sum of the moments of inertia of single bent piles without taking into account the contribution of the bending component according to Steiner, which is equal to the product of the moment of interference of the section of a single pile by the ratio of the cross-sectional area of the pile to the area of the elementary pile cell. At the same time, in the plane of the pile raft, in order to take into account, the effect of the separation of piles in the plan, an additional connection of the final torsional stiffness in two vertical planes is added to the head of each pile (see Figure 6):

$$C_{\varphi} = \frac{E(I_1 - I_2)}{B}, \tag{6}$$

where E is the elastic modulus of a concrete pile; B – the width of the pile cell; I_1, I_2 - the moments of inertia of a pile, group of piles, accounting the Steiner component and without it.

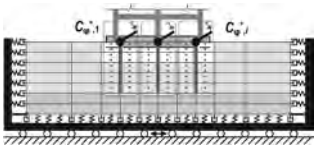

Figure 6. Diagram of a dynamic pile cell.

The following layers of the pile-reinforced soil mass along the perimeter of the pile raft are considered as reduced rigidity in accordance with the lithological structure of the base to the level of the bottom of the piles. The last underlying layer to a depth equal to half the length of the piles, by analogy with the circular cylindrical shear model according to (Fedorovsky V.G. et.al. 2003), is considered as a soil with dynamic modulus, determined by seismic methods.

It should be noted that not in all cases large direct physical models of the pile foundation are necessary (Nuzhdin, Mikhaylov, Yankovskaya, 2019a). If the analysis still indicates the need for the soil-structure interaction analysis, then the rules for constructing direct physical models of the foundation has been published earlier (Nuzhdin, Mikhaylov, Voskresenskiy, 2019b).

3 CONCLUSIONS

The considered complex numerically analytical model of a pile foundation make it possible to implement a universal finite super-element that changes its properties depending on the size of the foundation and the type of impact. The axisymmetric model of a volumetric body of rotation proposed by the authors allows displaying a detailed picture of the stress-strain state of a pile, both single, as part of a small group, and as part of a pile field or a combined pile-slab foundation.

Under static conditions, the rigidity of a horizontally loaded pile in any type of foundation can be represented as a beam on an elastic base. The solution of the differential equation can be performed both numerically and by the finite element method, with the determination of equivalent stiffness at the level of the pile head or at the corresponding nodes along the length of the shaft axis of a discrete pile.

Dynamic impacts always affect the foundation, which is already experiencing deformations from constant and prolonged loads. The approach proposed by the authors makes it possible to take into account the genetically nonlinear conditions of the formation of the stress-strain state of the pile foundation within the framework of the universal numerical-analytical model of the pile. After the perception of horizontal static horizontal loads by piles in the form of a beam on an elastic base, proceed to the integral dynamic rigidity of the pile field, determined on the basis of geophysical studies by seismic methods. This can be done both by uniformly lowering the horizontal coefficients of the bed along the lateral surface of discrete piles by changing the coefficient α, and by lowering the equivalent bending finite stiffness at the level of the pile heads.

Segmental retaining wall monitoring technique using single camera system with various conditions

Y.S. Ha, M.V. Pham & Y.T Kim
Pukyong National University, Busan, Republic of Korea

ABSTRACT: Various types of Segmental Retaining Wall (SRW) are widely used worldwide for land use in slope areas. Inspections are periodically performed on the retaining wall, and various studies have been conducted to analyze the behavior of the retaining wall according to load and rainfall. However, the collapse of SRW continues to occur, and most collapses of SRW are attributed to facing displacement and settlement caused by water pressure and earth pressure. In this study, the behavior of SRW was monitored from a single camera system consisting of monocular vision and feature matching considering various conditions such as noise and brightness in the image. Performances of image registration and behavior calculation were evaluated from the results of several experiments. Behavior measurement error in controlled conditions was distributed within 1.89mm, and RMSE and MRE were 1.22 mm and 3.68%, respectively.

1 INTRODUCTION

In order to secure the stability of segmental retaining wall (SRW), the agency in charge manages SRW according to the maintenance guidelines. A general safety inspection is periodically carried out at least two times a year, and a precision safety inspection is conducted once every 1-3 years, according to the Special Act on the Safety and maintenance of Public Structures to inspect the physical condition of SRWs (KALIS, 2019). In addition, Koerner and Koerner (2018) investigated the collapses of 320 geosynthetic reinforced mechanically stabilized earth walls around the world, the primary causes of the collapses were inadequate or improper design and/or construction. The major design inadequacy appears to be the use of fine-grained soils in the backfill and the lack of proper drainage systems. The major construction inadequacy is the use of fine-grained silt and clay as backfill soils and inadequate placement and compaction. In addition, the collapse of SRW continues to occur owing to various causes such as poor drainage systems, inadequate compaction of backfill material, insufficient length of reinforcement, and problems in design and construction.

In this study, a single-camera monitoring system was developed to monitor displacements occurring in individual blocks within SRW under various conditions. And the monitoring performance for SRW in laboratory conditions was evaluated, and the monitoring performance for SRW was analyzed considering the illuminance change that may occur in the field.

2 EXPERIMENT

2.1 *Laboratory experiment*

The laboratory experiment was performed preferentially to evaluate the matching and displacement calculation performance under controlled conditions in a laboratory environment. Figure 1a shows an experimental SRW (width: 650 mm, height: 270 mm) made of 121 blocks. Figure 1b shows the experimental setup, consisting of SRW blocks, a camera, and a total

DOI: 10.1201/9781003299127-385

station. The camera was installed at a position (θ_x = 43°, D = 1267 mm) in the range of incident angles (20–70°) suggested through the pilot-phase experiment. Four steps of facing displacement and settlement were generated step by step using the displacement generator under the structure.

The displacements were calculated by matching and analyzing the images of the evenly distributed 10 target blocks (red boxes in Figure 1a) taken before and after the behaviors. The matching performance was evaluated based on repeatability, matching score, number of inlier matching features, and mTRE. The displacement calculation performance was evaluated by comparing the reference displacements of the 10 parts, which were measured from the total station. The correlation between the matching and displacement calculation performance for the 10 parts was also analyzed.

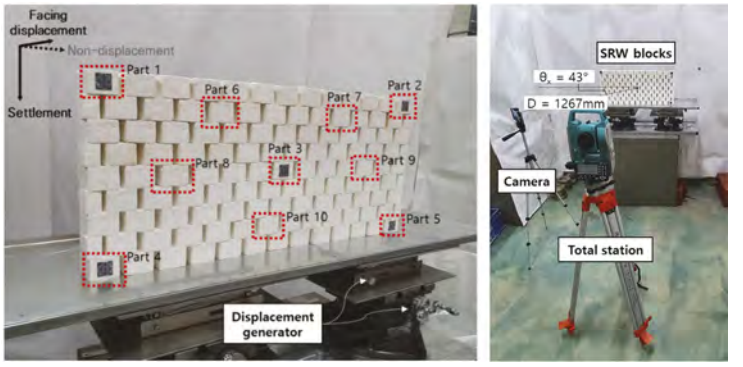

Figure 1. Laboratory experiments: (a) Monitoring targets for detection and tracking behavior, (b) experimental setup of camera and total station.

2.2 *Laboratory experiment with different illuminance*

In the case of short-time monitoring of SRW, there is no significant change in illuminance and position of the light source. However, when it is installed in the field and monitored for a long time, various changes in the SRW image occur, such as a change in illuminance and a change in the position of the light source according to the time change. The purpose of this study is to evaluate the performance of single-camera monitoring system matching and displacement calculation for illuminance change. Figure 2a shows the distribution of illuminance measured for one day in Busan in October. At noon when the sun rises vertically in the sky, it becomes bright up to 75,500 lx and maintains the brightness of over 50,000 lx even with obstacles such as clouds. In a location without illumination at night, it converges to 0 lx with or without moonlight. But SRWs have streetlights installed around them. Therefore, the illuminance was measured in the direction perpendicular to the ground, such as the facing of the retaining wall, at a distance of 5.5 m (2 lanes of road) from the street lamp. The illuminance of 36 lx was maintained in the state of the street lamp illuminating regardless of dawn and night. Figure 2b shows the experimental setup with different illuminances. The same block, total station, and camera were used in the laboratory experiment, and a floodlight was used for illuminance control. The camera was installed at a position (θ_x = 48°, D = 1, 160 mm). Facing displacement was generated using the displacement generator under the structure. In order to minimize the effect of changes in the position of the floodlight, the light on the front of the fixed floodlight was gradually blocked and the illuminance was adjusted. The detection and displacement calculation performance of the block was evaluated by generating a facing displacement for each illuminance. The displacements were calculated by matching and analyzing the images of the evenly distributed 10 target blocks taken before and after the behaviors.

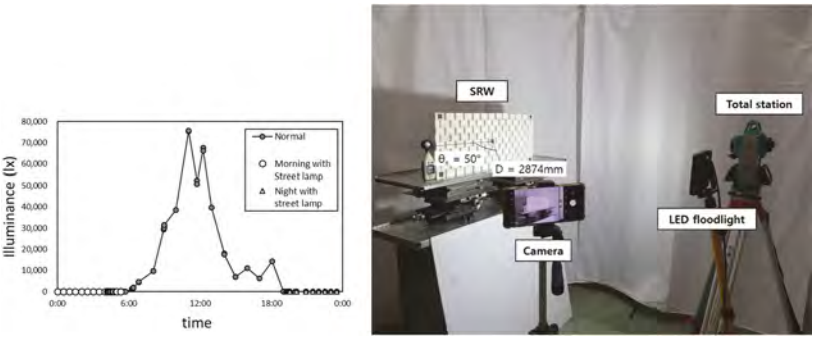

Figure 2. Experimental set up with different illuminance (a) daily illuminance distribution, (b) experimental setup.

3 RESULT AND DISCUSSION

3.1 *Laboratory experiment*

Figure 3 shows an example of the blocks trained and detected for the laboratory experiment. 9 images were used for validation, and 2 images are shown in the figure. Each column represents the original image, ground truth, and predicted mask. Although blocks could not be detected for some sections for each image, laboratory SRW blocks were detected with the precision of 92.28%, recall of 92.51%, and f1 score of 92.31%. Figure 4 shows the results of calculating the behavior based on the detected blocks. In the case of using mask R-CNN, since transformation by behavior is not considered, the error does not increase significantly for each behavior step. In addition, the performance is excellent with an error within 2.12mm. Figure 4b shows the MRE of ATs and NTs for the laboratory experiment. The MRE of NTs were smaller than those of ATs, sheet target was attached in front of ATs which was disturbed to detect the blocks.

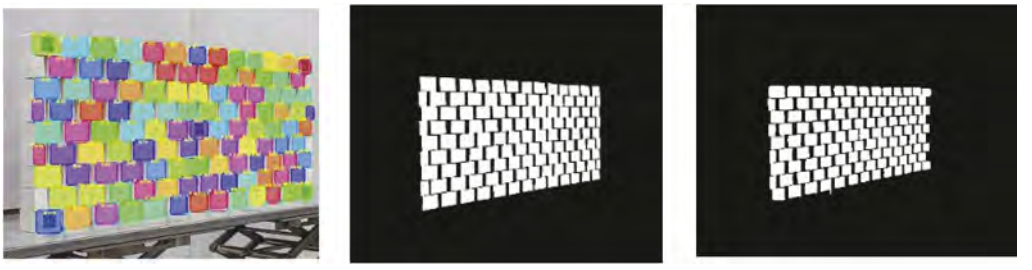

Figure 3. An example of the blocks trained and detected for the laboratory experiment: (a) detected image, (b) trained mask, (c) detected mask.

3.2 *Laboratory experiment with different illuminance*

Figure 5 shows an example of training and detection blocks for an experiment with different illuminance. Each column represents the original image, ground truth, and predicted mask, and the precision, recall, and f1 score for 9 images used for validation are shown in Table 4.6. In some cases, blocks could not be detected for some sections of each image, but laboratory SRW blocks were detected with the precision of 93.19%, recall of 95.10%, and f1 score of 94.08%. Figure 6 shows the results of calculating the behavior based on the detected blocks. Mask R-CNN shows similar performance in all illuminances because it detects blocks according to the trained target illuminance by changing the illuminance. However, in the case of the minimum value, it tends to gradually decrease as the illuminance increases, which means that detection performance can be excellent in images with high illuminance. The highest error for each illuminance occurs largely in part 1, 2, 4, and 5, and it is located at the corner of the

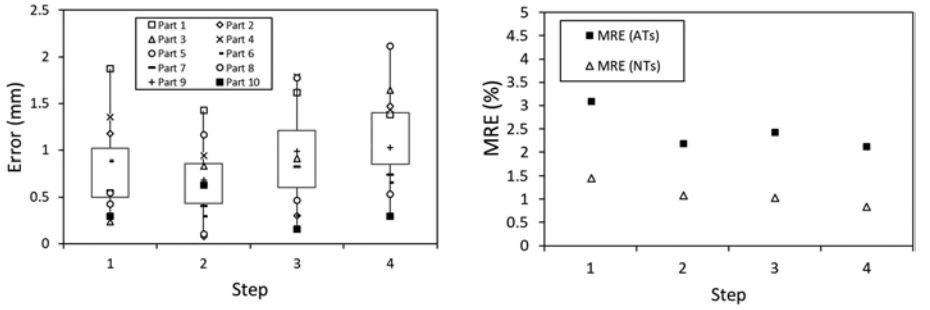

Figure 4. Results of displacement calculation error for laboratory experiment: (a) error, (b) MRE.

SRW structure, and detection performance is poor. MRE was distributed within 1.43 %. The block existing inside the structure, which is not at the edge of SRW, showed excellent performance with an error within 1.68mm despite the change in illuminance.

Figure 5. An example of training and detection blocks for an experiment with different illuminance: (a) detected image, (b) trained mask, (c) detected mask.

ABSTRACT: In this study, a large-scale box shear apparatus was improved to evaluate shear strength of coarse-grained materials. Interface friction problem occurred between specimen and inner side of shear box was successfully reduced by improvement of the box shear apparatus. The improved large-scale box shear apparatus was applied to evaluate shear strength of two different coarse-grained materials. Triaxial compression tests for both materials were also conducted in CD condition to compare with the box shear tests. It was found that the Interface friction caused by dilation of specimen affected shear strength of the coarse-grained materials and should not be ignored. The results (shear strength) obtained from the box shear tests are almost the same as the results of triaxial compression tests. It was revealed that the improved large-scale shear box apparatus can be used to evaluate accurately shear strength of coarse-grained materials.

1 INTRODUCTION

The box shear test is one of several direct shear test methods, and it is superior compared with the triaxial compression test because of the following reasons. (1) The structure of the apparatus is simple, and the test method is easy. (2) The stress state on the shear plane should be clear. (3) It is possible to perform tests under low confining pressure conditions. (4) There are no test restrictions, such as the self-sustaining limit of large specimens, even for coarse-grained materials. However, in the conventional large-scale direct shear test apparatus for coarse-grained materials such as rockfill dam materials, it has been reported that owing to structural problems of the test apparatus, the obtained shear strength shows an excessive value compared with the triaxial compression test result; for example, the internal friction angle ϕ shows a maximum difference of about 15° (JGS 1986). It has been proposed that the main reason for this is that because the vertical displacement of the shear box is constrained in the direct shear test (constant-pressure test), there is friction (interface friction) between the specimen and the inner surface of the shear box owing to positive dilatancy during shear test (Takada & Yunoki 1984, JGS 1986, Hongo et al. 1995). However, this problem has not been solved from a practical perspective, and the current situation is that the direct shear test is not actively used.

Many studies have been conducted to determine the effects of interface friction using small- and medium-sized single-shear tests (Takada & Yunoki 1984, Hongo et al. 1995, Shibuya 1995, Oshima et al. 1996, JGS 1997, Ishikawa et al. 2009). A summary of past research is as follows.

Takada & Yunoki (1984) developed a medium-sized box shear test (specimen (rectangular parallelepiped) dimensions: length 30 cm × width 20 cm × height 12 cm) for coarse-grained materials. This test apparatus is designed to move the upper shear box in the shear direction,

DOI: 10.1201/9781003299127-386

and it enables two types of tests: (1) the "pressure plate fixed-type" test that integrates the penetration shaft (loading plate) and the lower shear box; and (2) the "pressurized plate penetration type" test, in which the penetration axis penetrates the lower shear box. In the case of the pressure plate fixed-type test, because the shear box and the specimen move together, the effect of interface friction is negligible. By comparing the results for coarse-grained material (maximum grain size 15.9 mm) from both types of testers, it was noted that the shear strength is overestimated because of the effect of interface friction during specimen expansion, and that the shear strength is underestimated during specimen contraction.

Next, Oshima et al. (1996) installed two parallel plate load cells between the upper shear box and the vertical reaction roller, and they made improvements that enable the measurement of the change in upper vertical stress (σ_U) due to the occurrence of positive dilatancy (specimen (cylindrical) dimensions: diameter 12 cm × height 4 cm). Here, to consider the effect of interface friction, we conduct (1) a test in which the vertical stress σ_L at the bottom is constant in the conventional method while measuring σ_U (conventional constant pressure test), and (2) a test (true constant-pressure test) to control the vertical stress (σ_L) at the bottom so that σ_U is constant in order to verify that the strength constant of sand (maximum grain size 0.425 mm) could be obtained with good accuracy, and this was adopted in the Japanese Geotechnical Society Test Standard (JGS 1997) (Method for consolidated constant-pressure direct box shear test on soils JGS T 561-1997).

In addition, Ishikawa et al. (2009) improved the structure of a Mikasa-type direct shear test apparatus (Mikasa 1960) (size of specimen (cylinder): diameter 6 cm × height 2 cm) to prevent the generation of interface friction. This test apparatus is equipped with two independent air jacks and load cells between the upper surfaces of the upper shear box, and it has a structure that maintains a strictly constant pressure by slightly moving it up and down while keeping the upper shear box horizontal (the structure is the same as the "pressure plate fixed-type" test proposed by Takada & Yunoki (1984)). This test apparatus is capable of conducting tests under low confining pressure conditions. It is reported that the results of Toyoura sand (maximum grain size: 0.425 mm) and the results of the triaxial compression test obtained using this device were almost the same.

In this study, based on the above-mentioned previous studies, a large-scale box shear apparatus (specimen (cubic) dimension: length 30 cm × width 30 cm × height 20 cm) with reducing the interface friction was improved. Actual rock material and crushed stone material (maximum grain size 37.5 mm) were used in this study. Triaxial compression tests (CD test, specimen (cylindrical) dimensions: 15 cm in diameter × 30 cm in height) were also conducted. The effect of interface friction in a large-scale box shear test, the comparisons between results of box shear tests and triaxial compression tests were compared and discussed.

2 TEST MATERIALS

The materials used in the tests were two types of grain size adjustment materials (maximum grain size: 37.5 mm), rock material (referred to as Material No.1), and C-40 crushed stone (referred to as Material No.2). Figure 1 shows the grain size distribution curves of the materials.

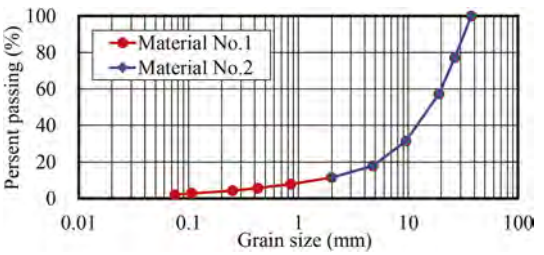

Figure 1. Grain size distribution curve.

3 IMPROVEMENT OF LARGE-SCALE BOX SHEAR TEST APPARATUS

Figure 2 shows the outline of the structure of the improved large-scale box shear test apparatus. This apparatus is a movable-type lower shear box. To prevent the generation of the interface friction, a vertical roller is installed between the upper shear box and the reaction plate, and the vertical movement of the upper shear box is made possible by following the volume change of the specimen that occurs during the shear test process.

In addition, hydraulic hand pumps (see Figure 2) are placed at both ends of the horizontal adjustment beams attached to the upper shear box to apply a moment in order to keep the upper shear box horizontal during shear test. Furthermore, in order to confirm the effect of interface friction on the shear strength evaluation of coarse-grained materials such as rock materials, we compared the conventional box shear test method in which the upper shear box is fixed in the vertical direction (see Figure 3, hereinafter referred to as "fixed-type") with the method in which the upper shear box can be moved vertically by using the test apparatus improved by the above method (hereinafter referred to as "movable-type"). With this test apparatus, it is possible to perform "fixed-type" or "movable-type" tests by respectively fixing or not fixing the upper shear box. Next, triaxial compression tests were performed under the same specimen conditions, and the shear strength characteristics were compared with the results of the movable-type large-scale box shear test.

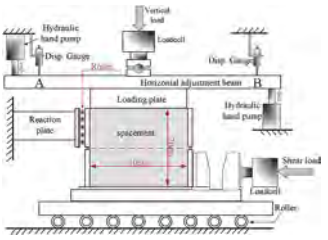

Figure 2. Schematic diagram of movable-type large-sized box shear test apparatus.

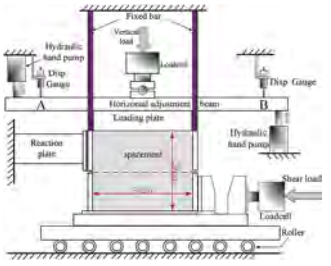

Figure 3. Fixed-type large-scale box shear test (conventional type).

4 TEST CASES AND CONDITIONS

The test conditions are as shown in Table 1. The specimens (cubic shape, dimensions: length 30 cm × width 30 cm × height 20 cm) for the large-scale box shear test were air-dried for both materials No.1 and No.2. The specimens were prepared by using compaction method in three layers so that the dry densities were ρ_d = 1.997 g/cm^3 and ρ_d = 2.004 g/cm^3 (both with degree of compaction (D_c) = 95%), and also so that the shear plane does not coincide with the joint plane.

For comparison, a medium-sized triaxial compression test (CD test) specimen (cylindrical with a diameter of 15 cm and a height of 30 cm) was also prepared by five-layer compaction with the same dry density as above.

5 HORIZONTAL AND VERTICAL STRESS CONTROL OF THE LOADING PLATE

The loading plate horizontal control of this test apparatus monitored the movement of the displacement gauge attached to the horizontal adjustment beam shown in Figure 2 and manually controlled the hydraulic hand pump. Figure 4 shows the relationship between the displacement error of the leveling beam and the shear displacement that was measured during the test. Here, the displacement error is the difference between the vertical displacement of point A and point B measured at both ends of the horizontal adjustment beam shown in Figure 2 (displacement error = point B displacement – point A displacement). When the value of the displacement error is positive, it means that point A falls and point B rises, and vice

Table 1. Test cases and conditions.

Test name	Movable-type large-scale box shear test	Fixed-type large-scale box shear test	Medium triaxial compression test
Specimen preparation	Compaction method	Compaction method	Compaction method
Specimen density (Dc = 95%)	Material No.1 ρ_d = 1.997 g/cm^3 Material No. 2: ρ_d = 2.004 g/cm^3	Material No.1 ρ_d = 1.997 g/cm^3 Material No. 2: ρ_d = 2.004 g/cm^3	Material No.1 ρ_d = 1.997 g/cm^3 Material No. 2: ρ_d = 2.004 g/cm^3
Test conditions	Constant pressure, unsaturated	Constant pressure, unsaturated	CD test, saturated
Shear rate	1.3 mm/min	1.3 mm/min	0.5%/min
Normal stress/Confining pressure (kN/m^2)	σ_n = 50, 100, 200, 300	σ_n = 50, 100, 200, 300	σ_3 = 50, 100, 200

versa when it is negative. The distance between the displacement gauges installed on the horizontal adjustment beam is 236 cm.

In some cases, the displacement error shown in Figure 4 momentarily reached ±0.8 mm, but it generally remained within ±0.5 mm (inclination angle is within ±0.005°), and it is determined that there is no problem with the accuracy of horizontal control. In addition, Figure 5 shows an example of the relationship between the controlled normal stress and shear displacement (Material No.2, unsaturated condition) in a movable-type large-scale box shear test under constant pressure conditions. The control of the normal stress is within the range of ±0.5 kN/m^2 to ±1 kN/m^2 (0.5% to 2%) of the set value of the normal stress, and it can be seen that a nearly constant pressure state is maintained.

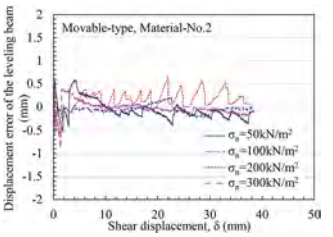

Figure 4. Result of horizontal control of loading plate (movable-type).

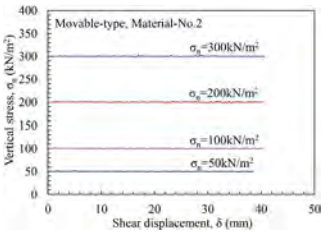

Figure 5. Relationship between controlled vertical stress and shear displacement (movable-type).

6 INFLUENCE OF INTERFACE FRICTION

In order to confirm the effect of interface friction, the movable-type large-scale box shear test and the conventional fixed-type large-scale box shear test were conducted under the same conditions using two materials, and a comparative study was carried out to determine parameters such as the condition of the specimen after the test, the shear strength characteristics, and the dilatancy characteristics.

Figure 6 shows the conditions of fixed-type and movable-type specimens after the large-scale box shear test.

For the fixed-type shown in Figure 6(a), it was confirmed that the gap between the upper and lower shear boxes remains unchanged, and that the upper surface of the specimen expanded beyond the top of the upper shear box owing to the volume change (positive dilatancy) on the expansion side that occurred during shear test. Therefore, as shown in Figure 7(a), it can be inferred that the occurrence of interface friction between the inner surface of the shear box and the specimen is the cause of the increase in vertical stress, which significantly affects the shear strength. However, Figure 6(b) shows the state of the specimen after shear test using the improved movable -type large-scale box shear test. Unlike the conventional fixed-type test, the upper surface of the

specimen after shear test did not expand beyond the upper edge of the upper shear box, and the shear gap opened with positive dilatancy. Therefore, it is clear that the part of the specimen above the shear zone was integrated with the upper shear box and floated in an upward direction.

Figure 8 shows a comparison of the relationship between shear stress and dilatancy for fixed-type and movable-type in the case where σ_n = 100 kN/m^2. From the figure, in the fixed-type test, the vertical displacement (positive dilatancy) generated during shear test is smaller than in the movable-type test because the specimen is constrained by interface friction. As a result, it can be interpreted that the shear stress of the fixed-type is larger than that of the movable-type test.

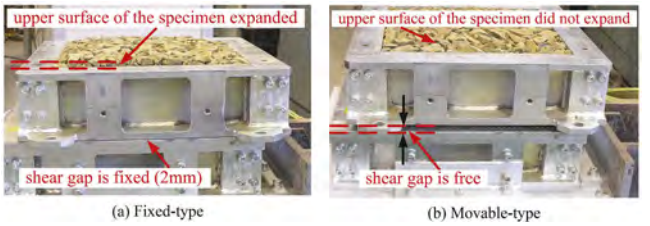

Figure 6. Comparison of specimen status after testing.

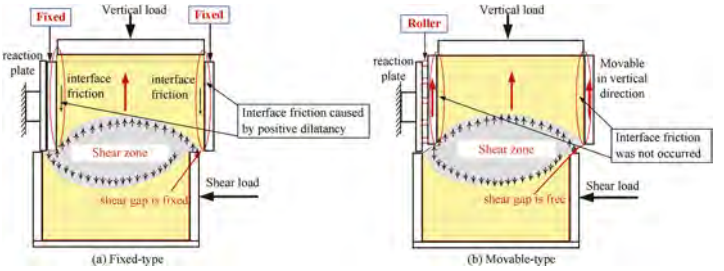

Figure 7. Mechanism of interface friction occurring during shearing.

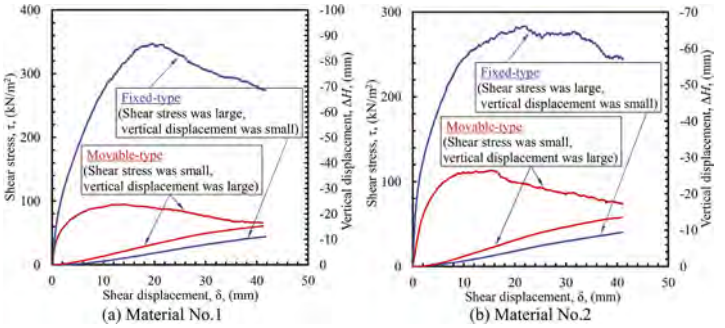

Figure 8. Comparison of shear processes.

7 COMPARISON OF TEST RESULTS

Figure 9 compares the shear strength for the fixed-type and movable-type tests. Figure 9(a) is the result of Material No.1, and Figure 9(b) is the result of the Material No.2. The results of the triaxial compression test are also plotted in the figure. The triaxial compression test results were organized as normal stress $\sigma_n = (\sigma_1+\sigma_3)/2 + (\sigma_1-\sigma_3) \times \cos 2\alpha/2$ and shear stress $\tau_n = (\sigma_1-\sigma_3) \times \sin 2\alpha/2$. Here, $\alpha = 45° + \phi_0/2$ and $\phi_0 = \sin^{-1}\{(\sigma_1-\sigma_3)/(\sigma_1+\sigma_3)\}$.

It can be seen that the proposed movable-type test results (shear strength) are almost the same as the triaxial test results. However, the fixed-type test results are considerably larger than those of the movable-type and triaxial tests (maximum c is about 10 times larger and ϕ is about 15° greater).

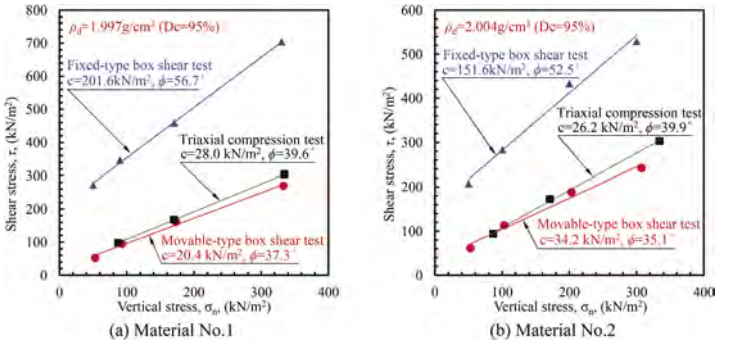

Figure 9. Comparison of test results.

8 CONCLUSION

Because the improved movable-type large-scale box shear test can obtain almost the same shear strength as the triaxial compression test, this test method was considered to be appropriate. In addition, the improved box shear test can be performed under low confining pressure, and it is possible to conduct the test using materials with a maximum grain size exceeding 63 mm. Therefore, the combination of uses of triaxial test and box shear test, it is expected that the evaluation of the shear strength of coarse-grained materials can be performed more rationally in the future. Furthermore, it is believed that it can also be used in some countries, where it is difficult to conduct large-scale triaxial tests.

Evaluation of the work of driving piles under dynamic loads

G.T. Tleulenova, A.R. Omarov, A.S. Tulebekova & G.K. Tanyrbergenova
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

R.K. Bazilov
LLP "KGS-Astana", Astana, Kazakhstan

ABSTRACT: The aim of the work is a complex of studies of the operation of driven piles in the presence of loads. To achieve this goal, the following tasks were set: to analyze theoretical and experimental data in the field of driven pile research; carrying out a calculated assessment of the capabilities of driven piles according to regulatory documents; comparison of comparative analyzes of indicators of bearing capacity of driven piles based on test results.

Keywords: pile, normative standard, tests, bearing capacity

1 INTRODUCTION

1.1 *Construction site*

The purpose of the tests is to determine the pile driving depth and the pile bearing capacity. The dynamic pile load tests on preliminary C70.30-8 driven piles and C70.30-6 working piles on the construction site of the Project "Construction of multifunctional family-entertainment and tourist area" in the city of Astana, were carried out by specialists of KGS-Astana LLP.

Driving of preliminary C70.30-8 piles in the amount of 21 pieces subjected to dynamic tests was carried out by KGS-Astana LLP on January 28 to February, 25, 2021. Driving of working C70.30-6 piles in the amount of 7 pieces, also subjected to dynamic tests, was carried out from January 16 to January 25, 2021.

When driving preliminary piles, a Junttan PM-20 pile-driving rig was used with an HHK-5A hydraulic hammer with a shock mass of 5000 kg with a cap, and a weight of 835 kg. When driving working piles, Junttan PM-25 pile-driving rigs were used with hydraulic hammers HHK-7A and HHK-9A with a shock mass of 7000 kg and 9000 kg, with caps weighing 990 kg and 1160 kg, respectively.

2 RESEARCH METHOD

2.1 *Dynamic pile load testing*

Characteristics of the tested piles: C70.30-8, 7.0 m long, section 30x30 cm. Absolute elevations: soil surface: 345.66m; the bottom of the piles according to the project: 336.325m.

Dynamic pile load tests are carried out in order to determine the possible depth of their penetration and changes in the value of refuses, as well as to assess the bearing capacity of the piles. Dynamic pile load tests should be performed in accordance with the requirements. The piles will be driven by a Junttan HHK-5A hydraulic hammer with a hammer weight of 5000kg and a cap with a weight of 835kg. Preliminarily, the pile surfaces are marked in graduations with paint every 1m, and every 0.1m on the last meter.

DOI: 10.1201/9781003299127-387

During the dynamic pile load testing the following types of work are carried out:

- delivery of piles to the point of driving,
- while observing measures that exclude breakages and cracks in the pile body;
- the customer defines and produces a geodetic breakdown of pile tests;
- test piles are driven to the design elevation or to their possible depth of penetration.

Testing of preliminary piles, stage 1:

- preliminary pile marking from the tip every 1m to 5m, then 10cm to the expected possible depth of penetration;
- moving the pile driving unit to the place of test pile driving;
- installation of piles at the point of their driving and driving piles with an impact energy that ensures penetration in dense soils, to the maximum depth;
- calculate the number of hammer blows for each meter of pile penetration, and on the last meters - for every 10 cm of penetration.

Testing of preliminary piles, stage 1: the 'rest' of the piles is maintained for 3 to 6 days; before after-driving, a millimeter measuring tape is attached to the driven piles;

- pile after-driving is carried out by single blows with the same equipment that was used during driving,
- the drop height of the striking part of the hammer during after-driving must be constant;
- after-driving is carried out with two consecutive counts of 3 and 5 blows.

The largest average refusal is taken as the estimated pile refusal; pile penetration is recorded using a measuring tape with an accuracy of 1 mm; in the process of pile driving, an observation log shall be kept, upon completion of the tests the pile test report shall be filled in.

3 TEST RESULTS AND DISCUSSION

Table 1 presented results of dynamic load test of construction site.

(*Continued*)

Table 1. (*Continued*)

	Pile number	Pile mark and section, cm	Abs. elevations of the soil surface near the pile, m	Depth of driving piles into the soil, m	Particular value of pile ultimate resistance, (t)	Bearing capacity of piles	Design allowable pile-bearing load, taking into account the reliability factor γ_k=1.4, (t)
17	P3 TP4	C7-30, 30x30			36.9		
18	P3 TP5	C7-30, 30x30			56.7		
19	P3 TP6	C7-30, 30x30			68.2		
20	P3 TP7	C7-30, 30x30			80.7		
21	P3 TP9	C7-30, 30x30			80.7		

The bearing capacity of the piles was determined on the basis of statistical processing of test results in accordance with GOST 20522-96.

4 CONCLUSION

The bearing capacity of the piles according to the results of dynamic tests was 48.7 tons for Parking Zone P1; 70.4 tons for Parking Zone P2; 42.7 tons for parking Zone P3. The design allowable pile-bearing load should be taken with consideration of the reliability factor γ_k = 1.4 SP RK 5.01-103-2013 Pile foundations should be taken equal to: 34.8 tons for Parking Zone P1; 50.3 tons for Parking Zone P2; 30.5 tons for parking Zone P3.

LLP "KGS-Astana", Nur-Sultan, Kazakhstan

ABSTRACT: The paper presents discussions of the bearing capacities of precast concrete piles from construction site of the Construction of multifunctional family-entertainment and tourist area in the city of Nur-Sultan, Kazakhstan. According to the design drawings construction site was planned to be installed by precast concrete piles. PCPs were composed with cross-section of 30 cm × 30 cm with the length of bottom segment 7.0m. In paper presented in-situ static vertical loading tests on C7-30 driven piles were carried out on the construction site of the Parking Zone P1, P2 of the Project 'Construction of multifunctional family-entertainment and tourist area in the city of Nur-Sultan, from 05 to 13 February, 2021. The permissible load on the pile, taking into account the safety factor γ_k =1.2 in accordance with Standard should be taken equal to – 681 kN, 800 kN respectively.

Keywords: load-settlement, in-situ SLT tests, pile

1 INTRODUCTION

1.1 *Construction site*

In-situ static load tests on C7-30 driven piles on the construction site of the Project 'Construction of multifunctional family entertainment and tourist area in the city of Nur-Sultan, were carried out by specialists of KGS-Astana LLP according to the Agreement with Renaissance Construction JSC.

Characteristics of the tested piles: Driven pile C7-30, section 30x30 cm, length 7.0 m (Figure 1).

Figure 1. Mounting kentledge system.

DOI: 10.1201/9781003299127-388

Table 1 presented absolute elevations of piles P480, P1210.

Table 1. Absolute elevations.

Pile number	P480	P1210
- soil surface at the pile	345.66	345.66
- pile heads	346.36	346.36
- pile bottom	339.36	339.36

Transportation, installation of the test and loading stand and cargo was carried out from 04.02.2021 to 11.02.2021.

2 RESEARH METHODS

2.1 *Equipment and devices*

Testing and loading stand. Support structure for the reception of reactive forces: main beam, support platform and load piles. Hydraulic jack. Loading for testing with static vertical driving loads shall be performed with an Enerpac CLS2006 185 ton hydraulic jack. Pressure gauge. The pressure shall be recorded by a MA100VU100 type pressure gauge with a graduation rate of 20 bar (kgf/cm2) up to 1000 bar (kgf/cm2).

Displacement measuring sensors. Pile displacements shall be measured by four digital electronic converters of 028DG1, 028DG2 and 028DG3 type. Digital dynamometer. The load shall be recorded by a digital Load Cell type dynamometer connected to the SLT2 system. Pumping station. The hydraulic jacks are pressurized with a P462 hand pump. Reference system. A steel equal angle 63x63x5, 4 m long, fixed to the reinforcement, driven into the ground to a depth of at least 1.0 m shall be used for the reference system. SLT2 monitoring systems. The instruments of SLT2 static load test monitoring system are specially designed to monitor static load tests and report data in accordance with Eurocode 7.

Figure 2. Assembling loads during mounting kentledge system.

This system allows monitoring the static load tests from a distance of up to 25 m, without the need for personnel to approach potentially hazardous system components that are under high load. The pile load was created using an Enerpac CLS 2006 185-ton hydraulic jack with an Enerpac P462 pumping station, resting against a test and loading stand, weighing 120.0

tons. The load was recorded with a pressure gauge up to 1000 atm. (kgf/cm2) of the MA100VU100 type with a graduation rate of 20 atm. (kgf/cm2) and a digital dynamometer of the Load Cell type connected to the SLT2 monitoring system (Figure 2).

The movement of each pile was measured by four digital electronic displacement transducers of 028DG1, 028DG2, 028DG3, 028DG4 type working in conjunction with SLT2.

The SLT2 system monitoring devices are specifically designed to monitor static pile load tests for the purpose of obtaining results in accordance with Eurocode 7 standards. This system gives an opportunity for controlling the static pile load tests at a distance of up to 25m. This system allows personnel (testers) to remotely monitor the pile settlement and the actual load on the pile, without approaching the potentially dangerous area of the test site structure, where the system is under high pressure and load.

3 DISCUSSION

These pile tests shall be carried out with static loads to establish the actual bearing capacity of the pile. A pile shall be loaded with a static vertical-driving, stepwise-increasing load, in accordance with the Table 2.

Table 2. Program of pile test.

Load step number	Loading per step		Total load:	
	kgf/cm2	kN	kgf/cm2	kN
1	40	104	40	104
2	40	104	80	208
3	40	104	120	312
4	40	104	160	416
5	40	104	200	520
6	40	104	240	624
7	40	104	280	728
8	20	52	300	780
9	20	52	320	832
10	20	52	340	884
11	20	52	360	936
12	20	52	380	988

The vertical load shall be brought to a value that causes the pile to move by at least 40 mm or to the maximum load provided for by this program (Figures 3 and 4).

Figure 3. Reference system with displacement transducers, hydraulic jack Enerpac CLS 2006, Load cell Comp load 100t.

Unloading of the tested piles shall be carried out in steps equal to the double loading steps, in accordance with the Table 3.

Table 3. General unloading pile.

Unloading step number	Unloading per step		General unloading	
	kgf/cm2	kN	kgf/cm2	kN
Unloading				
1	40	104	340	884
2	40	104	300	780
3	60	156	240	624
4	80	208	160	416
5	80	208	80	208
6	80	208	0	0

Figure 4. General view of the kentledge system with a container for test.

Strain gauge readings shall be taken immediately after each unloading step and observed after 15 minutes. After complete unloading (to zero), elastic displacements shall be monitored for 1 hour, with readings taken every 15 minutes.

In the course of the tests, a log of the established form shall be maintained, according to the test results, graphs of the dependence of the pile settlement on the load $S = f(p)$ and the change in the settlement according to the load steps $S = f(t)$ in time shall be plotted.

In the process of testing, in parallel with the electronic data collection by the SLT2 static load test monitoring system, a log of in-situ pile tests shall be maintained in accordance with GOST 5686-2012.

Table 4. Results of SLT of pile.

Pile	Pile cross section	Max applied	Displacement, mm	Bearing capacity, kN	Permission design load, kN
P480	30*30	936	40.62	818	681
P1210		988	40.56		

Table 4, Figure 5 presented results of piles P480 and P1210.

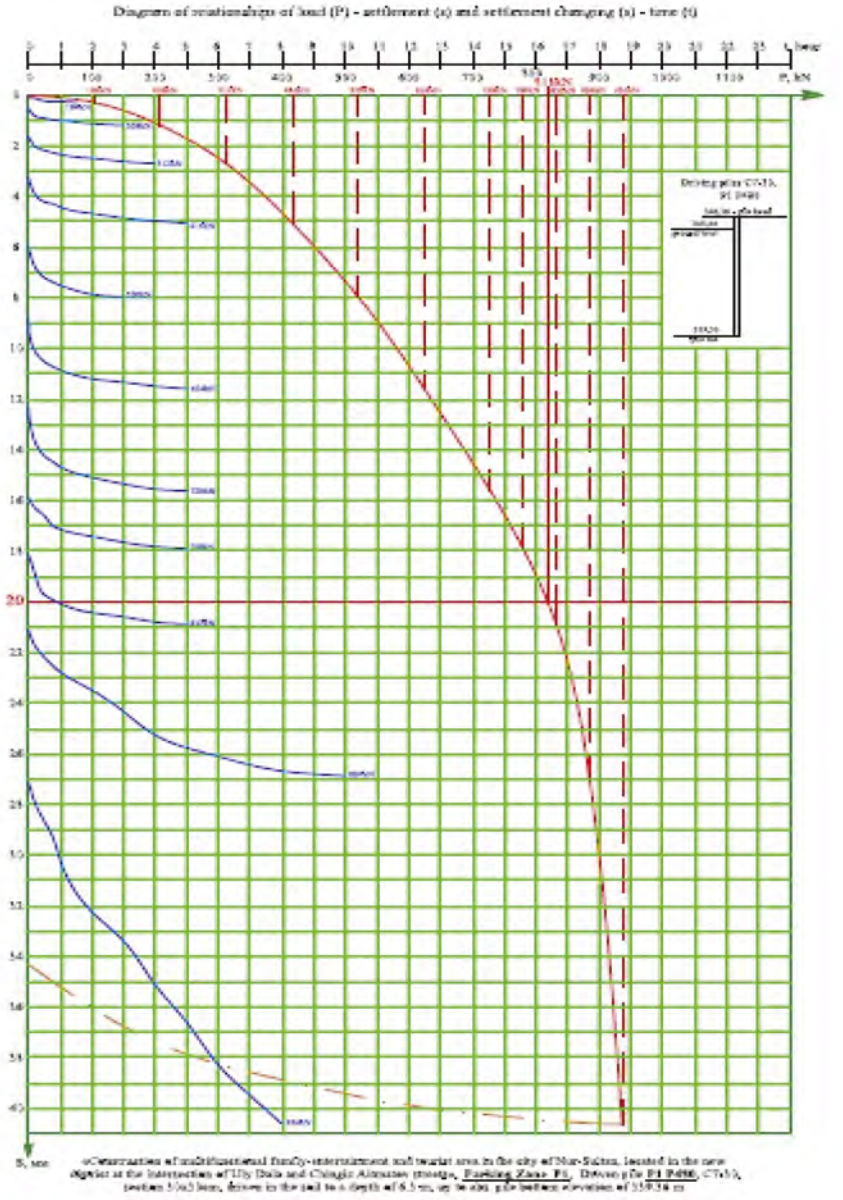

Figure 5. Results of SLT.

4 CONCLUSION

On the construction site of the Parking Zone P1 of the Project 'Construction of a multifunctional family-entertainment and tourist area in the city of Nur-Sultan, static tests of two C7-30 driven piles driven in the soil to a depth of 6.3m up to the abs. pile bottom elevation of 339.36 m were carried out from 05 to 13 February, 2021. The bearing capacity of the piles, according to the results of their static load tests at the above construction site, was 818 (Eight hundred and eighteen) kN. The permissible load on the pile, taking into account the safety factor γ_k =1.2 in accordance with Clause 4.4.1.11. SP RK 5.01-103-2013 'Pile foundations' should be taken equal to – 681 (Six hundred eighty-one) kN.

ABSTRACT: The natural climatic conditions of southern Kazakhstan are characterized by a geological structure, represented by deposits of macroporous and subsiding soils. Construction on these soils requires a set of measures to strengthen and improve mechanical properties. One of the hardening methods is deep mixing within the active compressible strata. However, the method is still limited in application. The main reason for the weak distribution of the method is the quality of the soil-cement column-column obtained by mixing and the effect of seismic action on its bearing capacity. It is the column that is the main element that increases the bearing capacity of the foundation soils. The article presents the results of a study of the physical and mechanical properties of columns obtained by deep mixing in subsidence loess soils in the south of Kazakhstan. The studies were carried out on samples taken from soil-cement columns from depths of 3 and 5 meters, in a natural and soaked state. The mechanical parameters were obtained by tests in uniaxial and triaxial compression devices. The dependences of the change in the mechanical parameters of the column material on the brand of cement, the degree of water saturation are obtained, and the properties of anisotropy are revealed. Based on the results of the research, calculations were made at the facilities of the city of Shymkent and recommendations were given on the use of reinforcing elements to increase the bearing capacity of weak foundations

1 INTRODUCTION

An important feature of the geological structure of the regions of the South of Kazakhstan is the distribution of weak macroporous soils. Such soils form mountain, foothill and counter surface deposits, which extend to a depth of 5 to 30 meters. Most often, by origin, such soils belong to alluvial deposits of the Middle Quaternary age, represented by loess-like sandy loams or loams. The latter belong to structurally unstable soils, especially in the case of active moisture and seismic loads. Both reasons are relevant for the regions of Kazakhstan, since in the foothill areas groundwater is distributed at a depth of 25-30 meters, but surface atmospheric and technogenic waters often weaken surface soils.

According to building codes, the use of subsidence soils as the foundations of structures is prohibited without the elimination of subsidence or special measures to strengthen and increase their bearing capacity. In some regions, there is a practice when soils are completely removed to eliminate subsidence, sometimes to a depth of 20-30 meters. Further, the pit was covered with the same soil with layer-by-layer compaction. However, when compacting such deep pits, compaction quality is very difficult to achieve.

Today, soil strengthening technologies, especially with the use of mechanization, have advanced far ahead (Nuzhdin,2000), (Mirsayapov,2017), (Shen,2008). Among them, the

*Corresponding author: khomyakov57@list.ru

DOI: 10.1201/9781003299127-389

direction of strengthening with reinforcing elements is developing most actively, among which it should be noted rolled wells filled with soil or concrete, jet-grauting technology, deep soil mixing, etc. In this article, we present some results of the application of deep mixing technology in Kazakhstan on the example of the city of Shymkent.

2 GEOLOGICAL CONDITIONS

In geomorphological terms, most of the territory of the city of Shymkent is represented by a hilly plain, crossed by river valleys and located within the ancient valley of the Sairamsu River. The surface of the site is relatively flat, with a slope to the northwest. The main natural waterways of the city of Shymkent is the river. Badam and Kochkarata with its branch - the Karasu rivers, as well as artificial watercourses-canals that cross the city of Shymkent in the general direction from east to west. Of the physical and geological processes in the region, a weak planar washout, erosional development of dens and subsidence phenomena are developed. The geological and lithological structure of the site involves alluvial deposits of the Middle Quaternary age, represented by loess-like loams and pebble deposits, overlain by a thin soil-vegetative layer and in places with bulk soil.

In the lower part of the geological profile, from a depth of 22.0-23.6 m, there is gravel soil with sand filler, with a content of up to 20-25%. The exposed thickness of gravel soil is 1.3-2.6 m. Table 1 shows a general view of the geological section and a selection of the main physical and mechanical properties of soils. 5 types of EGE have been identified.

EGE-1 - soil-vegetative layer; EGE-1a - bulk soil; EGE-2 - subsidence loam, occurring to a depth of 11.0-12.0 m; EGE-3 - subsidence loam, lying deeper than 11.0-12.0 m; EGE-4 - non-subsidence loam; EGE-5 - gravel soil with sandy aggregate.

3 MEASURES FOR STRENGTHENING THE SOIL OF THE BASE

The analysis of the geological profile allows us to say that the foundation soils have sufficient heterogeneity and weak physical and mechanical parameters. Over the entire thickness of EGE2 and EGE3, an almost chaotic change in depth of all parameters can be observed, and especially the

value of the initial settling pressure. There are large changes within the entire EGE2. There is some hardening towards the base of the layer, but then a decrease towards the top of the EGE3. The general trend of increasing the strength of the soil is observed only from a depth of 14-15 m from the surface. Starting from this depth, the value of the initial subsidence pressure steadily increases to 200-250 kPa and the value of the deformation modulus E increases to 7.0-10.2 MPa.

The recommended set of measures includes surface and deep hardening. Surface har dening includes the construction of a soil cushion, deep hardening - the use of wet deep mixing (DSM) technologies. Considering the above analysis of the geological structure, we believe that only the lower boundary of EGE3, EGE4 and EGE5 has sufficient bearing capacity. Since the thickness of the layer is small in terms of the geological structure in EGE3 and EGE4, then the strengthening elements of the overlying layers should be supported on EGE5.

The final constructive solution for the foundation of the buildings was adopted in the form of a soil cushion 1.5 meters thick from undrained soil. The pillow rests on an array, reinforced with DSM elements, 1.0 meters in diameter, made to a depth of 15 meters and supported by EGE5. Preliminary studies on the physical and mechanical properties of DSM are given below.

4 FIELD AND LABORATORY STUDIES TO DETERMINATE DSM PARAMETERS

DSM technology in Kazakhstan has a pioneer application. In this regard, studies were carried out to study the strength and deformation properties of soil-cement columns, arranged to strengthen the base. To obtain these data, experimental soil-cement columns were made in the city of Shymkent, from which, after gaining strength when reaching the age of 28 days from the moment of installation, test columns were excavated to a depth of 3 meters and cores with a diameter of 100mm, 50mm, 40mm were cut in horizontal and vertical direction for laboratory testing (Malinin, 2010).

Figure 1. General view of soil-cement column samples for core sampling .

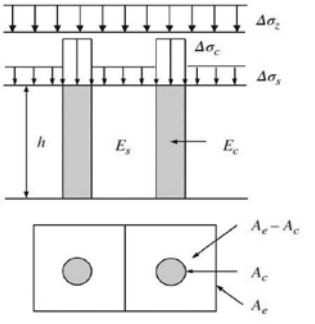

Figure 2. Scheme of the formation of a hardened soil array.

According to the test, cores taken in vertical and horizontal directions relative to the longitudinal axis of the column were examined to determine the physico-mechanical properties and possible anisotropy of the column material. The tests were carried out in accordance with the requirements of paragraphs 5.2 and 5.3 of GOST 12248-2010, Soils, "Methods for laboratory determination of strength and deformability characteristics." Uniaxial compression devices and a triaxial compression chamber were used for the tests.

The tests were carried out in the laboratory "Soil base and foundations" of KazNIISA and on the basis of the Faculty of General Construction of KazGASA. Core samples were taken at the facilities of Shymkent, Karatau district, Nursat residential area. Cores from experimental columns were taken in the vertical and horizontal directions, as shown in Figure 1. Vertical samples from the end of the columns, horizontal - with lateral drilling from a depth of up to 5.0m. The main purpose of the research is to determine the ultimate strength of the column material for uniaxial compression, the total deformation modulus and Poisson's ratio. The tests were carried out in the devices of uniaxial and triaxial compression, shown in Figure 3.

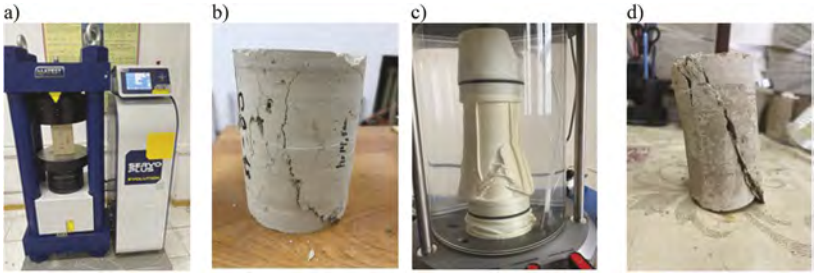

Figure 3. General view of the uniaxial compression device (a), the tested sample (b), the sample in the triaxial compression device (c) and the sample after destruction (d).

Tests were carried out separately for samples taken in the vertical and horizontal directions and for the natural and water-soaked states. The soaking of the samples was carried out by immersing the samples in water and keeping them for 2 weeks before the start of the tests. The main test results are given in Table 2.

Table 2. The results of determining the physical and mechanical parameters of soil-cement columns.

№	State	Core sampling direction	Density, kg/m^3	Ultimate strength for uniaxial compression, Rc, MPa		Deformation modulus,Eo, MPa	Poisson's ratio,ν

		vertical	1907,3	3,14	2,97		

5 METHOD OF CALCULATION OF BASES USING DSM

Currently, the method for calculating bases using DSM has its own features related to the working conditions of soil-cement columns in the soil base. It is known from international experience that when individual columns are subjected to vertical compressive load, crushing, shearing, failure or buckling failure may occur. Due to the difference in the modulus of elasticity of the DSM columns and the surrounding soil, higher stresses occur in the DSM columns than in the surrounding soil, then the composite soil foundation is loaded. This stress difference is often described as a stress concentration factor, which is defined as the ratio of the stress on the column to the stress on the surrounding soil. Field data show that the stress concentration factors generally range from 5.0 to 10.0 under design loads. It has been established by foreign experience that the constructive solution of foundations made by DSM can be considered as a composite foundation. Most of the theories developed to date for composite foundations are based on the condition of rigid load and equal strain. Under heavy load, the distribution of stresses on columns and soils can be simplified and, based on the balance of forces, the following relation can be established:

$$\Delta\sigma_z A_e = \Delta\sigma_s (A_e - A_c) + \Delta\sigma_c A_c \quad (1)$$

where $\Delta\sigma_z$ - is the average vertical stress applied to the composite foundation; A_e - area of influence (also called effective or working area) of one column; $\Delta\sigma_s$ - vertical stress on the ground; $\Delta\sigma_c$ - vertical stress on the column; A_c - column cross-sectional area, Figure 2;

Dividing Equation (1) by A_e on both sides and entering the value as $=A_c/A_e$ - area replacement factor, we get:

$$\Delta\sigma_z = \Delta\sigma_s\ (1 - a_s)\ +\ \Delta\sigma_c a_s \quad (2)$$

where $a_s = A_c/A_e$ is the area replacement factor, defined as the ratio of the cross-sectional area of the column to the area of the hardened array.

Based on the compatibility of soil deformations εs and columns εc, the following formula for determining the equivalent modulus for calculating base deformations is obtained:

$$E_{eq} = E_s(1-a_s)+E_c a_s \quad (3)$$

where E_{eq} is the equivalent modulus of the composite base; E_s = modulus of elasticity of the soil; E_c is the modulus of elasticity of the column. Further in the calculations, the value of E_{eq} will be used as the main deformation characteristic of the hardened array.

Knowing the total weight of the building and the bearing capacity of the columns, it is possible to determine the required amount of DSM. Columns are spaced within the contour of the foundation slab at certain intervals and critical condition and serviceability checks are performed (Liu 2012), (Khomyakov 2020, 2022).

6 CALCULATION SUBSTANTIATION OF THE HARDENED BASE

The subsequent calculation procedure was carried out using the PLAXIS 2D software package, specially designed for modeling the interactions between structures and the base soil using the finite element method. The calculation of the complex of buildings of 9, 12 and 16 floors has been performed. The pressure under the base of the foundation is accepted: for a 9-storey building -171 kPa, for a 12-storey building - 221 kPa, for a 16-storey building - 298 kPa.

The calculation procedure begins with determining the bearing capacity of the soil-cement column. The bearing capacity is determined taking into account the results of Table 2 and is equal to 1396kN. Based on this, a preliminary number of columns was calculated to strengthen the weak base. According to the method described above, the values of the equivalent module Eeq for each of the three EGEs through which the soil-cement column passes are determined.

Table 3. The results were obtained natural and water-saturated state of the base.

				Natural state				Water-saturated state		
№EGE	Average distance of columns, m	E_s MPa	E_c, MPa	E_{eq} equivalent modulus of massif deformation, MPa			E_c, MPa	E_{eq} equivalent modulus of massif deformation, MPa		
				9floor	12floor	16floor		9 floor	12 floor	16 floor
2	2,3	1,9	424,3	64,6	67,4	89,1	381,5	58,2	60,8	80,3
3	2,3	5,4	424,3	67,6	70,4	91,9	381,5	61,2	63,7	83,0
4	2,3	10,4	424,3	71,8	74,6	95,8	381,5	65,5	68,0	87,0

Note. Symbols in the table correspond to chapter 5.

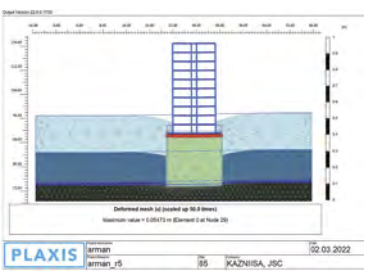

Figure 4. Deformations of the building during hardening of the base by the DSM method.

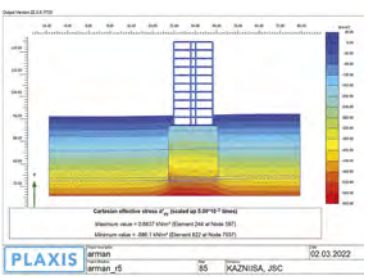

Figure 5. Effective stresses during hardening of the base by the DSM method.

Further calculations are aimed at optimizing the number of elements depending on the equivalent module and the required maximum settlement of the building. The results of calculations of

buildings for deformations and stresses are obtained in the form of mosaics and are shown in Figures 4 and 5. For all buildings, the final values of deformations are shown in Table 4.

Table 4. Calculation results in PC PLAXIS 2D.

Number of floors	Deformation modulus of columns, MPa	Number of DSMs, pieces	Stresses along the sole of the foundation, kPa	Settlement of the building after hardening, m	Coefficient of elastic base, kN/m3
9	424,3	86	171	0,054	3167
12	424,3	99	221	0,074	2987
16	424,3	126	298	0,16	1863

7 CONCLUSIONS

1. The geological conditions of southern Kazakhstan are different in that most of the territory is formed by soils with weak mechanical properties. These include subsidence, macroporous, swelling soils. In this connection, during the construction of buildings on these soils, measures are required to strengthen the base of the buildings.
2. At the present stage, for deep strengthening of soils, mechanical hardening methods based on mixing existing soils with cement mortar along the depth of the base are most actively used. Forming soil-cement columns have a strength much higher than natural soil. However, the properties of soil cement for the soil conditions of Kazakhstan have not been studied at all.
3. In KazNIISA, for the first time, studies of the properties of soil-cement columns on experimental sites were carried out. Samples were taken from the columns from a depth of 3-4 meters in the vertical and horizontal directions. The tests were carried out in the natural and water-soaked state in uniaxial and triaxial compression devices. The test results revealed anisotropy in the values of the compressive strength of about 20-28% and a decrease in strength at water saturation up to 10%.
4. Efficiency of foundation soil strengthening with the use of soil-cement columns is shown on the example of high-rise buildings of 9, 12 and 16 floors. According to the adopted method, the main parameter characterizing the hardened base and reducing its deformability is the equivalent reduced modulus of deformation. Its value was obtained with the optimal number of soil-cement columns and the allowable settlement of buildings. Calculations were performed in the PLAXIS 2D software package with checks on the bearing capacity of the foundation and the operational suitability of buildings.

Concept based approach for geotechnical safety support of the high-rise building construction under complicating factors

F.F. Zekhniev, D.A. Vnukov, D.E. Razvodovsky & A.N. Nikolaev
Research Center of Construction - Gersevanov Research Institute of Bases and Underground Structures (NIIOSP), Moscow, Russia

ABSTRACT: A new design of a high-rise building exceeding 100 m in height is considered. The superstructure was planned to rest on a five-level underground structure, the construction of which was interrupted some years ago. The intermittent low reinforcement of the foundation slab, the uncertain mechanical behavior of the foundation slab and adjacent excavation enclosure, deflection of the foundation slab and defects of the previously erected underground structure, as well as areas of frozen soil affected the design and construction processes. It was decided to increase structural stiffness of the underground construction and apply corrective measures during the construction of the superstructure. An observational design method performed with using geotechnical monitoring instrumentation proved the efficiency of the adopted design solutions.

1 INTRODUCTION

The observational method in geotechnical engineering, which was first defined by Peck, now is well known technique presented in Eurocode 7 and SP 22.13330. This method is more favorable when construction work is performed under significant uncertainty. The essence of the method includes preparing a preliminary design based on favorable and unfavorable data, a monitoring plan for verifying that the structure behaves acceptably during construction and action plan that is put into operation if defined limits. Economic crises often lead to the suspension of construction and the subsequent modification of the project. In this case monitoring data can be used to evaluate how well the actual construction process is proceeding in relation to the predicted behavior of existing structures as well as to control the construction process and update the design. In Russia observational method may be favorable in the design after changing the project of numerous multistory building. The article provides an example of the application observational method for multistory building in Moscow.

In Moscow, close to Kutuzovski Avenue, a redesigned high-rise building has been constructed since 2019. The building rests on a five-level underground structure. Being constructed in 1995-1999, the underground structure was embedded to a depth of 18,5 m below the day surface, and it covered the area of 72 x 63 m.

The underground structure was constructed in an open excavation that was secured by a diaphragm wall reinforced with three levels of anchors. The structure rested on a 2.5m thick reinforced concrete foundation slab. Structurally, it was a reinforced concrete frame with a 9 m column grid.

Compressible subsoil continuum comprised loam and clay with deformation modulus E = 15÷27 MPa, and a thin sand layer in the middle of the cross-section. The sand deformation modulus was 45MPa. The compressible subsoil overlaid the limestone deposit occurring at a depth of 18 m below the bottom of the foundation slab.

To a depth of 1 m below the slab bottom, subsoil with poor deformation properties was met in places. This resulted from the impact of external environmental processes on the surface of soil foundation during construction and preservation of the building.

Figure 1. High-rise hotel and business complex - design (left) and present time (right).

A new design presented the skyscraper as a 33-storey H-shaped building. Three lower levels of the underground section were of a rectangular shape. All bearing structures were included in a reinforced concrete frame. Taking into account construction conditions and long-term preservation of the construction, the designers picked out some factors affecting the design of the new building. Those factors included:

- The intermittent low reinforcement of the foundation slab;
- Uncertain mechanical behavior of the foundation slab and adjacent excavation enclosure;
- Non-uniform deformation soil properties and frozen areas under the foundation slab;
- Defects and leakage in underground structures;
- A total lack of monitoring data;
- Numerous reports on violating requirements of construction Codes during the construction process;
- The 35 mm deflection of the foundation slab that appeared after the underground structure was erected in 1999.

As far as the main design principle, the increase in frame stiffness of the erected underground structure with the maximum reduction in the load transferred to the foundation was accepted. To increase frame stiffness, shear walls and transverse diaphragms should be added to four lower levels of the frame.

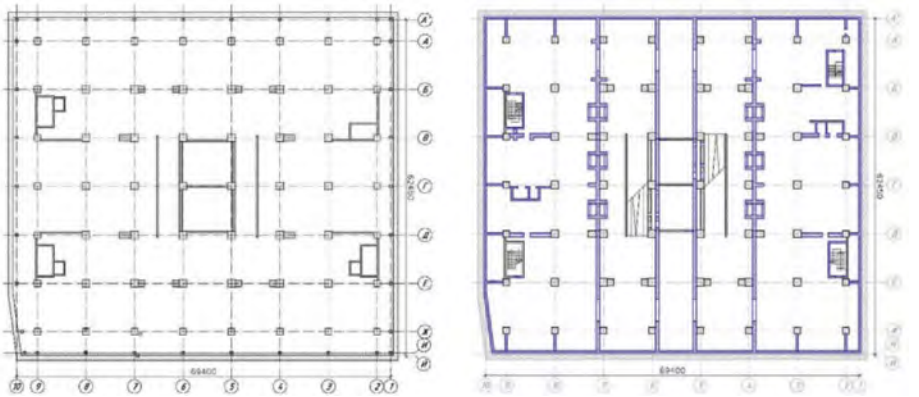

Figure 2. Scheme of the underground section before (left) and after (right) reinforcement with transverse diaphragms and shear walls along the section perimeter.

Diaphragms and shear walls changed spatial performance of the underground structure and limited deformations and stress in the foundation slab, produced by the erected superstructure. Another advantage of this design approach was a relatively low cost of the construction work performed without using specific equipment, but with opportunity to undertake visual quality control.

Considering uncertainties of the mechanical behavior of the underground section and soil foundation, an observational design method was applied. According to the method, the foundation design could be corrected on the base of monitoring results. If the foundation slab suffered significant deflection followed by the loss of its bearing capacity, a new foundation slab was proposed to replace the lower underground level [1].

2 GEOTECHNICAL MONITORING OF THE CONSTRUCTING BUILDING

Geotechnical monitoring was set up when the construction of a redesigned building was resumed in 2019, and it has still been in progress. The main bearing structures have been already erected and finishing work has been started by now.

To date, maximum additional settlement of the constructing building is 91 mm; maximum relative differential settlement is 0,0017. The average settlement of the foundation slab is 68 mm.

The measured deformation of the building foundation does not exceed regulation and predicted values, that is, mean settlement – 20 cm and 14,3 cm, relative differential settlement – 0,003 and 0,002 respectively.

Figure 3 shows the distribution of the measured deformations across the foundation slab area. In general, distribution of the foundation slab measured deformations qualitatively corresponds to the predicted distribution of deformations obtained during the design.

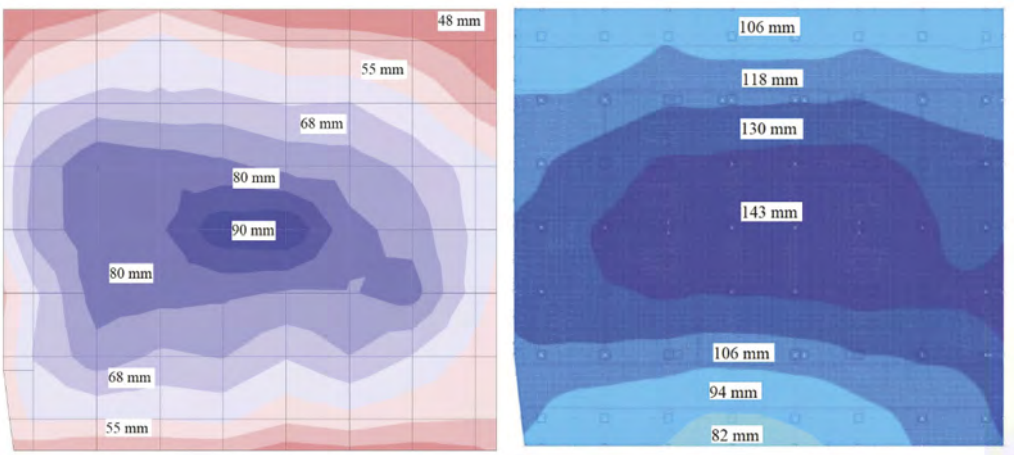

Figure 3. Distribution of the foundation slab settlements observed at 80% load (left) and settlements predicted from total loads (right).

The settlement values of the edge sections of the foundation slab are less than those of the central section are, because the diaphragm wall installed along the perimeter of the underground section constrains deformation of foundation edges. Another reason for that is underground structure and diaphragm wall interaction along the contact between them.

When the settlement rate of the slab central section was increasing against the edge sections, the authors recommended erecting the exterior sections of the aboveground structure prior to the central one. Currently, due to the recommended construction sequence, settlements uniformly develop across the area of foundation slab.

Geodetic monitoring of the "diaphragm wall" settlements confirmed its influence on the foundation deformation process. To date, the average settlement of the "diaphragm wall" is 18 mm, and the settlement of the edge section is 56 mm. Maximum settlement of the

"diaphragm wall" – 23 mm was observed along the A' - axis. Meanwhile, the average settlement of the edge section along the same direction was minimum, if compared with other edge sections, and amounted 50 mm (Figure 4).

The deformation measurement results indicate a significant effect of the "diaphragm wall" on the section of the underground structure, where crack appeared in the 2-nd floor framing beam to A'-directional protective wall connection (Figure 4 and 5). The crack width was up to 5 mm. It appeared when the reinforced beam of the second floor "caught" the edge of the "diaphragm wall".

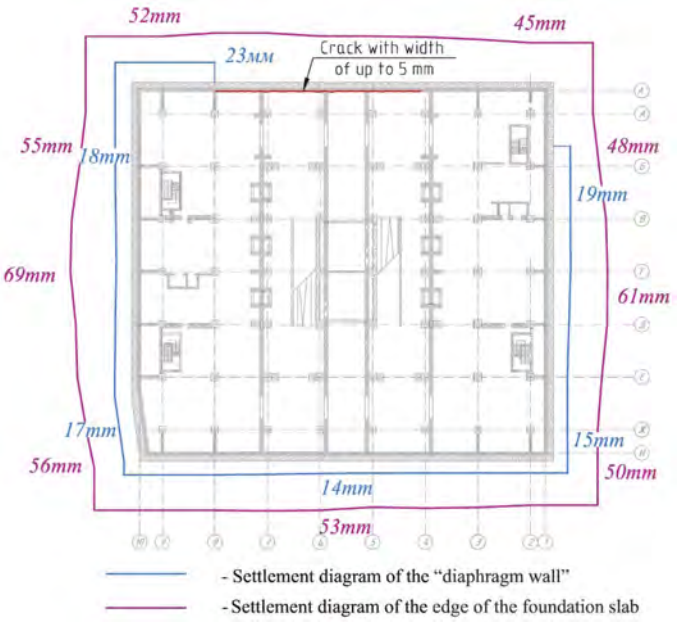

Figure 4. Deformation diagrams of the edge of the foundation slab of the constructing building and the adjacent "diaphragm wall".

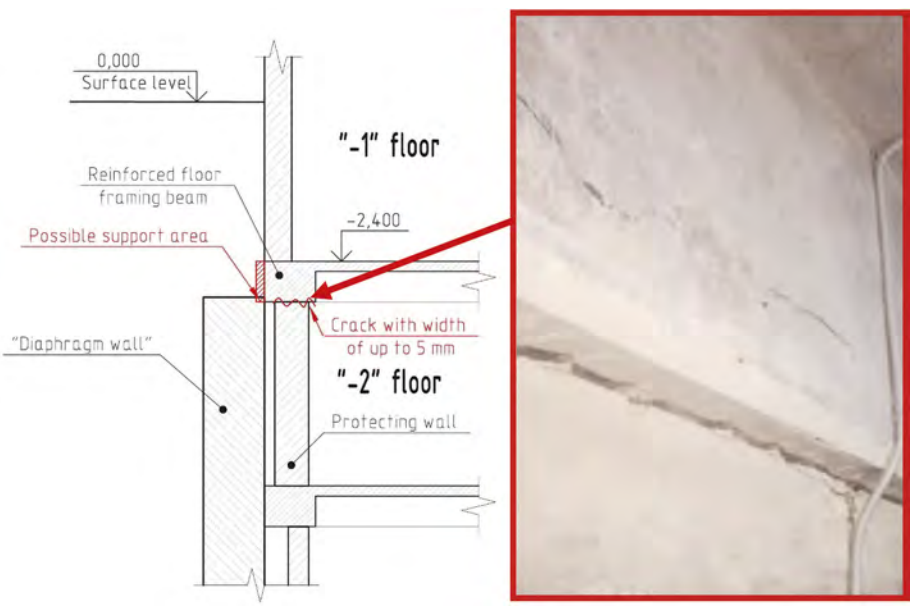

Figure 5. The crack observed in the 2-nd floor framing beam to A'- directional protective wall joint.

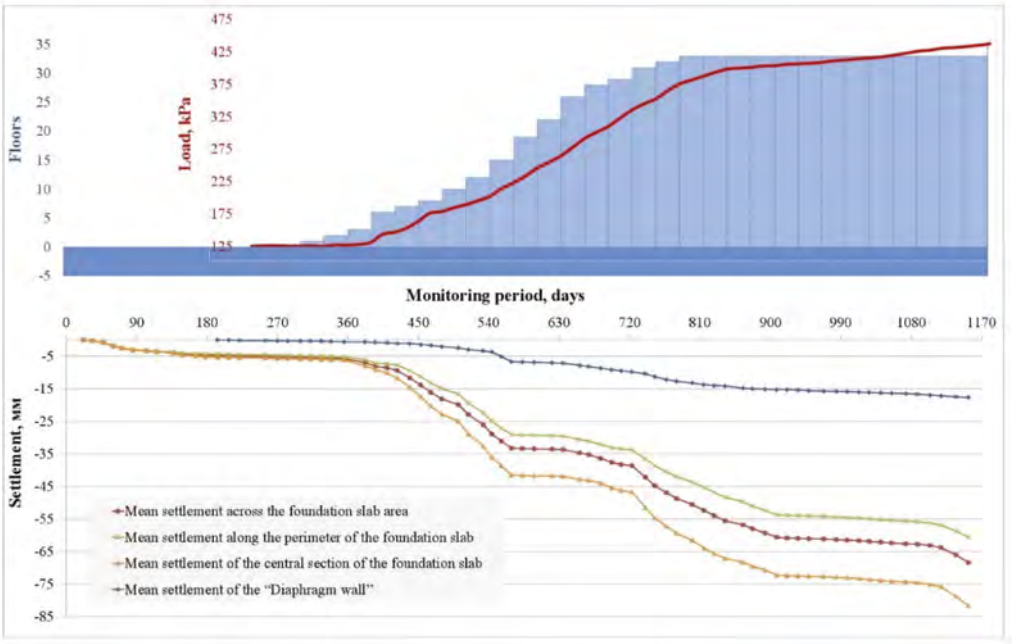

Figure 6. Diagram showing the development of foundation settlements and pressure on the foundation versus time.

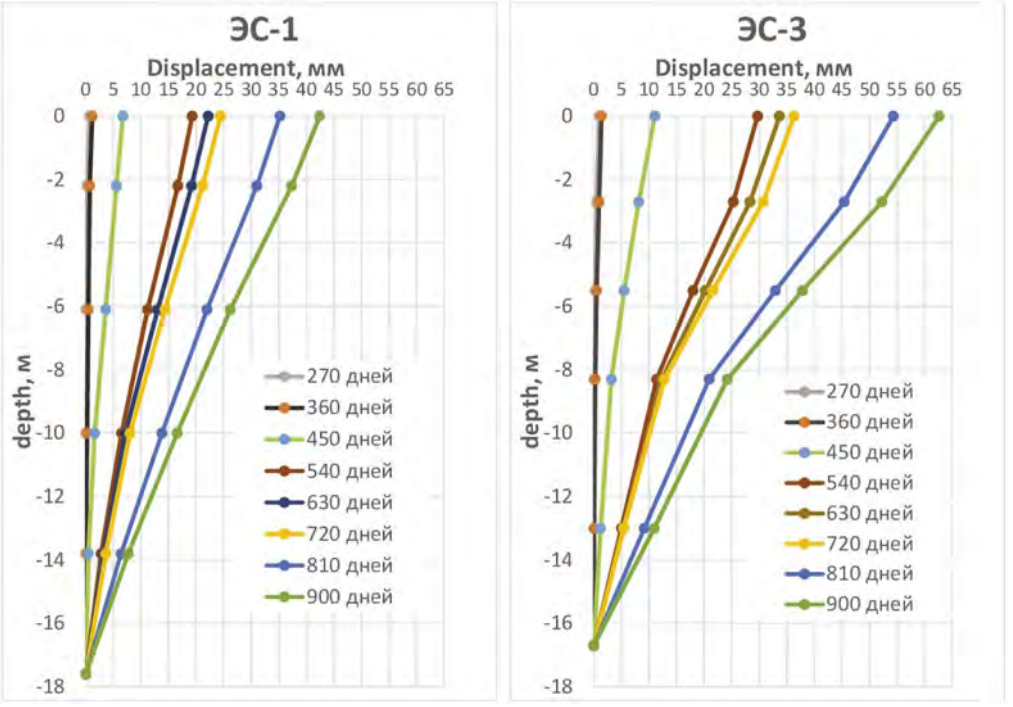

Figure 7. Changes in soil displacement in depth versus time, measured in extensometer wells (left – edge well, right – central well).

The foundation settlement incrementally develops in time with relatively even increase in load (Figure 6), which is largely due to the complex nature of the interaction of the underground structures with "diaphragm wall".

Analysis of the layer-by-layer soil foundation displacement measured using extensometer system shows that all soil continuum observed suffered deformation, wherein clayey layers occurring in the upper part of the compressible strata to the depth of 8 m possess relative compressibility.

3 CONCLUSIONS

Within the framework of the observational design method, instrumentation of geotechnical monitoring helps to assess building's behavior while the performance of the entire structure is uncertain.

Adopted design solutions and application of the corrective measures diminished the impact of hazardous geotechnical factors on the construction process. Those solutions and measures were as follows:

- Installation of the transverse diaphragms and shear walls, which increased stiffness of the underground structure, compensated the existed foundation for the lack of stiffness.
- Construction of the reinforced concrete frame and erection of the exterior structure sections prior to the central one minimized the difference of settlements between central

Presently, measured deformations of the foundation, as well as relative differential settlement, meet the required values.

Analytical and numerical solutions for temperature distribution in topsoil layers

T. Musabaev, T. Kayupov, D. Seilkhanova & G. Khafizova
Eurasian Institute of Technology at L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The article analyzes the analytical and numerical solutions of heat conduction under the theory of inhomogeneous bodies. The distribution of sub-zero temperature in an inhomogeneous half-space and accounting for the continuous inhomogeneity of the heat conduction rate and internal heat dissipation sources are given for the first time. The evaluation of the obtained results and the known solutions as per the European and national standards are reviewed. The comparison of numerical and analytical solutions for the test problems proves the accuracy of the obtained results. Given the availability of appropriate coefficients, these solutions are also correct for solving problems of chemical reactions with the release of heat, moisture transmission, diffusion, corrosion cracking, and other problems described by the equation of heat conduction.

1 INTRODUCTION

In winter, the atmospheric temperature in the northern regions of the country, in Nur-Sultan city, goes down to -40°C, but the depth of ground freezing is accepted to be 1,800 mm. At the same time, frosty days are changed to snowfall when the temperature rises to -10°C, and there is an alternation of day and night. Also, the ground is covered with snow. Is this standard depth of ground freezing sufficient?

The survey site is in the left-bank part of Astana, between the avenues of Kabanbay Batyr and Mangilik El, and is characterized by absolute levels (at the mouths of drilled wellbores) within the range of 348.33 - 348.74 m. This site has an embedded structure, next to which snow is not removed. The standard thickness of snow in the area of 100 cm will be taken as the thickness of the stale snow in the clearing. There is a 50 cm thick topsoil all around under the snow, consisting of interwoven plant roots and air pockets. We model this layer as peat heat insulating slabs per Table 1 SN RK [1] (Figure 1).

Table 1. Coefficient of heat conduction of materials.

DOI: 10.1201/9781003299127-391

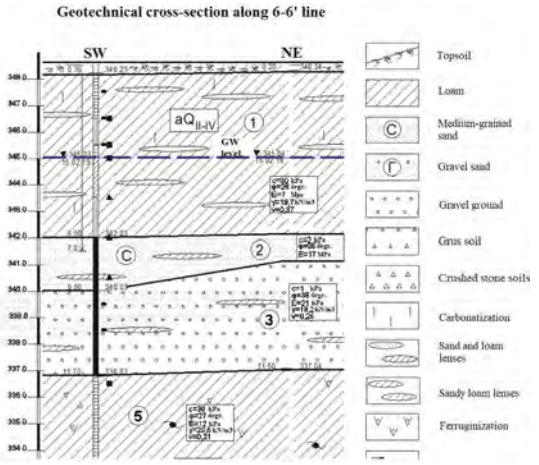

Figure 1. Geotechnical cross-section of the ground of the embedded structure on Mangilik El Avenue in Astana.

According to Eurocode 1, in case there are no internal sources of heat dissipation, the temperature distribution in layered structures shall be determined by the following formula (1) [2]:

$$T(x) = T_{in} - \frac{R(x)}{R_{tot}}(T_{in} - T_{out}) \tag{1}$$

where T_{in} is the indoor air temperature; T_{out} is the outside air temperature; R_{tot} is the total thermal resistance of an element, including the resistances of both surfaces (2); $R(x)$ is the thermal resistance from the inner surface and layers on the inner surface to the given point with coordinate x (Figure 1).

A similar formula can be found in formula (29) of SN RK [1], where the thermal resistance to heat transmission of layered structures can be determined by a similar one with (2) [2]:

$$R_0^{mp} = \frac{1}{\alpha_H} \cdot + \cdot \frac{h_1}{\lambda_1} \cdot + \cdot \frac{h_2}{\lambda_2} \cdot + \cdot \ldots \cdot + \cdot \frac{h_n}{\lambda_n} \cdot + \cdot \frac{1}{\alpha_B} \tag{2}$$

where α_B=8.7 is the coefficient of heat transfer from the inner surface of the land cover, taken according to Table 1 [1] as the coefficient of heat transfer from the inner surface of the walls; α_H=6 is the coefficient of heat transfer of the outer surface of the ground (snow cover), taken according to Table 1 [1] as the covering over the unheated basement; h_i is the thickness of the i-th layer, m; λ_i is the heat conduction of the material of the i-th layer, taken based on the results of tests in an accredited laboratory [1].

A comparison of the heat conduction values of the materials in the composition of the wall [3] as given in the Turkish and Kazakh national appendices to the Eurocode is listed in Table 1. As Table 1 shows, there is no significant difference in the numerical values of the heat conduction of materials, with the exception that in practice, the presence of some materials marked with the minus sign in Table 1 is not taken into account in thermo-technical calculations.

In the climatic conditions of Astana city, due to the presence of castle clay under the clay loam layer, the surface soils, except for the topsoil for the winter, are getting waterlogged and in some places are connected by an aquifer. The topsoil passes through the moisture like a sieve, supplies water to vegetation, and desiccates before the weather is cold. During waterlogging, all soil interstices are filled with water and freeze in winter, forming a monolith of soil and ice. Therefore, the thermal properties of the frozen soil layers can be equated with those

of ice [4]. It is seen from Figure 2 that the coefficient of heat conduction of ice is strongly dependent on temperature. For this reason, the value of the heat conduction coefficient of frozen ground is a function of temperature.

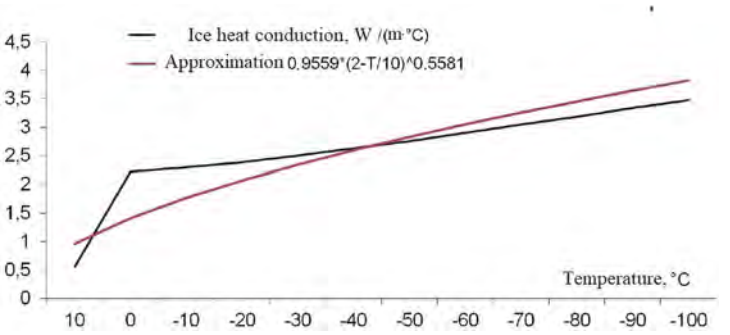

Figure 2. Ice heat conduction coefficient and the approximation of its graph by a power function.

As a rule, the depth of ground freezing does not reach the aquifer. Most likely that the aquifer is formed by the following processes such as ice formation, melting, ice surfacing in the water lens, raising and lowering of the surface soil layer due to the lunar attraction, as well as sand settlement to the bottom of the water lens.

Assume that the ground surface is covered with fresh snow with a heat conduction coefficient of λ_1 = 0.15 W/m °C [5] with a thickness of δ_1 = 0.2 m and a stale snow cover of λ_2 = 0.5 W/m °C [5] with a thickness of δ_2 = 0.8 m. The surface coating of the layered half-space is split into a topsoil layer (modeled as peat heat-insulating slabs of λ_3 = 0.064 W/m °C [1]) with a thickness of δ_3 = 0.5 m, frozen loam (as ice at -10°C λ_4 = 2 W/m °C [4]) with a thickness of δ_4 = 1.5 m, and other layers from Table 2. From [1] and [5], we will take the thermo-physical properties of other soil layers, as per the geotechnical cross-section (Figure 1).

Table 2. Heat transmission resistance in the multilayer land cover.

Layers	h, m	λ, W/m°C	Rlayer
Heat transfer coefficient of the outer snow surface	α_{out}=	6	0,17
Fresh snow	0.2	0.15	1.33
Stale snow cover	0.8	0.5	1.60
Topsoil: peat insulation	0.5	0.064	7.81
Frozen loam	1.5	2	0.75
Water saturated loam - aquifer	2	1.33	1.50
Clay	0.5	0.8	0.63
Dry loam	1.5	0.5	3.00
Coefficient of inner surface heat transfer	$\alpha_{in.}$=	8.7	0.11
Overall thickness of the concerned multilayer land cover	7	ΣR0 =	16.91

In establishing the thickness of the land cover, it is essential to identify the mark of the beginning of the temperature of 10°C for the considered region. Normally, the temperature of 10°C is observed at a depth of 10 m, 20 m, and 30 m as well. In this case, we accept the thickness of the land cover to be 7 m.

Figure 3 depicts plots of the distribution of coefficient of heat conduction of land cover layers by the depth and its approximation by a power function calculated using the least-squares method and a polynomial function, selected visually.

It is seen from Figure 3 that the standard values of the coefficient of heat conduction of land cover layers have a step pattern of distribution. With the polynomial approximation, it is possible to partially describe the ascending and descending branches of the normative graph

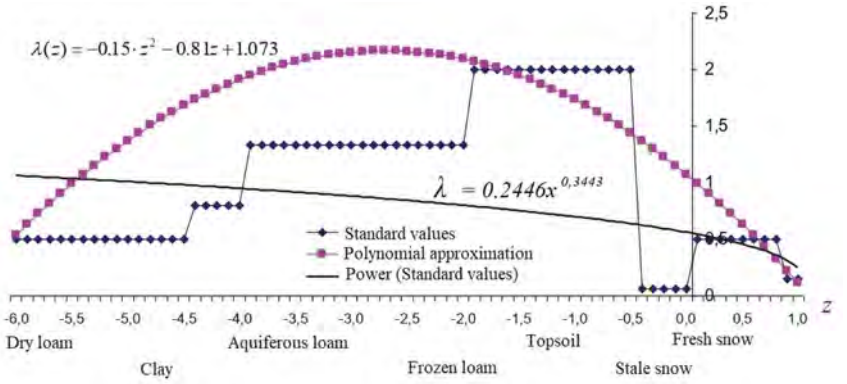

Figure 3. Graph of the variation of the coefficient of heat conduction of land cover layers by the depth and its approximation by the power and polynomial functions.

and the initial and final value. With the power approximation, it is possible to approach the standard values only on the surface layers. The efficiency of the approximation can be determined after plotting the temperature distribution with different methods, comparing and evaluating the obtained results.

The differential equation of heat conduction of one-dimensional problem (the properties of layers are given only along the z-axis which is perpendicular to the ground surface, and the properties and thickness do not change in each layer) in the orthogonal coordinates is written as follows:

$$\frac{\partial}{\partial r}\left(\lambda(r,z)\cdot\frac{\partial T}{\partial r}\right)+\frac{\partial}{\partial z}\left(\lambda(r,z)\cdot\frac{\partial T}{\partial z}\right)=\gamma\cdot c\cdot\frac{\partial T}{\partial \tau}-q(r,z) \tag{3}$$

where γ is the bulk weight, kg/m^3, c is the specific heat capacity, J/(kg °C), $\lambda(r,z)$is the heat conduction coefficient; $q(r,z)$ is the density of internal heat dissipation sources [6, 7, 8].

Let there are no internal heat dissipation sources, a steady-state problem of heat conduction ($\partial T/\partial\tau = 0$) is considered, and the coefficient of heat conduction of soils is changing in the following manner:

$$\lambda(z)=\lambda_0\cdot z^m \tag{4}$$

where λ_0=0.2446, m=0,3443 – approximation by power function, Figure 3.

By integrating (3) by z, we will get:

$$\lambda_0\cdot z^m\frac{\partial T}{\partial z}=C_1;\ T=C_1\cdot\frac{z^{1-m}}{1-m}+C_2 \tag{5}$$

where C_1 and C_2 are arbitrary constants determined from boundary conditions.

In this case, as boundary conditions, the laws of convective heat transfer of the medium with the wall surface are used [7]:

$$\lambda_0\cdot a^m\frac{\partial T}{\partial Z}=\alpha_B(T-T_B);\lambda_0\cdot b^m\frac{\partial T}{\partial Z}=-\alpha(T-T_H) \tag{6}$$

Here, a and b are, respectively, the coordinates of the outer and inner surfaces of the considered land cover; α_B, α_H are the heat transfer coefficients; T_B,T_H is the temperature of the environment near the inner and outer surfaces of the considered land cover.

We substitute the solution of (4) and (5) into (6), and then the solution of equation (3) is determined based on the solution of the system of equations:

$$C_1 \cdot \left(\frac{a^{1-m}}{1-m} - \frac{\lambda_0}{\alpha_B}\right) + C_2 = T_B; C_1 \cdot \left(\frac{b^{1-m}}{1-m} + \frac{\lambda_0}{\alpha_H}\right) + C_2 = T_H \tag{7}$$

$$C_1 = (T_H - T_B)/\left(\frac{b^{1-m} - a^{1-m}}{1-m} + \frac{\lambda_0}{\alpha_H} + \frac{\lambda_0}{\alpha_B}\right); C_2 = T_B - C_1 \cdot \leq \left(\frac{a^{1-m}}{1-m} - \frac{\lambda_0}{\alpha_B}\right) \tag{8}$$

Let the heat transfer coefficient of the wall change in the following manner:

$$\lambda(z) = -0,15 \cdot z^2 - 0.81z + 1,073 \tag{9}$$

By integrating (3) by z, we will get:

$$\frac{\partial T}{\partial z} = \frac{C_1}{-0,15 \cdot z^2 - 0.81z + 1,073};\ T = C_1\left(0,88ln\left|\frac{z+6,5}{z-1,1}\right|\right) + C_2 \tag{10}$$

By solving the quadratic equation (9), we get two roots: z_1 = 1.1 and z_2 = -6.5, which gives zero in the denominator. These points are beyond the range of consideration.

To solve the formulated boundary value problem (3) with boundary conditions (6) using the numerical method, the variation-difference method is applied. Following this method, the ground depth interval a ≤ z ≤ b of unit height and length is arbitrarily subdivided into M - 1 parts, i.e. an irregular rectangular mesh is introduced (Figure 4).

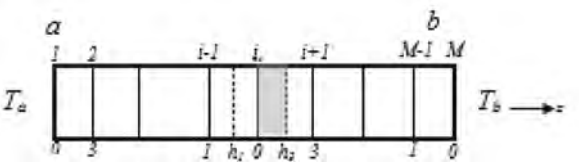

Figure 4. Difference mesh.

The numbering at the top refers to the difference mesh node number, and at the bottom - 0, 1, 3 - are the local numbers of the i-th node cells. The numbers in the cell number indicate which node the given cell is located near h1 and h3 are the mesh steps near the cells. The basic mesh is shown with solid lines, and the additional - with dotted lines, and the typical right cell 03 is shaded.

The equivalent functional of the Ritz method [9] is as follows:

$$I(T) = \int_V \left(\lambda(z) \cdot \frac{\partial T}{\partial z}\right)^2 dv - \alpha_n \oint_S \left(T^2 - 2T_n T\right) \cdot ds \tag{11}$$

where T is the temperature, °C, αn is the surface heat transfer coefficient; T_n is the ambient temperature near the surface with the outer normal n.

An approximate finite-difference expression of potential energy (11) is obtained under the assumption that all functions are constant in each cell. For instance, for a typical cell 03, derivatives are replaced by difference expressions, and the functions take the following values:

$$T = T_0, \frac{\partial T}{\partial Z} = \frac{T_3 - T_0}{h_3}, T_n = T_a, \alpha_n = -\alpha_a,\ \ dv = \frac{h_3}{2} \cdot 1 \cdot 1,\ \ ds = h_3 \cdot 1 \tag{12}$$

The values of the surface heat transfer coefficient αn for the cells where the direction of the outer normal n does not coincide with the direction of the z-axis are taken with the opposite sign. E.g., for cell 01:

$$\alpha_n = \alpha_b \tag{13}$$

The sum of potential energies of all cells will be the total potential energy of the whole body. The boundary integrals are calculated using the trapezoid formula. The minimum of this function is attained subject to the following conditions:

$$\frac{\partial I(T)}{\partial T_0} = 0 \tag{14}$$

By performing differentiation, one can obtain a difference approximation of the boundary value problem (3), (6), (11).

After reducing the constants, the equation for the right cell 03 has the following finite-difference expression:

$$(\lambda_0 + \lambda_3)\frac{T_3 - T_0}{2h_3} = \alpha_a(T_0 - T_a) \tag{15}$$

The equation is similar for the left cell 01:

$$(\lambda_0 + \lambda_1)\frac{T_1 - T_0}{2h_1} = -\alpha_b(T_0 - T_b) \tag{16}$$

The equations for the other cells are different in the absence of boundary elements and the presence of both right and left cells so that they are obtained by summing the summands of formulas (15) and (16)

$$(\lambda_0 + \lambda_1)\frac{T_1 - T_0}{h_1} + (\lambda_0 + \lambda_3)\frac{T_3 - T_0}{h_3} = 0. \tag{17}$$

The matrix of algebraic equations will be tridiagonal. That is why it is convenient to present the system of linear algebraic equations as follows [7]:

$$a_i T_{i-1} - c_i T_i + b_i T_{i+1} = -f_i \tag{18}$$

where a_i are the coefficients preceding T_1, c_i are the coefficients preceding T_0, b_i are the coefficients preceding T_3, fi is the product of coefficients preceding T_a and T_b and their values. The sweep method [10] is used to calculate the temperature.

The results of computing the temperature distribution in an inhomogeneous half-space under the snow cover, which are calculated by formulas: (1), (8), (10), and the numerical solution, are presented in Figure 5. The considered thickness of 7 m of the land cover is divided into 70 steps with a length of 0.1 m.

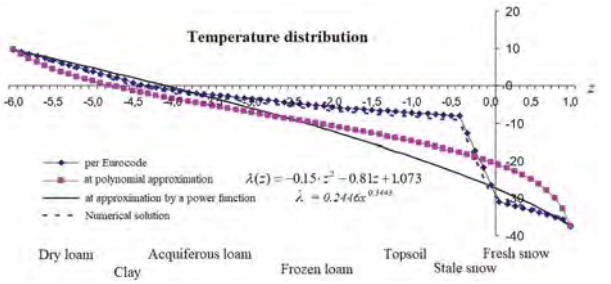

Figure 5. Temperature distribution in an inhomogeneous half-space under the snow cover.

It is seen from Figure 5 that formula (2) of Eurocode 1 [2] and formula (29) of SN RK [1] adequately describe the temperature distribution in the multilayer structure of the land cover formation. A linear law of temperature distribution is observed in each layer. The numerical calculation qualitatively repeats the temperature distribution result; quantitatively, there are differences of less than 2 % in some nodes.

The temperature determined using the power function qualitatively differs from other solutions, and the quantitatively adequate result is obtained at the point of temperature sign change. Such differences may be caused by the approximation of the heat conduction coefficient by a power function, which qualitatively differs from the set heat conduction coefficient variation law. The temperature distribution using formula (10) in the approximation of the heat conduction coefficient by a quadratic polynomial better conveys the behavior of the change in the Eurocode solution. But the dew point position by (8) is better compared to formula (10). Two analytical solutions based on the theory of inhomogeneous bodies, i.e., inhomogeneous models of the structure adequately describe the physical process of heat conduction in a multilayer half-space under the snow cover on the effect of sub-zero temperature.

2 CONCLUSION

1. As can be seen from the figure, all temperature distribution curves turn out to be qualitatively similar; in quantitative terms, there are differences near the surface layer.
2. The solutions of (8) and (10) types can be used as a test task to evaluate the results of physical and numerical experiments with complex boundaries or in two- and three-dimensional settings.
3. Based on the results of calculations in different models in a one-dimensional setting for Nur-Sultan city, the standard depth of ground freezing of 1,800 mm is not sufficient, as the dew point in Figure 5 goes down to 4 m.
4. The results obtained may change in case of using other models of soil, snow, ice, the thickness of the considered cover, heat transfer coefficients, as well as in case of two-dimensional or nonlinear non-steady solution taking into account heating pipe mains, sewerage systems, power supply networks as sources of heat and temperature fluctuations in the winter season.

Characterization of stockpiled Basic Oxygen Furnace (BOF) slag for railway ballast material application

S. Olagunju, Z. Suleimen, D. Mukhtarkhan, T. Darbayeva, A. Muratova, J. Kim & S-W. Moon
Nazarbayev University, Nur-Sultan, Kazakhstan

ABSTRACT: Railway ballast usually uses natural crushed stone to transfer the load from the rails to the ground. However, the material has a detrimental impact on the environment as the extraction of it is a destructive process, and it is also prone to degradation and fouling in rail tracks. Therefore, this research evaluates the Basic Oxygen Furnace (BOF) slag as an alternative to traditional ballast material in the Kazakhstani railway industry. The tested BOF slags were grouped into top and bottom stockpiled with a mean age of 3–4 years and 10 years, respectively. GOST standards were mainly utilized to analyze the feasibility of the use of BOF slag in Kazakhstan. As a result, both types of BOF slag represented complete satisfaction with the proposed standards. Therefore, the potentiality of the application of stockpiled BOF slag for railway ballast material is verified.

1 INTRODUCTION

Continuous steelmaking, which generates massive waste, is a critical factor in human development; one of these wastes is BOF slag. However, BOF slag poses a severe environmental threat due to its limited potential for reuse and increasing production volume (Naidu et al., 2020). BOF slag has been used for different purposes in the developed countries such as USA, German, and France (Yi et al., 2012). For instance, it is utilized as a part of cement production process in China, as highway pavement in Japan and Australia. BOF slag is also currently used in some parts of Europe to improve agricultural soil condition (e.g., Gencel et al., 2021, Proctor et al., 2000). Another initiative that is being made worldwide to further reduce the amount of BOF slag in circulation is the use of BOF slag as a railway. BOF slag has been utilized as a railway ballast in Brazil, USA, Canada, and Iran (Hussain and Hussaini, 2022). Previous research on BOF slag concluded that BOF slag has higher resistance against lateral pressure and more resistance to breakage when compared with natural crushed stones that are currently utilized as railway ballast (Koh et al., 2018). Therefore, this study characterized the stockpiled BOF slags to apply them to railway ballast materials in Kazakhstan.

2 EXPERIMENTAL WORKS

2.1 *Sample preparation*

The BOF material used in this experimental work was collected from the steel plant located near Karaganda in Kazakhstan. A series of laboratory tests were conducted to investigate the chemical, physical, mechanical, and environmental properties of top and bottom stockpiled BOF slag. The top material has a mean age of 3-4 years, whereas the bottom material has been stored for 10 years in a stockpiled condition. Before starting the main experimental work, the material required preliminary treatment and sorting because the excessive water and

DOI: 10.1201/9781003299127-392

dirt on the aggregates could directly affect further tests. Thus, the first step was oven drying the samples for 48hours at 95°*C* and sieving them according to the GOST standard (GOST 7392, 2014). The sieve sizes were chosen according to the standard for category B materials (square-sized sieves). The samples were sieved through different sieve sizes by shaking the machine for 10 minutes.

2.2 *Experimental methods*

Multiple tests were chosen to assess the slag in an application as ballast material. The most significant ones were selected from physical property requirements, strength, and resistance to environmental conditions. The physical property of BOF slags was evaluated by the Specific Gravity test conducted according to GOST 7392 - 2014. Mechanical properties of the BOF were investigated by Los Angeles (LA) abrasion method using ASTM C535 and aggregate crushing value (ACV) test according to BS 812-110. LA abrasion test was carried out to determine the abrasion resistance and toughness of the aggregates, while ACV test was performed to relatively measure the strength of aggregates needed to resist gradual compressive loads and to crush resistance. Environmental properties were determined through freeze and thaw and organic impurity tests. The freeze and thaw testing was conducted to assess the durability of BOF slag and its resistance to weathering and disintegration by repeated freezing and thawing processes. Meanwhile, an organic impurity test was performed to check the presence of injurious organic impurities. Both tests were carried out according to the GOST 7392 - 2014.

3 RESULTS AND DISCUSSION

3.1 *Chemical property tests*

X-ray diffraction analysis (XRD) and scanning electron microscopy (SEM) were conducted to analyze the chemical property of the stockpiled BOF slags. According to the results presented in Figure 1, stockpiled BOF material has Portlandite ($Ca(OH)_2$), Silicon Oxide (SiO_2), Calcite ($CaCO_3$), Periclase (MgO), Lead Arsenate ($PbAs_2O_6$), Wurtzite (FeO) and others. Comparing both types of BOFS, it can be seen that the intensity of compounds like portlandite and lime is approximately the same, meanwhile, the intensity of SiO_2 (Silicon oxide) is larger in the bottom BOF rather than in the top BOF (Table 1) which indicates that the bottom BOF slag has weaker structure, therefore, is more likely to break. The results for top materials which have a mean age of 3 to 4 years are better than for bottom slag with a mean age of 10 years caused by differences in materials from batch to batch.

Table 1. RIR values of free-lime, portlandite and calcite in top and bottom BOF slag.

BOF type	f-CaO	Portlandite, $Ca(OH)_2$	Calcite, $CaCO_3$	SiO_2
Top	2.54	1.40	1.49	3.04
Bottom	2.54	1.40	2.00	3.31

Along with elemental composition, surface pictures displayed the information regarding the compound of BOFS. The hexagonal plate shape of stockpiled BOF is dictated by the aging of the material that is typical for $Ca(OH)_2$ which forms as long as the material ages and free lime reacts to form portlandite ($Ca(OH)_2$) and calcite ($CaCO_3$). Figure 2 shows the propagation of $Ca(OH)_2$ and $CaCO_3$ that explains the hexagonal shape formations on the surface of the BOF slag.

3.2 *Physical property tests*

According to the GOST specification, the specific gravity of the BOF should be more than 2.40. The top and bottom stockpiled BOF slags' specific gravities constitute 3.29 and 3.25,

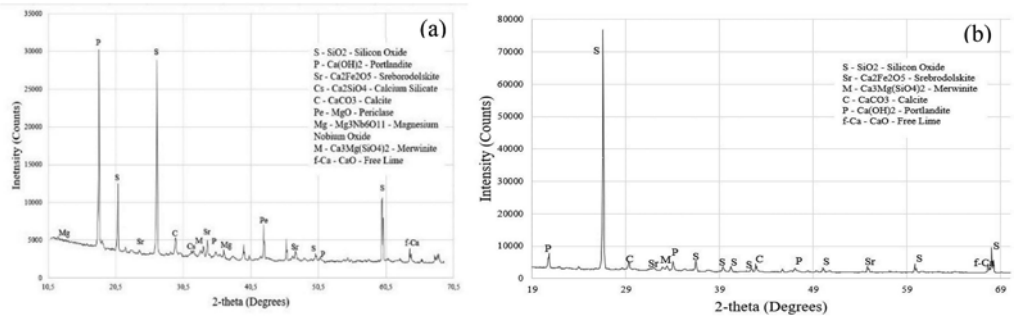

Figure 1. XRD for (a) Top and (b) Bottom BOF slags.

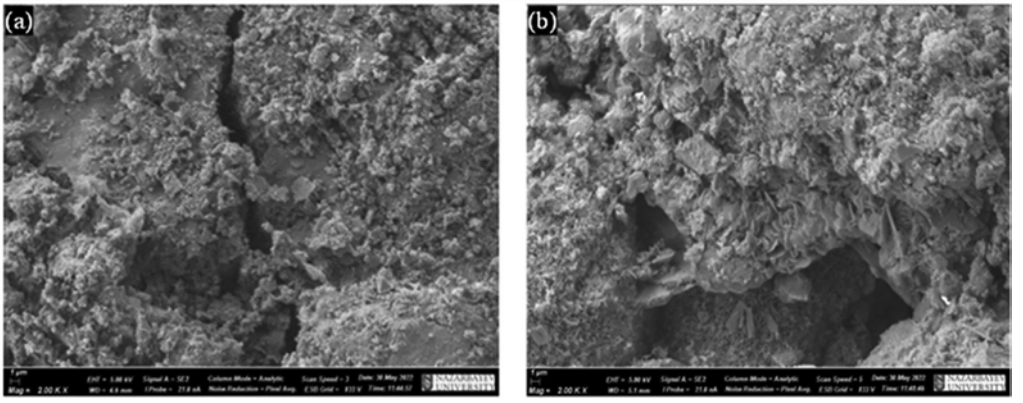

Figure 2. SEM images of (a) Top and (b) Bottom BOF slags.

respectively; satisfying the specification. As the aggregate's strength can be assessed by its specific gravity, the specific gravity that is more than the minimum required value signifies a strong aggregate, as in the case of the stockpiled BOF slag. As regards the absorption capacity, it is less than 2% required by British standards (BS EN 1097-6, 2022). The relatively low values for both stockpiled top (1.18%) and bottom BOF (1.15%) show low permeability of the BOF aggregates.

3.3 *Mechanical property tests*

Los Angeles abrasion and aggregate crushing value tests were performed to determine the strength properties of BOF slag. Both top and bottom stockpiled BOF slags satisfy the ASTM standard of railway ballast since their mass loss values of 22.8% and 23.9% respectively are less than 30% maximum mass loss standard set by AREMA. Therefore, BOF slag is strong enough to resist abrasion and wear and tear during usage. In terms of the aggregate crushing value test, the results have shown that aggregate crushing values for top and bottom stockpiled BOF slags are 19.3% and 20.5% respectively. According to the British Standard, the allowable value of the aggregate crushing value for railway ballast material should be less than 22% (BS EN 13450, 2020). The resulting values put the stockpiled BOF slags within the allowable limit as per the British Standard. Top stockpiled BOF slag provides a higher strength value in comparison to the bottom BOF slag, which makes top BOF slag more resistant to abrasion and crushing under the application of gradual compressive load.

3.3 *Environmental property tests (Freeze and Thaw test & Organic impurity test)*

Both stockpiled BOF slag satisfied the GOST requirement as their mass losses are 3.9% and 4.3% for top and bottom respectively and less than 5%. Therefore, the stockpiled BOF slag will provide great resistance to freeze and thaw in cold climate regions, where the freezing-thawing cycles occur constantly. As for the organic impurity test, it was observed that the sodium hydroxide solution that contains the samples was not colored, but there is a slight change in the turbidity of the solution. The solution colors do not match the reference colors of the ASTM color standard organic plate (ASTM C40M, 2020); this implies that there are no organic impurities present. It would be recommended to conduct preliminary treatment of aggregate by oven drying to burn out the undesirable organic impurity content.

4 CONCLUSIONS

The fast development of the railway industry in Kazakhstan leads to an increase in the extraction level of natural crushed stone for ballast application. The industry requires a sustainable solution that will be both economically and environmentally beneficial. Thus, the BOF slag stockpiled in the steelmaking industries could become a potential alternative to the traditional ballast material in Kazakhstan. Consequently, the sample BOF material was assessed by checking the compliance of its properties with the ballast requirements specified mainly in the GOST standard. As a result, the stockpiled BOF slag demonstrated complete compliance with the ballast material requirements of the obtained experimental program or testing standard. However, the superiority of top material over bottom could be noticed. According to the chemical analysis, the higher amount of SiO2 in the bottom BOF slag could lead to a comparable decrease in strength property. Nevertheless, the further assessment of BOF slag requires the practical investigation of performance in real-life scenarios.

ABSTRACT: One of the most important tasks facing the road industry is to improve the methodology and technology of road design and construction. Road design is a complicated complex of research works, which includes geological studies, determination of technical parameters, selection of design, and technological solutions. Designing in difficult ground conditions is especially difficult. The paper presents the peculiarities of design and construction of auto roads, the results of laboratory and field soil tests, a choice of road design considering the requirements of normative documentation. The recommendations for the choice of measures to ensure the reliability and durability of road pavement and the high level of reliability are presented.

1 INTRODUCTION

Improving the quality and efficiency of construction on subsidence soils largely depends on properly assessing their properties. The choice of methods for improving subsidence foundations and making the appropriate structural and technological solution plays a key role in the design. Traditionally, in the construction of buildings and structures, as well as road structures on weak and collapsing soils, the priority belongs to pile foundations. The expediency of improving subsidence foundations with these foundations is due to the high load-bearing capacity, reliability, and economic and technological efficiency. The proper determination of the bearing capacity of piles is one of the most critical stages in the design of foundations on collapsing soil bases. This parameter is often set experimentally from the condition of the piles on the ground. It is also necessary to improve the mechanical properties of collapsible soils by reinforcing them with geotextile materials.

The development of reliable methods for improving soil foundations in subsidence areas is an urgent task today. A distinctive feature of collapsible soils is their ability when stressed by their weight or the foundation's external load, to give additional settlements, called collapses, when moisture increases – soaking (Houston, S.L. 2002). Collapsible soils include loess, loess-like sand – clays, loams, and clays, some types of head loams and sand–clays, as well as, in some cases, fine and dusty sands with high structural strength, bulk clay soils, industrial wastes (grate dust, ash, ash deposits, etc.) Loess rocks (synonym of the term "dusty rocks") occupy a place between sandy and clayey rocks in the series of uncemented sedimentary rocks and, like them, have a polygenetic origin. The term "loess rocks" has two notions: "loess" and "loess-like" rocks (Gaaver, 2012). Loess is a rock with collapsing under natural pressure and additional loads; it has a homogeneous (non-laminated) texture and weak water-resistant structural bonds; the structure is often dusty-filmy and granular-filmy (Jiang, M. 2012).

DOI: 10.1201/9781003299127-393

The main features of loess soils are (Opukumo, A.W. *et al.* 2022):

1. Yellow-brown and pale-yellow coloration.
2. High dustiness (the content of dusty fraction (0.05-0.005 mm) over 50% with a small number of clay particles.
3. The raised porosity (40-55%) with a network of macropores in size 1-3 mm visible to the naked eye caused by the presence of thin vertical tubules.
4. Low natural humidity from 0.04 to 0.18 (Sr = 0.5).
5. Ability to keep a vertical slope of considerable height in a dry condition.
6. High carbonate content.

Loess-like soils are brown and red-brown, with many fine-dust particles, fewer macropores, and granular-aggregate and aggregate structures.

Today the world practice different methods (Bellil, Abbeche and Bahloul, 2018) and ways of eliminating subsidence properties of soils by their compaction or consolidation; the device of soil cushions is used (Akbari Garakani *et al.* 2019). To consolidate the subsidence soils, use the methods of one-solution silicification or thermal firing. The device of ground cushions creates a layer of non-subsidence soil in the foundation base (Zhussupbekov,A.Zh. *et al.* 2019; Tulebekova *et al.*, 2022). Another practice presented the construction of fixed soil columns and piles in weak dusty-clayey soils when combinations of jetting and boring methods (Awwad, T. 2019; Zhussupbekov A.Zh., Utepov, Ye.B. 2015) or combination of jetting technology with the immersion of ready reinforced concrete elements are also promising (Akhazhanov,S. 2020; Yessentay,D. 2021). Also, one of the effective methods of designing structures on subsidence soils is the reinforcement of foundation soils. One of the basic concepts of soil reinforcement is reduced to the scheme when the weak soil mass is reinforced with high-strength elements and diaphragms placed in the ground. In this case, both vertical and horizontal reinforcement is possible, which in each case has a different effect on the stress-strain state of foundation soils and the operation of foundations. The improvement of ground and soil base reinforcement is directly related to the materials used for reinforcement (Zhussupbekov, A.Zh., Zhankina, A.2021).

2 INVESTIGATION CONSTRUCTION SITE

The planned section of the road (km 240 + 00-km 440 + 00) is in the Karasay and Ili districts of the Almaty region (Figure 1).

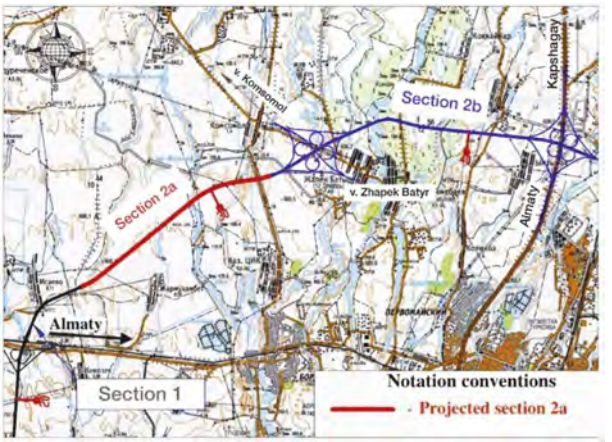

Figure 1. Section road for investigation.

2.1 *Engineering and geological conditions*

Geomorphologically, the construction site is located the foothills of the Zailiskiy Alatau (KGS 2019, 2020).

The climate of the district is sharply continental. The climate features of the region are determined by the latitude and presence of orographic elements on its surface. The combination of climate-forming factors causes the predominance of hot, dry weather with sharp seasonal and daily fluctuations in air temperatures. Summers are hot, and winters are moderately cold and mild. Heavy rains are noted in spring and summer.

The Tien Shan region is a complex mountain country formed due to repeated changes in tectonic conditions. The oldest geosyncline stage of tectonic development continued from the Archaea in places to the Ordovician. Orographically, the region is represented by a complex system of ridges and cavities. Precambrian and Caledonian fold structures form the Tien Shan region. Alpine folding began in the Upper Cretaceous era and continues intermittently to the present.

There is a general relief slope to the north. The relief was formed due to mudflows and the intense activity of river waters. It is a weakly hilly plain with river valleys. The remains of the I and II floodplain terraces are observed on it.

Hydrographically, the investigated section is located between the Kaskelen and Talgar rivers, including their feeders, and the planned route passes through them.

The planned route directly crosses the network of watercourses. Because the route of the designed road passes through these streams, they will directly affect the formation of engineering and geological conditions of the projected facility (Tulebekova,A.S. 2020; Zhussupbekov, A.Zh 2020).

The area's geological structure is characterized by loose Quaternary deposits lying on rocks of the Paleozoic bedrock. The indigenous sediments are represented by granitoid, granodiorite, and porphyrite intrusions in river basins crossing the Zailiskiy Alatau ridge. These rocks will not have a decisive impact on geotechnical profiteering, so a detailed description of the bedrock rocks is not given—soft deposits of medium- and modern-quaternary age form alluvial-proluvial complex of stones.

To detail the geological-lithological section along the axis of the route, 51 exploration wells were drilled to a depth of 6.0m. In total 199.0m were penetrated. Absolute elevations of wells are 631.59-680.70 m.

Route section from the surface is represented by topsoil with a thickness of 0.2 m. Lams from solid to fluid is penetrated with a thickness of up to 6.0 m below and sandy loams up to 1.5 m. There are layers of medium-grained sand and coarse penetrated with a thickness of 0.6 m below.

Filling soil is found on intersected existing roads. It is represented by semi-solid loam containing gravel and pebbles. Groundwater during the survey was penetrated at a depth of 1.0 - 7.8 m. The maximum penetrated power is 3.2 m.

The physical and mechanical properties of soils are given in Table 1.

2.2 *Field tests*

The tests of soil piles were carried out according to the requirements of GOST 5686-2020 (GOST 2012). The tests were carried out by the static pressing loads of 20 piles on this site (Figure 2). Loading the tested piles was made evenly, without blows, by loading steps whose size was no more than 1/10 estimated bearing capacity.

The loading and measuring devices consist of a power stand, DG200P250 jack, hydraulic pump, deflectometer 6PAO-0.01, roulette, and manometer.

The reading of each device was taken at each step of a pile loading, the first hour with an interval of 15 min., further with an interval of 30 min, before attenuation of movement of the pile called stabilization. Observations were accepted for the conditional stabilization of a pile.

Unloading of a pile was made by the steps equal to the doubled sizes of stages of loading, with the endurance of each step within 15 min. Counting on devices to measure deformations

was removed after each unloading step and in 15 min observations. Observations of the movement of a pile were carried out within 60 min after complete unloading (to zero) with the removal of counting from devices every 15 min. According to the project, the movement speed in soil was no more than 0.1 mm in the last 60 min.

Stamp tests were carried out in Section 2 to study the bearing capacity of the artificial base soil for the pipe at km 43 + 225.

The bearing capacity of the base soil under the Overpass bridge was studied at 3 points of stamp testing. A stamping unit with a rotary console acting on the principle of a balance beam was used to carry out the tests.

3 RESULTS

The results of the tests are given in Table 2.

Results of the test showed that the pile during the test perceives the design load of the pile head to equal - 71.0 tf. By results of the carried-out static tests of pile No. 33 on support No. 1 (Overpass bridge through the Borolday river 2 on KM 31+265) at the tenth step of loading, the equal 106.5 tf recorded deformation (deposit) - 40.28 mm. Gain of deformations on 4.24 mm is recorded after additional endurance for 26 h. The total gain of deformations was 44.58 mm, while a stabilization deposit isn't recorded. They are objectively analyzing increment of

Table 2. Test results.

deformations and overdue approach of stabilization to the 9th steps at the impact of efforts - 96.0 tf and schedules of the actual behavior of piles under loading perhaps reasonably to take for the extreme resistance of a pile of Fu at the pressing loadings the eighth step - 85.2 tf.

The carried-out static test of pile No. 42 on support No2 (Overpass bridge through the Borolday river 2 on personal computer 31+265), the pressing loadings showed that at the eighth step of loading, the equal 83.4 tf deformation - 45.965 mm was recorded that exceeds extreme size equal - 40 mm. According to SP RK 5.01–103–2013 (items 4.5.5), the pressing loadings take the loading of the seventh step for the extreme resistance of Fu pile- 72. 975 tf. The test results showed that the bearing capacity of pile No. 42 on support No2 on soil is sufficient to perceive design loading.

Static test of pile No33 of support No2 (Overpass bridge on personal computer 32+730) the pressing loading showed that at the eighth step of loading the equal 117 tf late stabilization (was recorded through - 34.5 hours) at the same time deformation was 38.32 mm. The seventh step loading for the extreme resistance of a pile of Fu - 102 tf is taken at the pressing loadings. The test results showed that the bearing capacity of pile No33 on support No2 on soil is sufficient to perceive a projected estimated pile load.

Test of pile No45 of support No1 (Overpass bridge through the Borolday river 2 on KM 31 +265), the following result was issued by the pressing loadings: at the eighth step of loading 85.6 tf, 41.43 mm settlement was recorded, at the same time stabilization of deformation didn't happen. The results showed that the bearing capacity of pile No45 on support No1 on soil is insufficient to perceive the maximum pressing design load. The actual bearing capacity doesn't exceed 74.9 tf, which is less than the projected capacity.

Static test of pile No. 33 of support No2 by the pressing loadings showed that the deformation - 41.715 mm was recorded at the sixth step of loading equal to 62.4 tf, at the same time, stabilization of deposit was not registered. The fifth step, 52.0 tf is taken for the extreme resistance of pile Fu at the pressing loadings. The tests showed that the bearing capacity of pile No. 33 on support No. 2 on soil is insufficient to perceive the maximum pressing design load. The actual bearing capacity doesn't exceed 52.0 tf, and there is less than the projected capacity.

The following conclusions can be drawn based on the results of stamp tests of artificial soil:
Point 1: Equivalent modulus of deformation of the structure E_d = 8.15 MPa.

The modulus of elasticity of the structure is not considered correctly due to extremely small elastic deformations and accumulation of residual deformations. No loss of bearing capacity occurs. Mean base modulus ratio Ee/E_d = 9.1 (Point1); Ee/Ed = 8.19 (Point 2); Ee/Ed = 6.85 (Point 3) presented in Figure 3.

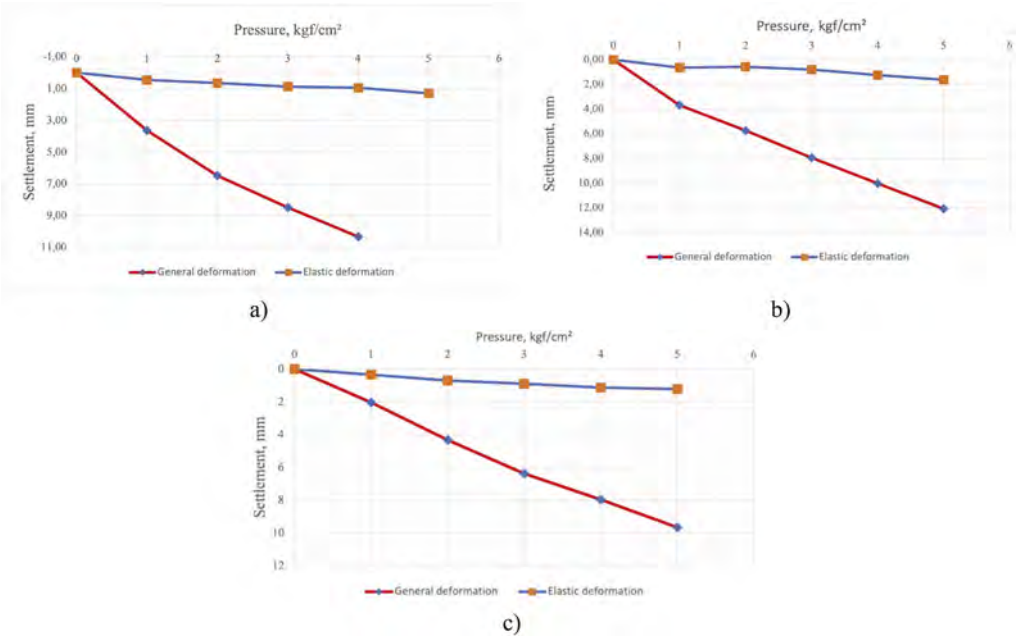

Figure 3. Stamping test results: a) Point 1; b) Point 2; c) Point 3.

4 CONCLUSIONS

According to the results of the study, it is concluded that:

1. The survey area is located within the IV road climatic zone.
2. Excavations with 25.0 m groundwater were penetrated at a depth from 0.4 m to 15.9 m from the day surface. The amplitude of seasonal variation of the groundwater level is + 1.0-1.2 m.
3. The standard depth of loam freezing is 0.79 m; loam, sandy, dusty and fine sands - 0.96 m; gravelly, coarse, and medium-grained sands - 1.03 m, coarse clastic sands - 1.17 m.
4. The area is in the zone with seismic hazard (according to SP RK 2.03-30-2017) [87] - 9 (nine) points.
5. The following conclusions can be drawn based on the results of the tests:

The average modulus of the structure deformation at 3 test points is following: E_d = 8.83 MPa. It is recommended to perform more thorough compaction, following the average ratio of the base modules Ee/E_d = 9.09 at the 1st point; Ee/E_d = 8.19 at the 2nd point; Ee/E_d = 6.85 at 3rd point.

ABSTRACT: Chemical-based soil stabilization brings adverse effects to soil ecology; hence, bio-based soil stabilization is becoming popular nowadays. The present study analyzes the suitability of using different biopolymers s as additives in pavement subgrade. Two biopolymers, Xanthan gum, and Agar are used in 0-1.5% quantity in MSWF, and their CBR values are calculated. The improved biopolymer-based MSWF is deployed in the pavement subgrade, and the pavement is analyzed based on rutting and fatigue at various pavement conditions. The flexible pavement analysis is carried out through a computer-based application IIT-Pave. It is found that the subgrade made of modified MSWF with a high percentage of biopolymer shows the minimum strain on the subgrade and bituminous layer. Hence, the biopolymers can be successfully used in pavement subgrade to improve its performance.

1 INTRODUCTION

Utilization of municipal solid waste and using biomaterials in engineering applications are two critical activities in the row of sustainability. 1.15 lakh metric tons per day (TPD) or 42.0 million tons of municipal solid waste are produced in urban India each year, of which 83,378 TPD are produced in 423 Class-I cities (Sharma and Jain 2019). The landfills are rising day by day. It is therefore required to reduce the load of landfills, and landfill mining is the workable technique in this row (Frändegård et al. 2013; Yi 2019; Hogland, Marika, and Marques 2010). In landfill mining, the dumped MSW is mined from the landfill and utilized for various other applications (Kandpal and Datta). The previous study shows that the soil-like material of the MSW can be utilized in different civil engineering applications, such as in roads and embankments (Somani 2021; Somani et al. 2022). But in most cases, the share and the compressive strength of this soil-like material or MSW-Fines are not enough per the requirement. In that case, stabilization of that soil-like material is required (Chandana et al. 2021; Goli et al. 2022). At the same time, the technique of the stabilization should be eco-friendly. To realize sustainability in a complete sense, it is required that most of the engineering activities should be inspired by green technology. Using biopolymer for stabilization is an eco-friendly approach (Chang et al. 2020; Latifi et al. 2017). In the present study, an attempt has been made to stabilize the municipal solid waste fines (soil-like material in MSW) using two polymers, Xanthan gum, and Agar gum. It is seen that places in India are flooded during rainy seasons it is hence any civil engineering material that is used in pavement subgrade is required to have good performance in soaking conditions. But generally, it is found that biopolymers disintegrate in the presence of water. To assess the performance of biopolymers in water, the test is carried out in wet conditions.

2 MATERIAL USED

MSW is collected from an abandoned landfill in Varanasi, India. The sample is collected by removing the top 15 cm upper layer. The sample is then dried in the sun and sieved from the No-4 ASTM (4.75 mm) sieve. The soil-like material passed after sieving is used in the present study. The passing soil-like material is denoted as municipal solid waste fines (MSWF) later in the study. For the biotreatment of the MSWF, two biopolymers are chosen: Xanthan Gum (XG) and Agar Gum (AG). These biopolymers and microorganism-based and algae-based biopolymers consecutively. Xanthan gum has numerous industrial applications like in food and cosmetics. It gets its name from the kind of bacteria employed in the fermentation process, Xanthomonas campestris, and is made from simple sugars. Xanthan gum is a good thinker and stabilizer; its civil engineering application is recently explored (Chang et al. 2015; Dehghan et al. 2019). Agar consists of two substances: the linear polysaccharide agarose and a heterogeneous collection of smaller molecules termed agaropectin. It is released during the boiling process because it serves as the structural framework in the cell walls of some types of algae. Even a tiny quantity of Xanthan Gum creates so much emulsion. When combined with the soil particles with water, it forms hydrogel, and the interparticle bonds thicken on dehydration. The quality of Agar is that it comes in gel form when the temperature goes up to 80º C, which solidifies and becomes semi-solid while the temperature downsides to 30-40º C. Due to this vast temperature difference, when it combines with soil, it is easily mixed and then remains semi-solid, enhancing the soil's mechanical properties (Smitha, Rangaswamy, and Keerthi 2021; Smitha and Sachan 2016). The basic properties of the MSWF are given in Table 1.

Table 1. Basic properties of MSW-Fines.

Properties	Values
Maximum Dry Density (MDD) (Mg/m3)	1.71
Optimum Moisture Content (OMC) (%)	17.0
Specific Gravity	2.23
Clay and Silt Size Particles (%)	60.8
Sand Size Particles (%)	39.2
Unified soil classification system (USCS)	CL
Plasticity Index (PI)	11.09

3 METHOD OF STUDY

ASTM standards are followed to determine the basic properties of MSWF. Xanthan gum and Agar gum are mixed separately in MSWF in the varying percentage of 0, 0.25, 0.5, 1 & 1.5% by the weight of water mixed in MSWF (W_b/W_w) while maintaining its maximum dry density. Here W_b is the weight of biopolymer and W_w is the weight of water mixed in MSWF. The wet mixing method adopted by (Bonal et al., 2021) is used for the test. As per ASTM D1883, the soaked CBR tests are carried out for all the MSWF and biopolymer mixes. To carry out the CBR test, about 5 kg of oven-dried MSWF is taken, and then the water-based biopolymer solution is mixed thoroughly into the MSWF as per the OMC of the mix. The mix is compacted in the CBR mold in three layers; each layer is compacted with 56 blows. After compaction, the compacted MSWF is submerged in the water for 96 hours then the standard plunger is penetrated the compacted mix. The CBR ratio is then calculated w.r.t. the load required for the penetration in standard material. For designing flexible pavement, IRC 37 2019 is adopted. The natural MSWF and biopolymer-treated MSWF are considered to be borrowed and compacted in a 500 mm layer in the subgrade. The designed pavements contain subgrade, granular sub-base, and bituminous layer. As recommended in IRC-37, the bituminous pavement layer is optimized using the computer program IIT-Pave to reduce the cost of the pavement.

4 RESULTS AND DISCUSSION

The MSWF is mixed with biopolymer in varying percentages and compacted in a CBR mold. The soaked CBR values are measured for each mix, and the results are shown in Figures 1(a, b). It can be seen that the CBR value of Xanthan gum mixed MSWF is increased with an increasing percentage of Xanthan gum for up to 1% Wb/Ww; beyond 1% of xanthan gum, the soaked CBR value is decreased. It is because when the Xanthan gum comes in contact with water, it forms hydrogels, and it also has lubricating nature when it is in the form of a gel. As xanthan gum is in excess, it shows a lubrication effect, and the plunger penetrates the compacted MSWF relatively more easily. It is also evident from other studies that Xanthan gum makes interparticle bonds and increases the mechanical strength of the soil. In the case of Agar gum, the CBR value of the mix is increased consistently. As the agar gum solidifies at 30-40ºC, it remains semi-solid even when submerged in water. The Agar also forms an interparticle connection, and the mechanical strength increases when the bond between particles thickens. The maximum socked CBR is reported as % and % in the case of Xanthan gum and agar gum, which shows an increment of % from the soaked CBR of natural MSWF.

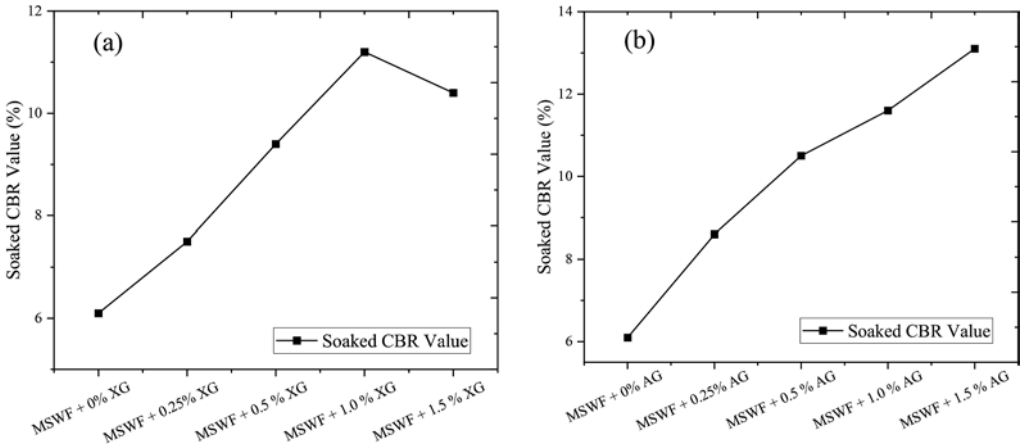

Figure 1. Variation of soaked CBR values (a) For Xanthan Gum (b) For Agar Gum.

Viability of the MSWF mixed with biopolymer in pavement subgrade: The CBR of the subgrade has a vital role in deciding the thickness of the upper layers of pavement. The CBR of the subgrade can be enhanced to optimize the sub-bases thickness, and the bituminous layer since the pavement rests over it. As recommended by IRC-37, the pavement subgrade can be strengthened by replacing the upper 500 mm of the weak soil with the borrowed high-strength soil in the subgrade. In the present study, the pavement will be designed over the subgrade modified with borrowed MSWF-Biopolymer mix. The bituminous layer's thickness is optimized to lower the cost of the pavement. The typical pavement layers are shown in Figure 2.

By following the procedure of designing pavement, the resilient modulus of the subgrade is calculated using Equation 1, and the resilient modulus of the granular subbase is calculated using 2. The present design is based on 90% reliability, meaning there are only 10% chances that the calculated strains will surpass the allowable strains. As per IRC-37, the pavement is tested for strain rutting over the subgrade layer and fatigue below the bituminous layer. The maximum allowable stain for rutting and fatigue criteria can be calculated using Equations 3 and 4. The pavement is designed considering two traffic cases: 50 MSA (Million standard axle) and 100 MSA. VG-40 bitumen grade is taken for the present bituminous layer, and the MR (Resilient modulus) of the VG-40 bitumen at 35° C is taken 3000 from IRC-37. Linear analysis-based software IIT-Pave calculates the flexible pavement system's actual strains.

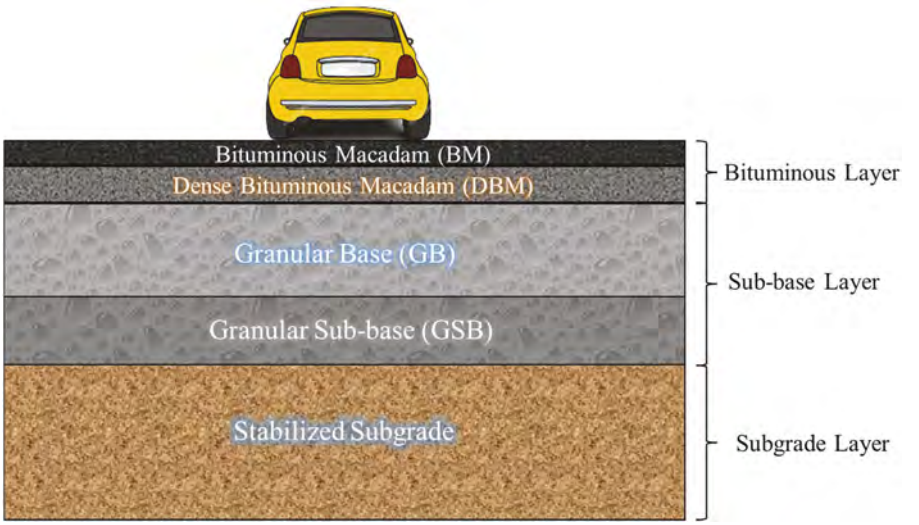

Figure 2. Details of pavement layers.

$$M_{RS} = 17.6\ x\ (CBR)^{0.64} \qquad \text{For CBR} > 5.00\% \tag{1}$$

$$M_{SB} = 0.2(h)^{0.45} x\ M_{RS} \tag{2}$$

Where M_{RS} = Resilient modulus of subgrade soil (in MPa).
CBR = California bearing ratio of subgrade soil (%)
M_{SB} = Resilient modulus of granular sub-base (in MPa)
Sub-grade rutting criteria

Where N_R = Subgrade rutting life
ε_v = Vertical compressive strain at the top of the subgrade
Fatigue cracking criteria for bituminous layer

$$N_f = 0.5161\ x\ C\ x\ 10^{-04}\ x\ \left[\frac{1}{\varepsilon_t}\right]^{3.39} x\ \left[\frac{1}{M_{Rm}}\right]^{0.854} \qquad \text{For 90\% Reliability} \tag{4}$$

Where N_f = Fatigue life of bituminous layer
C = Factor based on the % bitumen and % air voids in the bitumen layer
ε_t = maximum horizontal tensile strain at the bottom of bituminous layer (DBM)
M_{Rm} = Resilient modulus (MPa) of the bituminous mix
Allowable strain for rutting and cracking from equations 4 & 6
ε_v = 0.0003716 (rutting) | ε_t = 0.00017813 (cracking)

Table 2. Details of pavement for the MSWF subgrade stabilized with Xanthan gum (XG).

MSWF & Biopolymer mix	Soaked CBR Value (%)	MR subgrade (MPa)	MR of Sub-base (MPa)	Bituminous layer thickness (mm)
MSWF + 0% XG	6.1	56.0	175.0	175
MSWF + 0.25% XG	7.5	63.9	199.8	158
MSWF + 0.5 % XG	9.4	73.8	230.8	150
MSWF + 1.0 % XG	11.2	82.6	258.2	138
MSWF + 1.5 % XG	10.4	78.8	246.3	145

Table 3. Details of pavement for the MSWF subgrade stabilized with Agar gum (AG).

MSWF & Biopolymer mix	Soaked CBR Value (%)	MR subgrade (MPa)	MR of Sub-base (MPa)	Bituminous layer thickness (mm)
MSWF + 0% AG	6.1	56.0	175.0	175
MSWF + 0.25% AG	8.6	69.8	218.1	155
MSWF + 0.5 % AG	10.5	79.3	247.8	145
MSWF + 1.0 % AG	11.6	84.5	264.1	140
MSWF + 1.5 % AG	13.1	91.3	285.5	130

In the present analysis, the total sub-base thickness is taken as 450 mm, in which the granular sub-base and granular base are taken as 200 and 250 mm consecutively for all cases. The bituminous layer optimized thickness is given in Figure 3 and Tables 2–3. The bituminous layer consists two sub layer one is dense bituminous macadam (DBM) and bituminous macadam (BM), which is the surface course. The minimum thickness of BM is taken 40 mm. It can be seen that the bituminous layer thickness decreased for both cases of XG and AG, while for XG, the thickness reduced by up to 1% of XG. The maximum and minimum thickness of the bituminous layer is calculated at 175 mm, and 130 mm (for 1.5% W_b/W_wAG) for XG minimum thickness is analyzed as 138 mm.

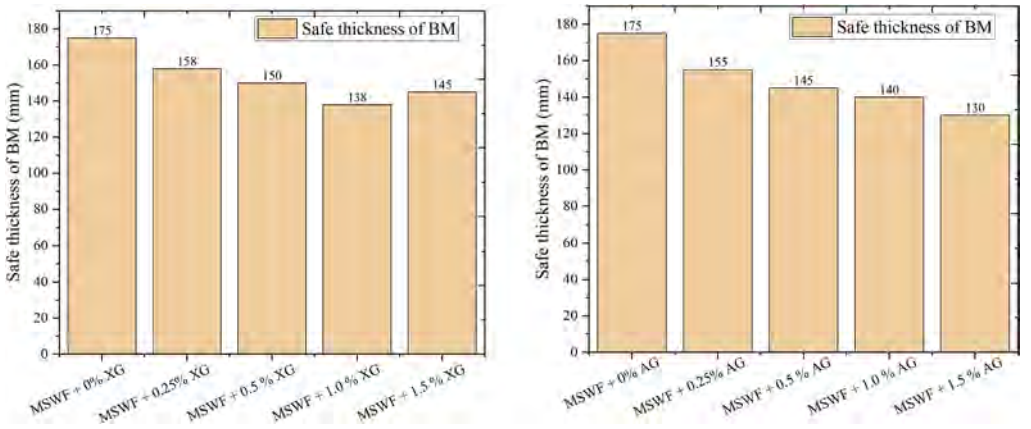

Figure 3. Bituminous layer thickness of pavement having biopolymer stabilized subgrade (a) Xanthan Gum (b) Agar Gum.

5 CONCLUSION

After performing the soaked CBR test, it is found that even after long-term soaking in water, the MSWF and biopolymer mix gives good resistance to penetration. For XG, the optimum percentage of biopolymer is observed at 1%, while for AG, the optimum percentage is reported at 1.5%. When the flexible pavement is designed while considering MSWF and biopolymer mix in the subgrade, it is observed that the bituminous layer thickness is reduced by as much as 25.7%, which is a significant reduction compared to the amount of biopolymer used for strengthening the subgrade. It is hence can be concluded that XG and AG stabilized MSWF can be used in pavement subgrade to reduce the thickness of pavement and also to optimize material cost.

Evaluation of resilient modulus of asphalt pavement in cold region with Thermo-Hydro-Mechanical coupling simulation

J. Si
Graduate School of Engineering, Hokkaido University, Sapporo, Japan

T. Ishikawa
Faculty of Engineering, Hokkaido University, Sapporo, Japan

ABSTRACT: To understand the actual response of asphalt pavement in cold regions, this study establishes a coupled thermo-hydro-mechanical (THM) Finite Element analysis of asphalt pavement incorporating a M_r-prediction model, which can adequately evaluate the influences of stress state, freeze-thaw, and water content on the resilient modulus (M_r). The FE analysis can not only obtain the changes in water content and temperature of the pavement, but also quantitatively reflect the synergistic effects on the resilient modulus. For this reason, the FE analysis can reproduce a typical Sandwich-Structure in the thawing season. This is of great significance to predict the mechanical properties and fatigue life of asphalt pavements in cold regions.

1 INTRODUCTION

Freeze-thaw action deteriorates the pavement in two ways as frost-heave and thaw-weakening. The frost heave induces the surface cracking in the asphalt mixture layer (hereafter referred to as "As layer"). On the other hand, the thaw-weakening means a drop of the bearing capacity for base and subgrade layers caused by rise in water content. Thus, it is necessary for precisely evaluating the fatigue life of the asphalt pavement to understand the variation mechanism of resilient modulus (M_r) influenced by the weather condition. Ishikawa et al. (2019) examined the effects of freeze-thaw actions and the concurrent seasonal fluctuations in water content on the resilient deformation characteristics of base course materials, while Lin et al. (2022) examined the climate effect on the resilient modulus of subgrade materials to evaluate the mechanical behavior of asphalt pavement. This study proposes a M_r-prediction model to replace the constant elastic modulus of base course and subgrade layer to the resilient modulus related to stress states and climate conditions. Besides, a two-dimensional (2D) FE model using the coupled Thermal-Hydro-Mechanical (THM) analysis is developed to study the behavior of asphalt pavement.

2 SIMULATION METHOD

2.1 *Pavement FE model*

The pavement FE model consists of the As layer, base course layer (C-40), anti-frost layer (C-80), and subgrade layer, as shown in Figure 1.

2.2 *Soil properties for unsaturated and freezing conditions*

For the water retention and unsaturated permeability characteristics, the VG model is adopted. Besides, VG model is combined with the Clapeyron equation to estimate the degree of saturation for liquid water in unsaturated soil subjected to freeze-thaw. The effective heat conductivity and volumetric heat capacity of the solid-fluid system is calculated as follows.

DOI: 10.1201/9781003299127-395

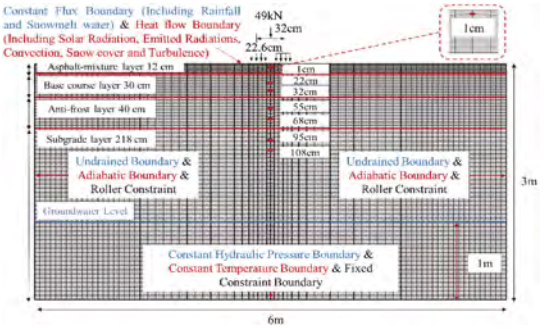

Figure 1. Pavement FE model.

$$\lambda_T = (\lambda_s)^{1-n}(\lambda_i)^{n-\theta_w}(\lambda_w)^{\theta_w} \tag{1}$$

$$C_{Ta} = (1-n)C_{Tp} + nS_wC_{Tw} + nS_iC_{Ti} \tag{2}$$

where λ_s, λ_i, λ_w is heat conductivity of soil particles, ice and water, respectively; θ_w is volumetric water content; C_{Tp}, C_{Ti} are volumetric heat capacity of soil particles and ice, respectively.

The elastic modulus (E_1) of As layer (Figure 2(a)) is obtained by the following equation.

$$E_1 = a \times \arctan(bT_1 + c) + d \tag{3}$$

where *a, b, c, d* are regression constants; T_1 is average temperature of As layer.

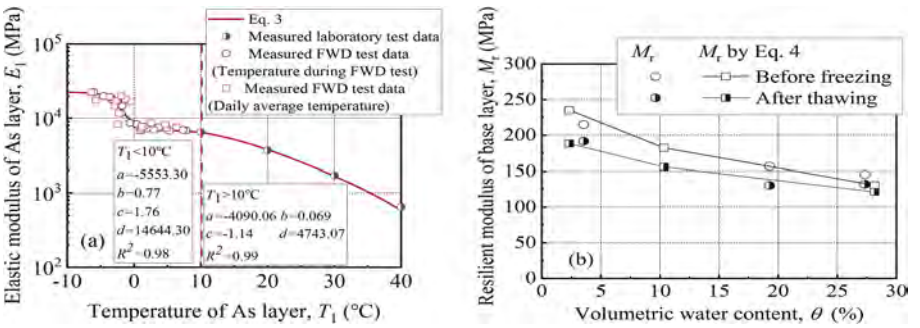

Figure 2. Estimated modulus of different layers (a. As layer; b. Base layer).

Lin et al. (2021) proposed a simple model to estimate the climate effect on the M_r (Figure 2 (b)), which capture the decreasing M_r with freeze-thaw and water content as follows.

$$M_r = F_{clim} \cdot k_1 p_a \left(\frac{\sigma_{ii}}{p_a}\right)^{F_{clim}\cdot k_2} \left(\frac{\tau_{oct}}{p_a}+1\right)^{F_{clim}\cdot k_3} \left(\frac{\psi}{\sigma_{net}}+1\right)^{F_{clim}\cdot k_4} \tag{4}$$

where F_{clim}, k_1, k_2, k_3, k_4 are regression constants; p_a is atmospheric pressure and set as 101 kPa in this study; σ_{ii} is bulk stress (kPa), defined as $\sigma_1+\sigma_2+\sigma_3$; τ_{oct} is octahedral shear stress (kPa); σ_{net} is net mean stress (kPa), defined as $[\sigma_{ii}/3\text{-}u_a]$; u_a is pore air pressure.

2.3 *Coupled THM analysis*

The THM coupled analysis is performed by considering the dependence of resilient modulus on temperature, water content and stress state, and obtaining the accurate M_r distribution through convergence analysis, as shown in Figure 3.

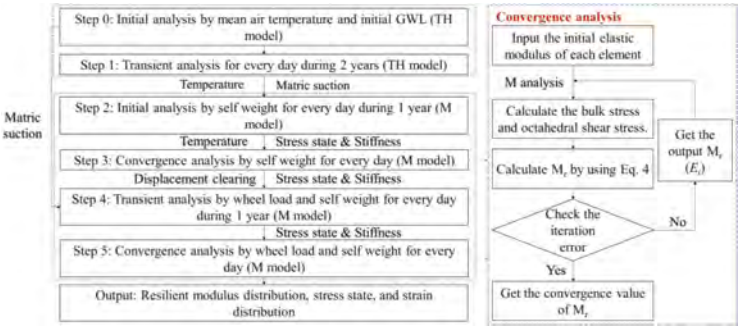

Figure 3. Flow chart of THM analysis and numerical simulation model.

3 RESULTS AND DISCUSSIONS

3.1 *Ground temperature and degree of saturation*

As shown in Figure 4, it is revealed that the fluctuation in ground temperature becomes remarkable at the shallow part of pavement structure. This indicates that the closer to the ground surface, the more significant the environmental impact on the ground temperature. Meanwhile, there is a tendency for the degree of saturation of base course layer to decrease rapidly after late December 2009, which was due to the freezing of pore water at a ground temperature lower than the frozen temperature. In thawing season on March, the thawing of frozen water and the snowmelt water infiltration contribute to high water content of the pavement structure. The change in water content, observed from the regular season to the thawing season, seriously influences the mechanical behavior of base course layer and subgrade layer. Besides, it is recognized that the annual change in the ground temperatures and the degree of saturation obtained from the proposed THM coupling simulation are al-most consistent with the measured results.

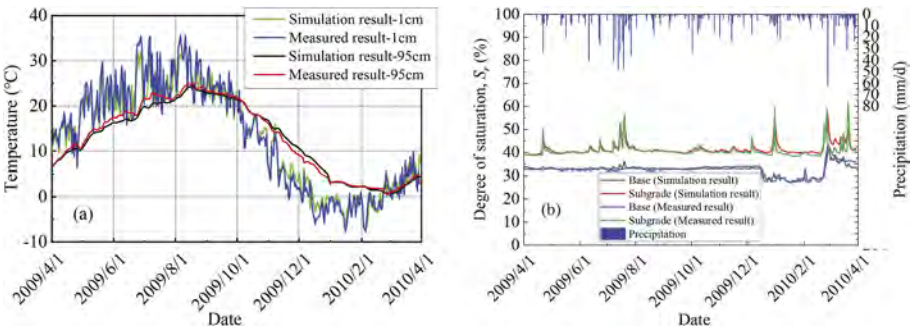

Figure 4. Distribution of temperature and water content (a. Ground temperature; b. Degree of saturation).

3.2 *Variation of resilient modulus distribution with time*

To separately evaluate the impact of weather conditions on resilient modulus, the distributions of resilient modulus are shown in Figure 5 under five different weather conditions (no rainfall and maximum rainfall in the regular season, the maximum frost-penetration depth state in the freezing season, and the full and partial thawing states in the thawing season). The resilient modulus increases as the depth increases, which is due to the bulk stress of soils increasing, and the octahedral shear stress is weakened along with the depth. Under the center of wheel loads, the resilient modulus at the surface of base course layer changes significantly, which is due to the stress concentration in this area. Besides, in the thawing season and rainy days, higher water content dramatically reduces the resilient modulus of base course layer and subgrade layer, and

freezing action improves the resilient modulus of base course layer. Moreover, the resilient modulus increases with increasing the matric suction away upward from the groundwater level, and the resilient modulus below the groundwater level increases with increasing the bulk stress as the matric suction keeps zero. Meanwhile, the resilient modulus dramatically decreases in the thawing season, which significantly impact the fatigue life of the pavement. Since the subgrade layer was not frozen in the winter, the resilient modulus was mainly affected by water content change. Importantly, the formation of a thin inside frozen layer in base layer forms a typical Sandwich-Structure of pavement in the thawing season. It significantly reduces the resilient modulus at the upper part of base layer, which seriously affects the safety of the pavement.

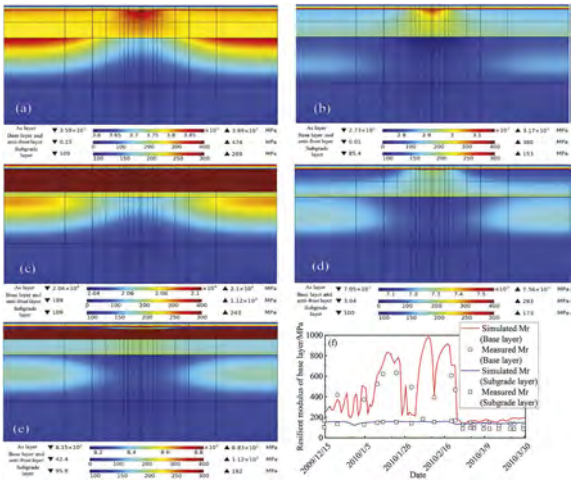

Figure 5. Distribution of resilient modulus (a. regular season-sunny day; b. regular season-rainy day; c. freezing season; d. thawing season; e. thawing season-partial; f. variation of average M_r with time).

4 CONCLUSIONS

- The proposed THM coupling simulation could reasonably reproduce the annual changes in temperature, water content and resilient modulus in the asphalt pavement. This indicates that it cannot only obtain the changes in water content and temperature of the pavement, but also quantitatively reflect the synergistic effects on the resilient modulus.
- The rise in water content leads to a significant decrease in the resilient modulus of pavement, while the freezing of pore water induces a dramatic increase. Therefore, the THM coupling simulation can reproduce a typical Sandwich-Structure in the thawing season.

Numerical analysis of embankments on soft clay supported with cement-mixed columns

Ashutosh Kumar Singh
Research Scholar, Indian Institute of Technology Roorkee, Roorkee, India

Anumita Mishra
Assistant Professor, Indian Institute of Technology Roorkee, Roorkee, India

ABSTRACT: Embankments constructed over soft soil are susceptible to bearing capacity failures, intolerable settlements and lateral stability problems. Therefore, columns supported with soil-cement mix (DCM) platform restrict the vertical deformation of the structure and lateral displacements. Soil arching has a significant effect on the behavior of columns-supported embankments. Therefore, the mixing of soil with cement as a load transfer platform enhances the performance of embankments. A numerical study is conducted to investigate the performance of soil-cement mix column supported embankment subjected to static loading. The effectiveness of the soil-cement mix is examined by comparing the lateral displacement and settlement for three cases: embankment on DCM columns with load-transfer platform, embankments on DCM columns only, and stone columns. Stress contours and stress variations are presented to show soil arching during the embankment construction. It is observed that the inclusion of soil-cement mix at the load platform and below the embankment reduces the settlement and lateral displacement by 73% and 38%, respectively, as compared to stone columns.

1 INTRODUCTION

The construction of embankments over soft soil is a challenging task for geotechnical engineers due to its low strength and high compressibility. Therefore, there are numerous methods available to improve the condition of soft soil, such as installation of stone columns, provision of drains to accelerate the rate of consolidation, reduction of weight of the embankment by using lightweight fill materials, stabilization of soft soil with cement, and bypassing the soft soil to the firm stratum with the help of rigid piles. Soil stabilized with binder provides an economical solution for the construction of roads and highway over soft soil (Chai et al., 2015; Yapage et al., 2014). The deep mixing technique stabilizes the soil by mechanically mixing it with dry or wet binder.

Several researchers have performed numerical studies to understand the performance of embankments on soft soil by ground improvement techniques. Most of the researchers have used granular columns below the embankment to reduce the settlement and increase consolidation (Mohapatra and Rajagopal, 2017; Xue et al., 2019).In the past, most studies focused on the performance of embankment supported over DCM columns (Yapage et al., 2014; Jamsawang et al., 2016; Ye et al., 2017; Venda et al., 2011; Huang et al., 2009). Dang et al. (2020) numerically studied the deformation characteristics of the fibre-reinforced load-transfer platform and columns-supported embankments. Past studies have also focused on geosynthetics reinforced and pile-supported embankments (Pham and Dias 2021). However, limited studies have been done on the use of soil-cement mixed as a load transfer platform (LTP). Soil-cement mixed as LTP would reduce the lateral displacement of the toe and would increase the load on the DCM columns. This LTP will act as a semi-rigid slab which will be an economical solution, and DCM columns will work effectively. It will also maintain continuity

DOI: 10.1201/9781003299127-396

between DCM columns and LTP. But in the case of GRPS embankments, geosynthetics are generally placed above the piles at a certain height to avoid mechanical failure.

The embankment fill between DCM columns tends to settle due to the presence of soft soil underneath it. The fill above the DCM columns will be partly restrained against this settlement. This resistance reduces the pressure on the soft soil but increases the pressure on the DCM columns. This mechanism is termed the 'soil arching effect' (Terzaghi 1943). The past researchers have proposed various parameters such as stress reduction ratio and stress concentration ratio, to predict the degree of arching (Liu et al., 2007; Han and Gabr, 2002). Stress concentration ratio (n) is defined as the ratio of stress on the DCM column (σ_p) to that on the soil (σ_s).

Based on past studies, this paper describes the effect of inclusions of soil-cement mixed as a LTP in the embankment supported with DCM columns and the degree of soil arching in DCM columns with LTP. The settlement, excess pore water pressure, lateral displacement at the toe, and stress distribution under construction and loading have been evaluated for embankments supported on stone columns and DCM columns with LTP. This study also compared the magnitudes of stress transfer in soil and columns for two cases, i.e., DCM columns with soil-mixed cement LTP and stone columns.

2 NUMERICAL MODELLING

Wijerathna and Liyanapathirana (2021) compared four different models (Plane strain with equivalent areas, plane strain with equivalent properties, axisymmetric unit cell, and three-dimensional unit cell). They confirmed that out of the four models, plane strain equivalent area model predicted better results. A two-dimensional plane strain analysis is performed using commercial finite element software PLAXIS 2D, by adopting the equivalent area method (Tan et al., 2008; Wijerathna and Liyanapathirana, 2021). The advantage of the 2D model is that it is less time-consuming and has better accuracy. The model is validated by a field study performed by tan and Oo (2008) to validate the developed numerical model. In the field study, the embankment is 20m wide at the crust, 1.8m high, and is filled with sandy material. The embankment is rested on a gravel layer of 1m thickness, underlain by soft soil of 5m thickness. The stone columns are 80cm in diameter and are placed at a square grid spacing of 2.4 m c/c to a depth of 6m. The ground water table is 1m below the ground or at the top of the soft soil.

In the present study, a plane strain analysis based on equivalent area approach is performed, in which the stone column diameter is converted into equivalent wall thickness. The properties will remain the same for soil and stone columns. For 2.4m spacing of stone columns and diameter of 0.8m, the equivalent wall thickness is 0.21m. The horizontal displacement is restrained at the left and right sides of the boundary, whereas the bottom boundary is restrained in both directions. The 15-noded triangular element is used for meshing to achieve better accuracy. The construction of the embankment is performed in 9 days, then consolidation is allowed until complete dissipation of excess pore water pressure. The height of the embankment is increased by 0.6 m in every 3 days, till it reaches a height of 1.8m. The numerical study is validated by comparing the settlement and excess pore water pressure with a field study performed by Tan et al. (2008). It is observed from Figure 1 that numerical results and field study show good agreement, and the error is about 3%for settlement and about 7% in the case of excess pore water pressure.

The validated model is further used for analysis to predict the behavior of the embankment supported on columns. Therefore, in the present study, stone columns are replaced by DCM columns, and a soil-cement mixed LTP is provided at the base of the embankment of 0.6m, as shown in Figure 2. In the Figure 2, the points SP-1, SP-2, and SP-3 are the stress points at the pile head, and SS-1, SS-2, and SS-2 are the stress points on the soil. The DCM columns or soil-cement mixed, fill material, soft clay, and stiff clay are modeled as a linear elastic-perfectly plastic material using Mohr-Coulomb (MC) model. The tensile strength of DCM or soil-cement mixed is considered using tension cutoff, i.e., $0.15q_u$. The properties of fill, soft

clay, stiff clay, and DCM or soil-cement mixed are shown in Table 1. Due to symmetry of the embankment, only half of the embankment is simulated. The purpose of providing crust over soft soil is to provide a drainage layer. Due to the relatively high permeability, the embankment fill and crust are assumed to behave in a drained condition. Due to the low permeability of DCM columns or soil-cement mixed, soft and stiff clay are assumed to be undrained.

3 ANALYSIS OF RESULTS

3.1 *Settlement, excess pore pressure, and lateral displacement*

Figure 3(a) shows the variation of settlement at the center of the embankment with time. From the figure, it has been observed that the inclusion of DCM columns reduces the settlement as compared to the stone columns. The settlement for stone columns, DCM columns, and DCM columns with LTP are 83mm, 22.84mm, and 22.27mm, respectively. The presence of binder in soil stabilizes the soil, and the soil becomes more confined compared to stone columns. Because of it, stone columns settle more than the DCM columns. It has also been observed that the stone columns take less time to reach a constant settlement than the DCM columns. The stage loading generates higher excess pore water pressure in DCM with LTP as compared to stone columns, as shown in Figure 3(b), due to which it will take more time to dissipate from the soil. The effect of LTP with DCM causes an insignificant reduction of settlement as compared to DCM columns. The reason is that the excess pore water pressure is nearly the same in both the cases, i.e., DCM and LTP with DCM. However, DCM with LTP restricts the lateral settlement at the toe of the embankment, as shown in Figure 3(c). The lateral displacement for unreinforced, stone columns, DCM columns, and DCM columns with LTP are 29.8mm, 17mm, 22.31mm, and 10.42mm, respectively. The lateral displacement for DCM columns with LTP reduces by 38.7% as compared to the stone columns. The LTP located at the base of the embankment behaves like a semi-rigid slab which helps in reducing the lateral displacement.

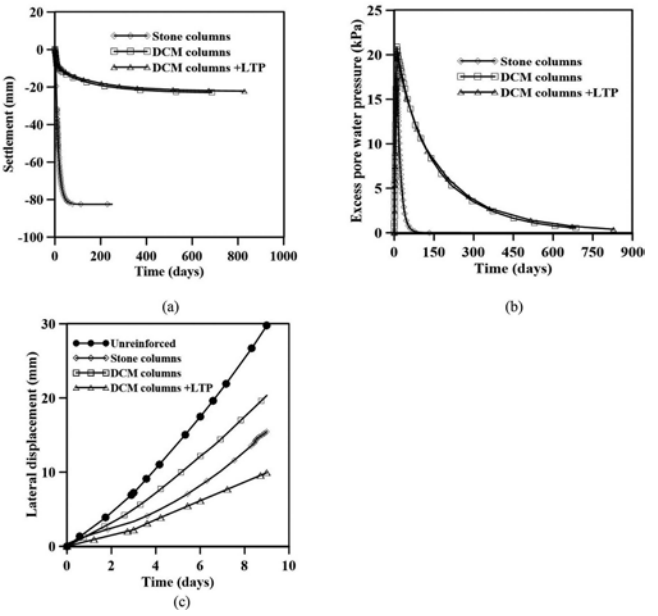

Figure 3. Comparison of (a) Settlement (b) Excess pore water pressure (c) Lateral displacement with time for different cases.

3.2 *Stress variation*

Figure 4(a) shows the variation of stresses for stone columns and LTP with DCM columns. The stresses for stone columns at the pile and soil are 19.2 kN/m^2 and 14.4 kN/m^2, respectively. In the case of stone columns, the stresses generated in columns and soil are nearly equal. The stresses for LTP with DCM columns at the pile and soil are 59.2 kN/m^2 and 11.3 kN/m^2, respectively. In the case of LTP with DCM columns, DCM columns take more load than the

surrounding soil. It means LTP with DCM columns is more effective than stone columns in terms of stress transfer.

Figure 4(b) shows the effect of static loading on developed stresses on piles and soil. The stress points under loading at the columns and soil are shown in Figure 2. The stresses on piles increase linearly with the increase in loading. The stress developed at the pile located at the center of the embankment (i.e., SP-1) is more than the other piles (SP-2 and SP-3). Similarly, the variation of stresses on the surrounding soil is the same, however, the rate of increase is slower, as evident from the slope of the line.

Soil arching occurs because of differences in the stiffness of the columns and surrounding soil. The stress concentration ratio for stone columns and DCM columns with LTP are determined as 1.33 and 5.24, respectively.

Figures 5(a) and (b) show the stress contour for stone columns and DCM with LTP. It is observed that stress concentration occurs at the soil and columns in the case of an embankment supported with stone columns. In the case of unreinforced embankments, stresses are distributed in the whole area. However, in the case of DCM columns and DCM columns with LTP, stress concentration is more at the columns as compared to the surrounding soil.

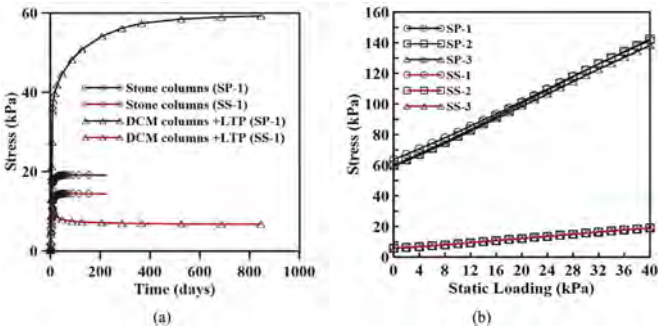

Figure 4. Comparison of stress with time for stone columns and LTP with DCM columns and under loading.

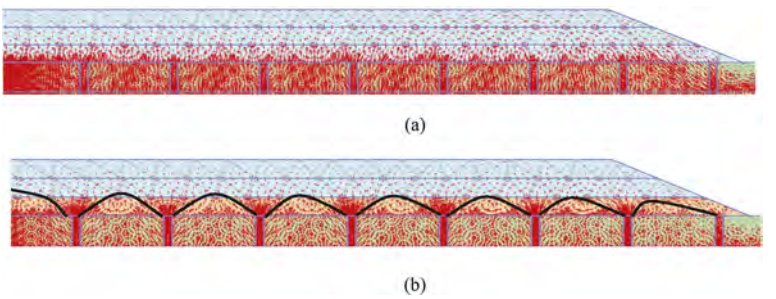

Figure 5. Stress contours for (a) Stone columns (b) DCM columns with LTP.

4 CONCLUSIONS

This paper presented a numerical investigation of embankment supported with DCM columns and soil-cement mixed as a load transfer platform. The comparison of embankment supported with DCM column with LTP and embankment supported with stone columns were also studied. The main findings of this numerical study are summarised below:

1. The effect of inclusion of LTP as soil-cement mixed is less in the case of settlement (at the center of the embankment), however, it helps in reducing the lateral displacement at the

toe of the embankment. A stiffer platform at the base of the embankment restricts the lateral displacement.
2. The dissipation of excess pore water pressure takes less time in the stone columns as compared to the DCM columns with LTP. The excess pore water pressure generated in the DCM with LTP (inside the soil shown in Figure 2) is higher than the stone column during the loading stage and, thus, takes additional time for dissipation.
3. The stresses on DCM columns are about five times higher than the stresses on surrounding soil. However, in the case of the stone columns, the stresses on stone columns are about 1.2 times more than the stresses on surrounding soil.
4. Soil arching is more effective in embankments supported with DCM columns with LTP in comparison to embankments supported with stone columns.

Causes of water encroachment in open-cut tunnel structures and innovative waterproofing, and repair systems for its elimination

Dmitriy S. Konyukhov, Tengiz E. Kobidze & Oleg B. Krymov
JSC Mosinzhproekt, Moscow, Russia

ABSTRACT: One of the topical problem of underground construction is the protection of under-ground structures from water encroachment. The problem is based on the impossibility to apply traditional waterproofing materials for underground constructions (bituminous-polymer rolls, polymer sprayed compositions) on inaccessible exterior insulated surfaces of runway slabs and wall structures constructed in open pits without slots for backfilling. Before the erection of supporting structures, the waterproofing coating is laid on the accessible surfaces of the concrete preparation and "diaphragm wall". This eliminates the adhesion of the waterproofing coating on the outer surface of the protected structures and results in the formation of a gap between the waterproofing and the protected structure. In the case of damage or defect of the waterproofing coating, the seeping ground waters migrate uncontrollably along the formed joint and penetrate into the building. The report presents the results of scientific and practical work performed in the JSC 'Mosinzhproekt' to eliminate the mentioned problem, including the development of design and techno-logical solutions using the methods of voile injection and manufacture of a two-layer seamless waterproofing membrane in the building environment as well as making changes to the effective regulatory and technical documents of the Russian Federation.

1 INTRODUCTION

One of the urgent problems in modern tunnelling is the problem of preventing or eliminating water encroachment of underground transport structures, built by Cut and cover and semi-closed-cut methods, which in these conditions completely lose their waterproofing protection, lose their water resistance and repairability, thus violating the conditions of their safe operation.

2 MAIN ISSUE

2.1 *Regulatory requirements*

The problem arises from restrictions on the use of traditional waterproofing materials for tunnel construction. The most widely used among them, approved by regulatory documents for waterproofing of underground transport structures (subways, road and railway tunnels, underground car parks, etc.) by cut and cover and semi-closed-cut methods include bituminous-polymer fusible roll materials and, to a lesser extent, sprayable polymer compositions based on bituminous-polymer composites, polyurea, methyl methacrylate resin (CS 120.13330.2012, CS 122.13330.2012, PS NOSTROY 2.27.123-2013).

According to paragraph 7.1.2 of PS NOSTROY 2.27.123-2013, to ensure the device reliable waterproofing of underground structures coating of cladding and sprayed materials should be applied directly to the building envelope from the outside (the side of exposure to

DOI: 10.1201/9781003299127-397

groundwater). However, these materials can only adhere to the surface of a prefabricated and seasoned ('old') concrete basement. Consequently, a prerequisite for their application to the external surfaces of the structures to be protected is the accessibility of the surface to be insulated. In the case of underground structures for transport purposes, such structures include only the containment walls with backfill cavities and roof slabs (Figure 1).

This restriction excludes the possibility of laying these materials on the outer surfaces of protected structures, which are not accessible to the surface to be insulated. Such structures include buckle slabs of all types of underground structures, walls constructed without backfill cavities and retaining walls for load-bearing 'diaphragm walls'. Therefore:

- in accordance with paragraph 5.6.3.20 of CS 120.13330.2012 and paragraph 5.4.6.4 of CS 122.13330.2012 for buckle slab waterproofing, the waterproofing coating should be placed on a concrete foundation mattress;
- when constructing underground structures using the 'diaphragm walls' technology or without cavities for backfill according to paragraph 5.6.3.24 of SP 120.13330.2012 and paragraph 5.4.6.10 of SP 122.13330.2012 the waterproofing shall be arranged on the 'diaphragm wall' surface, and the 'pressure wall' or permanent wall shall be made tightly against the 'diaphragm wall' to absorb the expected hydrostatic pressure for the design of waterproofing in given conditions until the amendment of CS 120.13330.2012 No. 4 (2020), although they contradicted the requirement of paragraph 7.1.2 of PS NOSTROY 2.27.123-2013 that waterproofing coating should be placed directly on the outer surface of building envelopes.

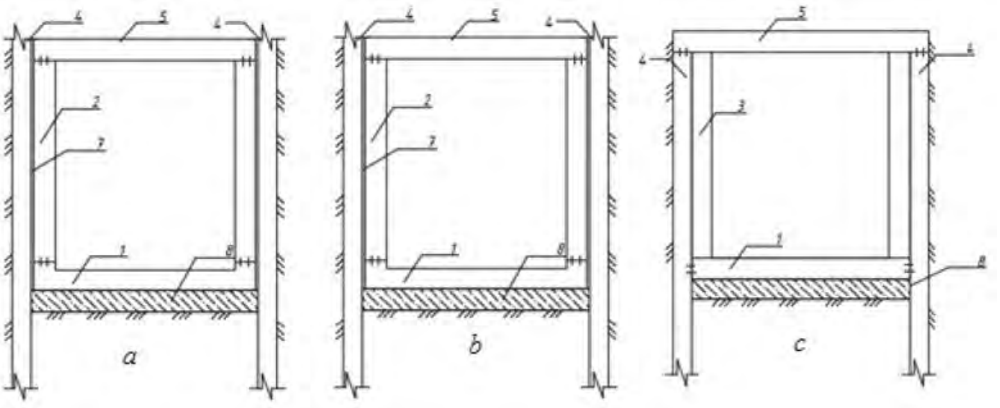

Figure 1. Variety of methods of construction of underground structures made of cast reinforced concrete: a – cut and cover method with backfill slots; b – cut and cover method without backfill slots; c – cut and cover and semi-closed-cut method with slab (cover) spacing discs, with a load-bearing 'diaphragm wall'; 1 – buckle (foundation) slab; 2 – bearing wall; 3 – pressure wall; 4 – excavation wall (in part b – bearing structure); 5 – floor slab (cover); 6 – cavities for backfilling; 7 – sliding plane (plane of mutual shift of the walls); 8 – concrete foundation mattress.

In the practical implementation of the above-mentioned design rules, the principle of waterproofing protection of building envelopes on the groundwater exposure side is observed, but the lack of adhesive bonding with the insulated surface deprives the waterproofing coating of the ability to localise seeping groundwater within the permeable damage and prevent uncontrolled groundwater migration across the outer surface of the protected structure (in violation of requirement CS 120.13330.2012 with Amendments No. 1-4, paragraph 5.5.3.18).

As practical experience shows, this leads to an unrepairable emergency situation, in particular:

- complete watering of the external surface of the structure being insulated and, as a rule, penetration of groundwater into the structure through filtering defects of concrete and

reinforced concrete structure itself (cracks, voids, weakened and highly porous areas of concrete, technological and expansion joints etc.) in the form of leaks of different intensity and damp spots on the internal surfaces of the structure;
– loss of repairability of the protected structure, because sealing one or a number of filtering defects (which would give a positive effect in the presence of a continuous adhesive bond of waterproofing with the concrete base) leads to an increase in the hydrostatic pressure of groundwater and, consequently, to the activation of 'sleeping' filtering defects and the appearance of new water appearing in other areas of the surface of the watered structure.

The loss of repairability requires costly and complex technological measures to restore the water tightness of a watertight structure, which include the use of water injection to provide a waterproofing coating on the outer surface of the protected structure or an impervious blanket in the surrounding soil mass.

In practice, the elimination of the possibility of such accidents required the elimination of contradictions between the considered normative rules for the design and waterproofing of building envelopes. For this purpose, the authors initiated amendments to paragraphs 5.6.3.17, 5.6.3.18 and 5.6.3.24 of CS 120.13330.2012 in order to establish uniform rules for the arrangement of a reliable and serviceable waterproofing of an underground structure based on the principle of a waterproofing coating to be installed by means of adhesive bonding directly onto the outer surface of the protected structure whether it has access to the insulated surface or not.

2.2 *Changes to the design rules in section 'Waterproofing of concrete lining' in CS 120.13330.2012*

Old Edition
5.6.3.17 The type and design of waterproofing of lining modes are determined by engineering and geological conditions of construction, magnitude of hydrostatic pressure, presence of aggressive effects of the environment, type of lining, possibilities to ensure water resistance of concrete under the accepted technology of construction works and other production conditions.
Revised version. Modification No. 2
5.6.3.17 The type and design of lining waterproofing of different modes are determined by the engineering and geological conditions of construction, magnitude of hydrostatic pressure, presence of aggressive environmental impacts, type of lining, possibilities to ensure water tightness of concrete under the accepted technology of construction works and repairability and other production conditions.
Old edition
5.6.3.18 Cut and cover tunnel structures shall have a continuous external waterproofing.
Revised edition. Modification No. 2 and 4
5.6.3.18 Cut and cover and semi-closed-cut tunnel structures should have a closed contour waterproofing to prevent uncontrolled migration of seeping groundwater to the surface of the isolated structures in case of damage.
Old edition
5.6.3.24 The flexible waterproofing, if necessary on the inside of the lining, should be protected by a reinforced concrete 'jacket' designed to withstand the expected hydrostatic pressure. It is necessary to ensure that the internal reinforced concrete structure is pressed tightly against the waterproofing.
Revised edition. Modification No. 4
5.6.3.24 The flexible waterproofing on the inside of the excavation enclosure 'diaphragm' wall or on the inside of the lining should be protected by an internal structure in the form of a pressure wall or secondary lining respectively designed to withstand the expected hydrostatic pressure. The waterproofing must have a continuous adhesive bond of at least 0.5 MPa between the waterproofing and the internal structure or, if an adhesive bond is not available, the waterproofing must be fitted with a sectional waterproofing control-injection system.

After the introduction of the new regulations, the use of traditional adhesive bonding materials and their laying techniques for waterproofing building envelopes with no access to the outside surface remains possible, but not a regulatory technical solution, leading to an unreliable and unrepairable waterproofing system. As a result, there is an urgent need to introduce a new generation of waterproofing materials into construction practice that can meet updated regulatory requirements.

The domestic market offers a number of innovative waterproofing materials, both domestic and foreign, which are capable of solving this problem. A distinctive feature of these materials is their ability to exhibit, in the form of pre-installed waterproofing coatings, a continuous adhesive bond to freshly poured concrete of protected underground structures with no access to the outside surface, such as buckle plates, wall structures constructed without backfill cavities and a pressure wall for a load-bearing 'diaphragm wall'.

2.3 *Innovative waterproofing, and repair systems*

These materials include the following.

1. The original waterproofing system based on the use of an innovative waterproofing composite material developed by the authors by combining the technical properties of two initial materials, which were selected (patent RU162638U1 16.12.2015, patent RU164721U1 14.01.2016):

- sprayable waterproofing polymer compositions with 'two-sided' adhesion, in particular, ethylene vinyl acetate polymer (EVA) and bitumen-polymer composite of 'Flexigum' brand, providing standard adhesion (≥ 0.5 MPa according to CS 120.13330.2012) not only with the 'old concrete' substrate covered with a layer of sprayed polymer, but also with the external surface of the concrete laid in the form of mortar on the ready-made waterproofing coating.
  The ability of long-term adhesion of bituminous-polymer waterproofing systems to concrete is confirmed by their traditional use in construction, and EVA polymer – by many years of experience in the construction of composite waterproofing lining of transport tunnels made of shotcrete, erected by mining method [6];
- geotextile nonwoven needle-punched material with a density of 250-500 g/m2 (GOST R 53225-2008) used as a reinforcing and strengthening element of the polymer coating, as well as an underlay - bedding for making a two-layer seamless waterproofing coating (polymer membrane with a base) in construction conditions by spraying a 4-6 mm thick layer of waterproofing composition on a ready-made geotextile underlay.

The application of the sprayed composition with double-sided adhesion and its modification in the form of a two-layer polymer seamless membrane with a reinforcing base, as well as the possibility of directional regulation of physical and mechanical properties of the waterproofing coating with a reinforcing web depending on the problem to be solved provide:

– the use of a waterproofing coating without a protective layer of fine-grained concrete when the reinforcement frame is tied and the buckle plate is subsequently concreted, due to the reinforcing geotextile fabric reinforcing the surface layer of the coating (Figures 2 and 3). This accelerates the waterproofing process, reduces the cost of waterproofing works and ensures a continuous adhesive bond between the waterproofing coating and the inaccessible exterior surface of the buckle plate;
– adhesion bonding of the sprayed polymer layer of the double-layer sprayed membrane to the inaccessible external wall surface of structures erected without backfill cavities. Preservation of this coating on the wall surface during subsidence of the underground structure, due to the free suspension of the double-layer membrane on the 'diaphragm wall' (Figure 4);
– the construction of a reliable waterproof three-layer sandwich wall structure by applying a sprayed waterproofing layer with double-sided adhesion to the levelled surface of the

'diaphragm wall' and the subsequent erection of a pressure wall of monolithic or shortcrete when building underground structures using the 'diaphragm wall'technology by 'top-down' method (Figure 5);

– reliability of waterproofing, safety of protected underground structures and their repairability due to:
  a) adhesive fixing of the seamless waterproofing coating directly on the outer surfaces of the protected structures with and without access to the outer surface according to the requirements of CS 120.13330.2012 with Amendments №1-4 and paragraph 7.1.2 of PS NOSTROY 2.27.123-2013;
  b) the local nature of water penetration due to the continuous adhesive bond between the waterproofing and the concrete substructure. Under these conditions, penetration of groundwater into an underground structure is possible if the location of the penetrating damage to the waterproofing coating or process joint and the filtering defect of the envelope structure coincide. The low probability of such coincidence increases the operational reliability and safety of underground structures. However, in the case of such a coincidence, the localization of groundwater within the pavement damage and its migration through the filtering concrete defect makes it easier to locate the site for local and relatively low-cost work to restore the waterproofing of the structure by injecting a sealing compound into the filtering concrete defect.

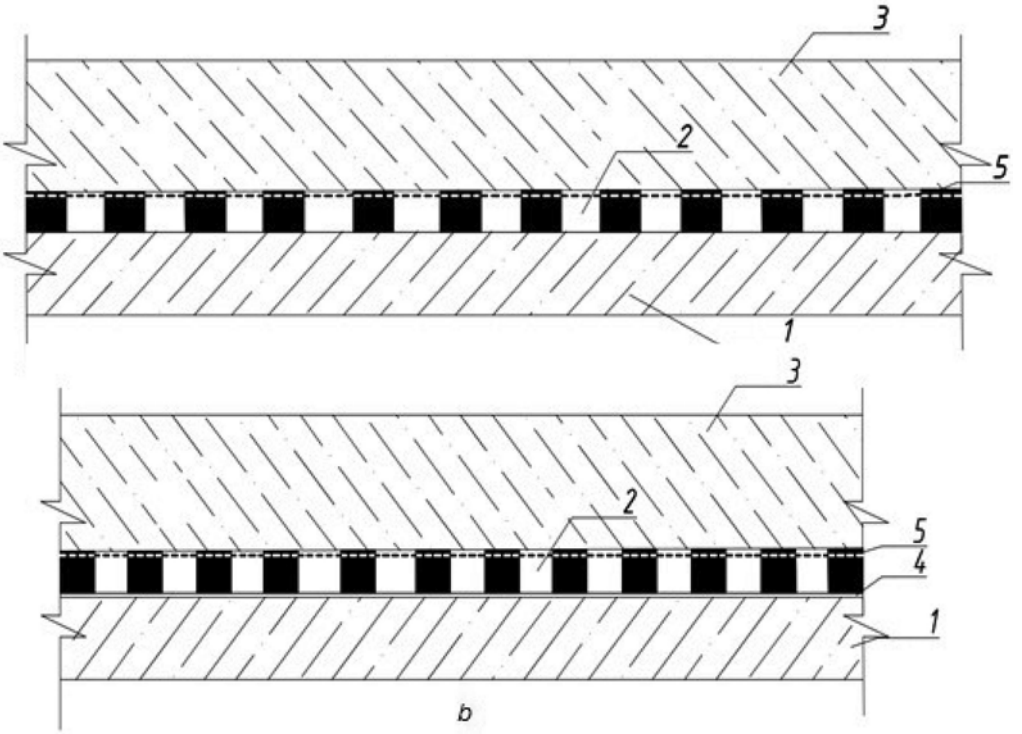

Figure 2. Seamless waterproofing of the buckle plate with sprayed compositions with double-sided adhesion: a – without underlay; b – with underlay of non-woven geotextile; 1 – concrete preparation; 2 – waterproofing layer; 3 – buckle plate; 4 – underlay of non-woven geotextile; 5 – non-woven geotextile, reinforcing the surface layer of waterproofing coating.

Technical characteristics of materials and structural and technological solutions for the installation of the developed waterproofing system under construction conditions were approved during bench tests and recommended for pilot application in the Moscow Metro facilities by an interdepartmental commission consisting of representatives of the Moscow

Metro State Unitary Enterprise, Mosinzhproekt JSC, Mospromproekt JSC, Lenmetrogiprotrans JSC, Mosmetrostroy JSC and Tunnelling Research Centre LLC.

A number of Russian companies are suppliers of roll-fed polymeric waterproofing membranes from foreign manufacturers that provide adhesive bonding to the inaccessible external surface of the protected structures of underground structures.

These materials are rolls of waterproofing polymer with a thickness of 2 to 4.5 mm, depending on the initial raw material (polyethylene, PVC or bituminous-polymer composite, respectively) with a special thin and reinforced surface layer, which provides:

- adhesion (≥ 0.5 MPa) of the waterproofing coating to the surface of the freshly placed concrete of the reinforced concrete structures to be erected without access to the external surface;
- the fine-grained concrete waterproofing membrane is rejected, and the reinforcement is tied, and the buckle plate is concreted immediately after the waterproofing membrane has been laid. The waterproofing coating made of these materials is arranged by laying rolls with an overlap of 10-15 cm and sealing them with the formation of technological joints (Figure 6).

Factory-ready membranes guarantee consistency of quality characteristics, significantly reduce the time of waterproofing and general construction works, as well as labour and material and financial costs during their performance, but the presence of technological joints requires their qualitative performance to ensure the operational reliability of the waterproofing coating.

All materials are certified, meet the requirements of CS 120.13330.2012 and have test protocols of concrete base samples with waterproofing coatings for resistance to lateral water migration, which confirm the reliability and water resistance of the adhesive contact layer at hydrostatic pressure of at least 0.5 MPa.

Rules for design and execution of waterproofing works with application of the considered new generation waterproofing systems for underground constructions of cut-and-cover and semi-closed type for transport purposes are concentrated in PS 75-03 Mosinzhproekt JSC.

Figures 7 and 8 show the diagrams of waterproofing for underground structures constructed without and with backfill cavities, respectively, using the new-generation materials under consideration, which differ in their adhesive bonding ability with freshly poured concrete.

3 CONCLUSION

The existence of contradictory rules in national and industry standards for the design of waterproofing of underground transport structures using traditional waterproofing materials

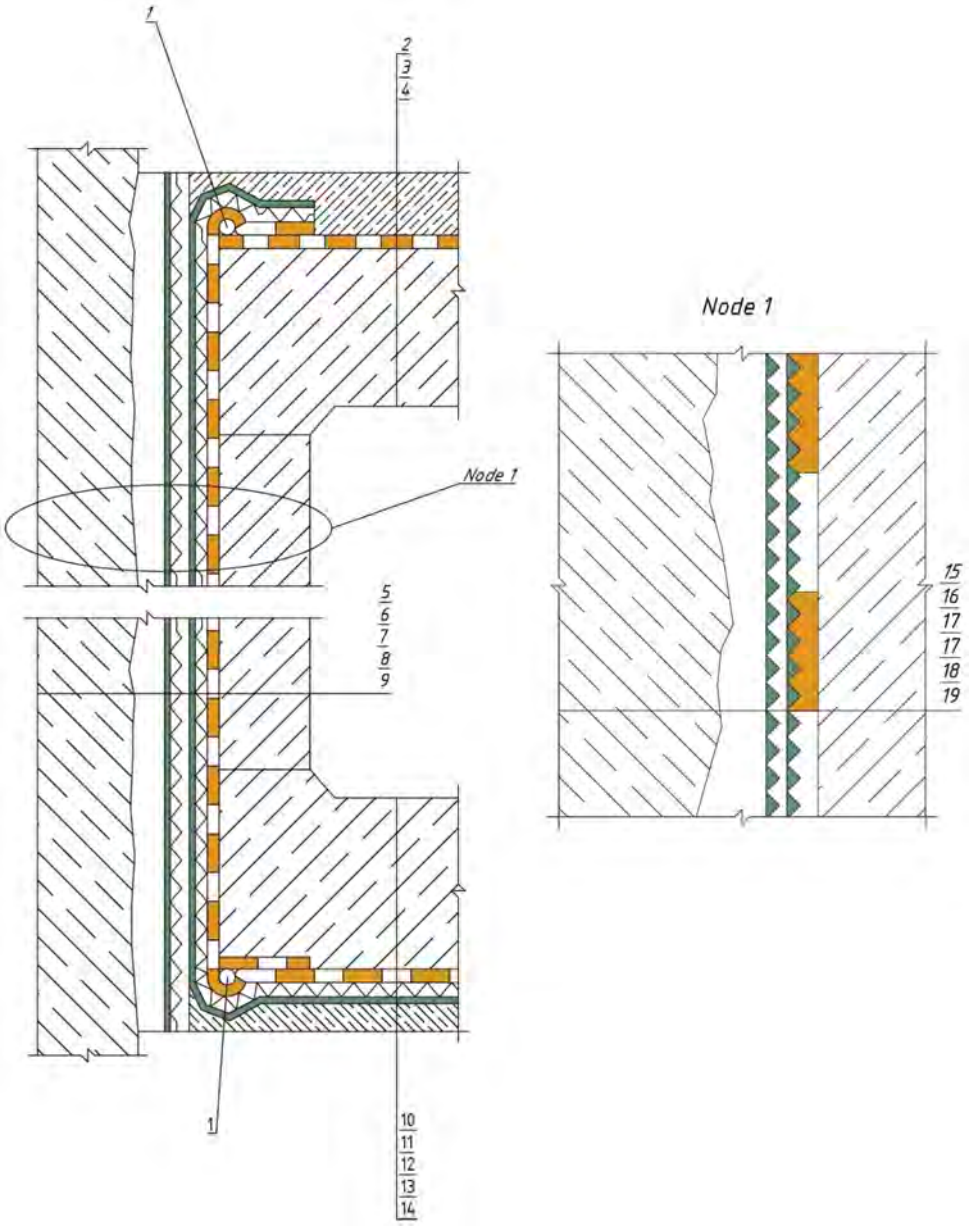

Figure 4. Waterproofing with two-layer sprayed waterproofing coatings with adhesion to freshly laid concrete of the monolithic wall construction of an underground structure without backfill cavities (Node 1): 1 – compensating loop; 2 – protective layer of concrete on mesh; 3 – sprayed waterproofing coating with primary and secondary adhesion; 4 – reinforced concrete floor; 5 – ditch sheeting – 'diaphragm wall'; 6, 11, 16 – levelling layer (if necessary); 7 – two layers of geocomposite material; 8 – waterproofing coating with primary and secondary adhesion applied to the geotextile of the geocomposite material; 9 – reinforced concrete wall; 10 – concrete buckle plate; 11 – protective sand cement screed; 12 – waterproofing coating with primary and secondary adhesion applied to the geotextile of the geocomposite material; sprayed waterproofing coating with primary and secondary adhesion; 13 – geocomposite material; 14 – concrete bedding; 15 – ditch sheeting - 'diaphragm wall'; 17 – geocomposite material (polyethylene film + geotextile, facing a layer of polyethylene film to the 'diaphragm wall'); 18 – sprayed waterproofing coating with primary and secondary adhesion applied to a geotextile geocomposite material; 19 – concrete load bearing wall.

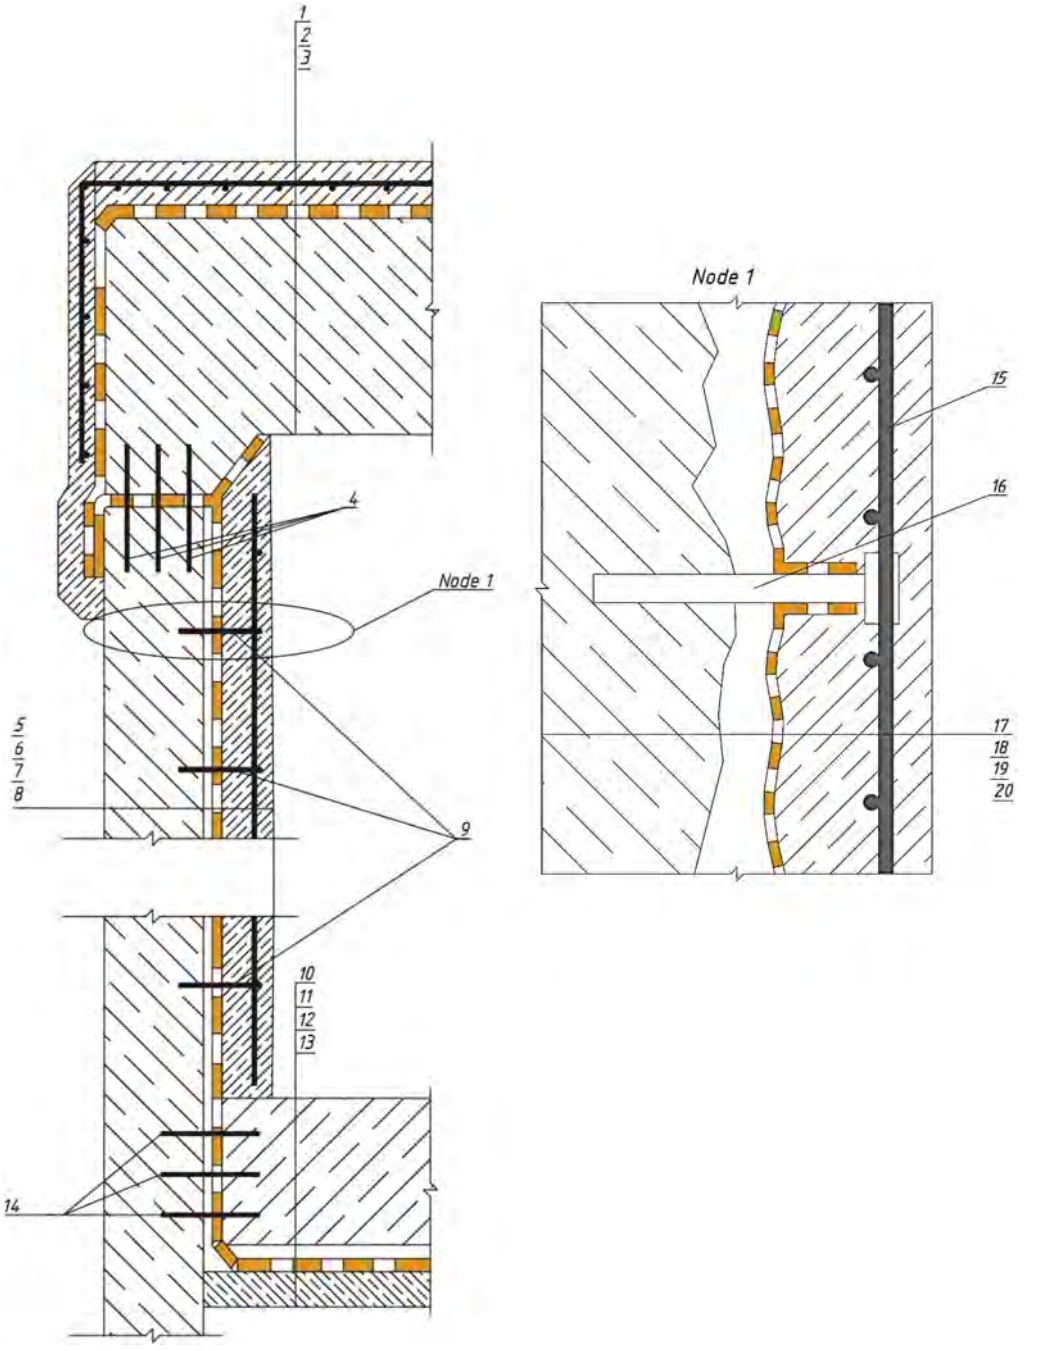

Figure 5. Waterproofing the load-bearing wall of an underground 'diaphragm wall' structure with sprayed polymer compound with two-sided adhesion: 1 – protective layer of concrete on mesh; 2, 7, 12 – sprayed waterproofing coating with primary and secondary adhesion; 3 – reinforced concrete floor; 4 – free length of 'diaphragm wall' reinforcement; 5 – load-bearing 'diaphragm wall'; 6 – levelling layer (if necessary); 8 – pressed wall of concrete on mesh; 9 – anchoring the pressure wall; 10 – buckle plate; 11 – protective sand cement screed; 13 – concrete bedding; 14 – anchoring the buckle plate; 15 – steel mesh; 16 – steel anchor; 17 – load bearing 'diaphragm wall'; 18 – levelling/smoothing layer (if necessary); 19 – sprayed waterproofing coating with primary and secondary adhesion; 20 – pressed wall on mesh.

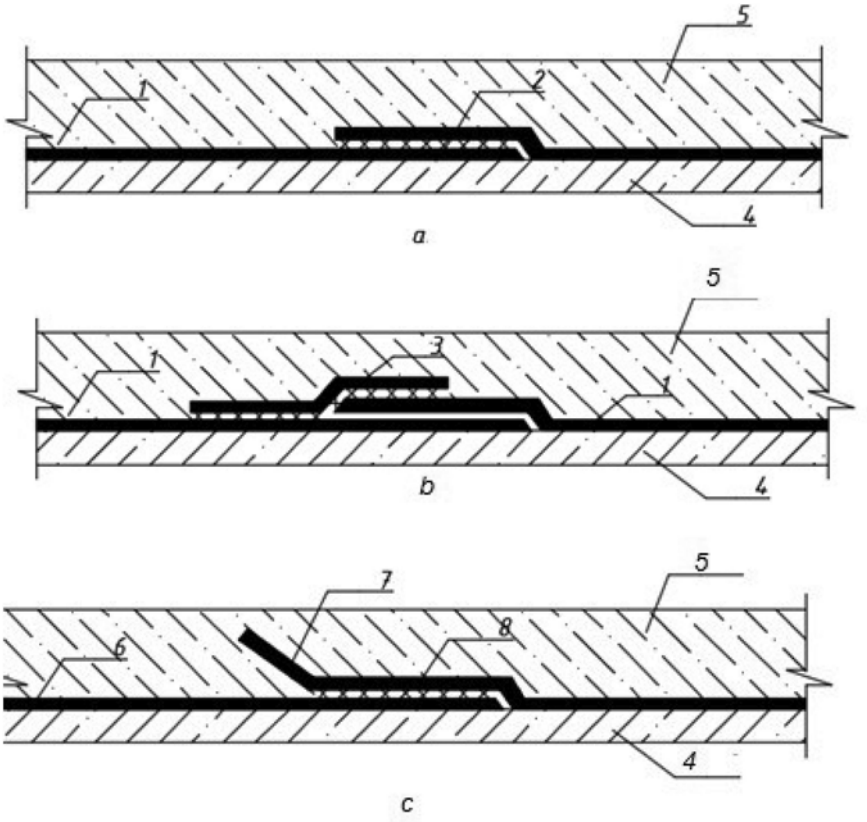

Figure 6. Waterproofing of the buckle (foundation) plate using factory-assembled 'free' laid three-layer sheet membranes and with adhesion to the freshly formed concrete. Laying diagram of three-layer sheet membranes with overlaps: a – self-adhesive longitudinal edge strips; b – transversal edges with overlapping adhesive sheets; c – Kolfen BSH bitumen-polymer-based membranes with overlapping longitudinal edges; 1 – three-layer sheet membrane; 2 – process joint of self-adhesive longitudinal edge strips; 3 – overlapping adhesive sheet; 4 – concrete surface; 5 – gutter board, laid on the waterproofing coating; 6 – rolls of Kolfen BSH; 7 – edge piece for welding; 8 – self-adhesive edge piece (joining of transversal edges of Kolfen BSH is made only with overlapping of the welding edge).

has led to incorrect technical solutions and to water leakage accidents in structures in operation. This has led to the necessity to:

– eliminate the contradictions in the current design rules;
– development of innovative waterproofing materials which meet the updated regulations.

The application of new generation waterproofing materials in the practice of tunnelling on the basis of the updated design rules guarantees:

– no possibility of making incorrect design decisions for waterproofing of underground transport structures;
– elimination of conditions for abnormal situations as a result of water encroachment of tunnel lining structures, which cannot be repaired and require costly rehabilitation work on the outside waterproofing of the structure or building;
– acceleration and reduction of the cost of repairable waterproofing works when constructing underground structures for transportation purposes, ensuring conditions for their durable, safe and low-cost operation.

Improvement of properties of black cotton soil subgrade through lime kiln dust and sand stabilization

A.A. Kibuka & S. Jjuuko
Makerere University, Kampala, Uganda

D. Kalumba
University of Cape Town, Cape Town, South Africa

ABSTRACT: The soil sample was blended with varying proportions of sand alone, and a combination of sand and Lime Kiln Dust (LKD). The laboratory results were analyzed based on the effect of the additives on the engineering properties of the soil sample. From the test results on neat soil sample, it was observed that black cotton soil had a high plasticity index, high swelling potential, and low bearing strength. The addition of sand-LKD to black cotton soil sample exhibited a significant improvement in strength, and reduction in the plasticity index and swelling potential. The application of 30% sand and 3% LKD increased the CBR value of the neat sample from 5% to 18%, reduced the PI value of the native soil from 49% to 10.2%. This combination satisfied all the Ministry of Works and Transport subgrade specification requirements and was considered as the optimum stabilizer content for black cotton subgrade soils.

1 INTRODUCTION

Black cotton (BC) soils are inorganic clays characterized by exceptionally low bearing capacity, high compressibility, low permeability, and high-volume change under changing moisture conditions (Amadi & Osu 2018, Kollaros & Athanasopoulou 2016). BC soils exhibit high swelling and shrinking due to changes in moisture content (Dalal et al. 2017). The soil is extremely hard when dry and loses its strength further upon wetting. The alternate wet and dry conditions in the soil bring about severe movements of the soil mass, thus structures built on BC soil experience recurring cracking and progressive damage in the form of settlement, unevenness, etc. (Dalal et al. 2017, Verma & Marv 2013). In Uganda, BC soils are mainly found in the semi-arid Karamoja subregion in the North East.

The high swelling and shrinkage properties of BC soil can be attributed to the presence of a considerable amount of montmorillonite clay mineral (Etim et al. 2017). It has an expanding lattice that easily adsorbs water, hence expanding. Montmorillonite is also associated with more surface area per unit mass than other clay minerals (Alshameri et al. 2014, Salima & Abdelhak 2013). Roads constructed on expansive subgrade soils have not fulfilled their intended functions of accessibility and mobility due to being in poor condition, to which the nature of the soil contributes to some extent (Ikeagwuani et al. 2019). At the same time, gravel roads with expansive subgrade soil, such as BC soil, have failed to perform their intended function of providing satisfactory ride quality due to deteriorations like cracks, bumps, slipperiness, and impassibility, especially in wet conditions (Verma & Marv 2013, Etim et al. 2017, Al Fouzan & Dafalla 2014). This is exactly the situation of the roads in North-Eastern Uganda, where most of the roads are almost impassable during rainy season, hence bringing businesses to a standstill. There is, therefore, a need for improvement of such problematic subgrade soil before it is built upon.

DOI: 10.1201/9781003299127-398

Different techniques have been adopted to enhance the engineering properties of black cotton soils and these include substitution and chemical stabilization, such as the use of lime. The optimal selection among the various methods is guided by various economic, practical, and environmental considerations. According to Ground Engineering Magazine (2009) & Edil et al. (2006), the reutilization of materials found on-site has proved to be more sustainable and environmentally positive than the conventional method of substitution (dig and dump) by dealing with unsuitable subgrade materials. Though stabilization is an economical and popular way of reusing on-site materials, the use of lime, either in isolation or with other stabilizing agents, has been found to be expensive, especially in third world countries (Zami & Lee 2009). Recent research has successfully utilized other effective and environmentally sustainable additives either in isolation or in combination with lime, including groundnut shell ash, bagasse ash, iron ore tailings, ground granulated blast furnace slag, and wood powder, to improve the properties of black cotton soil (Dalal et al. 2017, Ikeagwuani et al. 2019, Etim et al. 2017, Kang et al. 2015, Sreekrishnavilasam et al. 2007).

Research has shown that stabilization of locally available problematic soil by utilizing industrial and construction waste materials along with natural poorly graded river sand provides improved compaction and strength characteristics and reduces the cost of construction substantially (Kollaros & Athanasopoulou 2016, Kang et al. 2015, Gupta & Sharma 2016, Jjuuko et al. 2011, Schanz & Elsawy 2017). Lime kiln dust (LKD), a by-product from the manufacturing process of quick lime with high lime content, has potential in the stabilization of soils as a direct substitute for hydrated lime (Arulrajah et al. 2017).

This study investigated the potential use of lime kiln dust (LKD) and sand together as additives in the modification of BC soil in Uganda. Approximately, over 3600 kg of lime kiln waste dust is generated daily during lime production at Tororo Cement Limited. In addition, sand is naturally occurring and is one of the materials that are readily available in Uganda. Its constituents can easily be controlled. According to Adam & Agib (2001), in order to achieve higher quality and production cost reductions, proportions between soil, stabilizer, and compaction pressure need to be optimized, taking into consideration the specific characteristics of the soil. In spite of all this, little work has been done to determine the requirements of LKD and sand for stabilizing BC soil in Uganda to obtain optimum results. The work concentrated on the characteristics of BC soil, sand, and LKD samples, and on the effect of stabilizing BC soil by mixing it with dry sand and LKD.

2 MATERIALS AND METHODS

2.1 *Black Cotton (BC) soil*

Samples of black cotton soil were obtained from Nakapiripirit district (Namalu-Kaiku Road). The required amount of soil was obtained at depths of about 0.5 m below the ground level. Sufficient care was taken to ensure that the collected soil samples were fairly homogenous. The topsoil was ignored since it was more likely to contain organic matter and other foreign materials. The tests conducted on BC soil indicated a poorly graded material with a 99% proportion of fines passing sieve No. 200. It was classified as A-7-6 (55) according to AASHTO, an inorganic clay with a high plasticity index. A group index of 55 was greater than the required maximum of 20, indicating a poor subgrade material. The chemical constituents of the obtained BC soil sample were tested in Makerere University, Department of Geology and Petroleum Studies laboratory. The results obtained were CaO at 0.63%, MgO at 2.32%, Fe_2O_3 at 3.82%, Al_2O_3 at 17.29% and SiO_2 at 34.71%. Perkin Elmer Analyst 400 equipment was used in the analysis.

2.2 *Lime Kiln Dust (LKD)*

LKD is a waste product from the production process of quick lime. It is estimated that about 3600 kg of LKD is generated daily during lime production at the Tororo Cement Limited plant alone. LKD is suitable for stabilizing a wide range of soils, both cohesive and non-cohesive. This is also a cost-effective way of reusing it. LKD has been successfully used to

stabilize subgrade soils. It has been found to enhance values of the California Bearing Ratio, resilient modulus, and unconfined compressive strength, and lower the plasticity index (Kang et al. 2015, Heckel & Wahab 1996, Burnham et al. 1992, Daita et al. 2001, Solanki et al. 2010, Cetin et al. 2010). LKD used in the study was sourced from Tororo Lime Plant. It was packed in sacks and transported to the Geotechnical Engineering laboratory in Makerere University. The chemical constituents of LKD were determined in the laboratory of Tororo Lime Plant. Its chemical properties, as determined in the laboratory, included CaO at 71.52%, MgO at 2.66%, Fe_2O_3 at 1.47%, Al_2O_3 at 0.73% and SiO_2 at 2.38%. The values indicated high quantities of CaO, hence suitable for stabilization of BC soil with high amounts of SiO_2 and Al_2O_3.

2.3 *Sand*

Sand was obtained from River Lolachat in Nakapiripirit district. The grading curve for sand from the sieve analysis test was fitting in the grading envelope defined by the grading limits in the Ministry of Works and Transport (MoWT) specifications. The grading curve indicated uniformly graded sand with both coarse and fine particles. According to the Unified Soil Classification System (USCS), it was classified as Silty Sand, which bonds well with clay particles.

2.4 *Sample preparation*

The samples for laboratory testing were prepared in accordance with BS 1377 Part1:1990. It has been reported that some tropical soils are sensitive to pretest drying methods [44]. Therefore, all the samples of black cotton soil were air-dried. Other pretest sample preparation methods included pulverization using a rubber mallet, sieving, and sub-sampling (coning, quartering, and riffling)2. After air-drying, index property tests were carried out for classification.

In order to investigate the effect of sand and lime kiln dust on the properties of black cotton soil, specimens with specified amounts of sand, lime kiln dust, and soil were prepared in different mixes. The soil was blended with varying percentages of sand in the proportions of 0%, 20%, 30%, 40%, and 50%. Black cotton soil was further blended with lime kiln dust by keeping 30% sand constant and varying lime kiln dust in proportions of 3%, 4%, 5%, and 6% by mass. Most specifying bodies permit the use of recycled materials as a portion of the road improved subgrade. According to BS 6543 for waste materials and industrial by-products, a maximum of 50% LKD by weight of total mass could be used. The mixing was done mechanically on a metal tray. For consistency, soil was mechanically blended before mixing with sand and LKD. Tests of physical properties of the different blends/mixes were conducted.

2.5 *Initial consumption of lime kiln dust*

The method developed by Eades and Grim to measure the pH of soil stabilized with various percentages of lime or any other pozzolanic stabilizer was utilized. The quantity of lime kiln dust necessary to maintain the pH of 12.40 in the soil–LKD–water mix after one hour is considered to be the initial consumption of LKD of the material. It is the required minimum content of LKD that will stimulate the pozzolanic reactions to achieve a permanent gain in strength of the subgrade material. Samples of black cotton soil were mixed with distilled water and different proportions of LKD. The pH values for the different proportions of LKD were then read from the pH meter and recorded. The graph of pH against LKD content was then plotted and the minimum content of LKD needed to give a pH value of 12.40 was read from the graph. The initial consumption of lime kiln dust was determined as 5.6% at a pH value of 12.4. For adequate stabilization, an excess of lime kiln dust has to be added to black cotton soil.

2.6 *Laboratory tests*

Laboratory tests were carried out on the natural soil sample and blended soil mixtures. The tests were carried out to determine the index and strength properties of the native and blended soil samples. The results were analyzed based on the effect of the stabilizer in comparison with

the properties of the neat soil sample and stabilized soil samples. They were then compared against the MoWT specification requirements for subgrade construction. The tests were conducted in accordance with British Standards, Indian Standards, and American Society for Testing and Materials Standards, as shown in Table 1.

Table 1. Summary of laboratory tests.

Material to Be Tested	Tests	Standard Test and Designation
Black cotton soil	Particle size distribution (wet sieving and hydrometer)	BS 1377: Part 2: 1990
	Moisture content	BS 1377: Part 2: 1990
	Liquid limit	BS 1377: Part 2: 1990
	Plastic limit	BS 1377: Part 2: 1990
	Linear shrinkage	BS 1377: Part 2: 1990
	Compaction test	BS 1377: Part 4: 1990
	CBR Three-point method	BS 1377: Part 4: 1990
	Free swell test	IS 2720: Part 40: 1977
Sand	Particle size distribution	BS 1377: Part 2: 1990
Lime Kiln Dust	Optimum LKD Content	ASTM D6276
Blended mix of BC soil, Sand, and Lime Kiln Dust	Particle size distribution	BS 1377: Part 2: 1990
	Liquid limit	BS 1377: Part 2: 1990
	Plastic limit	BS 1377: Part 2: 1990
	Compaction test-stabilized materials	BS 1924: Part 2: 1990
	CBR Three-point method	BS 1377: Part 4: 1990

3 RESULTS

3.1 *Effect of sand on the index and strength properties of black cotton soil*

3.1.1 *Effect of sand on the gradation of black cotton soil*

The grading curves of the blended mixes improved with addition of sand. In addition, the group index of the blended mixes decreased with an increase in sand content. This was evidenced by an increase in the amount of particles retained on sieve No 200. The finer particles of BC soil were replaced with coarser particles of sand, resulting in uniform gradation of particles in the blended mixes (Kollaros & Athanasopoulou 2016).

3.1.2 *Effect of sand on atterberg limits of black cotton soil*

There was a reduction in the liquid limit, plastic limit, and shrinkage limit and plasticity index with increasing percentages of sand content in the black cotton soil as indicated in Table 2. The liquid limit decreased from 70.5% to 29.4% with increasing proportions of sand. The plastic limit slightly decreased from 21.5% to 12.4%, whereas the linear shrinkage decreased from 15% to 6.4%. There was also a general reduction in the plasticity index of the modified black cotton soil from 49% to 17.0%. These results agree with those of several researchers (Gupta & Sharma 2016, Jjuuko et al. 2011, Babu et al. 2016). This can be attributed to a reduction in the fine proportions needed for bonding of the clay particles, and the changes in soil texture on addition of sand from fine-grained clay to the increasingly coarse-grained nature of the black cotton soil–sand mix. Addition of more non-cohesive sand minimizes the binding ability of the mixes and their ability to retain moisture. The reducing plasticity automatically results in less swell ability, hence low susceptibility to cracking. All the blends were associated with liquid limits less than 50%. Such soil materials are suitable for pavement layers (Jjuuko et al. 2011).

3.1.3 *Effect of sand on the free swell ratio of black cotton soil*

From Table 2, it was observed that, as more sand was added to the soil, the free swell ratio of the blended mixes decreased and thus a reduction in the swell potential of the soil resulted. The same behavior was reported by Babu et al. (2016), and it follows the obtained results. This was due to

the reduction in the proportion of clay particles, which are responsible for its high swelling potential. This changed the nature of subgrade soil from swelling to non-swelling.

3.1.4 *Effect of sand on the Maximum Dry Density (MDD) and Optimum Moisture Content (OMC) of black cotton soil*

As more percentages of sand were added to black cotton soil, the maximum dry density slightly increased with increasing sand percentages. Similarly, the optimum moisture content decreased with increasing percentages of sand, Table 2. The same trend was reported by Gupta & Sharma (2016), Babu et al. (2016), Ningthoujam & Pramod (2018), and it is in accordance with obtained results. According to Jjuuko et al. (2011), soil type is a major variable in the resulting moisture density relationships. The alterations can be attributed to the variations in plasticity index and specific gravity of the mixes. Reduction in plasticity index minimizes the binding and moisture retention abilities of soil specimens. Well-graded soils exhibit higher MDDs than poorly graded soils, while finer soils exhibit higher OMCs and lower MDDs than coarser soils. Usually soils with MDDs greater than 2 Mg/m^3 and OMCs less than 15% are easier to compact.

The increase in the maximum dry density is attributed to the addition of the coarse sand particles into fine-grained black cotton soil. This is explained by the fact that addition of coarse-grained sand particles to fine-grained soil occupies the void spaces between the soil particles. Furthermore, the addition of sand particles to fine-grained clay results in a coarse-grained skeleton-like structure and the voids between the particles are filled with fine-grained or clay particles. This enhances the compaction properties of the material and hence results in higher densities. Therefore, an increase in sand content leads to a reduction in void spaces in the soil sample, thus resulting in an increased density.

The decrease in the optimum moisture content is due to the reduction in the volume of voids as more sand is added to fill the void spaces between black cotton soil particles. The fact that clay has a high voids ratio due to its high proportion of fines, means the addition of sand particles to it reduces its capacity to hold water. In addition, the sand particles have a coarse-grained texture with a less specific surface area and thus a lesser amount of water is required to slide the particles together to achieve the desired density.

Table 2. Laboratory test results of black cotton soil-sand mixes.

	Atterberg Limits						
Mix	LL	PL	PI	LS	Free Swell Ratio	MDD	OMC
Neat BC	70.5	21.5	49.0	15.0	2.3	1.571	18.6
20% SD	43.8	10.4	27.4	10.0	2.0	1.729	16.4
30% SD	39.4	14.3	25.1	8.6	1.8	1.796	14.2
40% SD	36.8	13.8	23.0	7.1	1.5	1.823	12.9
50% SD	29.4	12.4	17.0	6.4	1.3	1.905	11.4

3.1.5 *Effect of sand on the California Bearing Ratio (CBR) of black cotton soil*

The soaked CBR values increased appreciably with an increase in percentages of sand. The CBR value of neat black cotton soil increased from 5.0% to 23.0% with the addition of sand content. The modified soil samples had CBRs of 7.0%, 13.0%, 16.0%, and 23.0% with addition of 20%, 30%, 40%, and 50% of sand, respectively. The same behavior was reported by Babu et al. (2016). The CBR values increased with addition of sand content due to the rearrangement of the soil particles from fine-grained soil to an increasingly granular nature having an interlocked structure between the soil particles. This improves the strength properties of the material by increasing the density of the material. Replacement of fine particles of BC soil with coarser sand particles results in uniformly graded blends with enhanced cohesion and friction parameters. Therefore, the higher the density of the material, the greater resistance to penetration force, thus resulting in an increase in the CBR value. If properly mixed, placed, and compacted in the field, the composite mixes exhibit improved load-bearing capacity.

3.1.6 *Selection of the BC soil–sand optimum mix to be blended with LKD*

On the basis of the above results, the optimum mix for the BC soil–sand mix was decided based on:

- Plasticity index and CBR value in compliance with the MoWT specifications. A mix of 30% sand was considered as the optimum mix to be blended with varying proportions of lime kiln dust, as it proved to be the minimum mix and economical for use. This had a PI value of 25.1%, which was close to the required maximum of 25%, and a CBR value of 13.0%, which was above the required minimum CBR of G7. However, this did not satisfy all the MoWT requirements because of its swelling in nature, with a free swell ratio of 1.8 and plasticity index value that was greater than required. Therefore, further modification was necessary to satisfy all the required standards;
- Economic reasons. 30% sand may be more economical for use as it would require:
  - Less imported material,
  - Less in-situ material wastage,
  - Less energy consumed in site preparation (excavation to spoil),
  - Less site operation costs (transportation costs).

3.2 *Effect of Sand–Lime Kiln Dust (SD-LKD) combination on the physical and strength properties of black cotton soil*

3.2.1 *Effect of SD-LKD combination on the atterberg limits of black cotton soil*

The Atterberg limit results for the black cotton soil–sand–lime kiln dust (BCS-SD-LKD) mix are presented Figure 1. It can be seen that a slight increase in the plastic limit values was noticed with the addition of 3% and 4% LKD content, whereas the addition of 5% and 6% LKD content in BCS-SD mix altered the composite mix to a non-plastic condition. The results showed that the liquid limit values were not consistent with the increasing LKD content. The liquid limit gradually increased from 39.2% to 43.5% with the addition of 3% to 5% LKD content, respectively, and further addition of 6% LKD content slightly reduced the liquid limit to 42.6. The general reduction in the plasticity index of the composite mix was observed with the increasing LKD content. The plasticity index reduced from 10.2% to 0% with the addition of 3% to 6% LKD, respectively. The same trend was observed with the shrinkage limit values with the increasing percentage of LKD.

The reduction in the plasticity index may be attributed to the aggregation of clay particles from fine clay to an increasingly granular nature induced by cation exchange and flocculation and agglomeration reactions. The increase in liquid limit is attributed to flocculation and agglomeration of the clay soil particles due to the addition of lime kiln dust. This results in aggregation of the clay soil particles from a fine-grained nature to increasingly coarser aggregates (Bell 1996, Al-Rawas et al. 2005, Nalbantoglu & Tuncer 2001). These have the ability to increase the water-retaining capacity of the flocculated aggregated structure and hence increase the liquid limit as well as the plastic limit of the soil. The decrease in liquid limit is attributed to the effect of cation exchange reactions between the cations of the soil and those of lime kiln dust, which depress the thickness of the diffuse double layer due to the increase in cation concentration. The addition of 6% LKD induced a reduction in the water-holding capacity of the soil and hence a decrease in liquid limit. The same behavior was reported by Bessaim et al. (2018) and it follows the above results.

3.2.2 *Effect of SD-LKD combination on the MDD and OMC of black cotton soil*

From Figures 2 and 3, as higher percentages of LKD content were added to the BCS-SD mix, the maximum dry density slightly decreased, whereas the optimum moisture content increased. These results follow the results of several researchers (Makandar 2016, Achampong et al. 2013). The variations in the MDD and OMC of the soil are attributed to flocculation of the soil particles, as indicated by the Atterberg limits (Al-Rawas et al. 2005, Nalbantoglu & Tuncer 2001). The increase in the optimum moisture content is attributed to the increase in the shearing resistance of the soil particles. As more LKD content is added to the BCS-SD composite, the soil

particles are gradually cemented, increasing the particle resistance to compactive effort. This cementation of the soil particles induces a higher water-holding capacity and thus an increase in optimum moisture content and a corresponding decrease in the maximum dry density. In addition, the increase in OMC is due to the larger specific surface area of LKD particles and hence more water is required for sufficient lubrication of the blended mixture to obtain MDD. The increase in OMC may also be attributed to the flocculated and agglomerated clay particles, which tend to agglomerate, thus occupying larger spaces and leading to an increase in water content. The decrease in MDD is due to the fact that LKD has a lower specific gravity as compared to the BCS-SD composite. This is attributed to flocculated structure aggregation formed by the addition of LKD having a lower specific gravity and hence a reduction in MDD (Kang et al 2015). The MDD and OMC of all blends was greater than that of the neat soil sample. This can be attributed to the high lime content of LKD facilitating faster consumption of water in the mixes. Similarly, the higher specific area of LKD leads to higher water absorption and quicker reaction, hence dense matrix of hydrated LKD (Bernard et al. 2010).

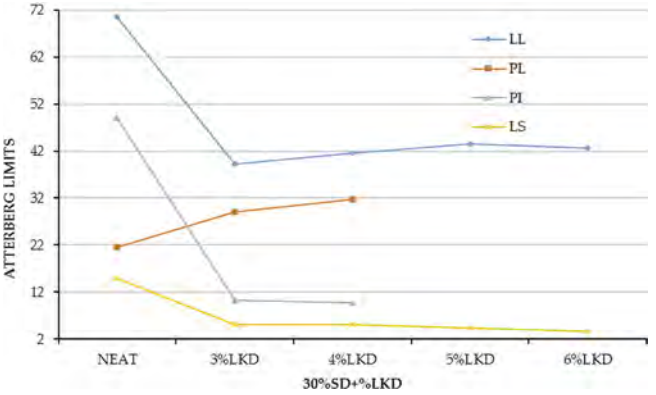

Figure 1. Variation of Atterberg limits with 30% Sand (SD) and LKD content.

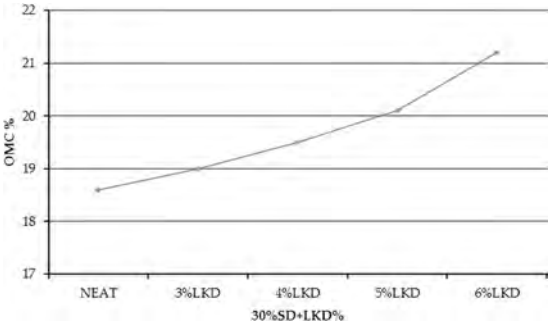

Figure 2. Variation of OMC with 30% SD and LKD content.

3.2.3 *Effect of SD-LKD combination on the CBR of black cotton soil*

The CBR results presented in Figure 4 show that the CBR value of the BCS-SD composite blended with LKD increased with addition of LKD content. The same trend was reported by Achampong et al. (2013). The increase in CBR values is attributed to the cation exchange reaction and flocculated structure aggregation of the soil particles (Bell 1996, Al-Rawas et al. 2005, Nalbantoglu & Tuncer 2001). In addition, the increase in CBR values may be related to the pozzolanic reactions, which are responsible for the strong cementing bond between the clay soil particles. These reactions resulted in the formation of cementitious compounds, i.e., calcium silicate hydrate

(CSH) and calcium aluminate hydrate (CAH) (Al-Rawas et al. 2005). The formed compounds crystalize with time and thus result in changes in clay plasticity, increase in shear strength, and changes in swelling properties. Therefore, addition of LKD to the BCS-SD composite resulted in the bonding of clay particles together, which increases the resistance to penetration and thus results in an increase in the CBR value.

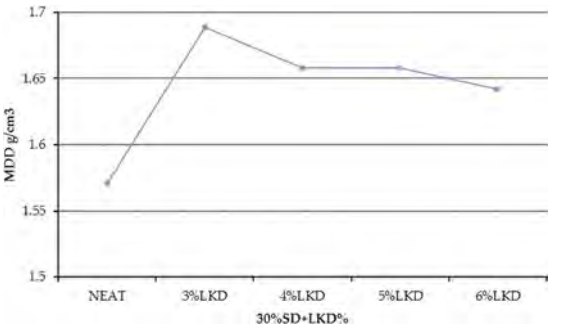

Figure 3. Variation of MDD with 30% SD and LKD content.

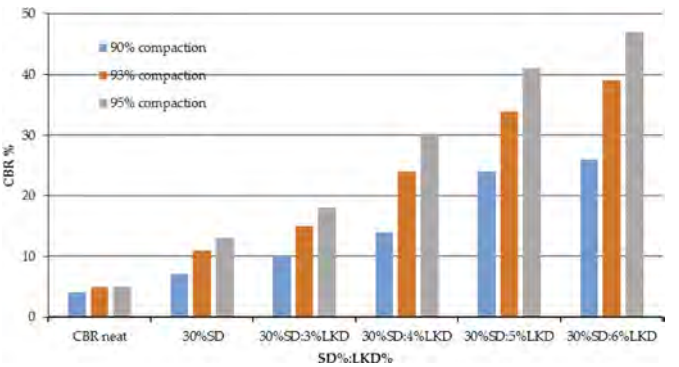

Figure 4. Variation of CBR with 30% SD and LKD content.

4 CONCLUSIONS

- The black cotton soil used in this study had the following physical properties: liquid limit of 70.5%, plastic limit of 21.5%, plasticity index of 49%, and free swell ratio of 2.3. For the strength properties: a CBR value of 5% at 95% compaction, MDD of 1.571 g/cm3 and OMC of 18.6%.
- There was a general reduction in the Atterberg limits with increasing percentages of sand. The liquid limit and plastic limit of the soil blended with sand decreased from 70.5% and 21.5% to 29.4% and 12.4%, respectively. The same trend was observed with plasticity index and linear shrinkage values from 49% and 15% to 17.0% and 6.4%, respectively.
- The variations in the free swell ratio of black cotton soil blended with sand show that black cotton soil had a free swell ratio of 2.3, which was reduced to 1.3. This implies that the black cotton soil changed from its swelling nature to a non-swelling nature after blending with sand.
- There was a reduction in OMC values and a corresponding increase in MDD with increasing proportions of sand. The maximum dry density of black cotton soil increased from

1.571 g/cm3 to 1.905 g/cm3 for the BCS-SD mix, whereas the optimum moisture content of the black cotton soil decreased from 18.6% to 11.4% of the blended mix. More so, the CBR of black cotton soil increased relative to increasing percentages of sand. The CBR values increased from 5% to 23% for sand content of 0% to 50%, respectively.

- BC soil treated with a combination of lime kiln dust and sand exhibited a general decrease in plasticity index and linear shrinkage values to levels lower than those achieved with sand content alone. The plastic limit values slightly increased with the addition of 3% and 4% LKD content, whereas further addition of 5% and 6% rendered the mix non-plastic. In addition, the liquid limit gradually increased from 39.2% to 43.5% with the addition of 3% to 5% LKD content, respectively, and furthermore, addition of 6% LKD slightly reduced the liquid limit to 42.6%.
- The compaction test results showed a reduction in the maximum dry density with a corresponding increase in the moisture content with the addition of LKD content. The MDD of black cotton soil increased from 1.571 g/cm3 to 1.689 g/cm3 for the final optimum mix, whereas the OMC of black cotton soil increased from 18.6% to 19.0% for the final optimum mix.
- The CBR results of the composite treated with LKD increased with the addition of various percentages of LKD. The soil treated with a combination of LKD and sand showed more strength gain than black cotton soil treated with sand alone. The CBR of black cotton soil increased from 5% to 18% for the final optimum mix. From the above results, the modified black cotton soil can be successfully used for subgrade construction.

Use of waste rubber inclusions for ballasted railway construction – A real-life case study

Chathuri M.K. Arachchige, Buddhima Indraratna, Cholachat Rujikiakamjorn, Yujie Qi & Anees Raja Siddiqui
Transport Research Centre, University of Technology Sydney, Sydney, New South Wales, Australia

ABSTRACT: The rail track substructure is an essential element in ballasted embankment, transferring the train loadings to underlying subgrade soil. To enhance track performance and embrace circular economy, three different track formations modified with rubber waste additives were constructed at the Chullora Technology Precinct (near Sydney), Australia. A blended mix of ballast aggregates and recycled rubber granules, geogrids made of recycled rubber panels, and recycled tyres infilled with granular waste are the three innovative concepts used in this real-life application. This paper evaluates the vertical stress distribution of modified track sections compared to the conventional ballasted track substructure under train loads. Monitoring outcomes demonstrate that stress redistribution due to rubber inclusion can increase track longevity.

1 INTRODUCTION

A typical ballasted railway substructure includes a ballast bed, a subballast (capping) layer, and subgrade soil. The stability and durability of the rail track closely rely on the load distribution of these underneath subsequent layers. With the increased demand for rail transportation, the speed and loading intensity of trains are constantly growing, leading to faster track deterioration. However, considering the safety and passenger comfort, the maximum vertical stresses along the substructure should be well controlled in practice (Seed et al. (1962). It is proven that the change in confining pressure, degree of compaction of substructure layers, rail superstructure arrangement and the train loading conditions are the main factors affecting the vertical stress distribution within the track substructure (Indrarathna et al., 1998, Zhang et al, 2016). Overstressing the track components leads to track degradation and frequent maintenance. This paper discusses the application of three recycled rubber-based innovations and their performance, particularly on redistribution of vertical stresses compared to the conventional track section: (i) Rubber Intermixed Ballast System (RIBS) as an alternative material for bottom ballast where 10% of the weight consist of rubber granules derived from waste tyres; (ii) Energy-Absorbing Rubber Geogrids (EARS) as a special type of geogrid made from used rubber conveyor belts; and (iii) Tyre Cell Track Foundation (TCTF) as an assembly of recycled tyres filled with granular waste in lieu of traditional capping material. These three innovative techniques were applied along a 380 m ballasted railway track built at the Chullora Technology Precinct, New South Wales, Australia.

2 CHULLORA RAIL PRECINCT

2.1 *Project description*

The test track section constructed in Chullora Technology Precinct was divided into four sections (Figure 1), namely (i) Section F-G: TCTF section, (ii) Section E-F: Control track section, (iii) Section D-E: EARS section and (iv) Section B-C: RIBS section. As shown in Figure 1, three 20-m long instrumented track sections were constructed with intermediate standard track sections to avoid the

DOI: 10.1201/9781003299127-399

boundary effects and in all sections, materials, earthworks, and track components complied with Transport for New South Wales (TfNSW) standards except for the modifications associated with rubber inclusions. An 81 Class locomotive (21.5-ton axle load) was chosen to operate on all the test sections running at around 10-13 km/h, as per the train speed restrictions.

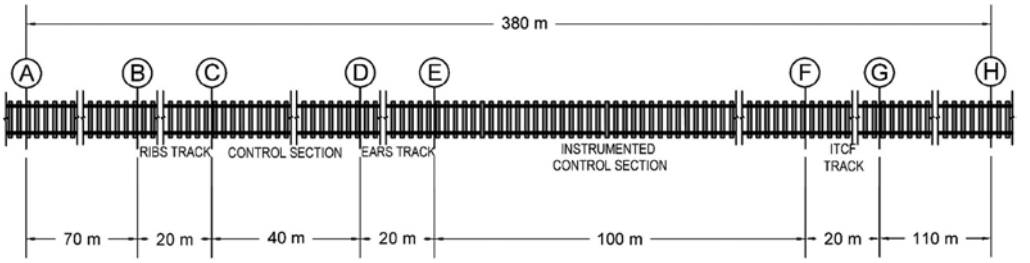

Figure 1. Plan view of the track.

2.2 *Rubber Intermixed Ballast System (RIBS)*

RIBS applied in the track was a blended mixture of conventional ballast material and 10% (by total weight) recycled granulated rubber in the size of 8-15 mm. More details on the properties and behaviour of RIBS can be found elsewhere (Arachchige et al. 2022). A calibrated volumetric mixer was used to mix rubber and ballast aggregates at the site. Figures 2a-b show a typical cross-section of the RIBS track in which a 150-mm thick bottom ballast layer was replaced with RIBS and the preparation of RIBS at the site.

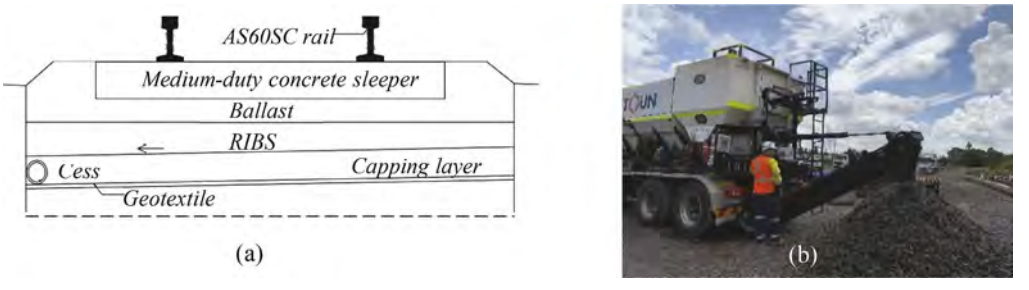

Figure 2. (a) Cross-section of RIBS track (b) Mixing materials at the site using a volumetric mixture. Energy-Absorbing Rubber Seam (EARS).

2.3 *Energy-Absorbing Rubber Seam (EARS)*

Rubber panels from end-of-life conveyor belts were utilized to manufacture EARS resembling geogrids with square apertures through water jet cutting. The aperture size of the rubber panel was 51×51 mm^2, while its thickness was 10 mm. The rubber geogrids were laid on top of the compacted capping layer of the EARS track section before placing the ballast layer (Figures 3a-b).

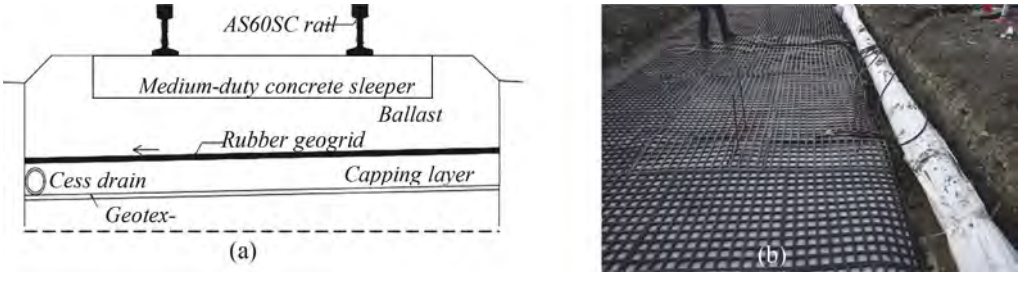

Figure 3. (a) Cross-section of EARS track (b) Rubber geogrids laid on top of the compacted capping.

2.4 *Tyre Cell Track Foundation (TCTF)*

Tyre Cell Track Foundation (TCTF) is an assembly of 200 mm thick, and 600mm diameter recycled tyres filled with granular materials placed on top of the subgrade, replacing the conventional capping layer (Indrarathna et al, 2022). A typical cross-section of a 20 m long TCTF track section and the tyre assembly during the construction are shown in Figures 4a-b.

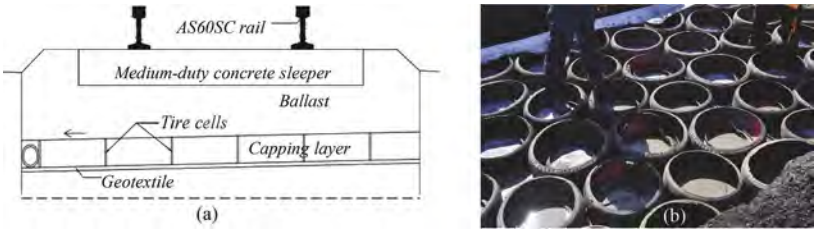

Figure 4. (a) Cross-section of ITCF track (b) Tyre cell assembly before granular filling.

3 PRESSURE DISTRIBUTION

Following Indraratna & Ngo (2018), the dynamic wheel load (P=112kN) applied on the rail was calculated using the formula, P=P$_s$$P = P_s \times IF$ where P_s was half of the axle load and IF was the dynamic amplification factor. Here, $IF = 1 + 5.21\ V/D$ where V was the train speed and D was the wheel diameter in km/h and mm, respectively. The applied loading on the rail from the locomotive is presented in Figure 5.

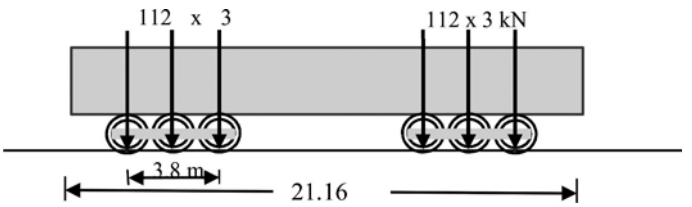

Figure 5. Applied loads from the locomotive.

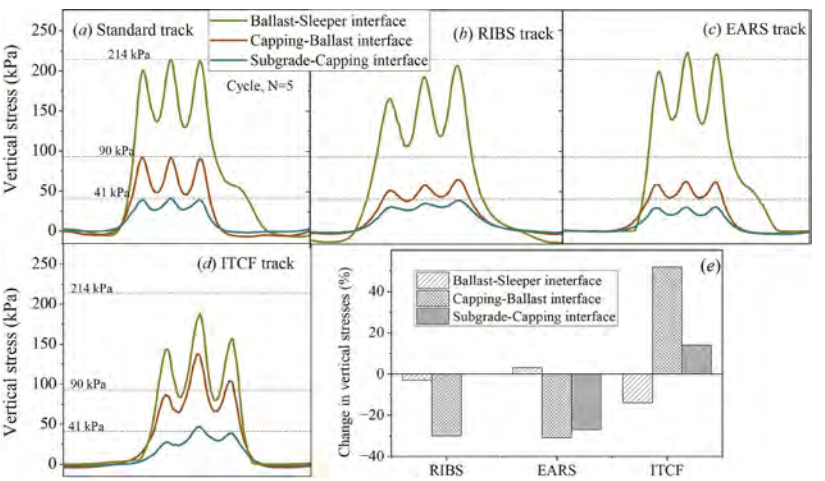

Figure 6. (a-d) Vertical stress distribution (e) Change in the vertical stress distribution at the interfaces.

In the analysis, a loading cycle represents the passing of one axle at a particular point in each track section, and the end of the axle is connected to a set of three wheels. At the initial stage of the loading, a few numbers of loading cycles were applied on the track, and Figures 6a-d show the vertical stress distribution of each track section subjected to the 5^{th} loading cycle (N=5), and Figure 6e shows the percentage of change in vertical stresses at the different interfaces of the substructure. At the ballast-sleeper interface, no significant change was observed in RIBS and EARS sections compared to the standard (conventional) track section; however, more than a 10% reduction was observed in the TCTF track section. On the other hand, significant stress reduction (around 30%) was observed at the capping-ballast interfaces of RIBS and EARS sections. Stresses at the capping-ballast and subgrade-capping interfaces of TCTF were increased by about 55% and 14%, respectively, due to the increased stiffness generated by the compacted granular materials in the confined tyre cells. Furthermore, in the EARS section, the vertical stress at the capping-subgrade interface was reduced by around 25% compared to the conventional track section. The reduced vertical stress distribution within the ballast layer is advantageous because it reduces particle breakage and related track degradation. Note that the stress relieving in RIBS and EARS sections is significant within the ballast layer and, in TCTF, the capping layer.

4 CONCLUSION

This paper discusses the three types of real-life applications of waste rubber-derived elements in rail infrastructure, namely rubber intermixed ballast system (RIBS), energy absorbing rubber seam (EARS) and infilled tyre cell foundation (TCTF). Manufacturing and the application procedure of RIBS, EARS and TCTF as a modification to the conventional ballasted track are briefly presented. The performance of each track section under typical train loading is further discussed in relation to vertical stress distribution along the subsurface profile. In general, RIBS and EARS reduced vertical stresses (by around 30%) in the ballast layer. In contrast, the tyre cell assembly adequately relieves increased vertical stresses at the capping-ballast interface of the TCTF section so that the stresses transfer into the subgrade is well controlled. Following the present results, this study confirms that substructure layers modified by rubber inclusions play a vital role in stress redistribution of the track. In addition, using waste rubber in infrastructure projects promotes sustainable construction applications by reusing non-biodegradable waste and reducing the carbon footprint.

ABSTRACT: Abrupt stiffness changes encountered in the transition zone lead to an accelerated deterioration of track components and passenger discomfort, eventually leading to an increase in maintenance cost and hindering smooth railway functioning. This paper aims to understand the major causes and analyse countermeasures deployed at the railway transition zone. The present study covers the chronological advancement made in the study of transition zone using numerical, analytical, and experimental models. As field experiments require significant investments in terms of instrumentation and setup, the numerical and analytical approaches have become popular among practising engineers. Along with understanding the present state of work, this paper explores the various loading techniques simulated with the help of a Finite Element Model to understand the details of carrying out such numerical experiments. A simple bridge embankment system is modelled to understand the suitability of the method of loading serving a particular purpose.

1 INTRODUCTION

Transition zones are the structural solution aimed at attenuating the problems encountered due to the variation in vertical stiffness. In locations where there is a shift of track support from engineering structure to soil subgrade, there is an abrupt variation of stiffness. This sudden change in the vertical support system leads to the variation of wheel-rail interaction, eventually causing the degradation of the track system. Consequently, the problems associated with the variation require regular maintenance which not only sums up to a hefty amount annually but also hinders the smooth flow of traffic. (Li and Davis, 2005). To curb the high maintenance cost of the transition zone, proper analysis and mitigation techniques are implemented. Transition zones requires around 200 million dollars for annual maintenance (Qian et al.) The study aims at understanding the different models which have been formulated over time to analyse the problems encountered and the mitigation techniques implemented. A finite element model has been prepared to understand the loading technique of the moving vehicle and the time required for computation along with the soundness of the results.

2 PROBLEMS ENCOUNTERED

Locations near the engineering structures, such as bridges, viaducts, culverts etc., are prone to accelerated track geometry degradation and other negative impacts on the track and vehicle

DOI: 10.1201/9781003299127-400

components. The researchers have conducted a good number of studies to investigate the behaviour of the bridge embankment transition zone. Triaxial accelerometers, Strain gauges, geophones, LVDT etc., have been used to measure the real-time response of the transition zone under moving train loading. FEM-based numerical modelling approach has been used to simulate the scaled models to obtain the response under different boundary conditions and loading parameters. The present segment is organised into three sub-segments- problems encountered in the transition zone, prevention measures and conclusions.

The variation in stiffness at the junction of the bridge embankment transition zone may generate low-frequency random vibrations in the car body leading to the discomfort of the passengers (Dahlberg,2010). Another major issue faced in the junction of the bridge embankment transition zone is the differential settlement. The uneven displacement in the bridge and the embankment due to the difference in stiffness leads to geometric irregularity causing the differential settlement (Gallage, Chaminda et al. 2013). Differential settlement in the railway transition zone leads to the formation of dips and bumps which further causes the formation of hanging sleepers near the bridge embankment junction (Wang, 2015, Hunt 1997). Mauer (1995) observed that the differential settlement due to geometric irregularities also affects the dynamic wheel load and the wheel-rail interaction forces. The abrupt change in stiffness, differential settlement and track irregularity aggravates the deterioration of the transition zone.

3 COUNTERMEASURES

With the increasing development of the high-speed railway, there arises a need for improvement in the performance of the transition zone. Numerous precautionary measures have been taken up by researchers to improve the track transition system. The behaviour of the transition zones is still very unpredictable although, to mitigate the existing problems encountered in the transition zone, some countermeasures are implemented by various researchers over the last few decades. The countermeasures can be divided into corrective countermeasures and preventive countermeasures (Wang, Markine (2018a)). Li and Davis (2005a) compared the track performance of a UP standard to bridge approaches with geocell in the sub-ballast layer, HMA (hot mix asphalt) and cement stabilised backfill. It was seen that a granular layer infilled in geocell used for correcting the issues of soft soil deformation highly improved the performance of the track. Punetha et al., 2021 observed that the use of geogrids in the sub-ballast did not show any significant improvement in the performance, however, the use of wedge-shaped engineered backfill at the bridge embankment contributed well to the improvement of the bridge embankment transition zone. The decrease in sleeper spacing in the study showed a reduction in the deformation in the region near the bridge, which is because of the increased stiffness. However, the region beyond the modified segment showed excessive displacement (Punetha et al., 2021). The abrupt generation of force at the transition section due to the difference in stiffness can be reduced by the usage of under sleeper pads. Dahlberg (2010) believes that under sleeper pads attenuate the wheel-rail interaction force, decreasing the detrimental effects of dips, bumps and hanging sleeper. Nimbalkar and Indraratna (2016) suggested that using geogrids and geocomposites reduces ballast settlement by nearly 35%.

The abrupt change in stiffness, varying speed of the train, and soil parameters of the underlying soil affect the dynamic response of the railway bridge-embankment transition zone. The dynamic wheel-rail interaction force and the differential settlement at the junction are the prime causes which lead to the degradation of the track performance. In addition, the increasing speed of the train further accelerates the deterioration of the track performance. Hence, special design considerations have to be made for High-Speed Railways. Due to the participation of several structural components at the junction of the transition zone, the dynamic response at the location is unpredictable. The numerical models which have been studied are predominantly elastic, however, degradation at the transition zone takes place with multiple passages of trains over some time. Under actual conditions of train loading, the ballast and sub-ballast do not behave linearly or elastically, giving rise to plastic deformation over time. The plastic deformation is not considered in the numerically simulated models, which is why there is a discrepancy with the actual field response.

The behaviour of the transition zone under dynamic loading is unpredictable under the influence of several structural elements. The performance of the critical zone is improved with the modifications, resulting in a reduced degradation rate of the bridge-embankment transition system.

4 3D SIMULATION OF THE BALLAST-TRACK SYSTEM

A simple ballast track model has been simulated using FE software ABAQUS. The mass and cross-sectional properties of UIC60 have been used to model the rail. The track has been modelled, representing the Indian Broad Guage section. For the train body simulation, only the wheels have been modelled, on which the weight of the vehicle body, bogie and other subparts has been applied as a point load. The movement of the vehicle is considered from the embankment to the bridge section. The bottom of the bridge is considered to be fixed, representing a rigid body, while the ballast bottom allows a displacement in the z-direction. Absorbent vertical boundaries have been implemented to prevent the reflection of waves. Figure 1(a) and 1(b) show the 3D modelling of the ballast track system and the schematic representation of the bridge embankment transition zone, respectively.

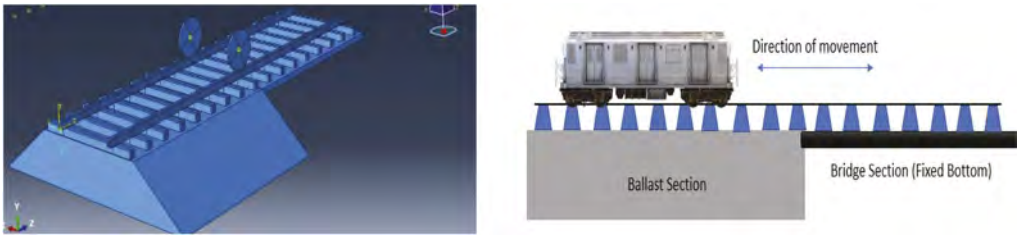

Figure 1. (a) 3D modelling of ballast track system; (b) Schematic diagram of the track transition zone.

5 DISCUSSION

This segment presents the differential settlement at the bridge-embankment transition zone. The current simulation assumes the train's movement from a softer stiffness region to a stiffer region. The sudden change in stiffness at the transition junction develops a differential settlement leading to the formation of hanging sleepers. In Figure 2, location zero represents the sleeper at the intersection of the bridge-embankment. There is a sudden displacement, when the train crosses the junction, however, the relative displacement ceases to exist at sleeper locations far from the intersection of the railway transition zone.

Figure 2. Relative settlement at sleeper location.

6 CONCLUSIONS

The representation of the vehicle in the current study is functional when the study's primary objective is from the perspective of geotechnical engineering. The computational time is reduced manifold for the simplicity of the model. However, the model needs to be modified to a full-scale car body to understand the impact of multiple subparts on the generation of dynamic force at the track level. The change in stiffness at the juncture leads to the generation of blunt wheel-rail interaction force, aggravating the deterioration of the track performance. Preventive and precautionary measures must be taken considering both the bridge-embankment junction's long-term and short-term behaviour and the local site conditions.

Field tests of railway ballast vibration

A.F. Kolos & A.A. Konon
Emperor Alexander I St. Petersburg State Transport University, St. Petersburg, Russia

ABSTRACT: The paper presents a review of authors work on railway ballast vibration testing on a few sites. The aim of testing is to get the level of vibration amplitude in terms of train speed and axle load. The rolling stock causes oscillations of track superstructure, which show up in the form of noise and vibration. The increase in loads and speeds of trains leads to a significant increase of dynamic vibration effects on the roadbed. Because of this exposure the intensity of uneven residual deformation accumulation of the railway track increases. It affects not only on the roadbed, but also on constructions of buildings and construction. The study of ballast vertical vibration displacement gives the following conclusions: 1. Displacement amplitudes and frequency range of ballast particles are derived. Both horizontal components increase linearly with approximately the same intensity with speed growth, and their values in the entire range of speeds do not exceed 225 μm in the transverse direction and 90 μm in the longitudinal direction. The vertical component also increases according to a nearly linear dependence up to 190 km/h, and at higher speed it stabilizes and even slightly decreases, which leads to almost the same values of the resulting vibration displacement amplitude up to 275 km/h. 2. No differences in the oscillatory process are revealed for different types of rail fastenings (KB-65, ARS-4 or Pandrol). 3. The obtained results can be used to simulate the vibrational dynamic effect in triaxial tests. Such modeling is necessary to study the sensitivity of crushed stone ballast to the loads, which is shown in a decrease in the strength and deformation properties of the ballast, to predict the bearing capacity and deformability of the ballast under various operating conditions.

1 INTRODUCTION

Stable ballast operation during the established overhaul period is possible only in case the ballast bearing capacity exceeds the loads occuring due to the movement of the rolling stock, and the resulting residual deformations and the rate of their accumulation do not lead to track damage. To assess ballast stability, it is necessary to determine the permissible stress in the ballast p_p, the permissible ballast deformation $[S]$ and operational loads from the rolling stock p, which, among other things, determine the residual deformation of the ballast S. Numerous studies prove the significant role of the vibrational dynamic impact of the rolling stock on the bearing capacity of soils (Butorina, M. et al. 2017, Kaewunruen, S. et al. 2008, Kolos, A. et al. 2017, Kolos, A. et al. 2020, Remennikov, A. et al. 2020, Serebryakov, D. et al. 2017, Konon, A. & Petriaev, A. 2018, Petriaev, A. et al. 2022), which fully applies to crushed stone. Thus, calculations of ballast strength and deformability should be performed concidering the action of inertial forces that arise in crushed stone under the influence of rolling stock, and the reduction under the influence of vibrodynamic load of the strength and deformation characteristics of crushed stone ballast.

To solve these problems, it is necessary to establish the relationship of oscillation propagation in the ballast. Oscillations of soil grains are characterized by displacement amplitudes (A), oscillation frequency (f), vibration velocity (V) and vibration acceleration (a). This article presents the results of railway ballast displacement amplitudes in different operation conditions.

DOI: 10.1201/9781003299127-401

2 MATERIALS AND METHODS

To study the vibrational dynamic effect of trains on the ballast in the period from 2000 to 2020, a group of authors conducted full-scale tests on different sections of the operated railway tracks, which differ in track structure and operating conditions. The description of the test sites is presented in Table 1.

All test sites had R-65 rails and reinforced concrete sleepers and were located at the straight section. Ballast layer was constructed using granite crushed stone of 25-60 mm grains.

The measurements were conducted with a set of equipment consisting of a digital seismic signal recorder ZET 048; a PC with licensed software; an amplifier; a 220 V power supply, a set of seismic sensors (seismometers). Devices for in-situ oscillation testing are shown in Figure 1.

Table 1. Characteristics of the test sites.

	Test site location						
	Moscow – Saint-Petersburg					Saint-Petersburg – Vyborg	Railway research institute of JSC Russian Railways test loop
Test site characteristics	№ 1	№ 2	№ 3	№ 4	№ 5	№ 6	№ 7
Superstructure	Continious welded rail						Jointed rail
Fastenings	KB-65	Pandrol	KB-65	KB-65	ARS-4	KB-65	KB-65
Ballast depth under the sleeper, cm	40	75	40	45	45	40	40

Train operation conditions	passenger and freight trains with axle load up to 250 kN and 120 kmph speed	speed passenger trains (140 – 200 kmph)	freight trains with axle load 270-300 kN	speed passenger trains (140 – 200 kmph)	high-speed passenger trains (more than 200 kmph)	passenger and freight trains with axle load up to 250 kN and 120 kmph speed	freight trains with axle load 270-300 kN
Sensor placement: scheme A scheme B scheme C	+	+	+	+	+	+	+

Statistical processing of measurement results was carried out. The average value of vibration displacement, the standard deviation, the maximum probable value and the coefficient of variation were determined. The probability level was assumed 0.994.

Displacement was measured in three axes as shown in Figure 3.

Figure 1. Test devices set.

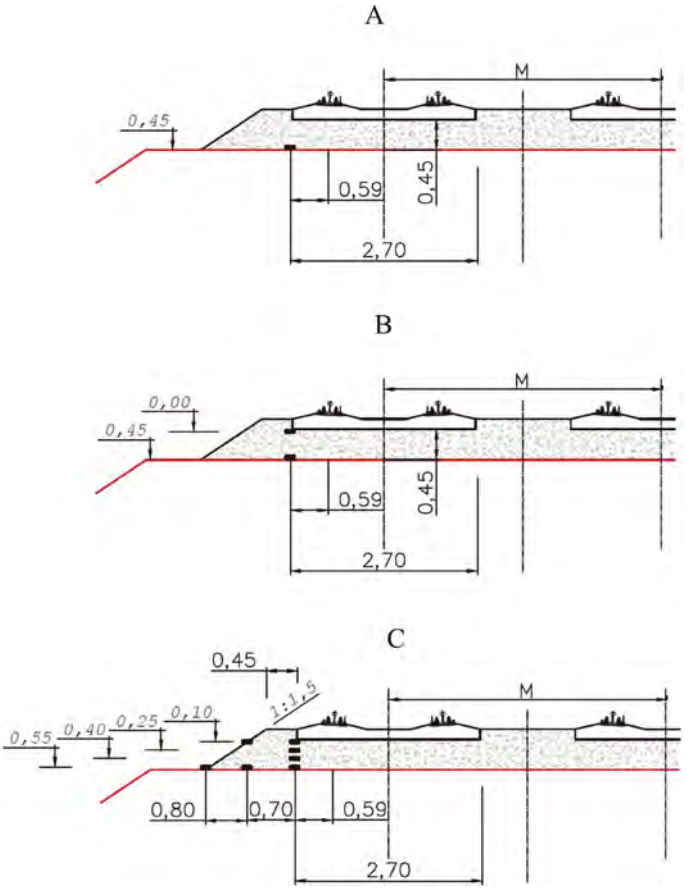

Figure 2. Seismometers installation schemes.

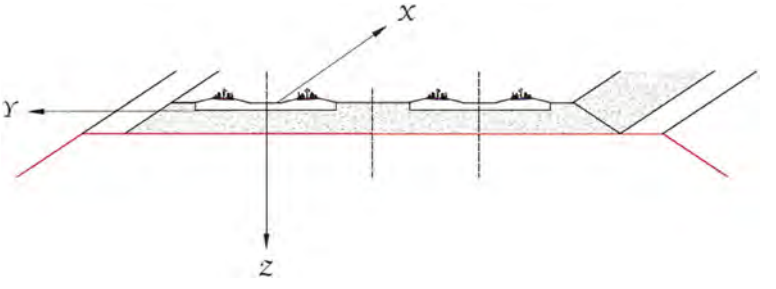

Figure 3. Axes of coordinates.

3 RESULTS AND DISCUSSION

Studying the amplitude-frequency characteristics of the ballast oscillation process is determined by the need to simulate the behaviour of crushed stone in triaxial tests when studying the mechanical properties of crushed stone ballast under the action of a vibration dynamic load.

Figure 4 shows the plots of the vibration displacement amplitudes registered under the sleeper when the high-speed 'Sapsan' train (Siemens Desiro RUS) is passing at a speed of 275 km/h, and Figure 5 shows similar data at a depth of 40–45 cm under the sleeper during the passage of a speed train "Aurora", moving at a speed of 141 km/h.

As Figures 4 and 5 show, the maximum amplitudes of vibration displacements are registered in the vertical plane along the Z axis (Figure 3, curves 2 in Figures 4 and 5) and coincide quite clearly with the rolling stock axles passage over the location of the seismometers. The vibration displacement amplitudes along the horizontal axis Y (curves 1 in Figures 5 and 5) have slightly lower values, and the lowest values are recorded along the X axis (curves 3 in Figures 4 and 5), This pattern is also typical for the movement of freight trains moving at speeds of 60–90 km/h.

Test data show that rather high ballast displacement amplitudes occur, reaching 420-450 μm at passenger train speeds of 200 km/h and higher. The features of the oscillation components growth with an increase in the speed of movement are distinctive. Both horizontal components increase linearly with approximately the same intensity with speed growth, and their values in the entire range of speeds do not exceed 225 μm in the transverse direction and 90 μm in the longitudinal direction. The vertical component also increases according to a nearly linear dependence up to 190 km/h, and at higher speed it stabilizes and even slightly decreases, which leads to almost the same values of the resulting vibration displacement amplitude up to 275 km/h (Figure 6).

Analysis of ballast vertical oscillations shows no differences in the oscillatory process are revealed for different types of rail fastenings (KB-65, ARS-4 or Pandrol). The obtained results provide the amplitude-frequency characteristics of the ballast oscillation process, shown in Table 2. These characteristics can be used to simulate the vibrational dynamic effect in triaxial tests. Such modeling is necessary to study the sensitivity of crushed stone ballast to the loads, which is shown in a decrease in the strength and deformation properties of the ballast, to predict the bearing capacity and deformability of the ballast under various operating conditions.

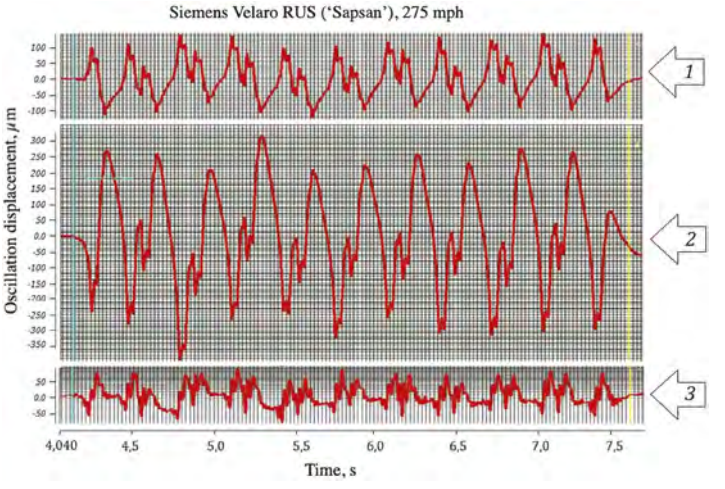

Figure 4. Amplitudes of vibration displacement under sleeper during the passage of the high-speed train "Sapsan" at a speed of 275 km/h: 1 – Y axis, 2 – Z axis, 3 – X axis.

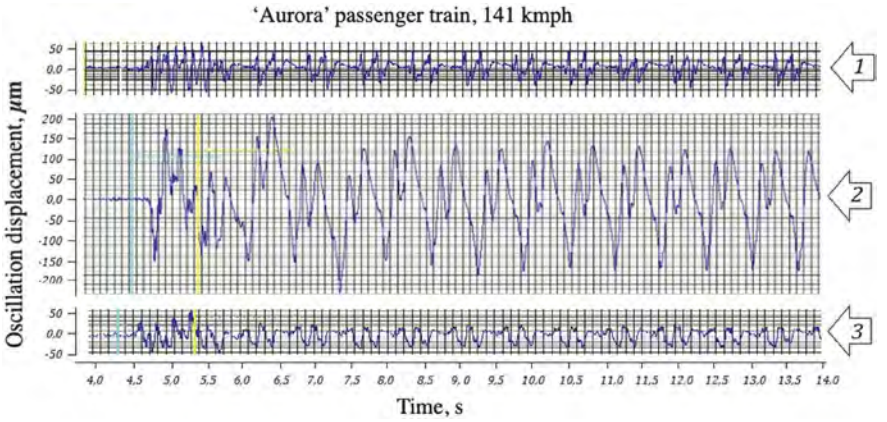

Figure 5. Amplitudes of vibration displacement under sleeper during the passage of the 'Aurora' passenger train at a speed of 141 km/h: 1 – Y axis, 2 – Z axis, 3 – X axis.

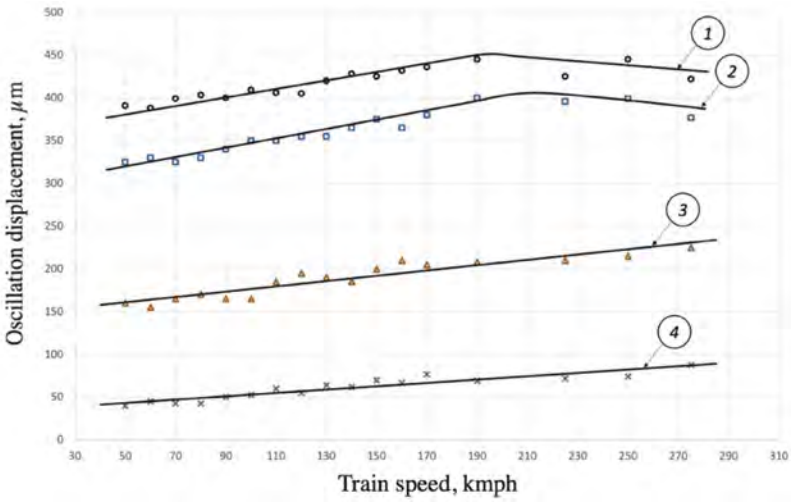

Figure 6. Amplitudes of ballast vibration displacement at passenger trains speed (under the sleeper): 1 - resulting; 2 - in the vertical direction (Z); 3 - in the horizontal direction perpendicular to the longitudinal axis of the track (Y); 4 - in a horizontal direction along the longitudinal axis of the track (X).

Frequency component	Vibration displacement amplitude and frequency	Vibration components along the axes			Descruption
		X	Y	Z	
Low	f_l, Hz	1,7-4,6	2,0-5,0	1,5-5,2	Cumulative force impact caused by the passage of rolling stock bogies
	A_l, μm	25-45	80-120	200-360	
Medium	f_m, Hz	5-50	5-50	4-40	Force impact caused by the passage of wheelsets (individual axles in the bogie)
	A_m, μm	5-10	20-35	50-100	
High	f_h, Hz	40-120	50-150	40-600	Oscillations of unsprung masses of rolling stock
	A_h, μm	0-5	0-15	10-15	

4 CONCLUSIONS

The study of ballast vertical vibration displacement gives the following conclusions:

1. Displacement amplitudes and frequency range of ballast particles are derived. Both horizontal components increase linearly with approximately the same intensity with speed growth, and their values in the entire range of speeds do not exceed 225 μm in the transverse direction and 90 μm in the longitudinal direction. The vertical component also increases according to a nearly linear dependence up to 190 km/h, and at higher speed it stabilizes and even slightly decreases, which leads to almost the same values of the resulting vibration displacement amplitude up to 275 km/h.
2. No differences in the oscillatory process are revealed for different types of rail fastenings (KB-65, ARS-4 or Pandrol).
3. The obtained results can be used to simulate the vibrational dynamic effect in triaxial tests. Such modeling is necessary to study the sensitivity of crushed stone ballast to the loads, which is shown in a decrease in the strength and deformation properties of the ballast, to predict the bearing capacity and deformability of the ballast under various operating conditions.

ABSTRACT: The paper presents the results of sub-rail pads field tests to assess the effect of the stiffness and number of standard and prototype sub-rail pads on the level of vibration transmitted to the track when trains pass in the rail junction area. In order to achieve this goal, vertical vibration accelerations arising from trains passing in the rail joint area were measured with different numbers of standard sub-rail pads and high elasticity pads. At all investigated types of rolling stock (passenger train, Lastochka, Sapsan) with standard vibration damping pads before their replacement in the area of the rail joint on the subgrade top 2-3 times higher amplitudes of vertical vibration accelerations were fixed than at the distance of 7 sleepers from the joint. Comparison of vibration acceleration amplitudes in the rail joint area with different numbers of dampers showed that 7 dampers installed on each side of the rail joint are most effective. A comparison of vibration-dynamic impact level of on the ballast in the area of the rail joint depending on the type of rolling stock with different axle load and speed has shown, that Lastochka and Sapsan have a greater impact on the track than passenger trains with a speed of 90 km/h and a load of 150-160 kN per axle. Vibration acceleration amplitudes in the ballast layer with 7 pads of increased elasticity Sylodyn NF (experimental) are 1.4-2 times smaller than those of standard - CP-204-M-ARS (standard).

1 INTRODUCTION

The railway track is experiencing increased dynamic loads due to the global trend of increasing the traffic, train speeds and axial loads. The increase in loads leads to accelerated track deterioration. The railway operation world experience and the field experiments results have indicated that the ballast layer is the element with the smallest margin of safety. The stability of the track geometric parameters depend on the state of the ballast. The shock-dynamic impact of rolling stock on the track is significantly enhanced in the rail joint area, which is a node with particularly difficult working conditions (Kolos 2020). Despite the fact that by far the most common is the long-welded rails, expansion joints of rails and switches (Petriaev 2020) require optimization of the design. In the rail joint area and adjacent sleepers, the rolling stock increased impact significantly affects the track stability. To solve this problem, elastic sub-rail pads are used (Petriaev 2017, Kaewunruen 2008, Sol-Sánchez 2015). The pads are made of various materials: high-strength polyethylene (HDPE), various elastomers, including natural rubber, polyurethane (Remennikov 2020), recycled rubber (Sol-Sánchez 2014), reinforced rubber (Carrascal 2018, Sol-Sánchez 2014). Optimization of their stiffness, thickness and the placement location choice is the important problem.

This article presents the results of sub-rail pads full-scale tests in order to assess the impact of their number and stiffness in the rail junction area on the vibration level transmitted to the railway track due to trains pass.

DOI: 10.1201/9781003299127-402

The measurement of vertical vibration accelerations occurring during the trains passage on the rail junction area with a different number of standard sub-rail pads of increased elasticity has been carried out.

2 MATERIALS AND METHODS

The study was carried out on the high-speed railway line St. Petersburg - Moscow. The test site was located on a straight track section. The roadbed was represented by a zero level. The characteristics of the upper structure of the railway track are presented in Table 1.

Table 1. Characteristics of the upper structure.

Parameter	Unit of measurement	Value
Type of rails		R65
Type of sleepers		IIIC-ARC
The ballast thickness	m	0.45
Track gauge	m	1.523
Rail level	mm	0-3
Space allowance	mm	12
The force of pressing the rails with the terminal	kN	7.7–9.7

The characteristics of standard CP-204-M-ARS (standard) sub–rail pad are presented in Table 2.

Table 2. Characteristics of CP-204-M-ARS pad.

Parameter	Unit of measurement	Value
Category		II
Execution		D
Thickness	mm	14
Weight	kg	0.46
Tensile strength at break	MPa	10
Elongation at break	%	300
Static compression stiffness	kN/mm	80

The appearance of the standard and experimental pad is shown in Figure 1.

Figure 1. Standard CP-204-M-APC gasket (standard, top) and Sylodyn NF high-elasticity gasket (experimental, bottom).

Sylodyn NF (experimental) high-elasticity under-rail pad are made of a material whose characteristics are given in Table 3.

Table 3. Characteristics of pad with increased elasticity Sylodyn NF (experimental).

Parameter	Unit of measurement	Value
Static scope of application	N/mm^2	1.5
Peak loads	N/mm^2	8.0
Mechanical loss factor		0.1
Rebound elasticity	%	70
Residual deformation during compression	%	<5
Static modulus of elasticity	N/mm^2	11.95
Dynamic modulus of elasticity	N/mm^2	16.85
Static shift modulus	N/mm^2	0.8
Dynamic shift modulus	N/mm^2	1.18
Min. breaking tensile stress	N/mm^2	7.0
Min. elongation at break	%	500
Abrasion	mm^3	90
Coefficient of friction (steel)		>0.7
Coefficient of friction (concrete)		>0.7
Specific volumetric resistance	Ω*cm	$>10^{11}$
Thermal conductivity	Wt/mK	0.15
Operating temperature range	°C	-30 - 70
Peak temperatures	°C	120
Flammability	class	E/EN 13501-1

Measurements were performed with integrated circuit piezoelectric accelerometers (type 393B04) by PCB Piezotronics. The sensors were installed at sleeper bearing level and 40 cm below. The placement of the sensors is shown in Figure 2. The seismic receivers were installed on a leveled platform with precise observance of the three directions measurement (vertical, horizontal across and along the track).

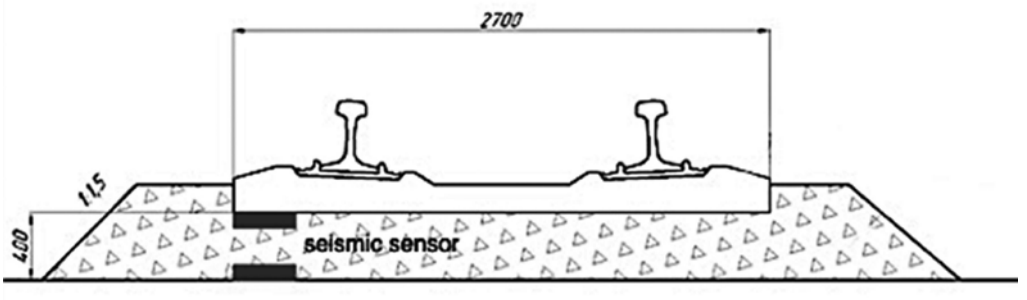

Figure 2. Layout of vibration sensors in the experimental section (cross section).

Passenger trains moved along the experimental section at speeds of 85-95 km/h, high-speed electric trains "Lastochka" (Siemens Desiro RUS) - 170 km/h, high-speed electric train "Sapsan" (Siemens Velaro RUS) - 190 km/h.

The measured parameters are vertical vibration accelerations in the area of the rail joint, in units of *g*.

The measurements were carried out using a set of equipment consisting of a digital seismic signal recorder ZET 048; a laptop computer with licensed software; a signal amplifier; a 220 V power supply, a set of vibration sensors (accelerometers and seismic sensors).

There were 30-40 train passages registered at in the joint area and at a distance of 7 sleepers from the joint for standard sub-rail pads and experimental ones.

The equipment scheme for registering vibration accelerations is shown in Figure 3.

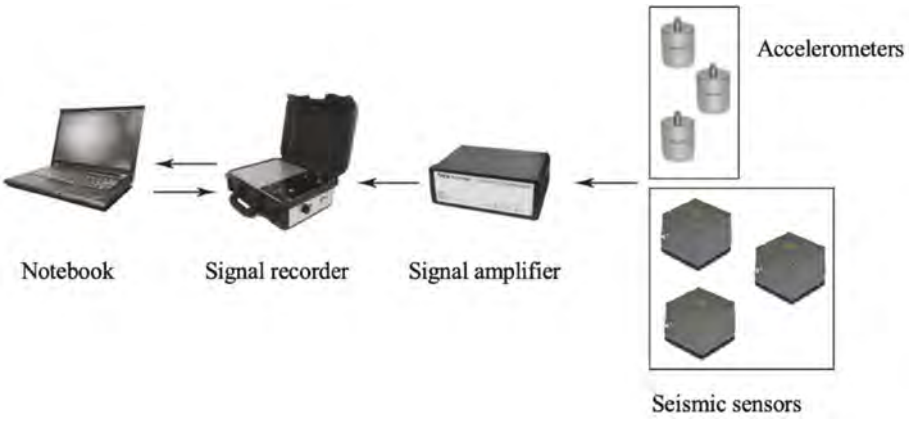

Figure 3. Oscillation amplitudes registration scheme.

The measurement results were statistically processed taking into account the following factors:

1. The statistical series included the measurement results during the movement of various types of rolling stock.
2. From each car, the maximum value of vibration accelerations is included in the statistical series.
3. Statistical processing of measurement results was carried out by methods based on the theory of mathematical statistics. In the course of statistical processing, the average value of vibration accelerations, the standard deviation, the maximum probable value and the coefficient of variation were determined. The probability level was assumed 0.994 due to "The methodology for assessing the impact of rolling stock on the track in terms of ensuring reliability" (order of Russian Railways No. 2706r, December 22, 2017).

3 RESULTS AND ANALYSIS

Comparative diagrams were plotted based on the results of the vibration accelerations measurement which occurs during train passage in the area of the rail junction. The results of the study are presented in Figures 4–6.

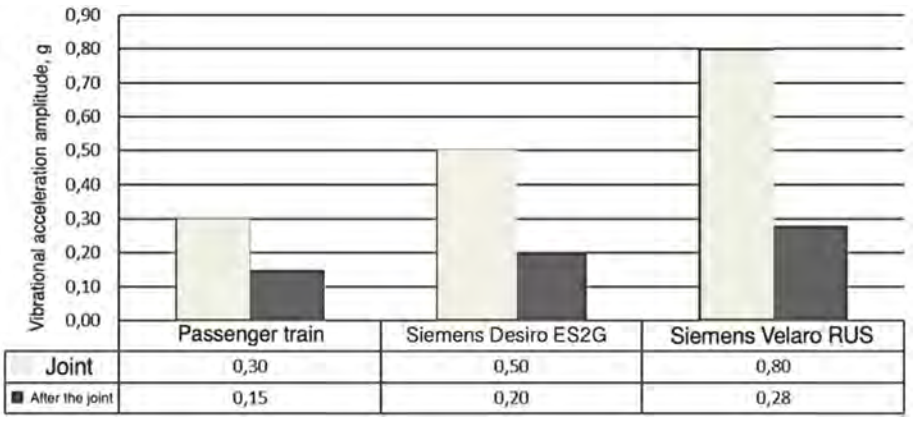

Figure 4. Amplitudes of vertical vibration accelerations on the subgrade top in the joint area and at a distance of 7 sleepers from the joint, with standard pads.

During the investigation, 2-3 times greater amplitudes of vibration accelerations were recorded near joint area compared with the point at the distance of 7 sleepers from the joint for the all types of rolling stock. The results obtained indicate an increased level of vibrodynamic impact on the sub-rail base in the joint zone.

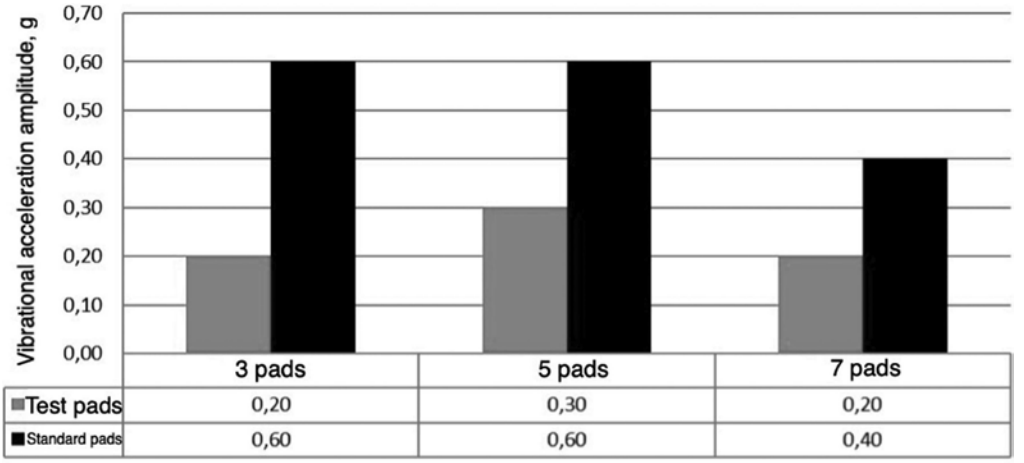

Figure 5. Amplitudes of vertical vibration accelerations on the subgrade top in the joint area and at a distance of 7 sleepers from the joint, with standard pads.

The vibration acceleration study results on the number of elastic pads are shown in Figure 6. A comparison of the amplitudes of vibration accelerations in the area of the rail joint with a different number of pads (both high elasticity and standard) showed that 7 shock absorber pads installed on each side of the rail joint work most effectively.

Analysis of the vibrodynamic impact level on the ballast in the area of the rail junction, showed that the Desiro and Velaro have a greater impact on the track than passenger trains with a speed of 90 km/h and a load of 150-160 kN per axle. At the same time, the level of the Desiro and Velaro impact is approximately the same. It is explained by the fact that despite the higher speed of the Velaro (190 km /h), it has a load of 170-180 kN per axle, and the Desiro, moving slower (170 km /h), has a load of 190-200 kN per axle (Figure 6). The amplitudes of vibration

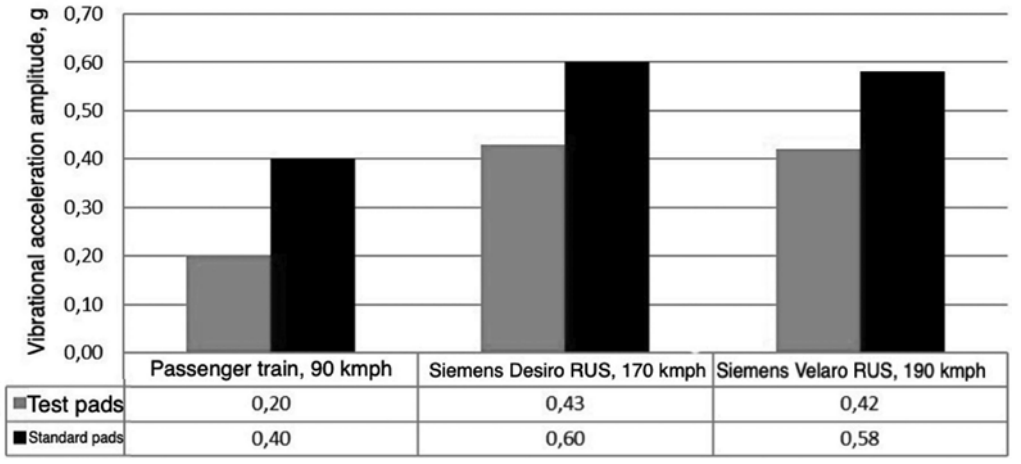

Figure 6. Vertical vibration accelerations amplitudes in the ballast at the sleeper bearing level in the sub-rail section in the area of the rail joint with 7 new standard and experimental sub-rail pads.

accelerations in the ballast layer with 7 increased elasticity pads of Sylodyn NF (experimental) are 1.4-2 times less than with standard CP-204-M-APC (standard).

This is primarily because experimental pads have less stiffness than standard ones and better dampen the vibrodynamic effect transmitted from rails to sleepers and further to the ballast, which inevitably leads to an increase in the track stability (Butorina 2017, Serebryakov 2017, Boronenko 2020, Blazhko 2017, Kolos 2017, Sakharova 2017, Sakharova 2018).

4 CONCLUSIONS

The study of ballast vertical vibration accelerations in the area of the rail joint with a different number of standard pads CP-204-M-APC and Sylodyn NF allow us to draw the following conclusions:

1. For all types of rolling stock studied with standard elastic pads, 2-3 times greater amplitudes of vertical vibration accelerations were recorded in the area of the rail joint than at the distance of 7 sleepers from the joint.
2. Comparison of vibration acceleration amplitudes in the rail joint area with a different number of pads showed that 7 pads installed on each side of the rail joint are the most effective solution.
3. Comparison of vibrodynamic impact level on the ballast in the area of the rail junction, depending on the type of rolling stock having different axle loads and speeds, showed that the Desiro and Velaro have a greater impact on the track than passenger trains with a speed of 90 km/ h and a load of 150-160 kN per axle. At the same time, the impact level of the Desiro and Velaro is approximately the same. This fact is explained by the fact that despite the higher speed of the Velaro (190 km /h), it has a load of 170-180 kN per axle, and the Desiro, moving slower (170 km/h), has a load of 190-200 kN per axle.
4. Vibration accelerations amplitudes in the ballast layer with seven pads of increased elasticity Sylodyn NF (experimental) are 1.4-2 times less than with standard - CP-204-M-APC (standard). This fact is explained primarily by the fact that the experienced elastic pads have less stiffness than the regular ones, and better dampen the vibrodynamic effect transmitted from the rails to the sleepers and further to the ballast.

Many years consolidation of soils under cyclic load at the base of shipping locks

O.P. Minaev
Military Academy of Logistics named Army General A.V. Chrulev, The Russian Federation

ABSTRACT: For the first time ever, the author of the paper considers the effect caused by cyclic navigational load on the long-term settlement of soils at the base of shipping locks during their operation. Ships go through a lock when it is filled with water and the level in the upstream and downstream waterways decreases, which results in cyclic load that has an impact on the foundation soils. Long-term monitoring of the Gorodets and Volga hydroelectric complex gives evidence that the final settlement of some sections of locks under operational load varies from 25 to 65 mm and 10 - 12 cm (plus 14 - 18 cm during the construction period) while the settlement lasted for 52 and 31 years respectively. The value of the residual settlement caused by static and cyclic loading decreases if the initial density of the foundation soil is higher, the same as the number of loading cycles for achieving it at given stresses from the external load. The author suggests effective vibrodynamic methods of compaction that should be applied in order to decrease the values of settlements from static and cyclic loads and reduce the consolidation time of water-saturated sandy soils under cyclic load.

1 INTRODUCTION

Most locks on the waterways of Russia are built on sandy subsoils of considerable thick mass (up to 12 m and over) and solid main bottom (Figure 1); with the sandy layer frequently varying in thickness within the limits of the structure.

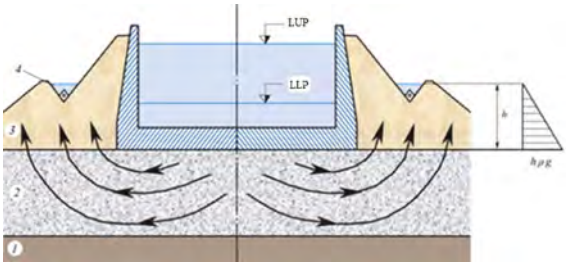

Figure 1. The diagram of the filtration consolidation in the foundation of the lock chamber: 1 – confining layer; 2 – filtration subsoil layer; 3 – chamber backfill; 4 – drainage.

Many years of monitoring the Gorodetz and Volga hydroelectric complex esprovide evidence, that the final settlement of individual lock sections under operational load varies from 25 to 65 mm and 10-12 cm (plus 14-18 cm during construction) while the settlements lasted 52 and 31 years respectively.

Unbalanced settlements and deformations in the design structures cause cracks, obliqueness and other defects, which affect normal operation. The experience in the operation of locks shows that if we analyze the outcomes and causes of the lasting lock deformations without considering the soil consolidation in the foundation area, obtain erroneous results.

DOI: 10.1201/9781003299127-403

When structures are built on sandy subsoils of thick mass (10-20 m), their settlements under static and especially dynamic loads can achieve considerable values amounting to several dozens of centimeters. However, the process of fading these settlements go through is relatively fast due to a higher coefficient of sandy soil filtration, which is several orders of magnitude higher than in the case of clay soils.

Given these conditions, the data below may seem paradoxical even though they are based on many years of monitoring of some locks built on sandy subsoils and operating since the 1950-60s.

Thus, the author of this paper was the first to raise a question about the effect that cyclic navigation load has on lasting settlements of locks during their operation (Figure 2).

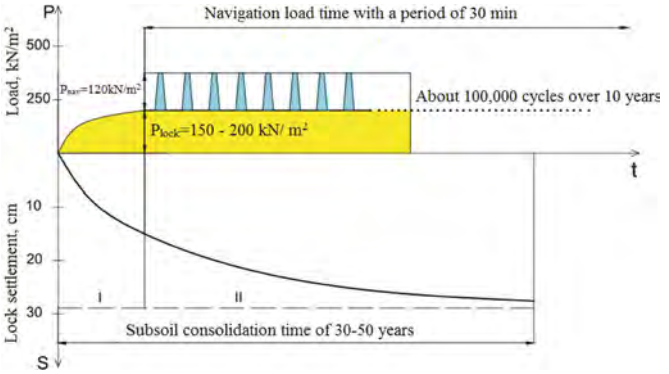

Figure 2. The "load-settlement" graph of the lock under: I –construction load; II –operational load.

Vessels go via a lock after it is filled with water and its level is lowered upstream and downstream the waterway, which results in the impact of cyclic load on the subsoils, according to what the author claims.

The paper provides the results of theoretical studies of sandy soil consolidation and laboratory tests of soil deformations under cyclic load, as well as field observations of the operating locks built on sandy subsoils. Benchmarking proves that in case loose soils are compacted to firm consistence in the foundation area of the lock, the settlements and the soil consolidation time reduce a lot.

2 THEORETICAL DEPENDENCES

The main consolidation equation worked out by V.A. Florin (Florin 1959) can be integrated only in the simplest cases of a one-dimensional problem. In this case, if there is no trapped gas, instantaneous soil load and instantaneous deformation of the soil skeleton, the main consolidation expression takes the following form according to Equation 1:

$$\frac{\partial H}{\partial t} = C_v \frac{\partial^2 H}{\partial z^2}, \tag{1}$$

where $Cv = (1 + e)\ K_f\ /\gamma w \times a$ is the consolidation coefficient, m^2/s; e is the soil porosity coefficient, K_f is the soil filtration coefficient, cm/s; γ_w is the specific gravity of water, kN/m^3; $a = 1 / E$ is the soil compaction coefficient, 1/MPa, E is the subsoil deformation modulus, MPa.

If the soil layer is compacted by evenly distributed load q, instantly applied at the point of time $t = 0$, it can be assumed that q causes the depth stabilized stress $\sigma * z = const$. Then $\sigma * z = q$, while $H = H\ (z,\ t)$.

The solution to Equation 1 will be the expression according to Equation 2:

$$H_{z,t} = \frac{4q}{\pi\gamma_w} \sum_{i=1,3}^{\infty} \frac{1}{i} \left(e^{-\frac{c_v i^2 \pi^2}{h^2} t} \right) \sin \frac{i\pi z}{h}. \tag{2}$$

The expression in Equation 2 can be used for determining the hydraulic pressures $H(z,t)$, obtaining stresses in the soil skeleton for any point of time t and measuring the settlement for the same points of time $S(t)$.

The solution to Equation 1 obtained for determining the settlements has the following form according to Equation 3:

$$S_t = \frac{a}{1+e} q \int_0^h [1 - \frac{4q}{\pi\gamma_w} \sum_{i=1,3}^{\infty} \frac{1}{i} (e^{-\frac{C_v i^2 \pi^2}{h^2} t}) \sin\frac{i\pi z}{h}] dz = \frac{aqh}{1+e} [1 - \frac{8}{\pi^2} \sum_{i=1,3}^{\infty} \frac{1}{i^2} e^{-\frac{C_v i^2 \pi^2}{h^2} t}] \quad (3)$$

$$= S_{consol} \times \mu,$$

where $\cos\frac{i\pi z}{h} \int_0^h dz = \cos i\pi - \cos 0 = -2$, μ is the degree of consolidation.

For the case under consideration we find the solution for the sandy soil layer with thickness h_1, lying on a water impermeable foundation (Figure 3), for the boundary conditions at $z = 0$ $H = 0$, at $z = h$ $\partial H/\partial z = 0$.

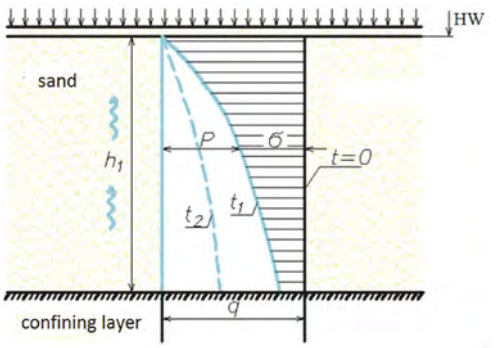

Figure 3. Pressure p in water and stresses in the soil skeleton upon consolidation affected by q of evenly distributed load of the soil layer on water-permeable foundation.

The expression for finding the heads $H(z,t)$ and settlement S_t can be obtained from to Equations 2 and 3 by substituting h for $2h_1$ in them.

Value μ varies from 0 at t = 0 to 1 at $t = \infty$ and is found according to the ratio

$$\mu = S_t / S_{consoll}, \quad (4)$$

The final settlement of the soil layer is found according to the dependence

$$S_{consol} = \frac{aqh}{1+e}. \quad (5)$$

Figure 3 shows the nature of the curves reflecting the excessive pressure in water ($pz = \gamma w \times H$) and stresses in the soil skeleton $\sigma z = q - p$ for various points of time t_1 and t_2 according to Equation 2. At t = 0 along the entire height of the soil layer, the heads $Ho = q/\gamma w = const$ According to Figure 3 the time of consolidation of the water-saturated soil layer $t_o > t_2 > t_1$. You can learn about the solution to this equation in more detail by referring to (Ivanov 1991) or the original source (Florin 1959).

We found the final lock settlements S_{final} and soil consolidation time t using Equation 3 for small and medium-sized sands, which the author obtained in his studies on dynamic soil compaction, as referred to below. For the two extreme cases of loose and dense fine and medium-

sized sands with the skeleton porosity coefficient after backfill e = 0.75 and after dynamic compaction e = 0.61, deformation modulus E of fine and medium-sized sands is taken to be 9 and 40 MPa, respectively.

It is known that the filtration coefficient K_f of fine and medium-sized sands varies from $0.5x10^{-2}$ to $0.5x10^{-3}$.Increases by an order of magnitude along with the growing density. The calculations consider the thickness of the sandy soil layer in the foundation area of the lock h_1 = 12 m and the filtration path length of the forced-out water estimated at a given vessel width b_{vessel} = 30 m.

The resulting calculations for the degree of consolidation $\mu = 0.96$ show that the final settlement of the lock on loose water-saturated sandy soils caused by instantly applied load with intensity of 320 kN/m^2, is 23.4 cm, having reduced to 5.7 cm. In addition, the consolidation time of the fine and medium-sized water-saturated sands in the foundation area of the lock under the instantly applied load does not exceed 6.0 hours.

3 ANALYSIS OF LABORATORY TEST RESULTS

According to Professor P.L. Ivanov (Ivanov 1991), the compression equipment under cyclic load and unload and at the same stresses shows that the accumulated residual deformation sattenuate. Gradually the load and unload curves merge and the soil behaves as an ideal elastic body. In slightly wet soils, load and unload curves sometimes merge after 20. . .30 loading cycles.

We may conclude that the soil porosity coefficient reduces from e_0 to e_1, and then progressively goes down to e_1,e_2... e_n with the increasing load cycles for stresses given. It means that during cyclic load, the residual settlement S_{resid} consists of the final settlement S_{fin} from the applied static load and additional settlement S_{cyclic} under cyclic load. Moreover, in the case of a higher initial density of the soil (e_o>e_1>e_2...e_n), not only does the value of the final settlement S_{fin} from the applied statistic settlement reduce, but so does the additional settlement S_{cyclic} from the cyclic load, the same as the number of load cycles needed for achieving the complete residual settlement S_{res} for the given stresses from external load.

The author obtained similar in the compression tests of slightly wet medium-sized sand for cyclic load in the laboratory of the Department of Ports, Bases and Foundations of the Institute of Water Transport, Admiral Makarov SUMIS.

4 RESULTS OF THE OBSERVED SOIL SETTLEMENTS IN THE FOUNDATION AREA OF THE LOCK

Throughout the operation of the locks, the services of the hydroelectric complexes constantly observe the deformations in the bases of the structures and regularly measure the settlements of the lock chambers. The table below presents the results of the observations.

Table 1. Results of field observations of locks settlement.

Navigable hydroelectric complex	Consolidation period, years	Consolidation term, years
Gorodetz – locks No. 15 – 16	1953 – 2005	52
Volga – locks No. 30 – 31	1962 – 1993	31

As seen from the table, the process of soil consolidation under the bottom of the lock can take several decades. Thus, the soil consolidation in the foundation area of the Gorodetz locks (according to the FBU "Administration of the Volga Basin") lasted about 50 years, while the period of consolidation in the foundation area of the Volga locks (according to the FBU "Volgo-Don") lasted about 30 years.

As an example, Figure 4 shows the settlement graph of the Volga hydroelectric complex.

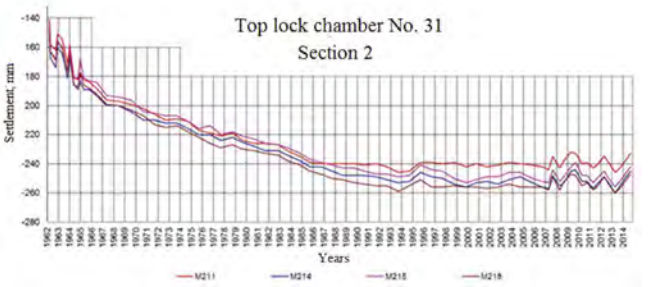

Figure 4. The settlement graph of the Volga lock sections.

From the settlement graph of the Gorodets and Volga hydroelectric complexes it has been found that the rate of the consolidation process curve has a dying form, close to an exponential curve.

For the Gorodets locks, the most intensive stage of filtration consolidation took place in 1953-1958 (5 years), while for the Volga locks it was in 1962-1967 (6 years). In this very period the intensity of settlements was 8 mm a year for the Gorodets locks, and 10 mm a year for the Volga locks. In later years the intensity of settlements reduces by 2-3 times. After fifty (thirty) years' period, the settlements virtually stopped.

5 THE CAUSE OF LONG-LASTING LOCK SETTLEMENTS

On the whole, the deformations of lock structures are caused by the long-lasting consolidation of loose sand subsoils being quite slow due to a navigation cyclic load on subsoils, which was noted for the first time ever by the author of this article. Let us clarify the above-said with the chronometric observations presented on Figure 5. This chronometric graph was drawn up from experience in operation of navigable locks.

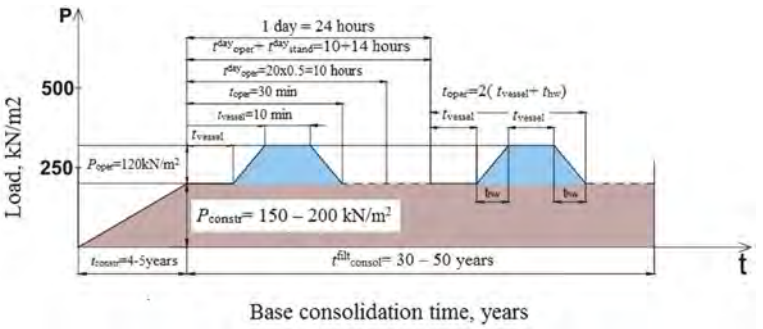

Figure 5. Chronometrical graph of base soil consolidation.

Designations: t_{constr} is the construction period of the lock, years; t^{filt}_{consol} is the term of filtration consolidation, years; t_{oper} is the operation time for the passage of a vessel, min; t_{vessel} is the net time of movement of a vessel in the lock, min; t_{hw} is the time of filling the lock with water or lowering the water level in the lock, min; t^{day}_{oper} is the total operation time of the lock per day, hours; t^{day}_{stand} is the standstill time of the lock per day, hours

We see from the graph on Figure 5 that the process of soil consolidation begins in the period t_{constr} of the lock construction, which lasts at least 4-5 years. According to the author's estimates, the maximum static load P_{constr} from the weight of the structure on the lock subsoils is 150 – 200 kN/m^2.

Under the effect of this load that was growing during the construction, the lock obtained a certain fixed settlement, which, in case of the Volga hydroelectric complex, amounted to 14-18 cm (See Figure 5).

In the operation of the locks, the subsoils are affected by the cyclic load P_{oper} for the time t_{oper} of the lock operating as a vessel passes it. Besides, the maximum intensity of this load, equal to 120 kN/m^2, occurs during the net time t_{vessel} within which the vessel passes upstream. The cyclic load increases for the time t_{hw} within which the water level rises in the lock up to 12 m and goes down to the initial value for the time t_{hw} within which the water level reduces to the upstream and downstream elevations, respectively.

The total time $t^{day}{}_{oper}$ of the impact of the load P_{oper} upon passage of 20 vessels through the lock is 10 hours a day, while the standstill time $t^{day}{}_{stand}$ of the lock is, correspondingly, 14 hours a day; the time of the impact of the maximum load P_{oper} does not exceed 3-4 hours a day.

The temporary cyclic load affects the subsoils many times. According to the estimates, the number of these impacts can vary from several tens of thousands to several hundred thousand times over 10–20 years of operation of the hydroelectric complexes. During the period of complete consolidation of the subsoils, which lasted for 31 years for the Volga hydroelectric complex,, the additional settlement was due to the effect of this cyclic load was 10–12 cm. Thus, the total settlement of the Volga hydroelectric complex achieved the values of 24 to 30 cm throughout the entire period of filtration consolidation of the sandy soils in the foundation area of the lock.

Figure 1 presents the resulting "load-settlement" graph of the lock.

The experience obtained during operation of locks shows that not only does this cyclic load act as a pump can cause long-lasting deformations and settlements, especially in the case of loose sandy subsoils, but it also results in the filtration flow of sandy subsoils throughout the operation of the navigable locks provided that the sealing of the water stop in the bottom of the lock. The latter can lead to dangerous local voids and extensive cavities under the bottom of the lock is damaged or totally destroyed.

In order to compact the subsoils of locks, it is necessary to use effective vibro-dynamic ways for compacting sandy soils that have been developed by the author and become widely used (Minaev 2011, Minaev 2014).

The measurement of the required degree of compaction of sandy soils shows that the compaction of sandy soils makes it possible to considerably decrease the final settlements and reduce the time of soil consolidation in the base of navigable river locks resulting from navigable cyclic load.

6 CONCLUSION

1. The author of this paper was the first to raise the question about the effect of the cyclic navigation load on the long-lasting settlements observed during operation of navigable locks built on sandy water-saturated subsoils.
2. In order to increase the resistance of the sandy soil structure to the process of liquefaction (Ishihara 1996, Idriss and Boulanger 2008, Kolosov and Morgunov 2021) under dynamic (seismic) load, reduce the values of settlements from static and cyclic loads and reduce the consolidation time of water-saturated sandy soils under cyclic load, we recommend that effective vibro-dynamic methods of soil compaction should be used.

ABSTRACT: It is a general practice to recommend high-permeable granular subbase layers in pavements to avoid moisture infiltration into subgrade. In this study, a three-layered pavement was prepared in a large-scale permeameter to estimate the drainage capacity of controlled and geocomposite-embedded subbase layers under realistic traffic loading. Preliminary studies indicate that the measured permeability of subbase layer was 4 m/day, which do not meet the design criteria of 300 m/day. Two types of geocomposites (GCs) viz., bi-planar (2D-GC) and tri-planar (3D-GC) were used to enhance the drainage capabilities. Results indicated that the improved permeability of the subbase was 410 and 725 m/day, respectively, for bi- and tri-planar GCs. The compression of GCs in the subbase layer decreased the permeability up to 40% for 2D-GC and 20% for 3D-GCs for a given load equivalency factors of 0.63 to 2.54. In addition, PLAXIS-2D analysis was performed to confirm the reinforcement function of GCs.

Keywords: Geocomposite, Permeability, subbase layer, Compressibility, PLAXIS 2D

1 INTRODUCTION

A typical flexible pavement includes the surface course/bituminous layers, base, and subbase courses. The bituminous layers improve the ride quality and enhance the stability of the pavement system. While the base and subbase courses provide structural support to the asphalt layers, and especially subbase layer enhances the drainage properties. However, the availability of good quality aggregates meeting the gradation requirements of granular subbase (GSB) material is becoming scarce. Hence, at times inferior-grade subbase materials are used in the pavement considering the cost-effectiveness and proximity of the materials (Saltan and Findik, 2008). It is essential to design the subbase in such a way that it drains off the infiltrated rainwater quickly to protect the subgrade. Besides, good drainage materials can improve the load-carrying capacity by reducing the pore pressure in the base and subbase layers (Kumar et al., 2006). When replacing poor-quality drainage materials, it is necessary to check the materials' drainage and structural capacity. Notable studies reported lower permeability of the pavement materials, less than the required for two lanes pavement (300 m/day) (Jones and Jones, 1989; Grover and Veeraragavan, 2010; Singh et al., 2020; Koohmishi and Azarhoosh, 2021).

Recently, practitioners are extensively using geosynthetic materials in the pavement to improve the structural stability. The geogrids are majorly used in the base and subbase layers to improve the structural capacity of the layers (Baadiga et al., 2021(a); Saride et al., 2022a). Few studies reported that the geocomposite (GCs) made of geonet and geotextile

*Corresponding author: sireesh@ce.iith.ac.in

DOI: 10.1201/9781003299127-404

combination could enhance the drainage and structural capacity of the pavement (Bilodeau et al., 2015; Zornberg et al., 2017; Li et al., 2017). However, the compressible nature of GCs can influence the drainage capability of the pavement system. Hence, it is also important to understand the effect of wheel load on the drainage characteristics of the GSB layer when GC's are considered. In the design, an equvalent single axle wheel load of 560 kPa pressure is considerd. A load equivalency factor (LEFs) is generally considerd to represent the mixed-axle loads in terms of a single-axle load. LEF multiplied by the number of axle loads within a given weight category and axle configuration gives the number of single-axle load applications that will have an equivalent effect on the performance of the pavement structures.

Pavement performance is also influenced by mechanical properties such as the thickness of each layer, properties of geosynthetics, load characteristics, and the interaction between geosynthetic and granular layers (Taherkhani and Jalali., 2017). The performance evaluation through large-scale experiments gives enough evidence of particular behavior of a limited combination of many parameters. Thus, examining the boundary conditions, geometric parameters on the behavior of geocomposites in pavements is possible through numerical analysis. Several studies tried to understand the reinforcement mechanism, influence of boundary, and geometrical parameters for different problems in pavements (Ling and Liu, 2003; Correia et al., 2018). Therefore, in this study, a series of large-scale permeability tests were carried out for GC-reinforced granular layers to improve the permeability through bi-planar (2D) and triplanar (3D) geocomposites. Further permeability corresponding to the traffic load on the pavement in terms of load equivalency factors (LEF) was studied. Finally, numerical analyses were conducted to understand the reinforcement effect of GC-embedded in the subbase layer.

2 MATERIALS

In this study, a granular material was used to simulate the subbase (GSB) layer between the subgrade and the wet mix macadam (WMM) (base) layer. The GSB and WMM materials were sourced from a near byquarry. The locally available red soil was used for subgrade preparation. Figure 1(a) shows the grain size distribution of all the pavement materials used in the study. The basic material properties were determined per the American Society for Testing Materials (ASTM), as seen in Table 1. The liquid and plastic limits of the soil were 50 % and 24 %, respectively, and the soil was classified as clayey sand (SC). The standard proctor compaction test resulted in the maximum dry unit weight (MDU) of 18.95 kN/m^3 and the optimum moisture content (OMC) of 14.2 %. The corresponding California bearing ratio (CBR) value was observed as 7 %.

The two different GCs were used in this study are 2D-GC and 3D-GC, as shown in Figures 1(b) and 1(c). The GC comprises a medium-weight non-woven, needle-punched,

polypropylene geotextile filter on both sides of a polyethylene drainage core. The GC ultimate tensile strength in machine direction is 21 kN/m and 20 kN/m for 2D and 3D-GC, respectively.

3 TEST METHODOLOGY

The permeability of pavement materials was determined using a large-scale permeameter of 600 x 300 x 450 mm in size. The loading arrangement was made on the permeameter to find pavement permeability for various LEFs. The permeability tests were carried out for subbase material sandwiched between the subgrade and WMM layers. The subbase layer is 200 mm thick, and the GC is located 50 mm below from the bottom of base layer. The detailed test bed preparation and aggregate layer construction are reported in Saride et al. (2022b). The schematic of the large-scale permeameter is shown in Figure 2. The following section details the results obtained based on the large-scale testing and numerical analysis performed through PLAXIS 2D finite element method.

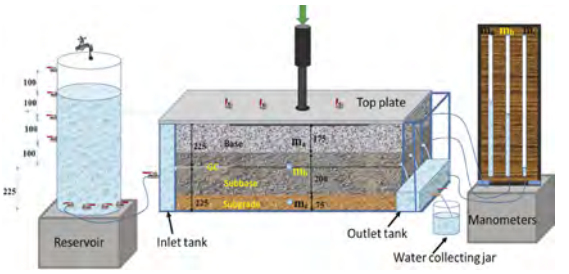

Figure 2. Schematic of the permeability test setup.

4 RESULTS AND DISCUSSION

Pavement performance highly depends on the thickness of layers, material properties, and drainage quality. In this study, a well graded subbase material was used to maintain the structural strength of the pavement, which means that the drainage characteristics of the layer are low. Hence, two different GCs were used to improve the drainage quality of the GSB layer. The single axle load with a dual wheel carrying an 80 kN load is considered as the equivalent single axle load in the design of pavement. However, in practice, the pavement layers experience much different stress conditions due to different class of vehicles. In this study, a single axle type H-10 (LEF = 0.63), type 3 heavy tandem axle (LEF = 1.9), and school bus (LEF = 2.54) were considered, and corresponding stresses were replicated on the pavement surface.

The permeability of the subbase without GC is measured to be less than 4 m/day, indicating a poor drainage quality. The same section, reinforced with the 2D-GC, the permeability is

improved to 410 m/day. At the same time, the permeability was reduced by 7 %, 15 %, 30 %, and 40 %, corresponding to the LEF of 0.63, 1.0, 1.9, and 2.54, respectively (Figure 3a). This observation suggested that under the typical wheel load conditions, GC undergoes compression resulting in lower permeability. Further, the permeability was reduced to 50 % by increasing the hydraulic gradient from 0.16 to 1.0. This permeability reduction corresponds to turbulent flow in the pavement layer (Bourgès-Gastaud et al., 2013). For the subbase layer with 3D-GC, the permeability was 725 m/day without traffic load. With increasing the wheel load on the pavement, the permeability was reduced by 6 %, 10 %, 18 %, and 22 %, corresponding to LEF of 0.63, 1.0, 1.9, and 2.54, respectively (Figure 3b). The permeability corresponding to equivalent single axle load for 2D and 3D-GC is 350 m/day and 651 m/day, respectively. The minimum permeability required for a two-lane pavement is 300 m/day (IRC:37, 2018), hence, the GC-embedded GSB layer under equivalent single axle wheel load satisfied this requirement. Besides, the permeability considering the LEF of 2.54 was, respectively, 245 m/day and 560 m/day for 2D and 3D GCs. The 2D-GC permeability is slightly lower than the permissible value, besides, 3D-GC meets the drainage criteria even with LEF = 2.54. Compared to equivalent single axle wheel load (LEF = 1) to LEF = 2.54, the permeability reduction is 29 % and 14 % for 2D and 3D-GC, respectively.

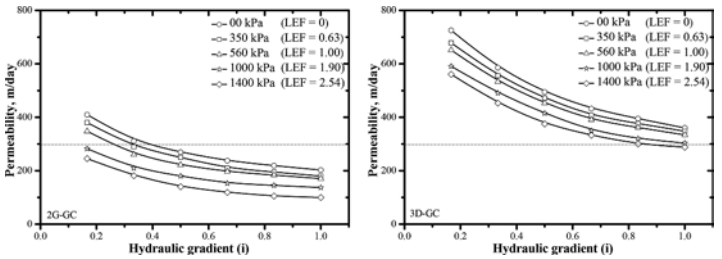

Figure 3. Permeability corresponding to hydraulic gradient for various LEF for (a) 2D- and (b) 3D-GC.

5 NUMERICAL MODELING

A numerical model was developed using PLAXIS 2D finite element software to analyze the reinforcement function of the geocomposite-embedded pavements. The model size was chosen to avoid interfering with the pavement boundary, which should be at least 15 times the size of the loading area. An axisymmetric model with 15-noded structural solid elements was chosen for the analysis. The subgrade thickness of 500 mm was maintained in all models, and the reinforcement was located 50 mm below from the bottom of base layer. Two different subgrade CBRs, equal to 4 % and 7 %, were considered to understand the effect of reinforcement on the weak subgrade corresponding to their calibrated density and moisture contents. The bulk unit weight for CBR 4 % and 7 % are 16.18 and 16.57 kN/m^3, respectively. The granular material properties from the present study, as reported in Table 1 were used. Unconfined compression tests for subgrade materials and large-scale direct shear tests were conducted for aggregate layers to get the shear strength parameters. The reinforcement was modeled using a linear elastic model with a stiffness of 500 kN/m.

A two-layered pavement with a 200 mm thick GSB layer over a 500 mm thick subgrade was modeled. Figure 4 depicts a deformed contour after applying 560 kPa contact pressure on a 150 mm radius plate for a subgrade CBR of 4 %. The vertical deformation corresponding to 560 kPa for 200 mm GSB is 14 mm for subgrade CBR of 4 %. When the subgrade CBR was increased to 7 %, the vertical deformation was reduced to 11.5 mm. With the inclusion of the GC layer, the surface deformation redused to 8.8 mm and 7.0 mm for CBR 4 % and 7 %, respectively. The stress distribution on the subgrade below the loading area for the 200 mm thick subbase layer was 125 kPa and 148 kPa for CBR 4 % and 7 %, respectively.

Further, it was reduced to 85 kPa and 104 kPa for GC embedded in the GSB layer. The contact pressure beneath the loading area will be more for stiffer subgrades. Baadiga et al.

(2021b) have observed similar results. The reinforcement can reduce the stresses on the subgrade by increasing the stress distribution area. It is observed that the reinforcement is more effective in weak subgrade layers. This is because the tensile strength of GC will render excellent support as deformation increases.

According to Ueshita and Meyerhof (1967), the elastic modulus was calculated corresponding to the pressure at 1.25 mm deformation. A modulus improvement factor (MIF) was defined as a ratio of an elastic modulus of the pavement with geocomposite to the elastic modulus of pavement without reinforcement at an elastic deformation of 1.25 mm. When comparing the CBR of 4% and 7% pavement sections, it is observed that in the reinforced sections, the MIF is higher when a weaker subgrade is considered due to more effectiveness of the GC. The MIF is observed to be 1.70 and 1.60 for 200 mm thick subbase overlying CBR 4 % and 7 %, respectively.

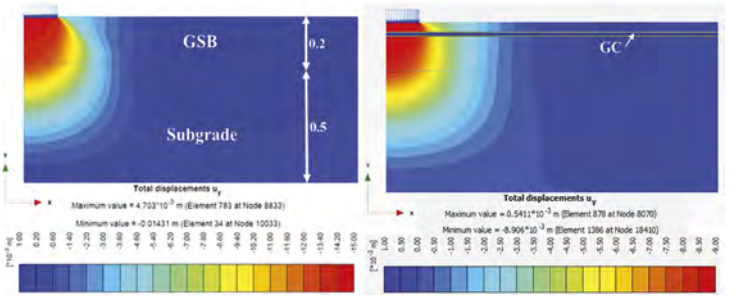

Figure 4. Displacement contour for unreinforced and reinforced modeled section using PLAXIS 2D.

6 CONCLUSIONS

To understand the drainage capabilities and effect of the load equivalency factor on the permeability of GC embedded pavement layers, large-scale permeameter tests were conducted by varying the wheel load on the pavement. Further, numerical analysis was conducted to understand the improvement of the pavement layers' structural capacity due to the GC's reinforcement effect. The study's findings lead to the following conclusions.

1. The permeability of the subbase materials without reinforcement was observed to be 4 m/day which does not meet the design criteria of 300 m/day.
2. Including 2D- and 3D-GC in the granular subbase layer the permeability improved to 410 m/day and 725 m/day, respectively, indicating excellent drainage capability of the geocomposites.
3. With the application of wheel contact pressure on the pavement, the permeability is reduced by 15 % and 10 % for 2D and 3D-GC, respectively.
4. Effects of various LEF on the permeability of GC-embedded pavement were conducted. An increase in the LEF from 1 to 2.54 reduces the permeability by 29 % and 14 % in 2D- and 3D-GC, respectively.
5. Numerical analyses showed that the reinforcement function is highly effective in weak subgrade conditions.
6. With the inclusion of reinforcement, the MIF increased to 1.70 and 1.60 for CBR 4% and 7% subgrade conditions.

ABSTRACT: The article deals with a calculation method and examples of application of a rapidly erected retaining wall design. The retaining wall has an increased resistance to dynamic loads, aesthetic appeal, and relatively low cost. The retaining structure is a stepped semi-gravitational structure made of blocks filled with soil. The joint work of the blocks is ensured by the forces of dry friction due to the dense placement of the filler soil inside each block, as well as due to the formation of a compacted wall base on the slope being strengthened. The task of constructing a simulation method of retaining structures consisting of blocks having no rigid structural connection and filled with a granular body is set. The given technique can be applied to any retaining walls of a similar design solution. Examples of constructing such walls in the climatic conditions of the Russian Far East are given.

1 INTRODUCTION

The specificities of solving the problem of protecting a soil massive from collapse (the main functional purpose of retaining structures) determine the range of application for a particular constructive solution. At present there exists a wide array of constructive solutions for retaining structures, such as solid (gravity), semi-solid (semi-gravity), piling, and reinforced soil structures (Anderson, 2012, Tsimbelman, 2009), among which are beneficially standing out retaining walls comprised of separate blocks with granular infill which can be classified as semi-gravity retaining walls. The walls of this type have received rather widespread use in regions with increased seismic activity, including Japan (Civil Engineering Research Centre, Japan, 2016).

The known positive aspects of prefabricated structure technology compared to monolithic structures, such as rapid installation and dismantlement, the lack of «wet» processes during construction, superior aesthetics, structural flexibility and comparatively high dynamic load resistance, can be attributed to advantages of such structures. The use of rubble (or other drainage material) as infill allows, in the majority of cases, to omit the installation of wall-adjacent drainage. The described conceptual constructive solution of retaining walls comprised of separate blocks with soil infill can be used in industrial, civil and road construction practices (Figure 1a).

Despite the mentioned advantages, the use of retaining structures of such constructive solution in Russian construction practice (Tsimbelman, Estrin, 2009) has yet to become widespread due to historically established dominance of traditional constructive solutions as well as certain issues of theoretical nature, which the work examined in this article aims to solve.

The primary goal of this work lies in identifying the constructive specificities inherent to retaining structures of the described type which significantly affect their calculation method, suggesting a formula for determining active ground pressure on the pressure face of the

DOI: 10.1201/9781003299127-405

retaining structure, as well as denoting tasks for future research of retaining walls comprised of soil-infilled blocks.

2 CALCULATION METHOD AND SPECIFICITIES

In essence, the calculation method for retaining walls comprised of separate soil-infilled blocks corresponds to the general calculation algorithm for similar structures regimented by existing Russian norms. The principal constructive specificity of the described structure lies in the fact that the levels of blocks making up the wall are not structurally tied to one another: soil-infilled blocks are held in the designated position due to the friction forces formed by the weight of the structure itself (Figure 1a).

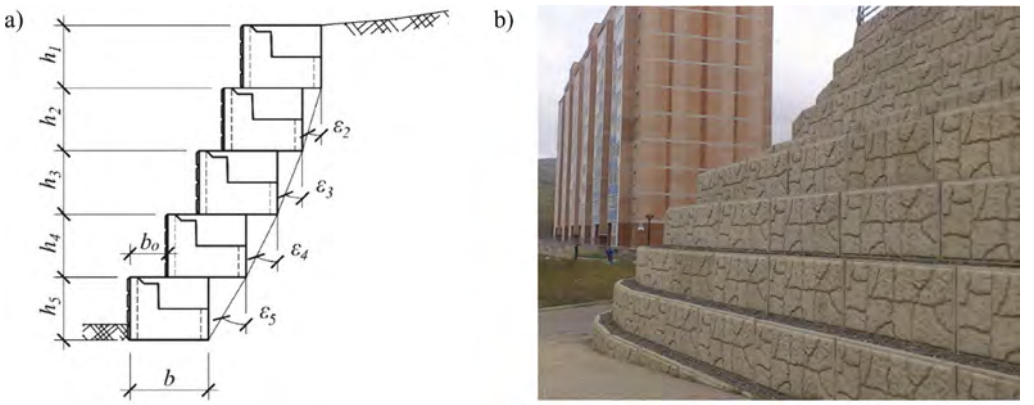

Figure 1. Retaining wall: a – infilled block layout scheme; b – retaining wall comprised of infilled blocks with height of up to 9 m (Vladivostok, Russia).

As a result, the first and foremost specificity of the calculation procedure consists of sequential (from top to bottom) determination of lateral earth pressure with simultaneous monitoring of the possibility of block-on-block displacement. During this process, the pressure face inclination angle will be changing from level to level, and the force of the overlaying block level and the earth load it receives will be transferred to the underlaying level with a cumulative total.

When determining active earth pressure on retaining walls with complex shape pressure face, generally employed methods are either approximate methods which do not consider the pressure face change with the height of the structure (Klein, 1964, Snitko, 1963) or the method of enumerating possible slide angles of the soil collapse prism (Civil Engineering Research Centre, Japan, 2016). Employing methods based on considerable tolerances does not consistently provide results with the required level of accuracy while the consequent enumeration method is exceedingly difficult to implement without the use of specialized computer software due to the bulkiness of the method.

The prerequisites to the method of determining earth pressure on retaining walls of the described design generally match classic solutions for which the balance of forces applied to the prism of soil collapse arising behind the pressure face of the wall is considered. The sliding prism is at an equilibrium by the forces of its own weight, the reaction of the retaining wall and the reaction of the rest of the granular body (Klein, 1964, Snitko, 1963, Brooks, 2018, Braja M. Das, 2007). Next, by expressing the reaction of the retaining wall from the equation and differentiating this expression by the soil collapse angle, a condition is found where earth pressure takes the maximum value. At the same time, determination of active earth pressure on each level of the wall must include taking into account the shape of the pressure face of the overlaying wall level, since ignoring this parameter can lead to significant discrepancies in calculations.

In the case of flat backfill surface under evenly distributed load and «polygonal» surface of the pressure face of the retaining wall, the value of active earth pressure E_a (kN/m) should be calculated using the formula proposed by the author (1).

$$Ea_i=\frac{\gamma}{2}\left(\sum_{j=1}^{i-1}\frac{h_j}{\cos(\varepsilon_j)}\frac{\cos(\varepsilon_j+\rho)}{\cos(\varepsilon_i+\rho)}+\frac{h_i}{\cos(\varepsilon_i)}\right)^2\frac{1}{\cos(\varepsilon_i-\varphi_s)}\lambda_i^2\left(1+\frac{2p\cos\rho}{\gamma\left(\sum_{j=1}^{i}\frac{h_j}{\cos(\varepsilon_j)}\cos(\varepsilon_j+\rho)\right)}\right)-\sum_{j=1}^{i-1}\frac{Ea_j\cos(\varepsilon_j-\varphi_s)}{\cos(\varepsilon_i-\varphi_s)} \quad (1)$$

where γ = specific gravity of soil (kN/m^3); ε = pressure face inclination angle (°); ρ = backfill surface inclination angle (°); φ_s = angle of internal soil friction on pressure face (°); h = retaining block height (m); λ_i = lateral earth pressure coefficient; p = load on original ground surface (kN/m^2); φ = internal soil friction angle (°); E_a = active earth pressure value (kN/m); i = number of the block for which active pressure is being calculated; j = sequence number of the block.

The lateral earth pressure coefficient in this case is calculated using the formula (2).

$$\lambda_i=\frac{\cos(\varepsilon_i+\rho)\cos(\varepsilon_i+\varphi-\alpha_i)}{\cos(\varepsilon_i+\rho-\alpha_i)\left(1+\sqrt{\frac{\sin(\varphi+\varphi_s-\alpha_i)\sin(\varphi-\rho)}{\cos(\varepsilon_i-\varphi_s)\cos(\varepsilon_i+\rho-\alpha_i)}}\right)} \quad (2)$$

where α_i = angle providing the transition from factual prism of collapse (with polygonal base) to arbitrary (with triangular base) (°).

This problem is directly connected to the question of determining the self-weight of the wall, since the volume of soil involved in the work of the wall (block infill and wall-adjacent prisms – Figure 1a) is separated from external surrounding soil by an arbitrary pressure face, for which active earth pressure is calculated and which is polygonal since for each row of blocks it has its own angle of deviation.

As an example, a retaining structure simple in configuration and small in height will be considered with height h = 3 m and flat horizontal infill surface (ρ = 0) upon which a load with an intensity of p = 10 kN/m^2 is evenly distributed. Specific gravity of soil γ = 19 kN/m^3, internal soil friction angle φ = 30°, angle of internal soil friction on pressure face φ_s = 20°, pressure face inclination angle of the first two blocks $\varepsilon_{1,2}$ = 11.31°, pressure face inclination angle of the third block ε_3 = 21.8° (Figure 2).

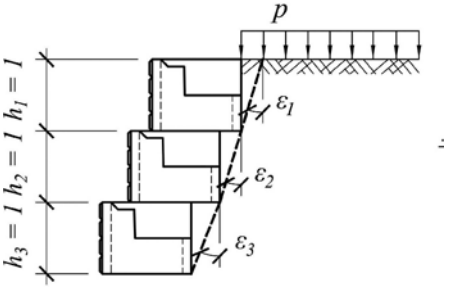

Figure 2. Retaining wall calculation scheme.

The calculation results using the formulae (1) and (2) are as follows: value of active earth pressure on the first block of the retaining structure E_{a1} = 4.36 kN/m; value of active earth pressure on the second block of the retaining structure E_{a2} = 8.62 kN/m; value of active earth pressure on the third block of the retaining structure E_{a3} = 9.32 kN/m.

A comparison of the received results and the solution obtained via the in-progress enumeration method (Civil Engineering Research Centre, Japan, 2016) proves the validity of the derived analytical expression for calculating active earth pressure value on each of the blocks of the retaining structure. The discrepancy between the received results and the results described in (Civil Engineering Research Centre, Japan, 2016) amounts to less than 1%, which

allows the use of the proposed formulae in calculating tall retaining structures of more complex configuration when the enumeration method calculation becomes irrational.

Due to the cyclicity of the procedure of determining earth pressure on the wall and the accompanying calculations it would be reasonable to form a software package allowing to automate the procedure of by-level load gathering and sequential calculations via a certain algorithm. The software must offer the selection of optimal form of the cross section of the retaining wall (number of rows, wall inclination, the presence and magnitude of recesses from row to row) depending on calculation conditions. The calculation procedure is implemented for a limited set of initial conditions in a pilot computer program (Kotik et al., 2019) for which interfacing modules are currently being developed.

3 APPLICATION PRACTICE

During the 2010-2022 period twenty-five retaining facilities implementing the described structure have been erected in the Russian Far East with the total area of 40 000 m^2 in six cities of federal and district significance, as well as a range of minor structures in the landscaping sector. The largest retaining structure built to date in Russia within city limits and comprised of infilled blocks using the proposed technology is situated in Vladivostok (Figure 1b).

The retaining wall was erected in December of the year 2010 with a maximum height of 9 m and a total area of 7668 m^2. During the more than nine-year lifetime the structure has not generated any criticism from maintenance services and supervising entities, no maintenance work on the structure is required. High operational reliability and aesthetic appeal of the structure, including greening potential and great integration into the surrounding landscape, allow the facilities of described structure to be used in low-rise and private real estate areas (Figures 3).

4 RESEARCH OBJECTIVES

Numerical modeling of retaining walls of similar constructive solutions was previously done predominantly in the plane formulation (Civil Engineering Research Centre, Japan, 2014). Taking into consideration the contemporary recommendations to calculation modeling of structures (cl. 6.1.9 SP 381.1325800.2018, cl. 5.1.10 SP 22.13330.2016, cl. 8.1.7 SP 248.1325800.2016), the task of creating a method of numerical modeling of retaining walls comprised of soil-infilled blocks in the spatial formulation with experimental verification according to the results of natural and semi-natural testing, or small-scale model testing in a laboratory environment on condition of following the provisions of similarity theory, is established. At the same time, special attention must be paid to the relevant question of delineating the conditions of medium interaction on the contact surface between the infill (representing a fundamental constructive material of the structure) and the block walls. This problem can be solved following the example of thin-walled soil-

Figure 3. Retaining structures comprised of infilled blocks with greening (Vladivostok, Russia).

infilled shell research (Bekker et al., 2015) since the hollow box represents a shell holding the infill (compacted rubble) in its designated position.

A justified numerical model will allow, first of all, to solve the problem of assessing the stress-strain state of the components of a retaining structure comprised of blocks with granular infill, and second, to create the algorithm of selecting the optimal form of the diameter (and form a set of standard solutions) depending on the purpose of the structure (technological and other loads) as well as the properties of infill, backfill and foundation soils.

5 CONCLUSIONS

The retaining structure comprised of separate thin-walled blocks with soil infill represents a promising constructive solution for civil, industrial and road construction purposes. The structure possesses an array of significant advantages which allow to shorten the construction period, avoid labor-intensive technological operations during installation, and, as a result, provide economic efficiency of the structure. It should be individually noted that the structure is well predisposed to withstanding dynamic loads (transportation vibration, impacts, seismic influences).

Despite the affirmative usage experience of erected retaining structures comprised of soil-infilled blocks (during the period from the year 2000 and onwards approximately 10 000 meters of retaining structures of this type have been erected in the Russian Far East), the scope of application is restricted by the difficulties of calculational and theoretical justification.

This article proposes a calculation formula for determining the value of active earth pressure on a retaining structure possessing a complex pressure face shape in the form of a polyline. Preliminary results of calculating active earth pressure on each of the blocks of the retaining structure have shown high convergence with results received via the enumeration method (the discrepancy value amounts to approximately 1%). Thus, the formulae suggested in this work can be used in determining active pressure on comparatively tall retaining walls with complex outline of the pressure face when employing approximate methods and methods based on value enumeration proves irrational due to their increased laboriousness.

Among the primary questions the need for forming an algorithm and an adaptation of the calculation method for Russian criteria is denoted. The research task of creating a method of numerical modeling of structures comprised of soil-infilled blocks in the spatial formulation is also established. Research must include calibration and verification of numerical models based on experimental data. The task of developing automatization means for the cyclical calculation procedure typical for this type of structure, as well as the task of forming an algorithm of selecting the optimal form of the cross section of the structure, are also established.

Compaction characteristics of coarse post-glacial soil improved by fiber-reinforcement and cement addition

K. Zabielska-Adamska, P. Dobrzycki & M. Wasil
Bialystok University of Technology, Bialystok, Poland

ABSTRACT: Stabilization with cement is an effective way to increase the stiffness of base and subbase layers and to improve the rutting of subgrade. Another way to improve the soil properties is to use fiber-reinforcement. The aim of the study is to investigate the effect of various percentages of cement additives: 1.5 and 3.0% and polypropylene fibers of various percentages: 0-0.3% on the compaction of post-glacial non-cohesive soil. The influence of the compaction method, the standard Proctor and the modified, was also analyzed. Problems with sample preparation were described too. The increase in the fiber and cement content resulted in an increase in the maximum dry density and a reduction in the optimum water content. The method of mixing the samples with fibers can have a significant effect on compaction parameters causing the maximum value of dry density to be underestimated.

1 INTRODUCTION

Soil compaction is characterized as the ability to achieve the maximum possible dry density, $\rho_{d\ max}$. The compaction depends on the compaction effort, the way it is used, and the type of soil and its water content. The laboratory test of soil compaction consists in its compaction in a standardized manner at different water contents and plotting the obtained results on a graph of the dependence of the soil dry density on the water content $\rho_d = f(w)$. The moisture at which compacted soil reaches its maximum dry density is called optimum water content, w_{opt}. The curves $\rho_d = f(w)$ of well-grained non-cohesive soils as well as sandy clays and clayey sands always have a well-defined peak value. The uniform sands and clays are characterized by gently sloping arches. The generally flat compaction curve applies to uniform soils, while the well-grained soil curve shows a clear maximum value.

The impact methods are the most common methods used for fine-grained soils: the standard Proctor test and the modified Proctor test, with energies corresponding to field compaction by lightweight soil compactors or heavy compactors, respectively. In the case of coarse-grained soils, the grains can be displaced instead of compacting, so according to the United States Bureau of Reclamation (USBR 5500-89), impact compaction can only take place on soils containing more than 15% of fine particles.

Cement addition influences non-cohesive soil compaction. With increasing cement percentage in the soil and cement mix, the maximum dry density increases and optimum water content decreases (Zabielska-Adamska 2008, Shooshpasha & Shirvani 2014, Choobbasti et al. 2015). Changes in compaction parameters, $\rho_{d\ max}$ and w_{opt}, after cement addition, are caused by an increase in solid particle density, a moisture content decrease, and a change in the grain-size distribution of the mix. The compaction characteristics of fiber reinforced non-cohesive soils are rather poorly presented in the literature. Silveira et al. (2021) tested the compaction of lateritic clayey sand with 0.1% and 0.25% fiber content, compared to the natural soil. The behavior of the maximum dry unit weight did slightly reduce with the fiber addition into the sandy soil, while the optimum water content did not change. The addition of 0.5% by weight of

DOI: 10.1201/9781003299127-406

fibers to fly ash resulted in decrease in maximum dry density and optimum water content (Kumar & Singh 2008). For comparison, after huge − 1-5% addition of fibers to clay a continuous reduction in the maximum dry unit weight along with an increase in the optimum moisture content was observed. This was explained by replacement of soil grains with fibers, which have less specific gravity compared with that of soil grains and the lubricating effect of absorbed water by fibers, which reduces the compaction impact (Mirzababaei et al. 2013).

Many references consider the effect of the addition of fibers or fibers and cement on the shear or tensile strength of the compacted mixture but take no notice of their impact on the compactibility, often referring only to the compaction curves of natural soils, for example (Consoli et al. 1998) or (Tang et al. 2016). The aim of the study was to explore the effect of various percentage cement additives: 1.5 and 3.0% and polypropylene fibers of 12 mm length and percentages: 0-0.3% on the compaction of post-glacial gravelly sand and show that addition strongly influenced the compaction parameters. The previous research of the authors (Zabielska-Adamska et al. 2021, 2023) has revealed the necessity of soil improvement in the case of cyclic tests. Consequently, the studies were conducted on two research samples of non-cohesive soil, cement-stabilized soils, and their mixes with different quantities of polypropylene fibers. The influence of the compaction Proctor method, the standard and modified, were also shown.

2 MATERIALS AND METHODS

The tested soil is a Pleistocene glaciofluvial soil consisting of well-rounded quartz crumbles, as well as angular grains, with a considerable addition of lytic particles and feldspars (Zabielska-Adamska et al. 2021). According to EN ISO 14688-1 standard the tested soil is gravelly sand (grSa) with the primary fraction as sand, and the secondary as gravel. Figure 1 shows the grain size distribution curve of tested soil based on the sieve analysis. The tested soil based on uniformity and curvature coefficients (Table 1) can be assessed as a material responding poorly to compaction.

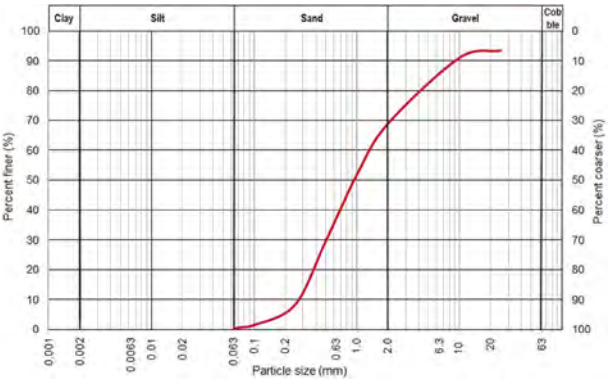

Figure 1. The gravelly sand grain-size distribution.

Table 1. Graining parameters of tested soil.

	Grain diameters (mm)			Coefficient of uniformity (−)	Coefficient of curvature (−)
Material	D_{10}	D_{30}	D_{60}	C_U	C_C
grSa	0.28	0.51	1.41	5.04	0.66

Compaction parameters, maximum dry density, $\rho_{d\ max}$, and optimum water content, w_{opt}, were founded according to the standard Proctor (SP) and modified Proctor (MP) tests, following EN

13286-2 standard. The compaction curves of gravelly sand with saturation lines are presented in Figure 2. The samples were compacted by the impact methods despite the absence of fines.

The soil and cement mix was produced with the addition of 42.5R Portland cement in the quantity of 1.5% and 3.0% of the dry mass of cement to the dry mass of soil in a tested sample. The soil and soil-cement mix with polypropylene fibers of 12 mm longest were also used. The fibers were added in amounts of 0.1%, 0.2% and 0.3% in relation to the dry mass of compacted soil. The soil or soil and cement were mixed with polypropylene fibers using a laboratory mechanical stirrer, which is of great importance for the homogeneity of the tested samples. The change in the mixing method of the samples from manual to mechanical mixing resulted in approx. 6% difference in the maximum dry density value for both compaction methods, reducing this value in the case of manual mixing (Figure 3), which is especially important for future conclusions. The polypropylene fibers are shown in Figure 4.

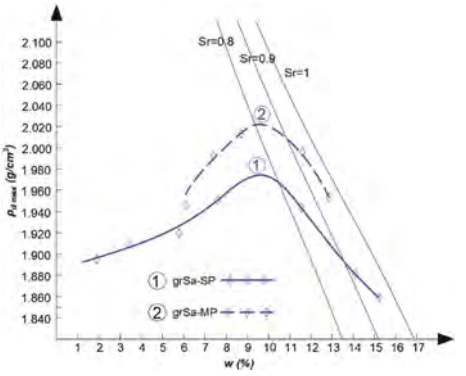

Figure 2. Compaction curves of gravelly sand by the standard (SP) and modified (MP) Proctor methods.

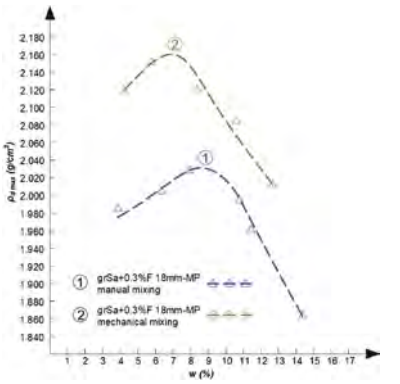

Figure 3. Compaction curves (MP) for manually and mechanically mixed soil with 0.3% fibers.

Figure 4. The polypropylene fibers with 12 mm longest added to the soil in a mass ratio of 0.1%, 0.2% and 0.3% to the dry mass of the compacted soil.

3 RESULTS AND DISCUSSION

The compaction parameters, $\rho_{d\,max}$ and w_{opt}, and specific dry density, ρ_s, of all tested materials are presented in Table 2. Figures 5−8 show the compaction curves obtained for all data set.

The cement addition to the gravelly sand increases the maximum dry densities of soil/cement mixes, while decreasing optimum water content values (Figure 5). Points ($\rho_{d\,max}$, w_{opt}) lie approximately along a line, more vertically for standard compaction than for modified.

The cement addition results in a moisture decrease by about 0.5% with a 3% addition of cement for standard compaction, and about 1% for modified. The $\rho_{d\ max}$ values increase with 3% cement addition by about 3.5% for both compaction methods.

Table 2. Compaction parameters of tested materials.

Material	ρ_s (g/cm^3)	Compaction method			
		Standard Proctor		Modified Proctor	
		w_{opt} (%)	$\rho_{d\ max}$ (g/cm^3)	w_{opt} (%)	$\rho_{d\ max}$ (g/cm^3)

C – cement addition, F – fiber addition.

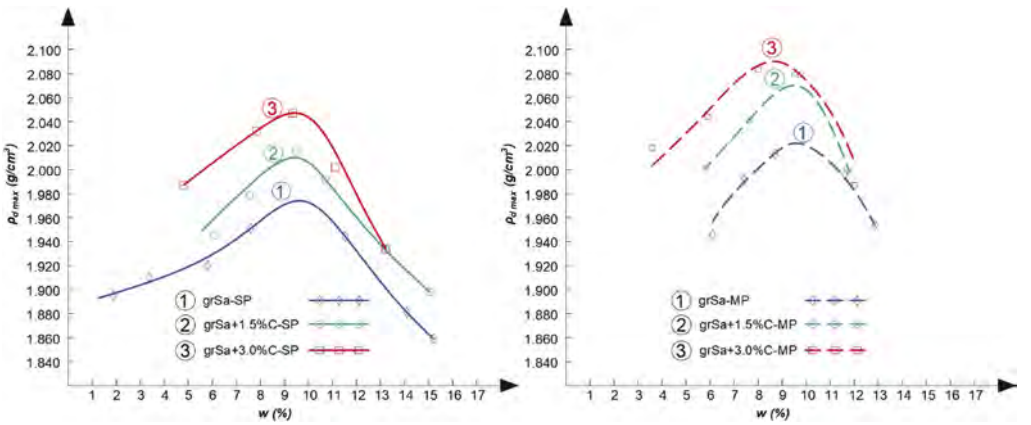

Figure 5. Compaction curves of gravelly sand with 0-3.0% cement addition: a) the SP test, b) MP test.

The fiber addition to the gravelly sand (Figure 6) influences the compaction parameters even more, especially in the case of the modified compaction. The maximum dry densities of mixes slightly increase, while reducing optimum water content values. The fiber addition results in a moisture decrease only by 0.3% with a 0.3% addition of fibers for standard compaction, and over 3% for modified. The $\rho_{d\ max}$ values increase with 0.3% fiber addition by about 3% in standard compaction, and about 7% in modified. In the case of the standard compaction of the mixture with the addition of 0.2% and 0.3% fibers, no increase in $\rho_{d\ max}$ was found. A similar relationship was found in the authors' own research of soil mixtures with 18 mm long fibers (Zabielska-Adamska et al. 2023). Probably more fibers make it difficult to move the soil when compacted with less energy. Therefore, the compaction of a soil-fiber mixture is more effective with the modified Proctor method.

The effect of the increase in compaction in the case of a mixture of soil, cement and fibers is much greater than in the case of each of the factors separately for both compaction methods. The addition of 0.3% of fibers and 1.5% of cement raises the maximum dry density by about 7% (Figure 7). Increasing the cement to 3% enhances the maximum density by about 10% (Figure 8).

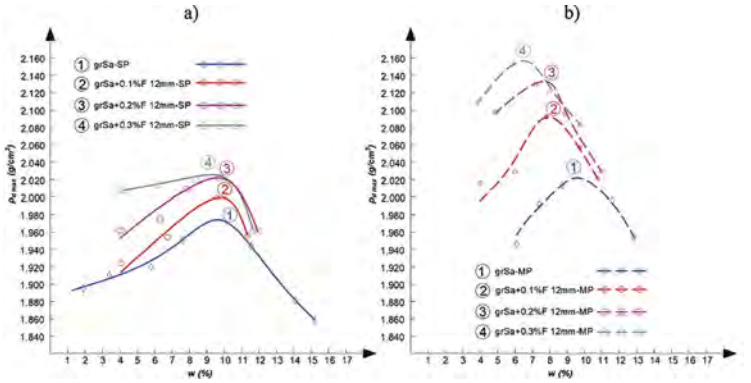

Figure 6. Compaction curves of gravelly sand with 0-0.3% fiber addition: a) the SP test, b) the MP test.

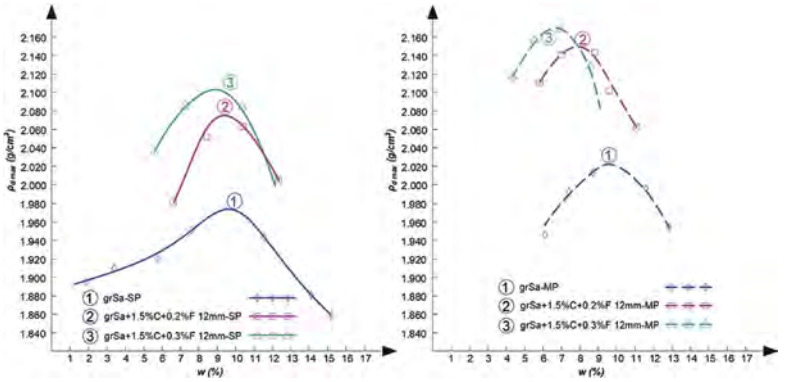

Figure 7. Compaction curves of gravelly sand with 1.5% cement and 0.2-0.3% fiber addition compared to natural soil: a) the SP test, b) the MP test.

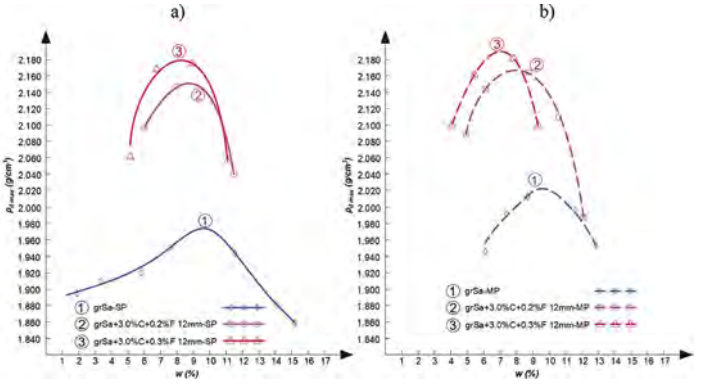

Figure 8. Compaction curves of gravelly sand with 3.0% cement and 0.2-0.3% fiber addition compared to natural soil: a) the SP test, b) the MP test.

Therefore, one cannot agree with the literature reports that the addition of fibers or fibers and cement slightly influences the compaction parameters or even lowers them. The reduction in maximum dry density after the addition of fibers may have been due to insufficient homogenization of the samples. Inaccurate mixing of samples with fibers causes the maximum value of dry density to be underestimated (Figure 3), which eliminates the effect of the additive on density.

4 CONCLUSIONS

Based on the compaction results of gravelly sand in a natural state and improved by polypropylene fiber and/or cement addition, the following conclusions are made:

1. The cement addition influences the compactibility of the gravelly sand. With increasing cement percentage in the mix, the maximum dry density increases and optimum water content decreases. Changes in compaction parameters are caused, among others, by increasing the solid particle density and adding fines to the mixture.
2. The fiber addition increases the maximum dry density and reduces the optimum water content, which is more evident in the modified Proctor compaction. With standard compaction energy, more fibers make it difficult to compact the mixture.
3. The effect of increasing compaction in the case of the mixture of soil, cement and fibers is far greater than for each of the factors separately for both methods of compaction.
4. The method of mixing the samples with fibers can have a significant impact on the compaction parameters. Manual mixing causes insufficient homogenization of the sample, which leads to an underestimation of the maximum dry density value.

Experimental test and numerical simulation on static and dynamic characteristics of new pile-supported slab subgrade structure in high-speed railway

Xiao Hong, Jin Feng & Fang Jia
Beijing Jiaotong University, Beijing, China

Hu Fei
CIECC Overseas Consulting Company Limited, Beijing, China

ABSTRACT: Pile-supported slab is a new type of subgrade structure, its working characteristics are still unclear. Based on the model similarity theory, the static horizontal loading model experiments and dynamic vertical excitation experiments of two spans were carried out. The characteristics of pile-supported slab are analyzed through the coupling model of train and pile-supported slab. The results show that: (1) The subgrade soil has an obvious horizontal restraint effect on the pile, and the variation of pile-soil interaction along the pile is different from bridge pile foundation. (2) Under the vertical excitation load, the supporting effect of the lower soil on the supported slab is obvious. (3) The pile, slab and soil of pile-supported slab have complex interaction, and the state equilibrium achieved after a certain number of dynamic actions. In general, the design of pile-supported slab adopted by high-speed railway is redundant, which has a lot of optimization space.

1 INTRODUCTION

The pile-supported slab is a new type of track substructure, which is mainly used in special sections such as transition zones between subgrade and rigid structures(Li et al. 2020), soft soil sections (Huang et al. 2015), etc. to provide better stability(Chen et al. 2014) and control the foundation differential settlement(Shan et al. 2021). The schematic diagram of the structure is shown in Figure 1. Currently, there are some engineering applications in several countries, such as Germany(Wang et al. 2006), Netherlands (Woldringh et al. 1999, Bachmann et al. 2003), China(Wei 2008, Wang et al. 2012), Korea (Lee et al.e 2013) and Africa (Messioud et al. 2017). However, due to the complexity of its working mechanism, the pile-slab structure is often designed based on field conditions with empirical design or based on experimental results (Wang et al. 2012). For example, the pile-slab structure of the Dutch high-speed railway is designed based on the experimental results of the Technical University Munich. In China, engineers mostly adopt a conservative design, without considering the supporting effect of the soil under the slab and the lateral restriction effect of subgrade soil the same as the design of the bridge. These restrict the popularization and application of pile-slab structure seriously. In fact, pile-slab structure differs from bridge structure and subgrade structure. Its resistance comes from the interaction between the pile, slab, and subgrade soil, which meets the engineering requirements.

For pile-slab structure, the key factors are the supporting effect on infrastructure slab and lateral restriction on pile foundation from subgrade soil. To find pile-soil and slab-soil interaction mechanisms, static horizontal loading tests and dynamic vertical exciter tests were designed. We intended to identify the law of pile-soil and slab-soil interaction under loading

DOI: 10.1201/9781003299127-407

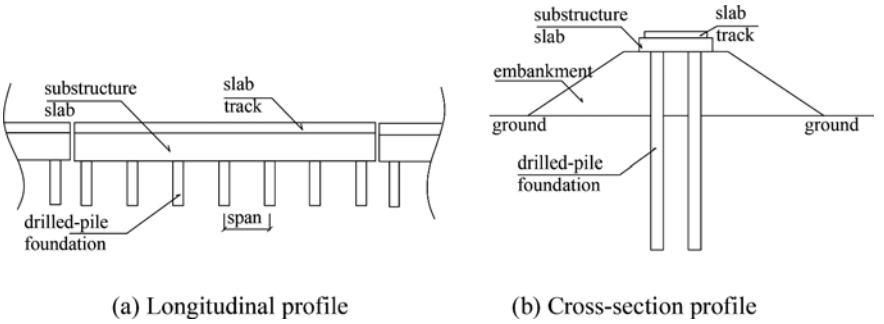

Figure 1. Sketch of pile-slab structure.

action by model testing, to provide theoretical guidance for the rational design of the pile-slab structure.

2 SCHEME OF MODEL TESTING

2.1 *Testing purposes*

The main purposes of these model testing are: ①mechanical behaviors of slab-soil interaction, including variation tendency of the supporting performance of soil under various loads; ②mechanical properties of pile-soil interaction, including pile-soil contact force variation with pile depth; ③effect of different spans on infrastructure slab; ④mechanical properties of slab with soil support under the slab and without soil; ⑤distribution of stress and of slab and pile.

2.2 *Similarity ratio of model*

After comprehensively considering the economy, model dimension size, the performance of loading equipment, and maneuverability, we chose 1:20 as the similarity ratio of the model. To satisfy the similarity of main parameters, such as actual stiffness and surface roughness of pile-soil, cohesive strength, and internal friction angle of soil in the embankment, we used prototype materials of pile and soil in the model testing. To be specific, we used a reinforced concrete grouting pile, whose strength grade is C30. Because the parameters of sand are clear, we chose sand as model soil. Taking compactness of subgrade and engineering practice into consideration, we chose the parameters of sand in the model testing as follows: moisture content is 11%, compactness is 93%, and dry density is 1.836 g/cm^3, so the calculated density $\rho = \rho_d(1+w) = 1.836\times(1+11\%) = 2.038$ g/cm^3.

2.3 *Model dimensions and manufacture*

2.3.1 *Model dimensions*

Considering the actual structure used in engineering practice, we chose a pile-slab structure with spans of 5.0m and 7.5m as the prototype, and designed two groups of model testing correspondingly, as shown in Figure 2.

2.3.2 *Model manufacture*

The track structure is the double-block ballastless track, and dimensions are as follows: length is 4.856m, width is 2.80m, thickness is 0.35m, and strength grade of concrete is C40. The sizes of infrastructure slab of the pile-slab structure are: length is 30.0m, width is 4.40m, height is 0.60m, strength grade of concrete is C40.

For convenience and rational reinforcement when making models, the ballastless track and infrastructure slab were poured together. ①Length: according to the pile-slab structure of 5m

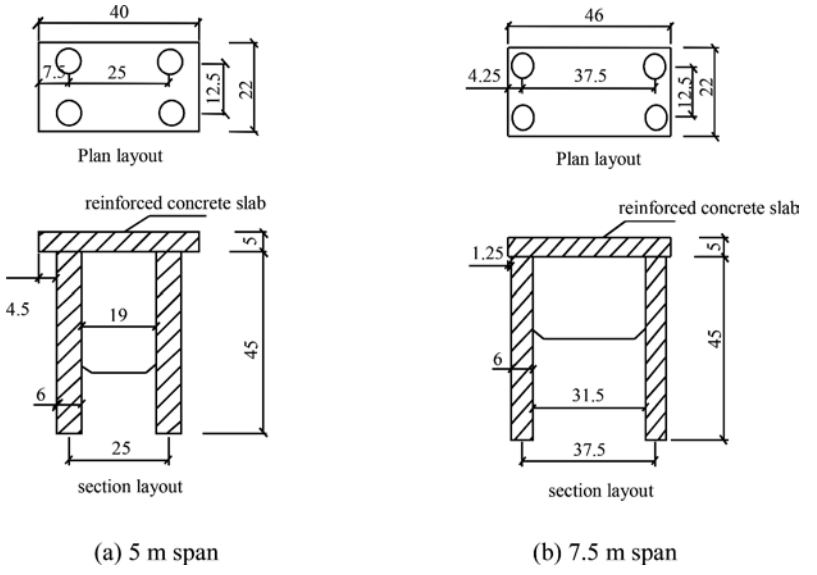

Figure 2. Sketch of pile-slab structural model (unit: cm).

and 7.5m spans, model spans are 500/20=25cm and 750/20=37.5cm. ②Width: width of the infrastructure slab is 4.4m, so the model width is 440/20=22cm. ③Thickness: the total thickness of the track and infrastructure slab is 0.35+0.6=0.95m, so the model thickness is 95/20 = 4.75cm ≈5cm. ④Gauge is 1500mm/20=75mm.

3 STATIC HORIZONTAL LOADING TEST

3.1 *Experiment scheme*

To eliminate the boundary effect under horizontal loading, these experiments were conducted on a horizontal ground of a natural foundation. Firstly, place the model into an empty hole and fill it with sand, ensuring the density of the soil body near the hole is consistent with the actual situation, then apply horizontal load. There are five levels of loading forces that are 1.15kN, 1.47kN, 1.96kN, 2.33kN, and 2.77kN. The following experimental data is obtained after stabilization of the structures, which are all applied load until 2.77kN. The sketch of loading and layout of measuring points are shown in Figure 3.

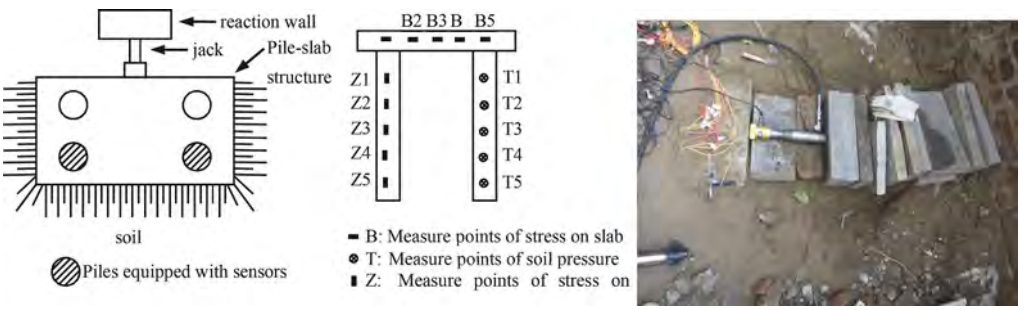

Figure 3. Layout of sensors for lateral loading.

3.2 *Analysis of experimental data*

3.2.1 *Pile-soil interaction forces*

The pile-soil interaction stresses of the two experimental models are shown in Figure 4. As is shown in Figure 4, pile-soil interaction of pile-slab structure with 5.0m and 7.5m spans both decreases rapidly with increasing depth, variation tendency of two spans is basically the same and influenced range is mainly the upper half of the pile. It can also be seen that the interaction stress of a 7.5m span is 4.275% more than the stress of a 5m span, which shows that span has little effect on pile-soil interaction under lateral loads.

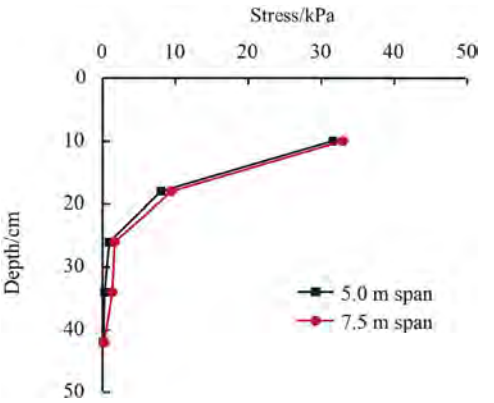

Figure 4. Variation tendency of pile-soil interaction forces with pile depth.

3.2.2 *Stresses of infrastructure slab*

The measured stresses infrastructure slabs are shown in Figure 5.

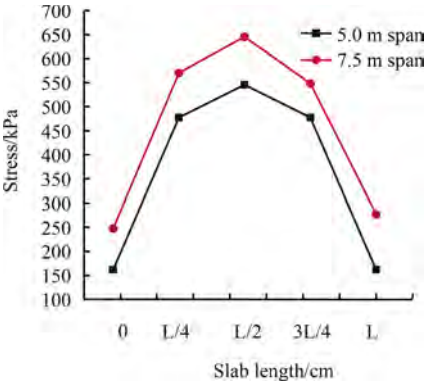

Figure 5. Variation tendency between lateral stress and length.

As can be seen from Figure 5, the variation tendency between lateral stress and length of these two spans under lateral load is basically the same, which likes a parabolic curve, and the maximum stress occurs in mid-span. It can be seen that the stress of slab with a 7.5m span is 19.266% more than the stress of a 5m span. It clears that the larger the span of pile-slab structure is, the greater the bending-tensile stress of the slab under lateral load. Obviously, in the design of the pile-slab structure at the curve section, if the unbalanced centrifugal force is very large, the stress of the infrastructure slab at mid-span should be checked.

3.2.3 *Bending stress of pile*

Measured bending stresses of piles under lateral load are shown in Figure 6. As can be seen from the figure, under lateral load, pile bending stresses of two spans both increase at first and then decrease, and their variation tendency is the same. This curve shape shows that the pile-soil interaction of pile-slab structure is obvious, and horizontal resistance is significant. Its mechanical behaviors are different from those of pile foundation in bridge and influenced range is mainly the upper half of the pile. As can be seen from the experimental data in Figure 6, pile stresses of the two spans have little difference, which means the spans of the pile-slab structure have little effect on the bending stress of the pile under lateral load.

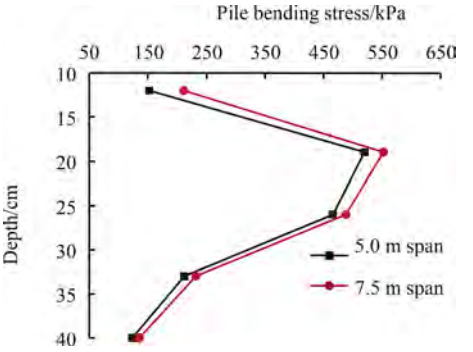

Figure 6. Relationship between pile bending stress and depth.

4 DYNAMIC VERTICAL EXCITATION TEST

4.1 *Experiment scheme*

Spans of corresponding prototypes of model testing were 5.0m and 7.5m, and loading frequency was 5Hz, using sinusoidal load with a dynamic amplitude of 2.97kN. Firstly, model testing with soil supporting was conducted, then soil under the slab was excavated (hereinafter called soilless supporting), making the slab separate from the soil, then a soilless supporting experiment was conducted. The layout of the sensors is shown in Figure 7.

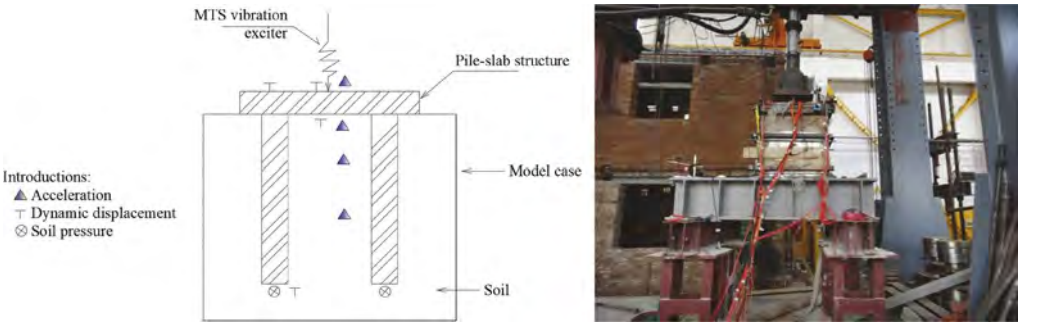

Figure 7. Layout of sensors for vertical excitation test.

4.2 *Analysis of experimental data*

4.2.1 *Acceleration of slab*

As the acceleration sensors buried in model soil were damaged when filling the soil, only the acceleration on the up of slab can be analyzed, which is shown in Figure 8.

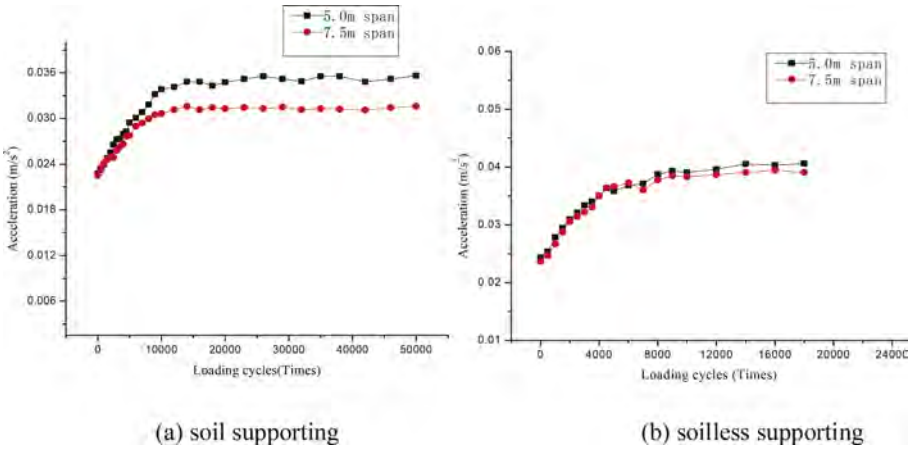

Figure 8. Relationship between acceleration of slab and loading cycles.

As can be seen from Figure 8, the relationship between acceleration and loading cycles of a 5.0m span is like that of a 7.5m span. They both have an early stage where acceleration increases with the increase of loading cycles, and it stabilizes after a certain number of loading times. In the case of soil supporting, 5.0m span stabilizes after 12000 loading times, and 7.5m span stabilizes after 14000 loading times. For the condition without soil support, the two models both stabilize after 6000 loading times. There is an obvious interaction between pile and soil under soil supporting conditions, and this structure needs more loading cycles to reach equilibrium.

It can be seen from the experimental data that, the acceleration of a 5.0m span is larger than that of a 7.5m span. Comparing the data after stabilization, it is not hard to find that, under soil supporting conditions, acceleration of 5.0m span is 12.0% larger than that of 7.5m span; under soilless supporting condition, acceleration of 5m span is 2.2% larger than that of 7.5m span. This is because the smaller the span is, the larger the stiffness of the structure, then the acceleration will be larger when other conditions are the same.

4.2.2 *Dynamic displacement of mid-span*
Measured data is shown in Figure 9.

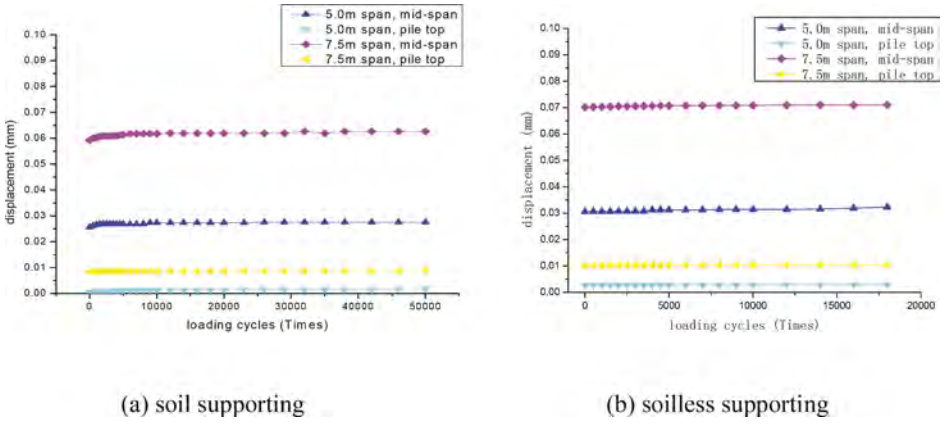

Figure 9. Relationships between loading cycles and dynamic displacement of pile top and mid-span of infrastructure slab.

As can be seen from Figure 9, the relationship between dynamic displacement and loading cycles of a 5.0m span is similar to that of a 7.5m span, the displacement of mid-span is larger than that of pile top.

It can also be seen that dynamic displacement of mid-span of 5.0m span is larger than that of 7.5m span. Comparing the data after 50000 loading cycles, under soil supporting conditions, dynamic displacement of mid-span of 7.5m span is 1.3 times larger than that of 5.0m span. Comparing the data after 20000 loading cycles, under soilless supporting condition, dynamic displacement of mid-span of 7.5m span is 1.2 times larger than that of 5.0m span. This is because the larger the span is, the smaller the stiffness of the structure, then the dynamic displacement will be larger when other conditions are the same. Moreover, comparing soilless supporting with soil supporting, the former stabilizes more quickly.

In addition, comparing two supporting conditions, the results show that the dynamic displacement of a 5.0 m span of soil supporting is 0.0048mm less than that of soilless support. The soil under the slab has an obvious supporting effect on the pile-slab structure and decreases the dynamic displacement of the slab effectively, and the larger the span is, the more obvious the supporting effect. Obviously, as for train ride comfort, the supporting effect of soil under the slab is beneficial to high-speed rail running.

4.2.3 *Soil pressure at the bottom of pile*

Measured data of soil pressure under pile bottom is shown in Figure 10.

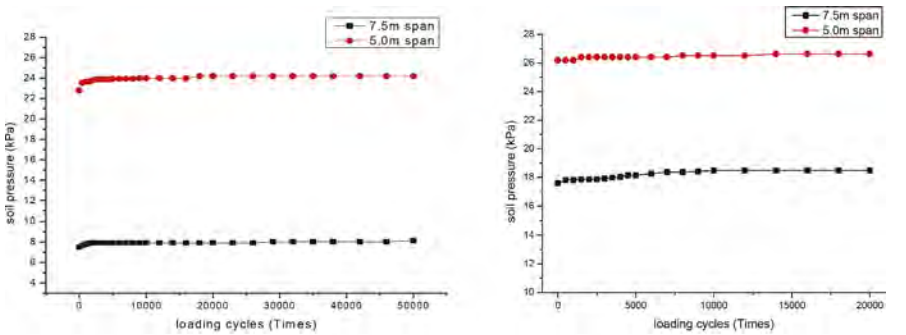

Figure 10. Relationship between loading cycles and soil pressure under pile bottom.

As can be seen from Figure 10, the relationship between loading cycles and soil pressure under pile bottom of 5.0m span is like that of 7.5m span. Both have an early stage that soil pressure increases with the increase of loading cycles, and they stabilize after a certain number of loading times.

It shows from the measured data that, soil pressure of mid-span of 5.0m span is obviously larger than that of 7.5m span. Comparing the data of stabilization after 50000 loading cycles, under soil supporting conditions, soil pressure of mid-span of 5.0m span is 2.08 times larger than that of 7.5m span. Comparing the data after 20000 loading cycles, under soilless supporting conditions, soil pressure of mid-span of 5.0m span is 39.08% larger than that of 7.5m span. This is because the larger the span is, the smaller the stiffness of the structure, and the more significant pile-soil interaction, the soil pressure under the pile is smaller when other conditions are the same.

In addition, comparing soil supporting with soilless supporting, for a 5.0m span, soil pressure of soilless supporting is 10% larger than that of soil supporting; for a 7.5m span, soil pressure of soilless supporting is about 1.42 times larger than that of soil support. The soil under the slab has an obvious supporting effect on the infrastructure slab, and the larger the span is,

the more obvious the supporting effect. The spans of engineering practices are as follows, the span of the Dutch high-speed railway is 5m(Bachmann et al. 2003), the spans of the Sui-Yu railway in China are 5m and 10m(Wei 2008), and the span of the Zhengzhou-Xi'an high-speed railway is 7m(Wang et al. 2012). Because the soil has an obvious supporting effect on structures with such spans, pile-slab structures with such spans should be considered in engineering design.

5 CONCLUSIONS

(1) Under the horizontal load, the pile-soil interaction is obvious. The test data show that the subgrade soil has an obvious horizontal restraint effect on the pile foundation, the bending stress of the pile shows a trend of first increasing and then decreasing, and the main action area is within the upper half of the pile, which is different from bridge structures.

(2) Under the action of horizontal load, the force and deformation laws of pile-slab structures with different spans are basically the same. The interaction stress of a 7.5m span is 4.275% more than the stress of a 5m span, and the stress of slab with a 7.5m span is 19.266% more than the stress of a 5m span. The span size has little effect on the force of the pile but has a great influence on the force of the slab. According to the test results, it is suggested that when designing the pile-slab structure in the curved section, if the centrifugal force of the uneven horizontal is large, the transverse bending stress at the mid-span position of the bearing slab should be checked.

(3) Under the vertical cyclic load, the acceleration, dynamic displacement, and pile subsoil pressure of the pile-supported slab have certain changes at the initial stage of loading, and the test values tend to be stable with the increase of loading times. Among them, the number of stabilization required by soil bearing is obviously larger than that without soil bearing. The results show that there is a complex interaction between pile, slab and soil in the pile-supported slab under dynamic load, and the state equilibrium will be reached after a certain number of dynamic cycles.

(4) The span of the slab has an obvious influence on pile-supported slab under the vertical cyclic load. The acceleration value of the 5m span is 12.0% larger than that of the 7.5m span. The mid-span displacement of the pile of 7.5m span is 1.3 times larger than that of a 5m span. The bottom stress of a 5m span is 2.08 times higher than a 7.5m span. It can be concluded from the results that the larger the span, the smaller the stiffness of the structure, and the more significant the interaction between the slab and the lower soil. From the economic point of view of engineering design, the bearing resistance of soil under pile slab structure should be considered in the design.

(5) The supporting with or without soil has an obvious effect on the pile-slab structure under the vertical cyclic load. The acceleration in the case of soilless supporting is apparently larger than that of soil support. The acceleration value of the 5m bearing slab span is 16.5% larger when without the soil supporting while the 7.5m bearing slab span is 25.3% larger. The mid-span dynamic displacement of the bearing slab increases significantly. In the unsupported state, it increases by 17.4% when the bearing slab span is 5m, and increases by 13.4% when the bearing slab span is 7.5m. The soil pressure at the bottom of the pile increases significantly, with an increase of 10% when the span of the bearing slab is 5m, and an increase of 1.42 times when the span is 7.5m. The soil under the slab has an obvious supporting effect on the bearing slab, and the larger the span is, the more obvious the supporting effect is. It is suggested that the structure should adopt a pile-slab structure with a larger span as far as possible under the condition of meeting the resistance, to give full play to the supporting effect of the soil.

ABSTRACT: In this work, a series of 2D numerical models of geosynthetic-reinforced soil (GRS) abutment based on centrifugal model test were established to study the characteristics of GRS abutment ultimate bearing capacity and related influencing factors. Firstly, the numerical model was calibrated and verified against the test results of centrifugal model test. Subsequently, parametric studies were carried out to investigate the influence of reinforcement strength, setback distance and beam seat width on the ultimate bearing capacity of the GRS abutment. The results show that reducing the reinforcement strength or increasing the beam seat width weakened the ultimate bearing capacity. While, increasing the setback distance within 0.3 times of abutment height increased the ultimate bearing capacity of GRS abutment. In addition, the response of stress distribution, lateral displacement and max tension of reinforcement to above factors was also discussed based on numerical results.

1 INTRODUCTION

Geosynthetic reinforced soil integrated bridge system (GRS-IBS) is an effective scheme to reduce the bump at the intersection of approach and bridge beam and prolong the service life of abutment (Adams et al. 2011; Adams & Nicks 2018). As the structure bearing the load of the bridge superstructure, it is of great significance to understand the bearing performance of GRS abutments. Previous field tests and laboratory tests have confirmed that the GRS abutments have a relatively high ultimate bearing capacity (Wu et al. 2006, 2008). Researches showed that the high bearing capacity of GRS abutments mainly attributes to the closely arrangement, usually less than 0.3m, of geosynthetics (Wu & Pham 2013). The field test results of mini-pier tests showed that the setback distance, the dimension of abutment bearing area, the height of reinforced soil abutment and other dimensional factors have a certain impact on the bearing capacity of GRS abutments (Adams et al. 2007; Nicks et al. 2016). However, due to the mini-pier tests were carried out under uniform axial load, further research on the above influence factors still needs to be conducted concentrating on GRS abutment under local load. Researchers have carried out many reduced-scale model tests of GRS abutments, and results indicate that the effect of reinforcement spacing on the stability of abutment is more significant (Xu et al. 2019). Increasing the setback distance will also increase the ultimate bearing capacity of the GRS abutment, but no longer impact when the setback distance increases to a certain threshold (Xiao et al. 2016). Through both reduced-scale model and large-scale

DOI: 10.1201/9781003299127-408

model tests, it was clarified that the GRS abutments adopting large facing block have obviously strong bearing capacity (Hatami & Doger 2021a, b). And the abutments adopting full height panel facing have stronger bearing capacity than the abutments adopting modular facing or wrapped facing (Zhang et al. 2022). The numerical simulation study showed that the reinforcement spacing and the fill properties have a great impact on the ultimate bearing capacity of GRS abutments (Helwany et al. 1999; Zheng & Fox 2017; Zheng et al. 2018). Although plenty of factors have been considered to study their influence on the ultimate bearing capacity of GRS abutments, the influence of the geometric characteristics of the abutments has not been clearly explored. In this study, FLAC 2D software was used to establish the numerical model of GRS abutment in plane strain state to study its ultimate bearing capacity and the distribution of earth pressure under the limit state. The baseline case was compared with centrifugal model test to verify the rationality of the model. Subsequent parameter studies included the effects of reinforcement strength and abutment geometry. The results obtained in this research are expected to enhance the understandings of bearing capacity of GRS abutments.

2 NUMERICAL MODEL

2.1 *Model geometry*

A centrifuge model of a GRS abutment which was tested at 10g (Figure 1a) was amplified in 10 times and used as the model of the numerical simulation baseline group. The centrifugal test model includes Concrete Masonry Unit (CMU) facing blocks, backfill and reinforcement. The baseline model had a total wall height of H = 6 m, and 30 modular facing blocks with 0.2 m in length and 0.2 m in height. A beam seat with a thickness of 0.2 m and a length of 1 m was set on the top of the GRS fill. The horizontal distance between the beam seat and the wall facing, that is, the setback distance, was 0.2 m. Linear Variable Displacement Transducer (LVDT), strain gauges and earth pressure gauges were set in the model as shown in Figure 1a to monitor the lateral displacement of the facing block, reinforcement strain and earth pressure respectively. Figure 1b shows the mesh of the numerical model. The numerical model adopted uniform reinforcement length of 4.2 m (0.7H), and the vertical spacing was 0.2 m. The lateral boundaries of the model were set with horizontal constraints, but allowed to move in the vertical direction. The bottom boundary was fixed in both horizontal and vertical directions.

2.2 *Constitutive models and properties*

A linearly-elastic perfectly-plastic Mohr-Coulomb (MC) constitutive model was adopted to define the backfill soil and retained soil in numerical model. According to centrifuge test and laboratory test results, a dry density of 1750 kg/m^3, a friction angle ϕ of 38° and a cohesion c of 0 kPa were adopted in the numerical models. Recommended by Coduto (2015), An elastic modulus of 20 MPa and a Poisson's ratio of 0.25 were used. The value of the dilatancy angle ψ was determined as 8° according to the empirical relationship of $\psi = \phi$ - 30° recommended by Bolton (1986).

Reinforcements were modeled using different linearly elastic structural elements depending on their location. For reinforcements between two CMU blocks, the beam structural elements with zero moment of inertia were used, while for reinforcements embedded in backfill, the cable structural elements were used. There were two types of reinforcement used in this study. Amplifying the wide-width tensile test results of the geotextile used in centrifugal test in 10 times, the reinforcement used in baseline group, recorded as G1, had a tensile stiffness of 850 kN/m at a tensile strain of 2% and an ultimate tensile strength of T_{ult} = 63 kN/m. The other reinforcement used in parameter study, recorded as WS, was a type of window screen and had a tensile stiffness of 160 kN/m at a tensile strain of 2% and an ultimate tensile strength of T_{ult} = 20 kN/m based on wide-width tensile test. Assuming that the thickness of

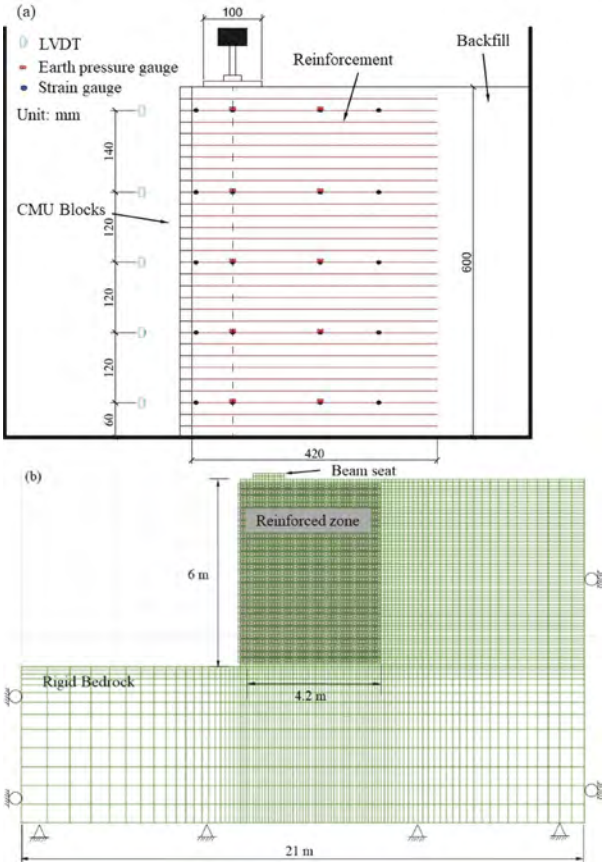

Figure 1. Layouts of the GRS abutment model: (a) cross-section and monitoring arrangement of the centrifuge model; (b) numerical model mesh for the baseline case.

the structural elements is 1 mm and the width were 1 m, the elastic modulus of the two kinds of reinforcement were 850 MPa and 160MPa respectively, calculated by dividing tensile stiffness by the sectional area.

The bedrock, CMU blocks and beam seat slab were all modeled by linear-elastic constitutive. Their input parameters are listed in the Table 1.

Table 1. Input parameters for bedrock, CMU blocks and beam seat slab.

Components	Density (kg/m^3)	Elastic modulus (MPa)	Poisson's ratio
Bedrock	2000	2000	0.2
CMU block	1800	20000	0.15
Beam seat slab	9600*	2000	0.15

*Calculated according to the dead load stress of the beam seat slab of 20 kPa.

2.3 *Interfaces*

The reinforcement-soil interaction was simulated by the embedded grout annulus around the cable structural elements, while the reinforcement-block interaction was simulated by linearly-elastic perfectly plastic interface elements on both upper and lower sides of beam structural elements. These interface elements were also adopted to model the soil-block interface or block-block interface. The properties of the reinforcement-soil interface and the soil-block

interface were determined by direct shear test. The reinforcement and the block were connected by friction; hence the reinforcement-block interaction properties were determined according to pullout test results of Awad & Tanyu (2014). Table 2 summarizes the types and parameters of interfaces in this work.

Table 2. Input parameters for different interfaces.

Interface	Modeling method	Friction angle (°)	Cohesion (kPa)	interaction coefficient
Reinforcement-soil* G1 (WS)	embedded grout annulus	28.3 (33.2)	0 (0)	0.69 (0.84)
Reinforcement-block**	interface elements	16.2	9.5	/
Soil-block and soil- beam seat*	interface elements	28.8	0	0.71
Block-bedrock***	interface elements	31	0	/

*Determined by direct shear test.
**Based on Awad & Tanyu (2014) and parameters of two types of reinforcement were assumed the same.
***Based on ACI 318-02 (ACI, 2002).

2.4 *Modelling procedure and load settings*

Before the construction of the abutment model, the bedrock element and corresponding constraints were activated first, and then an equilibrium were reached under gravity. A layer of the facing block, the backfill, the retained soil, and the reinforcement were installed, and then the interfaces were activated. The above steps were repeated until the installation of topmost layer was finished. At last, the beam seat was installed and interfaces were activated. In order to simulate the compaction effect during construction, a vertical stress of 8 kPa was applied on the top of each layer of the reinforced area and removed before the installation of next layer (Hatami & Bathurst 2005; Shen et al. 2020).

A vertical stress of 20 kPa from the end of the beam seat to the rightmost boundary of the model was applied to simulate the dead load of the approach. As the first stage of loading, the self-weight load stress of beam seat slab was also 20 kPa. The subsequent bridge load was achieved by applying vertical stress on the beam seat slab in an increment of 25 kPa before 400 kPa, and in an increment of 50 kPa after 400 kPa. During the loading process, the axial forces of reinforcements were monitored. When the axial force of any reinforcement reached its ultimate tensile strength, or the safety factor of the model is equal to 1, it could be considered that the abutment had reached the ultimate bearing capacity.

2.5 *Validation of the model*

To verify the accuracy of the numerical model, the simulation results of baseline were compared with the results of the centrifugal test. In order to facilitate the validation of the full-scale numerical model, the monitoring data obtained from the centrifugal model test had been converted according to the model similarity scale (n=10 g) and similarity principle of centrifugal test (Viswanadham, 2019). Figure 2a shows the lateral displacement profile of the facing block along the height of the abutment obtained from both centrifugal test and the baseline group. Although there are some discrepancies in magnitude, the measured and simulated lateral displacement of the facing block still show similar distribution trends. The measured and simulated additional vertical stresses below the centerline of the beam seat induced by the bridge slab load are shown in Figure 2b. It can be found that the simulation values match well with the measured results under different applied vertical stresses. Figure 2c shows comparison of measured and simulation reinforcement strain profile along abutment height below the centerline of the beam seat. Also, there are some acceptable deviations in magnitude, but the distribution trends of measured and simulated strains show consistency. In terms of the lateral

displacement of facing block, additional vertical stress and reinforcement strain, the numerical model established in this work can reasonably reflect the performance of the abutment in the centrifugal test. Therefore, the numerical model established in this section can be used for subsequent parametric study.

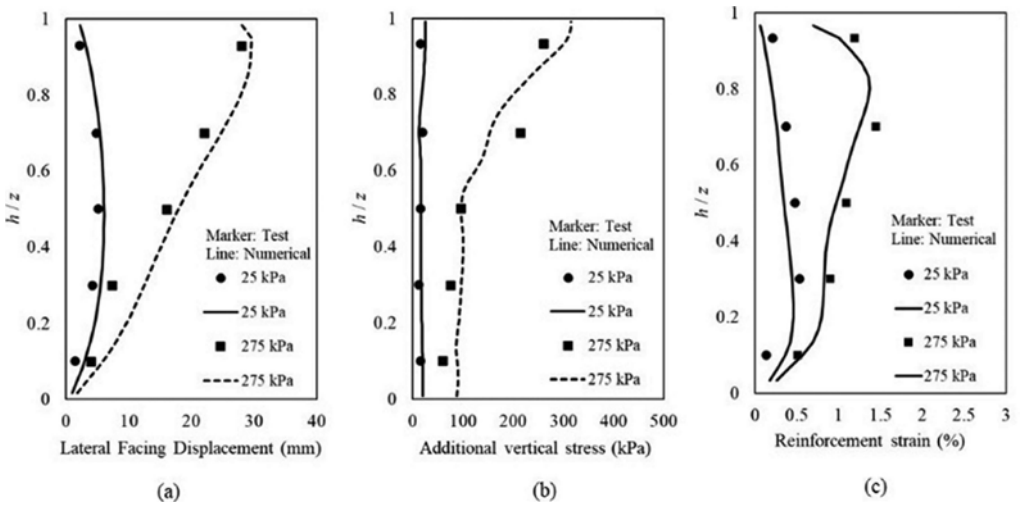

Figure 2. Comparison of centrifugal test results (converted according to the model similarity scale) and numerical results: (a) Lateral displacement of the facing block; (b) additional vertical stresses below the centerline of the beam seat; (c) reinforcement strain below the centerline of the beam seat.

3 PARAMETRIC STUDY

After the validation of the numerical models, parametric study was carried out to study the influence of some key factors on the ultimate bearing capacity of the GRS abutments and the performance of GRS abutments in the limit state. The factors included reinforcement tensile strength, setback distance and beam seat width.

3.1 *Ultimate bearing capacity*

Parametric study settings and corresponding simulation results of ultimate bearing capacity are drawn in Table 3. It should be mentioned that for all groups of simulation, the strength limit of reinforcement had been reached before the safety factor of the model was equal to 1. Hence, for all groups, the ultimate bearing capacity of the GRS abutment is defined according to the vertical load when any reinforcement reached its ultimate tensile strength. The simulation results show that weakening the reinforcement strength or increasing the beam seat width both have a negative impact on the ultimate bearing capacity of GRS abutments. It should be noted that although increasing the beam seat width reduces the bearing capacity per unit area, the total load that GRS abutments can bear increases due to the increase of the total bearing area. It indicates that GRS abutments can bear heavier bridge beams by increasing the beam seat width when space allows. The lengthening of setback distance increases the ultimate bearing capacity of GRS abutments until the setback distance is extended to 1.8 m (0.3H). Then, until the beam seat is close to the right boundary of the reinforced area, that is, when the setback is 3 m (0.5 H) in length, ultimate bearing capacity remains stable and does not increase with the lengthening of setback distance. It indicates that the bearing capacity of GRS abutments is improved most effectively when the beam seat is located in the middle of the reinforced area.

Table 3. Parametric study setting and ultimate bearing capacity results.

Model	Reinforcement type	Ultimate tensile strength of reinforcement (kN/m)	Beam seat dimension b (m)	Setback distance a_b (m)	Ultimate bearing capacity (kPa)
Baseline	G1	63	1	0.2	1500
Group 1	WS	20	1	0.2	478
Group 2	WS	20	1.5	0.2	438
Group 3	WS	20	2	0.2	419
Group 4	WS	20	1	0.4	501
Group 5	WS	20	1	0.8	522
Group 6	WS	20	1	1.2	545
Group 7	WS	20	1	1.8	575
Group 8	WS	20	1	2.4	579
Group 9	WS	20	1	3	575

3.2 *Additional vertical stress and lateral earth pressure*

The distribution of additional vertical stress under the center line of beam seat along the height at limit state is shown in Figures 3. It can be observed that the change of the tensile strength of the reinforcement has no obvious effect on the distribution trend of the additional vertical stress (Figure 3a). Similar to the response of the ultimate bearing capacity to the setback distance, the lengthening of setback distance moves the position where the maximum additional vertical stress value appears upward, and when the setback distance reaches 1.8 m (0.3H), the position no longer change (Figure 3b). Increasing the beam seat width makes the distribution of the additional vertical stress more uniform along the height, and the position where the maximum value appears moves downward (Figure 3c).

The distribution of additional lateral earth pressures behind the abutment facing along the height at limit state is drawn in Figures 4. Same as additional vertical stress, the tensile strength of the reinforcement does not have a significant effect on the distribution of the additional lateral earth pressures behind the abutment facing (Figure 4a). The increasing of setback distance leads to the continuous decrease of the peak value of the additional lateral earth pressure. And when the setback distance increases to 1.8 m (0.3H), the additional lateral earth pressure eventually no longer presents a single peak distribution (Figure 4b). It indicates that as the beam seat is far away from the abutment facing, the influence of the bridge slab load near the free facing is gradually weakened, especially at the higher position. Increasing the beam seat width has no obvious effect on the location of the peak additional lateral earth pressure, but the lateral earth pressure increases at the lower part of the abutment (Figure 4c).

Also, the calculated results using the Boussinesq solution for an area transmitting a uniform surcharge recommended by the FHWA for the GRS-IBS (Adams and Nicks, 2018) is drawn in Figures 3 and 4 with solid lines. When the bridge slab load is large, the basal earth pressure of the rigid beam seat cannot be simply approximated to the average distribution. Therefore, the calculation results of additional vertical stress according to the Boussinesq solution for an area transmitting a uniform surcharge are smaller than numerical result. It indicates that in order to accurately analyze the internal vertical stress distribution of GRS abutment under relatively large bridge load, firstly it is necessary to clarify the basal earth pressure of the beam seat, and then use the integral method to solve according to the Boussinesq solution for concentrated vertical force. The Boussinesq solution is to solve the internal stress distribution in the semi-infinite space, and cannot correctly consider the reduction of the additional lateral earth pressure due to the lateral displacement of the abutment facing. Therefore, the calculation results overestimate the additional lateral earth pressure behind the abutment facing. Although, in magnitude, the theoretical calculation results significantly underestimate the additional vertical stress and overestimate the additional lateral earth pressure, the distribution trends of numerical results and the calculation results of the Boussinesq solution are in good agreement.

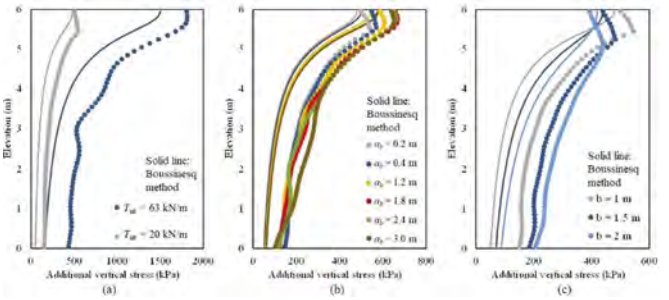

Figure 3. Distribution of additional vertical stresses under the beam seat centerline (a) effect of different reinforcement strength T_{ult}; (b) effect of setback distance a_b; (c) effect of beam seat width b.

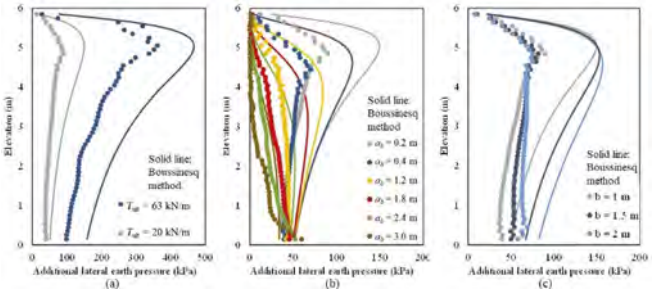

Figure 4. Distribution of additional lateral earth pressures behind the abutment facing (a) effect of different reinforcement strength T_{ult}; (b) effect of setback distance a_b; (c) effect of beam seat width b.

3.3 *Lateral displacement of facing block*

The profiles of lateral displacement of facing block are shown in Figure 5. As shown in Figure 5a, Due to the difference in the stiffness of the reinforcement, the lateral displacement of the cases with different reinforcement is slightly different in magnitude. However, the lateral displacement distribution trends of the two cases are not affected. With the increase of setback distance, the lateral displacement of the upper facing decreases, while the lateral displacement of the bottom facing slightly increases. At the same time, the peak lateral displacement of facing decreases, and its appearance position also moves downward (Figure 5b). This is because the father the beam seat is away from the free facing of abutment, the lower the height when the stress induced by bridge slab loading diffuses to the facing. Increasing the beam seat width results in a larger lateral displacement of facing block, and a lower position of the peak lateral displacement (Figure 5c). This phenomenon is consistent with the increase of the total load of the abutment when the beam seat width increases.

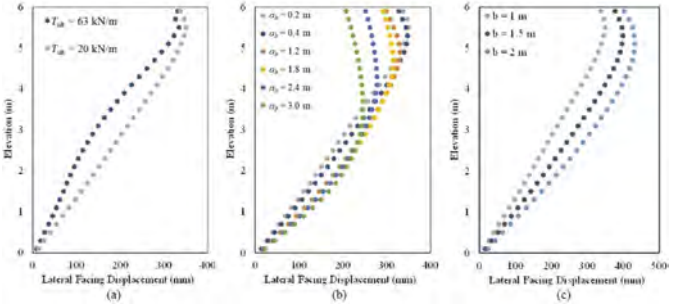

Figure 5. Distributions of lateral displacement of facing block (a) effect of different reinforcement strength T_{ult}; (b) effect of setback distance a_b; (c) effect of beam seat width b.

3.4 *Max tension of reinforcement*

Figures 6 shows the distribution of the maximum tension (T_{max}) in the reinforcement. Since the difference in the reinforcement strength, the maximum tension is normalized by the ultimate strength of the reinforcements. As shown in the Figure 6a, the effect of reinforcement strength is insignificant for the distribution of the maximum tension. With the increase of setback distance, longer reinforcements between the beam seat and the facing are mobilized to confine the backfill. Hence, the increase of setback distance leads to the decrease of the maximum tension of reinforcement (Figure 6b). Increasing the beam seat width results in smaller T_{max} in the upper reinforcement layers while larger in the bottom reinforcement layers. And the position of the reinforcement reaching the ultimate strength moves downward since the increase of the beam seat width (Figure 6c).

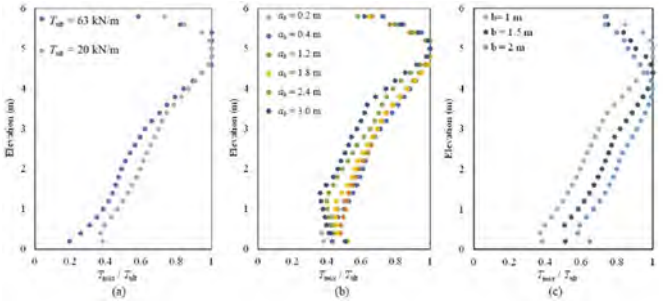

Figure 6. Distributions of maximum tension in the reinforcement T_{max} (a) effect of different reinforcement strength T_{ult}; (b) effect of setback distance a_b; (c) effect of beam seat width b.

4 CONCLUSION

In this work, the responses of GRS abutment subjected to bridge slab loading under ultimate stress condition state were evaluated by two-dimensional numerical simulation. A series of parametric studies were carried out to investigate the response of stress distribution, lateral displacement and max tension of reinforcement to various factors, including reinforcement strength, setback distance and beam seat width. The following conclusions are reached in this work:

1. The reinforcement strength only has an obvious effect on the ultimate bearing capacity of the abutment, while shows less effect on stress distribution, lateral displacement and max tension of reinforcement.
2. Increasing the setback distance within a certain range ($0.3H$) results in the increase of ultimate bearing capacity of the abutment and change the additional vertical stress distribution under the beam seat centerline. As the beam seat moves away from the abutment facing, the T_{max} of each reinforcement layer, the additional lateral earth pressure and lateral displacement of facing gradually decrease.
3. Larger beam seat width results in lower ultimate bearing capacity. And the increase of the beam seat width results larger stress distribution, lateral displacement of facing and T_{max} of reinforcement below the position where corresponding peak appears.
4. The Boussinesq solution for uniform surcharge results in a smaller calculated additional vertical stress distribution under the beam seat centerline and a larger calculated additional lateral earth pressure behind the abutment facing. The Boussinesq solution dose not consider the uneven distribution of the basal earth pressure under the rigid beam seat and the effect of the abutment facing at ultimate state.

ABSTRACT: This paper presents a calculation of the mass transfer of water and its accumulation in the soils of the base of the road, considering the engineering-geological zoning on the example of the city of Astana, Kazakhstan. A detailed analysis of the physical and mechanical properties of the foundation soils of the highway in the geoclimatic conditions of the city of Astana was carried out. The temperature fluctuations of the layers of the pavement and the base of the subgrade in the winter period were monitored by installing sensors in the layers of pavement and subgrade of the road. The depth of freezing in winter was determined, and the distribution of temperature in the depth of the pavement and base soils was analyzed. It has been established that the soil foundations of roads, as well as the layers of pavement, remain in a stably frozen state due to sub compensation of heat transfer of the underlying layers and have a sufficient margin of safety. It was determined that the mass transfer of water in gaseous state was 1.44 10^{-4} g/h per 1 dm³ of soil volume at a temperature of -5-8 °C at a depth of -60 cm under the road. To prevent negative impact and uneven deformation of the subgrade in zones 1-8 in Astana city, it was recommended to provide additional vapour barrier at a depth of 57-60 cm, before the construction of the underlying layer of gravel-sand mixture.

1 INTRODUCTION

The location of Kazakhstan in a sharply continental climate entails a pronounced effect of temperature fluctuations on the road structure (Teltayev et al. 2022). Moreover, not only the upper layers of asphalt concrete fall under the influence, but also the soil bases, which in winter freeze to a depth of 2 meters. The new capital of Kazakhstan, Astana, is a territory of active urban development. According to the Geoinformation Database (Zhussupbekov et al. 2021), the territory of Astana city can be subdivided into 8 subzones according to the composition of the soils, consisting of 6 main engineering-geological elements and the occurrence of soil subtypes. Subzones 4, 5, 7, 8 belong to the left bank of Yesil River or to the territory of new development (Figure 1).

The topsoil (EGE-1a) with the thickness less than 1 m does not serve as a foundation soil for highway construction and most often cut off or replaced with bulk soil. Beneath there are sandy clay loams $a(Q_{II\text{-}IV})$ designated as EGE-2a, with interlayering loamy sands and sandy

DOI: 10.1201/9781003299127-409

loam soils (EGE-2b), clays (EGE-2c) and silty soils (EGE – 2d). Horizontal layers of sands of various sizes (EGE-3a), gravelly sands (EGE-3b) and gravel soils (EGE-3c), belong to alluvial medium-Quaternary sand and gravel formations $a(Q_{II\text{-}IV})$. Below the alluvial layer there is eluvia layer of sandy clay loams $e(C_1)$ (EGE-4). Gravelly, gruss and rubble soils of eluvial formations of the weathering crust e(C1) of EGE-5 is widespread on the site and have been found at a depth of 7.0 to 23.0 m. Sedimentary rocks of the Lower Carboniferous (C1) that are represented mainly by sandstones, which are inter bedded with siltstones and mudstones of the same age throughout their entire thickness and serve as a reliable basis for the development of urban construction projects. The highway base soils in zones 1, 2, 3, 5, 6, and 7 are alluvial clayey soils represented by the engineering-geological element EGE 2a, in zone 4 sand layers with the engineering-geological element EGE 3a, and in 8 silty clay zone including alluvial deposits EGE 2d.

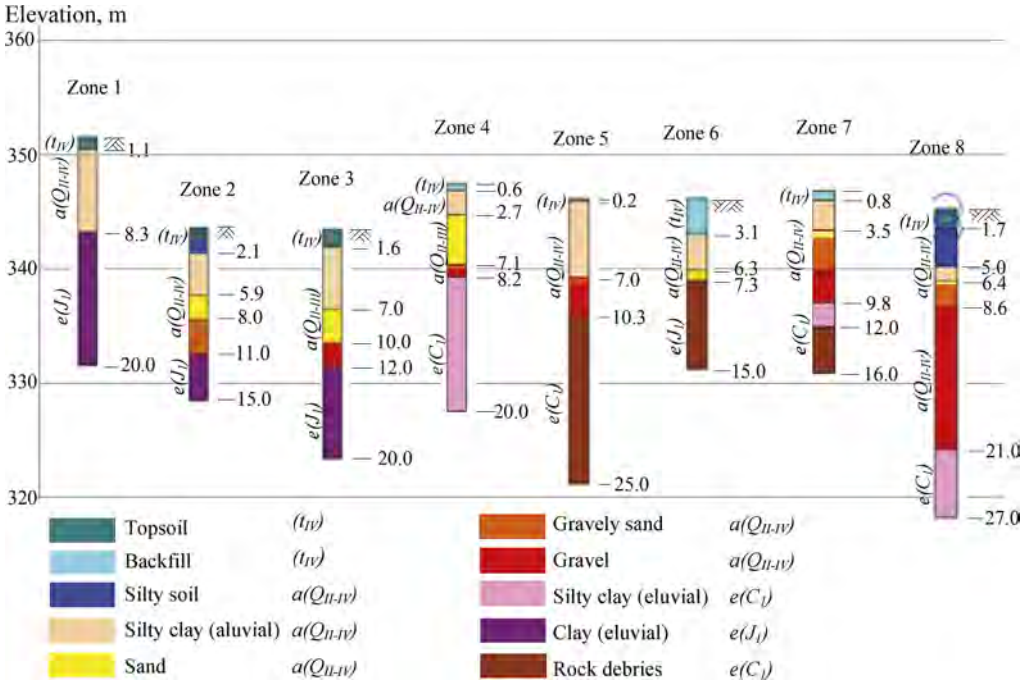

Figure 1. Geotechnical zoning of Astana city.

The constant impact of heavy vehicles and construction equipment further exacerbates the negative impact on the soil base of roads, especially in spring, when the bearing capacity drops tenfold due to the intensive melting of ice in the soil and an increase in its moisture content (Sarsembayeva & Zhussupbekov 2021, Teltayev, & Suppes, 2019). As it became known from previous studies, mass transfer in axially freezing soil significantly depends on the density of dry soil, namely on the porosity coefficient, as well as on the temperature difference between the layers along the height of the soil (Sarsembayeva et al. 2022). And the soils under the road are characterized by greater mass transfer due to lower temperatures in the dense upper layers of asphalt concrete, which are characterized by high thermal conductivity (Sarsembayeva & Collins 2017), and the leveling temperature isoline of the transition through 0° C degrees with soils on both sides of the road (Figure 2).

In order to study in more detail, the changes in the temperature field and also to find a preventive method for steam transfer in soils under the road, field observations of the temperature field in the construction of highways were carried out, and also determined the physical and mechanical properties of soils in the laboratory for further calculation of the volume of water transfer due to cryosuction forces.

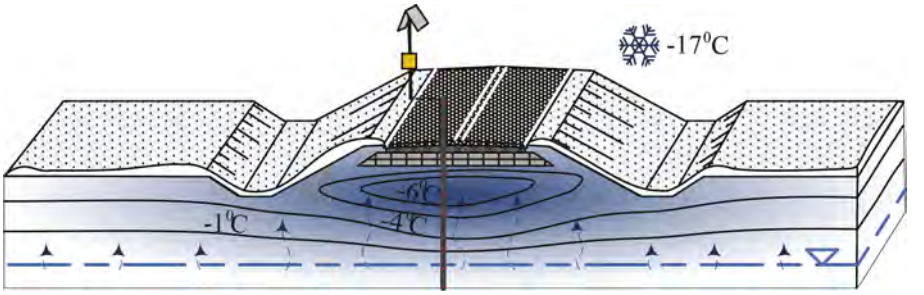

Figure 2. Moisture distribution due to cryosuction forces.

2 METHOD

2.1 *Testing site*

On the section of the road located near the airport of Astana, in the area of the Karkaraly highway, 8 km from the bypass road towards the town of Koshy, sensors were installed at a depth of 3 meters from the road surface to constantly monitor temperature and humidity changes (Figure 3).

Figure 3. Temperature and humidity monitoring station along the road.

The road is located in the 4th zone according to the type of soil in Astana. This means that alluvial loam deposits $a(Q_{II\text{-}IV})$ serve as the sub bases for the road foundation To assess the state of the subgrade and subbase soils, soil samples were taken near the roadside in winter period. According to the results of a laboratory study, the density of the loamy soil was 2.0 g/cm³, the

moisture in the natural state was 20.2%, the soil filtration coefficient for Quaternary loams was 0.01-0.13 m/day. The groundwater level was found at a depth of 2.0 m. Groundwater in this area is assessed as sodium chloride, very hard, slightly alkaline, brackish. In relation to concrete grade B4 on Portland cement, groundwater is non-aggressive and slightly aggressive, in relation to reinforced concrete structures it is moderately aggressive.

Table 1. The physical and mechanical characteristics of foundation soils.

Characteristic	Units	Value at 2 m depth
Moisture content	%	20.2
Liquid Limit	%	27.0
Plastic Limit	%	15.0
Plasticity Index	%	12.0
Consistency index	-	0.5
Bulk density	g/cm³	2.0
Particle density	g/cm³	2.7
Void ratio	-	0.7
Degree of saturation	-	0.8
Deformation modulus	MPa	6.5
Cohesion	kPa	23.5
Angle of internal friction degree	-	22

The road structure is a non-rigid pavement consisting of a 5 cm layer of hot mix asphalt, a bottom layer of a 10 cm thick hot mix porous asphalt concrete pavement, a 12 cm thick top layer of a hot high-porosity asphalt concrete mix, a bottom layer of a gravel-sand mixture 15 cm thick, an underlying layer of gravel-sand mixture 15 cm thick on the compacted base soil (Figure 4).

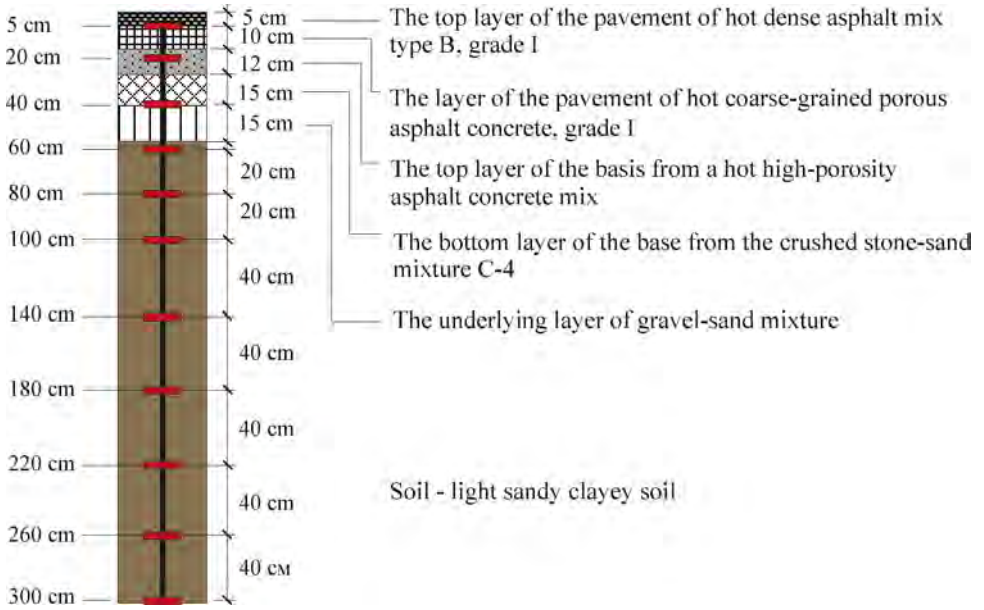

Figure 4. Highway structure and sensors allocation.

Temperature and moisture observations were carried out by automatic measurement by sensors embedded in metal capsules installed at a depth of 0.05; 0.2; 0.4; 0.6; 0.8; 1; 1.4; 1.8; 2.2; 2.6 and 3.0 m from the ground (Figure 2). The frequency of measurements was 1 time per hour.

2.2 *Calculation of mass transfer*

Calculation of the moisture transfer from the base layers upwards the freezing front is based on the measurement of temperature, density and moisture content, and detailed in ENERGIES. The volume of voids in soils is considered a decisive parameter for calculating the volume of steam in each gap and is assumed to be filled with saturated vapour under stable conditions or tending to such a state by sublimation or solidification at negative temperatures. The vapour speed is calculated as a heat transfer over cumulative void channel dimensions, vapour flow density corresponding to the temperature and time:

$$v_{vapour} = \frac{Q}{C \cdot \rho_{vapour} \cdot A_{air} \cdot \Delta T \cdot t} \tag{1}$$

where, – average speed of vapour, cm/h; – heat transfer in a gaseous state, – measured temperature difference, ºC; - C – specific heat of vapour passing through the cumulative air voids cross section, $J/kg \cdot ^oC$; - vapour density corresponding to the temperature, g/cm³; - cumulative cross section of the air voids, cm², corresponding to the porosity coefficient and moisture content; – time, h.

$$m_{ice} = \rho_{vapour} \cdot V_{air\ voids} = \rho_{vapour} \cdot v \cdot t \cdot A_{air} \tag{2}$$

where, - mass of built ice in grams; - is taken as an average density value of the vapour densities at the start and end time point, g/cm³.

3 RESULTS AND DISCUSSION

3.1 *Temperature monitoring*

The results of temperature monitoring showed large amplitude jumps during the day in the upper layers of asphalt concrete (Figure 4). The results are considered on the example of observation in February 2022. During February 13 transitions over 0°C were recorded, but the underlying layers of the gravel sand mixture remained frozen, apparently by compensating for the heat transfer of the underlying cooler layers. In contrast to the asphalt concrete layers,

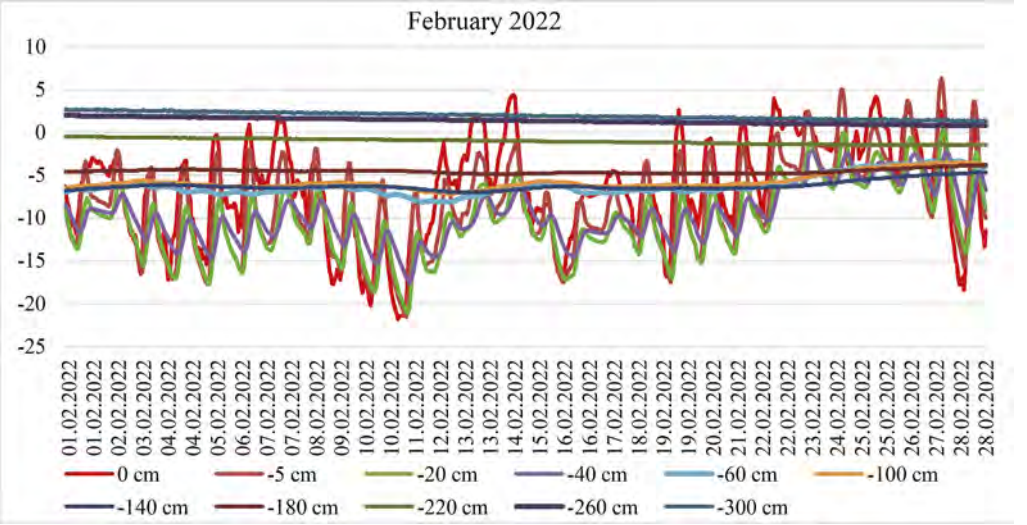

Figure 5. Temperature distribution in Kosshy road, Astana city, Kazakhstan.

which have sharp temperature fluctuations during the day, the temperature of the base soil maintained stable temperature ranges over the month. The relative stabilization of the foundation soils reached from a depth of -0.6 m at negative temperatures in the range of -6 -4°C. The freezing depth continues to steadily increase from 2.20m at the beginning of the month and 2.50 m at the end of February. Minimum air temperature dropped to -21.8 °C, while average temperature was -6.46°C.

3.2 *Moisture change*

Moisture content remained relatively steady in the soil bases except for places of phase transition: freezing and thawing. The decrease in saturated vapor pressure in the pore space in the frozen part caused the migration of moisture in the gaseous state towards the freezing front. The lack of pore pressure (negative pressure) is compensated by vapour migration from the warm part from below.

During the winter months the freezing front fell lower in depth, reaching the greatest freezing point in February (Figure 5). The difference from 21 to 11 % between the layers of 60 cm and 100 cm in November indicated freezing and an urgent solidification of moisture in the frozen part. In December freezing front occured at a depth of 100 cm and is accompanied by a drop in humidity in the pore space from 19 to 15%. And in January, freezing occurs at a depth of 140 cm and 180 cm, as evidenced by a drop in humidity from 21 and 23%, respectively, to 17% in a frozen state. During February, there is a decrease in humidity at a depth of 2.20 m, which means freezing of this layer.

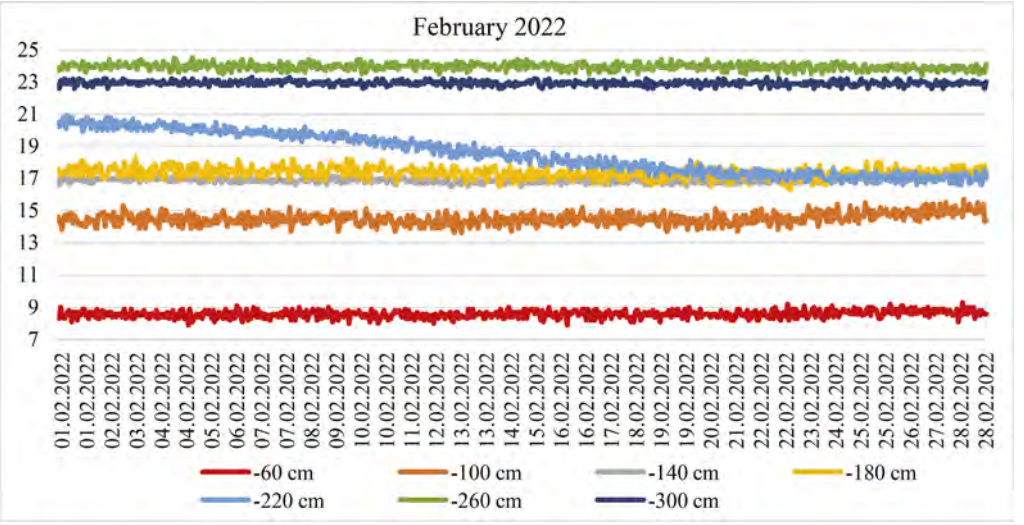

Figure 6. Temperature distribution in Kosshy.

Calculation of vapor migration from warmer to frozen layers according to the method described in (Sarsembayeva et al. 2022), defined that water mass transfer in a form of vapour is $1.44 \cdot 10^{-4}$ g/h per 1 dm3 of soil at with temperature fluctuations -5-8 °C. The rate of passage of vapour towards the freezing front in the light sandy clayey soil was 0.467 m/h. So, for 1 hour in 1 m³ of subgrade at a temperature of -5-8°C at a depth of -60-160 cm from the road surface due to the transfer of moisture from warmer soil layers, 0.144 g of ice is formed, and per day this amount is 3.46 g of ice. And since the freezing of the ground base in winter in Astana lasted 132 days, it can be assumed that during this time only due to the migration of water in a gaseous state, each 1 cubic meter of the road base in zone 4 collected 456.72 g of ice, which increases the moisture content of the soil up to 40% or more, which will significantly reduce the bearing capacity of the road during the spring thaw (Sarsembayeva & Collins 2017).

4 CONCLUSIONS

Thus, considering the above results of the study conducted in the 4th zone of the city of Astana, it was found that the effect of water transfer in frozen soils is greatly underestimated, and an additional layer of vapor barrier is needed to prevent the accumulation of ice lenses under the pavement structure.

1. The upper layers of asphalt concrete were subjected to 8 to 14 transitions through 0°C per month, while the temperature of the crushed stone-sand mixture at a depth of -37 cm remained stably frozen.
2. The base soils, located at a depth of -60 cm, consisting of light sandy loamy clay soils at a temperature of -5-8 ° C were the main zone of moisture accumulation in the form of ice.
3. The freezing of the clayey soil layer at the base of the highway was accompanied by a sharp drop in the humidity of the pore space from 21-23 to 11-14 %, due to the fact that part of the water in the gaseous state was sublimated, forming a negative cryosuction pressure in these layers.
4. Taking into account the physical and mechanical characteristics and the state of the soil base of this particular road it is proposed to lay an additional layer of vapor barrier over the soil base at a depth of -60 cm to prevent a migration in the form of vapour. Such isolation would decrease the heat conductivity in the soil subgrade but also prevent a water mass transfer from the adjacent soils to the highway subbase, thus the loss of bearing capacity during the spring thaw will be reduced.
5. The calculation of the mass transfer of water in the form of steam determined that 1.44 10^{-4} g/h is formed in the frozen layer per 1 dm3 of soil at temperature fluctuations of -5-8 °C. The rate of vapor transfer towards the freezing front in the soil was 0.467 m/h.
6. Freezing of the ground base during 132 days of the winter period in Astana leads to the formation of 456.72 g of ice due to the migration of water in the gaseous state in each 1 m3 of soil, which increases the humidity by 40% or more and significantly reduces the bearing capacity of the road during the spring thaw.
7. As a solution to the problem of water migration in the form of vapour, it is proposed to lay an additional layer of vapor barrier over the soil base at a depth of -60 cm.

ABSTRACT: The temperature and moisture at the points of a highway pavement and subgrade were measured by means of a special measurement system. By analyzing the results obtained, the peculiarities of temperature and moisture changes at different depths in the summer warmest and winter coldest days of years were established. The rates of freezing and thawing, the depth of freezing were determined. A comparative analysis of changes in air, the pavement and subgrade temperatures has been carried out.

1 INTRODUCTION

Main structural parts of a highway - pavement and subgrade for a very long period (for several decades) continuously operate under difficult conditions of the combined effects of mechanical, hydrological, weather-climatic and other factors (Ivanov et al. 1973, Yoder & Witczak 1975, Zolotar et al 1971, Huang 2004). In our opinion, the influence of weather-climatic and hydrological factors on the state, and therefore on the strength and durability of highways, has not been studied enough. This problem is especially relevant for many countries of the world, including Kazakhstan, which have a large territory with a wide variety of weather, climate and hydrological conditions.

Properties of many road materials and soils are highly dependent on temperature and moisture (Papagiannakis & Masad 2008, Teltayev & Radovskiy 2016). Their characteristics can change significantly during the cold period (Tsytovich 1973, Teltayev & Radovskiy 2016, Sarsembayeva & Zhussupbekov 2021, Sarsembayeva et al. 2022). These features of the behavior of road materials and soils should be taken into account when designing pavements for highways (SP RK 2015).

In Kazakhstan, since 2009, studies of temperature and humidity in pavements and subgrade of highways have begun (Teltayev & Aitbayev 2015, Teltayev et al. 2015, Teltayev & Suppes 2017a, Teltayev & Suppes 2017b, Teltayev et al. 2018, Teltayev & Suppes 2019a, Teltayev & Suppes 2019b, Teltayev et al. 2020, Teltayev et al. 2022).

This article is a continuation of these works and contains some results of temperature and moisture monitoring in pavement and subgrade of a highway located in Western Kazakhstan.

2 EXPERIMENTAL

2.1 *Test section of highway*

The site where the measuring system for long-term monitoring of temperature and moisture is installed is located at the 5th kilometer (km 4+700) of the "Zhetibai-Zhanaozen" highway

DOI: 10.1201/9781003299127-410

(Mangistau region). The highway has four traffic lanes. The width of the carriageway is 15 m (4x3.75 m). Shoulder width: 2x3.75 m. Reconstruction of the highway completed in 2020.

The pavement structure on the site consists of the following layers: stone mastic asphalt concrete (SMA) - 5.5 cm; coarse-grained porous asphalt concrete - 10 cm; coarse-grained highly porous asphalt concrete - 14.5 cm; a mixture of crushed stone and sand - 18 cm; a mixture of gravel and sand -20 cm. The total thickness of the pavement is 68 cm.

The highwaysubgrade and its natural soil base consists of the following soils: dusty sandy loam - 0.55 m; sandy loam - 1.20 m; sandy loam silty gruss - 1.80 m.

On the experimental section, the highway passes through an embankment with height 1.52 m. Groundwater is located deep (below 4 m).

2.2 *System for measuring temperature and moisture*

The system used for temperature and moisture was invented and assembled at the Kazakhstan Highway Research Institute. It consists of above-ground and underground parts. Its above-ground part is a vertical mast, on which are located electronic units for storing and transmitting measured values of temperature and moisture, two solar panels and a battery; the underground part of the measuring system includes temperature and moisture sensors, cables for transmitting measured temperature and moisture values to the electronic storage and transmission units.

Temperature and moisture sensors are installed at the points of the pavement, subgrade and natural soil base at the following depths from the SMA surface: 3 cm; 12 cm; 20 cm; 45 cm; 60 cm; 90 cm; 130 cm; 180 cm; 240 cm; 300 cm and at a height of 200 cm from the SMA surface.

3 RESULTS AND DISCUSSION

3.1 *Temperature on a hot day*

Figure 1 shows graphs for changes air temperature and temperature at points of the pavement and subgrade on the hottest summer day in 2022 (July 18-19, 2022). Analysis of the graphs revealed that:

- daily temperature fluctuations occur only in the upper part of the pavement (45 cm); at points located below the temperature practically does not change in the daily cycle;
- in the asphalt concrete layers (up to 20 cm) the daily temperature fluctuation is almost harmonic; the nature of the daily change in air temperature is also harmonic;
- about 11 o'clock in the morning air temperature and temperature of the asphalt concrete layers (up to 20 cm) are approximately the same and equal to 36-37 °C;
- the maximum temperature of the pavement of SMA (at a depth of 3 cm), equal to 54.5 °C and taking place at 17-18 hours in the afternoon, is noticeably higher than the maximum air temperature, equal to 44.3 °C;
- as expected, in the daily cycle the highest values of air temperature and temperature in the asphalt concrete layers occur from the second half of the day to midnight, and the lowest temperatures are noted from midnight to morning; the minimum daily values of air temperature and temperature of SMA (3 cm) are 24.5 °C and 32.1 °C respectively; changes in air temperature and temperature of SMA layer on the hottest day equal to 18.1 °C and 22.4 °C respectively.

3.2 *Temperature on a cold day*

Figure 2 shows graphs of changes in air temperature and temperature at the points of the pavement and subgrade on the coldest winter days of 2021 and 2022 (December 26-27, 2021).

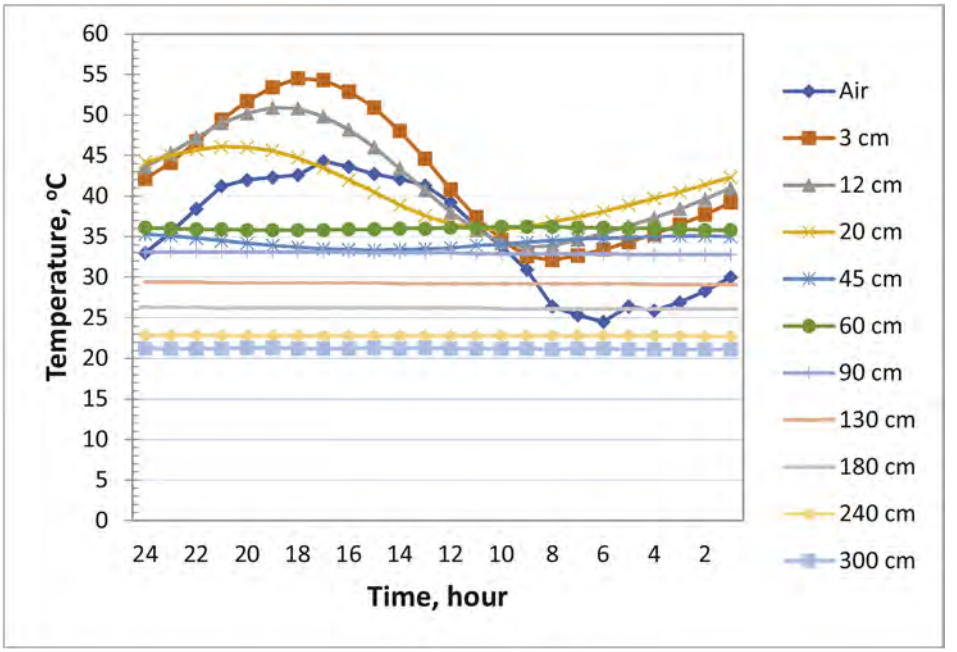

Figure 1. Graphs for changes air temperature and temperature at points of the pavement and subgrade on the hottest summer day in 2022 (July 18-19, 2022).

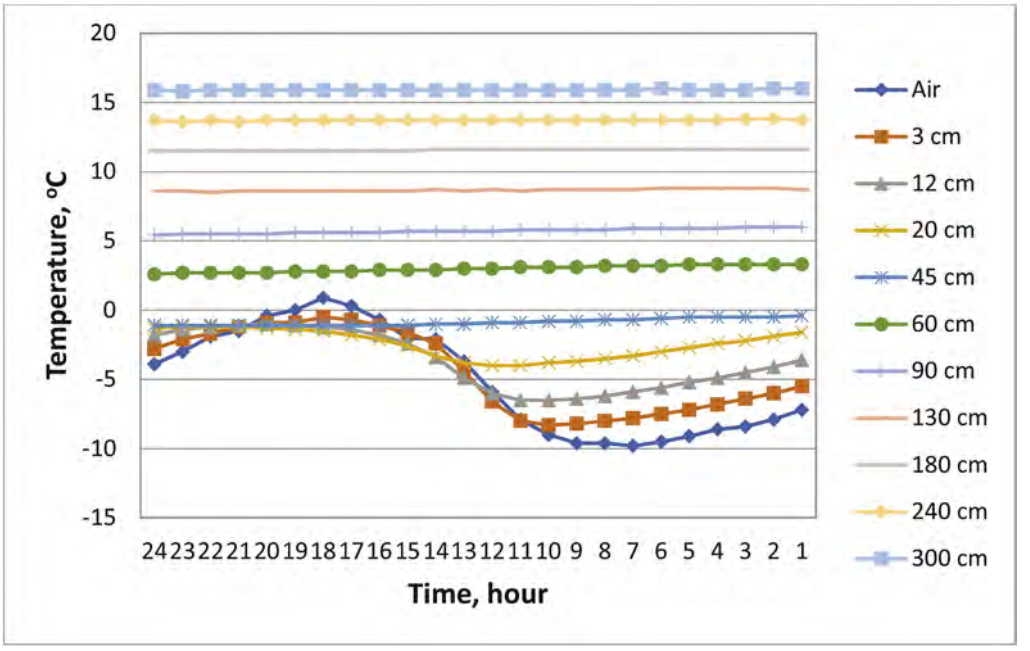

Figure 2. Graphs for changes air temperature and temperature at points of the pavement and subgrade on the coldest winter day in 2021 and 2022 December 26-27, 2021).

It can be seen from this figure that on the highway section under consideration, on the coldest winter days, the temperature in the pavement changes only in its upper part; at depths of

45 cm and 20 cm the daily temperature change was only 0.7 °C and 2.8 °C respectively. It has been established that:

– from 13:00 to 24:00 air temperatures and temperature in the asphalt concrete layers (up to 20 cm) are very close and range from 0.9 °C to -3.9 °C; At 7 o'clock in the morning the air temperature dropped to -9.8 °C; the lowest temperature of the asphalt concrete layers at depths of 3 cm, 12 cm and 20 cm was -8.3 °C (at 10 a.m.), -6.5 °C (at 10 a.m.) and -4.0 °C (at 11 a.m.), respectively; Thus, it can be assumed that in the daytime air temperatures and temperature in the upper part of the asphalt concrete layers are the same, and at night the upper part of the asphalt concrete layers is 2-6 °C warmer than the air.

3.3 *Freezing depth*

Information on freezing and thawing of the pavement on the site is presented in Table 1. Analyzing these data, it was found that:

– freezing started approximately in the middle of the first decade of November;
– the maximum freezing depth was 46 cm, which was reached at the end of January; it is important to note here that the maximum freezing depth does not exceed the thickness of the pavement layers of stable materials (asphalt concretes, a mixture of crushed stone and sand);
– average freezing rate was 1.16 cm/day;
– bottom-up thawing began approximately at the end of the second decade of January, and downward thawing began approximately in the middle of the third decade of March;
– the average thawing rate was 0.49 cm/day.

In the observed cold period, freezing of pavement occurred almost 2.5 times faster than thawing. This fact can be explained by the rapid onset of the cold period and slow warming in the spring.

3.4 *Moisture*

Graphs of changes in air moisture and moisture in the points of the pavement, subgrade and natural soil base in the hottest summer day of 2022 (July 18-19, 2022) and in the coldest winter day of 2021 and 2022 (December 26-27, 2021) are shown in Figures 3 and 4 respectively. It turned out that inthe hot summer day air moisture varies greatly in the daily cycle (from 22.1% at 17:00 in the afternoon to 52.6% at 6:00 in the morning, i.e., almost 2.5 times); the lowest moisture occurred in the period from 13:00 to 17:00, i.e. during the hottest period of the day, and the highest moisture was noted in the period from 2 to 8 hours, i.e. in the second half of the night and in the morning, when the air is relatively cool. Despite the strong change in air moisture in the hot summer day, its maximum daily value was only 52.6%.

In contrast to the hot summer day, in the cold winter day the air is saturated with moisture, the maximum value of air moisture reaches 100%. During most of the day air moisture has

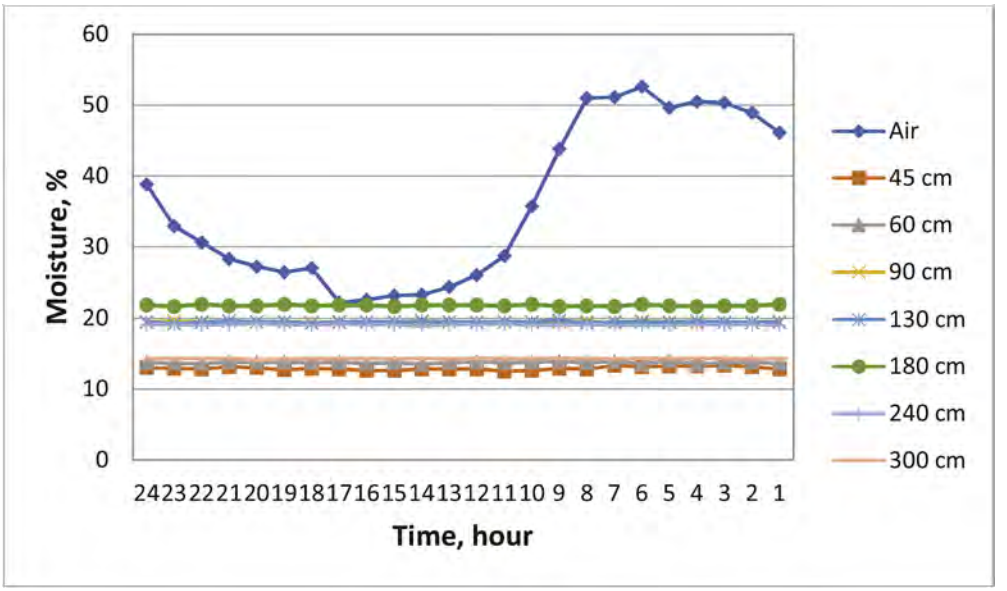

Figure 3. Graphs for changes air moisture and moisture at points of the pavement and subgrade on the hottest summer day in 2022 (July 18-19, 2022).

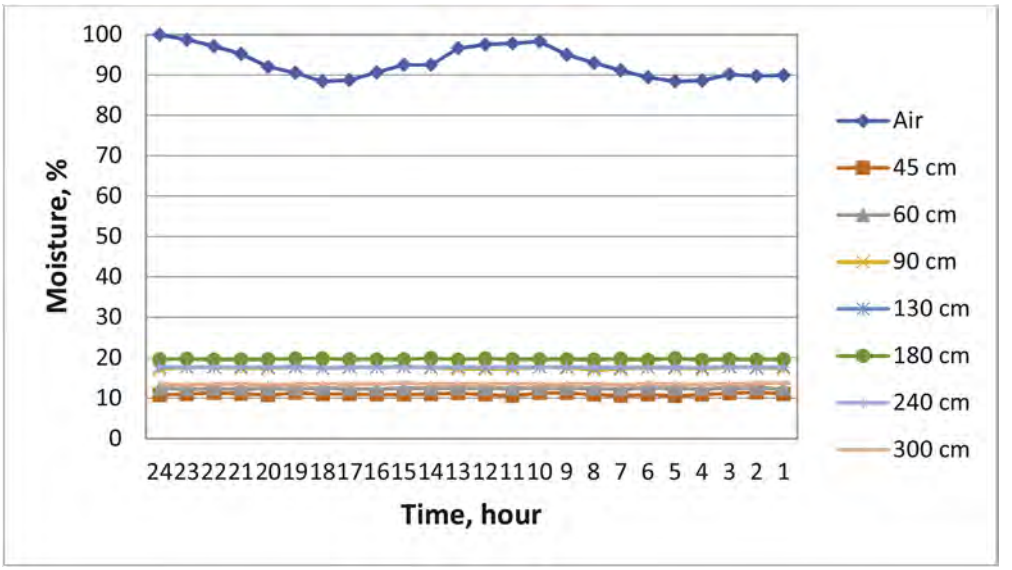

Figure 4. Graphs for changes air moisture and moisture at points of the pavement and subgrade on the coldest winter day in 2021 and 2022 December 26-27, 2021).

a value ranging from 90 to 100% and changes slightly during the day (from 88.4% to 100%, i.e. 11-12%).

The values of moisture at the points of the pavement, subgrade and soil base in the considered summer and winter days are given in Table 2.

Figures 3 and 4 and Table 2 show that:

– moisture in the points of the pavement, subgrade and soil base in the summer and winter days does not change in daily cycles;

Table 2. The values of moisture at the points of the pavement, subgrade and soil base in the considered summer and winter days.

Depth, cm	Moisture,%	
	summer	winter
45	12,8	10,9
60	13,9	12,4
90	19,4	17,2
130	19,4	17,7
180	21,8	19,6
240	19,1	17,7
300	14,3	13,5

- character of moisture distribution by depth in summer and winter is the same: the lowest values (11-14%) occur at depths of 45-60 cm (in pavement layers) and 300 cm, and the highest values (18-22%) are noted at depths of 90 -240 cm (subgrade and soil base);
- in the all points the moisture in winter is only 1.5-2.0% less than in summer;
- at a depth of 300 cm the summer and winter moisture values are almost equal: 14.3% and 13.5% respectively, i.e. the difference is only 0.8%; this shows that groundwater does not affect the distribution of moisture in the structural parts of the highway.

4 CONCLUSION

1. In the hot summer day in asphalt concrete layers of the pavement (up to 20 cm) temperature changes harmonically; the maximum values of air temperatureand temperature inthe upper asphalt concrete layer (depth of 3 cm) reached 44.3 °C and 54.5 °C respectively; daily temperature fluctuations occur only in the upper part of the pavement (up to 45 cm); 1n points located below the temperature does not change in the daily cycle.
2. In a cold winter day a noticeable temperature change occurs only in the upper part of the pavement (up to 20 cm); the minimum temperatures of air and in the upper asphalt concrete layer (depth of 3 cm) reached -9.8 °C and -8.3 °C, respectively.
3. The maximum freezing depth is 46 cm, i.e. 22 cm less than the total thickness of the pavement; the average freezing and thawing rates are 1.16 cm/day and 0.49 cm/day, respectively.
4. In the hot summer and cold winter days the moisture in the points of the pavement, subgrade and natural soil base does not change in daily cycle; distribution of moisture on depth in the summer and winter is qualitatively and practically quantitatively the same: moisture in the pavement base layers(45-60 cm) and in subgrade and soil base (90-240 cm) is in the range of 11-14% and 18-22% respectively.

Enhancing road infrastructure in Kazakhstan with modified sulfur and low-strength inert materials

A.U. Nugmanova & A.O. Yelshibayev
JSC Kazakhstan Highway Research Institute, Astana, Kazakhstan

ABSTRACT: The Republic of Kazakhstan has been working to improve its road infrastructure by using modified sulfur to strengthen low-strength inert materials, such as limestone-shell rock. This study aims to provide an overview of the existing research on this topic, highlighting the chemical modification of sulfur, the properties of low strength inert materials, and the potential applications of sulphurous stone in the construction industry.

Sulfur has been identified as a promising binder for composite materials due to its abundance, low cost, and unique physical properties (Youssef et al., 2015). However, in its elemental form, sulfur exhibits poor mechanical properties and low resistance to environmental factors, which limits its applications in construction materials (Yildirim & Şimşek, 2019). To overcome these limitations, researchers have focused on the chemical modification of sulfur using various organic modifiers, such as epoxy resins and unsaturated compounds (Zhang et al., 2017; Xie et al., 2018). These modifications have been found to improve the physical and mechanical characteristics of sulfur, resulting in a binder with increased strength, durability, and resistance to external factors (Youssef et al., 2015; Yildirim & Şimşek, 2019). Limestone and shell rock are examples of low strength inert materials that have been explored as potential substrates for sulfur-based binders. These materials are characterized by their low strength and porosity, which can be advantageous when combined with a sulfur binder due to the impregnation of the sulfur into the porous structure, resulting in improved strength and durability (Youssef et al., 2015). Additionally, limestone and shell rock are abundant and inexpensive, making them an attractive option for large-scale construction applications (Yildirim & Şimşek, 2019).

The combination of modified sulfur and low strength inert materials has been shown to produce a high-strength composite material, referred to as "sulphurous stone" (Youssef et al., 2015). The impregnation of sulfur into the porous structure of limestone or shell rock, along with the chemical modification of sulfur, results in a composite material with improved mechanical properties, such as increased compressive strength, flexural strength, and resistance to external factors (Yildirim & Şimşek, 2019; Zhang et al., 2017). Additionally, sulphurous stone has been shown to exhibit low water absorption and excellent resistance to freeze-thaw cycles, making it a suitable material for use in various construction applications (Youssef et al., 2015).

1 ADVANTAGES OF USING MODIFIED SULFUR IN ROAD CONSTRUCTION

1. Enhances the strength of low-strength inert materials: Modified sulfur has the potential to increase the strength of materials like limestone-shell rock, making them more suitable for road construction.
2. Environmental benefits: Sulfur is a byproduct of the petroleum industry, and utilizing it in road construction can help to reduce waste and improve the environmental situation.

DOI: 10.1201/9781003299127-411

3. Economic benefits: The use of modified sulfur in road construction can lead to an increase in the service life of pavements and a more efficient use of funds allocated for road maintenance.

2 SAMPLING OF ROAD BUILDING MATERIALS

Limestone-Shell Rock: This environmentally friendly, natural, low-cost material is abundant in the West Kazakhstan region. The characteristics and prevalence make it an ideal choice for road infrastructure. Sampling was carried out at a quarry in Aktau, Karakiya district, Zhetybai village (Figure 1). Tests were carried out in accordance with ST RK 1213-2003 to determine grain composition, crushability, abrasion, water absorption, frost resistance, and compressive strength.". The material, shell rock, was sampled at an air temperature of 35°C, in clear weather, in the amount of 140 kg.

Figure 1. Quarry LLP "Zhetybay-Dostyk".

Modified Sulfur: This material was sampled at the Tengiz oil field in the west of Kazakhstan, following GOST 127.3-93 guidelines for sampling and preparation of samples. It was provided to JSC "KazdorNII" in two bags of 50 kg each for determining physical and mechanical properties. With a low melting point and melt viscosity, solid crystalline sulfur has sufficient mechanical strength, hydrophobicity, and water resistance. The sulfur melt can penetrate deeply into the capillaries of materials and form a new material with an interpenetrating structure upon crystallization. Sampling of modified sulfur is carried out from vehicles, gondola cars, barges (Figure 2).

Figure 2. Sampling of modified sulphur.

3 DETERMINATION OF STANDARD PHYSICAL AND MECHANICAL CHARACTERISTICS OF ROAD BUILDING MATERIALS

Tests to determine the physical and mechanical properties of limestone-shell rock were carried out in accordance with ST RK 1213-2003 "Crushed stone from gravel from dense rocks and industrial waste for construction work. Methods of physical and mechanical tests". The following tests have been carried out in accordance with this standard:

1) Determination of the grain composition - by sieving the sample on a standard set of sieves. The results of this test are shown in Table 1.

Table 1. Grain composition of limestone - shell rock, fr. 5-20 mm.

	Sieve size, mm						
	20	15	12.5	10	7.5	5	< 5
Retained mass, g	742	668	526	368	1072	1064	560
Retained mass, g	14.8	13.4	10.5	7.4	21.4	21.3	11.2
Total total mass, %	14.8	28.2	38.7	46.1	67.5	88.8	100
Full passes, %	85.2	71.8	61.3	53.9	32.5	11.2	

2) Determining the crushability of crushed stone according to the degree of grain destruction during compression (crushing) in the cylinder. The crushability was determined with an accuracy of 1%. The results of this test are shown below:
   - Weight loss of crushed stone when tested in a dry state -34.2%, grade - 200.
   - Mass loss of crushed stone when tested in a water-saturated state - 43.5%, grade - 200.
3) The determination of crushed stone abrasion by grain mass loss was carried out in a shelf drum with balls. For crushed stone with a fraction of 10-20 mm, the number of cast-iron balls required for testing is 11 pcs, the number of revolutions of the shelf drum is 500 s. The weight loss during the test is 56.7% by weight, which corresponds to the I-4 type.
4) Determination of water absorption by comparing the mass of crushed stone samples in a state saturated with water and after drying. Crushed stone samples were placed in a vessel with water at room temperature so that the water level in the vessel was at least 20 mm higher than the top of the crushed stone sample. Water absorption is determined by the formula specified in ST RK 1213-2003 (section 4.18). The result obtained is 7.1% by weight.
5) Determination of frost resistance of crushed stone by weight loss of the sample during alternate freezing and thawing.
   The duration of the crushed stone freezing cycle in the chamber at a steady temperature of minus 18°C is 4 hours. After that, the vessel with crushed stone, placed in a bath with running water with a temperature of (20 ± 5) ° C, was kept in it until the crushed stone was completely thawed. The following results were obtained from this test: number of cycles 25; weight loss 5.6%; the corresponding grade for this limestone - shell rock F 25.
6) Determination of the compressive strength of the rock and bringing samples (cubes or cylinders) to destruction on a press. From the selected rock sample, using a stone-cutting machine, two samples were made in the form of a cube with an edge of 40–50 mm. The results of this test are shown in Table 2.

Table 2. Results of determining the compressive strength of shell rock.

Name	a, mm	b, mm	P, N (kgf)	R_f, MPa
Porous	5.82	5.75	565	1.7
Dense	5.67	5.67	1782	5.5
The arithmetic mean value of the shell rock				3.6

The sample was placed in the center of the press base plate. The load on the sample during testing should increase continuously and evenly at a rate of 0.5 MPa (5 kgf / cm ^{2}) per second, the destruction of the sample is shown in Figure 3.

Sulfur has low melting point (112.8-119.3°C) and melt viscosity ($6.5 \cdot 10^{-3}$ Pa·s). In solid crystalline form, sulfur has sufficient mechanical strength, hydrophobicity, water resistance (Table 3).

Figure 3. Destruction of the sample when determining the ultimate compressive strength.

Table 3. Physical and mechanical properties of sulfur.

The amount of sulfur, wt.%	Density, kg/m ^{3}	Water absorption, wt.%	Compressive strength, MPa
99.99	1.73	0.15	12.00

The sulfur melt is able to penetrate deeply into the capillaries of materials and, in the process of crystallization upon cooling, is firmly connected to the matrix, forming a new material with an interpenetrating structure.

Development of a technology for the impregnation of substandard inert materials with a melt and/or solution of sulfur to obtain high-strength "sulphurous stone"

Over the past few decades, there have been numerous advances in the synthesis of new types of sulfur-containing polymers and the modification of the properties of some important classes of polymers by adding sulfur moieties or polysulfides to polymer compositions. To obtain sulfur composite materials, stabilized polymeric sulfur is required. There are a large number of developments of methods for stabilizing polymeric sulfur. The use of sulfur as a binder in composite materials requires giving it a number of additional properties due to chemical modification. Chemical modification is carried out by reacting sulfur in the melt with various organic modifiers.

To modify sulfur, first, elemental sulfur was heated to 150-190 °C while stirring with a stirrer, then 0.5-1.5 g of sodium sulfate was added to the sulfur solution, the solution was stirred for 10 minutes. Next, epoxy resin was added, heated to a temperature of 170-180 °C, after stirring for 30 minutes, the first sample was taken, after 60 minutes - the second sample.

The reason for preheating the epoxy resin to 170-180 ºC is to increase the reactivity, this starts the boiling process and the formation of steam on the surface layer, which is able to react with the melt containing sulfur and sodium sulfate. This whole mixture is heated to 150 ºC and stirred, samples are taken after 30 and 60 minutes, the samples are shown in Figure 4. The resulting melt, as shown in the figure, is a non-contact polymerized mass of bright yellow color.

Figure 4. Sulfur modified with epoxy and sodium sulphate.

Structural (microscopic) analysis of sulfur melts.

To study the surface structure of the sulfur melt, the FLU.02.3201LED4 epifluorescence microscopy method was used.

Figure 5 shows an image of sulfur and its modified melt under the same conditions and on the same scale for comparison with each other. Figure 5(A) shows an image of elemental

Figure 5. Microscopic image of elemental sulfur (A) and its melt (B).

sulfur as a starting material. The structure of its surface showed that the particle size is small, large particles are marked with circles and an ellipse. Figure 5(B) shows a sulfur melt modified at 150 °C and, as can be seen from the figure, the melt particles are larger in size than in elemental sulfur. They are marked with elliptical and circular lines. Due to the addition of modifiers, the particle size becomes larger because of crosslinking and polymerization of sulfur.

Chemical modification is carried out by reacting sulfur in the melt with various organic modifiers. Unsaturated compounds, such as cyclic diene hydrocarbons, oleic acid, epoxy resin, and their oligomers, are the most widely used as modifiers.

To accelerate the process of interaction of elemental sulfur with the modifier, it is necessary to use initiating additives. Since sulfur reacts with epoxy resin under rather harsh conditions (170-180 °C), it is necessary to use physical and chemical methods of initiation. For the preparation of crushed sulfur, pre-washed and heated shell rocks in an oven at 160-200 °C for about 1 hour are introduced into the finished melt of modified sulfur and mixed for up to 30 and 60 minutes. The obtained samples of sulfur stone are dried for 24 hours at room temperature.

Laboratory study of crushed sulfur from industrial waste. Determination of the physical and mechanical properties of the obtained sulfur stone

Impregnation of limestone-shell rock with a melt or a solution of modified sulfur makes it possible to improve the physical and mechanical properties of substandard inert materials. Modified sulfur with resin and styrene was used to process crushed stone (Figure 6).

Figure 6. Crushed stone modified with resin (a); crushed sulfur stone modified with styrene (b).

In accordance with ST RK 1213-2003, the following results were obtained:

1) Determination of grain composition. The results are shown in Table 4 - for resin-modified crushed stone and in Table 5 - for modified sulfur stone styrene.
2) Determination of crushability of crushed stone by the degree of destruction of grains during compression (crushing) in the cylinder. The crushability was determined with an accuracy of 1%. The test results are shown below: the mass loss of crushed stone modified with resin, when tested in a dry state, is 17.65%, which corresponds to the grade - 600; the weight loss of crushed stone modified with styrene, when tested in a dry state, is 13.66%, which corresponds to a grade of 800.
3) The determination of the abrasion of crushed stone by the loss of mass of grains was carried out in a shelf drum with balls. According to this test, the weight loss for crushed sulfur stone modified with resin is -32%, which corresponds to grade I-2, the weight loss for crushed sulfur stone modified with styrene is -25%, corresponds to grade I-1.

Table 4. Grain composition of crushed stone modified with resin, fr. 5-20 mm.

	Sieve size, mm						
	20	15	12.5	10	7.5	5	< 5

Full passes, %	84.3	72.1	61.4	53.6	30.8	8.1	0

Table 5. Grain composition of crushed stone modified with styrene, fr. 5-20 mm.

	Sieve size, mm						
	20	15	12.5	10	7.5	5	< 5
Retained mass, g	815	620	558	401	1109	1026	471
Retained mass, %	16.3	12.4	11.2	8.0	22.2	20.5	9.4
Total mass, %	16.3	28.7	39.9	47.9	70.1	90.6	100.0
Full passes, %	83.7	71.3	60.1	52.1	29.9	9.4	0

4) Determination of water absorption by comparing the mass of samples of sulfur stone in a state saturated with water and after drying. By determining the water absorption of sulfur stone, the following results were obtained: water absorption of crushed stone modified with resin - 4.9% by weight; water absorption of crushed stone modified with styrene - 1% by weight.
5) Determination of frost resistance of crushed stone by weight loss of the sample during alternate freezing and thawing. According to this test, the following results were obtained for resin-modified crushed stone: number of cycles - 25; weight loss - 8.5%; the corresponding grade for this sulfur stone is F 25, whereas for crushed stone modified with styrene: number of cycles - 50; weight loss - 4.9%; the corresponding grade for this sulfur stone is F 50.
6) Determination of the compressive strength of crushed stone and bringing samples (cubes) to destruction on a press. The results of this test are shown in Table 6.

Table 6. Results for determining the compressive strength of crushed stone.

Name	a, mm	b, mm	P, N (kgf)	$R_{f,}$ MPa
Crushed stone modified with resin	50	50	16.42	6.6
	50	50	14.50	5.8

Crushed stone modified with styrene	50	50	21.31	8.5
	50	50	20.85	8.3
Arithmetic mean				8.4

To determine the physical and mechanical properties of raw and processed substandard low-strength limestone-shell rock (crushed stone), tests were carried out to determine the indicators of crushability, abrasion, water absorption, frost resistance and tensile strength of cubic samples. Based on the test results, when treating limestone-shell rock with modified sulfur, the indicators of physical and mechanical properties improve. The test results are shown in comparative Table 7.

Determination of radioactivity, chemical composition and harmful impurities in mineral materials.

Table 7. Comparative analysis of the test results of untreated and processed substandard low-strength shell limestone modified with sulfur.

The name of indicators	In original state	treated with modified sulfur	
Breakability of crushed stone according to the degree of destruction of grains during compression (crushing) in the cylinder, brand	200	resin 600	styrene 800
Abrasion of crushed stone according to the loss of mass of grains in the shelf drum with balls, brand	I-4	AND 2	I-1
Water absorption by comparing the mass of crushed stone samples in a state saturated with water and after drying, %	7.1	4.9	1
Frost resistance of crushed stone in terms of sample mass loss during alternate freezing and thawing, grade	F 25	F 25	F 50
Ultimate strength of the rock in compression and bringing samples to failure, MPa	3.6	6.2	8.5

In order to compare the chemical compositions of sulfur melts modified with epoxy resin with sulfur melts modified with styrene, the elemental composition of modified sulfur was determined by XRF, the results of which are presented in Table 8.

Table 8. Results of X-ray fluorescence analysis of the sulfur melt modified with epoxy resin.

Element	Relative concentration, %
Al	0.201
P	0.179
S	77.97
Ca	0.235
Fe	0.002

As can be seen from the table, the sulfur content in the sulfur melt modified with epoxy resin was 77.97%. In addition, elements such as Al, P, Ca, Fe can be present in a very small amount in the melt. Basically, this sulfur melt contained 98.0% pure sulfur, which decreased to 77.97% due to its polymerization. An x-ray of this sulfur melt can be seen in the following Figure 7.

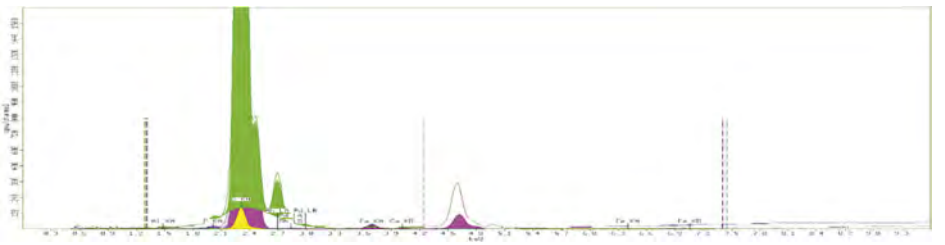

Figure 7. X-ray pattern of the molten sulfur modified with epoxy resin.

Together with the sulfur melt modified with epoxy resin, an X-ray phase analysis of the sulfur melt modified with styrene was carried out. The results of X-ray fluorescence analysis of the styrene-modified sulfur melt are shown in Table 9.

Table 9. Results of X-ray phase analysis of sulfur melt modified with styrene.

Element	Relative concentration, %
Al	0.178
P	0.177
S	63.938
K	0
Ca	0.242
Fe	0.002
Pd	0
Ag	0.019
CD	0
In	0.006

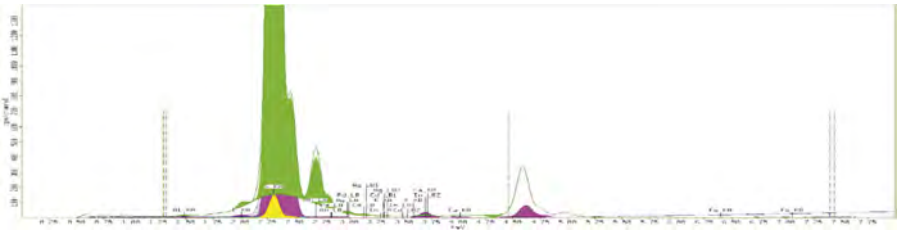

Figure 8. X-ray pattern of styrene-modified sulfur melt.

The sulfur content in the styrene-modified sulfur melt was 63.938%. This is less than the amount of sulfur that was in the sulfur melt modified with epoxy resin. Basically, the composition of this sulfur melt consisted of 97.5% pure sulfur, the amount of which decreased to 63.938% due to the fact that most of it is involved in polymerization. This melt also contains a small amount of the elements Al, P, Ca, Fe, Ag, and In. An x-ray of this sulfur melt can be seen in the following Figure 8. Before measuring radioactivity, samples are monitored at a temperature of 23 °C, air humidity 61% (sulfur, modified sulfur, shell rock, sulfur gravel) using a dosimeter-radiometer MKS-AT6130. All samples showed 0.12 μSv/h (Figure 9), which does not exceed the value of the natural natural gamma background (Limit from 0.07 to 0.20 μSv/h in Kazakhstan).

Figure 9. Dosimetric control of samples.
a- sulfur, b - modified sulfur, c - shell rock, d - crushed stone

4 DISCUSSION

According to the results of tests of limestone-shell rock, the following indicators were obtained: the grain composition of limestone - shell rock corresponds to a fraction of

5-20 mm; crushing strength in compression in the cylinder of a fraction of 10-20 mm in the dry state - 34.2% (weight loss), in the water-saturated state -43.5%, which correspond to the -200 grade; abrasion in the shelf drum was -56.7%, which corresponds to the brand - I1; water absorption by weight was 7.1%; frost resistance (freeze-thaw method), weight loss after 25 cycles is 5.6%, which corresponds to the F 25 brand; compressive strength: porous structure of the shell rock - 1.7 MPa; the dense structure of the shell rock is 5.5 MPa.

The main physical and mechanical properties of sulfur according to the test data obtained showed that the sulfur content is 99.99%, the color is yellow, the density is 1.73 kg/m 3, water absorption is 0.15% by weight, compressive strength is 12 MPa.After stirring the mixture for 30 minutes, the first sample was taken, after 60 minutes - the second sample. As the melting point of sulfur rises, it can be seen that the color of its modified melt changes from light yellow to burgundy. Analysis of the structure of sulfur and its modified melt showed that the particle size in the melt modified at 150°C is larger than in elemental sulfur. Due to the addition of modifiers, the particle size in the melts becomes larger as a result of crosslinking and polymerization of sulfur. Additional introduction together with epoxy resin of sodium sulfate in the amount of 0.5-1.0% made it possible: reduction of the reaction temperature to 150°C; the reaction time is reduced to 30 minutes; alkali resistance and resistance to sulfuric bacteria are provided; the adhesive properties of the modified sulfur to the shell rock are increased.

During the work on this topic, the results showed that the abrasion grade for limestone-shell rock before treatment with modified sulfur is I-4, after treatment -I-1; water absorption before treatment with modified sulfur is 7.1%, after treatment -1%, i.e. water absorption after treatment with modified sulfur decreased by 7 times; frost resistance grade for limestone-shell rock before treatment with modified sulfur F25, after treatment -F50 (but the weight loss after the test was 4.9% (at the limit) with a requirement of not more than 5% for grade F50 according to ST RK 1284); the ultimate strength of cubic samples of raw crushed stone corresponds to 3.6 MPa, after treatment with modified sulfur - 8.5 MPa, i.e. due to the modification of limestone-shell rock with gray, the tensile strength index increased by 2.4 times.

5 CONCLUSION

In conclusion, the use of modified sulfur and low-strength inert materials such as limestone-shell rock can result in the production of high-strength "sulphurous stone". The combination of these materials not only increases the strength of the resulting product but also provides a more sustainable alternative to traditional building materials.

ABSTRACT: The analysis of buildings and structures falling within the zone of influence of the projected tram line was carried out. Mathematical analysis of the level of vibrations occurring in buildings and structures were performed, taking into account the actual values of loads from rolling stock, engineering and geological surveys in the construction area and the results of the survey of buildings and structures falling into the zone of influence - an assessment of the technical characteristics of the sub-regions selected for the design of the tram line was carried out. Thus, the use of vibration-proofing sub-ballast mats in compliance with the laying technology allows us to bring the vibration indicators generated during the passage of tramcars to the normalized values for administrative and administrative premises of buildings, including taking into account the correction for non-constant vibration for residential premises.

1 INTRODUCTION

Investigations for the development of effective solutions for vibration-proof structures for the infrastructure of railways and urban rail transport is carried out in the CIS countries (SP 98.13330.2018, Methodology 2019, GOST 14837-1-2007, Tram car model 2017, Lakusic et al 2008, 2011, Weisemann et al 2012), Europe and Asia (Zou et al 2017). The series of reseaches and projections has been carried out In order to develop the tramway infrastructure in capitals for the purpose of the measuring the vibration impact generated by the passage of tram cars in order to assess the effectiveness of the vibration-proof structure of the tramway with the use of ballast mats during the implementation of the project of complex improvement of streets and public spaces and ensuring the preservation of cultural heritage objects Figure 1.

At the experimental site, during the measurement period, tramcars of the Vityaz project passed. Vibration parameters were measured within the existing tram routes to measure the vibration effect exerted by the passage of tramcars on the surrounding buildings. A program of experimental work has been implemented to measure the vibration effects generated by a tramcar within a 15-meter zone from the axis of the tramway and on the basement of a building falling into the previously estimated zone of influence - Figure 1.

Also, calculation schemes have been prepared with the application of the geological structure, physical and mechanical parameters of soils, existing and projected structures; the analysis of loads from tram cars, physical and mechanical parameters of soils (according to engineering-geological and geophysical surveys); the substantiation of the theoretical provisions of the

DOI: 10.1201/9781003299127-412

calculation in the form of an assessment of the impact of vibration effects of tram, parameters of materials, sub-ballast mats and modelling of the system.

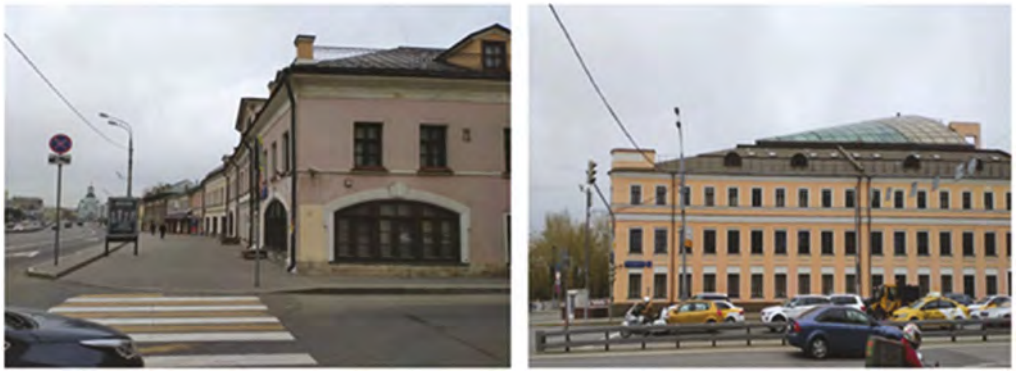

Figure 1. Heritage two-storey and three-storey buildings.

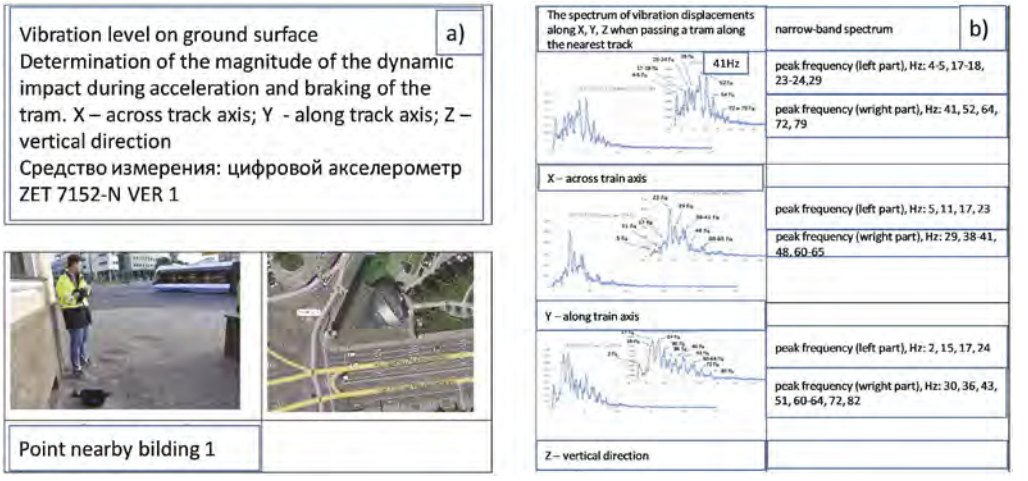

Figure 2. Results of field measurements.

2 SELECTION OF OBJECTS-ANALOGUES ON THE TRAMWAY INFRASTRUCTURE

The design area of the new tramway and the location of cultural heritage objects on this site. Thus, analogous objects were selected on the basis of full-scale inspections of the design object (Sergiy Radonezhsky Street), analysis of regulatory design documentation and previously implemented projects for the reconstruction of tram tracks, as well as from the condition of similarity of the location of buildings, track design (without vibration protection and with vibration protection) and density of urban development.

At this site, during the measurement period, tramcars of the «Vityaz» project are operated. Characteristics of the rolling stock - tram cars planned for circulation on the site: a six-axle three-section low-floor tram (tramcar) is produced, according to the characteristics meets the requirements of SP 98.133330.2012. The tram is designed to transport passengers on city lines

along a tram track with a gauge of 1524mm. Three traction trolleys, two of which are rotary - Figure 2, support the tramcar.

Tramway 71-931M

Track width	1524 mm
length	27,5 m
Height	3,5 m

Base wagon	8,994 m
Base bogie	1,8 m
Maximum velocity	75 km/h
Mass	37 t
Doors	6
Nominal capacity	188 (5 passenger / m2)
Full capacity	265 (8 passenger / m2)
Seats	60(64)

Figure 3. General view of the tram car and its characteristics.

The tramcar consists of two rotary and one non-rotating trolley (the structural difference in them lies in the performance of the pivot beam), specially designed for a low-floor car. When passing curved sections of the railway track, smooth running is ensured by two-stage springing and other equipment installed on trolleys, including a wheelset with a gearbox, traction motor, gear clutch and electromechanical braking system.

As initial data for dynamic calculation from tramcars, it is customary to use the values of vertical and horizontal loads. In the calculations of vibration-proof (vibration-insulated) VSP structures with the use of ballast mats, a design scheme is considered where the track structure is represented as a beam of infinite length lying on a solid elastic base loaded with a system of concentrated wheel loads replaced by equivalent single loads, respectively, when determining bending moments and stresses in rails and track plate using the function and when determining bending moments and stresses in rails – using the function, fasteners, on sleepers, on ballast and its base.

A probabilistic character was assigned for the calculations when determining the maximum values of loads.

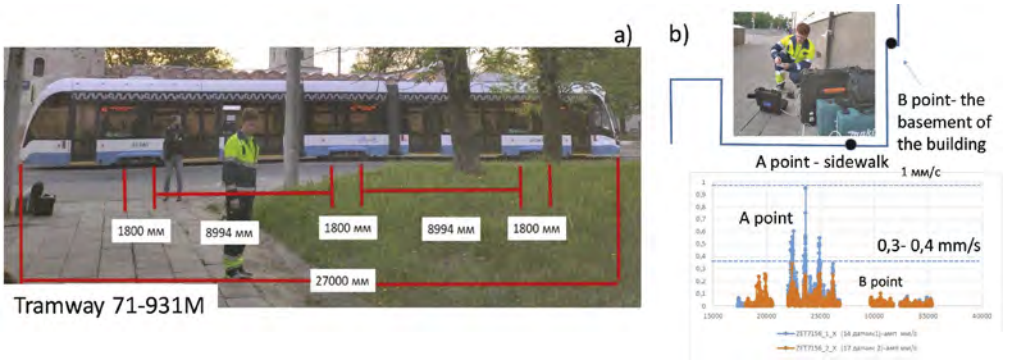

Figure 4. Tram car 71-931 Vityaz-M on Andronyevsky passage a) and spectrum of acceleration on two points nearby building.

Vibration-proofing mats PM-011 (development from 2018) are designed for laying on the site designed for use on railway, tram and subway tracks in order to reduce vibration effects that are transmitted from rolling stock to infrastructure facilities. The mat material is rubber from the upper and lower sides bonded with geotextile material.

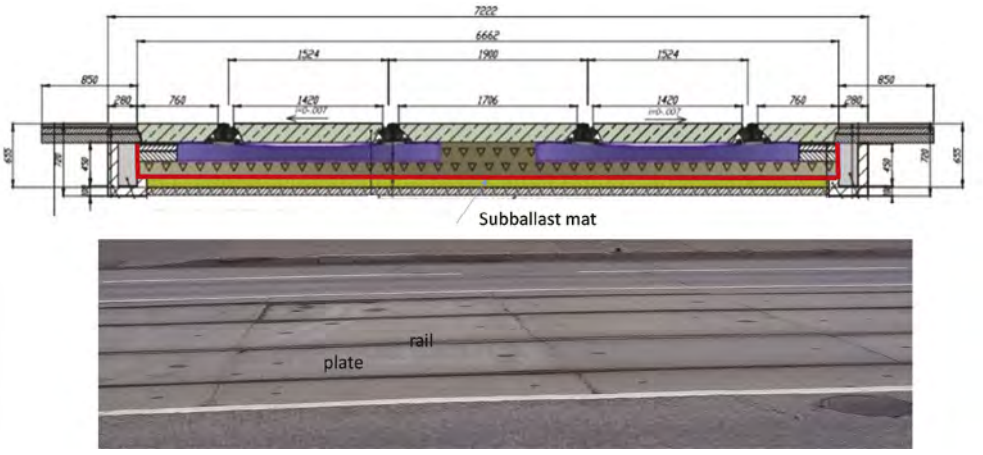

Figure 5. Tram track type with large size concrete plates.

According to the design experience for the specified parameters, the elastic draft of the rail at the speed of the tramcar 20km per hour is no more than 3 mm.

3 MAIN PROVISIONS OF THE CALCULATION METHODOLOGY

Vibration-insulating sub-ballasted mats PM-011 TU 22.21.42-004-02488336-2018 it is intended for use on railway, tram and subway tracks in order to reduce vibration effects that are transmitted from rolling stock to infrastructure facilities. Vibration-proofing mats are used as: sub-ballast gaskets on sections of railway and tram tracks exposed to increased axial loads, in places of exposure to increased dynamic loads (switches, artificial structures, transitional sections, small radius curves, etc.); sub-ballast mats on sections of railway and tram tracks both on the roadbed and on artificial structures.

Vibration-insulating mats are manufactured for the purpose of their application to solve the following tasks: isolation from mechanical noise in populated areas; protection of vibration-sensitive structures and buildings with increased requirements; sound insulation; reduction of static and dynamic pressures caused by the movement of trains and allow more evenly distributing loads at the base of the sub-track; increasing the stability of the track and reducing the (alternating) compression of crushed stone ballast.

Figure 6. Installation of tram tracks with vibration-proof mats, monitoring.

In buildings remote from the source of the vibro-dynamic impact, the levels of vibration acceleration at the main frequencies range from 25 dB to 27 dB. The use of vibration-isolating mats reduces this indicator from 5 to 7 dB. Vibration-proofing mats PM-011 are available in thickness

from 10 mm to 30 mm (in the project, the thickness of the mat is 20 mm). The upper and lower layer of the mat are made of synthetic geotextile material reinforced with surface firing.

The mat is filled with a granular composite material based on rubbers 5 or 5 EV 5 (the size of the granules ranges from 0.58 mm to 4 mm).

Dynamic parameters of the path without the use of vibration-proof mats. One of the main dynamic parameters of a system with one degree of freedom is its natural frequency.

To calculate the effective mass of the system, we calculate the length of an absolutely rigid beam *l* lying on an elastic base with an elastic modulus and a total stiffness. In this case, the deviation of the rail from the unit force will be equal to the deviation of an equivalent absolutely rigid beam of length.

We will take as the effective mass of the system the mass of rails, sleepers, ballast and the mass of wheel pairs on a section of length d. If the length d is less than the base of the trolley, then only one wheelset is taken into account. To calculate the mass of the ballast, the cross-sectional area of the ballast along the trapezoid is taken, taking into account the distribution of pressure in the ballast from the side of the sleeper at an angle of 45°. With a sleeper length of 270 cm and a ballast height of 40 cm, the cross-sectional area of the ballast (per rail thread) is calculated as follows: (2,7+0,4) ×0,40/2 = 0,62 m^2.

Results of calculating the natural frequency of a system with one degree of freedom for a track with sub-ballast mats (one rail thread): mat thickness = 42 mm; modulus of elasticity of the path, U=47800000 MPa; rigidity of the path, β=18211412 MN/m; length of the equivalent beam (support) 1.75 m; effective total mass of the system, m=3217.8 kg; the natural frequency of the system, f_0=11.20 Hz.

The vibration transmission coefficient K, represented as a logarithm of the ratio of oscillation amplitudes in decibels, shows how many times the vibration level of one structural element is less or more than the vibration level of another.

Using the vibration transmission coefficient, it is possible to evaluate the effectiveness of both individual structural elements and the entire structure as a whole. In this case, the vibration transmission coefficient from the rail to the ground was determined. In accordance with this, Figure 6 shows the curves of the vibration transmission function for the track structures under consideration.

Figure 6 show a comparison of the effectiveness of the upper structure of the path with sub-ballast mats compared with the upper structure of the path without sub-ballast mats.

In accordance with the manufacturer's data for the proposed vibration-insulating sub-ballast mats PM-011 TU 22.21.42-004- 02488336-2018 It is assumed that the vibration isolation efficiency is equal to 5 dB for the considered geometric mean frequencies of the octave range.

On Figure 7 shows the curves of the vibration transfer function for the track structures under consideration and the calculation results comparing the efficiencies of tramway structures with sub-ballast mats compared to the upper structure of the track without sub-ballast mats.

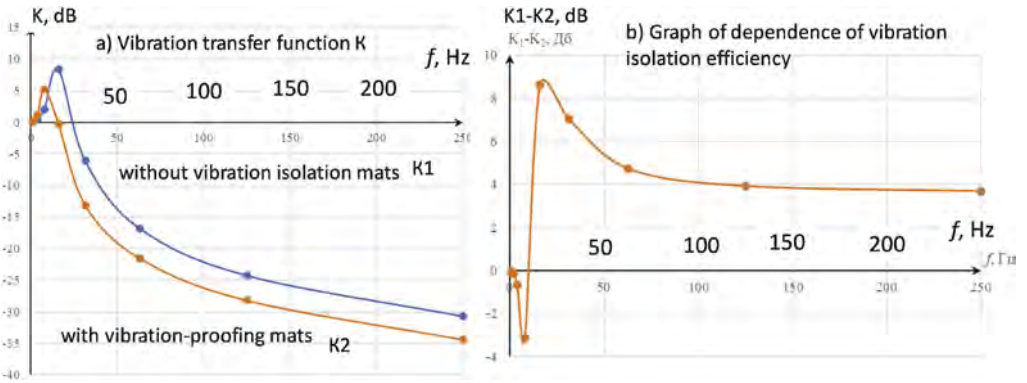

Figure 7. The results of calculation vibro - isolation efiiciency.

4 CONCLUSION

At the article presents the results of work on experimental and calculated determination of vibration velocities, vibration accelerations and prediction of vibration levels on existing buildings and structures near the projected tramway line.. Variants of technically feasible ways to reduce vibration levels to acceptable values in the premises of buildings located near the reconstructed tram line have shown that the main effective way to reduce vibrations is the use of vibration-proofing ballast mats, which is aimed at reducing the rigidity of the track structure and the implementation of a vibration-proof function. Indeed, to ensure the preservation of cultural heritage sites. It is necessary to use a vibration isolation system of the upper structure of the path. Strongly recommended to use a vibration-proof structure of the upper structure of the track with vibration-noise insulation sub-ballast mats, which reduce the level of vibration and structural noise to acceptable parameters. The prediction of the vibration level for existing buildings (without vibration isolation mats) revealed an excess of the permissible vibration level at the average geometric frequencies of the octave ranges: 8, 16 and 31.5 Hz. Thus, the condition of structures and buildings, objects of cultural heritage does not allow to accept the traditional design of tram tracks, without vibration-proof structures. Vibration-proofing sub- ballasted mats PM-011 were adopted for analysis with vibration isolation efficiency equal to 5 dB. The option of using sub-ballast mats along the contour of the pit (the base and side walls of the pit) for the device of tramway elements is a necessary technical solution to reduce the vibration effect to an acceptable level. The use of vibration-proofing sub-ballast mats, with the use of appropriate laying technology, will ensure the requirements for permissible values of vibration levels. The prediction of the vibration level for existing buildings, with the traditional version of the construction (without vibration isolation mats) revealed an excess of the permissible vibration level at the average geometric frequencies of the octave ranges: 8, 16 and 31.5 Hz. Thus, the condition of structures and buildings, objects of cultural heritage does not allow accepting the traditional design of tram tracks, without vibration-proof structures, without sub-ballasted mats.

ABSTRACT: The article describes the results of the water-temperature regime analysis in road structures in the cold regions of the Republic of Kazakhstan based on experimental studies. The types of extreme situations that reduce the strength and durability of road structures are listed. The freezing maps of the soil base of the road pavement, formed in different winter periods, are given. A relationship between the level of soil moisture and the value of negative temperature in it during the periods of winter freezing and spring thawing has been established.

Keywords: water-temperature regime, freezing map, winter freezing, spring thawing, humidity level

1 INTRODUCTION

Yang, et al. (2022) studied extreme thermal conditions of the soil are the main factors contributing to premature wear and destruction of road structures, including pavements built in regions with seasonal freezing and thawing.

During winter freezing, the pavement will be subjected to swelling pressure and a possible "frost heave" phenomenon. In addition, the pavement may even crack due to excessive tensile stresses caused by extremely low freezing temperatures in winter.

With the approach of summer, starting from May, the frozen soil will begin to thaw. This spring thaw of the soil can cause significant damage to the upper asphalt concrete layers of the road structure. Abundantly moistened by the thawed part of the moisture, the soil loses its bearing capacity, and the pavement seems to sag over it. If the melting is also accompanied by a spring, seasonal increase in traffic activity, then the risk of pavement failures increases many times over.

During transitional periods between extreme temperatures, before complete freezing and before intense thawing, so-called periods of uncertain freezing and thawing occur, when the temperature on the coating will fluctuate between plus temperatures during the day and minus temperatures at night. During this period, the pavement will be subjected to the "thermal fatigue" test, when thermal expansion is repeatedly replaced by low-temperature contraction.

Since in this paper we consider mainly cold regions of the country with seasonal freezing of the soil, we will not touch on another negative phenomenon, such as the formation of ruts on pavements caused by excessive overheating of the asphalt concrete pavement on summer days in the south.

DOI: 10.1201/9781003299127-413

In foreign scientific literature, considerable attention is paid to the issues of "thermal fatigue" of the road surface. Although everyone understands that freeze-thaw cycles have a great influence on the properties of asphalt pavement, the quantitative side of this effect is still poorly understood. In a detailed study of this issue, air voids, high temperature stability, low temperature cracking resistance and moisture sensitivity and other issues of the microstructure of the asphalt concrete pavement mix are analyzed. The micromorphology and chemical composition of the cement-asphalt mortar were observed using scanning electron microscopy by Ayar, (2018). Freeze-thaw cycles reduce the durability of asphalt pavement in areas that experience seasonal frost. According to Xu, et al. (2015), the destructive effects of freeze-thaw cycles are caused by the expansion of water in the asphalt mix when the temperature is below 0°C. The degree of damage caused by foamed water to the asphalt mix during multiple freeze-thaw cycles has been assessed. The results showed that freeze-thaw cycles accelerate internal damage to the asphalt mix and lead to an increase in air voids and a decrease in adhesive strength. The influence of freeze-thaw cycles on the fatigue characteristics of asphalt concrete mixture was studied by You, et al. (2018). Here it is shown that the fatigue life decreases as the saturation and freeze-thaw cycles increase. And the fatigue life was significantly reduced at high stress levels. Duoji, et al. (2021) demonstrated the flexural tensile properties of blends using freeze-thaw bending tests. It was shown that the bending tensile strength and strain decreased with increasing freeze-thaw cycles. The deterioration of flexural tensile properties decreased significantly at the beginning of freeze-thaw cycles, but became smooth after freeze-thaw cycles. It should be noted that all the above-mentioned works were carried out with the help of modern high-precision installations and devices.

2 KAZAKHSTAN EXPERIENCE IN STUDYING ROAD WATER-THERMAL REGIME

Based on the methodology for determining the freezing depth proposed by Teltayev, for the first time Teltayev and Sakanov (2004) created a separate map of the depth of freezing of roads in Kazakhstan. The map was subsequently included in the main state standards for the design of road structures. For the development of the mapping methodology, data on the actual frost penetration depths of roads and on air temperatures in the points of road pavement and subgrade were used. The number of data sources was limited.

In the development of this topic in the works Teltayev et al. (2015,2017,2019), studies were carried out to improve methods for determining the depth of freezing.

Starting from 2019, Kazakhstan has taken a course to strengthen the experimental base for research on the water-thermal regimes of roads.

Measuring stations equipped with temperature and humidity sensors, operating in automatic mode, and transmitting measured values to a database via the Internet, began to be equipped throughout Kazakhstan. In 2021, the number of such stations was increased to 28 units, which makes it possible to build maps of freezing depths with more accurate data.

3 WATER-THERMAL REGIMES OF ROADS IN KAZAKHSTAN COLD REGIONS

The cold regions include Kostanay, North Kazakhstan, Akmola, Pavlodar and East Kazakhstan regions of the Republic of Kazakhstan. They are united by a harsh, snowy and long winter. The depth of freezing in some years approaches 3 meters.

The chronological freeze-thaw map is one of the most effective tools for studying the patterns of formation of the water-thermal regime on a specific section of the road for a specific period of time. In terms of time, the map covers the period, including the moment of the beginning of the freezing of the road structure and the end of the thawing process. To demonstrate the methodology for constructing a freezing map, consider a road section near the city of Kostanay (section of the Karabutak-Kostanay-Yekaterinburg-Almaty, Kostanay city, km 1), Figure 1.

Table 1. Road pavement structure.

№	Layer material, soil	Layer thickness
1.	Asphalt concrete, type B	h_1=5 cm
2.	Coarse-grained porous asphalt concrete	h_2=13 cm
3.	Coarse-grained highly porous asphalt concrete	h_3=9 cm
4.	mixture	h_4=35 cm
5.	Soil - sand	h_5=90 cm
6.	Soil - black earth	h_6=148 cm

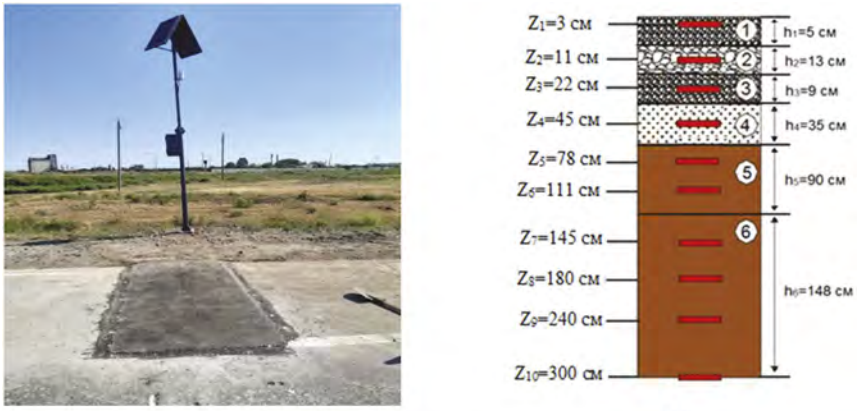

Figure 1. Measuring station near Kostanai. a) External view of the transmitting antenna of the measuring station near Kostanai. b) Schematic view of the road structure.

Table 2. Location depths of sensors.

Vertical coordinate of sensor	Z_1	Z_2	Z_3	Z_4	Z_5	Z_6	Z_7	Z_8	Z_9	Z_{10}
Value, cm	3	11	22	45	78	111	145	180	240	300

The mathematical model of the problem of the temperature regime in the considered multilayer road structure is a one-dimensional composite well with a unit cross-sectional area (Figure 1b).

The chronological freeze-thaw map (CFTM) of a multilayer road structure is the locus of points with zero temperature on the (n, z) plane, where n is an integer coordinate in hours, z is the vertical coordinate of a point on the mathematical model.

To build a map of freezing and thawing of a section of the road near Kostanay in winter, according to the data of an experimental study of the water-thermal regime, first, the moment of occurrence of negative temperatures at the points of the road pavement and the subgrade is established, and at the end, the completion of the thawing process is recorded, when at the points road construction everywhere only positive temperature.

At the measuring station in Kostanay in the winter period 2021-2022 the following dates are set: for the first time, the front of negative temperatures (zero line) crosses the sensor located at a depth of 3 cm at 18:58 on November 2, 2021. In turn, the negative temperature was last recorded by a sensor located at a depth of 180 cm at 5:58 on April 30, 2022. Thus, the process of freezing and thawing of a section of the road near the city of Kostanay will need to be monitored for all 180 days - from November 2, 2021 to April 30, 2023.

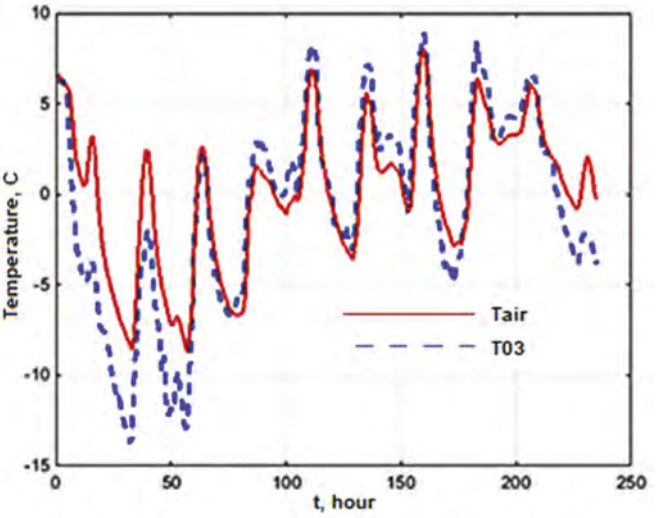

Figure 2. Temperature variations at a depth of 3 cm (T03) in comparison with air temperature (Tair) variations in the period from 0:58 AM on November 1 to 18:58 PM on November 11, 2021 (n=1: 234).

However, the processes of freezing and thawing do not always occur with the same intensity. At the initial stage, in the period from 0:58 on November 1 to 18:58 on November 11, 2021, which corresponds to the interval of change in the time coordinate 'n' from 1 hour to 234 hours, there is an unsteady process of formation of the temperature regime with frequent zero crossings (Figure 2).

The picture of temperature change at a depth of 3 cm, shown in Figure 3, is of interest from the point of view of the fatigue strength of the asphalt concrete pavement, when alternating compression and tension occur under the influence of temperature.

It is easy to see that this period of freezing does not affect the maximum depth of freezing of the soil base, which is the main subject of research. The physical processes occurring in this period of time (n=1:234) will be singled out as a separate problem, where the influence of a cyclic process caused by thermal forces of compression or tension will be studied.

Since n=235, the actual process of freezing of the road structure begins, when the temperature at its points is stably negative. It should be noted that the readings of the temperature sensors cannot be strictly equal to zero at any point of the integer time coordinate n. Therefore, if necessary, interpolation methods are used to determine the coordinates of the front of negative temperatures.

For the winter period of 2021-2022, the hodograph of the vector of negative temperatures runs through the time interval from n=235 to n=4302. At the last moment, the freezing depth is H=195 cm. Moreover, the maximum freezing depth is reached much earlier. The greatest freezing depth in the road structure of the section of the Karabutak-Kostanai-Yekaterinburg-Almaty, Kostanai highway, km 1 for the winter period of 2021-2022 was 225 cm. This depth was achieved at n=3783, which corresponds to 14:58 hours on April 8, 2022. Later, under the influence of heat from the bowels of the Earth, the ground base begins to melt, since at this time of the year the intensity of the negative temperature directed from top to bottom weakens. The process of soil thawing from bottom to top will be completed at the time n=4302, or at 5:58 on April 30, 2022 at a depth of Z=195 cm, when thawing from above reaches the same depth.

With the onset of spring, the frozen road structure begins to melt from above. The defrosting process starts at 15:58 hours on February 21, 2022. But, as in the initial period of freezing, this process is unstable, and frequent transitions through '0′ will continue until 08:58 hours on April 6th.

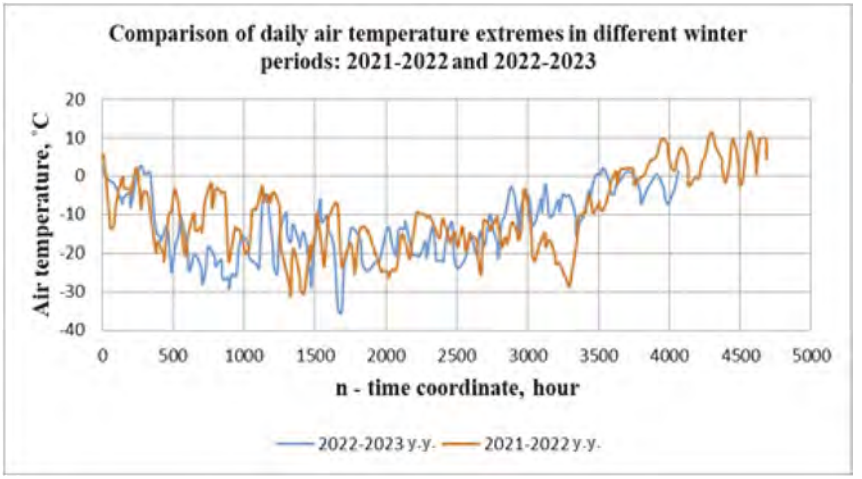

Figure 3. Comparison of daily air temperature extremes in different winter periods: 2021-2022 and 2022-2023.

It is clear that in order to assign the calculated values of individual parameters of the water-thermal regime, it is necessary to take into account the variability over the years of the weather in a given area. In this paper, such variability is demonstrated using the winter periods of 2021-2022 and 2022-2023 as an example. Figure 3 compares daily air temperature extremes in different winter periods: 2021-2022 and 2022-2023. Here, daily extremes were considered only to increase the visibility of graphic materials, since with an hourly demonstration, due to the high frequency of data, it will not be possible to discern individual features of the results.

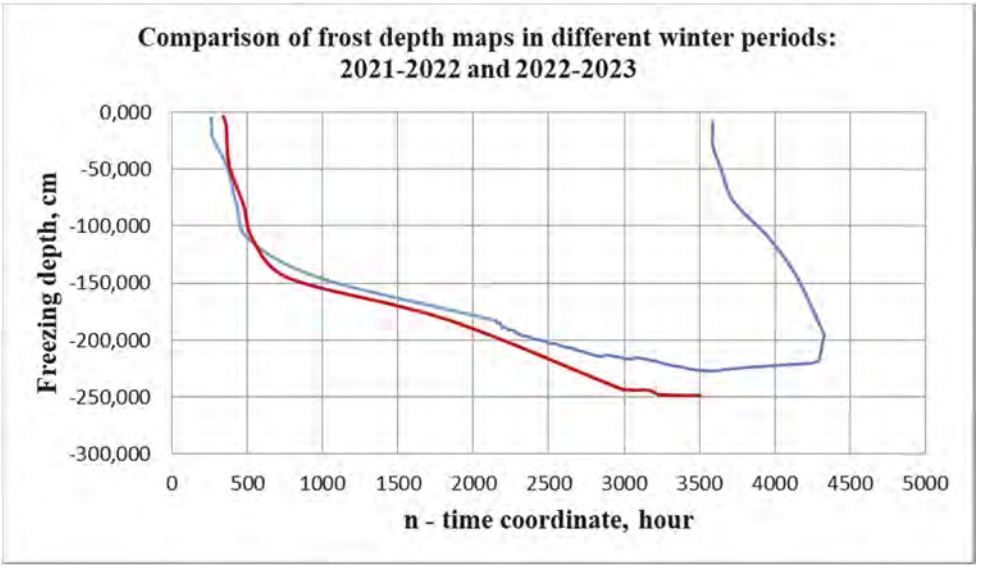

Figure 4. Comparison of freezing depths in different winter periods:2021-2022 and 2022-2023.

From the analysis of the experimental results, we conclude that during the winter period2021-2022 the minimum air temperature reached Tmin=-31.0°C, while for the winter period of 2022-2023. it was equal to Tmin=-35.5°C. However, such a slight difference of -4.5°C in air temperature will lead to a noticeable increase in the freezing depth (Figure 4).

An analysis of the numerical data of the graphs in Figure 4 shows that for the winter period 2021-2022. Freezing depth reached H=225.0 cm, while this parameter for the winter period of 2022-2023. Reached H=250.2 cm. It is clear that an increase in the freezing depth by as much as 25 centimeters or more can lead to a noticeable increase in soil waterlogging during the spring thaw. It follows that the change in weather conditions in the area where the road passes from year to year is a factor that should not be taken into account.
