SMART GEOTECHNICS FOR SMART SOCIETIES

Smart Geotechnics for Smart Societies contains the contributions presented at the 17th Asian Regional Conference on Soil Mechanics and Geotechnical Engineering (17th ARC, Astana, Kazakhstan, 14-18 August, 2023). The topics covered include:

– Geomaterials for soil improvement
– Tunneling and rock engineering
– Slope, embankments and dams
– Shallow and deep foundations
– Soil dynamics and geotechnical earthquake engineering
– Geoenvironmental engineering and frost geotechnics
– Investigation of foundations of historical structures and monitoring
– Offshore, harbor geotechnics and GeoEnergy
– Megaprojects and transportation geotechnics

Smart Geotechnics for Smart Societies will be of interest to academics and engineers interested or involved in geotechnical engineering.

Preface

The 17th Asian Regional Conference on Soil Mechanics and Geotechnical Engineering is organized by the Kazakhstan Geotechnical Society under the joint guidance favor of International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE) and the L.N. Gumilyov Eurasian National University. The main theme of the 17 ARC is Smart Geotechnics for Smart Societies. A number of subjects in modern geotechnical technology and activities are covered up to match the main theme. In a roll about of 60 years, we sincerely hope that the 17ARC will continue to bring great success following the glories of past ARCs (New Delhi 1960, Tokyo 1963, Haifa 1967, Bangkok 1971, Bangalore 1975, Singapore 1979, Haifa 1983, Kyoto 1987, Bangkok 1991, Beijing 1995, Seoul 1999, Singapore 2003, Kolkata 2007, Hong Kong 2011, Fukuoka 2015, Taipei 2019). 17 ARC is held for the first time in the very heart of Eurasia, in a country located at the junction of 2 continents, and this is its strength and peculiarity. Kazakhstan is located in the geographical center of Central Asia and located in two parts of the world, on the border of Europe and Asia; most of the country is in Asia, the smaller one is in Eastern Europe.

The origin of scientific thought in Kazakhstan goes back to ancient times. Archaeological research and written sources contain information about the culture of cities and settlements that existed in the 6th-11th centuries on the territory of Zhetysu, Central and Eastern Kazakhstan. The founders of this culture are the local Turkic tribes: Oguzes, Karluks, Kimaks, Kypchaks. The medieval cities of Kazakhstan were known throughout the world not only for their bazaars and crafts, but also famous for their poets, scientists, artists, rich libraries, and educational institutions. During the Second World War, many scientific institutions and higher educational institutions of the country were evacuated to the republic of Kazakhstan from Moscow and Saint-Petersburg (Russia). The research carried out by scientists in recent years is aimed at increasing the competitiveness of the science and technology.

In July 1995, the Kazakhstan Geotechnical Society was founded for the first time under the leadership of Doctor of Technical Sciences, Professor Askar Zhussupbekov. Technical Committee of ISSMGE TC305 Megacities Geotechnical Infrastructure for Megacities and New Capitals succefully operates on the basis of Kazakhstan Geotechnical Society and hosted several events annually. At the moment, over 40 scientists from all over the world are permanent members of TC305. Among the events organized: the Eighth Asian Young Geotechnical Engineers Conference (8AYGEC), the KGS-KGS forum, First International Workshop, the ENU-INU forum between the Incheon National University (INU) and the LN Gumilyov Eurasian National University, the Taiwan-Kazakhstan Geotechnical Engineering Seminar, ENU-HIT Scientific forum between the between L.N. Gumilyov ENU (Kazakhstan) and Hachinohe Institute of Technology (Japan), Second Geo-Institute – Kazakhstan Geotechnical Society Joint Workshop (USA) and many others. These events provide an opportunity not only to share information on geotechnical advances and problems and their impact, but also to get a cultural exchange between scientists from different countries: the guests can taste some of the finest cuisine, livestock meat can be cooked in various ways and is usually served with a wide range of traditional bread products, beshbarmak (horse meat). Refreshments often include black tea and traditional dairy drinks such as ayran (source milk), shubat (camel

milk) and kymyz (horse milk), but also experience the hospitality and cultural uniqueness of the formerly nomadic people.

The Conference Proceeding of the 17th Asian Regional Conference on Soil Mechanics and Geotechnical Engineering composes more than 400 scientific papers from 54 countries including the following topics divided by chapters: soil characteristics and properties, underground space and deep excavations, tunneling, slope, debris flow and embankments, dams, shallow and deep foundations, soil dynamics and geotechnical earthquake engineering, soil improvement, geo-environmental engineering, geotechnical reliability, risk assessment and management, geosynthetics and geo-products, engineering geology and rock engineering, forensic engineering, offshore and harbor geotechnics, geotechnical training and education, in-situ testing and monitoring, geo-energy, case history, investigation of foundations of historical structures, buildings and monuments, numerical analysis of soil-structure interaction, geotechnical infrastructures, marine geotechnics, mining and geotechnics, design and modeling, transportation geotechnics, engineering and technology, piling foundations, technologies and testing, press-in piling technology, trenchless technology in underground constructions, pipelines on problematical soil ground, frost geotechnics, BIM technology and geotechnical engineering, megaprojects and megastructures on difficulty soil grounds.

This Conference brought together the achievements of not only 26 Asian countries, but also representatives of Europe, America, Australia, and Africa. We would like to especially note the Japanese Geotechnical Society, Indian Geotechnical Society, Korean Geotechnical Society, Chinese Institution of Soil Mechanics and Geotechnical Engineering-CCES, Chinese Taipei Geotechnical Society, Kazakhstan Geotechnical Society, Iraq Geotechnical Society, and other Asian Geotechnical Societies in participating and assisting in the organization of the review process.

The 17 ARC conference serves as a valuable platform for companies operating in the geotechnical industry to showcase their latest products, technologies, and services to a targeted audience of professionals, researchers, and academics.

On behalf of the 17ARC organizing committee we would like to thank International Society for Soil Mechanics and Geotechnical Engineering and all the Technical Committees, Scientific Committee, International Advisory Board and of course to the Organizing Committee for their constant support and great contribution for making this Conference a success. We would also like to thank our sponsors and exhibitors and all participants of this conference for their active participation in it.

We hope that this Conference proceedings will not only be the conclusion of the research performed, but also motivate for further efforts and collaboration in the field of geotechnical engineering.

Technological and structural methods of construction of the underground part of unique facilities in St. Peterburg built during the last 10 years

R.A. Mangushev & A.I. Osokin
Saint Petersburg State University of Architecture and Civil Engineering, Russia

ABSTRACT: Engineering-geological conditions of St. Petersburg, which are characterized by a large thickness of soft water-saturated lake-glacial deposits, are presented. The main characteristics of soils and examples of static sensing results are given. There are considered the main technical characteristics of the foundations of the compound "Lakhta-Center", including a 462-m-hight skyscraper – the tallest building in Europe and a multifunctional center of 85 to 15 m. The main technical characteristics of the foundations of the unique Gazprom-Arena football stadium with an opening roof and a retractable field are presented.

1 INTRODUCTION

Saint Petersburg is the northernmost city in the world which has the population over one million people. Founded in 1703 in the delta of the Neva River as the capital of Russia, the metropolitan city was developing broadways for almost 300 years - most of the buildings were of 2 to 12 floors. Only in the early 21st century high-rise construction began on the periphery of the city, and now a number of floors reaches 25 and more in the buildings erected on piles. The construction of the Lakhta Center Multifunctional Complex on the coast of the Gulf of Finland was a unique event for the megacity, and the high-rise part of the Lakhta Center was completed in 2018. The unique building structures and technologies were used to construct its substructure.

2 ENGINEERING AND GEOLOGICAL CONDITIONS WITHIN SAINT PETERSBURG AREA

The central historical part of Saint Petersburg is formed by deltaic deposits of fine-grained and silty sands with a thickness of 2 to 5 m underlain by the thick layer of soft lake-glacial and marine deposits. These soils have comparatively high and non-uniform compressibility.

The lake-glacial deposits – clays, loams and sandy loams – are practically pervasive and have the stratified or ribbon structure. These soils are characterized by high natural moisture content and porosity, anisotropic mechanical properties, high compressibility, heaving properties and thixotropy.

In this part of the city, the relatively firm moraine deposits are encountered at a depth of 15 to 30 m from the ground surface.

Within the city area, primary deposits are represented by Proterozoic, Paleozoic and Ordovician deposits covered by Quaternary sediments. The main subway tunnels and sewage headers are located in these deposits. Figure 1 shows an example of the engineering and geological conditions of the northern part of Saint Petersburg.

DOI: 10.1201/9781003299127-1

3 LAKHTA CENTER MULTIFUNCTIONAL PUBLIC AND BUSINESS COMPLEX

3.1 *General information*

The Lakhta Center is a public and business complex located on the coast of the Gulf of Finland in Primorsky District of Saint Petersburg. The Complex includes a 462-m-high skyscraper and a multifunctional building divided by the atrium into the southern and northern blocks[1] (Figure 1).

The total area of the buildings is 400 thousand m². The skyscraper is considered as the northernmost in the world and the tallest in Russia and in Europe. Its height with a spire is 462 m, the total weight is 670 thousand tons, the number of floors is 87. The top floor of the skyscraper is located at the elevation of 372 m.

Figure 1. General view of Lakhta center multifunctional complex.

3.2 *Principal design features of the skyscraper substructure*

During the construction of the Public and Business Complex, a pile field of 2080 drilled cast-in-situ piles was used. In this case 264 piles of the diameter of 2 m were constructed under the tower, 848 piles of the diameter of 1.2 m - under the multifunctional building and arch, and 968 piles of the diameter of 0.6 m - under the stylobate (Figure 2).

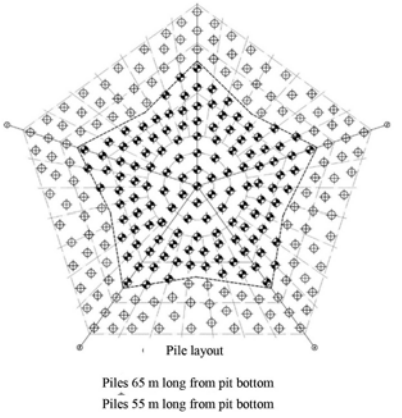

Figure 2. Layout of the pile field under the skyscraper building.

1. The architectural design of the Complex was developed under the guidance of Architect F. Nikandrov. The General Designer was ZAO Gorproekt, the General Contractor was Arabtech (UAE)

The box foundation of the skyscraper consists of three tightly reinforced slabs which are enclosed by a diaphragm wall in the form of a regular pentagon, which penetrates down to undisturbed firm Cambrian clays (Figure 3a).

A space between three slabs of the box foundation is formed by underground floors, in the center of which a reinforced concrete core of the skyscraper is located with 10 radial walls going from it to the external perimeter. The walls are 2.5-m- thick and of the total height of 11 m (Figure 3b).

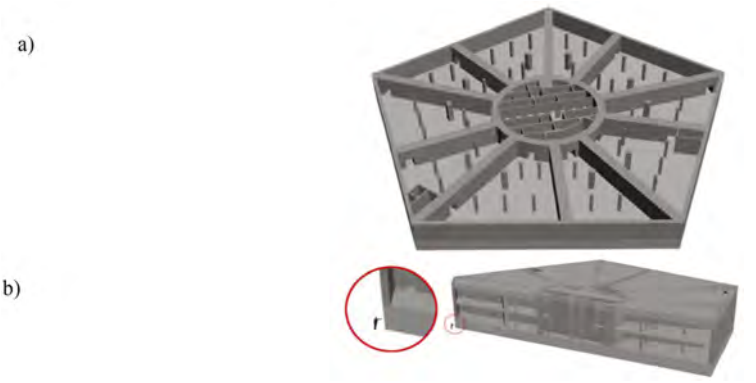

Figure 3. The box foundation and core of tower (a); the model of the box foundation and human scale (b).

The total height of the box foundation is 20 m, the inside diameter of the core is 24.5 m. The bottom reinforced concrete slab of the box foundation is 3.6 m thick, the diameter of its reinforcement bars is 32 mm with the reinforcement bars spaced at 16.5 cm. The total of 15 reinforcement mesh levels are installed in the bottom slab. The top slab is 2-m-thick, the middle slab is 0.4 m thick[2]. The reinforced concrete core, which is the main stability structure of the skyscraper, is made hollow: inside it, there are located utilities, vertical transport, service rooms and safety areas. The core is rigidly connected with the box foundation, which transfers the load from the tower to the piles.

The diaphragm wall is a retaining structure of the excavation pit which protects the excavation pit against underground water and pressure of soil. The disk spacer system held the walls of the excavation pit during the construction of the box foundation (Figure 4).

The total length of the diaphragm wall is 300 m around five sides with the height of 31.5 m and the width of 1.2 m. When the excavation pit was made the stability of the diaphragm wall was provided by 4 spacer disks. In construction of this retaining structure there were used 105 reinforcing cages with the weight of 20 tons. The bottom slab of the skyscraper box foundation is supported by the drilled cast-in-situ piles which were constructed according to the Bauer technology using a protective pipe of 2 m in diameter of two types: in the center of the building, there were 65 m long piles, while along the perimeter, there 65 m long 55 m long long[3]. (Figure 2). This was done in order to compensate a greater settlement produced in the center of the building as compared to the edges. The total number of piles was 264 of each type.

The bearing capacity of one pile is approximately 5 thousand tons, which is 2.5 times higher than the design load. In general, the total bearing capacity of the pile field is over 1,300 thousand ton, and thereby it supports the total load of 670,000 tones.

2. The construction of the diaphragm wall and the box foundation was carried out by ZAO Geostroy
3. The design and monitoring of the pile field was developed and conducted by Gersevanov Research Institute of Soils and Underground Structures (Gersevanov's Institute), the piles were constructed by Bauer (Germany)

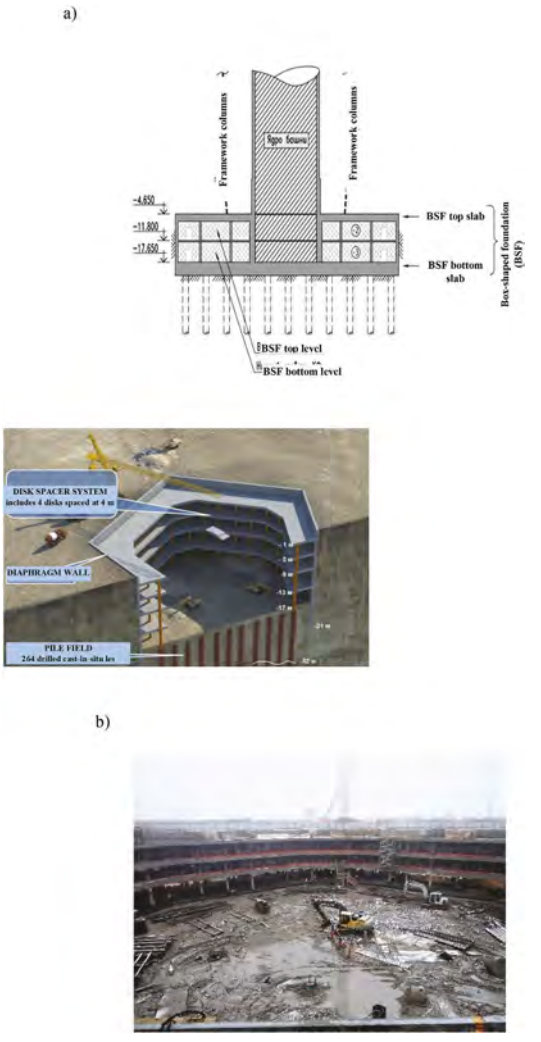

Figure 4. Sectional diagram and axonometric view of the diaphragm wall with spacer disks and pile field (a) and the general view of construction works (b).

3.3 *Specific features of substructure construction for the multifunctional buildings*

Two buildings located on the sides of the high-rise landmark are built with the height difference of 22 to 85 m and they have a two-level underground space (Figures 5 and 6).

Based on the load summary results, pressure was calculated underneath the mat with a thickness greater than 1 m. In order to provide the uniform settlement of the building, it was decided to specify the same diameter of the piles for the entire pile foundation. The piles were taken with D = 1.2 m and the length of 34 m with different spacing between them. The piles were installed at the interval of 3 m under the high-rise part of the building and the interval of 9 m under the foundation that carries a smaller load. The actual load-bearing capacity of the pile was taken equal to 1,400 tons. Thus, the optimum rigidity of each section with a characteristic load has been achieved.

Taking into account that the construction site is adjacent to the water area, as well as the high groundwater level, a retaining wall of the excavation pit (diaphragm wall) 27.5 m deep and 0.8 m thick was constructed and buried into undisturbed clays, whose roof is located at a depth of 25 m from the surface.

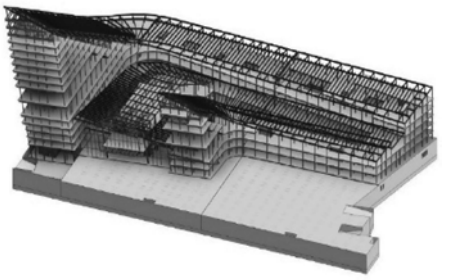

Figure 5. General layout of the load-carrying structure of the multifunctional building.

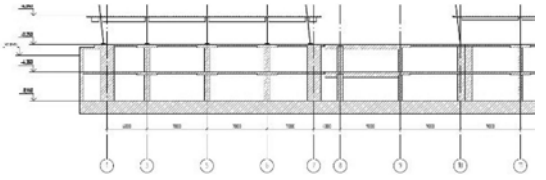

Figure 6. A fragment of substructure (no piles are shown) of the designed multifunctional building across one of sections.

The second purpose of the retaining structure was to secure the walls of the pit during the excavation of the latter and the construction of a zero-level part of the building. Figure 7 shows a fragment of the stage-by-stage excavation of the pit using berms and braces.

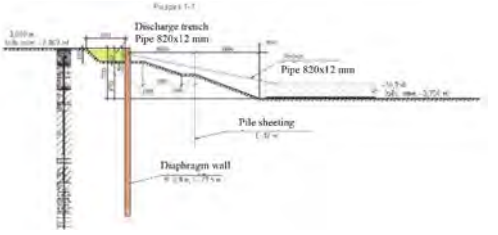

Figure 7. The layout of the diaphragm wall in soil conditions of the construction site.

4 PRINCIPAL STRUCTURAL SOLUTIONS FOR THE SUBSTRUCTURE OF GAZPROM-ARENA FOOTBALL STADIUM

The construction works on Gazprom-Arena Stadium were completed in 2016. The stadium successfully hosted Confederations Cup matches in 2017, 2018 World Cup matches and many other competitions. (Figure 8)

A new stadium was designed as an arena of oval shape in plan, with the 9-storey space which is located on the cone-shaped volume of a man-made hill.

The main functional purpose of the building is a multifunctional football stadium of the highest category, closed-type, year-round use with a retractable field, a sliding roof and viewing stands which accommodate 68,000 seats.

The following piles was used as foundations of the facility:

a) Drilled piles 24-m-long, 520 mm in diameter: 9000 ea. Soil bearing capacity of piles is 2600 kN (Figure 9). Concrete grades B30, B40, W8 and reinforcement A-500C were used for their construction.

Figure 8. General view of Gazprom-arena football stadium.

b) Drilled cast-in-situ piles 28-m-long, 500 mm in diameter: 1440 ea. Soil bearing capacity of piles is 8000 kN. Concrete grade B40, W8 and reinforcement A-500C were taken for their construction. The pile heads were united using reinforced concrete cast-in-situ rafts of variable thickness, H = 900 to 1500 mm.

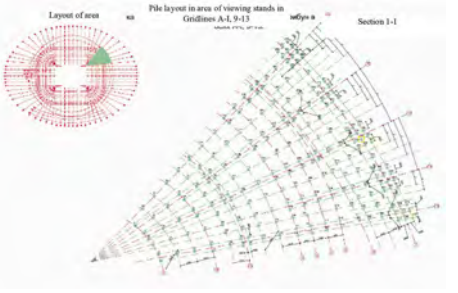

Figure 9. Principle of pile arrangement under viewing stands for one of segments.

The sliding roof is supported by 8 inclined pylons which rest on the structure. Taking into account high horizontal and moment loads which are transferred to the edges of the foundations of the pylons, the pile foundation structures for the roof supports are taken as space systems made of contiguous drilled cast-in-situ piles 1500 cm in diameter and 28-m-long (Figure 10).

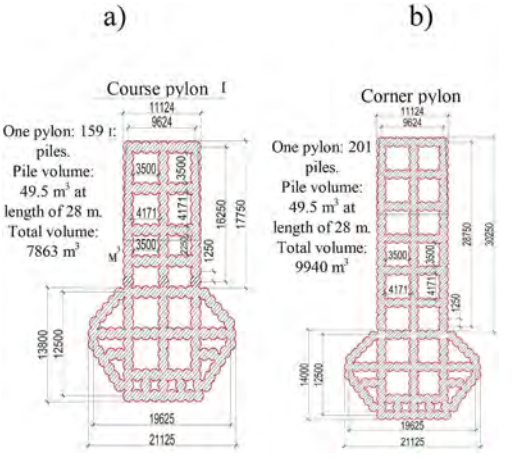

Figure 10. Construction of pile foundations for roof supports: a - course pylon; b - corner pylon.

Rolling out football field of the dimensions 120 x 80 m with the weight of 8,400 tons including the grass turf, heating and blow-off system, engines and the metal frame is moved outside the stadium pit (Figure 11).

Figure 11. General view of the roll-out field fragment.

To meet the above mentioned requirements a pile field was constructed under the slab of the retractable field. The pile field is made of drilled cast-in-situ piles 520 mm in diameter and 24-m-long spaced at 3.0 x 3.0 m; then, additional piles were constructed in the bridge area above the retractable field (Figure 8.30). A thickness of the raft slab was taken equal to 400 mm.

The construction works on Gazprom-Arena Stadium were completed in 2016. The stadium successfully hosted Confederations Cup matches in 2017, 2018 World Cup matches and many other competitions.

5 CONCLUSIONS

The foundations of the unique buildings and structures, which have been recently constructed on the thick layer of soft soils in Saint Petersburg, are made of drilled cast-in-situ piles that were driven to low-compressible primary soils - Cambrian clays – they have shown a high bearing capacity and provided the acceptable absolute and differential settlements.

Undrained instability and fluidization of soft subgrade soils under cyclic rail loading

B. Indraratna, T.T. Nguyen, J. Arivalagan, M. Singh, C. Rujikiatkamjorn & T. Doan
Transport Research Centre, Faculty of Engineering & Information Technology, University of Technology Sydney, Australia

ABSTRACT: The rapidly increasing demand for rail infrastructure to transport passengers and freight has inevitably led to a need for more robust and sustainable track foundations. However, heavy haul rail tracks often run across unfavourable soil conditions (e.g., saturated soft estuarine soils), resulting in frequent track failures accompanied with high maintenance cost. Recent site investigations along the South Coast rail line (NSW, Australia) showed considerable track degradation induced by subgrade mud pumping, requiring urgent attention and studies. This paper thus presents extensive laboratory and numerical investigations on the mechanism and possible solutions for mud pumping. While the effects of mud pumping on track performance are investigated through large-scale permeability and shear tests using the collected fouled ballast, the subgrade soil is subjected to cyclic triaxial and large-scale cyclic testing to understand the soil fluidization and fine particle migration. Transducers are installed at different layers to observe the depth-dependent response of soil foundation under various conditions. The results show that when specimens are subjected to unfavourable cyclic stresses, the fine particles migrate from the lower toward the upper soil layers along with the redistribution of pore water. When the water content of the upper soil layer reaches the liquid limit, the top of the specimen transforms into a slurry. Micro-analysis based on CFD-DEM coupling indicates a serious degradation in soil fabric and strength, thus the formation of mud under rising excess pore water pressure (EPWP). The study indicates that adding reasonable mass of cohesive fines can enhance the resistance of subgrade soils to fluidization, while geotextiles and geocomposites can also be used to mitigate mud pumping. Prefabricated vertical drains (PVDs) can continually reduce the buildup of EPWPs over the time due to the substantial reduction in drainage path, suggesting the efficiency of using the combined PVD-geocomposite system to mitigate mud pumping.

1 INTRODUCTION

1.1 *Subgrade failure under heavy freight trains*

In recent decades, the demand for faster and heavier freight transportation has pressurized geotechnical engineers worldwide to establish more robust and resilient rail track foundations. Alongside countries such as China, the USA, the UK, Canada and other European regions, Australian railways is one of the largest networks with rapid development in transport capacity. For example, the average train length is between 2-4 km, while the axle load is commonly 30 to 40 tonnes on mining and agricultural demands (Indraratna et al. 2014). However, this also results in devastating effects on the stability and longevity of track foundations, causing a greater degree of track deformation and foundation failures. In coastal regions where soft and saturated soils are prevalent, the repeated passage of heavy haul trains with increasing axle loads has been shown to exacerbate the accumulated excess pore water pressure (EPWP) and plastic deformation. When EPWP develops non-uniformly along the depth (localized response), it can stimulate the migration of pore water associated with fines, thus the formation of slurry track, i.e., mud pumping. The

DOI: 10.1201/9781003299127-2

infiltrated fines result in fouling of the ballast, reducing the interlocking between ballast particles (i.e., reduced shear strength) and impeding the drainage capacity (i.e., clogging) of the track foundation (Nguyen et al. 2019). Recent field inspections (Nguyen and Indraratna 2022c) have revealed a significant number of slurry sites along the South Coast (SC) rail line, NSW (Figure 1), many of which often repeat over year despite considerable maintenance cost. In low-lying regions, subgrade soil can be pushed upward (i.e., heave failure) under rising EPWP, seriously deteriorating structure and load bearing capacity of the track foundation. Hence, this phenomenon urgently demands a comprehensive investigation and feasible solutions.

Conventional studies (Selig and Waters 1994) indicated 3 different failure types of subgrade under rail tracks, i.e., (i) massive shear failure, (ii) progressive shear failure and (iii) attrition. However, these do not include the mechanism that transforms subgrade into fluid-like state. Furthermore, the internal migration of fines and moisture along the subgrade depth under repeated loads was not usually attended properly in past studies. Considerable effort has therefore gone to characterizing this phenomenon in the recent years (Duong et al. 2013; Chawla and Shahu 2016; Indraratna et al. 2020a). Past investigations (Hyodo et al. 1994; Indraratna et al. 2020a) indicated that the undrained shear failure can be characterized by the progressive advancement of excess pore water pressure and axial strain until the stress envelope reaches a failure line. On the other hand, when subjected to fluidization, soil becomes softened and fails under internal migration of pore water and fines, followed by the degradation in the stiffness and fabric of the specimens (Indraratna et al. 2020b; Nguyen et al. 2022). Subgrade instability is normally governed by complex combinations of internal and external factors. The internal factors can arise from soil characteristics such as particle size distribution, plasticity index (PI), void ratio and initial fabric (Vucetic and Dobry 1991; Polito and II 2001; Silva et al. 2022), whereas the external influences include the loading state and drainage condition (Sakai et al. 2003; Nguyen et al. 2019). Indraratna et al. (2020a) show that adding cohesive fines as well as increasing compaction degree can enhance soil resistance to fluidization. Despite abundant studies have been conducted to investigate the response of subgrade soils under repeated loads, the mechanism and causative factors that trigger the internal migration of soil particles and moisture still needs further explanation.

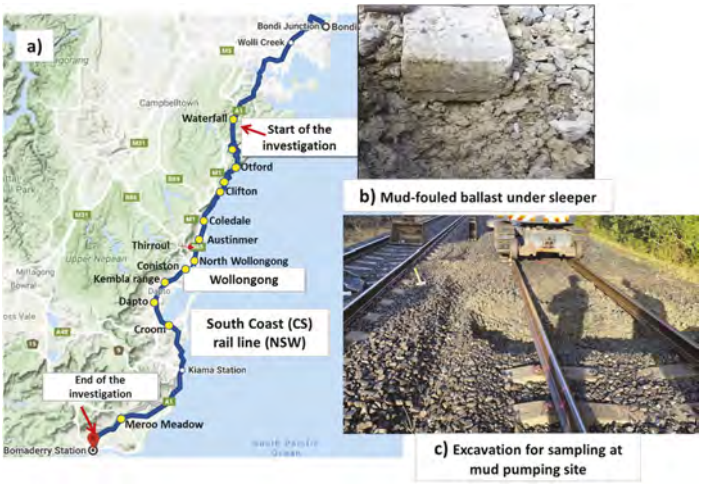

Figure 1. Field inspections of mud pumping sites including (a) locations along the South Coast (SC) line; (b) visual inspection of cohesive fines in ballast layer; and c) excavation for sampling.

1.2 *Use of geosynthetics to stabilize railway foundation*

Although a variety of solutions have been introduced, the most reliable and cost-effective solution for mud pumping and subgrade instability is still a critical question. The common practical method used to remediate a mud pumping track is replacement of the fouled ballast, however, this cannot always prevent the risk caused by subgrade mud pumping (Hudson et al.

2016). Increasing the thickness of ballast or renewing the subgrade (slurry) are expensive, but they are currently used in practice due to the simplicity and long-life effectiveness (Transport for NSW 2016). Additives such as lime and fly ash can also be used to increase the stability and cyclic resistance of substructures, they are time consuming and complex in construction while causing significant environmental impacts (Nguyen et al. 2019).

Geosynthetics are also commonly used to mitigate the migration of soil under railway and highways. Geotextiles have been used as a separation and filter layer under rail tracks for several decades, however, their effectiveness in preventing mud pumping is still now under debate (Raymond 1986; Sharpe et al. 2014; Hudson et al. 2016). Prefabricated vertical drains (PVDs) have been proved as a cost-effective method to shorten drainage path, thus accelerating the dissipation of EPWP as well as mitigating mud pumping (Indraratna et al. 2009; Singh et al. 2020). Short PVDs, i.e., installed in shallow depths within 6-8 m can prevent the accumulation of EPWP induced by the passage of heavy trains, meaning the less susceptibility of subgrade soil to internal instability. Furthermore, horizontal (i.e., transverse) drains can also be installed to facilitate drainage, thereby dissipating EPWP induced by train loads (Ito 1984).

Figure 2 shows the application of geocomposite material to prevent the migration of soil particles and associated mud pumping at Chullora, New South Wales (NSW). Although various geotextiles and geocomposites have been tested in the field and undergone large-scale laboratory testing, their effectiveness to prevent particle migration and fluidization varies widely. Some studies reported that geosynthetics have a limited efficiency and their performance could diminish quite significantly over the years (Selig and Waters 1994; Sharpe et al. 2014). Recent studies show that the installation of effective geosynthetics could prevent particle migration and potential track failures under dynamic loading (Lenart et al. 2018; Kermani et al. 2020). However, the use of geotextile allowed for in-plane drainage and dissipated the rapid development of EPWP. The pore arrangement in geotextiles should be large enough to provide adequate seepage (drainage capacity) and yet small enough to prevent particle migration (filtration) (Giroud 1996). Preventing particles from infiltrating into the overlying layers can increase the permeability of the drainage layer and provide continuous performance under loads.

Figure 2. Geocomposite installation to mitigate the fluidization potential of soft soil at Chullora, New South Wales (an ongoing pilot study supported by Sydney Trains).

This paper aims to review recent state-of-the-art studies around subgrade soil fluidization and the use of geosynthetics and geocomposites to prevent this failure under heavy haul rail tracks. Laboratory investigations from elemental to large scale model tests using real soil samples collected from mud pumping sites in NSW, Australia were extensively carried out at Transport Research Centre (TRC), UTS in recent years. Numerical model was also implemented to provide an insight into the micro-mechanism of soil fluidization under rising internal hydraulic gradient.

2 RESEARCH METHODOLOGY

2.1 *Cyclic triaxial tests*

It is critical to study the cyclic behavior of the subgrade soils prone to undrained instability and fluidization at a fundamental approach such as cyclic triaxial test. Disturbed soil samples were collected from several locations near Wollongong City. Basic geotechnical tests characterized the soils as low plastic clay, CL having a liquid limit less than 30 and a plasticity index of nearly 11. It is anticipated that low-medium plastic soils (PI < 26) are inherently vulnerable to mud pump due to the low cohesion between the soil particles (Duong et al. 2013; Chawla and Shahu 2016; Nguyen et al. 2019; Indraratna et al. 2020b). To achieve uniformity in sample preparation, the soil samples were compacted to a desired density ρ_d = 1600, 1680 and 1790 kg/m^3) using non-linear under-compaction criterion. The ratio of the initial specimen density to the maximum dry density of the soil is defined as Relative compaction (RC). The readers are referred to the following publication (Indraratna et al. 2020b) for further details on sample preparation.

To investigate the cyclic behavior of the reconstituted specimens, a series of stress-controlled undrained cyclic triaxial tests were performed using the GDS ELDYN dynamic triaxial testing equipment. The ELDYN system employs a pneumatic controller to apply the desired confining pressure. The pore pressure response was measured by employing a pore pressure transducer at the bottom of the specimen. Further, site investigations have revealed that mud pumping is a shallow phenomenon, therefore, the specimens were subjected to an effective confining pressure of σ'_{3c} = 15 kPa to simulate the shallow subgrade region. All specimens were back-saturated at a pressure of 400 kPa and then subjected to anisotropic consolidation (k_0 = 0.6).

The effect of varying axle loads was simulated by varying the cyclic stress ratio (CSR) from 0.2 to 1.0. The cyclic stress ratio (CSR) is defined as the ratio of the applied dynamic stress σ_d to twice of the effective confining pressure σ'_{3c}. The loading resulting from the passage of the trains was simulated through a sinusoidal waveform. The specimens were subjected to varying loading frequency (1.0 to 5.0 Hz) and the tests were concluded when the specimens experienced 5% cyclic axial strain or 50000 loading cycles. A generic representation for the fluidized specimen is highlighted in Figure 3 and the formation of a slurry at the top of the specimen at higher CSRs can be visually observed.

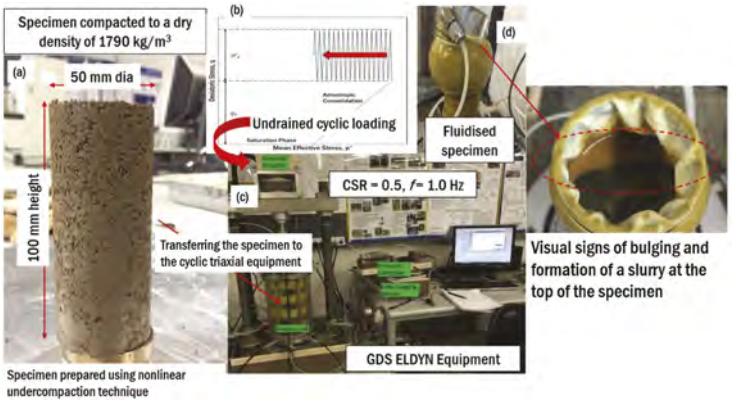

Figure 3. (a) Reconstituted specimen (b) Schematic for undrained loading (c) Cyclic triaxial rig (d) Typical fluidized specimen.

2.2 *Large-scale dynamic tests*

In order to capture the localized behaviour of subgrade soil as well as examining the efficiency of using geocomposite to stabilize subgrade soil under heavy cyclic loading, a series of large-scale dynamic tests were carried out at TRC.

2.2.1 *Testing materials*

Soil samples that had experienced mud pumping were collected from Wollongong, South Coast Rail line (NSW, Australia) for this study. The liquid limit (LL) and plastic limit (PL) of the soil were 42% and 26%, respectively and this soil could be classified as inorganic clay with medium plasticity. The maximum dry density (MDD) and optimum moisture content (OMC) were 1,682 kg/m^3 and 18.5%, respectively. The average water content after saturation was around 32% and the specific gravity was 2.59. A perspex hydraulic cell with a diameter (internal) of 140 mm and a height of 300 mm was used for the permeability tests. D_{cell}/D_{100} is greater than 42 and could avoid the effects of boundary wall friction (i.e. the ratio between the largest particle and the internal diameter of the cell is less than 1⁄6 (ASTM D3999-91 2003)). The compacted soil had a permeability of 8.9x10^{-7} m/s, as determined using the falling head method. Geotextiles and geocomposites with pore opening sizes of 10 to 80 μm, were used for the laboratory experiments. Geocomposite (T1) had a filter which sandwiched between two nonwoven geotextile layers with aperture opening sizes (O_{95}) of <10 μm. Prefabricated vertical drains (PVDs) had an assembled drain width of 100 mm, a thickness of 3.4 mm, and a drain filter pore size of 75 μm. All the properties of the geotextiles and PVD are listed in Table 1.

Table 1. Specification of geosynthetics used in the current.

Geotextile/geocomposite	T1*	T2	PVD	P
Tensile strength (EN ISO 10319 2008)	95 kN/m	22 kN/m	Drain Core and Filter material	PP and PET
CBR resistance (EN ISO 12236 2006)	18 kN	4.3 kN	Assembled drain width (ASTM D3774-96 1996)	100 mm
Pore size – Mean AOS (ASTM F316-03 2011)	<10 μm	60 μm	Assembled drain thickness (ASTM D5199-01 2001)	3.4 mm
Permeability (EN ISO 11058 2019)	0.35 l/m^{2}s	30 l/m^{2}s	Grab strength (ASTM D638-03 2003)	2.5 kN
Thickness (EN ISO 9863-1 2005)	9 mm	2 mm	Drain flow discharge (ASTM D4716-00 2000) at 200 kPa	2800 m^3/yr
Cone drop (EN ISO 13433 2006)	0 mm	22 mm	Drain filter pore size (ASTM D4751-99 1999)	75 μm

2.2.2 *Testing apparatus*

The Dynamic Filtration Apparatus (DFA) was designed at the University of Technology Sydney (UTS), Australia, to monitor the local EPWPs, soil porosity, development of excess pore pressure gradients (EPPGs) between different soil layers, and axial deformation under cyclic loading conditions (Figure 4). Four MPs with 1 kPa accuracy were placed on the center-line of the subgrade specimen at depths of 20, 40, 80, and 120 mm from the ballast/subgrade interface. Six pressure transducers (accuracy 0.5 kPa) were placed at the edge of cylinder at depths of 25, 55, 85, 115, 145, and 175 mm away from the ballast/subgrade interface. The local EPPGs that developed inside the specimen was calculated by measuring the differential hydraulic pressure at each layer. Amplitude Domain Reflectometry (ADR) probes were also installed along the subgrade depths and the variations in porosity could be monitored using the dynamic filtration apparatus (Arivalagan et al. 2021).

2.2.3 *Test procedures*

The collected soil from a mud pumping site was sieved through 2.36 mm. The target bulk density (1600 kg/m^3) and moisture content (17%) were achieved by compacting the dry soil and water to the desired volume. The 'nonlinear under-compaction' criterion was adopted to obtain a uniform density for the test specimen. PVDs with a modified size were used in the experiments based on the time factor and the average degree of consolidation for two soil cylinders, as proposed by (Ni 2012; Abeywickrama et al. 2021). Saturation was done with

filtered and de-aired water and monitored continuously by three ADR probes installed at different depths. A uniform vertical pressure of 30 kPa was applied to consolidate the soil specimen. The pore pressure that developed during consolidation process was monitored, and the settlement due to the applied loading was recorded continuously for two days. The geotextile was saturated before being placed onto the subgrade soil. After placing the ballast and/or geotextile, a sinusoidal load was applied through a servo-controlled actuator. In this study, a uniform cyclic stress was applied as a minimum vertical stress (σ_{min} = 30 kPa), and the sinusoidal vertical cyclic stress (σ_{max} = 70 –140 kPa), thus simulates a maximum axle load of 35-40 tonnes. The frequency varied between 1.0 and 5.0 Hz, which represents the train speeds of 40-220 km/h in a typical railway track conditions (Powrie et al. 2007; Indraratna et al. 2020b).

2.2.4 *Experimental phases*

The laboratory tests were undertaken to simulate (a) undrained conditions where an impermeable boundary was created at the top of subgrade surface, and (b) free drainage conditions where a layer of ballast directly placed over the subgrade specimen. These two tests can be used to evaluate the failure criteria and subgrade fluidization. Dynamic filtration tests were carried out using geocomposite (T1), geotextile (T2) and PVD (P) and laid at the interface between the ballast and subgrade specimens to evaluate how well geosynthetics control the development of EPWP and preventing or delaying the initiation of subgrade fluidization. A series of laboratory experiments were undertaken to investigate the role of geotextiles and PVD under different axle loads and speeds. The loading frequency and amplitude applied varied from 1 to 5 Hz and 20-35 kPa (i.e., σ_{min}= 30 kPa, σ_{max} = 70-100 kPa), respectively. The effectiveness of a combined PVD-geocomposite system was also measured in terms of controlling the development of EPWP and mitigating/controlling the initiation of subgrade fluidization. A horizontal drainage path was created by the inclusion of PVD, and laboratory experiments were carried out to examine how effectively radial drainage could reduce the critical EPWPs that developed under cyclic load.

2.3 *Numerical modeling of subgrade fluidization*

In order to understand how the micro-structure of soil evolves under rising EPWP, a numerical investigation based on discrete element method (DEM) coupled with computational fluid dynamics (CFD) was carried out. In this approach, solid soil particles were modelled by DEM, while fluid flow was described by the CFD. Interactions between two phases, i.e., solid and fluid were governed through fluid-particle interaction models such as the pressure gradient, drag and viscous forces. Variables between the two computation platforms were exchanged regularly to ensure the effects from its counterpart to be captured properly. Details

of theoretical background and numerical algorithm of this method can be found in past studies of the Authors (Nguyen and Indraratna 2020; Nguyen and Indraratna 2022a). In the current paper, a sandy soil which is often used for capping layer under railways was simulated. Fluid went through the soil domain from the bottom to the top under increasing hydraulic gradient, while responses of soil and fluid at micro-scale were captured over time and space (Figure 5). It is important to note that a representative soil element was modelled in this case to enable particle-scale response of soil to be captured. Periodic boundary which simulated the continuous contacts between particles while migrating was used.

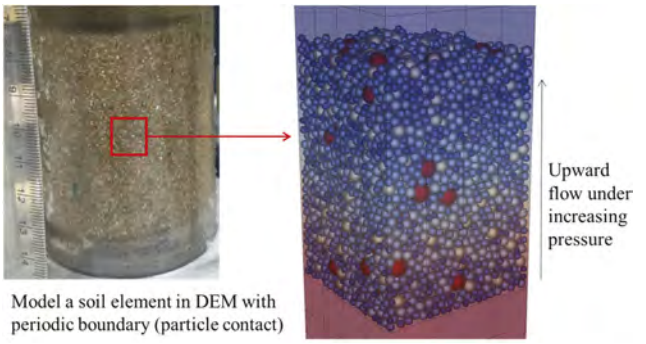

Figure 5. Numerical simulation of soil fluidization using CFD-DEM coupling.

3 RESULTS AND DISCUSSION

3.1 *Build-up of excess pore water pressure and migration of particles under cyclic loading*

When a specimen is subjected to increasing CSR, the specimen experiences larger deformations. However, there lies a critical cyclic stress ratio (CSR_c), wherein the mean excess pore pressure ratio (EPP) and cyclic axial strains shoot up rapidly. This is coupled with a sharp drop in the magnitude of the deviatoric stress q, indicating the onset of fluidization. Based on the test results, the CSR_c is dependent on the initial dry density of the soil specimen and the loading frequency. For example, as can be seen from Figure 6, the CSR_c for a specimen compacted at a dry density of 1790 kg/m^3 at a loading frequency of 1.0Hz lies between 0.4 and 0.5. Similar response was observed with soil samples collected from different mud pumping locations, despite different critical thresholds of load parameters and soil density (Indraratna et al. 2020a; Abeywickrama et al. 2021b).

The accumulation of excess pore water pressure governs the failure of the specimen under undrained cyclic loading. As seen from Figure 6, the increase in the CSR results in the increase in the build-up of excess pore water pressure. To quantify the effect of the EPWP, the incremental rate of EPWP was calculated. It is defined as the ratio between the EPWP and the log(N), where N is the number of cycles. It is observed that the rate of increment in EPWP at different CSRs (0.2, 0.3, and 0.4) is very similar (Figure 7a). The plots stabilize after the specimens reach 5% cyclic axial strain, and there is no considerable change after 2000 loading cycles. This implies that there is no further increase in the excess pore pressure. Figure 7b shows the variation of the incremental rate of EPWP with increasing CSR. When the specimen is subjected to a CSR = 0.5, there is a sudden increase in the excess pore pressure which results in the formation of slurry at the top of the specimen. For example, when the RC is 99%, the CSR_c lies between 0.4 and 0.5 for a frequency of 1.0 Hz. The CSR_c drops as the RC values reduces. It can be attributed to larger pore water pressure accumulation at lower RC as the specimen is in a relatively loose state.

A post-failure analysis was carried out for all fluidized specimens. Representative soil samples were carefully collected from the upper one-third and central region and were examined in the Malvern particle size analyzer. The results indicated an increase in the volume of fines (less than 75 microns) in the upper region of the specimen as opposed to the mid-region. This confirms that during the passage of trains, the fines migrate upwards and are transported by

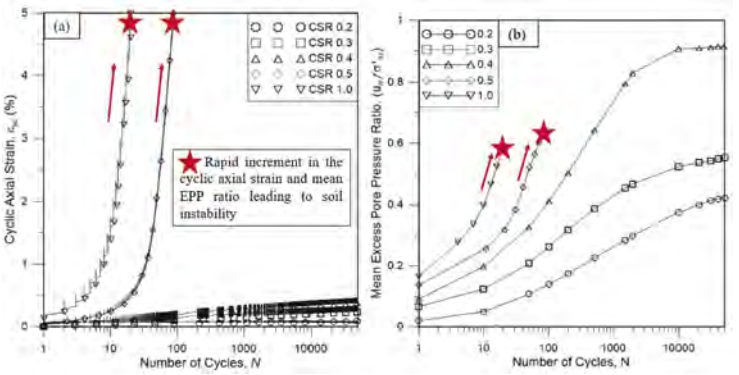

Figure 6. Generation of cyclic axial strains and mean excess pore water pressure (ρ_d = 1790 kg/m^3) (modified after Indraratna et al. 2020a).

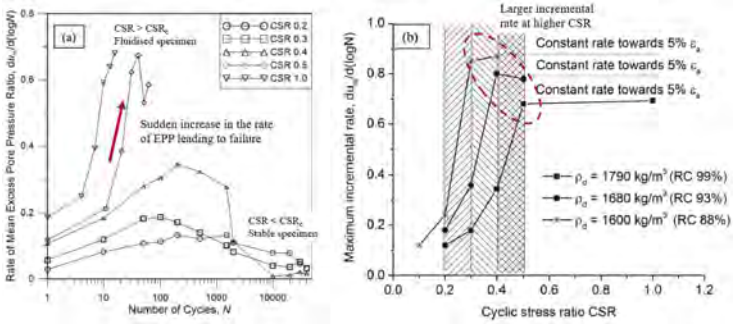

Figure 7. Variation in the incremental rate of EPWP with Number of cycles, N and CSR (modified after Indraratna et al. 2020a).

the displaced water which results in slurry formation or ponding of the slurry. Selig and Waters (1994) suggested that the cyclic nature of loading at the sleep-ballast interface generates a negative pressure which draws the suspended soil slurry from the subgrade level to the top of the ballast. Further, shallow subgrade with high water content (resulting from heavy rainfalls) during continuous railway loading may become susceptible to fluidization.

3.2 *Micromechanics of soil fluidization through numerical investigation*

The numerical results (Figure 8) show that when hydraulic gradient increases, soil particles are displaced under rising hydraulic forces acting on the particles, resulting in broken contact network and expanding porous system. For example, porosity of the simulated soil increases gradually under developing hydraulic gradient *i* before a sharp increase at the critical values of *i.* Meanwhile, the number of particle contacts drop immediately with rising *i* and become severe (i.e., the contact loss jumps from 20 to 35%) when *i* reaches the critical level (i.e., fluidization). While the change in porosity before the onset of fluidization is usually hard to measure in conventional laboratory due to its very sensitive magnitude, the response from particle contact network captured in the current CFD-DEM coupling model is apparent even at a small level of excess pore water pressure gradient or internal *i*. When the effective contacts of particles (i.e., the contacts bear effective stresses) are significantly vanished, soil behaves likes fluid with floating particles, thus fluidization. This microscale analysis indicated that preventing the accumulated EPWP and/or reinforcing contact network of soil are certainly effective approaches to mitigate particle migration and soil softening under rail tracks.

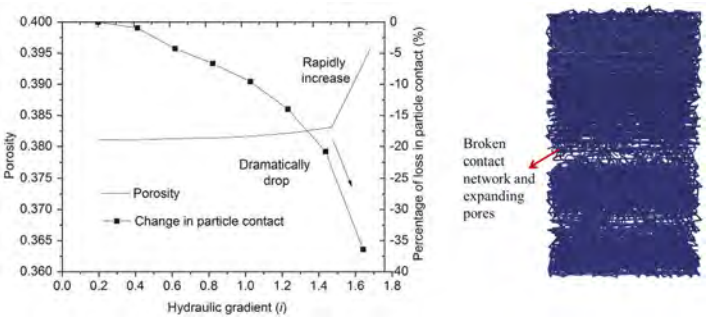

Figure 8. Degradation in micro-structure (porosity and particle contact) of soil under rising internal pore water pressure.

3.3 *Stabilization of subgrade soil using membrane and the composite membrane PVDs*

3.3.1 *Effectiveness of geosynthetics under cyclic loading*

The EPWPs that developed inside the specimen were measured because they were the main cause of instability in soft subgrade under continuous cyclic loading. Figure 9(a) shows the rapid development of EPWPs up to 500 cycles, where all the miniature pressure readings remain above 30 kPa when using geocomposite T1. The transducer MP2 (at 40 mm) measured the maximum EPWP of 37 kPa at 500 cycles. However, geocomposite with a filter membrane (AOS <10 μm) could dissipate the EPWPs below 10 kPa at the end of 75,000 cycles. When only using a geocomposite, the rate of excess pore water dissipation in Test T1 was higher near the ballast/subgrade interface (MP1) than the middle/shallow part of the subgrade (MP2 and MP3). In Test T2, until the test reached 65,000 cycles, the values from MP2 measured 40 mm below the interface were more than 20 kPa for T2 and with a very low rate of dissipation compared to geocomposite T1. As Figure 9(a) shows, T1 dissipated EPWPs by more than 76% and 52%, at 20 and 40 mm below the interface, unlike geotextile T2 at 75,000 cycles. This indicates that geocomposite (T1) dissipated the EPWP better than in comparison to conventional geotextile T2.

Undrained cyclic tests (impermeable boundary created by a geomembrane) indicated that the EPWPs that develops inside the soil specimen without a significant reduction over time might cause subgrade instability (Singh et al. 2020; Arivalagan et al. 2021). As shown in Figure 9(a), the magnitudes of EPWP that developed in Test T1 are more than 30 kPa at 500 cycles at all three depths; however, the presence of PVD (Test P+T1) certainly dissipates the EPWPs, especially in the deeper layers of soil. Therefore, the values of EPWPs from Test P+T1 are less than 15 kPa within 500 cycles and less than 4 kPa after 75,000 cycles. In other words, although a sole geotextile (Test T2) shows a maximum EPWP of more than 15 kPa at 75,000 cycles, there is approximately 80% reduction in EPWPs 40 mm under the interface due to the inclusion of the PVD-geocomposite system as shown in Figure 9(a) (i.e., the EPWPs at MP2 and MP3 remain below

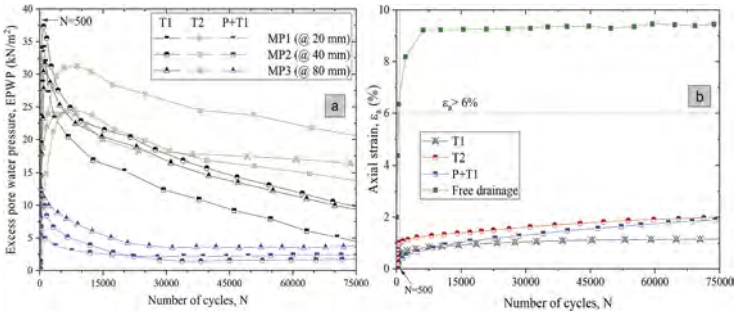

Figure 9. Generation of (a) EPWPs and (b) axial strains with geocomposite (T1), geotextile (T2), and a combined PVD-geocompoite system (after Arivalagan et al. 2022).

5 kPa). This proves that a combined PVD and geocomposite (P+T1) system can reduce the potential for subgrade fluidization during cyclic loading due to the continuous dissipation in EPWPs.

As Figure 9(b) shows, the maximum axial strain (ε_a > 6%) in free drainage tests (35 mm thick ballast was directly placed over the subgrade surface) only occurred after 500 cycles. However, the development of axial strain was controlled due to the inclusion of geotextiles at the interface. Geocomposite (T1) could provide more confinement at the ballast/subgrade interface and prevent the penetration of coarser ballast particles into the subgrade soil in Test T1. However, there was a continual increase in axial deformation due to the migration of fine particles through the pore openings of geotextile (T2) and the residual axial strain after 75,000 cycles remained above 2% for T2. This may lead to differential settlements in railway tracks under repeated cyclic loading conditions.

3.3.2 *Performance of geocomposites under varying cyclic stress*

A set of cyclic deviatoric stresses (i.e., σ_{max} of 70 and 100 kPa) were used to demonstrate how an increased axle load affects the cyclic behaviour of subgrade soil, and to assess the effectiveness of geocomposite T1. There was an expeditious development in EPWPs when the cyclic deviator stress increased up to 100 kPa when a sole geocomposite placed on the subgrade. As shown in Figure 10(a), geocomposite T1 could not reduce the cyclic EPWPs effectively at the middle to the lower region (i.e., the critical layers) when the cyclic stress increased to 100 kPa. The readings from miniature pressure transducers MP2, MP3, and MP4 remained above 35 kPa until the test ended and these results imply that an increased axle load in railway tracks (35-40 tonnes) generates a rapid increase in EPWPs, and the inclusion of geocomposite cannot dissipate them quickly under adverse hydraulic conditions. The increasing trend in axial strain was reported in previous studies when soft subgrade soil is subjected to a higher cyclic stress (Indraratna et al. 2020a). A similar increasing trend was observed at 100 kPa, where ε_a reached 5% before 75,000 cycles, as shown in Figure 10(b). The axial strain for 70 kPa (maximum vertical stress) was less than 1.5% until the test ended, but it rocketed up to 5.3% at 80,000 cycles at 100 kPa maximum vertical stress. Although geocomposite can mitigate the migration of fine particle at 70 kPa, a lot of fine particles accumulated during higher cyclic stress (under 35-40 tonnes axle load), which may induce subgrade instability due to excessive deformation in railway tracks.

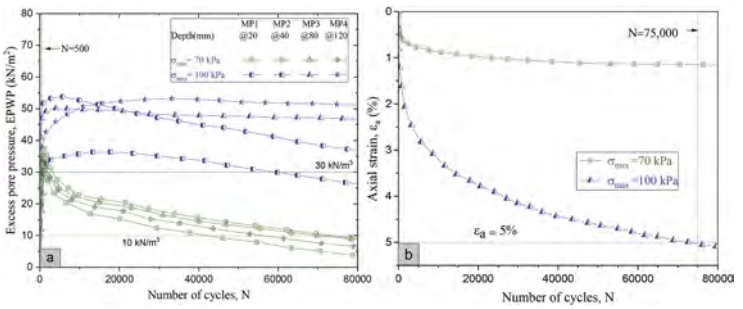

Figure 10. (a) Generation of EPWPs and (b) axial strains due to the inclusion of geocomposite (T1) under different cyclic stress (i.e. σ_{min} = 30 kPa, σ_{max} = 70 - 100 kPa) (modified after Arivalagan et al. 2021).

3.3.3 *The role of PVD-geocomposite system in a typical railway track*

The significant variation in drainage conditions at the interface and inside the soil were studied based on the generation of an excess pore pressure gradient (EPPG) at different depths. The EPWP measured at different soil layers by pressure transducers were used to calculate the EPPG. This can be defined as the ratio between changes in the excess pore water pressure head (unit = m head) and the corresponding distance between two specified locations (unit = m). The generation of critical EPPGs at various locations (inside the subgrade) can also induce instability by dislocating the fines from the original soil matrix. As Figure 11(a) shows, EPPG that developed in undrained tests rocketed above 40 after 500 cycles, and there was no significant reduction until

15,000 cycles. This non-uniform development of EPPGs in the middle and deeper subgrade soil, i.e., Layers (2-1) and (3-2), created a significant upward hydro-dynamic force that dislocated the finer particles towards the top layers. However, a PVD-geocomposite system (P+T1) reduced the EPPG at the top three layers of the soil within 2500 cycles. The EPPGs that developed in Layers (2-1) and (3-2) decreased by 67% and 90% due to the inclusion of PVD and geocomposite (T1), as shown in Figure 11(a). In addition, EPPG that developed at the middle and lower regions (Layer (3-2) and Layer (4-3)) was less than five until the end of cyclic tests.

The increase in the fine percentage and the formation of slurry at the interface (abrupt change in the water of soil) were used to assess the potential for subgrade fluidization in several studies (Indraratna et al. 2020b). Therefore, PSD and moisture content tests were conducted after each cyclic test. Malvern particle size analyzer was used to measure the particle size distributions at the top, middle, and bottom regions at the end of loading. Figure 11(b) shows that fine particles of less the 75μm had accumulated at the top surface in undrained tests where a lot more fines were lost in the middle layers (between 1 and 60μm) compared to the initial PSD. As shown in Figure 11(b), the inclusion of P+T1 prevented the migration of particles from the middle and lower regions. There were no significant variations in PSD, especially at the top and middle layers. This shows that PVD and geocomposite with an effective filter (P+T1) can prevent particle dislocation under critical hydro-dynamic conditions. Similarly, there was a large accumulation of fines (less than 1μm) in the top and middle layers in Test T2. Moreover, the water content for undrained and free drainage tests were close to the liquid limit at the top surface of the subgrade and the amount of high water near the interface causes softening and can induce fluidization as finer particles accumulate below 500 cycles. However, a PVD-geocomposite system helped to reduce the water content where they had a maximum water content of 30% near the interface, which prevented the soil softening under cyclic loading.

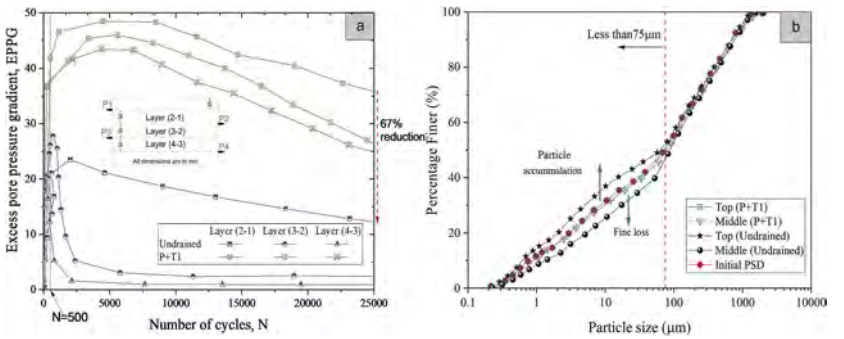

Figure 11. Undrained cyclic test and a combined PVD-geocomposite system (a) EPPGs and (b) variations in PSD (modified after Arivalagan et al. 2022).

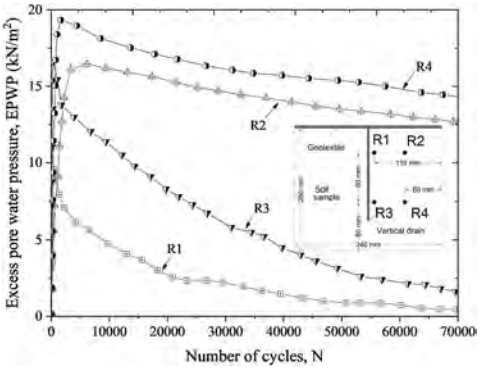

Figure 12. Dissipation of EPWPs due to radial drainage paths (P+T1).

Transducers (MPs) were installed at different locations from the centre (in radial direction 0 and 60 mm from the centre line) to measure how much the prefabricated vertical drains could alleviate the EPWPs (Figure 12). The EPWP measured at R1 (i.e., the shortest radial drainage path) is lower than at R2. Although the EPWPs developed at location R4 may take much longer to dissipate than R3, the PVDs successfully dissipate them before reaching their critical values. Furthermore, the EPWPs that developed at R1 and R3 approached zero after 70,000 cycles. The EPWPs measured at R2 and R4 decreased continuously as the number of cycles increased and were less than 14 kPa at the end of cyclic loading. Furthermore, PVDs can continually alleviate EPWPs during train loading and even during the rest period after each train passes.

3.3.4 *Effectiveness of PVD-geocomposite system under different axle loads and frequencies*
Figure 13(a) shows that the rapid generation of EPWP at 40 mm below the subgrade interface approached 50 kPa prior to reaching 5000 cycles when the maximum vertical stress increased to 100 kPa (approximately 35 tonnes axle loading). However, the EPWPs in the top and middle layers continued to dissipate due to the application of a PVD-geocomposite system. For instance, the EPWPs that developed at MP1 and MP3 were less than 25 kPa under varying cyclic stresses at the end of each cyclic test. In essence, the rapid generation of axial strain was controlled using geosynthetics because the axial strain was only 3% and 2.2% after 100,000 cycles at 30 and 35 tonnes axle loads, respectively. Figure 13(b) shows the effects of two different frequencies with the combination of PVD and geocomposite system. The results indicated that EPWPs that developed at all three locations (MP1, MP2 and MP3) decreased at a lower frequency. An increase in frequency (f=5 Hz) causes a significant increase in EPWPs at MP1 compared to the test under 3 Hz frequency. In addition, the rate of dissipation of EPWP is slightly higher in the test carried out at a lower frequency. The EPWPs that developed at MP1 are 4 kPa and 5 kPa for F=3 and 5 Hz at the end of the cyclic tests (Figure 13(b)). These results confirmed that a PVD-geocomposite system can still prevent critical EPWP generation even under higher frequencies.

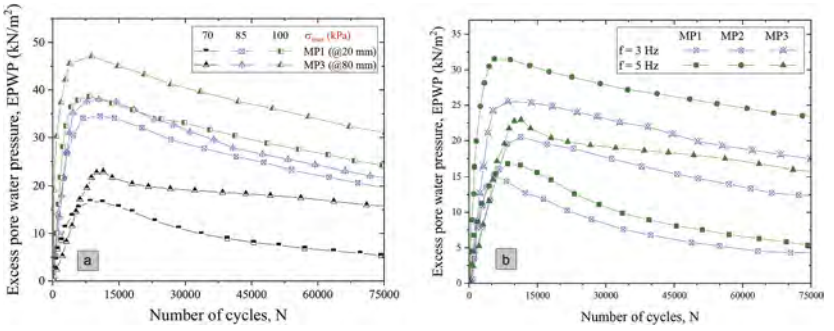

Figure 13. Performance of a combined PVD-geocomposite system under different (a) cyclic stresses (i.e. σ_{min} = 30 kPa, σ_{max} = 70 - 100 kPa) and (b) frequencies (3-5 Hz) (modified after Arivalagan et al. 2022).

4 CONCLUSIONS AND INDUSTRY IMPACT

Comprehensive experimental and numerical studies were carried out to investigate the mechanism and causative factors of subgrade fluidization under heavy haul trains. Geosynthetics and PVD-geocomposite inclusions to mitigate subgrade fluidization were proposed and examined through a large-scale model test. Salient findings of this study can be summarized as follows:

(1) The passage of heavy freight trains can cause a non-uniform accumulation of EPWP over the depth of subgrade soil, resulting in increasing excess pore pressure gradient (EPPG or an internal hydraulic gradient). When this gradient reached a critical level, the internal flows brought moisture and fines upward accompanied with stiffness degradation, thus

mud pumping. The heaver the train, the larger the cyclic stress ratio, the larger the accumulated EPWP and EPPG.

(2) The numerical investigation at micro-scale showed that increasing internal hydraulic gradient meant larger hydraulic forces acting on soil particles that pushed particles away while expanding the pore network (i.e., increasing porosity). As this continued to develop under repeated loading, the soil matrix significantly lost effective contacts between particles that resulted in reduced stiffness and fluidized soil.

(3) Increasing the relative compaction (or density) of soil can enhance the resistance to fluidization, however, when the axle load exceeded very high degree (CSR > 0.5), additional soil stabilization such as inclusion of geosynthetics should be considered.

(4) PVDs combined with a drainage membrane (geocomposite at the interface) facilitated the dissipation of EPWP and EPPG that significantly enhanced track stability by preventing soil softening and fluidization. The test results showed that a combined PVD-geocomposite system can effectively dissipate the pore water pressure even when the axle load and frequency reached high degrees (e.g., equivalent 35-40 tons and 120 km/h train speed over 75,000 loading cycles).

ACKNOWLEDGEMENT

Financial and technical support provided by the Australian Research Council (ARC) funded ITTC-Rail (i.e., LP160101254, LP200200915, DP220102862, IC170100006), and industry partners including TetraTech Coffey, SMEC, ACRI, Sydney Trains and Global Synthetics is gratefully acknowledged. Deformation of shield tunnels induced by adjacent construction

R.P. Chen, F.Y. Meng, H.N. Wu & H.Z. Cheng
College of Civil Engineering, Hunan University, Changsha, China

ABSTRACT: Shield tunnels are very sensitive to the ground motion. The protection of operating shield tunnels is important during the construction of underground space. This paper introduces three typical soil arching, termed as "upward", "downward" and "lateral" soil arching in light of their developing direction with respect to the ground gravity during the underground construction. Theoretical models are proposed to describe the ground stress and deformation transfer associated with the developing soil arching. The impacts of the nearby construction on the existing shield tunnels are evaluated considering the soil arching. It is found that a significant increase in structural deformation occurs when the loosened zone of soil arching develops to the existing tunnel. Countermeasures regarding protection of the nearby tunnels are developed by mitigating the expansion of the loosened zone and reinforcing the loosened zone. Finally, engineering applications of the countermeasures are also introduced.

1 INTRODUCTION

During the past decades, underground construction has been a promising alternative to extend the space of congested urban cities. More and more shield tunnels are constructed for subways, express roads, and pipe galleries. To further exploit the capacity of the underground space, shield tunneling and upward/lateral excavation nearby operating shield tunnels are frequently encountered. Shield tunnels are fabricated structures assembled by several lining segments and many bolts, featured with long joints, low stiffness and easy to deform. In adverse conditions (weak soil properties, close proximity, insufficient retaining system, and inappropriate countermeasures), the operating shield tunnels would suffer from intolerable deformations and structural damages like lining cracks, dislocations, and leakages at joints (Chen et al. 2016).

In essence, the shield tunnel deformation is determined by the ground deformation and stress change induced by the nearby construction. Soil mass excavation induced by construction could lead to uneven ground deformation, and hence the generation of soil arching. Development of the arching governs the ground stress transfer, deformation propagation, and the tunnel responses. Soil arching is one of the most common phenomena encountered in geotechnical engineering. Terzaghi (1943) proposes an analytical solution for depicting the soil arching above the trapdoor, followed by plenty of studies on the soil arching above the tunnel (Franza et al. 2019; Lin et al. 2022) and piled embankment (van Eekelen et al. 2013; Zhang et al. 2016). These types of soil arching are termed as the upward arching in light of its developing direction. In addition, excavation could also cause arching effect below base level and behind the retaining wall. The developing directions of the soil arching due to shield tunnelling and nearby excavation are different and hence exhibit distinct impacts on the existing tunnels. However, to date, the soil arching induced by the above nearby underground construction has not been well investigated and summarized yet, as well as the associated shield tunnel deformation and countermeasures.

This study introduces three typical soil arching in light of their developing directions. Theoretical models are proposed to describe the ground stress and deformation transfer associated with the developing soil arching. The impacts of the nearby construction on the existing shield tunnels are evaluated considering the soil arching. Countermeasures regarding protection of the nearby tunnels are developed by mitigating the expansion of the loosened zone and reinforcing the loosened zone. Finally, engineering applications of the countermeasures are also introduced.

2 SOIL ARCHING IN UNDERGROUND CONSTRUCTION

2.1 *Understanding and definition*

(1) *Upward soil arching*

Ground volume loss is inevitable during shield tunneling because of overbreak, unbalanced face support pressure, and poor shield tail grouting. The differential ground deformation induced by the volume loss could cause the occurrence of the soil arching above the tunnel, as shown in Figure 1(a). To recognize the characteristics of the arching, experimental and numerical studies have been carried out (Han et al. 2017; Franza et al. 2019; Lin et al. 2019). Lin et al. (2019) find that the shear bands develop obliquely upward from the bottom of the tunnel in sandy ground. Besides, the soil arching develops with the increasing trapdoor displacement (Iglesia et al. 1999), and hence that above the tunnel should develop with the growing ground volume loss.

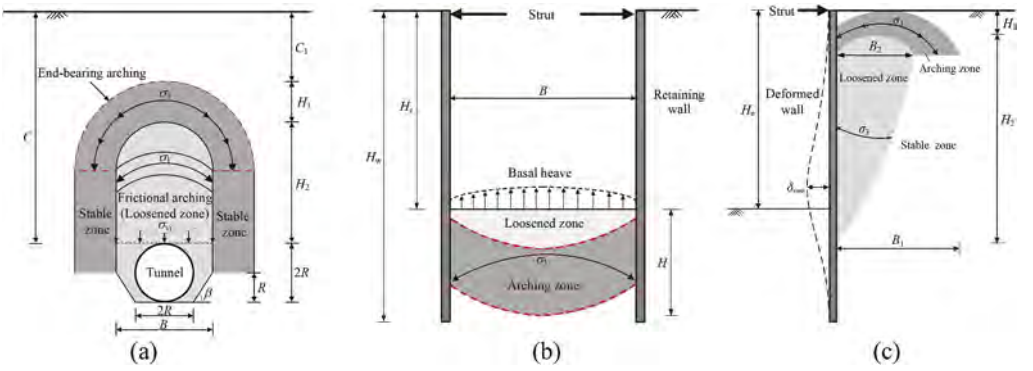

Figure 1. Illustration of the three typical soil arching for underground construction.

(2) *downward soil arching*

Uneven ground deformation occurs below the excavation base and behind the retaining wall, causing downward (Figure 1(b)) and lateral (Figure 1(c)) soil arching, respectively. Numerical simulation (Meng et al. 2022) and centrifuge modeling (Wu et al. 2022) are carried out to get an insight into the downward arching. Similar to the displacement and the width of the trapdoor, the excavation depth and the width are predominant variables influencing the boundary of the downward arching. Furthermore, the soil relative density is also a key factor governing the soil arching (Liu et al. 2022b). The model ground adopted in the centrifuge is dry Fujian sand (D_r=30% in Test 1 and 75% in Test 2), and the widths and final depth of the excavation are 15 m and 24 m, respectively. Figure 2(a) depicts the vertical distribution of the horizontal soil arching ratio (SAR) with varying distances to the excavation centerline, and an inflection point can be found on each curve. Within the loosened zone, the SAR sustainingly increases along with depth, and a steeper slope is found nearby the wall. In comparison, the SAR exhibits negligible change below the arching boundary. In Test 1, a greater distinction among curves in sections and a steeper arching boundary than that in G2 is found, especially in the loosened zone, which indicates that the dense sand layer leads to a more extensive nonuniformity of stress release. Take the inflection points of the curves of the SAR as the arching boundary, the variation of arching zone height with excavation depth is shown in Figure 2(b). The height of arching in the loose sand is larger than that in the dense sand for shallow excavation. This difference decreases with the growing excavation depth, which might be attributed to the similar soil behavior in the loosened zone and the arching zone when the excavation depth reaches a certain value, like the ending of the curve for support pressure versus face displacement for tunnel face stability for loose and dense sand (Kirsch 2010).

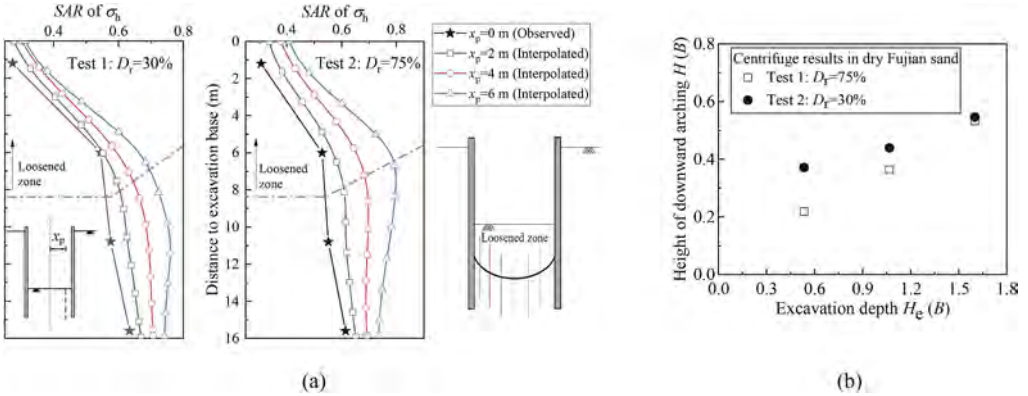

Figure 2. (a) distribution of horizontal soil arching ratio (SAR) below excavation depth; and (b) relationship between height of downward arching and excavation depth.

(3) *Lateral soil arching*

In terms of the ground responses behind the retaining wall, previous studies mostly concentrate on stress transfer and seldom take into account both soil movement and stress transfer (Hashash & Whittle 2002; Ng et al. 2012; Li et al. 2021), which are two key characteristics for lateral soil arching. Furthermore, there is not yet a criterion for determining the arching zone and loosened zone due to lateral excavation. Toward this end, a field test for investigating the lateral soil arching effect behind the retaining wall is carried out in an average 17-meter-deep, braced excavation in clayey ground (Chen et al. 2022a; Liu 2022). The ground movement, lateral earth pressure, and wall deformation are extensively measured, and the shear strain is calculated. It is found that soils behind the wall are predominantly subjected to horizontal extension and vertical compression, especially nearby the area where maximum wall deformation occurs. In comparison, soils neighboring the upper part of the wall experience increases in horizontal stress and hence compression. The soil arching zone and loosened zone are determined by the boundary at which the ratio of lateral earth pressure equals 1, the connected inflection points of lateral earth pressure, the lower sliding plane, and the wall. The arching zone transfers pressure oblique to the well-retained zone and the stable soil, resulting in the formation of horizontal compression zone and vertical extension zone, as well as an increase in lateral earth pressure around the crest of the wall. The major and minor principal stress arching are formed in the arching zone and loosened zone, respectively.

Figure 1(c) depicts the schematic of the lateral soil arching, based upon the above field observation. Similar to other two types of arching, the lateral soil arching develops with the increasing wall deformation. With the growing wall deformation, the height and the width of the loosened zone and arching zone increase. Finally, the arching zone might gradually disappear and the loosened zone would extend to the ground surface, with sharply increased ground movement and cracks along the shear plane. The evolution of the lateral soil arching mainly depends on the ground condition and wall deformation, which needs further investigation.

2.2 *Theoretical model*

To predict the earth pressure on the deep circular tunnel, Lin et al. (2022) propose a multi-arching model incorporating the earlier theories of Terzaghi (1943) and Hewlett & Randolph (1988). Figure 1(a) illustrates the concept and framework of the multi-arching model, which consists of the end-bearing arching, frictional arching, and stable zone. The end-bearing arching with a semi-circular ring shape is located on the upper part of the multi-arching model, whose arch feet act on the stable zone. The cover depth and thickness of this zone are C_1 and H_1, respectively. The inner and outer radius of the semi-circular ring are r and $r+H_1$, respectively. The height and width of the frictional arching are H_2 and B, respectively. The

transferred load q_1 from the end-bearing acting on the top of this zone is partly transferred to the stable zone by the frictional arching effect and the rest of the pressure acts on the top of the tunnel. This zone bears the pressure transferred from the end-bearing arching and frictional arching and provides sufficient support.

To figure out the model, two assumptions are made: (1) the ground loss induced by the tunnel over-excavation is absolutely compensated by the soil mass within the loosened zone, and (2) the frictional arching is composed of a semicircle and a rectangle with two triangles and a circle subtracted. The model geometric parameters include the width and height of the frictional arching, thickness of the end-bearing arching, which are determined based upon the earlier researches as listed in Table 1. On the basis of the geometries of the model, the stress in the end-bearing arching is calculated using the 2D semi-circular ring limit equilibrium model in piled embankments (Hewlett & Randolph 1988). Hence, the horizontal and vertical earth pressure above the tunnel can be calculated, which is verified by centrifuge modeling results (Franza et al. 2019). In comparison with the model of Terzaghi (1943), the multi-arching model yields more reasonable predictions for normalized average earth pressure on the tunnel (Lin et al. 2022).

Table 1. Geometric parameters of the upward arching model.

Parameter	Value	Meaning	Literature
B	$D(1+\cot\beta)$	D = tunnel diameter $\beta = 45°+\varphi/2$	Stein et al. (1989)
H	$D(k(\eta/\alpha)+b)$	$k = \frac{\pi \tan\beta}{4(1+\tan\beta)}$ $b = \frac{(\pi-4)\tan^2\beta + 2(1-\pi)\tan\beta + 4 - \pi}{8\tan\beta(1+\tan\beta)}$ η = ground volume loss α = rebound coefficient (0.1 to 0.24 and 0 to 0.08 for dense and loose sand)	/
H_1	$C\text{-}H>0.4B$, $H_1=0.4B$ $0<C\text{-}H\leq 0.4B$, $H_1=C\text{-}H$ $C\text{-}H\leq 0$, $H_1=0$	C = tunnel cover depth B = width of frictional arching zone	Lai et al. (2018)

Based on the multi-arching model (Lin et al. 2022), Chen et al. (2022b) propose a novel analytical approach to predict the tunneling-induced subsurface settlement on the tunnel centerline (Figure 3). In addition, stress-dependent modulus is adopted to consider the soil mechanical behaviors. This approach assumes that the soil material behaves elastically and isotropically, and the ground movement around the tunnel is oval-shaped. The ground settlement right above the tunnel crown is maximum and equals to the gap parameter g, determined by the physical gap, the over-excavation of the soil around the tunnel, and the 3D elastoplastic deformation of the soil in front of the tunnel face. The tunnel excavation leads to the unloading rebounding deformation within the frictional arching zone u_1 and end-bearing arching zone u_2. To obtain the ground settlement at a certain depth, g can be used to subtract the rebound deformation of the soil at its location. For instance, the ground settlement at the top of the end-bearing arching zone is

$$u_z = g - u_1 - u_2 \tag{1}$$

The magnitudes of u_1 and u_2 can be calculated by the Hooke's law, in which the ground stress change is determined by multi-arching model (Lin et al. 2022) and the stress-dependent elastic unloading modulus (Schanz et al. 1999). The applicability of this methodology is examined by three case histories and one model test, exhibiting satisfying results. Furthermore, the subsurface ground settlement trough can be determined by the calculated settlement at tunnel centerline and empirical settlement trough width coefficient.

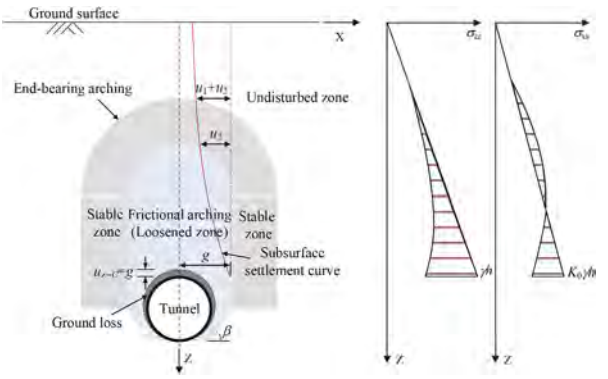

Figure 3. Analytical model for tunneling-induced subsurface ground settlement (after Chen et al. 2022b).

3 APPLICATION OF SOIL ARCHING

3.1 *Prediction of nearby tunnel deformation*

Two-stage method is proposed to predict the nearby tunnel deformation due to adjacent construction, which has been widely employed to solve the problem of tunnel-soil interaction. For tunneling underneath existing tunnel (Figure 4), in the first stage, the vertical unloading stress caused by the underlying tunnel is calculated based on the tunneling-induced subsurface settlement trough considering the soil arching. The maximum settlement of the trough is obtained by the method proposed by Chen et al. (2022b) and the width coefficient of the trough is determined by empirical results. The unloading stress at the level of the tunnel axis is calculated by the corresponding subsurface ground settlement and the coefficient of subgrade reaction. In the second stage, the responses of existing shield tunnel subjected to the corresponding vertical unloading stress are determined by an analytical model. In this analytical model, the existing shield tunnel was treated as a Timoshenko beam (Wu et al. 2015) resting on a Winkler foundation model. The applicability of this method is validated by several case histories in China, and good agreement is achieved in most cases in which soil improvement between the tunnels is not carried out.

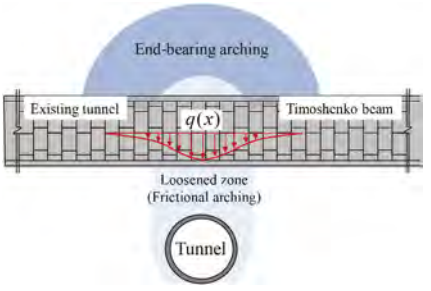

Figure 4. Theoretical upward arching-tunnel interaction model.

3.2 *Mitigating the tunnel deformation*

As aforementioned, nearby excavation-induced tunnel deformation is determined by the ground stress change and soil disturbance degree. The development of the soil arching governs the above two factors. Hence, mitigating the development of the soil arching is an effective alternative for reducing the tunnel deformation. The specific countermeasures for mitigating the tunnel deformation in the cases of downward excavation, upward excavation, and lateral excavation are introduced in the subsequent section associated with engineering application.

(1) *Downward excavation*

The overlying existing tunnel deformation is determined by the upward soil arching. Horizontally grouting above the underneath tunnel could reinforce the ground, avoid the underneath tunnel face instability and prevent the loosened zone from developing vertically. Besides, a key issue involved in this countermeasure is mitigating the disturbance of grouting on the existing tunnel due to the close clear distance between the two tunnels. Spoil discharge jet-grouting (SDJG) technology [S. Nakashima and W. Nakanishi, "Allaround type reinforcing and consolidating method in the ground and apparatus thereof," US Patent No. 5,401,121 (1995)] can erode the soil with mixed cement slurry to generate improved columns and also remove the discharging spoil by negative pressure. The spoils can be discharged synchronously during jet-grouting, and the pressure outside the nozzle can be adjusted to a required value by controlling the discharge in light of the measured pressure in front of the injection rod.

This technology is adopted in the intersection of Metro Line 2 and Metro Line 4 in Changsha, China (Wu et al. 2020). The minimum disturbance between the two lines is 2.9 m, and the main soil encountered is medium sand. The calculated ground settlement above the tunnel crown of Metro Line 2 without ground improvement reaches 22.1 mm, as shown in Figure 5-(a). SDJG is employed in this project to construct horizontal columns to reinforce the soils above the Metro Line 4 (Figure 5(b)). The length of the SDJG column is 42.8 m and the radius is 1.0 m, and the measured average unconfined compressive strength reaches 3.5 MPa. The measured earth pressure change nearby the grouting area ranges from 0.06 to 0.10 MPa and the existing tunnels experienced negligible deformation during SDJG construction. The measured vertical displacement of left tunnel is smaller than 4.0 mm after the shield advancing for Metro Line 4.

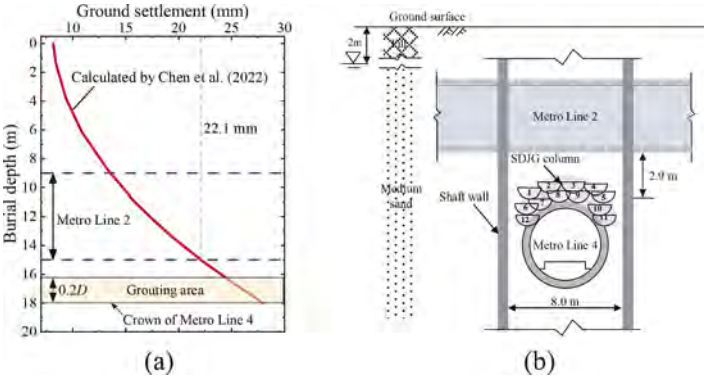

Figure 5. (a) calculated ground surface settlement above the shield tunnel of Metro Line 4 in case of no grouting; (b) SDJG column above Metro Line 4 and relative position of the two metro lines.

(2) *Upward excavation*

Through field observation, Meng et al. (2020) investigates the responses of underlying tunnels of Metro Line 11 subjected to the 3090 m-long collinear overlying excavation in granite residual soil for Guimiao Road in Shenzhen, China. The maximum excavation depth, width, and the minimum residual cover depth of the left tunnel are 18 m, 46 m, and 6 m, respectively. The curve of normalized tunnel heave and unloading ratio, defined as the ratio of excavation depth to tunnel cover depth, is depicted in Figure 6. It is easy to find that the tunnel heave experiences a sharp increase when the unloading ratio reaches about 0.55, which cannot be well estimated by the elastic two-stage solution (Liang et al. 2017) without considering soil arching. Furthermore, based on this case history, Meng et al. (2022) carries out an explicit numerical investigation on the downward soil arching and associated tunnel responses. By changing the tunnel cover depth and keeping a constant excavation depth, the increase of tunnel heave with decreasing tunnel cover depth becomes sharp when the tunnel crown enters into the loosened zone. The

calculated height of the loosened zone is about 14.3 m in the case that the excavation depth is 17.3 m and the width is 49.6 m which are common geometries in this project. The numerical results demonstrate that the tunnel begins to be located in the loosened zone when the unloading ratio reaches 0.55, well agrees with the observed threshold unloading ratio for the sharp increase in tunnel heave.

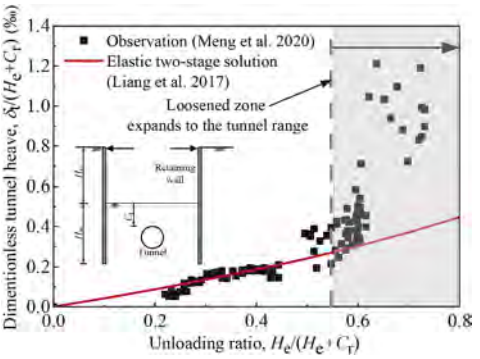

Figure 6. Measured and calculated tunnel heave subjected to upward excavation in granite residual soil.

For an upward excavation with a certain excavation depth, the excavation width and length are key parameters influencing the height of loosened zone. As shown in Figure 7, the loosened zone might extend to the underlying range in case of regular excavation because the excavation width is not well controlled. In cross section, remaining soil method on one-half side of the excavation base is suggested to reduce the height of the loosened zone. The remaining soil can be excavated until the base slab and superstructure of the other half side of the excavation base are constructed. The height of the remaining soil is determined by the aimed value of decreased loosened zone. In terms of longitudinal section, spaced shaft excavation is an effective approach to decrease the excavation length and thus the height of the loosened zone. This approach is carried out in the order of anti-heave pile installation, shaft excavation, anti-heave slab construction, backfill, and finally excavation. The small-sized excavation range could further reduce the ground stress relief and the frictional stress on the interface between the anti-heave pile and the surrounding soils could decrease the tunnel heave during the final excavation stage.

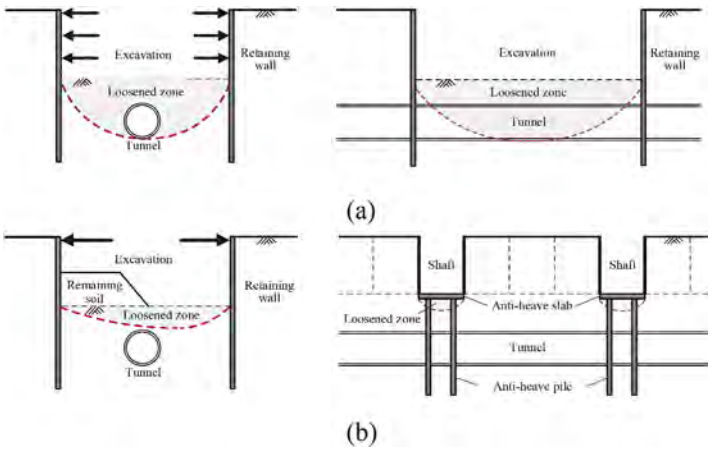

Figure 7. Countermeasures for controlling development of loosened zone: (a) regular excavation in cross section and longitudinal section; (b) remaining soil and spaced shaft excavation with anti-heave structure.

The above countermeasures are adopted in the aforementioned Guimiao Road project. The excavation width, unloading ratio, adopted countermeasures, and measured tunnel heave for different areas are listed in Table 2. For K1+180 to K1+620 with moderate unloading ratio and relatively low excavation width, zoned excavation in longitudinal and transverse directions, and jet-grouting pile reinforcement around the tunnel are adopted. In cross section, the height of the remaining soil is about 2 m to ensure that the surcharge on the excavation base exceeds 30 kPa. The measured tunnel heave in this area does not exceed 9.0 mm. For K2+390 to K2+643 and K3+773 to K4+013, the unloading ratio is moderate and the excavation width is much smaller than K1+180 to K1+620. Hence, no specific countermeasure for controlling the tunnel heave is adopted and the measured tunnel heave is smaller than 8.0 mm. In comparison, for K2+643 to K2+857, the unloading ratio reaches 0.73 and the countermeasures are the same as K1+180 to K1+620, resulting in the significant tunnel heave ranging from 14.8 mm to 23.5 mm. The excavation parameters for K2+857 to K3+476 are about the same as K2+643 to K2+857, but spaced shaft excavation is adopted for decreasing the tunnel heave. The shaft length and width are 15.6 m and 7.2 m, respectively. The thickness of the anti-heave slab and the length of the pile are 1 m and 18 m, respectively. The measured tunnel heave ranges from 1.0 mm to 8.5 mm.

Table 2. Adopted countermeasures and observed tunnel heave in Guimiao Road project.

Area	Unloading ratio	Excavation width (m)	Countermeasures	Tunnel heave (mm)
K1+180 to K1+520	0.58	90	Zoned excavation in longitudinal and transverse directions, and jet grouting pile reinforcement	6.3-8.9
K1+520 to K1+620	0.52	70		5.0-8.5
K2+390 to K2+537	0.54	38	/	1.6-5.1
K2+537 to K2+643	0.64			5.9-7.9
K2+643 to K2+857	0.73	41	Zoned excavation in longitudinal and transverse directions, and jet grouting pile reinforcement	14.8-23.5
K2+857 to K3+476	0.73	40	Spaced shaft excavation with anti-heave structure, in which the depth of anti-heave pile is 18 m and the thickness of the slab is 1.0 m	1-8.5

(3) *Lateral excavation*

The width and height of the loosened zone behind the retaining wall increase with the growing wall deformation. Similar to upward and downward excavations, responses of the lateral tunnel are greatly influenced by its relative position with respect to the loosened zone. Hence, to avoid large tunnel deformation, preventing the loosened zone from extending to the tunnel by decreasing the wall deformation is a promising alternative. Strengthening retaining system, using hydraulic servo strut, zoned excavation, and ground improvement are frequently adopted.

Take a narrow excavation next to the existing shield tunnels of Metro Line 5 in Wuhan, China as an example (Liu 2022; Liu et al. 2022a), the minimum clearance between the excavation and the right tunnel is only 4.6 m. The excavation depth ranges from 16.8 m to 23.4 m, with a total longitudinal length of 132 m. The 6.2 m-diameter shield tunnel has a cover depth of 10.0 m to 13.5 m which is just about the depth with the maximum wall deformation. Strongly weathered silty mudstone is predominantly encountered within the tunnel range. To limit the tunnel deformation, the first three levels of concrete struts and one-level steel struts, combined with longitudinal zoned excavation (a total length of 132 m is divided into 5 sections), are adopted to reduce the wall deformation. The measured maximum deflection of the

retaining wall and horizontal displacement of the right tunnel are only 8.8 mm and 5.8 mm, respectively. Throughout the lateral excavation, the measured lining strain is within the elastic range and no damage are found on the tunnel linings and joints.

4 CONCLUSIONS

This study deals with the deformation of shield tunnels induced by adjacent underground construction. Emphasis is put on the excavation-induced soil arching effect and associated tunnel responses, and corresponding countermeasures for mitigating the tunnel deformation by limiting the development of soil arching. The main conclusions can be drawn as follows.

(1) Underground excavation causes three typical soil arching effect, namely upward, downward, and lateral soil arching according to the developing direction. Arching zone and loosened zone are determined by the ground stress transfer and deformation. The soil arching develops with increasing ground volume loss, excavation size, and retaining wall deformation, respectively. Significant ground deformation would occur when the arching fully develops. Theoretical model for the upward soil arching above the shield tunnel is proposed, as well as the analytical solution for predicting the subsurface ground settlement.
(2) Field observation and numerical simulation all indicate that the tunnel deformation experiences a sharp increase when the loosened zone develops to the existing tunnel. Coupled theoretical model for soil arching and existing tunnel is established, which could yield varying tunnel deformation with different developing statuses of soil arching due to adjacent excavation.
(3) Limiting the development of soil arching is a promising alternative for decreasing the tunnel deformation subjected to nearby excavation. Reinforcing the soils above the tunnel crown by SDJG column, reducing ground stress relief by zoned excavation and spaced shaft excavation and anti-heave structure, and decreasing the retaining wall deformation by longitudinal zoned excavation and strengthening the structs are proved to be effective countermeasures for downward tunneling, upward excavation, and lateral excavation.

Monitoring of backward erosion piping in river levees using distribution of surface settlement

M. Okamura
Ehime University, Matsuyama, Japan

M. Imamura
Kajima Corporation, Osaka, Japan

ABSTRACT: River levees occasionally breach during flooding in the mechanics of backward erosion piping and its impact is enormous. Current inspection methods cannot detect the pipe until it manifests at the exterior surface. There is a strong need for non-destructive techniques that can identify progression of the pipe. Okamura et al. (2017) found that small but characteristic deformation appeared on the surface of levees above pipes after a flooding event. They proposed a method for estimating the size and location of the pipes based on the characteristic shape of the deformed slope. In this study, centrifuge tests were conducted to observe evolution of surface deformation as piping progressed. Moreover, this method was applied to a levee along the Naka River, where significant sand boiling occurred at the levee toe during recent flooding events. In addition, a number of penetration tests were conducted at small intervals to identify the pipe locations in a more direct manner. It was found that the penetration tests were effective in detecting the pipe locations. The detected locations compared well with those estimated from the surface topography.

1 INTRODUCTION

Backward erosion piping is a failure mechanism for less-permeable river levees founded on sandy aquifers. The piping initiates in the form of concentrated leaks at the landside soil surface when the hydraulic loads generated by seepage exceed the capacity of the soil to resist the loads. Shallow pipes are formed at the surface of the sandy aquifer by the erosion of sand particles, beginning at the landside ejection holes and progressively extending towards the riverside. The erosion process continues when the river water level is high; eventually, the pipe forms a direct connection between the landside and riverside, which accelerates the widening and deepening of the pipe, resulting in levee collapse and breach (ICOLD, 2015). Once a levee breaches, its impact on the surrounding is enormous (TCYRL, 2013). Meanwhile, a small number of the levees breached in the mechanism of backward erosion piping, although numerous sand boils occur in Japan every year (Yasuda et al., 2016; Okamura et al., 2020). It is important to know how the breaching is imminent.

In the current practice, it is quite difficult to diagnose the severity of backward erosion piping during a flooding event or even after the event (Wang, et al., 2014). Many attempts to detect pipes and loosened zones resulting from the mechanism have been conducted; however, unfortunately, they were mostly unsuccessful even though cutting edge geotechnical site investigation techniques including georadar, seismic exploration, and electric resistivity exploration were used (Okamura et al., 2016). Consequently, many levees with sand boils have been remedied after flooding events without knowing the piping progress.

When a pipe is formed in a levee or foundation soil, stresses of the levee change accordingly, leading to a deformation which may not be sufficiently large to be detected by the eye observation.

DOI: 10.1201/9781003299127-4

Okamura et al. (2017) surveyed levees after flooding events and found that small hollows with the peculiar shape appeared on the surface of the levees near sand boils. The surface subsided several centimeters in a shape of a Gaussian like curve, which is known as a characteristic shape for ground surface subsidence immediately above tunneling (Mair et al. 1993, Mahmound & Magued, 2011). The levee surface settlement could be a good indication of progression of piping.

Technology of land surveying has been rapidly progressing in recent years making it possible to build a digital elevation model (DEM) of the ground surface of a large area in a short time. A laser profiler mounted on an unmanned aerial vehicle (UAV) have been used to build DEM of high resolution, more than 1000 points/m^2, and with an accuracy on the order of a centimeter. Photographing from UAV incorporation with SfM (Structure for Motion) technique are also employed for this purpose. These techniques greatly help to improve understanding of the precise deformation of levees that was not possible before.

This paper describes results of centrifuge tests to investigate evolutions of levee surface settlement as a piping progresses in the mechanism of backward erosion piping. Shape and location of pipe developed below levees and levee surface settlement were closely observed. In addition, the survey technique was applied to a levee where sand boils were observed due to recent flooding events to detect hollows appeared on the surface. Moreover, a small diameter cone was penetrated at a short interval around the detected hollows to identify the locations of pipes or loosened soil because of backward erosion piping, which verified the effectiveness of surface settlement survey as a indicator of pipe progression.

2 CENTRIFUGE TEST

2.1 *Model preparation*

The models were constructed in a rigid container with internal dimensions of 530-mm-long, 120-mm-wide, and 230-mm-high. Figure 1 indicates the model configuration comprising a uniform medium dense sand bed with pervious and impervious retaining walls on the riverside (upstream) and landside (downstream), respectively, and a model levee resting on the bed. A clean silica sands, Keisa #6B, were used in the tests; Figure 2 presents the grain size distributions and physical properties. Dry sand was air-pluviated in the model container to a depth of 60 mm at a target relative density of D_r = 60 %. After the surface of sand bed was carefully levelled using a vacuum device, the model levee was placed on the sand bed. The model levees were either compacted clay or an acrylic block. The clay levee was constructed using a mixture of fine silica sand (d_{50} = 0.06 mm) and Kaolin clay (IP = 23) mixed at 3 : 7 by weight. The material was prepared at a water content of 35 % and compacted to dimensions of L = 190 mm base width and 70 mm high. The acrylic levee of same width was fabricated by gluing acrylic plates, which was transparent for observing the pipes developing on the surface of the sand bed. To prevent the acrylic levee from sliding on the bed during the flooding experiment, a weight was put on the levee.

A high-speed camera was placed on the levee to closely observe sand ejecta appeared at the toe and pipe below the transparent levee during flooding events. An in-flight laser profiler capable of moving on linear ways was mounted to obtain a 3D profile of the surface of the clay levees.

2.2 *Test procedure*

The model was set on the centrifuge platform of a geotechnical centrifuge at Ehime University and spun to 40 g. Water was supplied by a pump to saturate the sand bed prior to flooding events. Table 1 summarizes the test conditions. In the tests, the upstream water head (H) was controlled, whereas the water table was maintained constant at the sand surface on the downstream side, giving rise to the head difference across the levee, H. In test 1 in which acrylic levee was used, the progression gradient (H_l/L), the average gradient across the levee that causes progression of pipe of length l, was observed. The upstream water head was increased

in steps with an ample duration of approximately a few minutes until a pipe was initiated with sand ejecta at the toe of the levee. The head was lowered once and increased stepwise again until the pipe length was extended to a centimeter or two, where the pipe developed just below the levee was observed through the transparent levee using the high-speed camera. This cycle of head change was repeated each time the pipe progressed a few centimeters until the pipe finally went through to the riverside. In the test 2 and 3 with the clay levee used, the cycles of head change similar to the test 1 was applied to the model. In these tests, the pipes were no longer visible by the camera, and progression of piping was inferred from the amount of sand ejecta appeared on the downstream surface. During the interval of each cycle 3D profile of the levee surface was obtained using the laser profiler. For test 2, the cycle was repeated until the pipe reached the upstream toe and direct connection was established. Whereas for test 3, test was halted before the piping tip reached the upstream.

The centrifuge was spun down and levees were carefully removed to expose the surface of foundation soil. The 3D profile of the sand bed surface and the pipe was obtained with the laser profiler.

In this paper, all the results and comparisons are presented in model units without applying any scaling factors commonly used in centrifuge modeling.

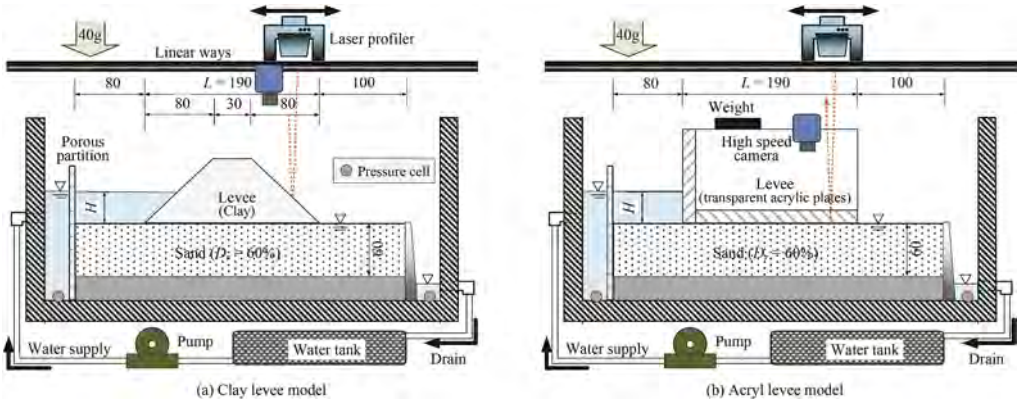

Figure 1. Caption of a typical figure.

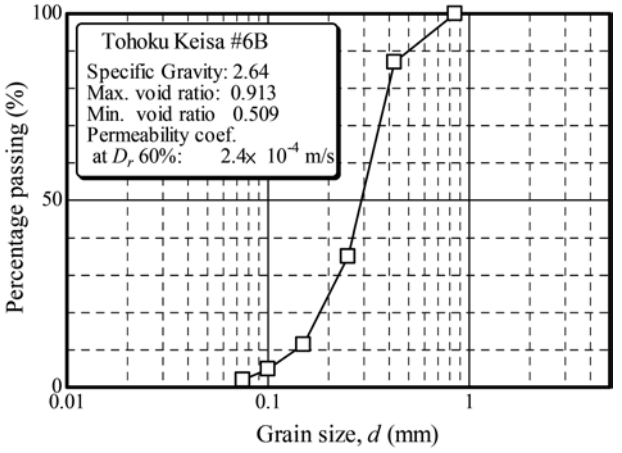

Figure 2. Grain size distribution of sand used.

Table 1. Test conditions.

Test	Sand bed D_r (%)	Material of levee	Unconfined strength of the levee (kPa)	Length of pipe at the end of test (mm)
1	59	Acryl	>50000	190 (breakthrough)
2	62	Clay	54.0	190 (breakthrough)
3	61	Clay	14.5	80

2.3 *Results and discussions*

Figure 3 illustrates the time histories of hydraulic gradient (H/L) and normalized length of pipe (l/L) in test 1. Here, l does not indicate the actual meandering pipe length; it represents the distance from the pipe tip to levee toe. H_l/L remains nearly constant to approximately 0.3 for l/L= 0–0.3, and thereafter, decreases with the increase in l/L. This may be explained by the fact that an increase in l/L resulted in a virtually lower seepage length (distance from the upstream toe to the piping tip) than the original length L. Hence a lower gradient H_l/L would be required to transport the sand grains within the pipe. In fact, in preliminary tests performed on the models similar to those in this study, the pipes developed intermittently until l/L reached approximately 0.3. After the pipe length became longer than, say, $l/L > 0.4$, the rate of pipe development accelerated, leading to failure, while the upstream head was maintained constant throughout the tests.

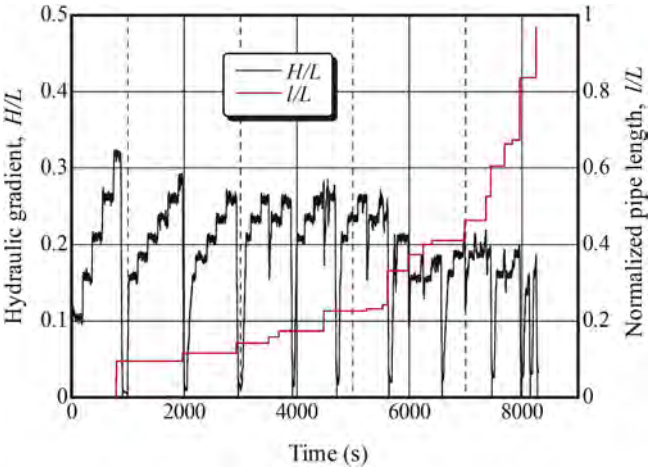

Figure 3. Time histories of hydraulic gradient and normalized length of the pipe (test 1).

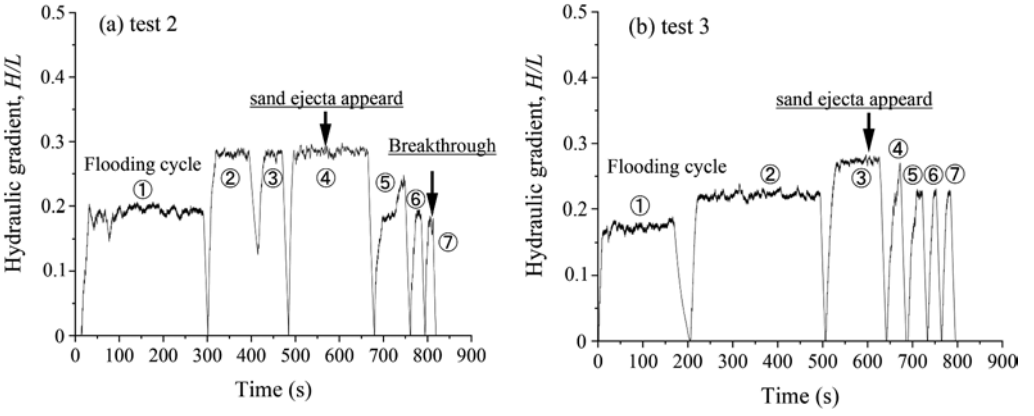

Figure 4. Time histories of hydraulic gradient for test 2 and 3.

Figure 4 presents the time histories of hydraulic gradient for test 2 and 3. For test 2, sand ejecta appeared in 4th cycle (t = 600 s) at the levee toe while keeping the gradient to 0.29. Thereafter amount of sand ejecta increased in 5th and 6th cycles in which the gradients were 0.22 and 0.19, respectively. The pipe broke through the sand bed in 7th cycles at H/L = 0.18; the gradients for the piping initiation and breakthrough are consistent with test 1.

At the end of each cycle the levee surface profiles were obtained with the laser profiler. Figure 5 depicts contours of the surface settlement after the 4th, 5th, 6th and finally 7th cycle for test 2. After the 4th cycle, a very small but clear hollow appears on the levee slope adjacent to the sand ejecta (Figure 5(a)). The hollow increased the depth and extended towards upstream side as the amount of ejecta increased (Figure 5(b) – (c)). After the 7th cycle where rate of water outflow from the exit of the piping suddenly increased during the cycle, the levee largely settled (Figure 5(d)). Figure 6 shows a photo and contours of the surface of foundation sand after removal of the levee for test 2. It is apparent that the hollow of the surface appeared immediately above the pipe. This is also the case for test 3 in which the pipe extended to l = 90 mm from the levee toe and the hollow appeared on the slope immediately above the pipe from the toe to the crest shoulder. It can be concluded that the hollows are good indicator of progression of pipe below levees.

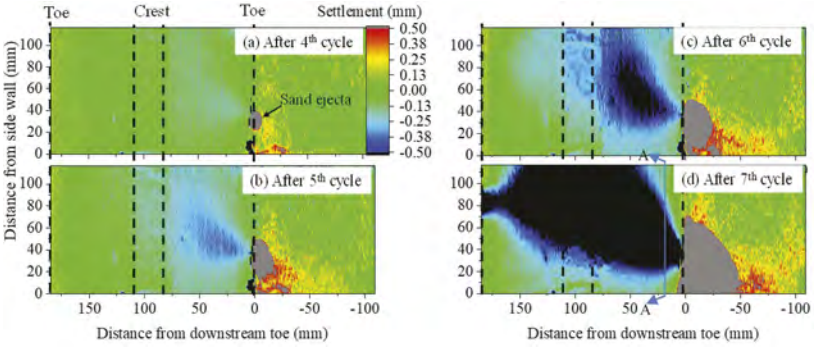

Figure 5. Evolution of settlement appeared at the levee surface (test 2).

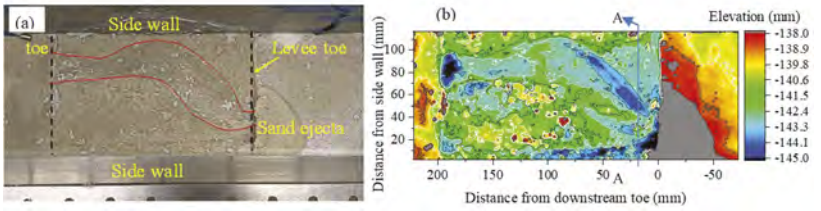

Figure 6. Surface of foundation sand exposed after the test (test 2).

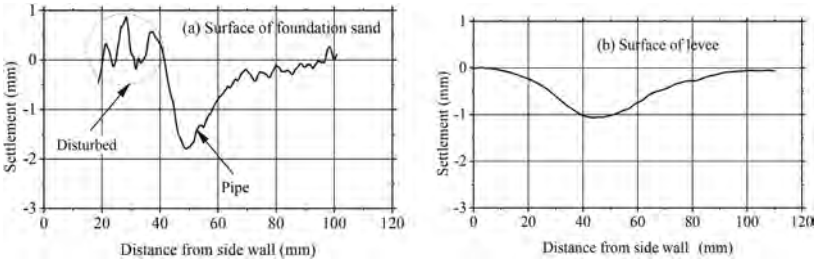

Figure 7. Cross sections of foundation sand exposed after the test and levee slope at l = 20 mm (test 2).

Figure 7(a) depicts cross-sections of the pipe at the distance from the toe l = 20 mm for test 2 (section A-A in Figures 5(d) & 6(b)). Sections of the piping channel are typically 2-mm-deep and 30-mm-wide in the range of l = 0–50 mm. While for test 3, the depth and width of the piping channel are typically 1.5-mm-deep 15-mm-wide, which are smaller than those for test 2. Van Beek et al. (2015) reported the observation of their tests that the pipe depth was approximately 7-14 times the grain size of sand. Considering the fact that their pipe dimension was observed after the pipe broke though the foundation sand and reached upstream water, the pipe depth of test 2 in this study is comparable to those by van Beek et al. Figure 7(b) shows a cross-section of the hollow on the levee surface at l = 20 mm. The hollow with a gaussian-like shape has the maximum depth approximately a half of the pipe, whereas the width is more than double of the pipe. The observed hollows are approximated with gaussian curves and size and depth of the pipes were predicted using the model (Okamura et al., 2017). Not shown in this paper, the prediction agrees well with the observed pipe in test 2 and 3 (Imamura, 2018).

3 APPLICATION TO A LEVEE

3.1 *Test site*

The Naka River in Tokushima prefecture, Japan, has undergone several flooding events during the past decade in 2012, 2014, and 2015. Extensive sand boils appeared near the left bank at 13.4 km from the river mouth. Figure 8 shows an aerial photograph of the levee. The crest is used for local traffic and approach roads to the crest are installed on the hinter land side slope. The levee is 6.7 m high with a riverside slope angle of 1V : 2.5H. In this area, water leakage was observed along the toe over an area of 30 m during the flooding events. Two significant sand volcanos formed in the area at zones A and B as indicated in Figure 8(b). The small circles in the figure indicate locations where the mini-ram sounding was conducted. Four survey lines were set and a total of 47 mini-ram soundings were conducted on lines Aa, Ab, Ac and Ba.

A cross section of the levee and the foundation soil is shown in Figure 8(d). The levee consists mostly of sandy gravel (Bg), with a gravel content of 20–60% and a fines content of 5–20%. The levee soil is medium dense with an SPT- N value of 2–15. Below the levee, a sand layer (As1) 1.5–2.5 m deep lies atop a thick gravel layer (Ag1, Ag2 and Dg). On the river-side slope, an impermeable sheet has been placed to prevent infiltration of river water and rain.

The sand layer As1 is underlain by highly permeable gravel layers. During flooding, a high pore water pressure in the gravel layer on the hinterland side causes a high upward hydraulic

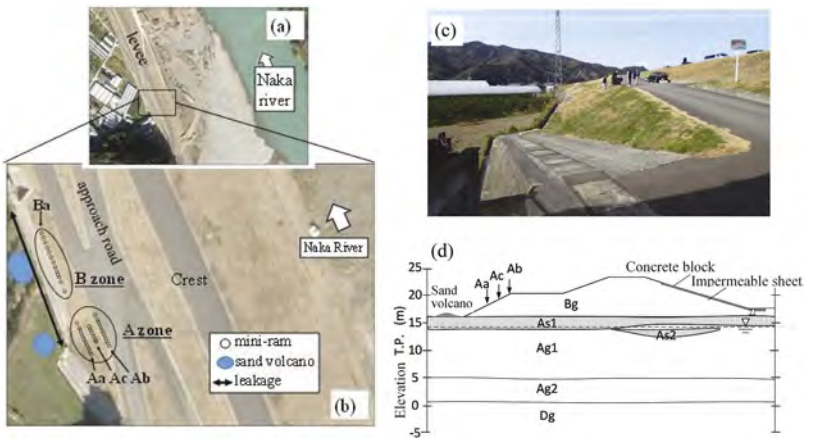

Figure 8. Test site. Location of (a) test site and (b) mini-ram sounding, (c) photo of Zone A and B, and (d) cross section showing soil condition in the levee and foundation.

gradient in the As1 layer. Moreover, the levee is at the foot of a mountain as can be seen in Figure 8(a). The gravel layer is shut off by bed rock, which makes the pore pressure in the gravel layer even higher.

3.2 *Dynamic cone penetration tests*

Mini-ram sounding (JGS, 2017) is an in-situ test in which a 36.6-mm diameter cone is driven by a hammer of 30-kg free falling from a height of 30-cm. The number of blows required to drive the cone 20-cm is recorded as N_{dm}. To remove the effects of skin friction, torque M_v is measured to rotate the rod. The corrected blow count, N_{dc}, is provided in equation (1), which is approximately one-half of the standard penetration test (SPT) N value.

$$N_{dc} = N_{dm}/2 \; - \; 0.14\, M_v \tag{1}$$

Instruments and procedures of the mini-ram sounding were the same as those of Swedish ram sounding except for the smaller cone diameter and driving energy. Because of these differences, the mini-ram was more suitable to identify weak and thin layers. Moreover, in this study, the depth of the tip was recorded and the blow count for every single blow was obtained as follows:

$$N_{d1} = \; 20/d - \; 0.14 M_v \tag{2}$$

where d denotes the penetration depth in decimeter via a single blow.

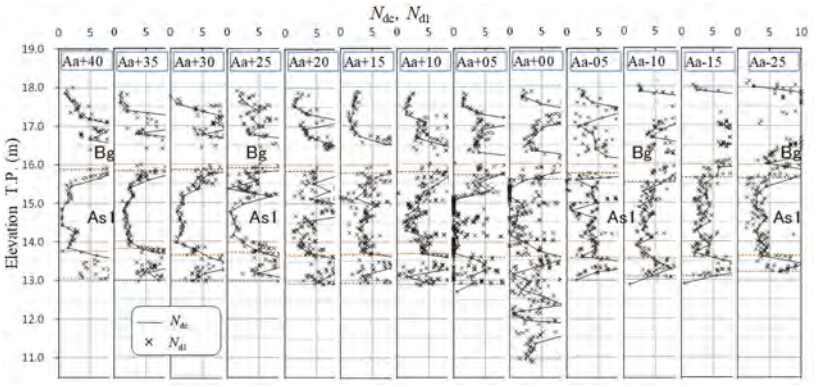

Figure 9. Corrected blow count on line Aa in zone A.

Figure 9 presents the corrected blow counts N_{dc} and N_{d1} along the survey line Aa. The tests were conducted at a very small interval of 0.5 m to better observe the distribution of pipes and loosened zones in the soil. The numbers after "Aa" in the figures denote the horizontal distance (in decimeters) along the survey line from the midpoint. The elevation of the surface of the levee on this survey line is approximately T.P. 18.0 m. N_{dc} increased with depth from the surface and reached approximately 15 at the bottom of the levee (T.P. 15.9 m). The solid lines and cross marks represent N_{dc} (the average corrected blow count for every 20 cm driving) and N_{d1} (the blow count for every single blow), respectively. At three locations from the upstream side, Aa+40, Aa+35 and Aa+30, N_{d1} in the sand layer (As1) was higher than 0.5, while N_{d1} was 0 at a depth at As+25. Because it is unusual to observe N_{d1} = 0 in sand with small fines content, the location where N_{d1} = 0 is considered as either a pipe or loosened sand because of the backward erosion piping. Such extraordinarily low blow counts, and thus loosened sand, was also encountered at Aa+15, Aa+10, Aa+00, and Aa-05.

Figure 10 shows the locations where the zero blow counts were observed. In zone A, the locations are identified by the Aa and Ab lines. It seems that a pipe or loosened zone developed from the location of the sand volcano and branched somewhere between the volcano and Aa line, further extending and reaching to the Ab line. In zone B, four locations with zero blow count were identified along the survey line, Ba, adjacent to the sand volcano.

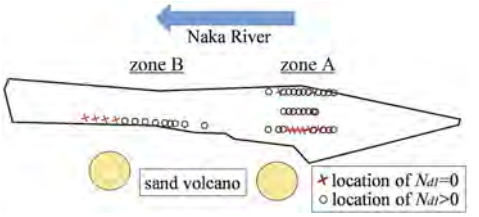

Figure 10. Locations where a zero-blow count was observed.

3.3 *DEM*

A laser profiler was used to obtain DEM of the levee. The profiler was mounted on a UAV and flew at an altitude of approximately 30 m at 20 km/h. The grass on the levee was cut by mowers in advance. Figure 11(a) indicates contours of the site including zones A and B. The slope was divided into 6 area from (i) to (vi) and their elevation was approximated with planes. Deviations in height of each data point of DEM from the plane is shown in Figure 11(b). There are two significant hollows of 10 cm to 20 cm deep on the slope near the locations of sand volcano, i.e. at boundaries between area (i) and (ii), and (ii) and (iii). It should be noted that any significant hollow did not exist except for these two locations.

Figure 12 compares the locations of pipes estimated from the shape of hollows (Okamura et al., 2017) and those identified via the mini-ram sounding. In the plan view (Figure 12(a)), the locations obtained from the two methods agree quite well. The locations of two pipes in zone A, which developed from the sand volcano and reached below the approaching road, were consistently identified by the mini-ram. The estimated pipe location in zone B is approximately 4 m from the locations where the zero blow count (N_{d1}) was observed. However, the N_{d1} estimated from the shape of hollow was also very small, largely less than 1.0. The blow count could be more significantly affected by the skin friction of the penetration rod in this

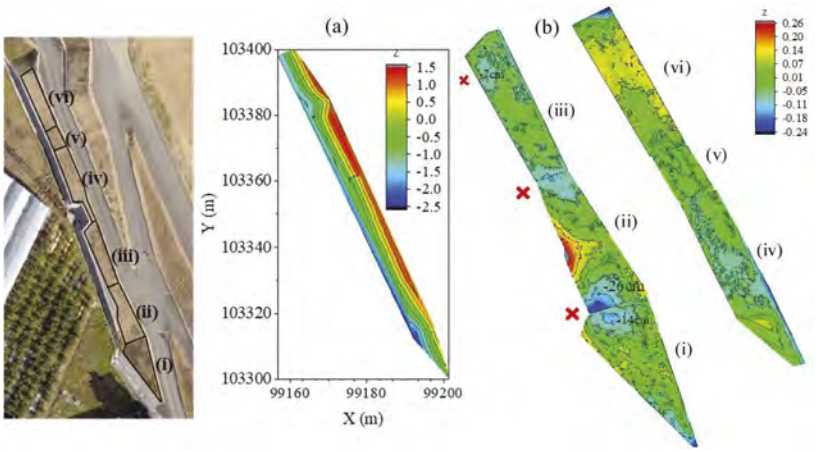

Figure 11. (a) Contours of levee slope, (b) deviation in elevation from the approximated plane.

zone than that in zone A because the thickness of the levee soil along this survey line was relatively large. This indicates that to identify zero blow count locations, careful attention should be paid to the effect of skin friction.

The estimated depth of the pipe is shown in Figure 12(b) and (c). Unlike the horizontal location and width, the estimated depth of the pipes is sensitive to the assumed aspect ratio, H/B, which is assumed in the estimation. Based on the observed shape of pipes in centrifuge test in this study as well as those in Okamura et al. (2022), aspect ratio is approximately 0.1. Considering the con-figuration of the soil layers at this particular site, the thin sand layer immediately below the levee is most susceptible to the backward erosion piping. It should be mentioned that the DEM of the levee surface used in this study was recently obtained after flooding events. The current shape of the levee is not only influenced by recent flooding events but also by such actions as erosion of rain water, weathering, and animal and human activities over a few decades since the levees were finally raised to their current height. A difference in height at two points of time, before and after a flooding event, could be used rather than a point of time for information.

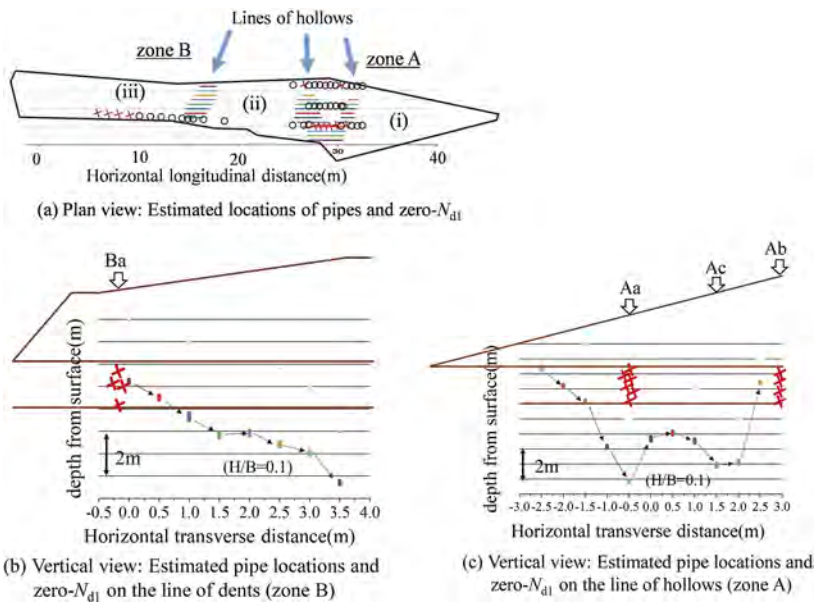

Figure 12. Locations of pipes estimated from the shape of hollows and those identified by the mini-ram sounding.

4 CONCLUDING SUMMARY

Backward erosion piping is a failure mechanism for river levees founded on sandy aquifers. In the current practice it is quite difficult to diagnose the severity of backward erosion piping during a flooding event or even after the event**.** **A**ttempts to detect pipes and loosened zones resulting from the mechanism have been conducted, however, they were mostly unsuccessful. Okamura et al. (2017) have surveyed levees after flooding events and found that small hollows with the peculiar shape often appeared on the surface of the levees near sand boils. This fact suggests that the surface hollows of several centimeters deep in a shape of a Gaussian like curve, which is known as a characteristic shape for ground surface subsidence immediately above tunneling, may be a good indication of progression of piping.

This paper describes results of centrifuge tests to investigate availability of surface settlement as the indicator of progression of backward erosion piping. Evolutions of levee surface

settlement as a piping progresses under the levee was observed in detail. In addition, the survey technique was applied to a levee of Naka river where sand boils were observed due to recent flooding events to detect hollows appeared on the surface. Moreover, a small diameter cone was penetrated (mini-ram sounding) at a short interval around the detected hollows to identify the locations of pipes or loosened soil because of backward erosion piping, which verified the effectiveness of surface settlement survey as a indicator of pipe progression.

In the centrifuge tests, model levees resting on a uniform sand bed were subjected to hydraulic load on the riverside and pipes developed in the mechanism of the backward erosion piping at the surface of sand bed. It was observed that a hollow appeared at the toe when sand begun to eject from the sand bed and the hollow extended towards riverside as the amount of sand ejecta increased. The tip of hollow was immediately above the tip of pipe developed under the levee. It is confirmed that hollows appear on the levee surface immediately above the pipe and are good indicator of progression of pipe below levees.

For the Naka river levee, mini-ram sounding was conducted at 47 locations at a small interval of 0.5 m, which was found effective in detecting pipes. The locations where zero-blow counts were observed were immediately in front of sand volcanos. A 3D profile of the levee surface was obtained using a laser profiler mounted on a UAV. Small hollows in a shape of the Gaussian like curve with a maximum depth of 10– 5 cm and a width of 4–6 m were found on the slope of the levee near the sand volcanos. The hollows are considered to have formed by the loss of sand because of pipe development. The depth and width of the pipes were estimated from the shape of the hollows using the method developed by Okamura et al. (2017) which agreed reasonably well with those detected by mini-ram sounding.

Though the accumulation of further site investigation data is clearly needed, this method has the apparent potential to improve maintenance and health evaluations of levees in which undermining by the mechanism of backward erosion piping is suspected.

Energy geotechnology: A new era for geotechnical engineering practice

L. Laloui & M. Sutman
Laboratory of Soil Mechanics, Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: Energy geotechnology provides low carbon, cost-effective and local energy solutions to structures and infrastructures, which opens a new era for the geotechnical engineering practice, by extending the conventional role of structural design to the one of addressing acute energy challenges of our century. The paper initially goes over the idea behind energy geotechnology by highlighting its scope and applications to various geostructures for structural support and energy supply of built environments. Aspects of primary importance for maximizing the energy, geotechnical and structural performance of energy geostructures and solutions to address this challenge are presented. Moreover, analytical solutions and design tools, as well as performance-based design of energy geostructures are introduced. The goal of this paper is to uncover the great potential of energy geotechnology on the path of less dependency on fossil fuels and to emphasize the new critical role of geotechnical engineers to take full advantage of this technology.

Keywords: Energy geostructures, Renewable energy, Thermo-mechanical, Design, Application

1 INTRODUCTION

The residential sector was responsible for 25.4% of final energy consumption in Europe in 2016, of which space heating and hot water production represented 82.6% in total (Eurostat, 2018). Fossil fuel based and conventional electric equipment still dominates the global building market, accounting for more than 70% of space heating and 90% for hot water production, which is also responsible for 28% of global energy-related CO_2 emissions in 2017 (IEA, 2019). Moreover, due to global warming, economic growth and urbanization, the use of energy for space cooling more than tripled between 1990 and 2016 (IEA, 2018), which is mainly covered by electricity. Yet, global energy needs are expected to expand by 30% by 2040 as a result of a global economy growth with an annual rate of 3.4%, a projected population increase by 1.6 billion, as well as an inevitable growing urbanization (IEA, 2017).

Several initiatives and policies at national and international levels are being established in the construction sector (ASHRAE, 2008 and European Directive 2010/31/EU, 2010) for the implementation of zero- or nearly zero-energy buildings. As an example, ASHRAE Vision (2008) presents requirements to enable buildings to produce as much energy as they use by 2030. On the other hand, European Directive 2010/31/EU (2010) requires all new public buildings to be nearly zero-energy by 2018 and all new buildings by the end of 2020. Therefore, the development and the diffusion of reliable, economically viable and environmental-friendly technologies to satisfy a noteworthy part of the energy needs of the building sector is an important challenge.

Conceptually, energy geostructures is a technology enabling the use of renewable energy sources for efficient space heating and cooling. In this technology, any geostructure in contact with the soil and already required for structural support are equipped with geothermal loops,

DOI: 10.1201/9781003299127-5

for heat exchange operations to exploit the near surface geothermal energy. The idea behind energy geostructures comes from the fact that the temperature of the ground remains the same throughout the year below a depth of 6-8 meters. Therefore, with the integration of the geothermal loops and the water-antifreeze mixture circulating within them, the heat is extracted from the ground to heat the buildings during winter. Similarly, during summer, the extra heat coming from the building side is injected into the ground to cool them. In this system, ground source heat pumps (GSHP) are often required which works intermittently in order to adapt the temperature of the circulating fluid to meet the energy demands from the building side.

The heat energy that can be provided by the energy geostructures depends on various factors, including, but not limited to, the thermal and hydraulic properties, and mean temperature of the ground, geothermal and geotechnical design of the geostructures, and the energy demand from the building side. However, 40-150 W/m, 20-40 W/m^2 and 20-60 W/m^2 are achievable energy extraction or withdrawal amounts from energy piles, energy walls and energy tunnels, respectively. As a practical example, a recent numerical investigation was performed at the Laboratory of Soil Mechanics (LMS), considering a five-storey office building, with net heated/cooled area of 2400 m^2, bearing on 32 piles with 0.5 m diameter and 20 m length which were used as energy piles. The results of the analysis show that the energy piles can supply 100% of the heating demands and most of the cooling demands of the office building in Sevilla, Spain. An auxiliary air conditioning system was required only during July and August, to provide the remaining 11% and 6% of the cooling demand (Sutman et al., 2019).

2 ENERGY ASPECT

2.1 *Typical energy problem*

Operation of energy geostructures to meet the heating and cooling demands from the building side involves heat exchange within the three components of the ground source heat pump system, being the primary circuit, the GSHP and the secondary circuit (Figure 1).

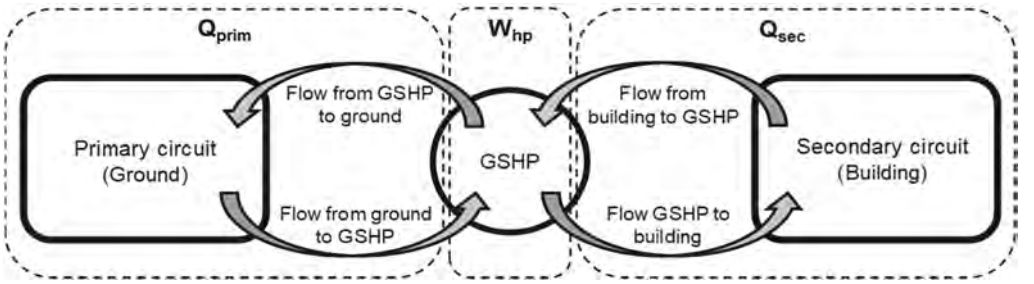

Figure 1. Heat exchange within the three components of ground source heat pump system.

In the primary circuit, the heat exchange occurs between the ground and the GSHP, where the heat is extracted from or withdrawn into the ground for heating or cooling the building side, respectively. The heat exchange mechanism that occurs between the ground and the energy geostructure is shown in Figure 2, through the example of an energy pile, for both building heating and cooling purposes. Regarding the building cooling mode, shown by the white arrows, the temperature of the circulating fluid returning from the building side is warmer than the ground temperature, which results in a thermal gradient. The circulating fluid exchanges heat with the ground loop wall through convection, which is followed by a heat conduction through the wall of the ground loop and the pile until reaching the pile-soil interface. Finally, the heat is transferred within the ground mainly by conduction and partially with convection if a moisture migration takes place. Similarly, during the building heating mode, the returning fluid temperature is colder than the ground temperature and the heat exchange occurs in the reverse direction, as shown by

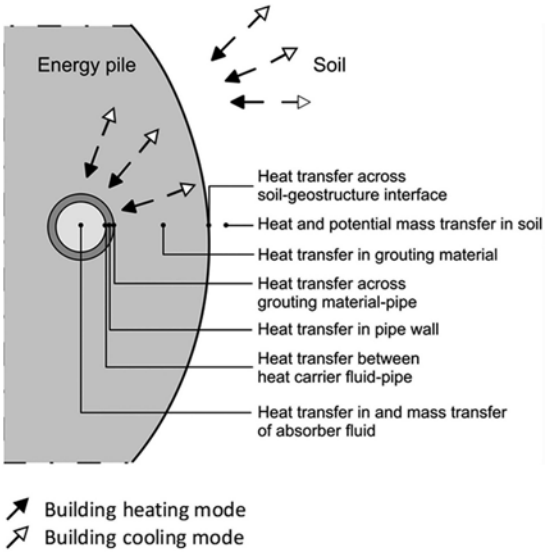

Figure 2. Heat exchange between the energy pile and the ground.

the black arrows. Assuming pure thermal conductivity within the energy pile and the ground, the energy conservation equation reads:

$$\rho c \frac{\partial T}{\partial t} - div(\lambda \boldsymbol{grad} T) = 0 \tag{1}$$

where ρ is the density, c and λ are the specific heat capacity and thermal conductivity, respectively, including both fluid and solid components, T is the temperature, t is the time and *div* and ***grad*** are the divergence and gradient operators, respectively. The energy conservation equation for the incompressible circulating fluid within the loops can be written as:

$$\rho_f A_p c_f \frac{\partial T_f}{\partial t} + \rho_f A_p c_f u_{f,i} \cdot \mathbf{grad} T_f = div\left(A_p \lambda_f \mathbf{grad} \mathrm{T}_f\right) + \frac{1}{2} f_D \frac{\rho_f A_p}{d_h} |u|^3 + q'_w \tag{2}$$

where ρ_f, c_f, and λ_f are the density, specific heat capacity, and thermal conductivity of the fluid, respectively; A_p and d_h are the cross-sectional area and hydraulic diameter of the pipe, respectively; T_f is the temperature of the fluid; $u_{f,i}$ is the velocity vector; f_D is the Darcy friction factor; and q'_w represents the heat flux per unit length that is exchanged through the pipe wall.

In the secondary circuit, the heat is transferred to or from the building side for heating or cooling purposes, respectively. In between the two circuits, there exists the GSHP to transfer the heat between the two circuits. The efficiency of the GSHP is quantified by the coefficient of performance (*COP*) through examining the amount of energy input to operate the GSHP (W_{hp}) and the energy that can be supplied to the building side (Q_{sec}), as shown below:

$$COP = \frac{Q_{sec}}{W_{hp}} \tag{3}$$

2.2 *State of the art on the application of energy geostructures*

To reveal the actual energy performance of energy geostructures, a comprehensive investigation was performed by incorporating information from (i) a survey targeting international construction companies involved in energy geostructures, (ii) available literature on operational energy geostructures and (iii) complementary results by Di Donna et al. (2017). Figure 3 presents the state of the art on energy piles, based on the integration of the

information from 157 energy pile projects, in terms of extracted thermal power with respect to the diameter and length of the piles. On the other hand, Figure 4a and 4b represent extracted and injected heat for heating and cooling purposes for energy walls (17 projects) and energy tunnels (11 projects), respectively.

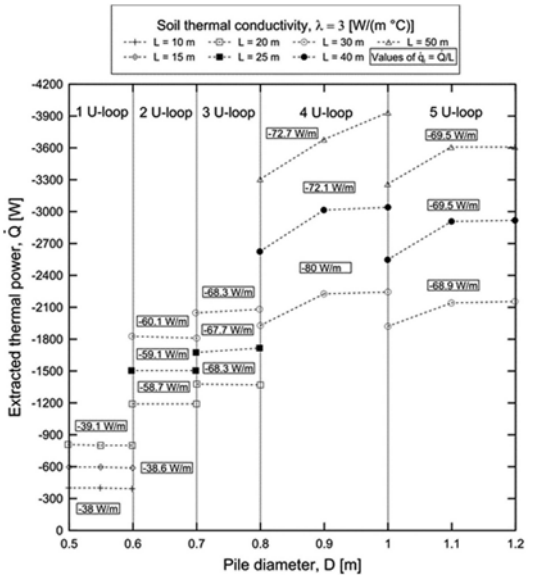

Figure 3. State of the art on application of operational energy piles (Laloui and Rotta Loria, 2019).

3 GEOTECHNICAL ASPECT

As shown in the previous section, energy geostructures concept, a technology capable of exploiting geothermal sources for both space heating and cooling, is undoubtedly an outstanding candidate to cut down the governance of unsustainable resources. Yet, the use of conventional geostructures for heat exchange purposes is associated with temperature changes, hence thermal loads and displacements, along the geostructures and within the surrounding soil, which needs to be taken into consideration in addition to the typical geotechnical design.

In order to understand the extent of temperature change effects on energy geostructures, several in-situ tests were performed on single (Laloui et al., 2006; Bourne-Webb et al., 2009; You et al., 2016; Loveridge et al., 2016; McCartney and Murphy, 2017; Sutman et al., 2017; Sutman et al., 2019) and a group of energy piles (Mimouni et al., 2015; Rotta Loria et al., 2016), energy walls (Xia et al., 2012) and energy tunnels (Adam and Markiewicz, 2009; Frodl et al., 2010; Nicholson et al., 2014; Barla et al., 2019). Moreover, several models or tools with varying complexity were developed for the analysis and design of energy piles (Knellwolf et al., 2011; Bourne-Webb et al., 2014; Salciarini et al., 2013; Rotta Loria and Laloui, 2016; Makasis et al., 2018, Sutman et al., 2018), energy walls (Kürten et al., 2015; Sterpi et al., 2017; Sailer et al., 2019) and energy tunnels (Barla and Di Donna, 2018; Bidarmaghz and Narsilio, 2018). The previous research answered the most fundamental questions on the mechanisms governing the thermal and structural behavior of energy geostructures. These efforts opened a new era for the geotechnical engineering practice, by extending the conventional role of geotechnical design to the one of addressing acute energy challenges of our century.

3.1 *Full-scale experimental analysis on energy piles*

The two pioneering full-scale in-situ tests on energy piles performed at Swiss Federal Institute of Technology in Lausanne (EPFL), investigating (i) the response of a single energy pile to

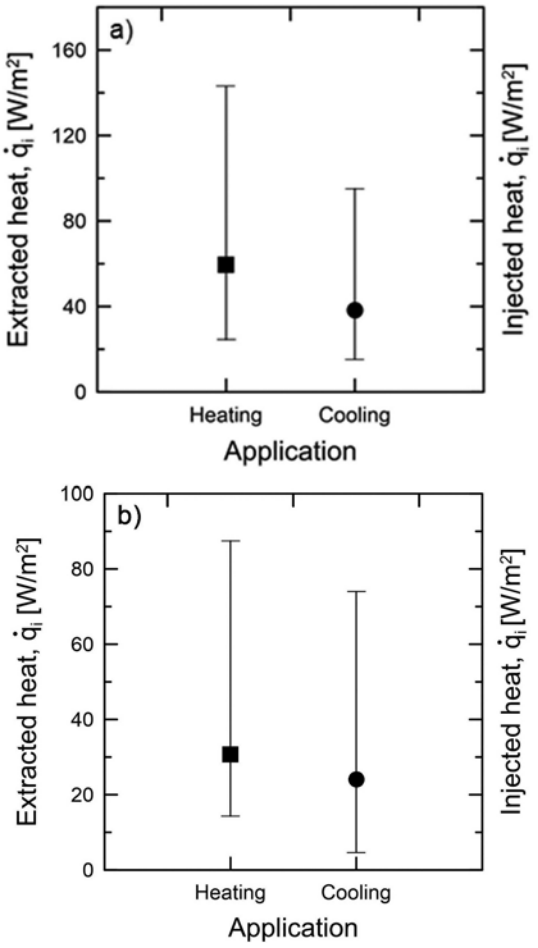

Figure 4. State of the art on application of energy walls and tunnels (Laloui and Rotta Loria, 2019).

combinations of thermal and mechanical loads and (ii) the response of a group of closely spaced energy piles to thermo-mechanical loads are presented in this section. Compressive stresses and upward shaft resistance mobilization are considered positive, according to the adopted sign convention.

3.1.1 *Response of a single energy pile to combinations of thermal and mechanical loads (Laloui et al., 2003)*

A pioneering field test was performed at EPFL campus, on a single energy pile, with a diameter of 0.88 m and length of 25.8 m, under a newly constructed 5-storey building (Bâtiment Polyvalent). The single energy pile was one of the 97 bored piles constructed under the building. Along the test pile, polyethylene (PE) tubes were installed vertically on the reinforcing structure with a U-shaped configuration to permit the passage of the heat-carrying fluid. The test pile was instrumented by a considerable amount of sensors to enable the measurement of temperature, strain and toe load variations during the thermal load applications.

The soil profile at the field test site consists of alluvial soil at the first 12 m (Layers A1 and A2) which is followed by a sandy gravelly moraine (Layer B) and bottom moraine (Layer C) until around 25 m. Finally, a molasse layer (Layer D) is found under the moraine. The ground water table at the test site is located at ground surface. Further information on soil and soil-pile interaction, as well as the test pile and instrumentation can be found in Laloui et al. (2003).

A heating and passive cooling cycle was applied to the test pile following the completion of each storey of the building with the purpose of evaluating the influence of structural load on the development of thermally induced axial stresses and displacements. Figure 5a shows the results of the last test which was performed after the construction had been finalized. The distribution of the mechanical load profile shows the absence of toe resistance which implies that the structural load was entirely carried by the mobilized resistance along the shaft of the test pile. The following temperature increase, with a magnitude of 13.4°C, resulted in generation of thermally induced compressive axial loads with a significant mobilization of the toe (2000 kN) and thermally induced axial loads at the pile head (1000 kN).

Shaft resistance mobilization due to mechanical and thermal loads along the same test pile is shown in Figure 5b and 5c. The mechanical load application resulted in downward displacement of the pile which is associated with positive shaft resistance mobilization. The subsequent temperature increase caused the portion of the pile, above the null point, the depth at which no thermally induced displacement is observed, to possess an upward displacement, resulting in a decrease in corresponding shaft resistance (Figure 5b). On the other hand, the portion below the null point displaced downward, further mobilizing the positive shaft resistance (Figure 5c).

3.1.2 *Response of a group of closely-spaced energy piles to thermo-mechanical loads (Mimouni and Laloui, 2015; Rotta Loria and Laloui, 2017)*

A second field test was implemented at EPFL campus by equipping four out of 20 piles under a water retention tank within the Swiss Tech Convention Center to evaluate the thermally induced group effects among closely-spaced energy piles. The piles were 0.9 m in diameter and 28 meters in length. Each test pile was equipped with four 24 m long U-loops connected in series which were installed 4 m below the pile heads in order to prevent the thermal interaction with the water retention tank. The test piles were instrumented with vibrating wire strain gages at every 2 meters along the length, a pressure cell at the toe and radial optical fibers. Moreover, thermistors and piezometers were installed within boreholes at close proximity to the test piles to monitor the temperature and pore water pressure changes during the field test. The field test site is 200 m away from the single energy pile test location, resulting in similar stratigraphic characteristics (Mimouni and Laloui, 2015).

Heating with maximum temperature increase of 20°C and passive cooling cycles were applied to single (EP1) and the group of four energy piles (EPall) (Rotta Loria and Laloui, 2017). Figure 6 shows (i) thermally induced axial strains and stresses along EP1 when serving as the only operating pile among the group of four piles (20EP1) and (ii) average thermally induced axial strains and stresses along the length of all four piles during full geothermal activation of the group (EPall). The comparison of tests 20EP1 and 20EPall shows that the presence of thermally induced group effects govern the higher development of axial strain when more energy piles operate as geothermal heat exchangers in a closely spaced pile group than when only one energy pile serves this purpose (Figure 6a). Figure 6b shows the comparison in terms of thermally induced axial stresses where an opposite behavior was attained corresponding to a decrease in thermally induced axial stresses as the number of thermally active energy piles increases. This phenomenon is associated with the increased deformation of energy piles operating in a group (Figure 6a) which results in lower thermally induced blocked strains, since the temperature change and hence the free thermal strains are the same for Test 20EP1 and 20EPall, and therefore lower observed axial stresses. Moreover, tensile stresses were observed at the bottom portion of the energy piles during test 20EPall, which is associated with the thermally induced deformation of the molasse layer resulting in a pull-down effect. This effect was less pronounced during the test 20EP1 since the compressive stresses induced by the restrained expansion of EP1 overcame the tensile stresses exerted by the surrounding molasse layer.

Comparison of thermally induced strains and axial stresses per unit temperature change corresponding to geothermal operation of a single energy pile (Test 20EP1) and a group of energy piles (Test 20EPall) is presented in Figure 7a and 7b, respectively, which are average values along the active length of the piles. The figures clearly show greater average vertical strains and lower average axial stresses with increasing number of active energy piles. In terms

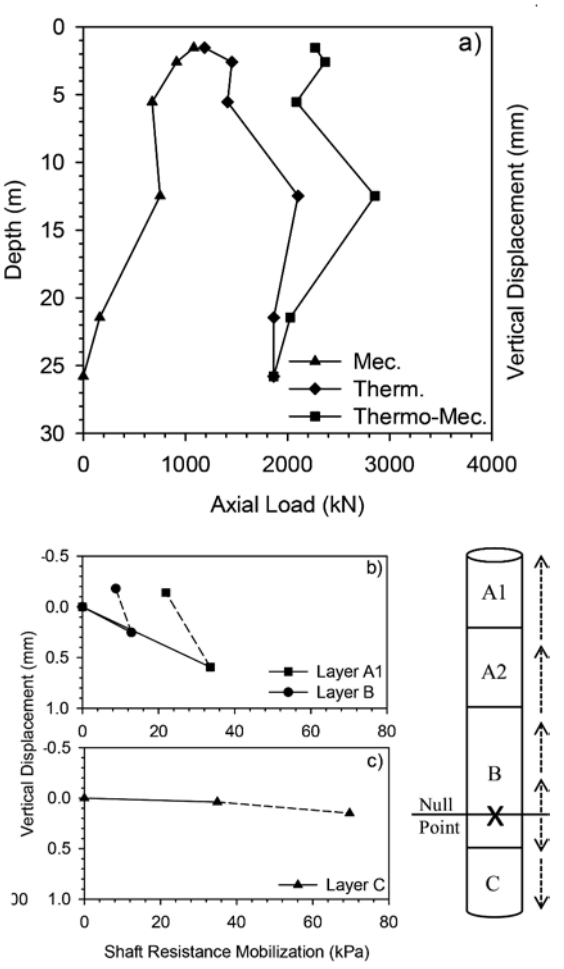

Figure 5. A) Mechanical, thermal and combined thermo-mechanical loads. b, c) Shaft resistance mobilization along the test pile.

of design aspects, analysis of a single pile in a closely-spaced group will lead to a conservative estimate of vertical stresses that can be employed during the preliminary design stages, but is not the case for the vertical strains.

3.2 *Analytical methods for the analysis of energy piles*

Full-scale in-situ tests provided the most fundamental information regarding the response of a single and a group of energy piles to thermo-mechanical actions. Moreover, finite-element methods, the majority of which have been validated by the results of the in-situ tests, were developed, and are considered to be the most rigorous approach for the analysis of energy piles. However, these comprehensive methods require a considerable number of geotechnical parameters, as well as high computational efforts, which renders them more suitable for research purposes rather than for practical piling problems. For the design and wider application of energy piles, a reasonable balance between excessive complexity and unsatisfactory simplicity should be established for the development of practical analytical models. Therefore, several simplified analytical methods have been developed by the Laboratory of Soil Mechanics to serve as preliminary design guidance of single and groups of energy piles.

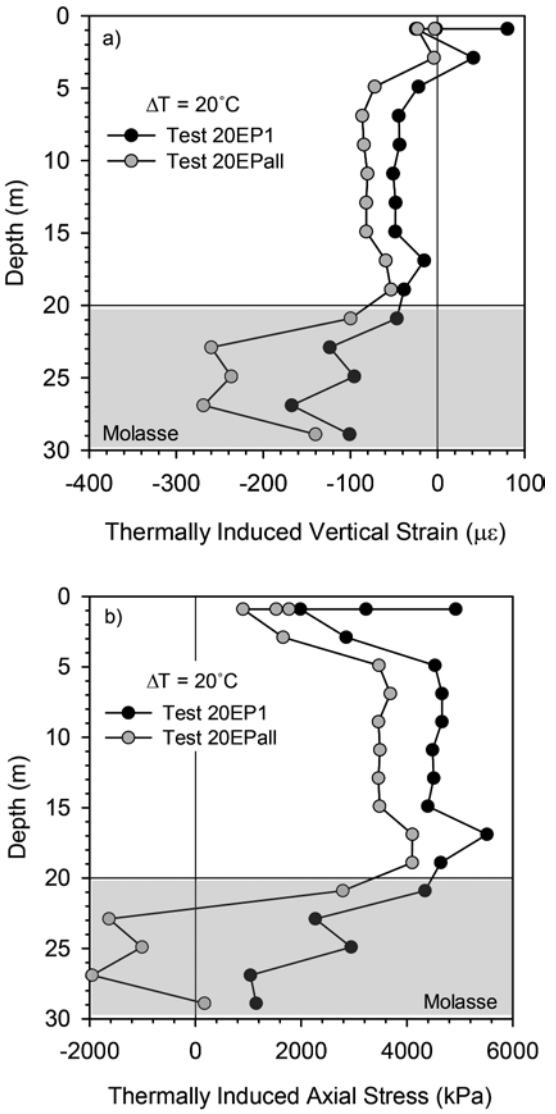

Figure 6. A) Thermally induced axial strains b) Thermally induced axial stresses during tests EP1 and EPall.

3.2.1 *Load-transfer approach for single and group of energy piles (Knellwolf et al., 2011; Ravera et al., 2020)*

The load-transfer approach, where the soil-pile interaction is represented by springs distributed along the pile shaft and toe by neglecting the continuity of the soil domain, is one of the most common analytical methods employed for the analysis of conventional piles (Seed and Reese, 1957; Coyle and Reese, 1966). In this approach, numerous analytical and empirical methods have been proposed to define the load-transfer curves (Randolph and Wroth, 1978; Frank and Zhao, 1982; Kraft et al, 1981). Later on, considering that most piles are implemented in groups in practice, the load-transfer curves have been modified to consider group effects (Randolph and Clancy, 1993; Comodromos et al., 2016). Given the great potential of the load-transfer approach in providing a practical tool for the analysis of axial loaded conventional piles, the approach has been implemented for the analysis of single and groups of energy piles.

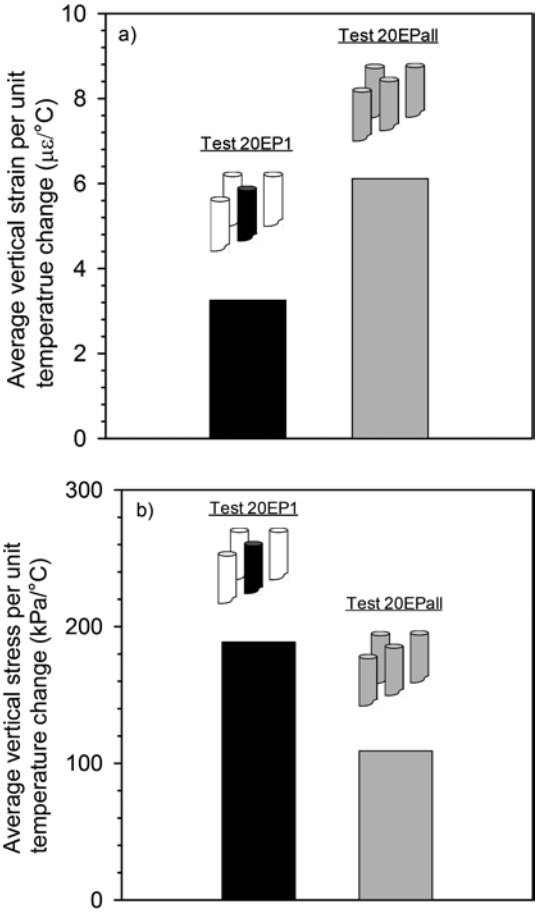

Figure 7. Thermally induced group effects in terms of a) Axial strains and b) Axial stresses (redrawn after Rotta Loria, 2019).

The load-transfer approach has first been modified for single energy piles by Knellwolf et al. (2011), where the pile is divided into rigid elements that are connected to each other and to the surrounding soil by the springs (Figure 8a). In order to define the relationships between the mobilized shaft friction/toe resistance and displacement, the method from Frank and Zhao (1982) was utilized, relating the shaft and toe stiffness to Menard pressuremeter modulus and dividing the load-transfer curve into three main sections: (i) initial linear part characterizing the elastic response, (ii) second linear part associated with the elastoplastic response and (iii) final plateau referring to perfectly plastic response as represented in Figure 8b by full lines for single isolated piles. The presence of a slab above energy piles was considered in a simplified way by introducing an additional spring linked to the pile head. The analytical model is validated by the results of both EPFL single pile in-situ test (Laloui et al., 2006) and Lambeth College in-situ test (Bourne-Webb et al., 2009) and has also been implemented in the Thermo-Pile Software developed by Laboratory of Soil Mechanics for the analysis and design of energy piles.

Following the same logical sequence as the one of conventional piles, the load-transfer approach for single energy piles has subsequently been extended to characterize the response of groups of energy piles to thermo-mechanical loads in a simplified, yet rational manner (Ravera et al., 2020). To represent the interaction between a group of energy piles, a displacement ratio (R_d) was introduced adapting the displacement response of a single isolated energy pile to the one of an energy pile in a group:

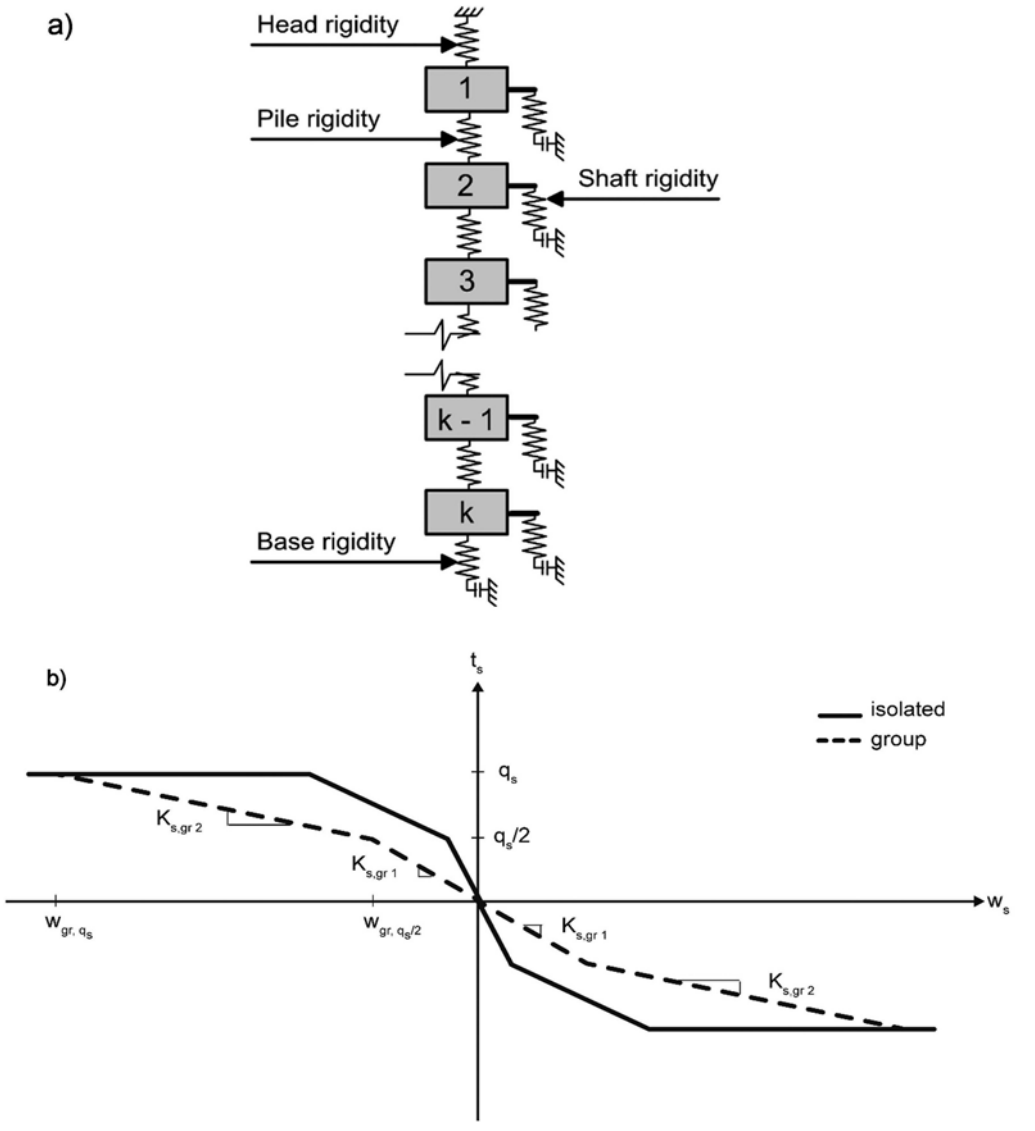

Figure 8. A) Modelling approach b) Load-transfer relationship for single isolated energy pile and energy pile in a group.

$$R_d = \frac{w_{gr}}{w_{is}} \tag{4}$$

Where w_{gr} is the average displacement of group and w_{is} is the displacement of a single pile subjected to same average load. As in the case of the approach proposed for conventional piles (Comodromos et al., 2016), the displacement ratio depends on the geometric configuration as well as the variations in the displacement field introduced by thermal and mechanical loads. In this approach, the ultimate shaft resistance of an energy pile in a group is considered to be the same as the one of a single isolated energy pile, while the displacement ratio is applied to adapt the displacement necessary to mobilize it. The load-transfer curve attained for a single energy pile in a group is represented by dashed lines in Figure 8b and is determined as follows:

$$w_{gr} = R_d w_{is} \tag{5}$$

$$t_{s,gr} = t_{s,is} \tag{6}$$

where w_{gr} and $t_{s,gr}$ are the displacement and shaft resistance of an energy pile in a group, and w_{is} and $t_{s,is}$ are the displacement and shaft resistance of a single isolated energy pile, respectively. The load-transfer curve in Figure 8b is determined using the method proposed by Frank and Zhao (1982), yet, any method developed for single conventional piles can be employed provided that a displacement factor is applied. Finally, since the behavior of a pile in the group highly depends on its location, the displacement ratio may also be corrected by introducing a location weighting factor (Comodromos et al., 2016).

The proposed method has been implemented in Comsol Multiphysics Software and its competence in analyzing the behavior of a group of energy piles has been investigated through the results of the full-scale in-situ test performed at EPFL campus, on a group of four energy piles. The material properties considered in the analysis as well as the development of the load-transfer curves are explained in detail by Ravera et al. (2020). Comparison of experimental data from the full-scale in-situ test (Rotta Loria and Laloui, 2018) and the numerical results obtained through the implemented method is presented in Figure 9a and 9b, in terms of thermally induced axial stress and mobilized shaft resistance, respectively at 20°C temperature increase. The numerical results were attained employing two sets of parameters for the molasses layer in compliance with the ones presented in Knellwolf et al. (2011).

The comparison presented in Figure 9 corresponds only to the geothermal activation of the group of energy piles, excluding the stresses generated by the body load and structural loads. The stress variation corresponds to the average value of the mean temperature variations along the uninsulated portions of all four energy piles in the group and the mobilized shaft resistance is determined by employing the stress variations. A good agreement between the experimental and numerical results is observed in the figure, despite the simplifications inherent in the theory.

It was previously shown in Figure 7 that thermally induced vertical stresses decrease for the same temperature change as the number of geothermally active energy piles increases due to increased vertical strains caused by group interactions. The agreement between experimental and numerical results corroborates the additional value of this method, which allows determination of the thermally induced vertical stress along the depth of an energy pile in a group in a simplified and rational manner.

3.2.2 *Interaction factor method for group of energy piles (Rotta Loria and Laloui, 2016; Ravera et al., 2019)*

A second analytical method was extended from the interaction factor method in the framework of conventional pile groups (Poulos, 1968) to the one of energy pile groups in order to provide a simplified yet rational analysis tool for estimating the vertical displacement of energy pile groups subjected to thermal loads (Rotta Loria and Laloui, 2016). The method allows the estimation of the head displacement of any energy pile in a group by employing the interactions between two energy piles and the superimposition of the individual effects of adjacent piles in the group as follows:

$$w_k = w_i \sum_{i=1}^{i=n_{EP}} \Delta T_i \Omega_{ik} \tag{7}$$

where w_i is the vertical head displacement of a single isolated pile per unit temperature change, ΔT_i is the applied temperature change to pile i, and Ω_{ik} is the interaction factor for two piles corresponding to the center-to-center distance between pile i and k. Interaction factor charts, characterizing a group of two energy piles and taking into consideration pile slenderness ratio and spacing, pile-soil stiffness ratio, Poisson's ratio and non-uniform moduli of the soil have been developed to determine Ω_{ik} (Rotta Loria and Laloui, 2016).

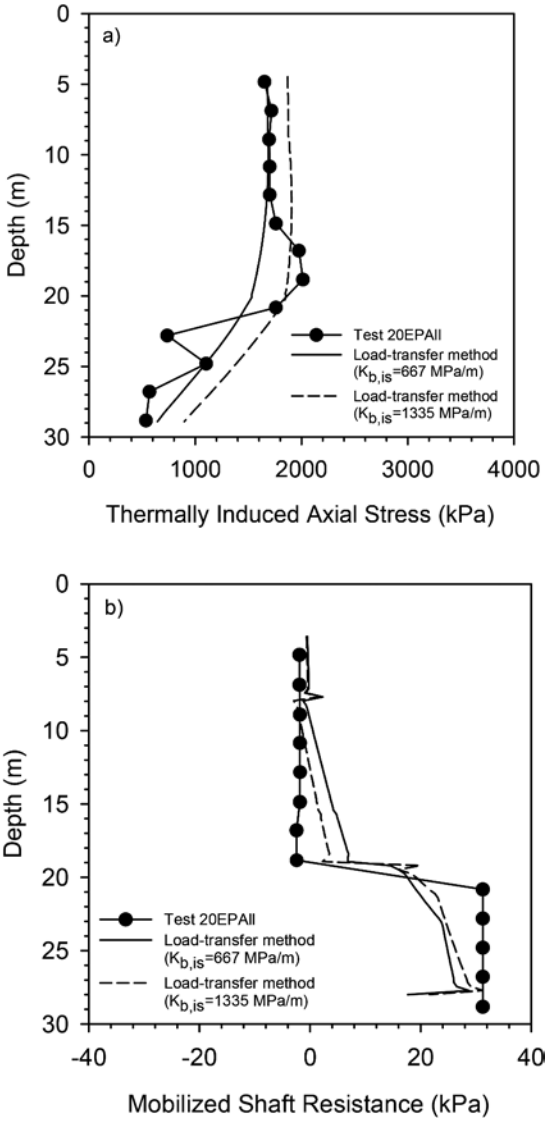

Figure 9. Comparison between experimental data and numerical results for a) Thermally induced axial stresses and b) Mobilized shaft resistance (redrawn after Ravera et al., 2020).

The formulation above provides solutions regarding the displacement interaction for free standing energy pile groups or energy pile groups with a perfectly flexible slab. However, in practice piles are often rigidly attached to a pile cap which stands on the soil (Poulos, 1968). Therefore, it is essential to consider thermally induced mechanical interactions which are governed by the changes in deformation field, due to the interplay between the energy pile-slab-soil responses. With this purpose, the interaction factor method was further extended to take into account the presence of the pile cap (Ravera et al., 2019). 3D steady state finite element simulations were carried out employing Comsol Multiphysics Software to propose a formulation of the interaction factor for energy pile groups under a slab and to propose design charts for the analysis compatible with the former study. The influence of the rigid pile cap is expressed in terms of pile-cap displacement ratio as follows:

$$R_c = \frac{displacement\ of\ pile\ with\ cap}{displacement\ of\ free\ standing\ pile} \tag{8}$$

Employing the pile-cap displacement ratio, displacement determined in free standing conditions can be adjusted to consider the contacting slab as follows:

$$w_k = R_c w_i \sum_{i=1}^{i=n_{EP}} \Delta T_i \Omega_{ik} \tag{9}$$

The combination of the two methodologies (1) interaction factor method for free standing energy piles and (2) extension of the method to consider the presence of the slab yields the following ultimate methodology illustrated in Figure 10. The first three steps belonging to the original methodology (Rotta Loria and Laloui, 2016) and the following two steps corresponding to the extension of the method (Ravera et al., 2019), are as follows:

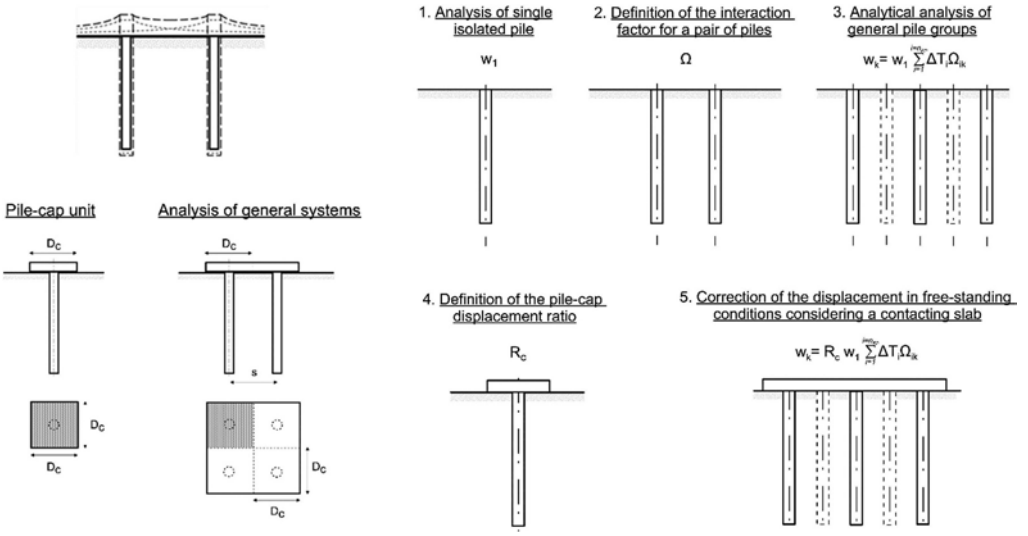

Figure 10. Steps of interaction factor method for the analysis of energy piles with contacting slab.

Step 1: Displacement of an isolated energy pile is computed by employing any suitable practical or sophisticated method as long as it returns representative displacement values for the considered case.

Step 2: Interaction factor is determined for a pair of two energy piles employing the design charts provided by Rotta Loria and Laloui (2016). A sample design chart regarding an energy pile with a slenderness ratio of twenty-five bearing in a soil with a Poisson's ratio of 0.3 is presented in Figure 11a, for various soil-pile stiffness and normalized displacement.

Step 3: Vertical head displacement of any pile in the group in free standing conditions is calculated employing Equation (7).

Step 4: Pile-cap displacement ratio is determined referring to the design charts presented by Ravera et al. (2019). A sample design chart, compatible with the one presented for Step 2, is shown in Figure 11b for pile cap thickness of 0.6 m.

Step 5: Displacement determined in Step 3 for free standing conditions is corrected by employing Equation (9).

The rather approximate yet rational methodology presented above enables the estimation of the head displacement of any energy pile group configuration with a slab supported on soil through the displacement of a single isolated energy pile and superimposition of the individual effects of adjacent piles and the slab in the group, providing a practical tool to perform displacement analysis of energy pile groups in the early stages of the design process.

4 DESIGN OF ENERGY PILES

Full-scale in-situ tests that have been performed on energy piles, as well as the numerical and analytical tools that have been developed over more than two decades, revealed the most fundamental information leading to the recommendations regarding the design of energy piles. According to these findings the design of energy piles at ultimate limit states can be considered as a conventional process by considering that the reactions provided by the soil above and below the null point compensate for each other ensuring equilibrium and, provided that the structural elements are characterized by adequate ductility and rotation capacity (Rotta Loria et al., 2020). However, regarding the serviceability limit states, the effects of both mechanical and thermal loads should be examined by taking into consideration the vertical displacement of single and group of energy piles, as well as the deflection or angular distortion.

Regarding the combinations of actions, Rotta Loria et al. (2020) recommended $\psi_0 = 0.60$, $\psi_1 = 0.50$ and $\psi_2 = 0.50$ for the combination, frequent and quasi-permanent values of variable actions, respectively. Regarding the consideration of thermal loads during cooling of the building side (i.e. temperature increase along the energy piles), two design combinations must be considered, assuming the effects of the thermal loads make them the dominant load ($\Delta T_k = Q_{k,1}$, where $Q_{k,1}$ is the dominant variable load) or if not ($\Delta T_k = Q_{k,i}$, where $Q_{k,i}$ is the i^{th} general variable load), since it is not known if the thermal loads are dominant with respect to the mechanical ones. Regarding the heating of the building side (i.e. temperature decrease along the energy piles) a single design combination must be considered ($\Delta T_k = Q_{k,1}$).

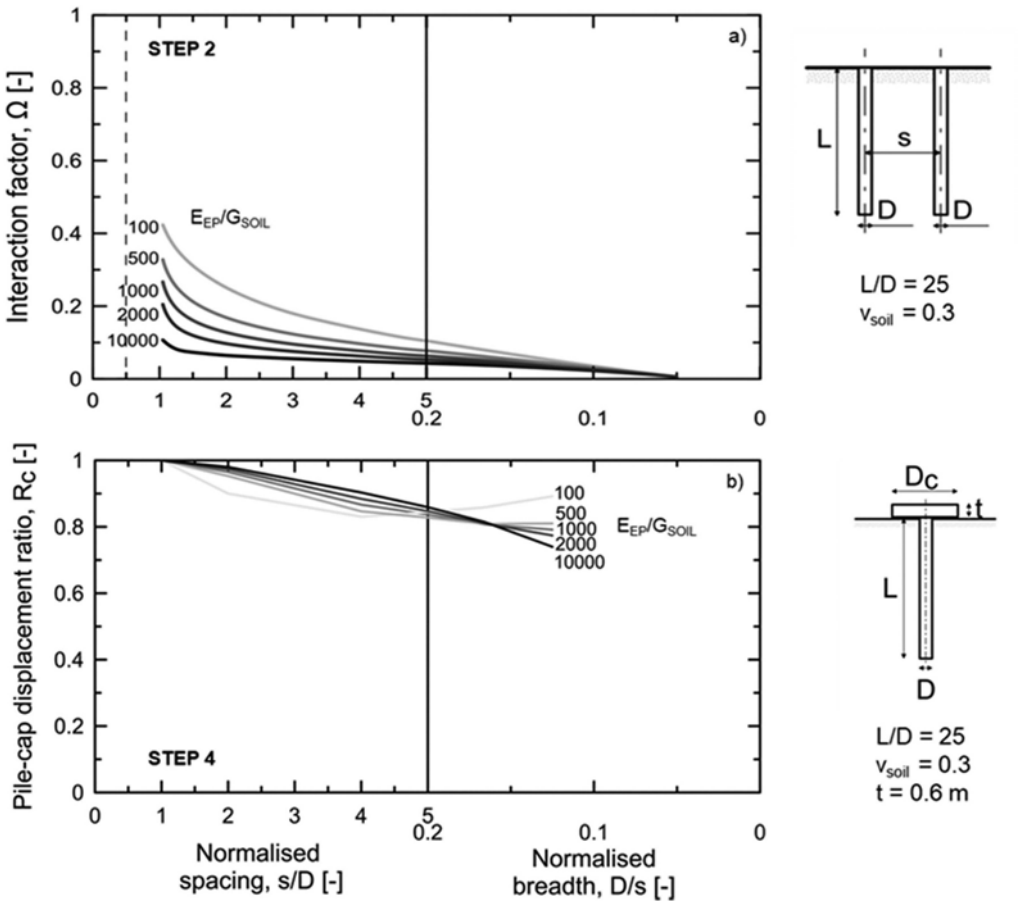

Figure 11. A) Interaction factors, b) Pile-cap displacement ratio for L/D = 25.

Finally, when the influence of thermal loads is analyzed during the design of energy piles, (i) piles free at the head and (ii) piles that are fully restrained should be considered to attain conservative estimations of vertical displacement and stress, respectively.

5 CONCLUSIONS

The fundamental research in the field of energy geostructures, compiled and expanded by the Laboratory of Soil Mechanics over more than two decades, revealed that this emerging technology provides low carbon, cost-effective and local energy solutions to structures and infrastructures, which opens a new era for the geotechnical engineering practice.

The research activities performed by LMS in this field has exclusively covered various elements related to energy geostructures, including but not limited to energy, geotechnical, structural and design aspects. Related to the energy aspect, it has been revealed that typically, 40-150 W/m heat energy can be extracted from and withdrawn into the ground with the use of energy piles, while 20-40 W/m^2 and 20-60 W/m^2 are achievable with energy wall and energy tunnels, respectively. Furthermore, two state-of-the-art in-situ tests have been performed on single and a group of energy piles, which not only revealed the most fundamental knowledge regarding their thermo-mechanical behavior, but also provided invaluable information for the validation of numerical models and analytical tools developed in the area.

To provide satisfactory tools for design and wider application of energy piles, several practical analytical tools have been developed for energy piles including the load-transfer method for the assessment of axial stress, displacement and mobilized shaft resistance along single and groups of energy piles, as well as the interaction factor method for the estimation of vertical displacement of energy pile groups with and without a rigid slab. Incremental research efforts performed in the area, from both experimental and analytical points of view, have eventually led to development of recommendations for the design of energy piles for both ultimate and serviceability limit states. Overall, research outcomes achieved over more than two decades revealed that the energy geostructures concept is a mature and ready-to-be-employed technology.

The questions that remained to be answered now are no longer about how an energy geostructure responds to thermal actions, but rather on how the energy performance, as well as the geotechnical and structural adaptations should be assessed to maximize its cost efficiency.

ABSTRACT: Engineering parameters reflecting dynamic responses have been used for reliable subsurface characterization in the field. The objective of this study is to summarize the innovations in in situ devices using dynamic penetration systems. The devices cover the Instrumented Dynamic Cone Penetrometer (IDCP) in small- and large-scale energy-monitoring modules for Standard Penetration Tests (SPT) and Seismic Dynamic Cone Penetrometers (SDCP). For the IDCP, Dynamic Resistance (DR) was experimentally estimated by the F^2, F-V, and F methods and their reliability was compared, while the DR was correlated with the DCPI to assess its applicability in the field. The large-scale IDCP for the deep and dense layer estimates the DR as well, which shows the functions of relationships with the DCPI and static cone resistance. Likewise, an energy monitoring module was installed at the rod head and the SPT sampler. The transferred energy ratios acquired by the energy-monitoring module at the rod head and sampler were compared, and the DR was reasonably correlated with the static cone resistance. Finally, the SDCP simultaneously measured the penetration index and maximum shear modulus, which can characterize both strength and stiffness of the layer. This study suggests that the innovation of dynamic in situ devices may allow for more reliable and efficient subsurface characterization.

1 INTRODUCTION

Dynamic penetration system has been widely used for subsurface characterization because of their applicability to hard layers using simple testing procedures. Among dynamic penetration systems, the dynamic cone penetration test (DCPT) has been adopted for use in fields with low accessibility owing to its mobility (ASTM D6951). Subsequently, the dynamic cone penetration index (DCPI) acquired by the dynamic cone penetrometer (DCP) has been correlated with many engineering parameters, such as the California bearing ratio for pavement design (Kim et al., 2019). However, the dynamic penetration system is limited because energy loss occurs during the driving of the penetrometer (Byun and Lee, 2013; Lee et al., 2019). Therefore, an instrumented dynamic cone penetrometer (IDCP) was developed for the reliable characterization of layers considering dynamic responses (Byun et al., 2014; Kim and Lee, 2020; Kim et al., 2022a).

In addition, a large-scale IDCP was developed for characterization of the deep and dense layers of intermediate geomaterials (Lee and Byun, 2020). When stiffness of the ground gradually increases from very soft to stiff, the subsurface characterization method should be modified from quasi-static for soft soils to dynamic for stiff soils. The standard penetration test (SPT), which is also one of dynamic penetration system, has been applied to ground investigations at deep depths. For accurate strength characterization, the transferred energy into the rod head was evaluated and the N value was corrected to the reference energy ratio of 60% as N_{60}. However, energy correction using the transferred energy into the rod head has a limitation

DOI: 10.1201/9781003299127-6

owing to energy losses at the joints and SPT sampler. An energy-monitoring module was developed to consider these energy losses (Hong et al., 2022; Park et al., 2022).

The stability of the ground subjected to repetitive dynamic and wheel loads is influenced by the stiffness and strength (Clark et al., 2002). DCP has the advantages of portability and profiling the target ground with depth. However, the DCP only produces the strength characteristics of the target ground using the dynamic cone penetration index (DCPI), and the stiffness of the target ground is estimated from the correlations between the stiffness properties and the DCPI suggested by previous studies (Mohammadi et al., 2008; Lee et al., 2014). Therefore, a seismic dynamic cone penetrometer (SDCP) was developed based on the DCP apparatus for direct evaluation of the stiffness properties of the target ground with depth (Hong et al., 2017).

The objective of this paper is to introduce innovations in dynamic in situ tests by measuring the tip or sampler responses or sensing soils near the tip. Dynamic in situ tests include dynamic cone penetration tests, standard penetration tests, dynamic cross-hole tests, and water-content measurements. The device and field tests for these tests are discussed. This manuscript is a summary and reorganization of the research conducted and the articles published by and in the Geo-Engineering (or Geowave) Laboratory, Korea University.

2 INSTRUMENTED DYNAMIC CONE PENETROMETER

2.1 *Device*

The IDCP is composed of guide, hammer, anvil, driving rod, and cone tip, as shown in Figure 1. The hammer with a weight of 78.5 N falls through the guide from a height of 575 mm, which has potential energy identical to that of conventional DCP. The cone tip has an apex angle of 60° and a diameter of 24 mm, and the driving rod is composed of hollow steel pipes with inner and outer diameters of 14 and 24 mm, respectively, to install sensors inside the rod. A load cell composed of four strain gauges was installed at the cone tip and used to measure the force based on a Wheatstone bridge circuit, which amplifies the output voltage and compensates for temperature and bending effects. An accelerometer was installed at the cone tip to acquire the acceleration signals during driving. Note that the dynamic signals can be acquired by calibrating the electrical signals to the force and acceleration. Finally, the dynamic signals were visualized on the oscilloscope through the amplifier and bridge box and stored on a computer (see details in Byun et al. 2014; Kim et al. 2019; Lee et al. 2019).

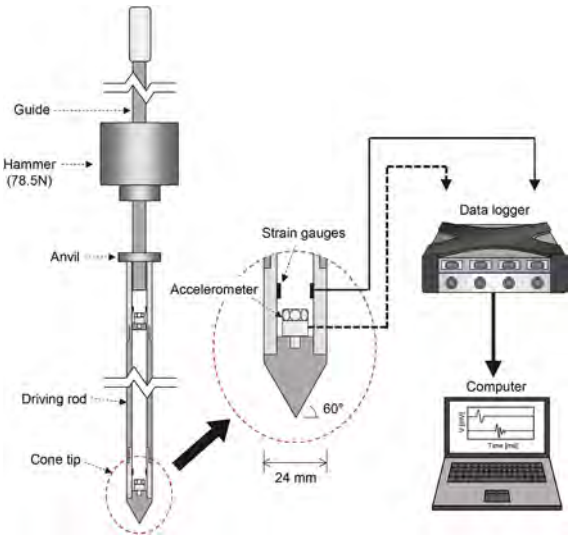

Figure 1. Measurement system of instrumented dynamic cone penetrometer (Lee et al., 2019).

2.2 *Experimental study*

For a direct indication of the soil layer strength, the dynamic resistance (DR) with a unit of stress was used in the DCPT as follows:

$$DR = \frac{1}{A} \times \frac{PE}{\Delta d} = \frac{1}{A} \times \frac{mg \times h}{\Delta d} \tag{1}$$

where A, PE, Δd, mg, and h denote the cross-sectional area, potential energy, displacement, hammer weight, and falling height, respectively. DR allows efficient profiling of hard layers rather than DCPI using conventional DCP.

From the DR concept in Equation (1), DR at the cone tip can be evaluated using dynamic signals. Previous studies have proposed various DR evaluation methods, such as the F2, F-V, and F methods (Kim et al., 2021), as follows:

$$DR_1 = \frac{1}{A} \times \frac{1}{\int_0^t V\,dt} \times \left(\frac{c}{AE} \int_0^t F^2\,dt \right) \tag{2}$$

$$DR_2 = \frac{1}{A} \times \frac{\int_0^t F \times V\,dt}{\int_0^t V\,dt} \tag{3}$$

$$DR_3 = \frac{1}{A} \times \frac{\int_0^t F\,dt}{\Delta t} \tag{4}$$

where F, V, t, c, and E denote the force from the strain gauges, the particle velocity from the accelerometer, time, wave velocity, and Young's modulus, respectively. Typical dynamic signals calculated using the three methods are presented in Figure 2.

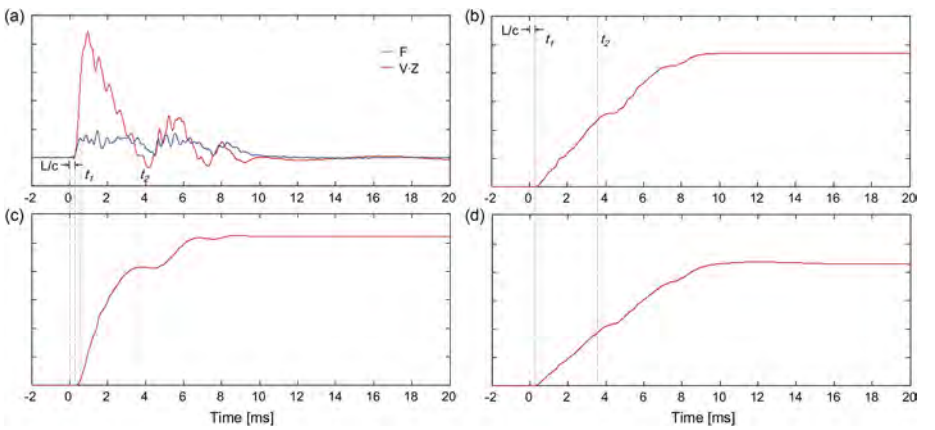

Figure 2. Typical dynamic signals: (a) force-velocity; (b) force square integration; (c) transferred energy; (d) force integration (Kim et al., 2021).

In Figure 2, t_1 and t_2 correspond to L/c and first zero velocity at the cone tip, respectively. Based on the time determination, the F^2, F-V method, and F methods were compared.

The comparative test results show that the relationship between the DRs and estimated t_1 and t_2 using the identical integration method provides an insignificant trend. Among the DR evaluation methods, the F-V method and F–methods present well-matched correlations when t_2 is selected. Compared to the DR estimated by the potential energy method, the F-V and F methods with t_2 show a proportional trend with a high determinant coefficient. For a smaller driving rod length, the F-V method and F methods with t_2 are efficient in acquiring more reliable layer profiles because t_1 is extremely small. Considering the integration interval

effect of the dynamic response obtained from the accelerometer, the F method can be effectively used for DR estimation using IDCP, as previously adopted by Lee et al. (2019).

Laboratory and field tests were conducted to investigate the performance of the IDCP. Byun and Lee (2013) performed lab-scale dynamic cone penetration tests using an IDCP, as shown in Figure 3(a). Weathered soils were compacted in a square-shaped chamber at a depth of 1 m, with two steel pipes grouted with mortar embedded in the compacted soil. The test results showed that the transferred energy at the cone tip was smaller than that at the rod head, regardless of the penetration depth. The energy-corrected cone tip resistances showed better detection of the erratic layers in stiff soils, for which the DCPI may not have been detected. Lee et al. (2019) also used IDCP for dynamic cone penetration tests in a square-shaped chamber filled with soils with three different dry unit weights. The IDCP shows the power function relationship between the DR and DCPI. For stiff soil, the DR varied more sensitively with soil strength than the DCPI. Byun et al. (2014) applied the IDCP to evaluate the strength variation and thickness of the active layer in the Arctic region (see Figure 3(b)).

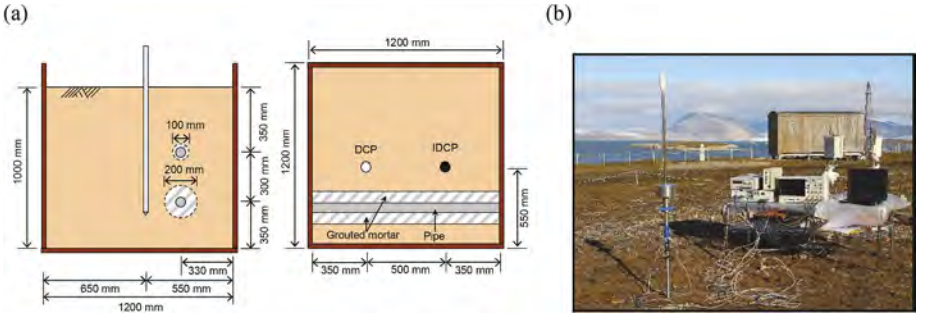

Figure 3. Dynamic cone penetration tests using the IDCP applied in (a) rectangular container and (b) field (Byun and Lee, 2013; Byun et al., 2014).

An in situ modulus detector (IMD) was developed to evaluate the resilient moduli of the subgrades based on the same instrumentation as the IDCP (Byun and Kim, 2022; Kim et al., 2022b). Unlike the IDCP, a rubber buffer was placed on the anvil of the IMD to apply dynamic loads to the subgrade and minimize high-frequency noise in the dynamic signals, as shown in Figure 4. The IMD can provide the resilient modulus profile of the subgrade, which can be affected by hammer drop height, water content, and soil density.

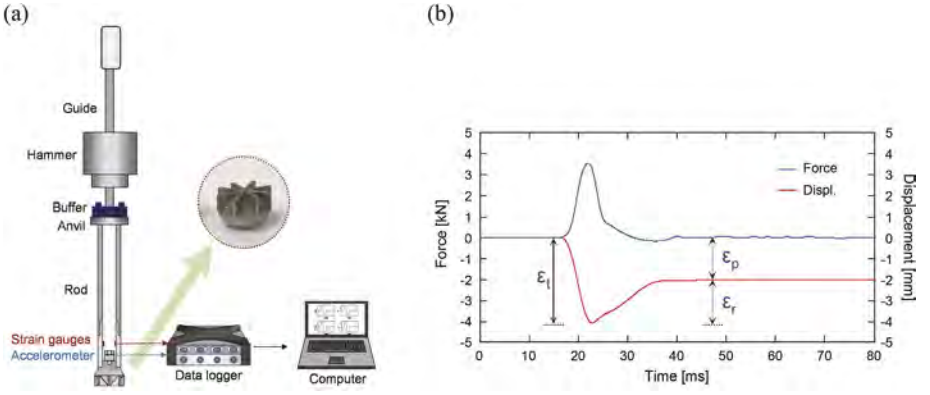

Figure 4. Resilient modulus estimation: (a) in-situ modulus detector; (b) typical tip response (Byun and Kim, 2022; Kim et al. 2022b).

3 LARGE-SCALE INSTRUMENTED PENETROMETERS

3.1 *Device*

The cone tip and rod head of the large-scale IDCP have the same outside diameter of 44.5 mm, and each component includes an accelerometer with a maximum amplitude of 100,000 g and four strain gauges with a resistance of 350 Ω, as shown in Figure 5(a) and (b). Pile driving analyzer (PDA) sensors were installed on the rod head to verify the sensors mounted at the cone tip. Based on the wave propagation, the dynamic response at the cone tip is detected later than that at the rod head, as shown in Figure 5(c).

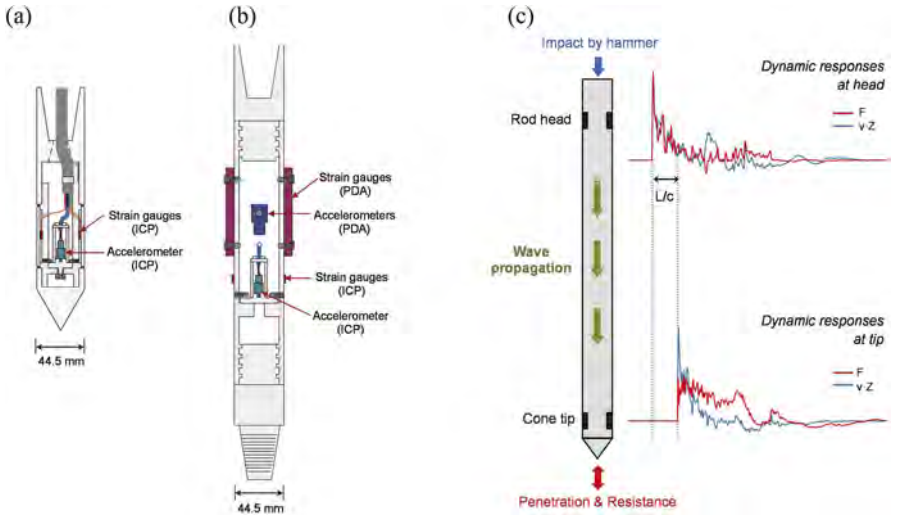

Figure 5. Schematic drawing of large-scale instrumented dynamic cone penetrometer: (a) cone tip; (b) rod head; (c) typical waveforms during driving (Lee and Byun, 2020).

3.2 *Experimental study*

Dynamic cone penetration tests using a large-scale IDCP were performed at two sites with different soil profiles (Lee and Byun, 2020). A previous study reported that the maximum transferred energy estimated at the rod head was the same for IDCP and PDA sensors, showing equally good performance. The force and velocity responses at the cone tip depend on the soil strength, and DR can be correlated with the DCPI and static cone resistance, as shown in Figure 6.

4 ENERGY MONITORING MODULE FOR SPT

4.1 *Device*

An energy-monitoring module was developed to improve the results of the standard penetration test (Hong et al., 2022). The measurement system of the energy-monitoring module is shown in Figure 7. The energy-monitoring modules are connected to the rod head and sampler to estimate the transferred energies. An accelerometer and load cell configured with four strain gauges were installed in the energy monitoring modules. The accelerometer and load cell signals were obtained using a data logger and analyzed using a laptop.

4.2 *Experimental study*

The standard penetration test with energy monitoring modules was conducted until a depth of 14 m (Park et al. 2022). The transferred energy ratios at the rod head and sampler were calculated

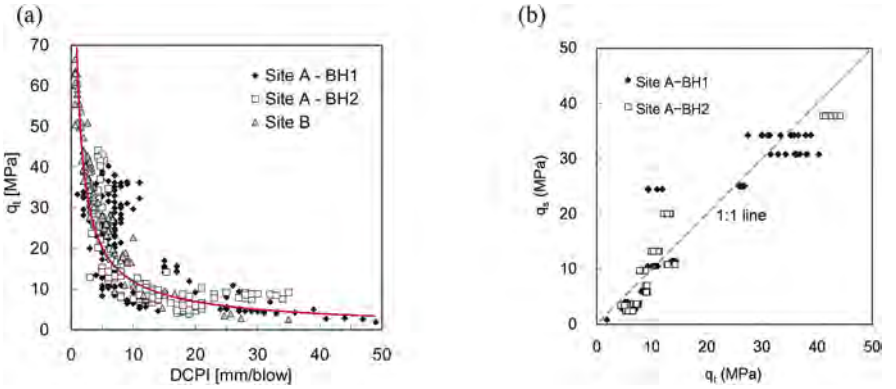

Figure 6. Correlation between the dynamic resistance and soil resistance indices: (a) dynamic cone penetration index; (b) static cone resistance (Lee and Byun, 2020).

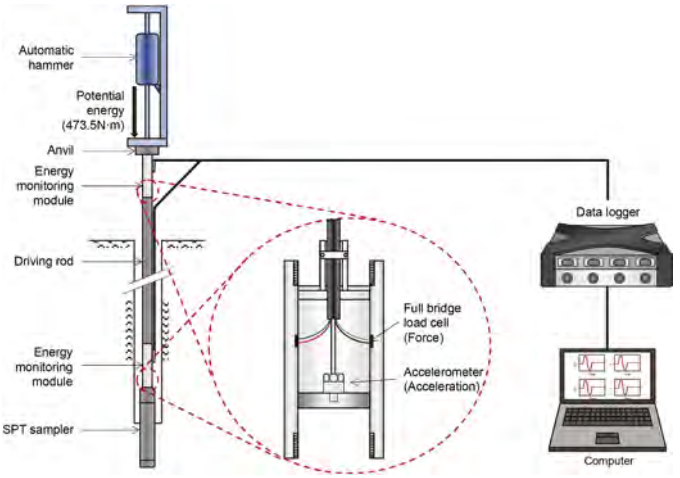

Figure 7. Schematic drawing of energy monitoring module for SPT energy measurement.

based on the potential energy (473.5 N·m) according to the depth, as shown in Figure 8. The average transferred energy ratio was 71.5% at the rod head and 48.2% at the sampler. The transferred energy ratios at the rod head and sampler generally decrease with increasing depth.

DR was calculated based on the energies transferred into the rod head and sampler to estimate the accuracy of the transferred energy ratios. DR is the work done against soil during penetration; thus, the corrected cone tip resistance, which is the result of the cone penetration test, should be similar to the DR in sand. The DR calculated based on the transferred energies is plotted against the corrected cone tip resistance in Figure 8. The DR based on transferred energy into the sampler was more similar to the corrected cone tip resistance than that into the rod head.

5 SEISMIC DYNAMIC CONE PENETROMETER

5.1 *Device*

The seismic dynamic cone penetrometer (SDCP) is composed of a hammer with a weight of 118 N freely falling from a drop height of 575 mm, an extendible driving rod with a diameter of 20 mm, and a cone tip part with a diameter and apex angles of 24 mm and 60, respectively, as shown in Figure 9(a). In the cone tip part, a uniaxial accelerometer with a range of 10,000 g is installed and connected to the data logger.

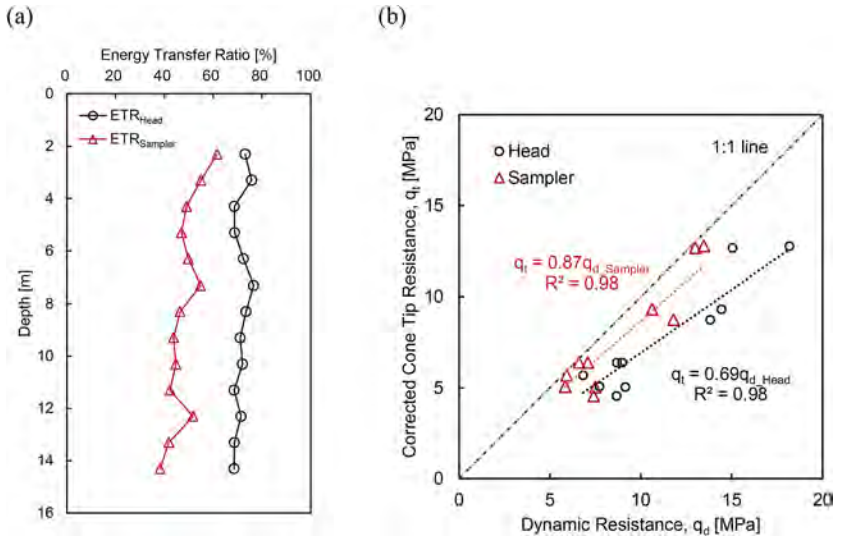

Figure 8. Test results of energy monitoring module in SPT: (a) Transferred energy ratios at the rod head and sampler according to the depth; (b) Relationships between corrected cone tip resistance and dynamic resistances (Park et al. 2022).

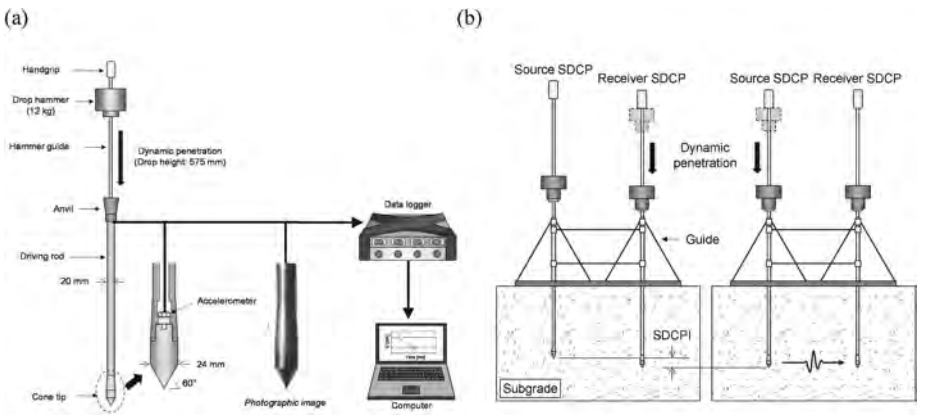

Figure 9. SDCP: (a) Schematic drawing; (b) Test procedure (Hong et al. 2017).

An SDCP test was conducted using two SDCPs. One of the SDCPs generates a seismic wave (source SDCP) while the other SDCP measures the seismic wave (receiver SDCP). The procedure for the SDCP test is illustrated in Figure 9(b). The source and receiver SDCPs and a guide for the vertical alignment of the SDCPs are located on the ground surface, and the receiver SDCP penetrates the ground to the target depths for stiffness evaluation. After the penetration of the receiver SDCP, the dynamic penetration of the source SDCP was conducted while simultaneously recording the blow counts and penetration depths. The recorded blow counts and penetration depths were used to calculate the seismic dynamic cone penetration index (SDCPI) using Equation (5), which indicates the strength characteristics of the target ground:

$$SDCPI\,[mm/blow] = D_{n+1} - D_n \tag{5}$$

where D_{n+1} and D_n are the penetration depths at the $n+1^{th}$ and n^{th} blow counts, respectively.

When the penetration depth of the source SDCP was similar to that of the receiver SDCP, accelerations were measured using both SDCPs during the dynamic penetration of the source

SDCP. The accelerometer in the source SDCP detects the time of hammer impact, which can be considered the generation time of the seismic wave, and the accelerometer in the receiver SDCP measures the seismic wave propagating in the ground. Note that the uniaxial accelerometer was vertically installed in the cone tip part; thus, the seismic wave measured using the receiver SDCP gathered the shear wave corresponding to the shear wave.

The travel time of the shear wave (Δt) is the time difference between the first arrival time of the shear wave and the generation time of the seismic wave as determined by the SDCPs. Therefore, the shear wave velocity (V_s) can be calculated using Equation (6)

$$V_s\,[m/s] = \frac{L}{\Delta t} \tag{6}$$

where L is the distance between the source and receiver SDCPs. Accordingly, the stiffness of the target ground can be profiled based on V_s by adjusting the depths of the SDCPs.

To verify the SDCP test, V_s was measured using both SDCP and bender elements (BE) in a laboratory chamber test, as shown in Figure 10(a). V_s evaluated using the SDCP is directly proportional to that measured by the BE, as shown in Figure 10(b). Therefore, it is considered that the SDCP test produces a reliable V_s profile for the target ground.

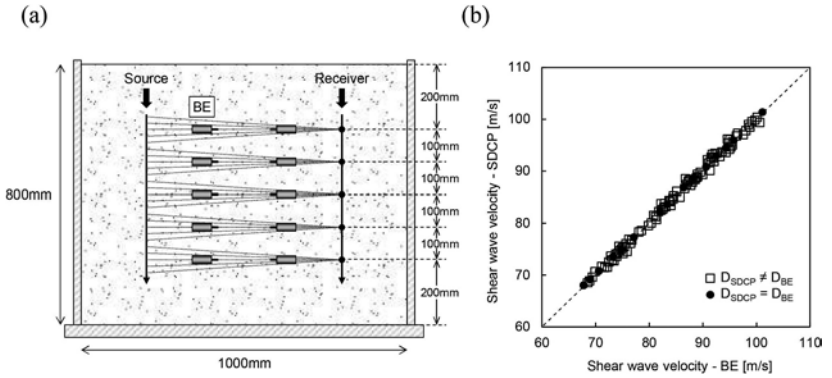

Figure 10. Calibration tests: (a) Schematic drawing of chamber; (b) Shear wave velocity comparison.

5.2 *Experimental study*

For the application of the SDCP, the SDCP test was conducted on a compacted subgrade located in the Republic of Korea (Lee et al., 2021). The distance between the sleeves of the source and receiver SDCPs was set as 576 mm. The receiver SDCP penetrated to a depth of 1,000 mm with a depth interval of 100 mm, and the source SDCP penetrated to a depth of 1,080 mm. Based on the experimental results, the penetration index (SDCPI) and V_s were profiled with depth. In addition, the maximum shear modulus was estimated based on V_s and the density of the subgrade, as shown in Figure 11.

The experimental results show that the SDCPI is measured as 5–7 mm/blow within a depth range of 50–880 mm, and significantly decreases and converges to approximately 2 mm/blow from a depth of 900 mm. V_s was evaluated to be approximately 169 m/s at a depth of 100 mm and gradually increased to 254 m/s at a depth of 800 mm. From a depth of 900 mm, V_s dramatically increases and is approximately 336 m/s at a depth of 1,000 mm, which corresponds to the strength characteristics estimated based on the penetration index.

6 SUMMARY AND CONCLUSIONS

As the test results of dynamic penetrometers are easily affected by energy loss, an innovative method such as an energy monitoring module is required. An energy-monitoring module,

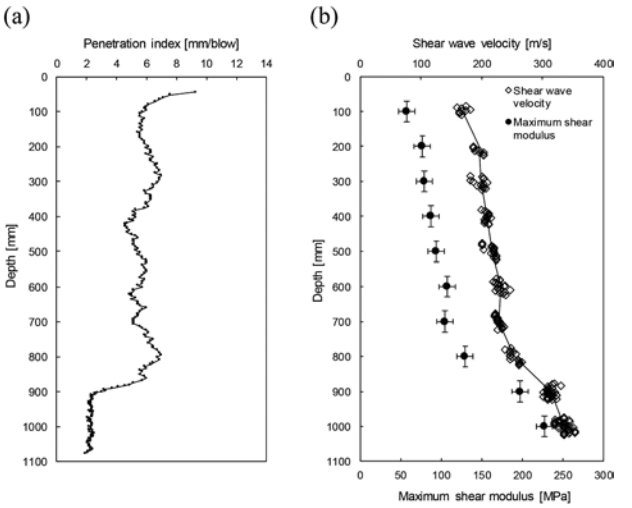

Figure 11. Test results of SDCP: (a) penetration index; (b) Shear wave velocity and modulus.

configured with an accelerometer and load-cell four strain gauges, was installed at the cone tip or near the sampler. The summary and main observations of the new in situ dynamic tests are as follows:

- The instrumentation at the cone tip of the IDCP can provide the force and velocity responses during driving and enable the estimation of the dynamic resistance (DR) suggested as a new soil strength index. Laboratory and field application tests showed that the DR estimated using the IDCP can be used to reliably characterize the soil strength instead of the DCPI. Furthermore, the same instrumentation, with the addition of a buffer to the IDCP device, can provide a resilient modulus estimation of compacted soils.
- The large-scale IDCP showed strong correlations between the DR, DCPI, and static cone resistances. Therefore, the large-scale IDCP and its DR estimation may be used effectively for characterizing dense layers, especially where low DCPI and high static cone resistance occur.
- An energy-monitoring module was developed to correct the standard penetration test. The transferred energies into the rod head and sampler were calculated using the energy monitoring module. Compared with the cone penetration test, the transferred energy into the sampler was more similar to the actual penetration energy than that into the rod head. Therefore, the energy-monitoring module can be effectively used for energy correction in standard penetration tests.
- A seismic dynamic cone penetrometer (SDCP) was developed to characterize the stiffness and strength of the target ground. The SDCP evaluates strength and stiffness based on the penetration index (SDCPI) and shear wave velocity (Vs). The Vs evaluated by the SDCP was verified via comparative analyses with those measured using bender elements, and the applicability of the SDCP was successfully tested in the field test. Therefore, SDCP may be an effective testing method for the investigation of both strength and stiffness of the target ground.

Considering in-situ dynamic penetrometers instrumented with accelerometers and loadcells provided insightful resistances or shear wave velocity profiles, they could be used effectively for subsurface characterization.

Contributions of physical modeling and numerical analysis to seismic behavior of reinforced soil retaining structures

Hoe I. Ling
Columbia University, New York, NY, USA

Dov Leshchinsky
University of Delaware, Newark, Delaware, USA
ADAMA Engineering, Clackamas, Oregon, USA

ABSTRACT: This paper summarizes several studies that the authors have been involved in the field of physical modelings and associated finite element analyses for reinforced soil retaining walls under static and earthquake loadings. Full-scale and centrifuge model tests were considered as benchmarks for verifying the numerical models. Material models of different complexities were developed in simulating the monotonic and cyclic behavior of soils and geosynthetic materials. The calibrations of the models and details of finite element analysis were presented. The responses, such as accelerations, wall deformations and geogrid tensile forces obtained from the analyses were compared with the experimental results. The analyses were able to reproduce many aspects of seismic behavior of reinforced soil retaining walls.

1 INTRODUCTION

The conventional design of geosynthetic-reinforced soil retaining walls (GRSRW) has been based on force equilibrium analysis where internal and external stabilities are examined (e.g., Leshchinsky et al., 1995, 2014). The seismic design of GRSRW involves an extension of the static force equilibrium analysis, with the earthquake inertia force considered as a pseudo-static event (Bathurst and Cai, 1995; Ling et al., 1997; Ling and Leshchinsky, 1998; Tatsuoka et al., 1998). The time history of the input motions and its amplifications are not accounted for in a pseudo-static analysis. Moreover, the effects of repeated loadings on the soil behavior cannot be considered through a pseudo-static analysis. Although Ling et al. (1996) proposed a simplistic method that used permanent-displacement limit for design, rigid body motions of reinforced soil typically may not occur during earthquakes.

The use of numerical tools, such as finite element procedures, incorporated with robust soil constitutive models aided to the understanding of the behavior of GRSRW. The past several decades have witnessed a tremendous growth in the applications of finite element method to geotechnical problems involving primarily monotonic loading conditions. Recently, dynamic analyses considering earthquake loading have become feasible. In such analyses, advanced elasto-plastic model is a must for considering realistically the soil behavior subjected to cyclic loading. Several dynamic finite element studies have been reported for reinforced soil retaining walls, but they are based on equivalent linear analyses (Segrestin and Bastick, 1988; Yogendrakumar et al., 1992; Cai and Bathurst, 1995; Helwany et al., 2001).

In this paper, finite element simulations were conducted on a concrete block GRSRW under static loading, and centrifuge models and full-scale GRSRW under earthquake loading. Advanced constitutive models for soils and polymeric reinforcement materials were adopted. The advanced soil models were generalized plasticity model (Ling and Liu, 2003) and unified

DOI: 10.1201/9781003299127-7

generalized plasticity model (Ling and Yang, 2006), which was based on the critical state concept and that considered both the effects of pressure level and density. The physical models, constitutive models, and numerical procedures are summarized in this paper. The results of simulations are presented, compared and discussed.

2 STATIC ANALYSIS: PWRI WALL

A well instrumented full-scale reinforced soil retaining wall that has a block-type facing is selected for comparing a simplistic analysis with an advanced analysis. In the simplistic analysis, the hyperbolic soil and reinforcement models are used with 4-node soil elements. In the advanced analysis, sophisticated plasticity soil and reinforcement models were considered. The wall is first described followed by the descriptions of material models and analysis.

2.1 *Descriptions of test wall and instrumentations*

The wall was constructed and instrumented by the Public Works Research Institute (PWRI) in Tsukuba, Japan. Basic information of PWRI Wall has been reported by Tajiri et al. (1996). The geometry of the wall is shown in Figure 1. It was 6 m high, constructed directly on a concrete floor inside a test pit. A silty sand (mean grain diameter: 0.42 mm) was used as backfill. A uniaxial high-density polyethylene (HDPE) geogrid was used as reinforcement. The strength of the geogrid was 55 kN/m. The wall was constructed using six primary and five secondary geosynthetic layers, each 3.5 m and 1.0 m long, respectively. The geosynthetic layers were bolted to the concrete modular blocks using the nuts and metal frame. A total of 12 concrete blocks were used, each 50 cm high and 30 cm wide, except the top and bottom blocks which were 45 and 55 cm high, respectively.

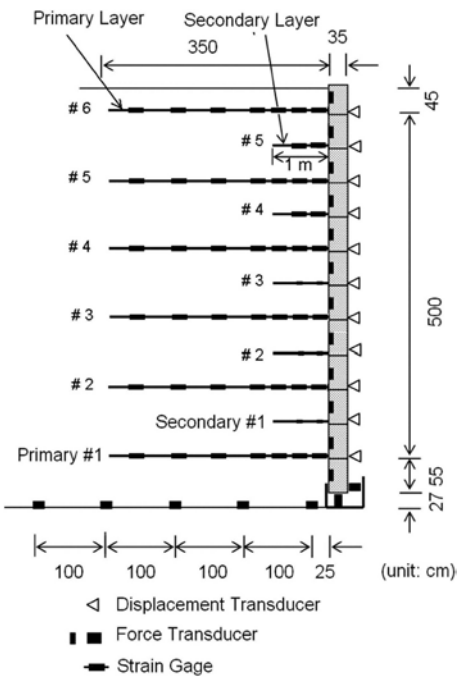

Figure 1. Wall instrumented by PWRI, Japan.

Table 1. Material properties used in simplistic finite element analysis of PWRI Wall.

Soil						
γ (kN/m^3)	ϕ_o (°)	$\Delta\phi$ (°)	K	m	R_f	ν
16.0	45	5	207.2	0.5	0.81	0.42

Concrete			
	γ (kN/m^3)	E (kPa)	ν
Concrete Foundation	-	2.0x10^6	0.17
Modular Block	23	2.0x10^6	0.17

Geogrid Reinforcement		
J_o (kN/m)	T_f (kN/m)	λ
826.45	54.6	0.47

Interfaces		
	δ (°)	T_c (kN/m)
Concrete-Concrete (no slippage)	45	50
Concrete-Concrete (slippage)	19.6	0.5
Concrete -Soil (with Geogrid)	16.5	55
Concrete-Soil only	16.5	0.5

A total of 52 strain gages were used to measure the elongation of the geogrid. The horizontal displacement of the wall face was measured at 12 locations along the height. The lateral force acting on the facing blocks was measured using 11 force transducers. The vertical and horizontal forces acting at the toe of the facing were also measured. The vertical force due to the weight of the backfill soil was measured at 6 locations along the base of the backfill.

2.2 *"Simplistic" finite element analysis*

The "simplistic" analysis has been presented in Ling et al. (2000) using the finite element program M-CANDE (Ling and Tatsuoka, 1992; Ling et al., 1995; Ling and Leshchinsky, 2003), which was modified from program CANDE (Katona et al., 1976). The program simulates time-independent behavior under two-dimensional plane strain conditions. The construction sequence, and inclusion of reinforcement and interface elements was simulated incrementally, and each increment of analysis was iterated until the solution converged at the element level. A nonlinear geosynthetic model was added to CANDE following previous analyses of reinforced soil structures. The soil behavior was expressed using a nonlinear elastic soil model (Duncan and Chang, 1970; Duncan et al., 1980), which has also been used by a number of researchers (see review in Ling and Liu, 2009).

The foundation, backfill and facing blocks were represented by 4-node quadrilateral elements. The two-node beam elements without flexural rigidity were used to represent geosynthetic layers. The interface elements were used to simulate the interactions between different materials at the wall facing. The wall construction consisted of a total of 38 increments. Compaction was not included in the construction simulation.

The nonlinear elastic geosynthetic model is given by Ling et al. (1995). The tangent stiffness J_{tan} is obtained from a hyperbolic load-strain (T - ε) relationships:

$$J_{\tan} = J_o(1 - \lambda\frac{T}{T_f})^2 \tag{1}$$

where J_o, T, T_f and λ are the initial stiffness, reinforcement load, failure strength and failure ratio, respectively.

The 3-node interface element (Katona, 1983) was used in M-CANDE. It was formulated from the constraint approach, and is numerically more stable than the commonly used Goodman interface element, which is based on the stiffness method. The mid-node is used to store the energy of the element during computation. Because of the node-to-node contact assumed in the interface element, the connection strength between the geosynthetic and modular blocks could be simulated using the interface tensile strength.

A linear elastic model was used for the foundation and concrete blocks. The parameters for the soil, concrete and geosynthetic are summarized in Table 1. The comparison between the experimental and fitted results of hyperbolic relationships is given in Ling et al. (2000).

2.3 *"Sophisticated" finite element analysis*

The sophisticated finite element analysis was conducted under two-dimensional plane strain conditions using a modified version of Diana-Swandyne-II (Chan, 1993; Zienkiewicz et al., 1998). Both higher order elements and material models were used in the analysis. The finite element algorithms were modified to also handle the construction sequence together with additional material and element models (Liu, 2003). The soil consisted of 8-node quadrilateral elements and 6-node triangular elements, both calculated using full integration technique (9-point and 6-point integrations, respectively). The geogrid layer was simulated using 3-node one-dimensional elements. A total of 38 increments were used to simulate wall construction. The solution was obtained using a quasi-Newton-Raphson nonlinear iteration scheme. The stiffness matrix was updated every 10 steps and a total of 500 steps was used in each increment with a convergence tolerance of 0.003.

2.3.1 *Generalized plasticity soil model*

A generalized plasticity soil model (Ling and Liu, 2003), which was an improvement over Pastor-Zienkiewicz-Chan model (Pastor et al., 1990), was used to express the soil behavior. Generalized plasticity does not require a prescribed yield surface but uses loading direction vectors for determining the plastic strain increments. Ling and Liu (2003) considered the pressure-level dependency of the stiffness, dilatancy and strength of the sand in the model. The model has been validated against the laboratory test results of several types of sand having different relative densities and under drained and undrained conditions. For the formulation and notations of the model, refer to Ling and Liu (2003).

The generalized plasticity model requires 15 parameters for simulating cyclic loading, whereas 11 are needed for monotonic loading. Table 3 summarizes the parameters and respective values for the backfill sand. Figure 2 shows the comparison between the experimental and simulated results. The model was able to simulate the pressure-dependent stress-strain-dilatancy behavior satisfactorily.

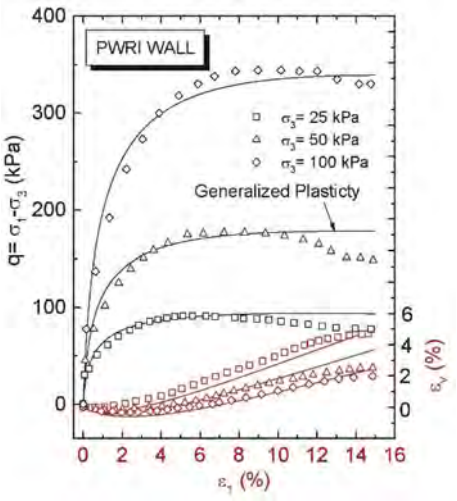

Figure 2. Simulation of backfill sand (PWRI wall) by generalized plasticity model.

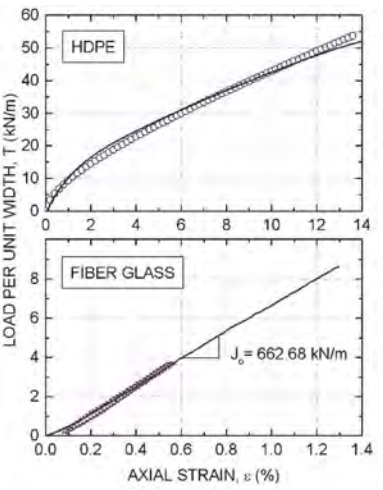

Figure 3. Simulation of HDPE and fiber glass reinforcements by bounding surface model.

2.3.2 *Reinforcements*

Ling et al. (2001) formulated a bounding surface model to simulate the uniaxial cyclic behavior of geogrids. The main features of formulation are:

Total stiffness

$$J_T = \frac{J_p J_e}{J_p + J_e} \tag{2}$$

Bounding line for monotonic loading

$$T_+ = A + J^o_{P+}\, \varepsilon_p \tag{3}$$

Hardening parameters for monotonic loading

$$h^L = h^L_o + h^L_k \sqrt{\varepsilon_p} \tag{4}$$

A total of 9 parameters are required for cyclic loading, whereas in the case of monotonic loading, it is reduced to 5 parameters. For HDPE geogrid (unit: kN/m), *Je* = 2500, A = 28.5, $J^o_{P+} = 2810$, $h^L_o = 150$ and $h^L_k = 900$, where *Je* is the elastic stiffness, A and J^o_{P+} are used to define the bounding line, and h^L_o and h^L_k are for the hardening parameters during loading. Figure 3 shows the results of simulation and comparison with the test results for HDPE geogrid.

2.3.3 *Concrete blocks, interfaces and other materials*

The concrete blocks were assumed linear elastic with typical properties: $E = 2.0\times10^6$ kPa, $\nu = 0.17$, $\gamma = 23$ kN/m^3. The block-block and soil-block interactions were studied using large-scale direct shear tests, from which the interface friction angles were obtained as $\delta = 19.6°$ and 16.5°, respectively (Table 1). The interface between geogrid and sand was modeled for several cases of analysis using a thin interface element. This thin layer element had an elastic (expressed using Young's modulus and Poisson's ratio) followed by a rigid-plastic sliding behavior (expressed using an angle of friction). The elastic properties of the interface were $E = 5{,}000$ kPa and $\nu = 0$. Since the geogrid layers were bolted to the blocks, the connection strength was assumed to be the failure strength of the geogrid and simulated using elastic perfectly plastic interface model. The angle of friction between the soil and geogrid was larger than that of the block-block, block-geogrid and block-soil. The relative displacement should occur between these interfaces before an opportunity for pullout will occur between the soil and geogrid, thus the geogrid layers were assumed to be fully compatible with the soil deformation.

2.4 *Comparison of results*

2.4.1 *Horizontal displacements*

The horizontal displacements of the wall obtained from the analyses are compared with the measured results for the different fill heights during the course of construction (Figure 4). Note that each concrete block was represented by three elements in the analysis, thus the results appeared clustered in sets of three. The measured and analyzed results agreed favorably for the construction height 4 m and above. The trend of deformation is well replicated. It is of interest to see that the results obtained from the simplistic and sophisticated analyses are close to each other, although the results obtained from generalized plasticity model were slightly larger than those of the hyperbolic model.

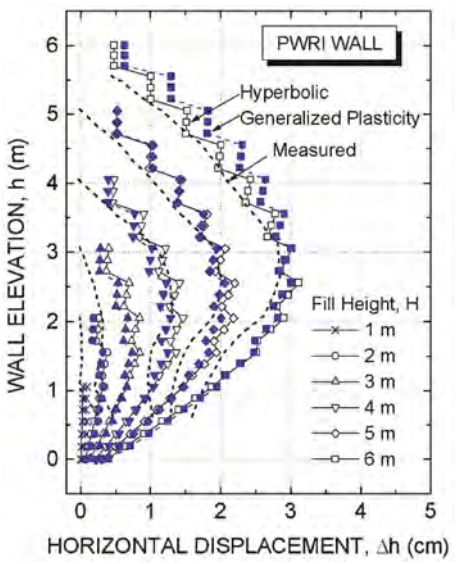

Figure 4. Wall facing block displacements.

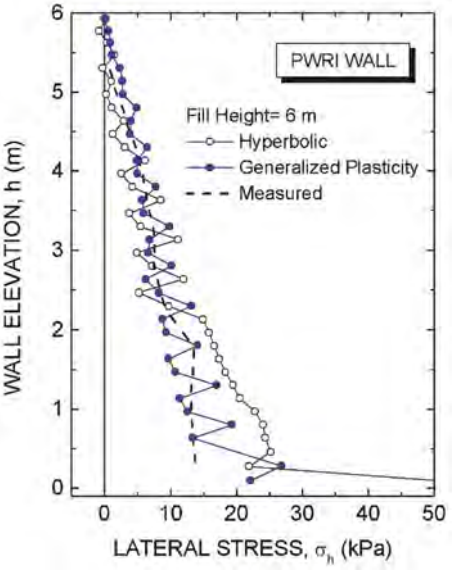

Figure 5. Lateral stress behind the blocks.

2.4.2 *Lateral stress*

The lateral stress distributions behind the blocks at end of construction are shown in Figure 5. The experimental results were obtained from the force transducers, of diameter 20 cm, installed at the backfill side of the blocks. For the plasticity model, the results at different elevations were obtained by averaging the values obtained from the 9 gauss points in the interface elements. The values differed within a soil element, whereas the values obtained from the integration points in the soil element located near to the blocks are close to the average value of the interface elements. The distributions obtained from the analyses are close to the measured values. The results of simplistic and sophisticated analyses fluctuated along the wall height, but the distribution obtained from the nonlinear elastic model is slightly larger than that of the generalized plasticity model toward the bottom of the wall.

2.4.3 *Geogrid tensile strains*

The strain distributions in the six primary geogrid layers, with layer 1 located at the bottom and layer 6 at the top, are shown in Figure 6 for the wall at its completed height. It is seen that the analyzed and measured results gave good agreement. The difference in results at the front end of the reinforcement layers could be attributed to the possible stress concentration due to relative settlement (overhanging) and creep in the geogrid that were not accounted for in the presented study. For the sophisticated analysis, the results at the back of the reinforcement were relatively well simulated. There is only slight difference between the results obtained from the nonlinear elastic analysis and sophisticated analysis. The sophisticated analysis gave larger strain for the bottom reinforcement layers compared to simplistic analysis, and it was the reverse for the top layers, for both primary and secondary reinforcement layers.

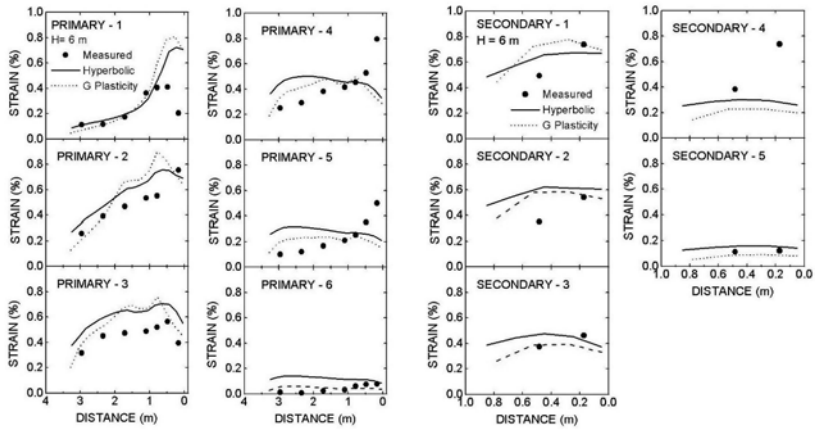

Figure 6. Strains in the geogrid layers.

3 DYNAMIC CENTRIFUGE MODEL TESTS

3.1 *Centrifuge models and instrumentations*

A total of five dynamic centrifuge tests of geosynthetic-reinforced soil retaining walls were conducted using the facilities available at the Tokyo Institute of Technology (Takahashi et al., 1999; Takemura and Takahashi, 2003). The models were 15 cm high that represented a prototype wall of height H= 7.5 m under 50-g acceleration.

The model wall was 21.5 cm long and had a 5-cm deep foundation (Figure 7). The wall model was constructed in an aluminum container having inner dimensions 45 cm (length) × 15 cm (width) × 25 cm (height). The side walls of the container were detachable. Rubber forms were used at the two ends of the model as boundary wave absorber. Note that the curvature of the wall crest surface was introduced to accommodate for the centrifugal acceleration field that varied across the length of model due to the inflight orientation of the centrifuge platform and

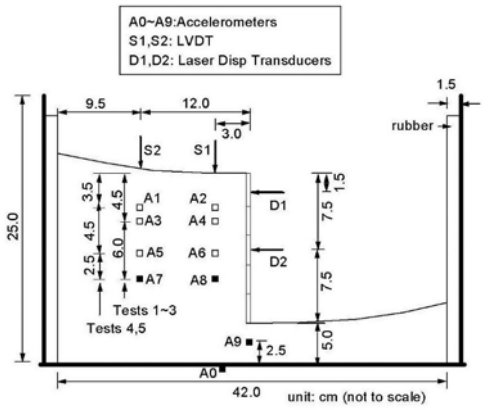

Figure 7. Centrifuge model setup and instrumentations.

Table 2. Reinforcement layout for centrifuge tests.

Test #	Length	Spacing
1	1.0H	0.2H
2	0.8H	0.2H
3	0.6H	0.2H
4	0.8H	0.1H
5	0.6H	0.1H

container. Geosynthetic reinforcement of different lengths (0.6H, 0.8H, 1.0H) and vertical spacings (0.1H, 0.2H) were used. Table 2 summarizes the reinforcement layouts for the tests.

The construction sequence of the reinforced soil wall, such as placement of backfill, geogrid, wall facing and compaction, was not modeled in-flight. In fact, such a modeling technique was found reasonable for earthquake loading where the dynamic effects are more significant than the static effects. The wall model was prepared under 1-g conditions at an upside-down position by first laying down the wooden template in order to produce a curved backfill that met the orientation of the box in the centrifuge. The moist sand with the geogrids and accelerometers were introduced into the box and compacted statically in layers to the required density using a bellofram cylinder. The geogrid layers were attached to the aluminum facing panels of thickness 2 mm. The plates were hinged. At the end of construction, the bottom platen of the box was installed and the container was reversed to the upright position. The top plate was then removed and the displacement transducers were installed in front of the facing and along the wall crest.

A limited number of accelerometers, displacement transducers and strain gages were used because the small size of the model did not allow for intensive instrumentation compared to a full-scale model. In Tests 1-3, five accelerometers were used: two were in the unreinforced backfill (A3, A7) and reinforced soil zone (A4, A8), respectively, and one measured the acceleration in the foundation soil (A9). In Tests 4 and 5, three accelerometers were used in the unreinforced (A1, A5, A7) and reinforced (A2, A6, A8) soil zones, respectively. In addition, the horizontal displacements of the wall facing were measured using two laser displacement transducers (D1, D2) and the settlement of the wall crest was measured at two locations using linear variable displacement transducers (S1, S2). Three geogrid layers were instrumented with strain gages in each test. Four strain gages for each layer were used in Tests 1 and 2, whereas three strain gages were used in Test 3 (layers 1, 3, 5 from the bottom) and Tests 4 and 5 (layers 3, 6, 9 from the bottom). The first strain gage was located 15 mm from the back of the panel, and the other gages were 30 mm apart. However, as discussed later in the results, these strain gages could not measure accurately the strain of the reinforcement because the epoxy used was stiffer than the reinforcement.

The container with the model wall was mounted to the shaking table in the centrifuge. After bringing the centrifuge to 50-g acceleration, shaking was initiated using sinusoidal wave of 100 Hz (prototype frequency of 2 Hz). The input waves were of prototype accelerations 0.2g having 20 cycles of shaking (0.25 second or 12.5 seconds in prototype).

3.2 *Material models*

3.2.1 *Backfill soils*

Inagi sand (D_{50}= 0.4 mm, γ = 17.8 kN/m^3, C_u= 2.3) was used in the backfill and foundation. A generalized plasticity soil model as described in Section 2.3.1 (Ling and Liu, 2003) was used to express the soil behavior.

Two drained triaxial tests (σ_3= 100 kPa and 300 kPa) and a strain-control cyclic triaxial test (σ_3 = 100 kPa, stress amplitude = -50 ~ 85 kPa) were used to calibrate the model. Table 3 summarizes the parameters and respective values for the Inagi sand. Figure 8 shows the comparison between the experimental and simulated results under monotonic and cyclic loadings. The model was able to simulate the pressure-dependent stress-strain-dilatancy behavior satisfactorily.

3.2.2 *Reinforcements, aluminum panels and other materials*

The glass-fiber reinforcement exhibited linear elastic behavior with negligible hysteresis for 10 cycles of loadings (Figure 3), thus the load-strain relationship is defined by the elastic stiffness *Je* (=662.68 kN/m) when using the bounding surface model. The rubber foam and aluminum panel in the centrifuge models were assumed as linear elastic materials having elastic moduli E= 3,000 kPa and 7.0×10^7 kPa, respectively. The joint between the aluminum plates was modeled by assigning a small elastic modulus E= 10.0 kPa. The Poisson's ratios for the rubber, aluminum and panel joint were v= 0.5, 0.3 and 0.0, respectively.

Table 3. Parameters for sands (Generalized Plasticity Model).

	Parameters	PWRI Wall Sand	Centrifuge Inagi sand
ϕ_{p0} (°)	Peak value of the angle of internal friction at atmospheric pressure	39.4	33.0
$\Delta\phi$ (°)	Change of angle of internal friction with 10-fold increase in pressure	0.5	0
M_g	Slope of the critical state line in $p' - q$ plane	1.4	1.32
M_f	Slope of failure line in p'-q plane	0.645	0.4
G_0/p_a	Normalized Elastic modulus	500.0	800.0
K_0/p_a	Normalized bulk modulus	550.0	700.0
k_s	Parameter related to plastic coefficient	0.01	0.07
β_{10}	Parameter related to plastic coefficient	3.1	1.0
β_0	Parameters related to plastic coefficient	20.0	10.0
α	Parameter related to soil dilatancy	0.47	0.25
H_0/p_a	Normalized plastic modulus number	500.0	190.0
H_u0/p_a	Normalized unloading plastic modulus number	-	800.
r	Coefficient related to stress memory factor	-	3.2
r_u	Exponent related to unloading plastic modulus	-	0.0
r_d	Parameter related to densification in unloading plastic modulus	-	350.0

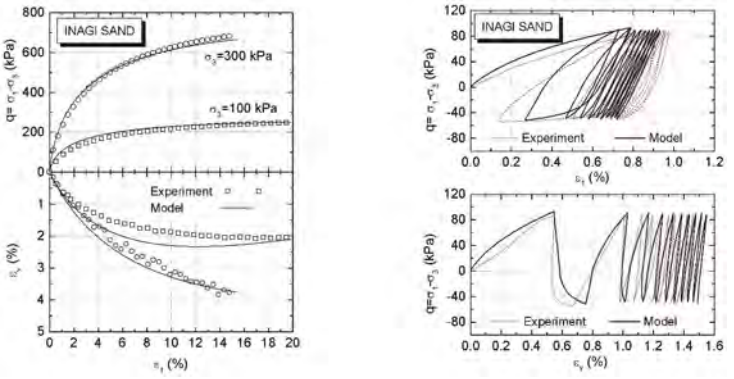

Figure 8. Monotonic and cyclic behavior of Inagi sand.

3.3 *Finite element simulations*

The finite element meshes for the centrifuge models were designed considering the different vertical reinforcement spacings and lengths used in each test. The soil consisted of 8-node quadrilateral elements and 6-node triangular elements, both calculated using full integration technique (9-point and 6-point integrations, respectively). The geogrid layer was simulated using 3-node one-dimensional elements. The base is assumed to be rough/rigidly and the two ends are smooth.

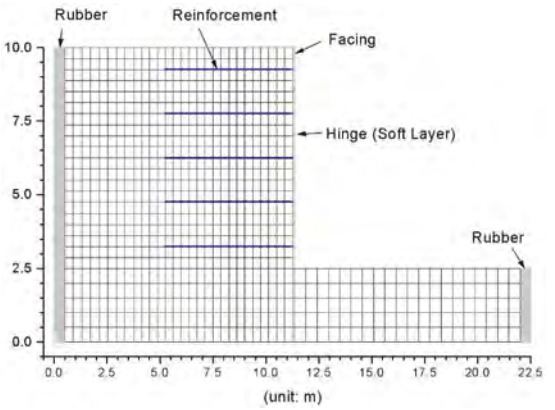

Figure 9. Finite element mesh (Test 3).

Figure 9 shows the mesh used for centrifuge Test 3. A total of approximately 1,000 elements were used, and the number differed slightly in each analysis because of the total number of layers of reinforcement and interfaces. A gravity turn-on analysis was first performed to obtain the initial stress conditions for the walls. The stresses at each Gauss point were used as the initial values for subsequent dynamic analysis. A nonlinear elastic model, whose shear modulus is dependent on the square root of the mean effective stress, was used in computing the initial stresses. A Mohr-Coulomb failure criteria, with tension cut-off, was used to detect soil failure. The soil internal angle of friction and the Poisson's ratio were assumed to be 33° and 0.3, respectively.

The dynamic analysis was initiated using the input motion at the base of the mesh. In the dynamic analysis, the time integration was performed using the generalized Newmark method (Katona and Zienkiewicz, 1985) with coefficients $\beta_1 = 0.6$ and $\beta_2 = 0.605$. In addition to material damping that is simulated by the constitutive models, system viscous damping (Rayleigh damping) was considered in the analyses for the sand and interface (5%), rubber (10%) and aluminum (5%), where the values were determined based on the fundamental frequency of reinforced soil walls. No system damping was assigned to the geogrid. The analysis was iterated to convergence with a tolerance of 0.05 using the norm of relative displacements.

3.4 *Comparison of dynamic analyses*

While the analysis was conducted using the dimensions of the centrifuge model, the results are presented for the prototype full-scale structures. The results obtained from the analysis are compared with the experimental results for the cyclic loading having an amplitude of 0.2g subject to 12 s (20 cycles) shaking. Note that the interfaces between the soil-geogrid and soil-wall panel are not considered in these analyses. Liu (2003) has conducted additional studies that showed that the effects of modeling interfaces were very small for the five tests. Figure 10 shows typical results of acceleration response, wall face deflection and settlement during duration of shaking in Test 3. The results for the four other tests, which are presented in Liu (2002), also gave good agreement.

The results showed that the acceleration amplified slightly with height for both reinforced and backfill zones. Figure 11 shows that the amplification ratio, which is defined as the acceleration at the top of the wall to the input peak acceleration, was less than 1.5 for the tests,

except in Tests 1 and 4 where the measured value was slightly greater than 1.5. There was a little phase lag in acceleration recorded in the reinforced and unreinforced soil zones.

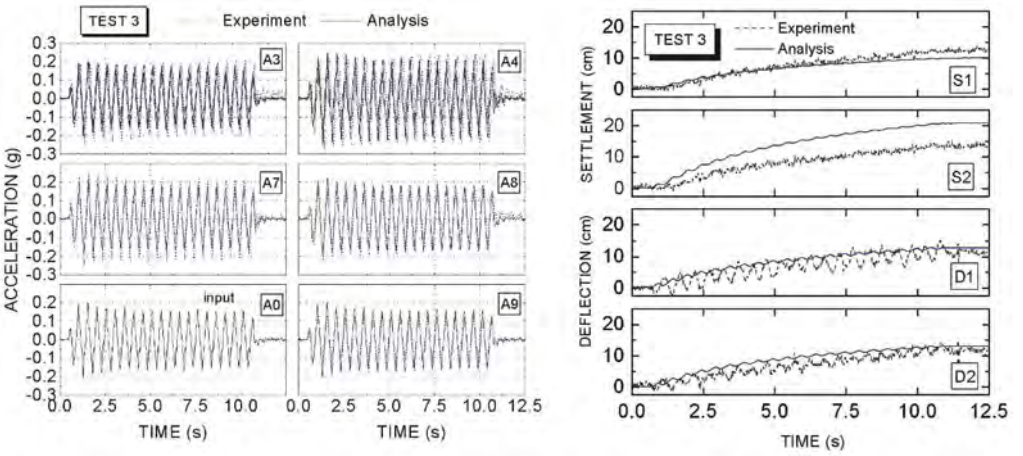

Figure 10. Dynamic response of Test 3.

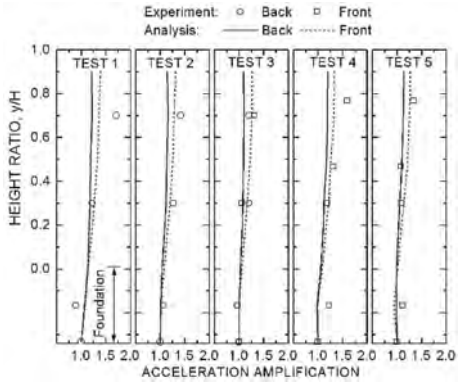

Figure 11. Amplification ratio of acceleration.

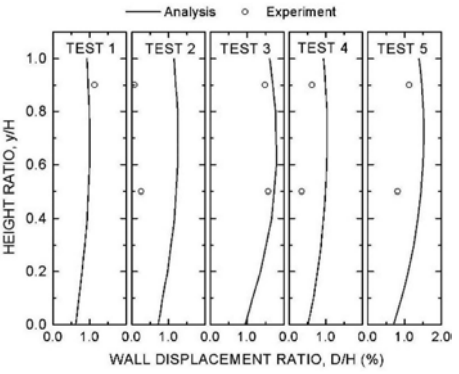

Figure 12. Wall lateral displacements.

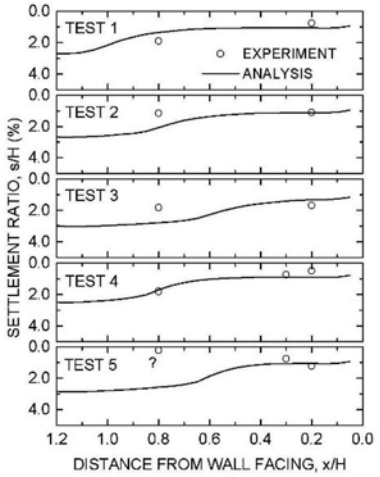

Figure 13. Wall settlements.

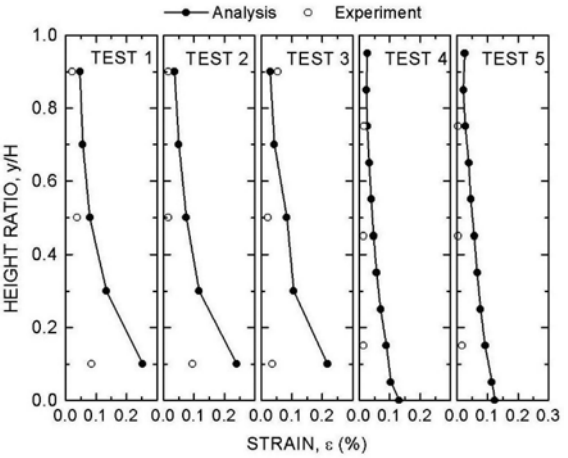

Figure 14. Largest strains in geogrid layers.

The wall face displacements and crest settlements shown in Figures 12 and 13 were accumulations of displacement over a period of 12-second shaking. Figure 12 shows the comparison of wall face displacement at the end of shaking between the analyzed and measured values. There were, however, only two experimental values per wall. Except for Test 2, the experimental results are close to the results of the analyses. Test 3 gave the largest horizontal deformation among the five tests, but it was less than 2% of the wall height.

The results of crest settlement are shown in Figure 13. It is seen that the largest settlement occurred behind the reinforced zone, and was likely due to soil densification and also to the sliding out of the reinforced soil mass. Such results are seen only with the aid of numerical analysis because of the limited number of measurements in the centrifuge tests.

The maximum tensile strain in each geogrid layer was obtained and plotted in Figure 14. The results showed that larger strains were mobilized in Tests 1, 2 and 3. Tests 4 and 5 gave a smaller maximum strain compared to the other tests because of smaller vertical reinforcement spacing. The measured results were smaller than computed due to the problem of strain gage attachment. That is, the epoxy used in attaching the strain gages was stiffer than the geogrid.

Based on the results of wall face deformations, Tests 3 and 5, which had the shortest reinforcement length, rendered the largest deformation. The strain in the reinforcement was also larger for shorter reinforcement length. Thus, an increased length of reinforcement minimizes lateral wall deformations and strains in the reinforcement layers. On the other hand, the acceleration amplification and crest settlement were not affected much by the length and spacing of the reinforcement.

4 FULL-SCALE SHAKING TABLE TESTS

4.1 *Wall layouts and instrumentations*

A total of four full-scale shake table tests with sandy soils were conducted, where the first three tests were reported in Ling et al. (2005a). The walls were 2.8 m high, 2 m wide and 4 m long in the direction of horizontal shaking. They were backfilled with a fine sand (D_{50} =0.27 mm), which was compacted in 10-cm layers at a moisture content of 9.5% to achieve a relative density of 55% (corresponding to a unit weight of 14.3 kN/m^3). The foundation of the wall was 20 cm thick, constructed with the same type of sand. The angle of internal friction of the backfill sand obtained from the triaxial compression tests was 38°.

Several types of geogrid were used as tensile reinforcements: two polyester (PET) geogrid of strengths 35 kN/m and 20 kN/m, respectively, and a polyvinyl alcohol (PVA) geogrid of strength 20 kN/m. They are hereafter denoted as PET-35, PET-20 and PVA-20, respectively. The geogrids were placed at regular vertical intervals (40 cm or 60 cm) between concrete block facing at the front end of the wall. These concrete blocks were hollow, of height 20 cm, depth 30 cm and width 45 cm, and they created a facing of slope angle 78°. The core of the block was filled with gravels and compacted.

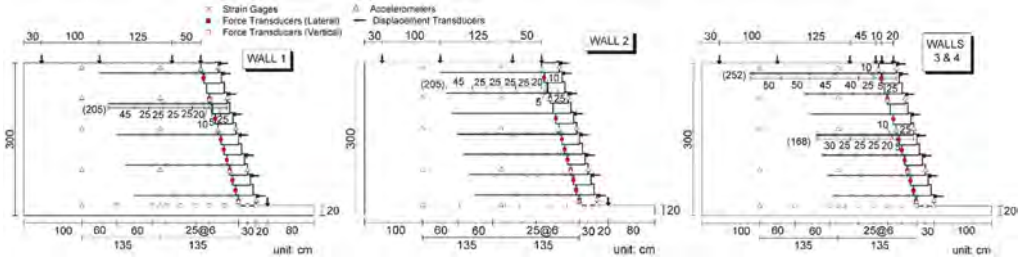

Figure 15. Full-scale shaking table tests (layouts and instrumentations).

The reinforcement layouts are shown in Figure 15, where the lengths of reinforcement were L= 205 cm (0.73H) in Walls 1 and 2, and 168 cm (0.6H) in Walls 3 and 4. In Walls 1 and 2, the length

of reinforcement was constant throughout the height, but in Walls 3 and 4, the top reinforcement layer was a PVA-20 geogrid of length 252 cm (0.9H). In Wall 3, the geogrid layer was grouted to the two top blocks. PET-35 was used in Walls 1 and 2, whereas for Wall 3 the top layer was PVA-20, and the rest of bottom layers were PET-35. The vertical spacings of reinforcement were 60 cm (3 blocks) in Wall 1 and 40 cm (2 blocks) in the other three walls. Walls 3 and 4 were identical except for the types of geogrid used; Wall 1 used single layer PET-35 whereas Wall 4 used double layer PET-20 (a layer of long geogrid overlaid by a short 1-m layer of geogrid).

The motions recorded by the Japan Meteorological Agency during the 1995 Kobe earthquake (North-South and Up-Down components) were used in the tests. For each wall, two shakings were applied. In the first shaking, the motions were scaled to give half the maximum acceleration, and in the second shaking the original motions were used. The first two walls were subjected to only horizontal acceleration, whereas in other walls horizontal and vertical accelerations were applied simultaneously. The instrumentation scheme of the wall is shown in Figure 16, where 20 accelerometers were used to measure the horizontal (and additional 20 accelerometers for vertical accelerations in Walls 3 and 4) at several locations in the backfill soil. The accelerations of the block facing were measured at various heights. The horizontal displacements of the block facing were measured at 8 different heights and the settlements of the backfill were measured at 4 different locations using the laser and linear variable differential transducers, respectively. The strains in each geogrid layer were measured using 8 plastic strain gages. For Wall 4, 5 additional strain gages were installed in the short (1-m) geogrid layers, occupying the same locations as the long layers. The lateral force acting on the blocks and the vertical force at the base of the wall and backfill soil were each measured using 10 force transducers.

4.2 *Finite element analysis*

The dynamic finite element procedure used in the analysis were identical to that of the centrifuge model simulation. However, additional robust soil and geosynthetic models were implemented.

A static analysis was conducted first to obtain the initial stresses for the dynamic analysis. The static analysis used a generalized elastic model, with the shear modulus dependent on the square root of mean effective stress ($p^{0.5}$) and the strength obeying Mohr-Coulomb failure criteria (G at 100 kPa = 60,000 kPa, ν= 0.33, ϕ=38°). The sand model for dynamic loading is described subsequently. The one-dimensional bounding surface model was used for the geogrids, whereas the concrete blocks were assumed as linear elastic material. The interface models were used to simulate soil-structure interactions.

Since each wall was subjected to two shakings, the residual stresses at the end of first shaking acted as the initial stresses for the second shaking. A total of 1,500 steps were used in the static analysis, and 7,000 steps for each dynamic shaking with the time interval of 0.002 seconds. The time stepping parameters were β_1=0.6 and β_2=0.605. The stiffness matrix was updated every 10 steps in the analysis with an incremental displacement convergence criterion of 0.003.

4.3 *Sand model (Unified generalized plasticity model)*

A unified generalized plasticity model based on the concept of critical state was used. In addition to pressure dependent behavior of sand, the effect of density was considered. This is a significantly different model compared to many other sand models, which are valid for only one particular density. Thus, using a single set of 16 parameters, the behavior under different densities and confining pressures can be simulated in this model. Note that the earlier version of model (see Section 2.3.1) proposed by Ling and Liu (2003) requires the same number of parameters for a single density. The formulation of the model is given in Ling and Yang (2006) and the model has been validated against monotonic and cyclic loading test results of several types of sand.

Four drained monotonic and one drained cyclic loading tests were used to calibrate the model. The specimens were prepared at two different void ratios (e= 1.01 or Dr= 55% and e= 0.83 or Dr= 90%) and each subjected to two confining pressure (30 kPa and 70 kPa) under drained monotonic loading. The cyclic test was conducted by Burke et al. (2005) at a confining pressure of 70 kPa and Dr=55%, with the deviator stress varying between -25 kPa and 95 kPa.

The sand parameters are summarized in Table 4. The calibrated results are compared with the experimental results in Figures 16 and 17 for monotonic and cyclic loadings, respectively.

The effects of pressure dependency on the stress-deformation behavior under the medium dense and dense conditions are well simulated. The results for cyclic loading, including hardening behavior under repeated loading, is also well depicted. Note that in the parametric studies (Ling et al., 2005b), it was shown that this hardening behavior affects the dynamic response of the soil structure significantly.

Table 4. Sand parameters and calibration.

Parameters		Values
Elastic Moduli	G_o/p_a	450
	K_o/p_a	480
Critical State Line	e_Γ	1.08
	λ_c	0.037
Phase Transformat-ion Line	M_g	1.6

h^L_k	1800.0	1800.0	1800.0
h^U_k	1.5	1.5	1.0

4.4 *Geogrid model*

The geogrid is modeled using one-dimensional bounding surface concept as described in Section 2.3.2. There are two non-parallel bounding lines and hardening parameters that are different for loading and unloading. This is to account for the fact that polymeric geogrid sustains

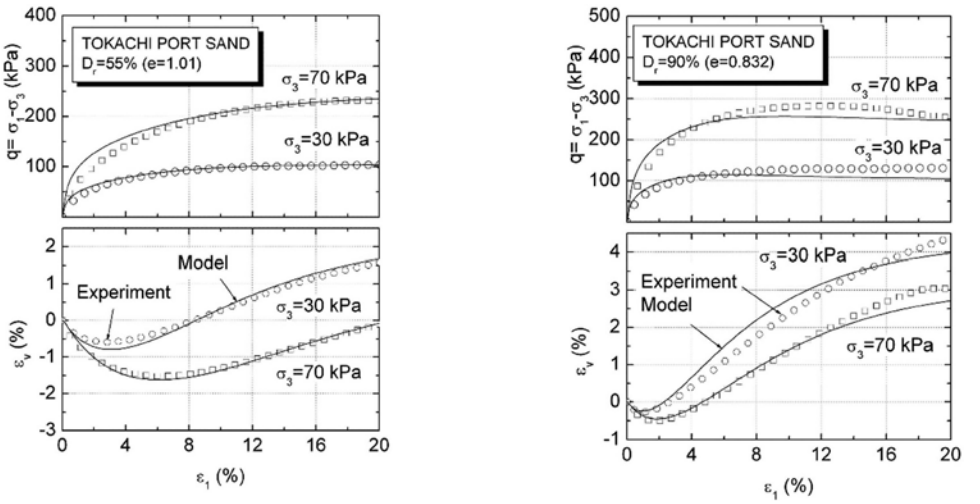

Figure 16. Monotonic behavior of loose and dense Tokachi Port sand.

negligible compression. In this series of analyses, a power function is used to account for the S-shape load-strain relationship of polyester geogrids.

The bounding lines in the tension and compression sides of the load-strain curve in the plastic region are expressed using exponential and linear functions, respectively:

$$T_+ = A + J^0_{p+} \cdot \varepsilon_p^D \tag{5a}$$

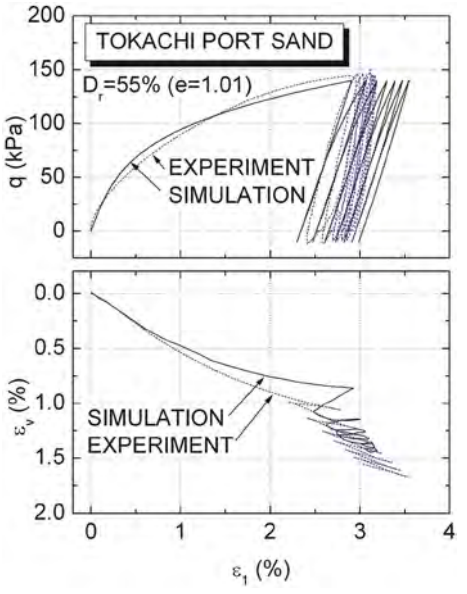

Figure 17. Cyclic behavior of medium dense Tokachi Port sand.

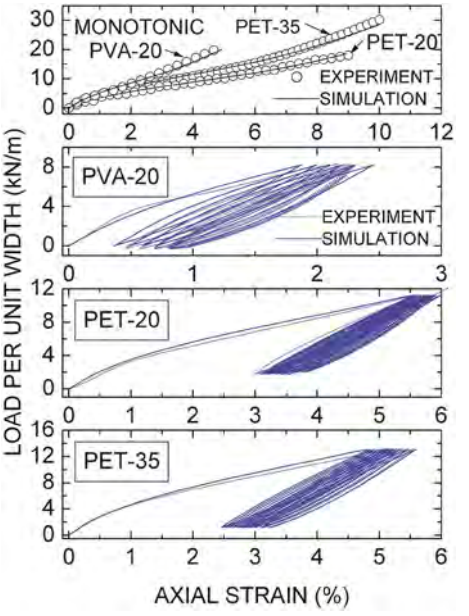

Figure 18. Monotonic and cyclic behavior of geogrids.

$$T_- = B + J^0_{p-} \cdot \varepsilon_p \tag{5b}$$

where A and B are intercepts of the tension and compression bounding lines, respectively, J^0_{p+} and D are the number and exponent for the tension bounding line, and J^0_{p-} is the slope for the compression bounding line.

The hardening functions for loading and unloading are the same as original version of model proposed by Ling et al. (2001):

$$h^L = h^L_o + h^L_k \ \varepsilon_p^{\alpha_L} \tag{6a}$$

$$h^U = h^U_o + h^U_k \sqrt{\varepsilon_p} \tag{6b}$$

where h^L_o, h^U_o, h^L_k, h^U_k, and α_L are constants. Thus, including the elastic stiffness J_e, the modified geogrid model is characterized by a total of 10 parameters, instead of 9 in the original version of model. The parameters for the three types of geogrids are summarized in Table 5. Cyclic loading tests were conducted at 40% load level for PET-35 and PVA-20 geogrids, whereas it was 60% for PET-20 geogrid. The satisfactory comparison between the experimental and simulated load-strain results under monotonic and cyclic loadings are shown in Figure 18.

4.5 *Facing blocks and interfaces*

The concrete blocks are much stiffer and stronger than soils, thus they are assumed as linear elastic material (E= 2.0×10^6 kPa, ν= 0.2). The expanded polystyrene (EPS) boards, which were used as reflective wave absorbers in the tests, are expressed as a linear elastic material (E= 2.0×10^6 kPa, ν= 0.2). The interactions between soil-geogrid (δ=34°), soil-block (27°), block-geogrid (35°) and block-block (35°) were determined from direct shear tests (Burke et al., 2005). The thin-layer interface elements having elastic perfectly plastic behavior were used to simulate the interaction between these materials. The elastic properties of the interface elements are E= 1.5×10^4 kPa and ν= 0.2. In Wall 4, the interaction between the short and long geogrid layers was simulated using a friction angle of 35°.

4.6 *Rayleigh damping*

In addition to the material damping properties, which can typically be handled through an elasto-plastic soil model, the system damping needs to be considered in solving dynamics problems. For a linear system, the use of damping ratio may be straight forward, but for a nonlinear system like soil structure, selection of damping ratio has never been trivial although 5% damping is typically used based on the experience of equivalent linear analysis. The issue of Rayleigh damping has been discussed by several researchers, such as Chan et al. (1993) and Dewoolkar et al. (1999).

The system damping affects the results of response significantly. For shake table tests with a maximum acceleration of 0.4g, 15% damping produced most satisfactory results, while for a maximum acceleration of 0.8g, smaller damping of 5% was sufficient. This is likely due to the fact that less damping is available in the soil model when the material is close to elastic, whereas at large strain the material damping becomes large enough such that a reduced system damping is adequate.

Rayleigh damping (Clough and Penzien, 1975) is used in the dynamic analysis. It is proportional to the mass and stiffness matrices (**M** and **K)**:

$$\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K} \tag{7}$$

where α and β are coefficients related to damping ratio ξ and angular frequency ω:

$$\xi = \frac{\alpha}{2\omega} + \frac{\beta\omega}{2} \tag{8}$$

α and β are calculated by selecting a ξ and two frequencies outside which damping is larger than the selected ξ. The fundamental frequency of a wall of height 3 m was about 7.25 Hz (Ling, 2003), thus by setting $\alpha = 0$, β was obtained as 0.0022 for Rayleigh damping of 5%.

4.7 *Finite element mesh and boundary conditions*

Figure 19 shows the finite element mesh of the walls. Note that Walls 3 and 4 share the same mesh, but in Wall 4, the solid line of reinforcement consists of short and long layers of geogrid and interfaces. The solid elements used for soils, concrete and EPS were 8-node quadrilateral and 3-node triangular elements. The interface were 8-node elements. Full integration of 9 and 6 points, respectively, were used for the quadrilateral and triangular elements. The geogrid was simulated using 3-node one-dimensional bar elements, with 3 points of full integration.

The side boundaries of the walls were frictionless but restrained from lateral displacements. The bottom boundary was fixed from lateral and vertical displacements. The earthquake accelerations were input to these nodal points at the bottom of the mesh.

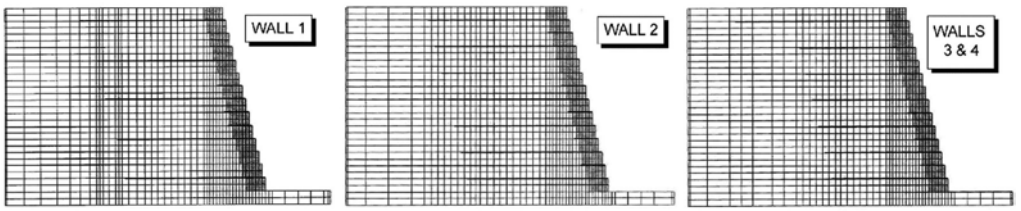

Figure 19. Finite element mesh for full-scale walls.

4.8 *Results of simulation and comparison*

Although two shakings were applied to each of the 4 walls, the deformations induced by the first shaking were negligibly small, in the magnitude of a few mm. Thus, this paper focuses on the presentation and comparison of the results during the second shaking.

4.8.1 *Wall deformations*

The horizontal displacements of the front facing and settlements of the backfill are two most important quantities in examining the wall deformation. From performance or serviceability view point, the residual deformations are quality of concern. Figure 20 show typical time-response of the wall horizontal displacements (Wall 3) and settlements (Walls 2 and 3) during shaking, respectively. Since Walls 3 and 4 included both horizontal and vertical shakings, the response would resemble to that of field earthquake conditions. Note that in the tests, the displacement transducers were attached to the steel frames, which were fixed to the steel box and subjected to shaking. Thus, the time response of the displacement transducers could have been affected by the vibration of the frames, but the residual deformations were unaffected.

The sharp spikes at large displacement, such as that located on the top part of the wall, are not captured in the analysis. The displacement at smaller deformation, say below mid-height of the wall, are simulated. It has to be noted that during strong shaking, deformation recorded through video cameras located directly above the wall showed that the blocks separated from the backfill momentarily. The possibility of separation could not be simulated in this presented numerical procedures. The abrupt settlements at the back of the wall in the experiments are not well depicted. The front part of the walls shows slight heaving in both analyses and experiments.

The residual horizontal displacements and settlements that are critical to wall performance are determined satisfactorily in the analyses (Figure 21). The analysis and experiment give a larger horizontal displacement on the upper part of the wall compared to the bottom part. For the backfill settlement, in addition to the measurements by the laser displacement transducers, rulers were used to measure the settlements at the end of shakings because the targets for the laser transducers were disturbed as the backfill surface deformed largely with the formation of cracks. The results obtained from the ruler measurements for Walls 1 and 2 are included for comparison. There were some discrepancies between the laser and ruler measurements in Wall 1, but the results obtained from the two methods were quite similar in Wall 2.

4.8.2 *Acceleration response and amplifications*

The base accelerations recorded in the experiment was used as input to the finite element analyses. Figure 22 shows the horizontal and vertical acceleration response at different heights of Wall 3. The agreement between the experiment and analysis was very good. It has to be noted that the acceleration response at different locations of the same heights (at the block, in the backfill close to the blocks, in the reinforced zone and in the backfill of the walls) are quite similar for both the analysis and experiment.

The comparison between the experimental and finite element results of maximum horizontal and vertical accelerations are shown in Figure 23. In general, the analysis gave slightly smaller accelerations compared to the experiments for Walls 1 and 2, especially in the blocks. For Walls 3

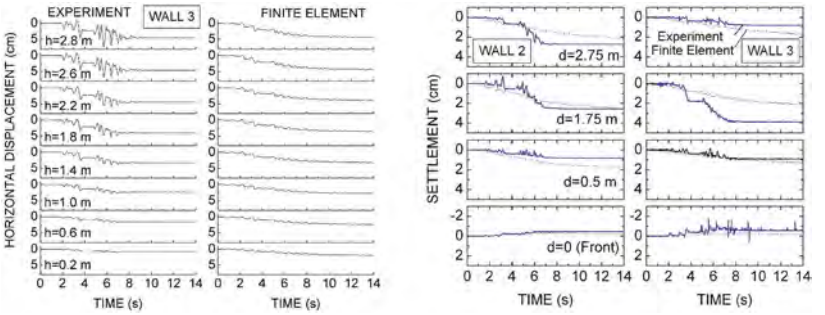

Figure 20. Deformation response of walls.

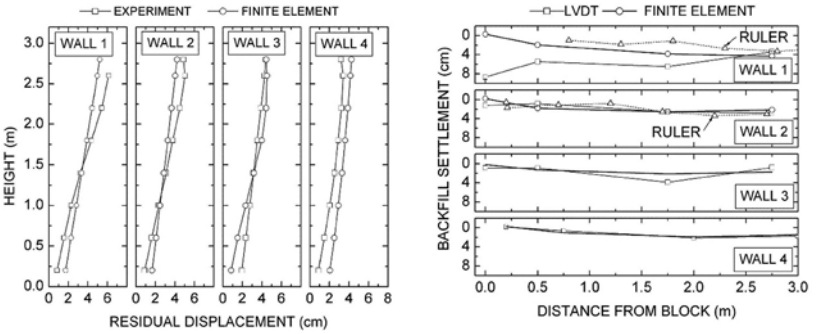

Figure 21. Residual lateral displacements and settlements.

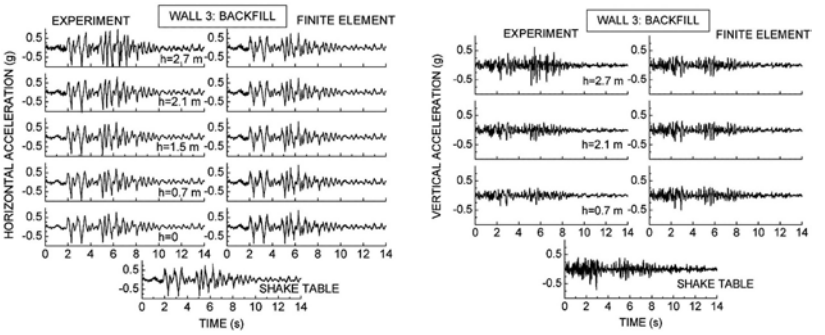

Figure 22. Horizontal and vertical accelration response for Wall 3.

and 4, a slight overestimation was seen in the analysis. Overall the difference was not very large. It has to be mentioned that the top two blocks in Wall 1 were not grouted, thus they tended to respond more vigorously compared to Wall 3 where they were grouted. The acceleration amplification was small in the walls, mostly less than 1.5. For the largest amplification at the top block of Wall 1, the ratio was less than 2.

4.8.3 *Tensile force in geogrid reinforcements*

Figure 24 show the results of measurement and finite element analysis of the tensile force along the geogrid layers. The peak and residual values are compared. In general, the analyses gave slightly higher values than the measurements, but because the tensile forces are relatively small, the difference was about 5 to 10% the strength of geogrids. There were difficulties in interpreting the measurements as the tensile force was converted indirectly from the strain gage readings.

The measurements were affected by other factors such as construction, methods of strain gage attachment, as well as calibration of strains, as discussed in Ling et al. (2005a).

5 SUMMARY AND CONCLUSIONS

This paper documented a series of studies on reinforced soil retaining walls, starting from simple finite element analyses with nonlinear elastic models under static loading conditions to sophisticated dynamic analyses using advanced plasticity models. With the constitutive models that simulated both monotonic and cyclic behavior of soils and geosynthetic reinforcements, the responses of geosynthetic reinforced soil retaining walls could be reproduced satisfactorily. The physical models, both full-scale and centrifuge model testings, provided invaluable results for validation of numerical procedures.

Temperature and moisture monitoring in pavement and subgrade in Kazakhstan

B.B. Teltayev
"Joldasbekov Institute of Mechanics and Engineering", LLP "Road Research and Production Center", Kazakhstan

ABSTRACT: Some important results of long-term measurement and analysis of temperature and moisture in layers of pavement and subgrade in different regions of Kazakhstan are presented. Most of the measurements in natural conditions were carried out in the period from 2010 to 2022 using specially invented and designed measuring devices, the latest model of which is capable of storing and transmitting the information obtained over distances.The values and peculiarities of the change in temperature and moisture in time and its distribution in depth are established. The processes of freezing and thawing in the subgrade have been studied. A map of the freezing depth of roads has been drawn. The content of unfrozen water was determined. The effect of temperature and moisture on stresses and strains at critical points of the pavement and subgrade was evaluated by calculations. Recommendations have been developed for design of pavement structures, taking into account temperature of an asphalt concrete layers and moisture content in subgrade.

1 INTRODUCTION

The main structural elements of highways, which determine their bearing capacity and durability, are pavement and subgrade. Pavement and subgrade work together, perceiving all kinds of impacts together (Ivanov et al. 1973, Yoder & Witczak 1975, Zolotar et al 1971, Huang 2004).

Back in the second half of the last century, the main principle of landscape design of roads was formulated (Babkov 1980): "Design roads in conjunction with the landscape." The road, designed in relation to the local landscape, and built in compliance with these design requirements, becomes an element of the landscape. Thus, the operated highway, being part of the landscape, is affected by all local complex non-stationary changes in climate, weather, hydrological and other phenomena.

Temperature affects almost all layers of pavement and subgrade. It is known that mechanical (deformation and strength), physical and other characteristics of asphalt concrete strongly depend on temperature. At negative temperatures, the moisture contained in subgrade soil experiences a phase transition (Tsytovich 1973).

From the above, it is clear that it is important to know the qualitative and quantitative characteristics of temperature and moisture changes in the layers of pavement and subgrade for the correct design and efficient operation of roads.

This work contains important for science and practice results of monitoring changes in temperature and moisture in the pavement and subgrade of a number of highways located in different regions of Kazakhstan, carried out by means of special measuring systems. On the example of a section with an asphalt concrete pavement of the Astana-Burabay highway, the influence of temperature and moisture on the mechanical indicators (stresses and strains) that occur in the pavement and subgrade under the act of an automobile load is estimated.

DOI: 10.1201/9781003299127-8

2 SYSTEM FOR MEASURING TEMPERATURE AND MOISTURE

In order to carry out long-term monitoring of changes in temperature and moisture in the structural elements of roads in Kazakhstan, special measuring systems with sensors were invented and created. The first three of them were installed on sections with cement concrete pavement (km 19 +750) and asphalt concrete pavement (km 76+30) of the Astana-Burabai highway in 2010. Then these measuring systems were improved (they can save the measurement results) and in 2013 they were installed on the roads located in four regions of the republic: "Almaty - Bishkek", km 58 +895 (south-eastern region); "Kyzylorda - Shymkent", km 2097 + 00 (southern region); "Atyrau - Astrakhan", km 598+50 (western region); "Oskemen - Zyryanovsk", km 0 + 75 (eastern region). In the future, these measuring systems were improved once again (they could save and transmit measurement results over long distances via wireless communication, power was supplied through solar panels) and in 2021 were installed on roads located in 16 regions of the republic.

3 TEMPERATURE IN PAVEMENT AND SUBGRADE

As one should expect, as the main factor, determining temperature variation in points of pavement and subgrade of a highway, is an air temperature variation. It was stated that, first of all, it should be mentioned that variation in time of air temperature and, as a result, pavement surface temperature has complicated dependence. Both amplitude of daily variation and its distribution in days of months is of random nature. It is seen that graphs of air and pavement surface temperature variation qualitatively coincide well, but there are considerable quantitative differences. Meanwhile, the following common regularity occurs: as a rule, asphalt concrete pavement surface temperature is higher than air temperature. The more absolute value of air temperature the more the difference in values of air and pavement surface temperature is.

The temperature within an asphalt concrete pavement, as well as air temperature, is varied both in "quasi-month" and annual, as well as in daily cycles. However, amplitude of daily temperature variations is decreased with the depth increase. Periods for temperature variation become longer that 24 hours with further depth increase. For bigger depths temperature variation occurs practically only in annual cycle.

Thus, it can be considered that temperature variation on surface and in points of an asphalt concrete pavement occur in daily, "quasi-month" and annual cycles; in the mid depths (30-100 cm) daily harmony disappears, only "quasi-month" and annual cycles remain; in bigger depths (120-140 cm and more) temperature variation occurs practically only in annual cycle.

4 CHARACTERISTICS OF WINTER PERIOD

4.1 *Freezing depth*

The freezing depth is an important characteristic of roads in winter. In many countries of the world and in Kazakhstan, the freezing depth is taken into account when designing pavement structures (ODN 2001, SP RK 2015). It can be noted that the well-known general thesis is that the greater the freezing depth, the more strong the requirements for the design of the pavement and the subgrade soil. Obviously, in the winter (cold) period, the properties of pavement materials (especially asphalt concrete and materials containing organic binders) and subgrade soil change greatly. Some of the moisture contained in them passes from a liquid state to a solid state (ice). Of course, this greatly changes the physical, mechanical, rheological and other characteristics of asphalt concrete, soils and other materials. Therefore, not only scientific, but also important practical interest is the study of the process of freezing of the roadelements.

It has been established (Teltayev & Suppes 2017a) that in the cold regions of the republic in winter, pavement and road subgrade have only one long period of freezing and thawing.

On the highway "Astana - Burabay" (northern region of the republic), the pavement and the upper part of the subgrade are in a frozen state for an average of 130-140 days; the average long-term maximum freezing depth is 253 cm; freezing and thawing rates are 2.11 cm/day and 3.51 cm/day, respectively; the thawing process occurs 1.7 times faster than the freezing process.

According to measurements made in 2017 and 2018 (Teltayev & Suppes 2019a), on the "Oskemen-Zyryanovsk" highway, km 0+75 (eastern region of the republic), the maximum freezing depth was 217 cm; freezing and thawing rates - 1.81 cm/day and 2.18 cm/day, respectively; the thawing rate is 1.2 times greater than the freezing rate.

In warm regions, a "warm" winter may experience two short periods of freezing and thawing (Teltayev & Suppes 2019b, Teltayev et al 2020). It is obvious that in such a casethe maximum freezing depths and duration of the frozen state will be significantly less than in cold (northern) regions. So, on the "Kyzylorda-Shymkent" highway in winter season of 2014-2015 years, the freezing depths and the durations of the frozen states were 75 cm and 82 cm, 18 days and 20 days, respectively (Teltayev et al. 2022).

Based on the results of long-term monitoring of temperature regime in road pavements and subgrade, a map of freezing depth of roads in Kazakhstan has been developed (Figure 1). It is clearly seen that the lines of equal freezing depths are subparallel and directed downward from the northwest to the southeast. As expected, greatest depths of freezing (260-270 cm) occur in the northern part of the republic, and the smallest ones in the south (60-70 cm). According to the distribution of freezing depth, the western region of the republic can be divided into two subregions: the first of them - the northwestern subregion is similar to the central region (130-200 cm); the second subregion - the southwestern one is similar to the southern region (60-130 cm). The eastern region of the republic is slightly softer than the northern one (190-230 cm).

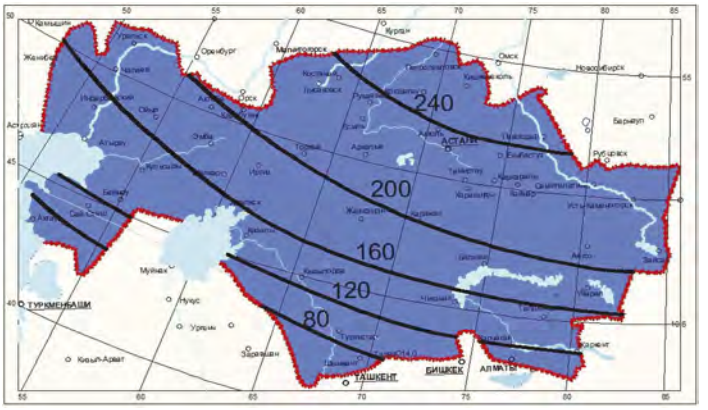

Figure 1. Map of freezing depth of roads in Kazakhstan.

4.2 *Unfrozen water*

Graphs showing changes in moisture at points of the subgrade of the "Oskemen – Zyryanovsk" highway (km 0 + 75) are shown in Figure 2. As you can see, the graphs of moisture changes are complex: there are long periods with stable moisture and short periods in which moisture changes (decreases and increases) sharply. These characteristic sharp changes moisture at different depths were noted at different points in time. It can be seen that the times of a sharp decrease in moisture in the autumn and winter seasons and the times of a sharp increase in moisture in the spring come the later, the deeper the subgrade point is located. These abrupt changes in moisture take place when the temperature passes through 0°C, i.e. these changes show the phase transitions of water from liquid state to solid one (ice) in winter and from solid state to liquid one in spring (Figure 3). The maximum moisture after thawing in spring is greater than before freezing in winter, which can be explained by the movement of vaporous and liquid moisture from below (Sarsembayeva et al. 2022a, Sarsembayeva et al. 2022b) and water infiltration from above.

As can be seen in Figure 4, the dependences of the unfrozen water content on temperature for different depths in the subgrade do not coincide, which can be explained not only by different values of the initial moisture content, but also by different values of pressure, type and characteristics of the soil (density, porosity, granulometric and chemical properties, etc.) at different depths.

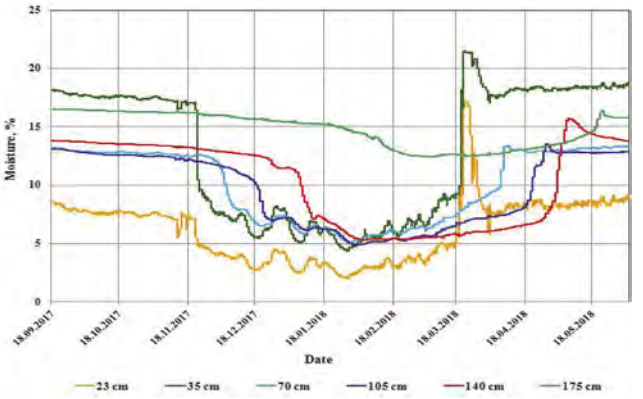

Figure 2. Graphs for moisture changes at points in the subgrade of the “Oskemen - Zyryanovsk” highway.

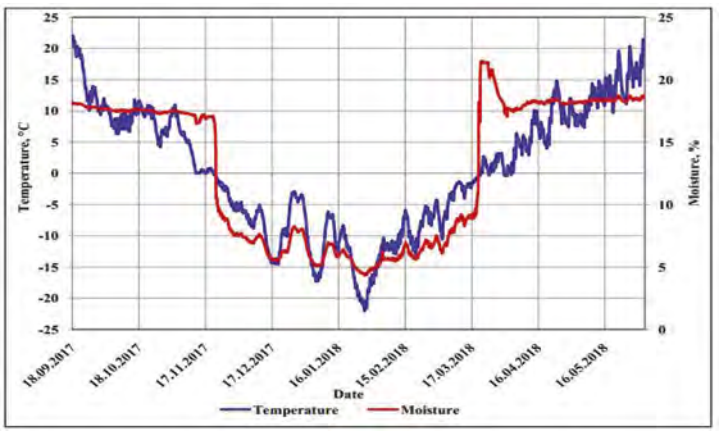

Figure 3. Joint graphs of moisture and temperature changes at a depth of 35 cm in the subgrade of the road “Oskemen - Zyryanovsk”.

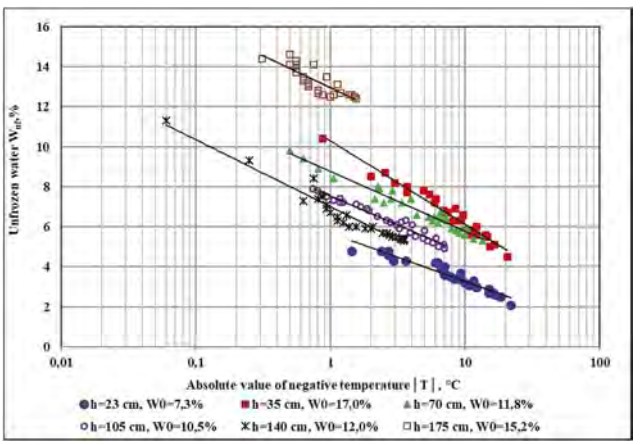

Figure 4. Dependences of unfreezing water content at different depths in the subgrade of the highway “Oskemen - Zyryanovsk”.

5 EFFECT OF TEMPERATURE AND MOISTURE ON STRESSES AND STRAINS

To demonstrate the effect of temperature and moisture on stresses and strains in layers of road pavement and subgrade under acting of an automobile load, the section with an asphalt concrete pavement (km 76 + 30) of the Astana - Burabay highway was selected.

5.1 *Pavement structure*

Pavement structure of the section consists of the following layers: 1- stone mastic asphalt concrete, 6 cm; 2 - dense asphalt concrete, 9 cm; 3 - crushed stone treated with bitumen, 12 cm; 4 - crushed stone and sand mix treated with cement (7%), 18 cm; 5 - crushed stone and sand mix, 15 cm; 6 - sand, 20 cm. Subgrade is constructed from heavy sandy clay loam: moisture in the plastic limit W_P = 18.7 %; moisture in the liquid limit W_T =34.8 %. Underground water is deep (lower than 3.0 m).

5.2 *Calculation scheme*

In order to calculate stresses and strains in the selected structure of pavement and subgrade the calculation scheme with 13 layers was accepted, out of which the first 6 simulate the pavement layers, and the other 7 layers correspond to the layers of subgrade. The materials of all the layers and soil are considered as elastic one. The lowest soil layer (the 13th layer) is considered as an elastic semi-space, which has infinite thickness. Stresses and strains in such multilayer elastic system are determined with the use of the solution of Prof. Privarnikov A.K. (Teltayev & Aitbayev 2015, Teltayev et al. 2018). On the surface of the upper layer there is a load q=0.6 MPa, uniformly distributed within the circle with diameter of D=42 cm. It corresponds to the axial load of 13 tons.

5.3 *Deformation characteristics of asphalt concretes*

Asphalt concrete is a viscoelastic material and its deformation behavior depends on temperature and load duration (Huang 2004, Papagiannakis & Masad 2008, Yoder & Witczak 1975). In this paper the elasticity modulus of stone-mastic and porous asphalt concretes was calculated under the modified formula of Hirsh (Christensen & Bonaquist 2015). Elasticity modulus of the bitumen is calculated under formula, suggested in (Teltayev & Radovskiy 2016). In calculations of the values for elasticity modulus of the asphalt concretes the load duration was set as equal to 0.1 of a second.

Figure 5 Shows the graphs of the mean half-monthly values of temperature for asphalt concrete layers of "Astana - Burabai" ftom December 2013 till December 2014. Figures 6 and 7 show the values of elasticity modulus and Poisson's coefficient of the asphalt concretes, obtained under the above expressions. It should be noted that the mean half-monthly values of the top and bottom layers for the asphalt concretes of the highway are practically the same.

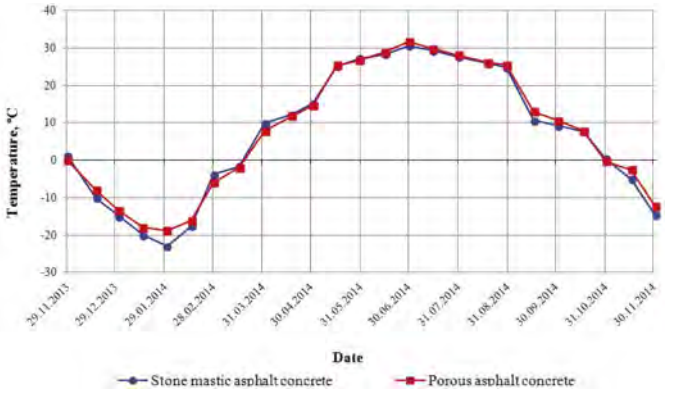

Figure 5. Mean half-monthly values of temperature for asphalt concrete layers.

As one should expect, the character of variation for elasticity modulus of the asphalt concretes is fundamentally opposite to the temperature: the higher the temperature, the lower the elasticity

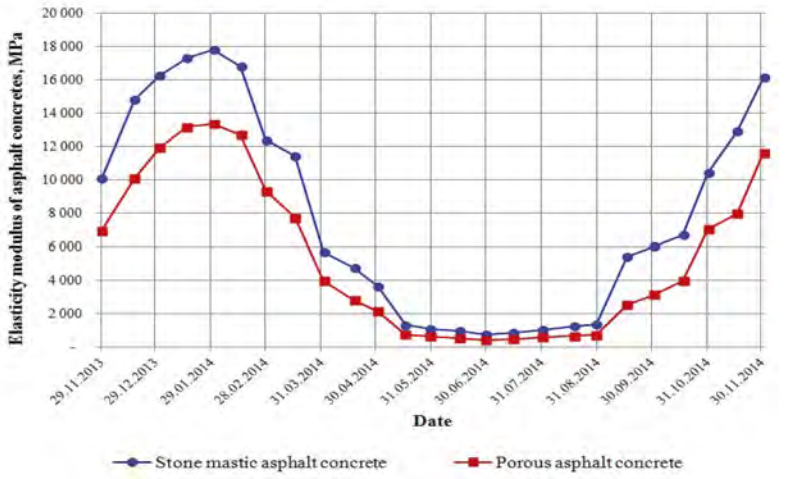

Figure 6. Values of elasticity modulus of asphalt concretes.

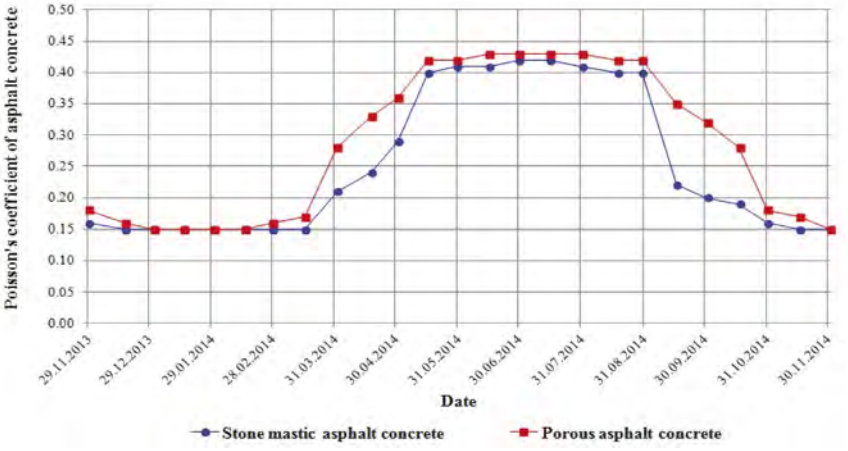

Figure 7. Values of Poisson's coefficient for asphalt concretes.

modulus, and vice versa, the lower the temperature, the higher the elasticity modulus. And qualitative character of variation of the Poisson's coefficient coincides with the temperature: the higher the temperature, the higher the Poisson's coefficient, and vice versa, the lower the temperature, the lower Poisson's coefficient. At high temperatures (in summer) the values of elasticity modulus for both asphalt concretes are practically the same, but at low temperatures (in winter) they are essentially higher for stone mastic asphalt concrete, than for porous asphalt concrete. At high (in summer) and low (in winter) temperatures the values of Poisson's coefficient for both asphalt concretes are practically the same, but at intermediate temperatures (in spring and autumn) they are somewhat higher for the porous asphalt concrete than for stone mastic asphalt concrete.

5.4 *Deformation characteristics of interlayers*

Values of elasticity modulus and Poisson's coefficient of the materials of pavement interlayers (crushed stone, treated with bitumen; crushed stone and sand mix, treated with cement (7%); crushed stone and sand mix; sand) are fixed under the standard document (SP RK 2015).

5.5 *Deformation characteristics of soils*

The values of elasticity modulus for the soil of subgrade (heavy sandy clay loam) at the positive temperatures are set under the standard document (SN RK 2015) depending on soil moisture, and at negative temperatures they are obtained according to the data of the Professor N.A. Tsytovich (Tsytovich 1973) depending on the value of negative temperature and the amount of unfrozen water. The upper part of the subgrade for the highway with thickness of 140 cm (from 80 cm to 220 cm from the asphalt concrete pavement surface) was divided into 7 layers, each of them had the thickness of 20 cm. It was set that for each of those soil layers the temperature and moisture had constant values.

5.6 *Stresses and strains in asphalt concrete layers and subgrade*

Figure 8 represents the graph, showing deflection variation for the surface of the first layer of pavement from stone mastic asphalt concrete. As it is seen, variation of mechanical characteristics for asphalt concrete layers and soil impacts greatly on the deflection value of the pavement surface. Qualitative change of the deflection is of quasi-cyclic nature. It is found that the least deflection values occur from the middle of February to the middle of March, and the biggest ones occur in the beginning of July. The biggest deflection is approximately 5 times more than the least one. Deflection of pavement surface is the only characteristics, which can be measured by non-destructive method. Therefore it is currently used in many countries, including Kazakhstan, for evaluation of strength for the pavement structure (SP RK 2015). It is considered that during spring defreezing of subgrade the pavement structure has the lease strength and the biggest deflection value of the pavement surface. But the graph of deflection shows that the biggest deflection of the pavement surface occurs in the beginning of July, i.e. in summer, but not in spring. In our paper (Teltayev et al. 2018) stated that in the beginning of July the asphalt concrete layers of the pavement have the highest temperature. Therefore, it becomes clear that the biggest pavement deflection in summer season is specified by essential decrease of stiffness (stiffness modulus) of the asphalt concrete layers due to the highest temperatures.

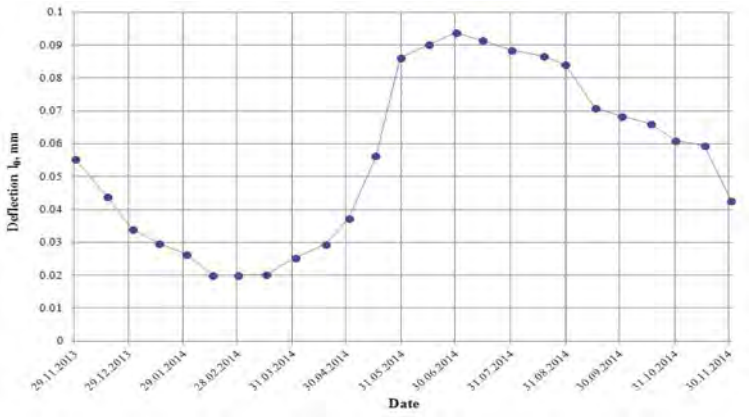

Figure 8. Deflection of the surface for the first pavement layer from stone mastic asphalt concrete.

The next important characteristics for mechanical behavior of pavement are horizontal stress σ_r^2 and strain ε_r^2 in the bottom surface of the second asphalt concrete layer. Stress σ_r^2 and strain ε_r^2 are considered during evaluation of fatigue strength of the asphalt concrete layers. The USA and many other countries include strain ε_r^2 into relevant calculations, but in the countries of the former USSR - the stress σ_r^2. It is found out (Figure 9), the qualitative character of variation for these factors is different. Graph for variation of stress σ_r^2 is identical to the graph for variation of the mean half-monthly temperature of the asphalt concrete: the lower the temperature the higher the stress. In hot period (in summer), when the stiffness

(elasticity modulus) of the asphalt concretes becomes low, the stress changes its sign, i.e. transforms from tension into compression.

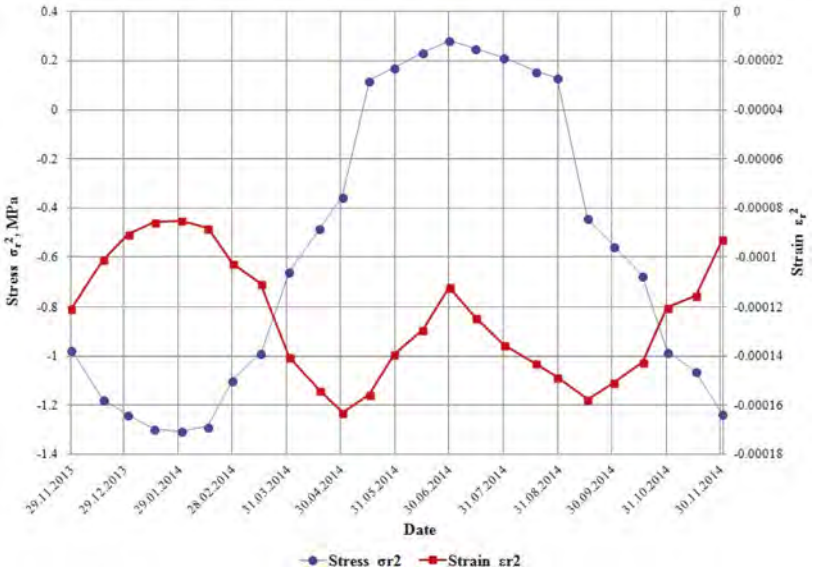

Figure 9. Horizontal stress and strain in the bottom surfaceof the second asphalt concrete layer.

The biggest value of the tensile strength σ_r^2 occurs in the end of January and it is equal to 1.32 MPa, and the biggest value of the compressive strength occurs in the beginning of July and it is equal to 0.28 MPa. The strain ε_r^2 is changed in a more complicated way during annual cycle, but, contrary to the stress σ_r^2, it remains only tensile. Its lowest value, equal to 0.000085 occurs in the end of January, and the biggest values, equal to 0.00016 approximately, occur in the beginning of May and in the middle of September.

The graphs of variation for vertical stress σ_z^{sg} and strain ε_z^{sg} in points of subgrade, located in three different depths, are shown in the Figures 10 and 11. It is seen that freezing of soil impacts greatly on stress and strain in the subgrade. The largest variation of stress and strain during annual cycle occurs on the surface of subgrade and with the increase of the depth the impact of freezing decreases. For example, on the surface of subgrade the biggest vertical

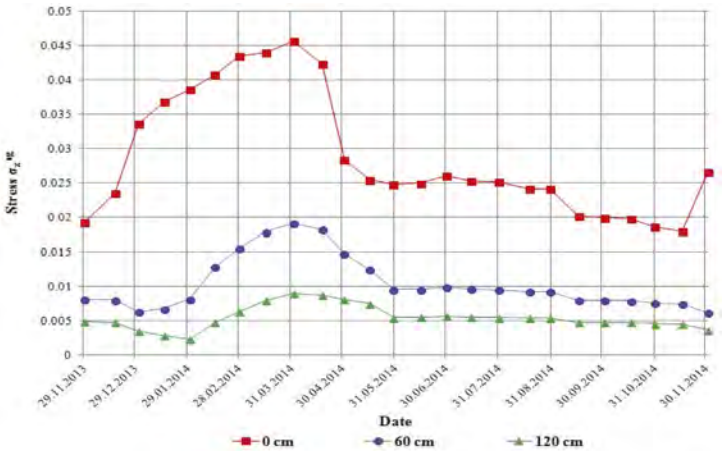

Figure 10. Vertical stress in subgrade.

stress σ_z^{sg} in the end of winter season reaches 0.045 MPa, and in the beginning of winter season it decreases to 0.018 MPa. During freezing the soil becomes stiff and the strain decreases sharply. And with the beginning of defreezing the stiffness of soil decreases sharply, which causes sharp increase of the strain. In the case considered the biggest vertical strain, equal to 0.00043, was registered on the surface of subgrade in the middle of May and it decreases gradually in time before freezing starts.

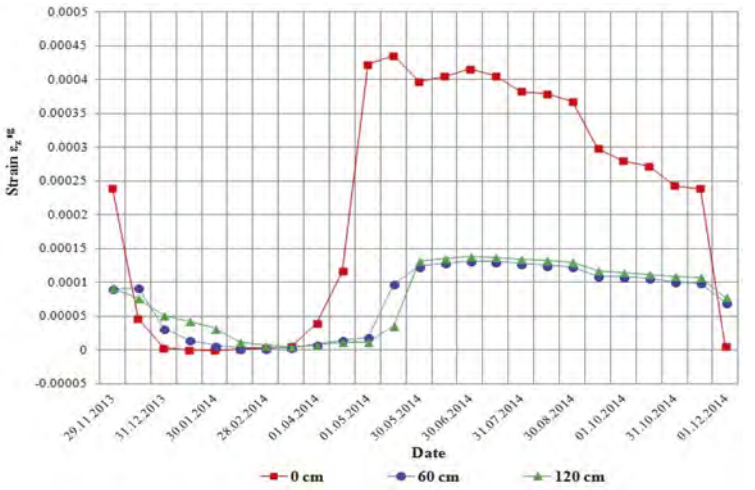

Figure 11. Vertical strain in subgrade.

6 CONCLUSIONS

1. Temperature variation on surface and in points of an asphalt concrete pavement occur in daily, "quasi-month" and annual cycles; in the mid depths (30-100 cm) daily harmony disappears, only "quasi-month" and annual cycles remain; in bigger depths (120-140 cm and more) temperature variation occurs practically only in annual cycle.
2. In cold regions of the republic in wintera pavement and road subgrade have only one long period of freezing and thawing.In warm regions, a "warm" winter may experience two short periods of freezing and thawing.
3. Greatest depths of freezing (260-270 cm) occur in the northern part of the republic, and the smallest ones in the south (60-70 cm); the western region of the republic can be divided into two subregions: the first of them - the northwestern subregion is similar to the central region (130-200 cm); the second subregion - the southwestern one is similar to the southern region (60-130 cm); the eastern region of the republic is slightly softer than the northern one (190-230 cm).
4. In points of subgrade abrupt changes in moisture take place when the temperature passes through 0°C, i.e. these changes show the phase transitions of water from liquid state to solid one (ice) in winter and from solid state to liquid one in spring; the maximum moisture after thawing in spring is greater than before freezing in winter.
5. The dependences of unfrozen water content on temperature for different depths in subgrade do not coincide, which can be explained not only by different values of the initial moisture content, but also by different values of pressure, type and characteristics of the soil (density, porosity, granulometric and chemical properties, etc.) at different depths.
6. Changes in temperature and moisture strongly influence stresses and strains in a pavement and subgrade.
7. When designing pavement structures, it is recommended to divide the entire design period into a number of characteristic sub-periods; in each sub-period, set the calculated values of temperature and moisture, mechanical and all other indicators of materials and soils; apply the principle of damage accumulation.

On the landslide hazard and resilience with the impact of climate change in Taiwan

K.J. Shou & W.J. Lin
Department of Civil Engineering, National Chung-Hsing University, Taiwan

K.L. Wang
Department of Civil Engineering, National Chi-Nan University, Taiwan

ABSTRACT: This study aims to investigate the landslide susceptibility and resilience of the study area located in Central Taiwan, including the mountain highway and the villages in this area. After calculating the landslide susceptibility values by Logistic Regression model. By considering the core concept of resilience, the control factors were adopted and the data was collected for the study area. In order to explore the temporal behavior of landslide resilience, the population density, electricity consumption per household, and the cost of reconstruction were adopted as the indicators to establish the landslide disaster resilience model. Based on the data layers, the comprehensive linear regression model was established and used for the resilience interpretations, with suggestions on the village human mobility and the rehabilitation budget for resilience enhancement. This study can help for landslide disaster mitigation, especially for the enhancement of landslide resilience of the villages in mountain areas.

1 INTRODUCTION

Following the Hyogo Framework for Action, initiated on the 2005 World Conference on Disaster Reduction (WCDR), Sendai Framework for Disaster Risk Reduction (SFDRR) was presented in 2015, in which the disaster resilience was more clearly defined to improve the capabililty of recovering from a disaster, by the countermeasures in the aspects of social, economy, policy, etc. The most popular definition of resilience could be "the capability of an ecosystem enduring external disturbance and returning to the state before the disturbance". But it is still scarce for the research on the quantitative disaster resilience, including the geohazard-related reslilience. In view of the rainfall induced landslide hazards in Taiwan, quantifying and enhancing the resilience are critical to protect the life, property, and infrastructure in the landslide area. This study comprises two major part, i.e., calculating the landslide susceptibility as a hazard factor, and collecting data of the control factors, then establishing the landslide resilience model of the research area.

2 METHODOLOGIES

The study area is located in the upstream of Wu River watershed in Central Taiwan, with focuses on the mountain highway and the six villages (see Figure 1). Data of the landslide causative factors and the resilience control factors before and after rainfall events in study area were collected, then the landslide susceptibility values were calculated and the landslide disaster resilience models were established.

2.1 *Landslide susceptibility analysis*

This study adopted the Logistic Regression method of Lin (2016), with the nine causative factors, i.e., elevation, slope, slope, dip slope index, distance to fault, distance to road, distance

DOI: 10.1201/9781003299127-9

to river, greenness index, and 72 hour cumulative rainfall. Among them, the hourly rainfall data during 2012~2017 was further analyzed to find the largest 72-hour cumulative in a quarterly basis for each rainfall station, such that we can explore the spatial changing trend of rainfall in the study area.

Considering the villages as the analysis units, the Thiessen's Polygon method was used to obtain the rainfall distribution, as shown in Figure 2. By introducing the seasonal rainfall data to the following Logistic Regression model of Lin (2016), as described in Equation (1), we can obtain the seasonal landslide susceptibility values of each village.

$$\ln[P/(1-P)] = -0.577 \times F_1 + 1.545 \times F_2 + 0.077 \times F_3 - 0.038 \times F_4 - 0.242 \times F_5 - 0.102 \times F_6 - 0.458 \times F_7 - 3.564 \times F_8 + 0.560 \times F_9 - 0.406 \quad (1)$$

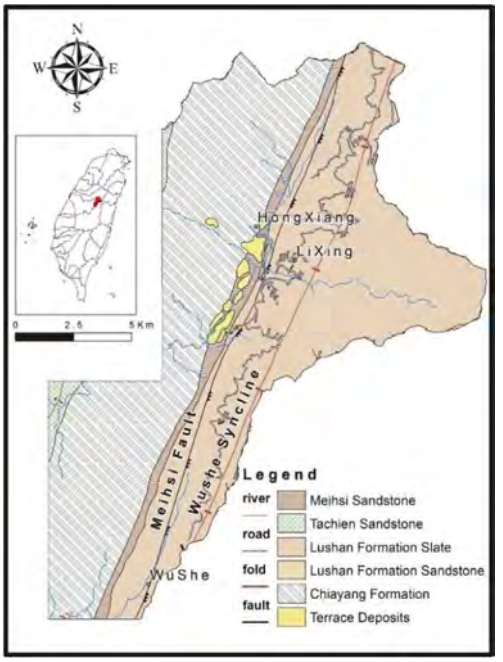

Figure 1. The location and geology of the study area study are in the upstream of Wu River watershed in Central Taiwan.

2.2 *Landslide disaster resilience*

Based on a review of the behavior of landslide hazard, nine control factors were selected for assessing the landslide resilience in the study, including population density, average electricity consumption per household, elder ratio, shelter ratio, fire fighter ratio, medical manpower ratio, income tax, and reconstruction budget.

This study further applied linear regression analysis based on the resilience of landslide disasters defined by Equations (2) and (3). Karen (2011) quantified the resilience of landslide disasters with time dependence, using Equation (2) to define the incremental resilience r(t), as the cost per unit time C(t) multiplying unit time In c(t) and dividing by total time (NI). In Equation (3), by integrating r(t) according to time, the resilience Re can be obtained.

$$r(t) = \frac{C(t)Inc(t)}{NI(t)} \quad (2)$$

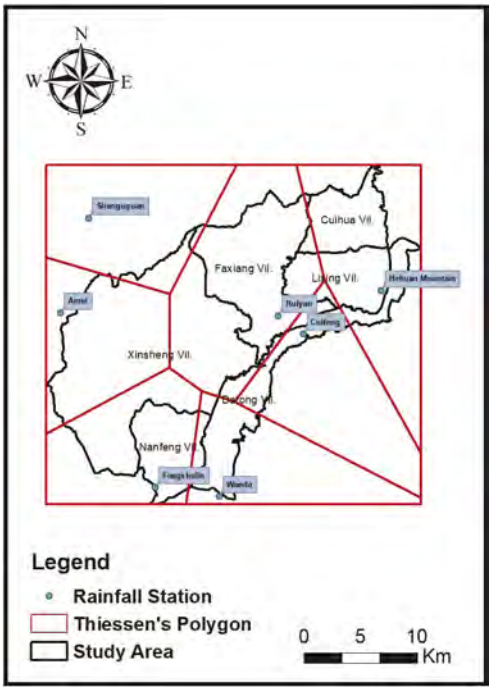

Figure 2. The Thiessen's Polygons to obtain the rainfall distribution of the six villages in the study area.

$$Re(t_s) = \int_{t_0}^{t_s} r(t)dt \tag{3}$$

3 LINER REGRESSION ANALYSIS

In order to more properly establish the landslide resilience model, this study tried to use different control factors and divided the data into high season and low season for linear regression analysis. Before further establishment of resilience model, the correlation of those control factors for the major resilience indicators were analyzed.

3.1 *Population density*

The linear regression analysis was carried out for the high season and low season of different time periods, namely 2012-2016, 2016-2017, 2012-2017, 2012-2015, and 2015-2017. The independent control factors include landslide susceptibility (RI1), elder ratio (RI2), shelter ratio (RI3), fire fighter ratio (RI4), medical manpower ratio (RI5), income tax (RI6), and rehabilitation budget (RI7).

The difference between low season and high season is that the impact of landslide susceptibility on population density is reduced, that is, it shows that the impact of landslides on the study area is relatively lower during the period when the population density is lower. The results suggest that, whether in high season or low season, the best model for forecasting is the 2012-2015 period, as they can properly to predict the population density in 2016-2017. Therefore, the population density could be considered as a dependent factor to assess the recovering from a landslide disaster.

$$Y = -0.731 * RI1 - 0.594 * RI2 + 0.434 * RI3 - .260 * RI4 + 0.820 * RI5 - 0.543 * RI6 - 0.124 * RI7 + 1.879 \tag{4}$$

3.2 *Electricity consumption*

Similarly, the linear regression analysis for the resilience indicator, i.e., electricity consumption, was carried out for the high season and low season of different time periods. Comparing the R^2 coefficients of five models of electricity consumption, i.e., 0.597-0.436, it shows the regression is barely acceptable. The weightings of the control factors on the electricity consumption for the 2016-2017 model (as shown in Equation (5) can be ranked as: landslide susceptibility, medical manpower ratio, shelter ratio, reconstruction budget, income tax, elder ratio, and fire fighter ratio.

$$Y = -0.199 * RI1 - 0.617 * RI2 + 0.419 * RI3 - 1.310 * RI4 + 0.820 * RI5 - 0.505 * RI6 - 0.138 * RI7 + 1.486 \quad (5)$$

Based on the highest R^2 value, it suggested the best mode for both high season and low season is the 2012-2015 model. This model was applied to predict the population density of 2016-2017 with error between 1~53 %, best for Xinshen village and worst for Nanfeng village. For the low season, the error is between 0~66%, 0% for Faxiang village and 66% for Nanfeng village. The results suggest there are variation of error temporally and spatially.

Table 1. The prediction errors of regression models for different seasons in 2016-2017.

		% of Error				
Year	Season	Xinsheng	Lixing	Faxiang	Nanfeng	Cuihua
2016	1	2%	3%	10%	45%	8%
	2	6%	5%	9%	46%	7%
	3	6%	5%	12%	44%	17%
	4	4%	6%	18%	53%	12%
Ave		5%	5%	12%	47%	11%
2017	1	6%	19%	8%	8%	28%
	2	2%	19%	1%	24%	19%
	3	3%	27%	8%	10%	23%
	4	1%	26%	2%	13%	27%
Ave		3%	23%	5%	14%	24%

4 LANDSLIDE RESILIENCE ANALYSIS

This study applied the model of Karen (2011) to study the resilience of landslide disasters, to explore the differences in reconstruction budget in different time scales.

4.1 *Model based on reconstruction budget*

In order to compare the performance of the reconstruction budget on the resilience, the linear regression analysis was carried out by letting reconstruction budget as the dependent variable. The cases of analyses were numbered as shown in Table 2. Case A is for the reconstruction budgets in 2008-2011 and 2012-2016; Case B is for the reconstruction budgets in 2012-2015 and 2016-2017; Case C is based on the reconstruction budget as dependent variable for linear regression, for the periods of 2012-2015 and 2016-2017, and matching with Equations (2) and (3).

The linear regression analysis model with R^2 of 0.623 was used to estimate the 2012-2017 reconstruction budget (see Figure 3); then introduce the data into the formula of Karen (2011) to obtain the resilience, as shown in Figures 4~6. The results show that the resilience of Lihang, Datong, Nanfeng and Cuihua villages changed from negative to positive in the post-2015 period, while that of the remaining two villages (Xinshen and Faxiang) was positive and increasing. In terms of the concept of disaster resilience, the lower the cost of rehabilitation,

the higher the resilience, indicating that its villages do not need too much money to deal with natural disasters. However, it is suggested to have more evidence to support the findings of this study.

Table 2. Different group settings for the resilience analyses.

Case	Groups of data	
A	2008-2011	2012-2016
B/C	2012-2015	2016-2017

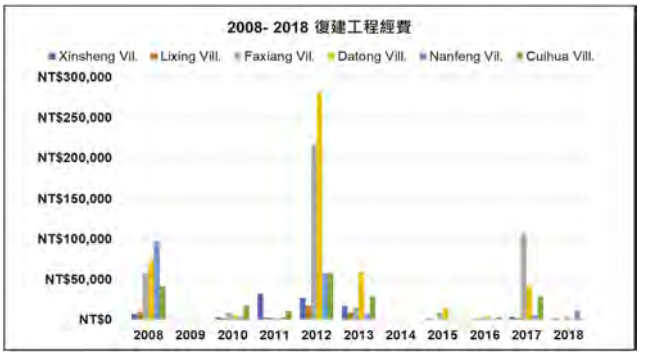

Figure 3. The 2008-2018 reconstruction budgets for the villages in the study area.

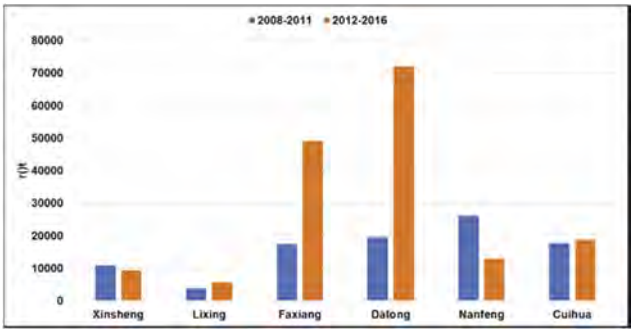

Figure 4. The resilience values of the six villages in the study area, for Case A with the reconstruction budget model.

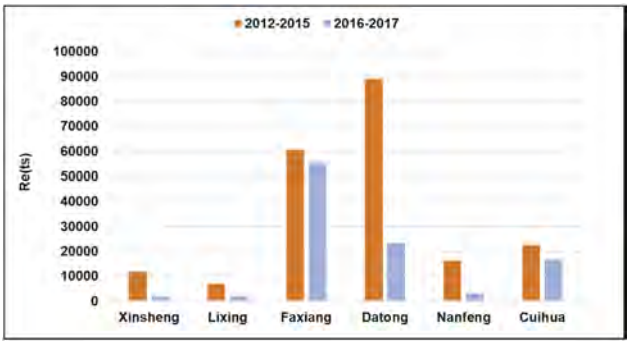

Figure 5. The resilience values of the six villages in the study area, for Case B with the reconstruction budget model.

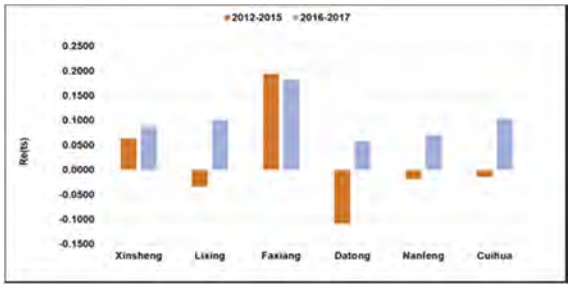

Figure 6. The resilience values of the six villages in the study area, for Case C with the reconstruction budget model.

4.2 *Model based on population density*

For the population density model, the applied data was obtained by the best regression formula, with the largest R^2 value. The seasonal data of 2012-2017 was used as C(t). In order to compare the temporal behavior of population density of each village, two periods of time, i.e., 2012-2015 and 2016-2017, were considered. The unit time of an increment Inc(t) is one season, and the total time (seasons) NI(t) is 16 seasons in 2012-2015 and 8 seasons in 2016-2017.

The results in Figure 7 indicate Nanfeng village is obviously different from the other villages. It could be due to the high regression error of 54%, that also reflects an abnormal behavior of population density. Unlike the other villages, there is no significant variation of population density in Xinsheng and Faxiang villages. Similar to electricity consumption, the population density is an indicator of economic activity. The larger of those two indicators, the larger disaster resilience.

Figure 7. The resilience values of the six villages in the study area, for Case B with the population density model.

4.3 *Model based on electricity consumption*

Similarly, the regression formula with the highest R^2 value is also used to calculate the average electricity consumption per household for each season of 2012-2017 as C(t). The unit time of an increment Inc(t) is one season, and the total time (seasons) NI(t) is 16 seasons in 2012-2015 and 8 seasons in 2016-2017. According to the results of the regression analysis, although the R^2 value is acceptable, but the average error in the performance of the forecast results is up to 68% (Faxiang Village). However, Cuihua village possesses the largest increases in population density and electricity consumption, also has the highest disaster resilience out of the six villages.

Two different interpretations are summarized according to different indicators of disaster resilience. First of all, the reconstruction budgets are as the cost of post-disaster repair, the more budget invested the more time the region needs to return to a stable state. Therefore, as a wayward evaluation value the greater the disaster resilience is lower. Based on the results of Cuihua Village, the population density and electricity consumption are the highest compared with other villages, and the comparison with the calculation results of the village's reconstruction

budget shows that the reconstruction budgets of the village in 2008-2018 were relatively large compared with other villages. In order to compare the performance of the reconstruction budget.

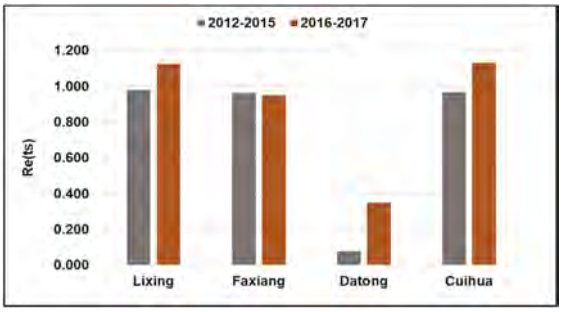

Figure 8. The resilience values of the villages in the study area, for Case B with the electricity consumption model.

5 CONCLUSIONS ANS DISCUSSIONS

This study adopted the upstream of Wu River as the research area, and chose the control factors by to establish the resilience model by linear regression method. In order to incorporate the concept of disaster resilience, population density, electricity consumption, and reconstruction budget were used as the indicators of resiliece. And the following conclusions are drawn from the analysis results:

For the landslide susceptibility, this study adopted the Logistic Regression model of Lin (2016) to produce landslide susceptibility values. The 99% percentile susceptibility value of the grid unit was conservatively considered as the landslide susceptibility of the village. In the establishment of landslide disaster resilience assessment indicators, covering the hazard, preservation, response and reconstruction indicators. The following four groups of control factors were adopted for the resilience analysis, i.e., (i) landslide susceptibility, (ii) population density and electricity consumption, (iii) elder ratio, shelter ratio, fire fighter ratio, and medical manpower ratio, (iv) income tax and reconstruction budget.

Based on the analysis results using the resilience model of Karen (2011), with considering reconstruction budget, population density, and electricity consumption as resilience indicators, it suggests the smaller the value calculated by the reconstruction budget represents higher resilience. On the other hand, for population density and electricity consumption, the smaller the calculated value the smaller the resilience.

Through the analysis of population density as a dependent variable, it is possible to find the time at which the villages return to the pre-event stable state. However, for the quantitative analyses, the number of samples is crucial to obtain promising results. It is suggested to optimize and simplify the resilience model of the most important indicator factor. Such that the error of the model can be reduced and the efficiency of the evaluation can be increased.

ACKNOWLEDGEMENTS

This research was made possible by the financial support of the Ministry of Science and Technology (Project No. 109-2625-M-005-001) of Taiwan. We also deeply appreciate the databases and support from the Central Geological Survey project (Project No. 97-5826901000-05).

Geotechnical contribution in Central Asia: Practice and lessons learnt

W. Kwiatkowski & A. Korpach
Keller Central Asia LLP, Atyrau, Kazakhstan

ABSTRACT: Presented is some geotechnical experience of Keller Central Asia LLP based on projects executed since 2014 in the Central Asia region. Only some selected execution experience is shared without detail description of well-known technologies. The wet soil mixing technology deserves special attention as it was implemented in Kazakhstan in year 2020 for the first time by Keller Central Asia LLP. Selected local experience related to concrete precast piles and Deep Soil Mixing (DSM) will be shared in this article.

1 INTRODUCTION

Keller Central Asia LLP is a regional part of Keller Group plc., with its office located in Atyrau, Kazakhstan since 2014. Having the first category construction license, design and testing licenses as well as ISO 9001 certifications, allows Keller to provide the full range of professional geotechnical services at the local market.

Keller Group plc. with its history since 1860, is the world's largest and innovative independent ground engineering contractor. With permanent operations in more than 40 countries across five continents, Keller has the financial strength, know-how, capacity, and the global reach to tackle some of the largest and most demanding projects around the world. The local presence allows Keller to solve geotechnical problems and helps to service our Clients in Central Asia. Keller has successfully developed many of the ground engineering techniques which are now widely accepted in the construction industry, i.e.: ground improvement, special grouting, piling and earth retention, anchors, nails, micropiles, instrumentation, and monitoring.

Keller Central Asia LLP executed its first job in Tengiz Oil&Gas field and that time it was the largest geotechnical project in the region as well as in Keller's history. Subsequent projects followed Tengiz one and required the use of different geotechnical solutions including a first time application of wet soil mixing in Kazakhstan.

Special attention will be put on Deep Soil Mixing (DSM) as this is relatively new technique in Kazakhstan, and design and execution aspects are fundamental for its proper application. So far, DSM has been implemented by Keller Central Asia LLP as soil improvement for infrastructure, residential projects and retaining walls for deep excavations. However, DSM can be also used for bridges, wind turbines foundation systems or filtration barriers when properly designed and executed.

2 CONCRETE PRECAST PILES

Concrete precast piles are well-known and widely used foundation method in Kazakhstan. It is usually the fastest and often the cheapest method which can be used in different soil conditions and typically regardless of the weather conditions. The concrete precast piles are usually square section 300x300, 350x350 or 400x400 mm made of concrete C20/25 or C25/30 with non-prestressed reinforcement and length up-to 16 meters. Concrete precast piles are classified

DOI: 10.1201/9781003299127-10

in the standard catalogue "Series 1.011.1-10" of typical concrete constructions, where working drawings for different types of piles can be found. Based on the market research done in 2014, there are more than 200 piling rigs with hammers for concrete precast pile driving in Kazakhstan. Most of the piling rigs are owned and used by general construction companies where geotechnics is not part of their core company profile.

Keller Central Asia LLP was awarded the contract for procurement and installation of ca. 40,000 concrete precast piles at Tengiz Oil&Gas field (Western Kazakhstan) in 2014. Pile installation was done within a 3,5 year period using owned, as well as locally sourced piling rigs and personnel.

Based on the above mentioned project, the authors would like to share some insights which are often ignored and not taken into consideration during the execution of many smaller projects.

2.1 *Application of bitumen protective coating on the concrete precast piles external surface*

The geotechnical conditions in western Kazakhstan are typically a mixture of sand, clay, loam and sandy loam. The ground level is ca. 24,0 to 25,5 meters below sea level and the ground water table varies, depending on the season, between 1,0 to 2,5 meters below the terrain. The region is located within the Caspian sedimentation basin where the soil and ground water contain chlorides and sulphates, moderate to highly aggressive to concrete and reinforcement steel.

The aggressiveness of the soil and water is the reason for bitumen coating application to the piles. This practice has started in the late 90's and still continues for almost all projects in the region where concrete precast piles are designed. However, Keller's experience shows that bitumen application has significant negative impact on piles bearing capacity, as well as durability problems with the coating during transportation, handling and storage of the coated piles.

During execution of the Tengiz project, 167 vertical static load tests were performed. The first tests showed relatively large final settlement (after complete unloading) as well as significant creeping (lack of settlement stabilization) of tested piles. The discussion with the Client and engineering team brought us to the conclusion that concrete admixture shall be incorporated instead of bitumen coating. The concrete admixtures available now on the market are intended for concrete sealing and cause significant reduction of concrete permeability as well as an increase in resistance to aggressive chemical compounds, such as sulphates or chlorides.

Finally around 40% of piles had bitumen coating and 60% were fabricated with a concrete admixture. The comparison of piles behaviour with bitumen and concrete admixture is shown in the table and figures below. This demonstrates that incorporation of concrete admixture instead of bitumen application was a positive decision.

Table 1. Comparison of pile behaviour under loading (both piles 14 m long at the same area no. 41).

Parameter	Pile 0059 with bitumen coating	Pile 0063 with concrete admixture
Maximum settlement at load 1605 kN	39 mm	4,8 mm
Final settlement (after complete unloading)	35 mm	2 mm
Duration of load test	4000 minutes	1650 minutes

The conclusion is pretty clear, the influence of bitumen coating on pile settlements and creeping is significant. This has been confirmed by a number of other tests done on both types of piles within the project duration.

There are also other practical disadvantages of bitumen coating application compared to concrete admixture. The most important are degradation of coating when exposed to the sun and mechanical damages of coating during transportation and lifting operations, both shown in the Figure 5a and b below.

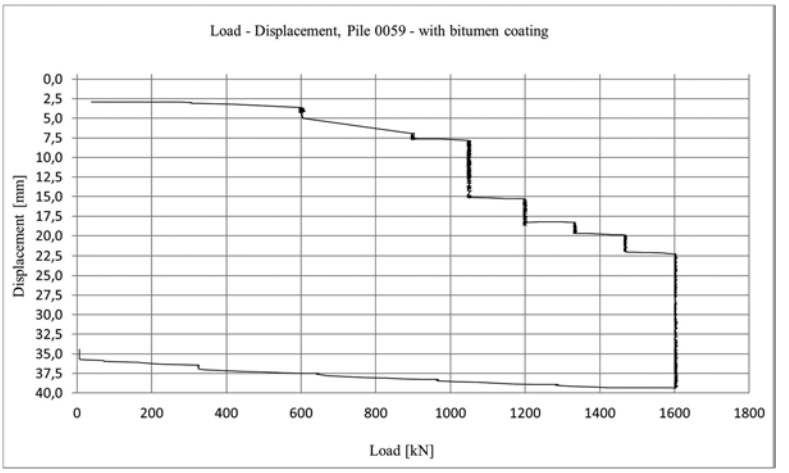

Figure 1. Load – displacement curve for pile 0059 with bitumen coating.

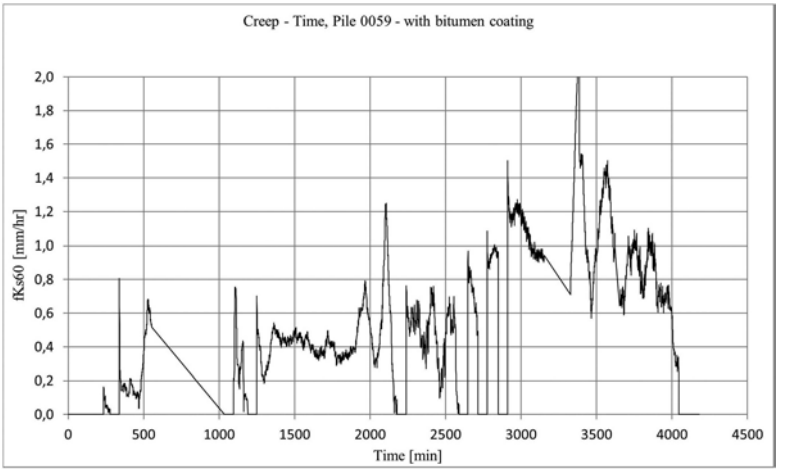

Figure 2. Creep – time curve for pile 0059 with bitumen coating.

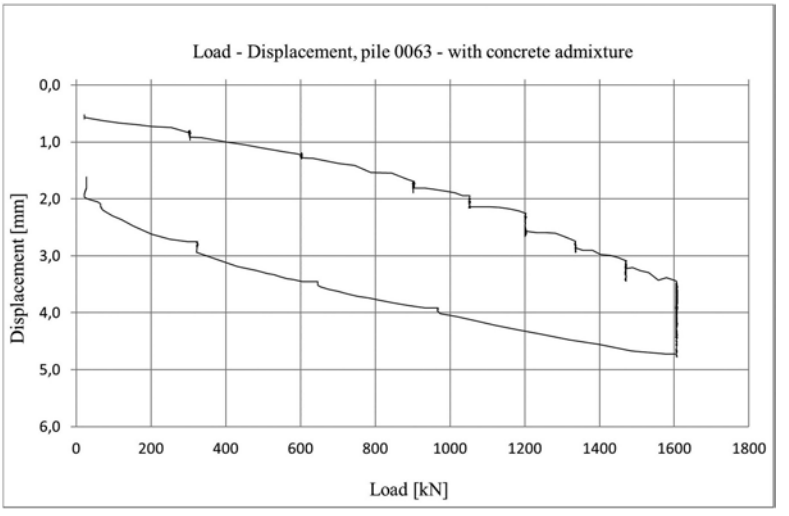

Figure 3. Load – displacement curve for pile with concrete admixture.

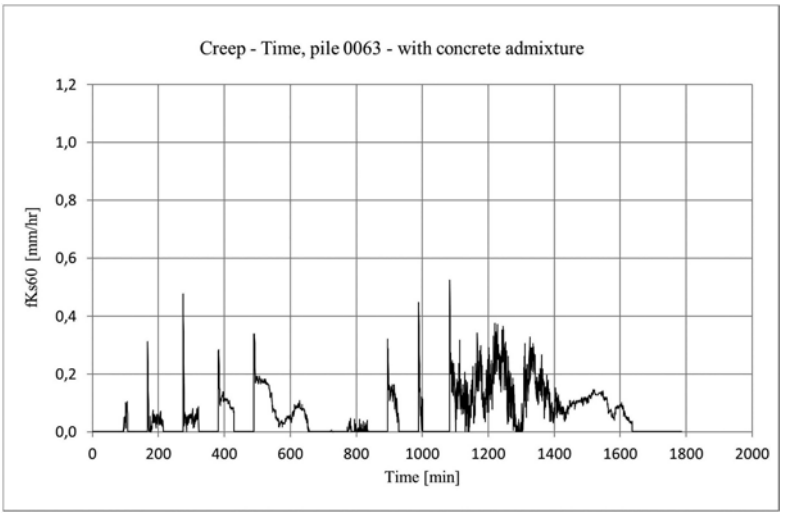

Figure 4. Creep – time curve for pile 0063 with concrete admixture.

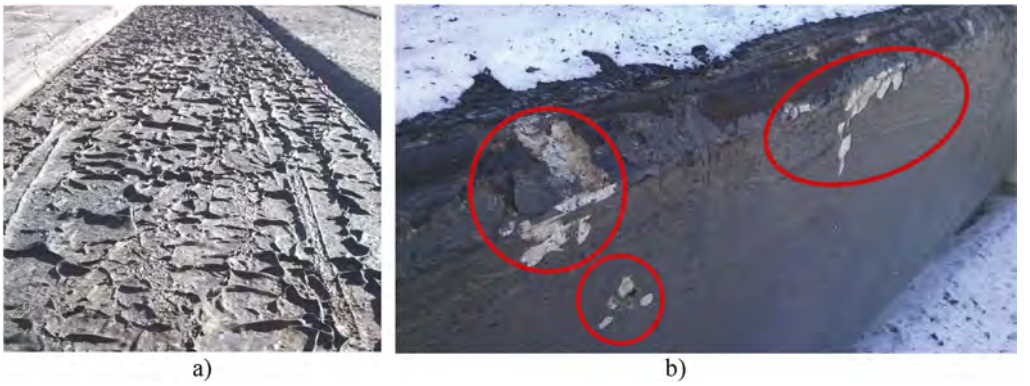

Figures 5. Degradation of bitumen coating a) sun exposition b) during transportation and lifting operations.

2.2 *Concrete precast piles heave and re-tapping (re-striking) of the piles*

Driving of concrete precast piles may initially spear technically straight forward and in many cases piling contractors just drive piles at the designed depth without controlling the driving criteria, internal stresses or pile behaviour after driving. In fact, driving of concrete piles is much more complicated than it seems. One of the aspects regarding concrete precast piles is heave control and potential retapping of the piles.

The phenomenon of piles heave was observed during execution of piles at Tengiz project and it will be presented based on data for Generator 1 (project Area 52) shown in Figure 6.

All piles at Generator 1 met driving criteria before they reach the design depth. Consequently, piles were sticking out above the ground (see Figure 7). This caused additional impediment for post-driving geodetic survey check and later cutting/trimming of the piles.

All elevations of the piles were checked just after driving and later re-checked over some period of time and installation of the adjacent piles. A very dense pattern of the piles (1,2 meters axially between the 400x400 mm cross-section piles) was the reason for pile heave as well as horizontal displacement (moving of already driven pile by the next ones). The geodetic survey showed the heave of practically all piles, with an average value of 26 mm with maximum of 98 mm at Generator 1.

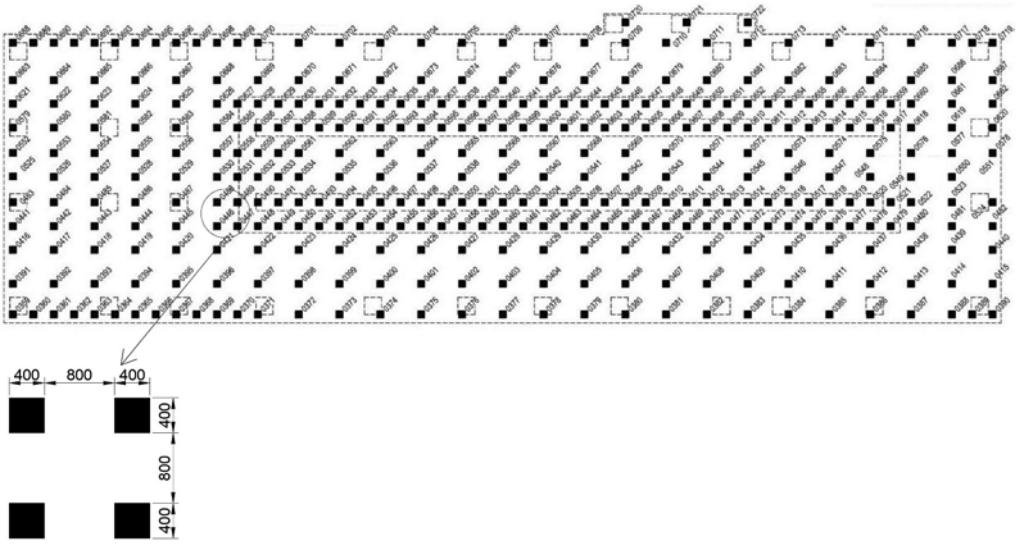

Figure 6. Piling layout, Generator 1, Area 52.

Figure 7. Concrete precast piles at Generator 1, area 52.

Consequently, sequence of piles driving was changed as well as re-tapping of the piles was implemented. The crane suspended hammer was used for re-tapping activity, which is shown in Figure 8.

Figure 8. Retapping activity with crane suspended hammer.

3 DEEP SOIL MIXING (DSM), WET METHOD

Soil mixing is an advanced ground improvement technique requiring considerable expertise in planning, design and execution. The technique leads to significant improvement of the mechanical and physical properties of the in-situ soil, which is mixed with cement or compound binders to form the so-called soilmix (or soil-cement). The resulting stabilised soil generally has a higher strength, lower permeability and lower compressibility than the original soil. The soil to be improved is mixed mechanically in-situ either with a binder in a slurry form (wet method) or with a dry binder (dry method). Slurry jetting can be also used to enhance mechanical mixing, and increase column diameter. The ability to choose between dry and wet processes enables Keller to offer tailored soil mixing applications.

There are many publications where different aspects of soil mixing are described and discussed between professionals including design approach, execution details as well as quality control. The paper describes and presents experience gained with wet deep soil mixing process based on almost 100,000 linear meters of DSM columns done by Keller to date in the Central Asia region.

3.1 *Design of DSM*

The design approach and methods are widely described in many standards and publications, however the most important parameters of DSM soil-cement material are unconfined compression strength *UCS* and deformation modulus E_0 which are based on the local experience, database and statistical analysis.

To determine *USC* and E_0 Keller Central Asia LLP undertook test fields and commissioned laboratory tests for DSM columns performed in Shymkent at 2 projects, in similar soil conditions. The detailed results of laboratory tests are described in the separate report (KazNIISA JSC 2022), however, it will be shortly summarized herein.

The scope of tests covered determination of *UCS* and E_0 (for natural humidity and water saturated) based on 90 tests for determination of *UCS* and 22 tests for determination of E_0 and Poisson ratio *v*. The results are summarized in Table 2.

a) b)

Figure 9. Test DSM columns a) and core samples b).

Table 2. Results of *UCS* and E_0 determination.

Humidity of the core sample	Direction of core sample	Density (kg/m^3)	Characteristic unconfined compression strength *UCS* [MPa]	Deformation Modulus M_0 [MPa]	Poisson ratio *v*
Dry (normal humidity)	horizontal	1721	6,36	424,3	0,287
	vertical	1725	4,68		
Wet (water saturated)	horizontal	1921	3,70	381,5	0,316
	vertical	1907	3,14		

The above presented results were reached for cement content in soil-cement material: 340 kg/m^3 and are valid only for the soils in Shymkent region where DSM technology is now commonly used.

Based on the local standards, calculations of settlements of the objects and bearing capacity of DSM columns system shall be performed for the worst soil parameters, i.e. for water saturated collapsible soils with decreased parameters.

The required design value f_{cd} of the compressive strength of soil-cement material can be calculated as follows (Topolnicki, 2016):

$$f_{cd} = 0,85\frac{f_{ck}}{\gamma_m} \tag{1}$$

where:
0,85 - reduction factor for potential long-term effects affecting strength of the deep mixed soil, γ_m = partial safety factor for the deep mixed soil, applying γ_m = 1.5 for permanent and transient loads, and γ_m = 1.3 for accidental loads, f_{ck} - characteristic compressive strength of soil-cement material.

This practically means that for average f_{ck} = *(3,70+3,14)/2 = 3,42 MPa,* the maximum load on 1000 millimetre diameter DSM column shall not exceed: F_{max} = *1521 kN.*

One of the typical DSM column layouts for a 16-floor residential building located in Shymkent is shown at the Figures 10 and 11.

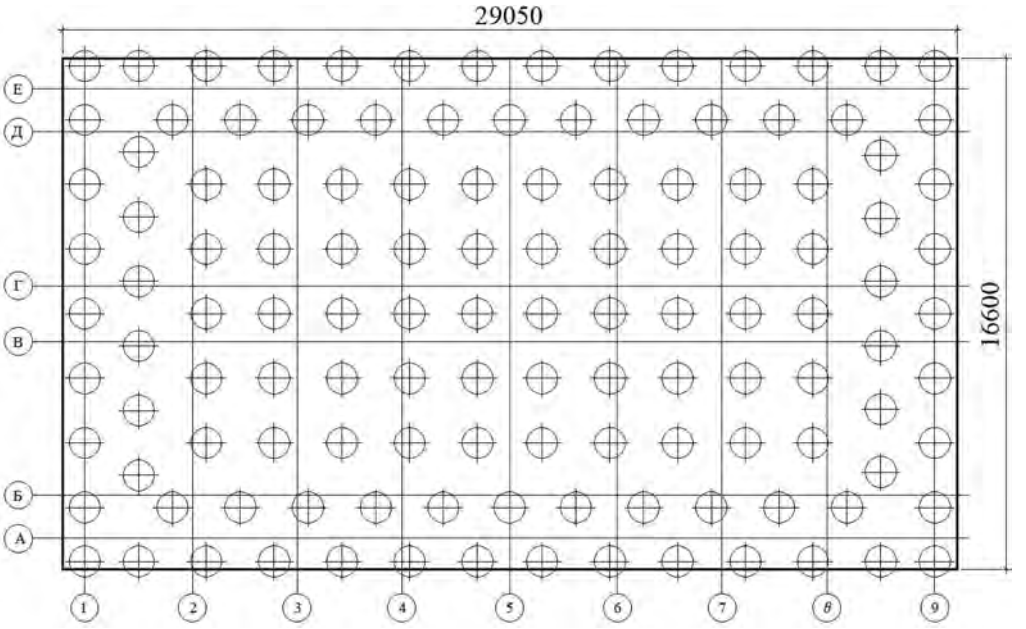

Figure 10. DSM layout, 126 DSM columns, average design pressure under the foundation slab: 398 kPa.

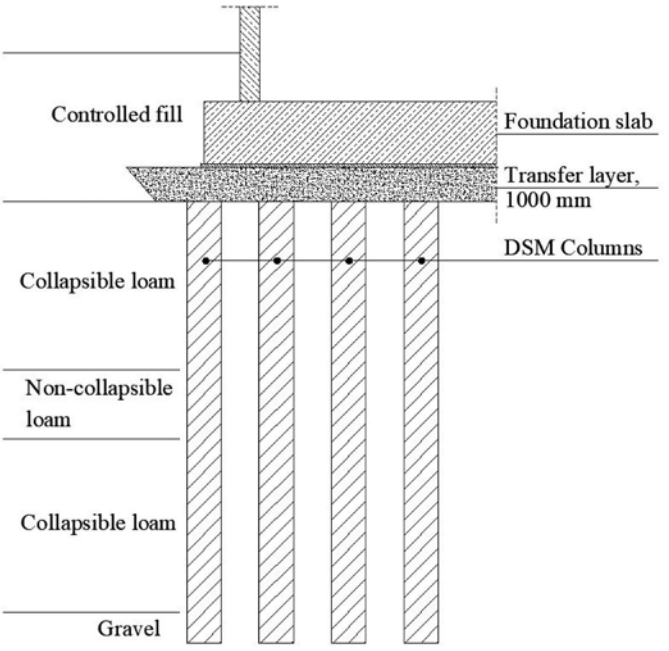

Figure 11. Soil improvement with DSM technology under the 16 floor residential building – cross section.

3.2 *Execution good practice and quality control of DSM columns*

Soil mixing may appear straightforward, however in fact this is advanced technology which requires advanced quality control and know-how based on the experienced gained in the past.

The standard quality control of DSM consist of:

– Control of cement slurry density. For this, computer controlled mixers and areometers are used. Each part of cement slurry prepared in the mixers shall follow the mix design (recipe) as well as a check on the density of slurry for each part shall be performed.
– Volume of cement slurry pumped for each DSM column. Knowledge about volume of cement slurry as well as its density is crucial for each DSM column. This allows calculation of the cement content in the soil-cement mixture, which must be closely controlled.
– Unconfined compression strength of soil-cement mixed material. Collection of the samples is possible from a "fresh" already executed DSM column or/and by core drillings. The samples are usually collected on a daily basis.
– Sometimes, a vertical static load test of single or/and group of DSM columns is performed.
– Real time observation and recording of the following production parameters: - column depth, - execution date and time, - total volume of the cement slurry, - actual flow of the cement slurry and distribution of cement slurry over the time, - distribution of the cement slurry volume along the DSM column - drill pressure, - crowd force, - BRN (Blade Rotation Number)

The quality of the DSM columns depends on many factors but mixing process and consequently homogeneity of the DSM column is one of the most important. For better control of the mixing process the BRN (Blade Rotation Number) shall be observed (Topolnicki, 2018).

$$\mathrm{BRN} = \Sigma \mathrm{M} \left(\frac{R_p}{V_p} + \frac{R_w}{V_w} \right) \cdot n \tag{2}$$

where:
BRN - blade rotation number [rev./m], ΣM- total number of mixing blades (a full diameter blade is counted as two blades), R_p - rotational speed of the mixing tool during penetration [rev./min], V_p - penetration velocity [m/min], R_w – rotational speed of the mixing tool during withdrawal [rev./min], V_w - withdrawal velocity [m/min], n - number of restroking cycles to full depth.

The BRN value is especially important in the soils where the mixing process is difficult (e.g. clays). BRN shall be controlled for every column, and needs to determined by an experienced engineer and piling rig operator for every project individually, however it shall be not less than 400 [rev./m] for well mixed DSM column.

4 CONCLUSIONS

When concrete precast piles are executed, many aspects shall be taken into account. Some of these aspects are: corrosion protection and piles heave, described in this article. The general practice in western Kazakhstan is to use bitumen protection of concrete precast piles, however as described herein, it is considered that this approach is incorrect and concrete admixtures shall be applied instead. The examples and comparison of both solutions are presented in Section 2 where significant negative impact of bitumen coating on bearing capacity and creeping is described.

Concrete precast piles are commonly used within the residential construction sector. Many construction companies don't sufficiently consider the driving process and many instances where external stresses are exceeded or heave becomes apparent have been observed. The heave phenomenon described in Section 2 of this article may have influence on building settlement when not properly controlled.

The DSM technology was implemented in Kazakhstan by Keller Central Asia in 2020 for the first time. The design process differs from the traditional "piling" approach and some other aspects are important. The author has highlighted the very basic issues regarding DSM design, however the experience, real projects and advanced calculations are much more complicated and advanced and it needs to be developed in Kazakhstan.

The DSM execution process requires modern equipment with advanced control and recording system in place. Beside proper design, the high level execution of DSM is needed to obtain safe and cost effective foundation solutions.

ABSTRACT: Land reclamation from the sea is one of best methods to expand the land and obtain the suitable land for the construction of port and harbor, and industrial complex. The man-made land is being normally created along the costal line in the way of sea-dike construction and fill the dredged soil inside the dike by hydraulic method due to the lack of good soil from landside. In this case, the most of dredged soil in west coast of the Korean Peninsular is composed of soft clay, silty, and silty sand. The magnitude of self-weight consolidation settlement level is a great concern for proper estimation of volume of dredged filled soil. The self-weight consolidation tests for the dredged soil obtained from sea were conducted under the conditions of 300%, 600%, and 1000% water contents. The consolidation settlement factors such as void ratio, water content, volume change ratio, and sedimentation consolidation coefficient were determined to propose a self-weight consolidation relationship. The settling factors are derived according to the self-weight consolidation theory by finite strain. In addition, the volume change ratio was derived through the relationship between the interfacial height and the actual soil height, and the settlement amount and the volume change ratio according to elapsed time were predicted. This result is compared with the results of field surveying by using field surveying equipment as well as drone surveying. Based on the results of this study, when the fine-grained soil content (#200 sieve passing) of the dredged soil is 30% or more, the estimation of the settlement amount by the self-weight consolidation theory and experiment work shows a deviation of about 4% compared to the actual value of the field. It is found that the settlement amount of dredged soil by self-weight consolidation theory can be predicted more accurately than that of existing Port and Fishing Port Design method (2015) which gives a deviation of about 8.5%.

1 INTRODUCTION

As the supply of good soil from land for land reclamation project in coastal area is rather limited, therefore the use of sea route dredged soil is being increased. When the reclaimed area is large, there are many errors in the estimation of the settlement amount of the dredging reclaimed land site, and the settlement management at the reclaimed area is not effectively performed due to practical problems. The methods of landfilling are a method of pumping dredged soil to a landfill by pump type dredging ship with the capacity of 20,000 HP. In the dredging process of seabed soil excavating and transporting it to the landfill site through the

DOI: 10.1201/9781003299127-11

discharge pipe, the soil may float out, and some of it may be lost to the outside of the planned landfill site. At this time, the accumulation soil in the planned area with considering soil loss is called the retention volume.

When designing a landfill site, the retention ratio is calculated by the average after self-weight consolidation test or calculating the retention ratio according to the grain size and species of the dredged soil. The settlement rate is expressed by the settlement amount for the ground layer thickness and settlement value by Terzaghi's one-dimensional consolidation theory (1943). Richart (1957) suggested the finite stain theory with the relationship between effective stress and void ratio for one-dimensional consolidation analysis of soft clay. The sedimentation and self-weight consolidation behavior of dredged soil were studied by Mikasa (1963) by using Osaka clay and Gibson et al. (1967) by one-dimensional non-linear finite strain consolidation theory. Imai (1980) conducted sediment experiment work on the Japanese dredged clay and studied the interaction behavior between settling and consolidation.

Yano (1985) predicted the settling volume of dredged soil in the landfill site by using interfacial height change with elapsed time, which is widely used in Korea. Lee & Lee (2011), Lee & Choi (2016) investigated the behavior of self-weight consolidation for the dredged soil in western coastal region in Korea. Shin et al. (2017) presented about the determination of retention ratio by the results of self-weight consolidation test for ship navigation route dredged soil in Incheon region, Korea. Figure 1 shows the location of the ground investigation site in west coast of the Korean Peninsular for this research.

Figure 1. Location of the ground investigation from the ship navigation route in the Gunjang harbor in Mid-west coastal region of Korean Peninsular.

2 SETTLEMENT OF DREDGED SOIL BY SELF-WEIGHT CONSOLIDATIOJN THEORY

The percentage of retention volume against total volume is called the retention ratio. Estimating the dredging volume based on the retention ratio is based on Equation 1:

$$M = \frac{M_0}{R} \tag{1}$$

where, M is the volume of dredged soil for landfill site (m^3), M_0 is the volume of the landfilled soil (m^3) considering the settlement rate and the shrinkage rate, and R is the average retention rate (%) of the landfill by the pump dredger.

Korea Port and Harbor Authority (KPHA) issued the design standard (KDS, 2015) proposed the retention ratio (R) for different types of soils, that is, $R < 70\%$ for clayey soil, $70\% < R < 95\%$ for sand and sandy silt, and $95\% < R < 100\%$ for gravel. Korea Rural Community

Corporation (KRCC, 2011) gives more detail information regarding on the soil loss rate with considering the particle size as described in Table 1. This manual indicates that the soil has a particle size bigger than 1.2 mm, there is no soil loss. However, if the soil has a particle size less than 0.75 mm, then soil loss rate is greater than 35%.

Table 1. Classification of soil loss rate by soil particle size (KRCC, 2011).

Particle size (mm)	Loss rate (%)	Remark
More than 1.2	-	
1.2∼0.6	5∼8	
0.6∼0.3	10∼15	
0.3∼0.15	20∼27	
0.15∼0.075	30∼35	
0.075	30∼100	

The volume of the landfilled soil (M_0) in the land reclamation project can be estimated with the consideration of consolidation settlement at the original soil ground (R_s) as well as compression ratio of dredged filled soil or self-weight consolidation settlement (R_c).

Therefore, the volume of the landfilled soil (M_0, m^3) can be written as Equation 2:

$$M_0 = \frac{M_0}{1 - R_0} \times (1 + R_0) \tag{2}$$

3 SELF-WEIGHT CONSOLIDATION AND RETAIN RATIO

3.1 *Self-weight consolidation theory*

Self-weight consolidation settling curves are classified into sections of flocculation, settling with increasing settling velocity, and consolidation settling. At this time, the starting point of consolidation settlement is generally based on the inflection point at which the settling velocity slows down.

The time of self-weight consolidation is the time corresponding to the intersection point of the tangent line in the settlement section and the consolidation settling step. In the time-settling curve, the point that meets the tangent line at the bottom curve becomes the end point of settling, and this end point can be estimated as the self-weight consolidation time.

Figure 2 shows the method for determining the starting point of self-weight consolidation through the separation of the settling and consolidation step.

When a sample having the same initial water content and different contents of fine particles has settled and consolidated, the dredged soil, which has the form of section settlement, enters the self-weight consolidation step according to the passage of time through the sedimentation and accumulation steps.

In the relation between the interface height and sedimentation time, a linear relationship Equation 1 can be obtained, and the interface can be obtained as Equations 3 and 4:

$$\log H = \log h_1 - C_S \cdot \log t \tag{3}$$

$$H = h_1 \cdot t^{-C_S} \tag{4}$$

where, h_1 is a constant indicating the height at which $H = h_1$ at t = 1 (min), and C_s is the settling consolidation coefficient.

The beginning point of the straight line is the start point of self-weight consolidation, while the end of the straight line is defined as the self-weighted consolidation end point.

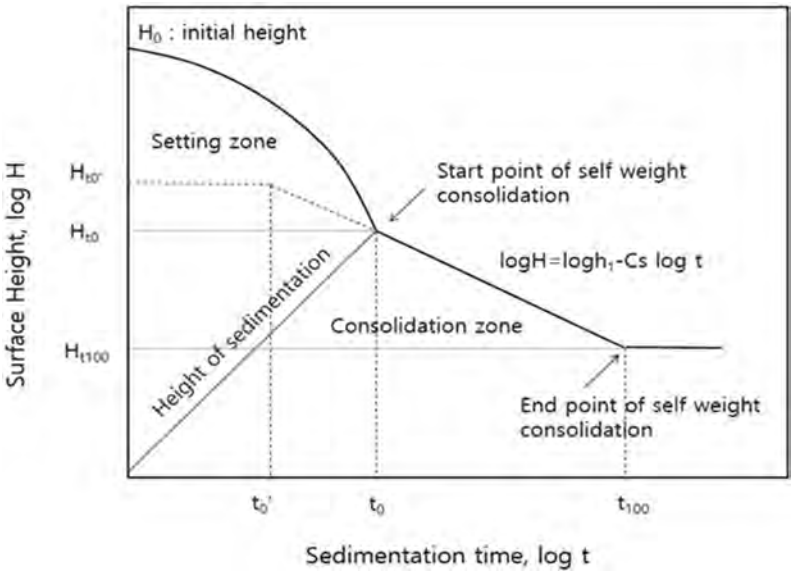

Figure 2. Determination of the starting point of self-weight consolidation.

The coefficient of sedimentation self-weight consolidation can be expressed as the slope between the two points, as expressed in Equation 5:

$$C_s = \frac{\log(\mathrm{H}_{t0}/\mathrm{H})}{\log(t/t_0)} \tag{5}$$

where, H_{t0} is the interface height at time t_0.

The relation between the real soil height and the interface height is given by Equation 6:

$$H_s = \frac{H}{1 + G_s/G_w \cdot \bar{w}} = \frac{H}{1 + \bar{e}} \tag{6}$$

where, H_0 is the initial interfacial height, G_s is the specific gravity of the soil, G_w is the specific gravity of water, $\bar{w}$ is the average water content of the dredged soil, and $\bar{e}$ is the average void ratio of the dredged soil.

The dredged soil with the same initial water content and different heights were settled, then assuming that the consolidation settling start time shown in each settling curve is expressed as t_0, and the time when entering the creep behavior is t_{100}, the self-weight consolidation formulae in the consolidation settling zone between the time (t = $t_0 \sim t_{100}$) and the interface height (H) can be obtained.

Figure 3 shows the height of the real soil height with the interfacial height at time (t_0,t_{100}).

When the self-weight consolidation starts and end point according to the water content ratio are indicated by the real soil height of the logarithmic scale, a linear relationship is established.

From this, it is possible to obtain the real soil height for the initial surface height of the landfill, as shown in Equation 7:

$$\log H = \log h_2 + C_k \log H_s \tag{7}$$

where, h_2 is the surface height, and is the intercept at the real soil height H_s = 1, and C_k represents the slope of the surface height-real soil height graph.

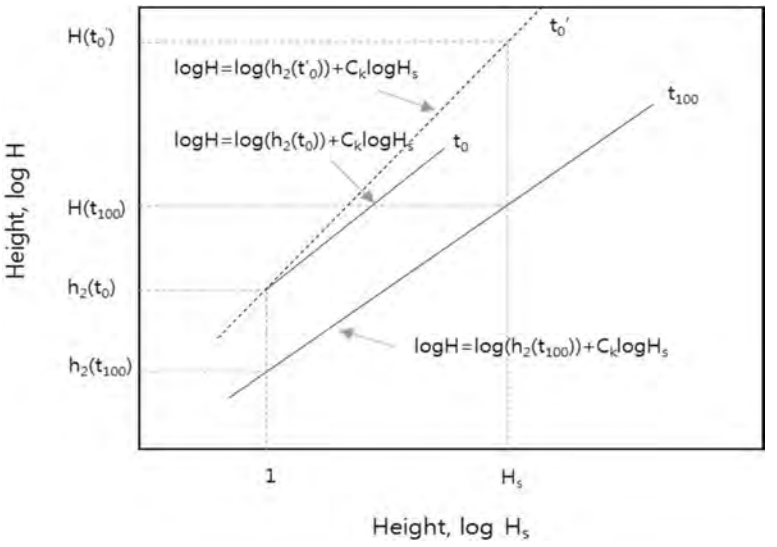

Figure 3. Height of dredged soil with Hs at t=0 and t=100.

The landfill height is estimated using the real soil height calculated from the sedimentation consolidation test. It is possible to finally calculate the volume change ratio by using the relationship between the void ratio and the water content ratio.

4 SELF-WEIGHT CONSOLIDATION AND RETAIN RATIO

4.1 *Sampling and physical properties test of dredged soils*

Dredged soil samples were obtained from the ship navigation route in the Gunjang harbor in Mid-west coastal region of Korean Peninsular to determine the physical properties and to perform the self-weight consolidation test. The dredging equipment was mounded on the self-elevation platform barge at the soil sampling site and drilled the bore hole by using hydraulic drilling machine down to weathered rock layer in the ocean as shown in Figure 4. The detail types of soil sampled with respect to the boring depth of GL-10m is described in Table 2. Total 9 boring holes were drilled under the water depth from 10m to 17m. The thickness of sedimented clay layer ranges from 3m to 10 m with overlying a thinner layer of sandy soil on the top. The situation of offshore boring sites is shown in Figure 4.

Table 2. Each depth of layer by soil type on the offshore drilling area.

Boring No.	Depth of soil layer (m)			Depth of boring (GL.-m)	Depth of water (DL.-m)	Remark
	Sedimentary layer		Weathered granite soil			
	Clayey soil	Sandy soil				
1	8.0	2.0	-	10.0	15.72	
2	3.0	7.0	-	10.0	12.82	
3	-	1.0	2.0	1	17.12	
4	8.0	2.0	-	10.0	10.99	
5	9.0	1.0	-	10.0	12.35	
6	10.0	-	-	10.0	14.03	
7	5.0	-	2.0	5	10.75	
8	2.9	-	1.1	2.9	10.89	
9	4.0	6.0	-	10.0	10.35	

Figure 4. Situation of each boring number on the offshore drilling.

The soil specimens from No. 7 & No. 8, and No. 1, No. 6, No. 9 are classified as Silty soil (ML) and clayey soil (CL) by USCS, respectively. The soil specimens from No. 2-4 and No. 5 are classified as Silty clayey soil (CL-ML) and silty soil mixed with shell fragment (OL) by USCS, respectively. Most of soil specimens from 9 boring holes are consisted of clay and silty soil with a small portion of sand. The proportion of fine-grained soil for given soil specimens is more than 90%, that is, 50% for silty soil, 40% for clayey soil, and 10% is colloid state with grain size less than 0.001 mm. A liquid limit for most of soil gives less than 40% and natural water contents of 31.9-50.9%. The grain size less than 0.005 mm (#200 sieve) is consisted of 75-98% along with grain size less than 0.002 mm is approximately 10~30%. The clayey soil deposited in this area is normally consolidated clay or under-consolidated clay. The physical properties of dredged soil obtained from offshore sites are tabulated in Table 3.

Table 3. Physical properties of dredged soil obtained from offshore sites.

			Atterberg Limits (%)		Grain Size Distribution %, Finer than		
No.	w_n (%)	G_s	LL	PI	0.075mm	0.425mm	USCS
1	31.9	2.62	39.7	17.1	100	100	CL
2	34.4	2.64	25.8	4.0	100	100	CL-ML
3	25.8	2.64	26.5	6.6	-	-	CL-ML
4	50.9	2.65	27.0	5.7	100	100	CL-ML
5	36.2	2.57	41.5	11.9	100	100	OL
6	36.8	2.65	34.3	14.9	100	100	CL
7	50.1	2.61	39.0	13.5	100	100	ML
8	34.7	2.59	31.7	7.0	100	100	ML
9	33.8	2.61	26.0	10.0	100	100	CL

4.2 *Settlement analysis of dredged soils by using the self-weight consolidation test*

In the laboratory self-weight consolidation test through column test, the downward movement of suspended soil particle can be divided into two parts as shown in Figure 3. The first part is categorized as sinking and sedimentation of soil particles which gives concave curve. The second part is a downward linear line between soil elevation height and sedimentation time, that is, self-weight consolidation zone. The gradation of downward linear line is called sedimentation-consolidation coefficient or self-weight consolidation coefficient (C_s) as given in Equation 5. The end point of linear line is indicated that the self-weight consolidation process is terminated.

Table 4 describes the self-weight consolidation test results for soil specimens with the moisture contents of 300%, 600%, and 1000%, respectively. From the soil-water interface height with corresponding sedimentation elapsed time as shown in Figure 3, the self-weight consolidation

coefficient is determined by using Equation 5. The self-weight consolidation coefficient (C_s) is decreased with the increase of water contents of soil. The self-weight consolidation coefficient (C_s) ranges from 0.073 cm/min to 0.127 cm/min. The silty soil gives the higher value of Cs that that of clayey soil. Because the sea water contributes slow-down of sedimentation velocity due to dispersion of clay particle. Therefore, the larger size of soil particle gives a greater sedimentation velocity that that of smaller size of soil particle. The self-weight consolidation coefficient (C_s) of various soil specimens describes with the water contents of 300%, 600%, and 1000%, respectively.

Table 4. Coefficient of self-weight consolidation for various soil specimens.

Soil Type	Water content (%)	Initial height (cm)	Start point		End point		C_s (cm/min)	Ave. C_s(cm/min)
			t_0 (min)	H_0 (cm)	t_{100} (min)	H (cm)		
CL	300	100	1020	43.90	7090	37.25	0.085	0.079
	600	100	760	22.90	2880	20.60	0.079	
	1000	100	280	16.10	4320	13.20	0.073	
CL-ML	300	100	135	13.80	1089	11.05	0.106	0.101
	600	100	115	14.10	910	11.35	0.105	
	1000	100	120	14.00	1200	11.30	0.093	
OL	300	100	307	14.8	1087	12.6	0.127	0.111
	600	100	270	15.45	1270	13.00	0.112	
	1000	100	260	15.40	1440	13.10	0.094	
ML	300	100	300	15.8	1085	13.50	0.122	0.113
	600	100	280	16.1	1280	13.45	0.118	
	1000	100	240	15.9	1440	13.30	0.100	

The relationship between the height of the real soil height and the interfacial height is established as shown in Figure 5 by using the self-weight consolidation test data in Table 5. The heights of dredged soil slurry were varied as 30 cm, 50 cm, and 100 cm during the self-weight consolidation test as described in Tables 5 and 6.

Table 5. Result of H and Hs from initial height of dredged soil (w=1000%).

Initial Height, H_0 (cm)	Specific gravity, G_s	Water content of specimen, w (%)	Void ratio, e (e= $G_s \times w$)	Height, H (cm)	H_s (= H/1+e)
30	2.63	106	2.794	4.35	1.15
50	2.63	106	2.794	7.24	1.91
100	2.63	106	2.794	14.50	3.82

Table 6. Relationship between H and Hs in the soil column of CL (w=1000%).

Soil type	Water content (%)	Initial value (t_0)		Final value (t_{100})	
		A	B	A	B
CL	1000	0.5798	0.9989	0.5441	0.9772

Therefore, this consolidation test data is plotted in Figure 5 for CL soil specimen with 1000% of water content. Similar self-weight consolidation tests were performed for soil specimens, CL-ML, OL, and ML with variations of water contents, 300%, 600%, and 100%, respectively.

Based on the real soil height (H_s) in the graduated cylinder obtained according to the interfacial height (H) due to the variations of heights of dredged soil slurry during the self-weight consolidation tests, determined A and B parameters for various soil types and test conditions and tabulated in Table 7.

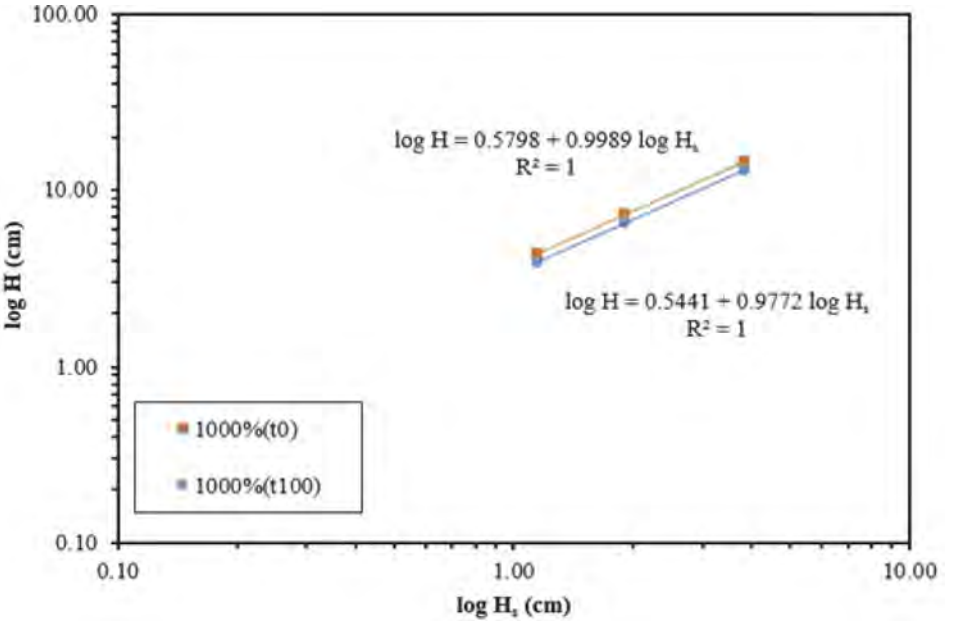

Figure 5. Relationship between H and Hs in the soil column of CL.

The coefficient of self-weight consolidation for clayey soil gives lowest value while the greater water content gives lower value. The intercept value obtained from the relationship between real soil height (H_s) and interfacial height (H) ranges from 1.0 to 1.2 for sandy soil and a little bit higher than 1.0 which contains a bit of fine-grained soil. However, the soil specimen contained more than 70% of clay and silty soils gives an intercept values from 0.59 to 0.65, and hence it caused the low value of actual landfill height.

Table 7. Correlation equation using relationship of H and H_s.

Soil type	Water content (%)	Initial line (t_0)	Final line (t_{100})
CL	300	$\log H = 0.5911 + 0.9946 \log H_s$	$\log H = 0.5682 + 0.8648 \log H_s$
	600	$\log H = 0.5798 + 0.9989 \log H_s$	$\log H = 0.5051 + 0.9802 \log H_s$
	1000	$\log H = 0.5798 + 0.9989 \log H_s$	$\log H = 0.5441 + 0.9772 \log H_s$
CL-ML	300	$\log H = 0.6021 + 0.9978 \log H_s$	$\log H = 0.5315 + 0.9989 \log H_s$
	600	$\log H = 0.6021 + 0.9978 \log H_s$	$\log H = 0.5051 + 0.9991 \log H_s$
	1000	$\log H = 0.6021 + 0.9978 \log H_s$	$\log H = 0.4914 + 1.0059 \log H_s$
OL	300	$\log H = 0.6128 + 1.0073 \log H_s$	$\log H = 0.5563 + 1.0011 \log H_s$
	600	$\log H = 0.6232 + 1.0024 \log H_s$	$\log H = 0.5563 + 0.9914 \log H_s$
	1000	$\log H = 0.3232 + 1.0024 \log H_s$	$\log H = 0.5441 + 0.9922 \log H_s$
ML	300	$\log H = 0.6532 + 1.0002 \text{og} H_s$	$\log H = 0.6021 + 0.9290 \log H_s$
	600	$\log H = 0.6532 + 1.0002 \log H_s$	$\log H = 0.6021 + 0.9875 \log H_s$
	1000	$\log H = 0.6532 + 1.0002 \log H_s$	$\log H = 0.5911 + 0.9929 \log H_s$

5 DETERMINATION OF RETENTION RATE

The self-weight consolidation settlement and ratio of soil volume change after completion of dredged landfill were predicted by using the self-weight consolidation equation. The ratio of soil volume change is defined as soil specimen volume during the self-weight consolidation after dredging against the volume of original ground. When the disturbed soil becomes a same void ratio as original ground, then soil volume change ratio becomes 1.0. The variation of soil

volume change during the self-weight consolidation test for CL soil specimen is described in Table 8. The initial soil volume change ratio was 1.79, and after 4 years later, it becomes 1.51 on the progress of self-weight consolidation. The soil volume change ratio becomes approximately 1.36-1.44 after 8 years later with completion of dredged work. This value gives retention ratio of 69%-74%. The variation of void ratio, water content, and volume change for 300%, 600%, and 1000% of water contents are shown in Figures, 6, 7, and 8, respectively.

Table 8. Volume change ratio of CL material on w=1000%.

No.	Elapsed time		Log H	Height (m)	Void ratio	Water content (%)	Volume change ratio
	Day	Year					
1	1	0.00	0.778	6.00	2.78	106.00	1.79
2	30	0.08	0.772	5.92	2.73	104.17	1.77

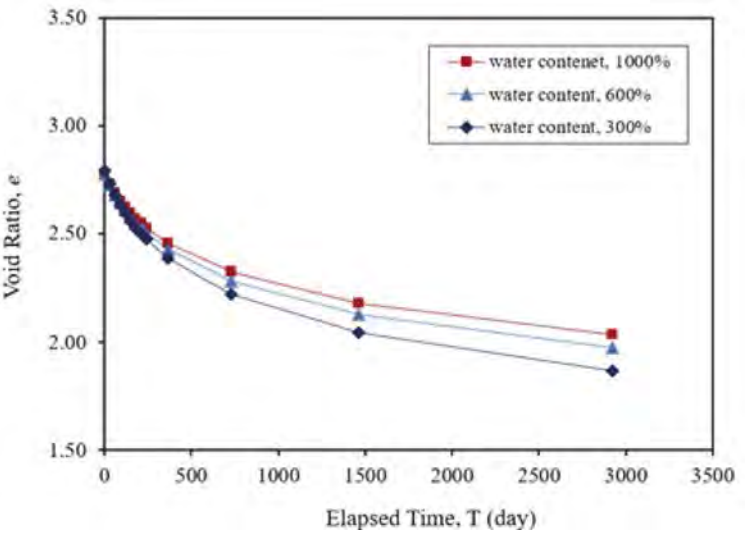

Figure 6. Variation of void ratio with elapsed time for low plasticity clay (CL).

This study was focused on the area where it has a spillway. The sandy soil is deposited near to the discharge pipe which transported dredged soil into the reclamation site. The suspended fine-grained soil particles which passed through #200 sieve is deposited around spillway where the silt pocket is normally formed. The soil specimen obtained in this area is consisted of clayey and silty soils (CL-ML). After the interfacial height was established by the result of self-weight consolidation test, the water content of soil slurry was ranges 100%-135% with the corresponding void ratios of 2.73-3.50. The initial soil volume change ratio was 1.87, and after 4 and 8 years later, it becomes 1.50 and 1.42, respectively, with completion of dredged work. This value gives retention ratio of 70% against the final height of dredged fill site.

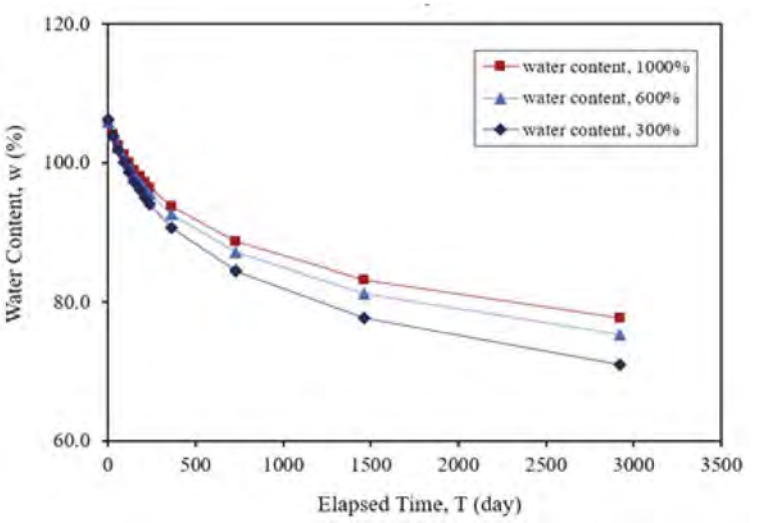

Figure 7. Variation of water content with elapsed time for low plasticity clay (CL).

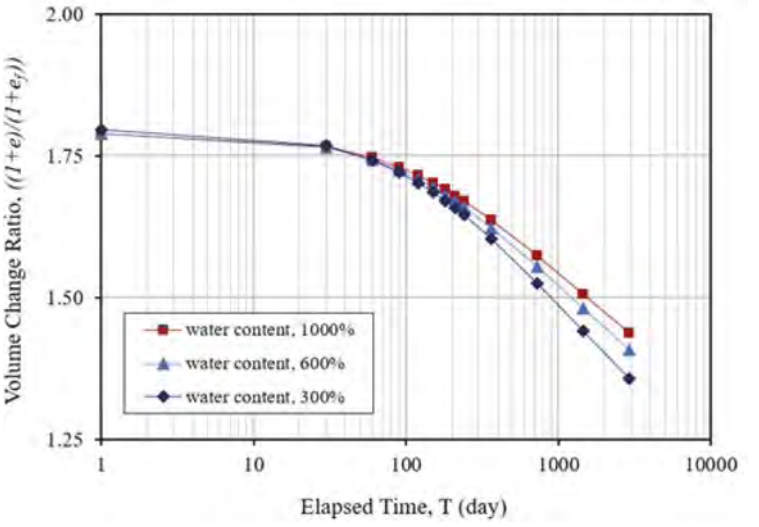

Figure 8. Volume change ratio with elapsed time for low plasticity clay (CL).

The soil specimen contains an organic silty clay (OL) shows the initial soil volume change ratio was 2.01, and after 4 and 8 years later, it becomes 1.61 and 1.44, respectively, with completion of dredged work. This value gives retention ratio of 69% against the final height of dredged fill site.

The soil specimen contains a silty soil (ML) shows the initial soil volume change ratio was 1.48 - 1.58, and after 4 and 8 years later, it becomes 1.68 and 1.48 - 1.58, respectively, with completion of dredged work. This value gives retention ratio of 63% - 68% against the final height of dredged fill site.

The summary of self-weight consolidation tests for the soil specimens of CL, CL-ML, OL, ML in Table 7, after the interfacial height was established by the result of self-weight consolidation test. The water content of soil slurry was ranges 100% - 135% with the corresponding void ratios of 2.73-3.50. The initial soil volume change ratio was 1.79 - 2.13, and after 8 years later, it becomes 1.36 - 1.58, respectively, with completion of dredged work. This value gives overall retention ratios of 63 - 74% against the final height of dredged fill site.

6 COMPARISON ANALYSIS FOR EXTIMATION OF VOLUME OF DREGED FILL SOIL

The volume of dredged fill soil has been estimated by following the design standard (2015) by the Korea Port and Harbor Authority (KPHA). In the process of estimation for dredged fill soil volume, the retention ratio (R) for sand and sandy ranges from 70% to 95%, and for clayey soil gives less than 70% of retention ratio. This means that the retention rates are greatly different depending on the soil particle size. The land reclaimed block for this study is potential deposited area of suspended soil particles among the huge land reclamation project site. The results of ground investigation on offshore area, the sandy soil is deposited in the upstream area of ship navigation route while the fine-grained soil is deposited in the spillway area. Therefore, the study area is deposited more silty soil as well as clayey soil rather than sandy soil. The soil specimens obtained from field is classified as clayey soil. The result of self-weight consolidation test indicates that the real net height of dredged fill soil is lower than that of retention rate (82.5%) given by the design standard of KPHA

In case of average height of dredged fill soil is about 6 m at the reclaimed site, the magnitude of settlements is estimated by using the design standard of KPHA, actual field surveying, and self-weight consolidation test result. The settlement levels with corresponding retention rates given for the design standard of KPHA (82.5%), actual field surveying (74.0%), and self-weight consolidation test result (72.0%) are 105.5 cm, 156.8 cm, and 180.9 cm, respectively. Based on the settlement level by actual field surveying, the deviation rate by KPHA's method can be reduced by 50% if the result of self-weight consolidation test is used.

7 CONCLUDING REMARKS

The proper estimation of volume of dredged fill soil for a large-scale land reclamation project is necessary. Current methodology for estimation of dredged fill soil is rough and not systematic method. The adoption of self-weight consolidation test for the soil specimen obtained from the dredging site is more realistic and reduce the risk of lack of dredged fill soil (approximately 50% at this particular site) at the land reclamation project. The design standard (2015) by the Korea Port and Harbor Authority (KPHA) should be clearly described:

(1) where the soil specimen should be obtained, (2) what kind of soil property tests must be conducted, and (3) the self-weight consolidation test is necessary for the given soil specimen.

The detail plan of construction management for the sea dike construction as well as controlling to avoid silt pocket. The UAV (Unmanned Aerial Vehicle) surveying by using Drone is also a good method to effectively survey the large area in a such short period of time which can help the proper estimation of ground settlement level and predict the level of dredged fill soil at the land reclamation site.

Engineering challenges behind demolition of a highrise structure by delayed detonation techniques at Delhi, India

Anil Joseph
Geostructurals Pvt Ltd, Kochi, India

A. Boominathan
IIT Madras, Chennai, India

ABSTRACT: Delayed detonation techniques by implosion is successfully used in many countries for demolition of high rise structures in heavy urban and densely populated areas without inducing damages to neighboring structures. This paper deals with engineering challenges behind demolition by implosion technology of Supertech Twin Towers at New Delhi, India. After completing 32 floors of Apex and 29 floors of Ceyane tower, work was stopped in 2014 for violating building norms. Buildings were brought down by controlled implosion on 28th August 2022 as per the Supreme Court verdict. The towers were surrounded by numerous adjacent multistoried apartments and a buried gas pipeline passing within the plot of Supertech twin towers. Bringing the building down within the plot without affecting the built environment was the major challenge. After detailed engineering analysis, proper instrumentations, safety measures to prevent flying debris and to control touch down vibration, the demolition was successfully completed.

1 INTRODUCTION

Demolition is the method of deconstruction of structure by manual (non-engineering) or mechanical (engineering) methods. Normally the demolition is carried out on structures which has completed its life span - to replace the existing structure with new development, or when the structure has undergone irreparable damages due to fire, earthquake etc. or when the building is found to violate the rules of construction and the authorities has ordered for demolition. Nowadays demolition by implosion is becoming common in many countries. Implosion is defined as the designed collapse of a building using explosives within its own foot print (McKenzie et al.2019). Explosive demolition is the preferred method for safe and efficient demolition to bring dangerous multistoried structures to ground in comparison to conventional demolition methods (Jalandar et al.2014). Detonation of small quantities of strategically placed explosives can demolish an unwanted high-rise in a matter of seconds (Mark & Douglas. 1995). The ground motion caused by blasting demolition is usually a combination of blasting vibration, backlash vibration and touch down vibration and it could damage nearby structures if the amplitude of these vibrations are high (Wang & Li. 2010). Touch down vibration is caused by the collision of buildings falling to the ground and it has huge energy, long duration and complex function process, hence this vibration has a much harmful impact on the surrounding build environment. Therefore, the touch down vibration due to blasting has become a research focus in hazard control for demolition of buildings (Yang and Shi.1985, Lu et al. 2003, Zhou.2009). During the demolition by blasting techniques, it is to be ensured that the impact of vibration induced by the touchdown of the collapsing structure does not adversely affect the safety of the buildings nearby and delayed detonation techniques are adopted for the same (Akhil et al. 2020). The damage potential of buildings/structures, however, varies widely depending on the type and quality of construction, nature of excitation, the surrounding soil strata, structural resonance, etc. (Anil et al. 2022). This paper discusses the

grounds behind the demolition of Supertech Twin Tower, Noida, Engineering challenges behind its demolition, Evaluation made to study the impact of implosion on adjacent building, Precautionary measures adopted, instrumentation systems carried out and the observation made after the successful completion.

2 ABOUT THE PROJECT

Noida, short for New Okhla Industrial Development Authority, is a planned city located in Gautam Buddha Nagar district of the Indian state of Uttar Pradesh. The Supertech Twin Towers were located in Sector 93A, Noida, Uttar Pradesh and is close to the Noida-Greater Noida Expressway. Figure 1 shows the location of the Supertech Twin Tower, Noida. The Noida Supertech Twin Towers consisted of two buildings, Apex and Ceyane Towers. They were planned to have 40 floors each. The two structures had different heights, Apex had 32 floors and stood at 103 metres (338 ft) tall while Ceyane had 29 floors and stood at 97 metres (318 ft). Both towers together had a built-up area of around 7.5 lakh square feet.

Figure 1. Image of location of Supertech Twin Tower, Noida.

3 BACKGROUND AND TIMELINE – SUPERTECH TWIN TOWER, NOIDA

In the year 2005, the Noida Authority sanctioned the building plan for the construction of Emerald Court comprising of 14 towers, each with ground and nine floors (G+9) and the construction commenced for those 14 towers.The entire amount of leased space given to the corporation was expanded to 54,819.51 sq m in June 2006, and the plan was revised to G+11 with the addition of two new buildings. The architect updated the design in 2009 and added two additional towers with a total height of 24 storeys. The proposal was once more altered in 2012 to increase the height to 40 stories with two basements for parking. The neighborhood's Residence Welfare Association (RWA) filed a lawsuit in Allahabad High Court challenging the illegal addition of towers that were being built in 2012 but were not originally part of the plan. The high court determined the towers to be unlawful in April 2014 and ordered their demolition. The construction works were stopped in the year 2014, when the height of Apex tower was 103 meters and height of Ceyane tower was 94 meters. Figure 2 shows the image of Supertech Twin Tower, Noida before demolition.

4 CHALLENGES BEHIND DEMOLITION OF SUPERTECH TWIN TOWER, NOIDA

Emerald Court and ATS Village, two multistory building complexes, flanked the Supertech Twin Tower. Since Emerald Court and Supertech Twin Tower formerly shared a retaining wall and

Figure 2. Supertech Twin Tower, Noida before demolition.

a basement, separating them prior to the explosion was a crucial undertaking. Over 5000 people and about 2500 vehicles had to be evacuated from the area around the towers before the explosion, which presented additional challenge. It was extremely difficult for the Supertech Twin Tower to collapse and tumble since Aster 2, an apartment in Emerald Court, was only 9 metres away. Implosion has to be carried out without affecting nearby buildings in both ATS Village and Emerald Court. Underground GAIL gas pipelines were passing within the plot area of Supertech twin tower. The pipelines were 4m below the ground level and was located at a minimum distance of 23m from the towers as indicated in Figure 3. The pipeline was crucial as it supplies CNG for Noida and East Delhi. The demolition plan was to make apartment collapse into the open space near ATS Village. The total weight of Apex tower was 41720 tonnes and of Ceyane tower was 18150 Tonnes. 633 flats were booked but since the construction was not completed, the towers were uninhabited.

4.1 *Soil type and the foundation provided*

The region's soil is a medium-density alluvium soil with a predominance of sand and silt and little to no clay. Hard rock strata are followed by extremely dense silty sand deposits as the subsurface layers of these alluviums. 5m below the current ground level, there was a water table. The Super Tech Twin Towers have two basements and a piled raft system as their foundation. Aster-2 has just one basement, and it is built on a raft foundation that rests on medium-density alluvium soil. In the first basement level, the buildings were joined.

4.2 *Prediction of impact of Touch down vibration on Aster -2*

Delay detonation techniques are used to reduce the impact of falls reaching the ground. In both horizontal and vertical planes, the blast is delayed. To lessen the load that hits the ground after the explosion, structures are pre-weakened, and rubble is heaped in the basement to serve as a cushion layer. Pre-weakening entails removing all non-load-bearing walls, fixtures, mechanical devices, plumbing and piping (electrical, water, sewage, and communications), stairways, and facades, including all glazing, from the building while leaving the fundamental structural components, such as columns, beams, and floors, in place. Numerous

Figure 3. Layout of GAIL gas pipeline within the compound of SuperTech Twin Tower.

columns that contain closely pitched spirals or stirrups made of circular or rectangular steel must be exposed and chopped before they can be drilled and loaded with explosives. By removing the concrete matrix surrounding the steel reinforcing, shear walls can be mechanically pre-weakened, creating plastic hinges that will help the structure collapse once the implosion is initiated.

The formula used to determine the size of the explosive charge required to breach concrete is as per Eq. (1) (McKenzie et al.2019):

$$P = R^3 KC \tag{1}$$

Where,
P = TNT required (lbs)
R= Breaching radius (ft)
K= Material factor which reflects hardness and mass of the material to be demolished
C= Tamping factor

Figure 4 shows the layout of primary blast floors where charges will be placed in all columns and the secondary blast floors where the charges in 40% of columns.

Before conducting the implosion, the structure was examined to predict how the touch down vibration of the implosion would affect it. The peak particle velocity within a 10 m radius after the blast was predicted by the UK-based company Vibrock to be between 22 and 34 mm/s, and between 3 and 5 mm/s up to a radius of 100 m. These predictions were based on the implosion time isochrome, collapse time contour, direction of the pull, and the type of soil found at the site. The damage level for peak particle velocities up to 35 mm/sec is none, which is shown in Table 1(Chi En et al.2010). The British Standards BS 5228 advises between 15 and 50 mm/s of vibration frequency to prevent hairline plaster cracking, and when the values surpass 15 mm/s, cosmetic harm is probable. The characteristics of earthquake-induced vibrations and those caused by demolition-induced vibrations differ significantly, according to Vibrock's report. In particular, compared to earthquake vibration, which can persist for many minutes and typically consists of energy at less than 1 Hz, the vibration produced by the demolition event will be of relatively high frequency content (10 to 40 Hz) and brief duration (2-5 seconds).

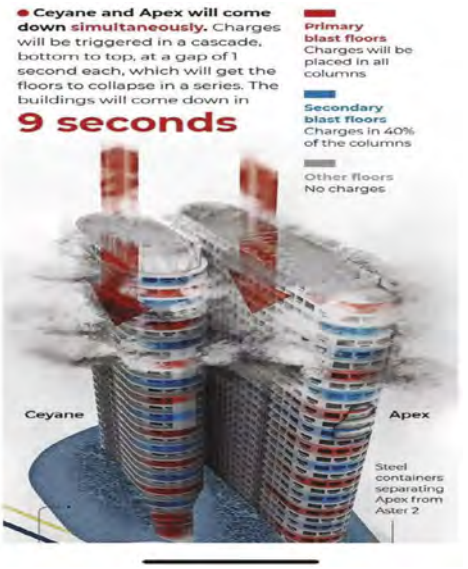

Figure 4. Layout of primary and secondary blast floors of Supertech Twin Tower.

Table 1. The relation between the damage level of buildings and vibration velocity.

Maximum Velocity of Mass Point (mm/s)	Damage Level
35	None
55	Very finest plastering cracking
80	Cracking
115	Severe Cracking

5 EVALUATION MADE TO STUDY THE IMPACT ON ADJACENT BUILDING

5.1 *Structural analysis of adjacent building: Aster -2*

Aster 2 has a basement, ground floor, and 12 floors. The Aster 2 was given top priority and was closely watched throughout deconstruction because it was only 9m from the Supertech Twin Tower. Aster 2's structural performance was assessed and modelled using ETABS, and it was exposed to various load combinations, including blast loading, and earthquake impact.

M20 and Fe 415 were the chosen concrete and steel grades for the analysis. Various load combinations were applied to the structure in accordance with the recommendations in IS 456. The seismic forces were calculated using IS 1893, the dead and live loads were obtained in accordance with IS 875, and the blast loads were acquired from data from Vibrock, UK. The maximum peak particle velocity that is predicted to occur within a 9-meter radius following the blast is 36 mm/s, which is stimulated in the model based on the vibration intensity report. Figure 5 depicts the arrangement of a typical floor, a 3D ETABS model, and a 3D rendered representation of Aster-2.

According to the analysis's findings, the maximum storey drift in the X direction for blast vibration is 720×10^{-6}, while it is 2700×10^{-6} for earthquake vibration. It has been determined that the maximum storey drift in the Y direction for blast vibration is 690×10^{-6} and that it is 2030×10^{-6} for earthquake vibration. The maximum storey displacement in the X direction is 12.5 mm for blast vibration and 95 mm for earthquake vibration. The maximum storey displacement in the Y direction for blast vibration is 16.5 mm, and if an earthquake occurs, it is 71 mm. The maximum allowable storey displacement, according to IS 1893 part 1 2016, is h/250, while the allowable displacement for Aster-2, which has a height of 48m, is 192 mm. It

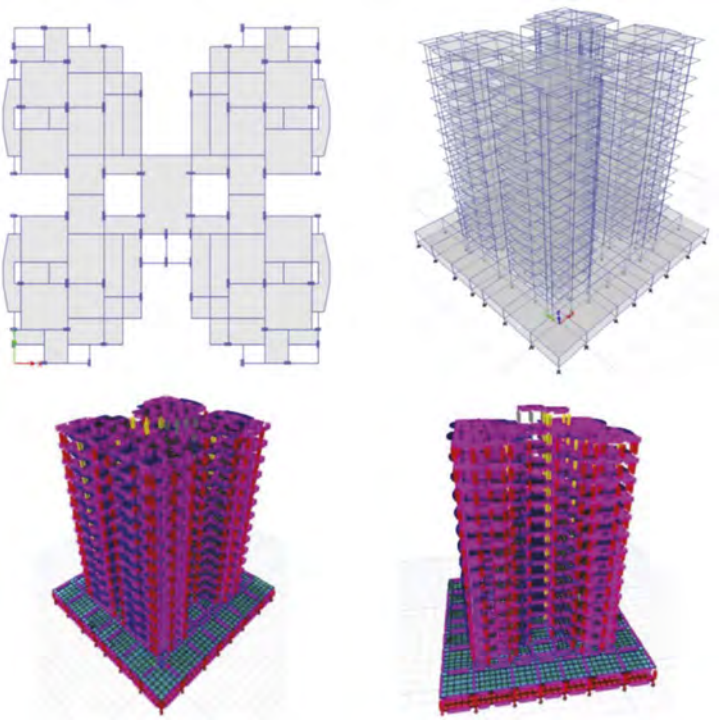

Figure 5. Layout of typical floor, 3D ETABS Model and 3D Rendered view of Aster-2.

was observed that the storey drift and displacement are well within the permitted range according to the codal regulations.

6 PRECAUTIONARY STEPS ADOPTED

6.1 *Test blast*

The test blast was conducted to determine the kind, calibre, and volume of explosives required for the demolition as well as to assess the intensity and blast radius. On April 10, 2022, at 2:30 PM IST, the Supertech Twin towers underwent a test blast. Four pillars in the basements and one on the tower's 14th floor each received test blasts. The implosion time isochrome, collapse time contour, and pull direction for the primary blast were all decided upon in light of the findings.

6.2 *Rapid visual assessment of adjacent building and strengthening*

Prior to the explosion, a visual inspection of the nearby structures, including a door-to-door survey of each apartment within the safety zone of 50 metres, was conducted to ascertain any structural damage. Pictures were also taken and recorded to compare the same after the demolition process. The typical observations made throughout the visual assessment procedure are shown in Figure 6. As illustrated in Figure 7, non-destructive tests were performed on a number of columns to determine the structure's current strength. The typical outcomes are listed in Table 2.

6.3 *Protection work for gas pipe lines, Berms, geotextile wrapping*

The 200mm gas pipeline was 23 m away from the building and was buried at a depth of 4 m. below the surface of the ground. Steel plates that were 2-3 mm thick were placed on the

ground above to protect it. Figure 8 (a) illustrates the placement of protection berms over the plates that are about 2 m high, shielded with a geotextile layer, and rubber tyres designed to deflect impacts.

In order to prevent the flying debris, the columns were covered with 4 layers of shown in Figure 8 (b) and then a further layer of non-woven geotextiles. Perimeter curtains were also provided on all blast floors as a second layer of insurance against flying debris as indicated in Figure 8 (c). As seen in Figure 8 (d), the nearby buildings were additionally covered with geotextile fabrics as a precaution against flying debris and dust collection. As shown in Figure 8

(e), a container wall was employed to divide the higher Apex from Aster 2. These containers were secured at the lower basement level, loaded with debris, and raised to the two-story level. Between the containers and columns of Aster 2 and 3, rubber tyres were inserted. A cushion layer formed of demolished waste materials was installed in the basements to control the touch down vibrations caused by the rubble falling on the ground. Figure 8 (f) shows the formation of berms and pits around the structures to lessen the transmission of vibration .

Protection works adopted for demolition of Supertech Twin Tower (a) Berms for protection of gas pipeline (b) Wire Mesh Wrapping around columns (c) Perimeter curtain geotextile walls on blast floors (d) Suspended Geotextile Curtains for adjacent buildings (e) Container wall for protection of Aster 2 (f) Impact Cushion Berms.

7 INSTRUMENTATION SYSTEMS CARRIED OUT

7.1 *Measuring ground vibrations*

Geophones and accelerometers were used to record vibration readings. Accelerometers were installed on top of the GAIL gas pipeline, while geophones were positioned 33 - 62m from the twin tower building's plinth edge and 3 m below ground level in the basement. Due to the equipment being damaged by the fall of buildings, the accelerometer data were lost. According to data gathered from accelerometers and geophones, the peak particle velocity in the vertical direction at the basements of ATS Village and Emerald Court varied from 6.42 mm/s to 7.27 mm/s and 7.25 mm/s to 7.28 mm/s, respectively. Figure 9 depicts the positioning of accelerometers and geophones. The crack meters were installed wherever minor cracks were noted in the structures within the safety zone. Figure 10 displays the standard crack meter positioning.

Figure 9. Measuring ground vibrations by placing Accelerometers and Geophones.

Figure 10. Crack meter reading pre and post blast.

8 POST DEMOLITION WORKS

The demolition of the structure was carried out on 28th of August 2022 at 2.30PM. After the demolition, the post blast survey of the adjacent buildings was carried out. Few superficial cracks were noted to be widened after the blast. Since, these cracks are of superficial in nature, they do not affect the structural elements. The comparison of the readings of crack meter pre and post blast is indicated in Figure 10. The vibration measurements from geophones indicate only minor impact on the structure within the safety zone as explained in Section 7 of Instrumentation system carried out. Some glass and windows were found damaged and was rectified. The demolition waste is used as fill materials for the construction of roads and a minor quantity is recycled as aggregates. The steel components were removed from the debris and is send to steel plants for recycling. Figure 11 shows the structure after the collapse and Figure 12 shows the image of the build environment before and after the blast.

Figure 11. Structure after the collapse.

Figure 12. Build environment before and after the blast.

9 SUMMARY AND CONCLUSIONS

Applying the implosion method in highly populated urban regions presents a number of difficult issues, necessitating appropriate prudence and preventative measures. Based on the implosion time isochrome, collapse time contour, direction of the pull and type of soil identified at the site, the UK-based company Vibrock predicted that the peak particle velocity within a 10 m radius of the blast would be between 22 and 34 mm/s. According to the codal laws, it was determined from the evaluation done to study the influence on nearby buildings that the storey drift and displacement caused by blast-induced loadings are well within the authorised range. According to geophone data collected during the blast, the peak particle velocity in the basements of ATS Village and Emerald Court was lower than expected, demonstrating the effectiveness of the preventative measures taken. There were no discernible differences between the crack meter readings before and after the explosion. Using the controlled implosion with delayed detonation strategy, high rise buildings in urban areas can be successfully brought down with a great level of speed and cost effectiveness, with minimum damage to neighbouring structures and the technology will be used extensively in the near future for redevelopment projects.

Study of slope failure in two regions: A comparative study between Penang Island Malaysia and North Sumatera Indonesia

F. Ahmad
School of Civil Engineering, Universiti Sains Malaysia, Engineering Campus, Nibong Tebal, Penang, Malaysia

I. Puji Hastuty
Lecturer, Department of Civil Engineering, Universitas Sumatera Utara, Sumatera Utara, Indonesia

ABSTRACT: Penang and North Sumatra are two of the regions which seldom have cases of slope instability which causes landslides. Two different site for the study are in the Penang Island, Malaysia and the North Sumatera along Medan-Brastagi Road, Indonesia where the condition for both sites seem to be similar where the area are prone to its natural disaster which lead to landslide after the area has been developed either for road construction, building a housing scheme or a resort development. The condition of the area development that took place required to cut and fill along the terrain and usually the hill site are made of rough topography with undulating hill site reliefs and the slope angles are between 60°-90°. The literature on landslide susceptibility analysis will be reviewed in accordance to its geological formation and the rainfall analysis that has shown the triggering factors after rainfall event. The main summary of the incidences will be reviewed and classification approaches that have been developed to study the parameters, methodologies, and tools used to obtain a landslide hazard map. Base on the hazard map, the area can then be identified and verified by identification the main factor that causes the slopes failure/landslides. In summary the numbers of site in hillside development in Malaysia or Indonesia are due to rainfall, storm water activities and poor slope management and maintenance. Therefore, it is important to practice good planning, proper design, sustainable construction and regular maintenance so as to achieve a community safe slope and cost-effective hill site development.

1 INTRODUCTION

1.1 *Locations*

Penang Island and Medan, North Sumatra are the areas where landslides often occurred as in Figure 1 showing the location of the study in the map. Most of the prone area were located alongside the developed area and majority were along the road side. As for both area they can be classified as a landslide prone area where both sites have rough topography with the undulating hillside reliefs where the slope angle can be between 60-90 degree. As in Penang Island the failure has been due to induced rainfall where the data shown almost every year the landslide occurred, same as in Medan, the road along Medan-Berastagi. The record on both landslide susceptibility analysis in Penang Island and Sibolangit - Karo areas, where the two sites as shown in Tables 1 and 2. This article presents summary review and classification of the main approaches that have been developed with the parameters, methodologies, and tools used to obtain a landslide hazard map.

1.2 *Site conditions*

The in-situ behavior of soils is complex because it is heavily dependent on numerous factors. To acquire appropriate understanding, it is necessary to analyze them not only through geotechnical

engineering skills but also through other associated disciplines like geology, geomorphology, hydrogeology, climatology and other earth and atmosphere related sciences. However, it is known that the problems, even when tackled within the framework of geotechnical engineering, are huge and arduous. It is understood that geotechnical problems with socio-economic impacts like landslides can only be addressed within a framework that accounts for behavioral features in natural soils. Research is actively taking place in many countries, each focusing on natural deposits of local importance, and a unified framework that can account for all important effects is still being developed [Grove, 1980]. The development of this unified framework requires a huge and joint effort from as many sources as possible taking underway the best of their academic and technical skills and using best possible instruments. Therefore, the study is to summarize the index, strength, compressibility and field properties of tropical residual soils of Penang and North Sumatra base on general conditions and its correlations.

2 METHODOLOGY

2.1 *Data collections*

The study of the slope failure requirements was done as follow:

- To characterize landslide parameters.
- To evaluate slope failure during field study.
- To analyze the factors that trigger landslides.
- To develop risk map using GIS and risk assessment.
- To follow the guideline of hillside development for local government.

The main purpose of this review is to analyze the factors for both sites where the review result will indicate the failure of the slopes concerned were based on the rainfall event and factors affecting the failure which led to land sliding.

2.2 *Risk assessment*

Base on all the parameters of landslide vulnerability analysis that has been carried out in Sibolangit District using Geographic Information System (GIS) (Puji Hastuty et al, 2020) this was observed by the population density and slope angle factors. The data from Badan Pusat Statistik [2018], population density in Sibolangit is around 21.5 – 582.5 people/km2. Final hazard map can be obtained by calculation of total score; the scoring/ weighting method referred to Puslittanak Bogor [2004]:

$$\text{LHI} = (0.4\text{PD} + 0.2\text{JD} + 0.2\text{NW} + 0.1\text{NE} + 0.1\text{NC}) \quad (1)$$

Where, LHI = landslide hazard index, PD = Population Density, JD = Job Description, NW = Number of Women, NE = Number of Elderly, NC = Number of Children.

The parameters used in this study were angle of slope, slope water management, soil conditions, seismicity, constituent rocks, vegetation, and rainfall where scoring and weighting referred to Peraturan Menteri Pekerjaan Umum No.22/PRT/M/2007 [5] which can be formulated as follows:

$$\text{LHI} = (0.1\text{CP} + 0.2\text{SE} + 0.1\text{PC} + 0.1\text{SD} + 0.2\text{BC} + 0.2\text{PD} + 0.1\text{ME}) \quad (2)$$

Where, LHI = landslide hazard index, CP = Cropping Patterns,
SE = Slopes Excavation and Cutting, PC = Pond Construction, SD = Slope Drainage,
BC = Building Construction, PD = Population Density, ME = Mitigation Efforts.

Based on Figure 2 for Medan and Figure 3 for Penang, it can be seen that population density in areas with slopes above 45% affects the level of vulnerability to landslides in Penang island and Sibolangit District and Karo Regency. The reason is that the land has changed its function due to the need for regional infrastructure. From Figure 2(a) and (b); it was concluded that three villages were classified as very high landslide prone areas with a population density of 423.81-582 people/km2 and a slope of > 45%. Study conducted in Penang by Ahmad (2014) described >500 people categorized as very high-density population, developed areas such as residential buildings with no less than 100 units; the number of people at risk is very high. The land is also not suitable for development because it is very risky to humans and the environment and is considered the most likely to experience slope failure. According to Althuwaynee (2017), high population density is directly related to the high density of residential buildings where the population density is between 700-1500 person/acre, but this area is not the riskiest areas to landslide. Slope instability generally occurs due to natural processes, but some of the results of uncontrolled human activities in exploiting nature can also be a factor causing slope instability which can lead to landslides. The

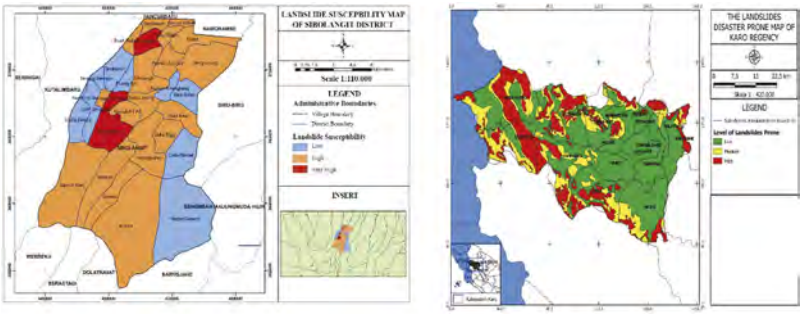

Figure 2. Landslides susceptibility Map; (a) Sibolangit District (b) Karo Regency.

risk is concentrated more of population concerned in terms of direct social impact towards the safe community and safe infrastructure.

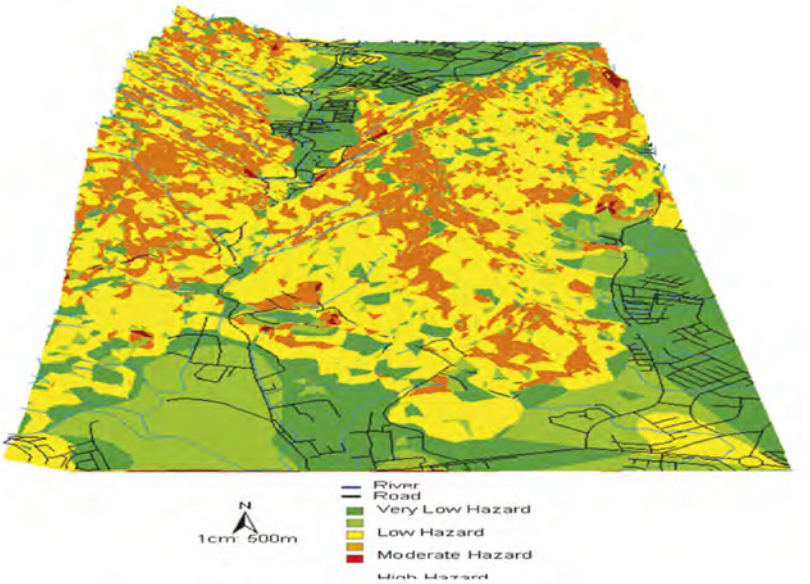

Figure 3. 3D Landslide susceptible map of Penang Island.

3 RESULT AND DISCUSSION

3.1 *Rainfall*

The geography of Penang, Malaysia and Medan is situated in close proximity to the equator, hence exposing this region to the tropical humid and dry climate every year. In addition, this region has received an abundance of tropical rain each year in conjunction with the monsoon or rainy season. This monsoon season usually occurs twice a year (November until March) and (May-September). For the record, in 2017, Peninsular Malaysia recorded an average rainfall of 2702 mm. This indication of high annual rainfall can be a significant factor contributing to a landslide where it shows the significant factors causes landslide. This is due to the presence of sporadic extreme precipitation that triggers the unforeseen slope failure. Therefore, the effect of climate is vital in inducing the occurrence of the landslide (Ahmad, 2018). The rainfall of 30 years show the pattern of rainfall exceed the average rainfall in Penang. Figure 4 shows the time series plot of annual mean total rainfall for all stations from 1984 to 2013. For Sumatera regencies, 90% of the area were having rainfall intensity of 2001-2500mm/year and this were considered extremely high and other of the regencies were between 1500-2000mm/year (high intensity). This shows that the area is exposed to extreme conditions when it comes to rainy season which is almost the same as in Malaysia. The yearly rainfall for Karo Regency as shown in Figure 5.

The study of rainfall thresholds for predicting the landslide for Peninsular Malaysia, which elaborates on the landslide classification, the triggering factor of landslide for Malaysia, the mechanism of intense rainfall induced shallow landslide, the historical development of I-D threshold for estimating the mass movement [Abdul Muaz, 2021]. Then, it will explain the effect of antecedent rainfall that influence the slope failure, and the application of rainfall threshold in the Landslide Early Warning System (LEWS). The 30 days antecedents as in Figure 6, show an example of 15 August till 13 Sept 2013, at Air Itam in Penang that indicate the pattern of rainfall.

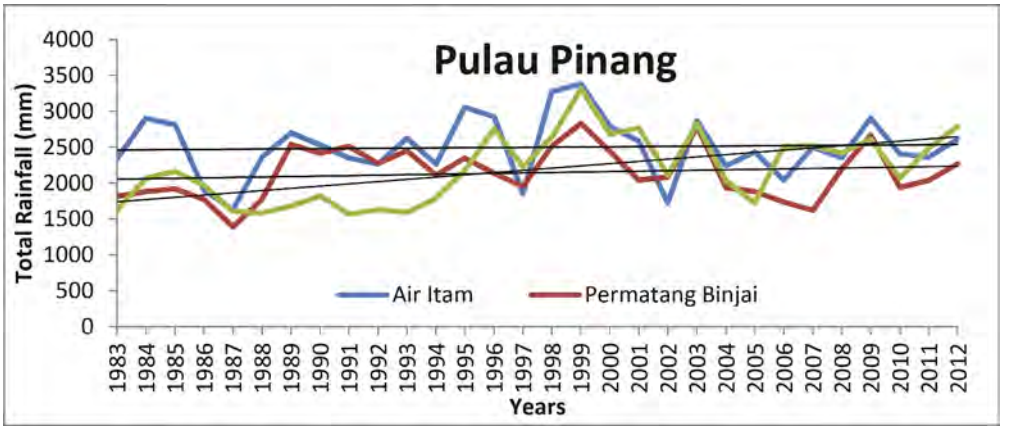

Figure 4. Time series plot for Pulau Pinang.

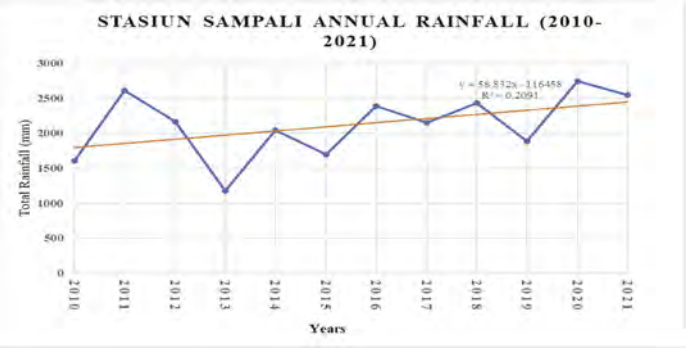

Figure 5. Annual rainfall for Karo regency (2010-2021).

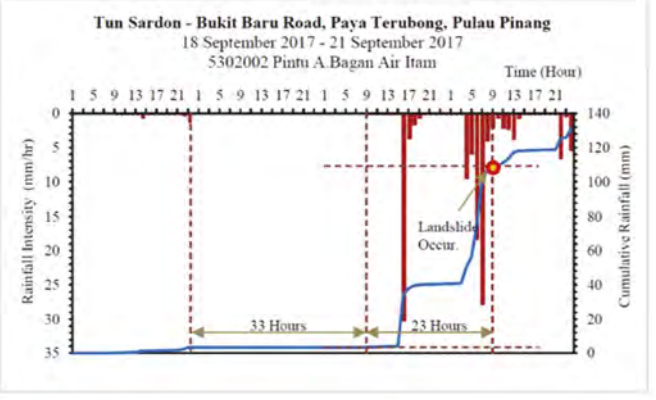

Figure 6. 30 days antecedent rainfall for the landslide at Bendera Hill, Air Itam, Penang [Muaz, 2020].

3.2 *Landslide occurances*

From the Figure 7 at Medan – Berastagi road, Karo Regency; it was concluded that five districts were classified as high landslide prone areas. Uncontrolled human activity in exploiting nature has a big share in the occurrence of landslides. The construction of building,

excavation, and slope cutting are the parameters that influence the occurrence of landslides the most. The reason is because it has an indicator weight by 20%, so that the high landslide hazard level is mostly located in areas that have a high level of construction and slope cutting, Puji Hastuty et al (2021).

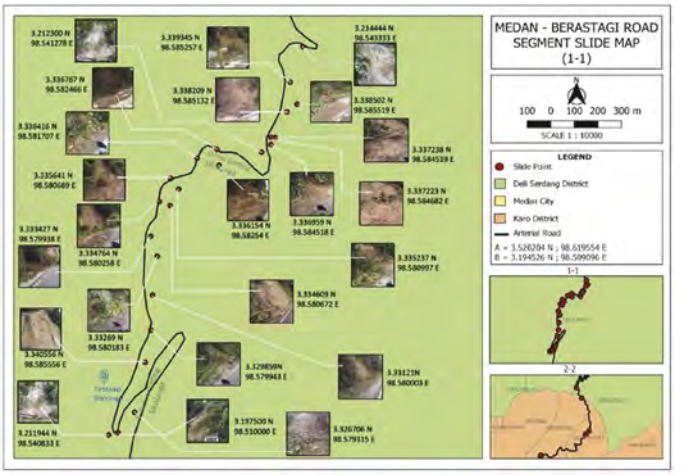

Figure 7. Landslide events along Medan – Brastagi road.

As for Penang Island, the landslide events that were critical cases are as listed in Table 3 and Figure 8 to show the occurrences of the failure after heavy rainfall over long hours during the monsoon season.

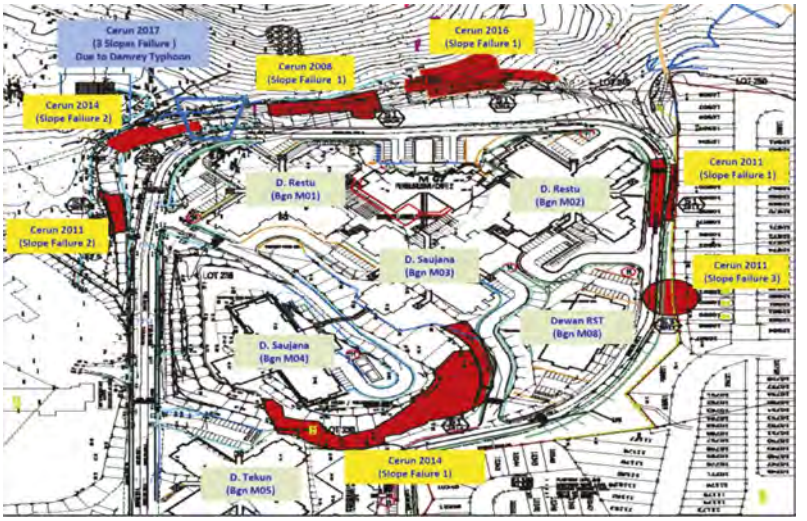

Figure 8. Landslide/Slope failure events at University Sains Malaysia from year 2011 till 2017.

4 CONCLUSION

In Malaysia or in Indonesia we can conclude that the behaviour of landslide due to slope instability are caused by development in hilly area. These activities created the disturbance to the geological and properties of the sites plus the triggering factors that happen after certain durations of rainfall events due to monsoon season and the fact that due to climate change. The unpredictable increase of rainfall intensity does affect the conditions of the slope especially if the slope is exposed and this can cause or triggered ingression of water on the ground.

As for housing development and human activities show that the growth is very significant increase especially to developed at high land or hilly terrain area. Therefore, the right guideline for hillside development needs to be follow and need to design in accordance to the slope stability requirement.

ACKNOWLEDGEMENT

Electrokinetic enhancement of microbial induced calcite precipitation used in improving the shear strength of soft clay

Mahdi Karkush & Nawar A. Ali
Department of Civil Engineering, University of Baghdad, Baghdad, Iraq

ABSTRACT: In recent years, and from the principle of sustainable development to reduce chemical pollution, researchers around the world have begun to use microorganisms to induce the precipitation of calcium carbonate which is a biological ground improvement method that has been successfully used to improve sandy soil. Also, the electrokinetic method is a soil improvement technique without excavation, unlike traditional methods. In this study, MICP and electrokinetic techniques were used to improve the geotechnical properties of soft clay. A large bench scale will be used for this purpose. The test model was using graphite electrodes with a voltage gradient of 50 V/m. This study was carried out in two phases. The first phase included using a concentration of prepared Bacillus sonorensis 12×10^{-7} cfu while the second phase was 1×10^{-4} cfu for cementation reagent (0.25M, 0.5M, and 1M) during the period of treatment for each phase. The results showed the following. precipitation of calcite was considered to be the main reason causing a significant increase in shear strength by about (600-1350%) for Bacillus sonorensis 1×10^{-4} and (800-2000%) for Bacillus sonorensis 12×10^{-7} cfu.

1 INTRODUCTION

Electrokinetic is a reliable method for transport under the electrical potential of charged particles and fluid. The EK shows changes in soil pH due to electrolyzes, water flow between electrodes, and cathode migration. This treatment has proved to be less costly than other methods in the processing of organic, toured, and clay silt. Otherwise, this approach also gives a nondestructive advantage to the site. Electrokinetics been proven as hardening technique for soft clay in recent years through the electroosmosis of the pore water in the soft clay and at the same time the injection of a chemical grout into the soft clay, in order to increase the soft clay properties. Laboratory and field studies have confirmed the efficacy of this approach many times (Chien et al., 2009). The techniques of artificial cementation are not always practical and are environmentally friendly. The reduction in the use of artificial cementation techniques can, however, be accomplished by replacing environmental techniques or materials. The Microbial Induced Calcite Precipitation (MICP) is a form of soil stabilization. This technique uses microbes as the primary soil stabilization element. Efficient implementation of MICP can be applied in a wide range of areas of civil engineering, such as wall retaining stability, embankments, and dams, soil erosion management, stabilizing cohesionless soil to promote soil stability, increasing shallow and piled foundation hold capacities and reducing liquefaction potential soil (Ivanov & Chu 2008).

MICP is a soil treatment process based on the urease hydrolysis of bacteria containing the urease enzyme, resulting in calcite precipitation in the presence of dissolved calcium ions. Electrokinetic is a reliable method for transport under the electrical potential of charged particles and fluid. The EK shows changes in soil pH due to electrolyzes, water flow between electrodes, and cathode migration. This treatment has proved to be less costly than other methods in the processing of organic, toured, and clay silt. Otherwise, this approach also gives a nondestructive

DOI: 10.1201/9781003299127-14

advantage to the site. Soft clay is a late alluvial deposit that has probably been formed over the last 10,000 years by its flat terrain (Abbawi 2010). They have high natural moisture levels generally (40%-60%), while plasticity is between (45%-65%). The major problems of soft soil are excessive settlement, low shear strength (bearing capacity), and Liquefaction (Abbawi 2010). Bacterial transportation is limited in fine-grained soils (and thus bacterial activity). Because bacteria are of a typical 0.5 to 5 μm size, they are not conveyed via silty or clayey soil and are not used for the induction of carbonate precipitation in those layers (Mitchell and Santamarina 2005).

Consequently, the Electrokinetic technique can enhance this green technique in fine-grained textured soil. Precipitation of microbiologically induced calcium carbonate (MICP) is a relatively common reaction that has been successfully used to improve sandy soil. Presently, only sandy soils are subject to specific research findings and only small studies are performed with single specimens. Over the past decade, numerous researchers have experimentally studied MICP (Dejong et al. 2006; Whiffin et al. 2007; van Paassen, 2009; Karkush et al. 2022) to provide a fair level of understanding of the processes involved. Nevertheless, soft clay layers also need improvement in the engineering industry to increase their strength. The use of the new microbial-induced soil enhancement technique in practical applications, therefore, depends on whether the technique applies to soft clay layers and can strengthen them effectively. Although few studies have been published on clay soils (Chien et al. 2018, Sharma and Ramakrishna 2016, Karkush & Altaher 2017a,b; Karkush and Ali 2019a,b), results are inconsistent and remain in the laboratory stage due to the uncertainty and complexity of the clay soils, the geochemistry of the soil, bacteria, and environmental factors. The objectives of the present study are to investigate the effect of MICP enhanced with EKs to improve the shear strength of soft clay soil.

2 SOIL AND MATERIALS USED IN TESTS

2.1 *Soil sampling*

A clayey soil sample was brought from Al Nahrawan city which is located 35 km to the east of Baghdad city from a depth of 9 m below the existing soil surface. Standard tests have been conducted to specify the chemical, physical, and mechanical characteristics of the soil samples. The physical and mechanical soil tests were conducted on the soil samples at the Laboratory of soil mechanics at the Department of Civil Engineering/University of Baghdad, while the chemical tests are conducted for both treated and untreated soil samples in the Department of Materials Research/Ministry of Science and Technology. Table 1 shows the results of physical, mechanical, and chemical tests.

Table 1. The physical and chemical properties of natural soft soil.

Index property	Test standard	Value	Index property	Test standard	Value
Liquid limit, %	ASTM D 4318	49	Gypsum content, %	BS. 1377:1990	1.17
Plastic limit, %	ASTM D4318	24	Chloride content, %	BS. 1377:1990	0.628

pH Value	ASTM D 4972	8.45			

2.2 *Bacterial selection*

The bacteria selected in this study are previously isolated by Ali et al. (2020) from the Iraqi soil sample. The bacteria obtained from local sources denoted as C11 was identified to be Bacillus sonorensis. These isolates were routinely maintained in a growth media called nutrient agar which was supplemented with 20 g urea substrate, serving as a source of energy and nitrogen. The media was stored at 4°C in the fridge, before being used for subsequent tests of treatment. The bacteria were cultivated in the same way from a bacterial culture not grown for more than one month.

2.3 *Preparing of urea nutrient agar and bacteria culturing*

Urea nutrient agar was generally used to cultivate all the Bacillus spp. that could hydrolyze the urea. Table 2 shows the solid and liquid contents of the media. To prepare this media, the solid components were added to distilled water to bring the volume to 1 L and mixed well. The mixture was then gently heated and brought to a boiling temperature. Later, it was autoclaved for 15 min at 15 kPa pressure at 121°C. After autoclaving, it was cooled to 50–55°C. The urea solution was prepared by dissolving 10 g of urea in 50 mL of distilled water, and then the prepared solution was sterilized using a bacterium filter (diameter of this filter 0.25 μm). A total of 50 mL of sterile urea solution was added to the mixture and mixed well. The urea nutrient agar medium was then immediately poured into approximately 20 culture plates under a laminar flow hood.

Table 2. Details of the solid and liquid contents of the media.

Composition	Quantity
Nutrient agar	28 g/l
Urea solution Add 20 g of urea to distilled water and bring the volume to 100 ml, mix well, filter, and sterilize.	50 mL

2.4 *Purging solutions*

To prepare the bacterial treatment solution, a urea medium was first created. Nutrient broth (3 g), NH_3Cl (10 g), $NaHCO_3$ (2.12 g), and 450 ml of distilled water, as shown in Table 3, were mixed to create the urea medium solution. Each of the solid ingredients was mixed thoroughly in 450 ml of distilled water until it had dissolved. After autoclaving, Distilled water with urea after sterilization using a bacterium filter (diameter of this filter 0.25 μm) was then added to reach the final required volume (500 ml). The tube of diluted culture was added to the flask of the treatment solution. The flasks containing the growth medium were then cultivated for 48 hours with agitation (130 rpm) in an incubation shaker under aerobic batch conditions at 37°C. For injection, after incubation adds sterilized calcium chloride. While for the electrokinetic test the solution of bacteria and urea was added to the Cathode chamber without mixing with urea Cementation reagent was prepared by adding equal molars of Urea and Calcium Chloride ($Ca^{+2} + CO_3 \rightarrow CaCO_3$). The concentration of bacteria and cementation reagent (urea, calcium chloride) was a governing parameter and hence was decided based on the study by Lee et al. (2012) and varied 0.25M, 0.5M, and 1.0M.

Table 3. Bio-cement treatment components.

Component	Amount	Component	Amount	Component	Amount
Nutrient broth powder	3 g	$NaHCO_3$	3 g	Urea ($NH_2(CO)NH_2$)	0.25M, 0.5M, 1M
NH_4Cl	10 g	Distilled water	1 L	$CaCl_2.2H_2O$	0.25M, 0.5M, 1M

3 PHYSICAL MODELLING AND TESTING PROCEDURE

3.1 *Physical model*

The electrokinetic (EK) model was manufactured locally and modified to achieve the objectives of this study. A schematic and the detailed dimensions of the electrokinetic system used in the experiment are shown in Figure 1. The major components of the system are:

1) A power supply: which is used to apply a constant voltage and read a continuous electrical current during the time of the experiment. It is capable of supplying a maximum voltage of 60 Volts and a maximum current of 5 Amps.
2) Electrodes were made from graphite plates (Graphite Laminate SLS) placed into the chambers. The graphite electrodes do not corrode or introduce any secondary products into the system. The electrodes in this work are 20 mm thick, 150 mm long, and 300 mm high.
3) Two Mariotte bottles maintained a constant water level across the specimen and prevented any hydraulic gradient. Any excess fluid transported owing to electro-osmotic flow was collected in cylinders placed at the end of the chambers. Normally, the flow will be from the anode to the cathode. However, as the electro-osmotic flow direction is reversed under the polarity reversal condition, the Mariotte bottles and cylinders were placed on both sides.
4) A voltmeter was used to measure the voltage potential between two points in an electrical circuit across the specimen.
5) Electrokinetics rectangular cell: the electrokinetics cell consists of three compartments, one for the soil sample and two for electrodes (anode and cathode) which was made of a stainless-steel plate with 5 mm thickness braced externally by steel angles at their corners, edges, and each side and inner coated with two layers of fiberglass to prevent electric conduction manufactured of dimensions 800 mm in length, 600 mm in width and 550 mm in height. The dimensions of the soil compartment are (600×600×550) mm; the electrodes (anode and cathode) compartment each is 600 mm in length, 100 mm in width, and

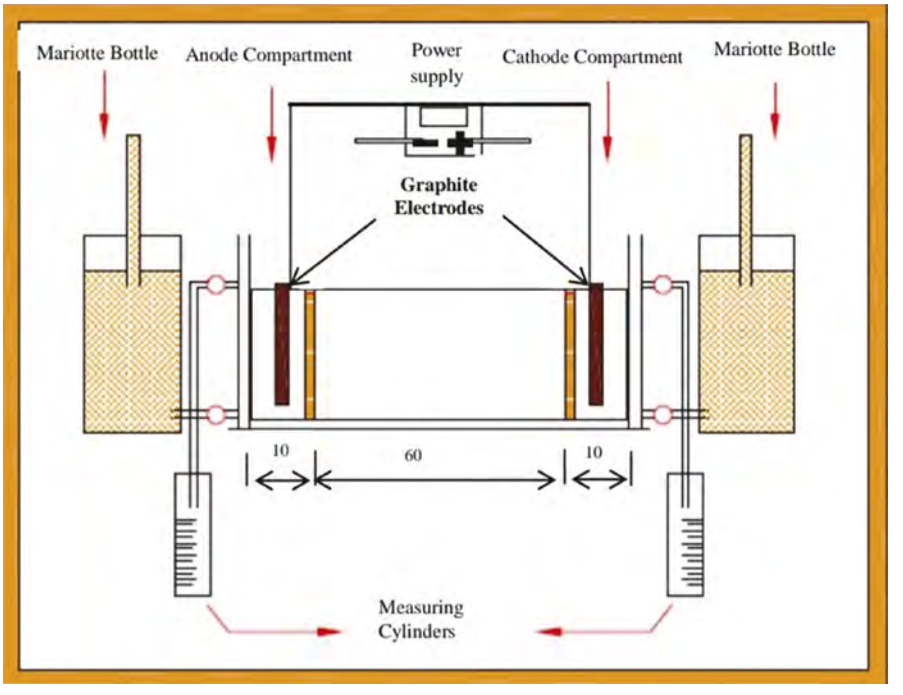

Figure 1. Schematic diagram of the electrokinetic setup.

550 mm in height. Each electrode compartment comprises a valve to manage the flow into the cell, a graphite electrode, and filter paper. The filter paper is used to prevent soil particles from the entrance into the anode reservoir or the cathode reservoirs.

6) Also, a pH meter (HANNA HI 96107) is used to measure changes in the pH of the solution in the cathode and the anode compartment and measure the pH of the soil after treatment. The outflow through the electrode compartment was also monitored to determine the electro-osmotic flow (EOF).

3.2 *Preparation of soil samples*

Trial testing was conducted to control the efficiency of the preparation process before the preparation stage of the bedding soil. Two key aspects of critical importance for preparing the homogenous soft soil bed have been tested via control tests. The first is to depart with various contents of water (or liquidity indexes) the variation of shear strength. Various trials have been done and typical findings are shown in Figure 2. With an increased liquidity index, the shear strength of the soil decreases. The second point, the variation in soil shear strength with time after mixing is determined. Such experiments provided the time required to recover strength in the remolded soil after a period of rest following the mixing process. Six samples have been prepared individually and placed in five layers inside CBR molds to achieve this aim. A special hammer for removing entrapped air was gently tamped on each layer. The samples were then wrapped with a plastic sheet of polythene and left for 8 days. Every day, the van shear system measured the undrained shear strength. Figure 3 demonstrates the effects of the increase in undrained shear strength over time. For the liquidity index range, with an increased liquidity index, the time influence decreases.

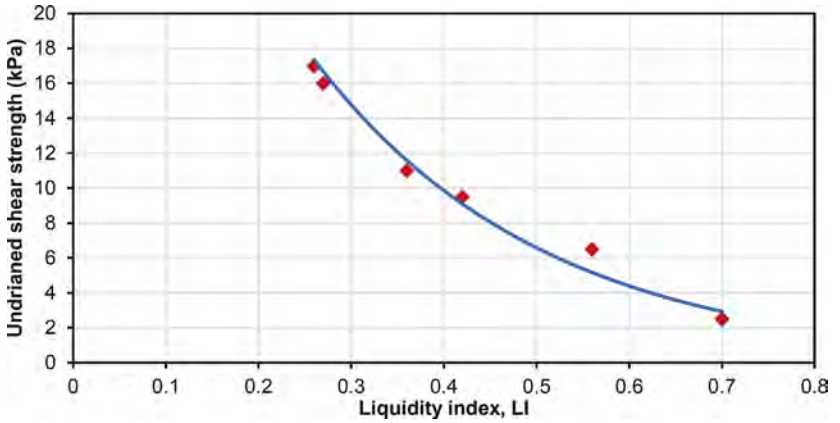

Figure 2. Variation of undrained shear strength with liquidity index for the remolded clay after 96 hrs.

The test was carried out at a liquidity index of 0.4 with c_u equal to 10 kPa. In order to achieve the necessary coherence, 650 kg of natural soil was mixed with enough water. The required water was thoroughly mixed with every 10 kg of soil by hand until the entire volume was completed and saved in plastic bags, not less than four days, to achieve uniform moisture content. The soil was then placed in a container of steel (600×600×400) mm in ten layers; each layer was tamped gently with a manufactured metal hammer of 10 kg and the dimension of (100×100) mm to remove any entrapped air, as shown in Figure 4. This process continues for the ten layers until reaching a thickness of 400 mm of soil in the steel container. The top surface was scratched and leveled after finishing the last layer so that a smooth surface could be made as near as possible, then covered by polythene sheets to ensure no moisture loss. Over the bed was placed a wooden panel of the same size as the floor area of the bed soil (600 to

600) mm and a fixed pressure of 5 kPa was applied. The prepared soil had been permitted to recover its strength (10 kPa) for a maximum of four days.

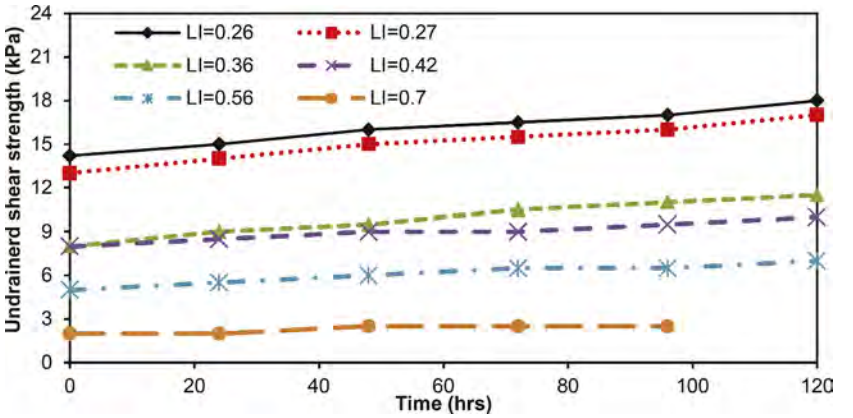

Figure 3. Variation of undrained shear strength versus time for the remolded clay.

3.3 *Testing procedure*

The testing procedure can be summarized by the following points:

1) Prepare the electrokinetic cell with all parts described previously (electrodes, treatment solution, and equipment and device used to control hydraulic and voltage gradients).
2) Putting the soft soil sample in the electrokinetic cell. The filter papers were inserted into the perforated sides of the soil container walls.
3) The electrode compartments are stuffed with a treatment solution. The anode reservoir was filled with calcium chloride solution was injected into the anode chamber for 3 days (T1) at the beginning of the test then add 0.1 M of NaOH was to maintain a pH higher than 2, whilst the cathode reservoir was filled with a solution of bacteria with urea (bacteria culture, urea, Nutrient broth (3 g), NH_3Cl (10 g), $NaHCO_3$ (2.12 g) for 7 days (T2).
4) Then, the electrodes are connected to the power supply with a potential gradient of 50 VDC/m applied to the soil sample.
5) The electric current across the soil sample, the water flow within the cathode compartment, and pH in the anode and cathode compartments were measured every day during the test period.
6) The shear strengths were measured by a vane shear device after 4 days of curing across the soil specimen at the horizontal distance of 0, 150, 300, 450, and 600 mm from the cathode to the anode. In the transverse direction, the vane shear test was conducted at three points at the same level, so the shear strength measured at each distance is the average of three readings.
7) The test is stopped when the current becomes constant or there is no noteworthy change in EO flow was observed.
8) At the end of each experiment, the aqueous solution from the reservoirs and the electrode compartments are gathered and examined. The electrodes, the tubing, and the reservoirs are exchanged at the beginning of each new test; Table 4 shows the main conducted experimental program.

4 RESULTS AND DISCUSSION

Figures 4 and 5 clearly show the undrained shear strength profile of the treated soft soil for soil treated with bacterial concentrations 10^7 and 10^4 cfu/ml with different cementation

Table 4. Main experimental testing program.

Phase 12×10^{-7}					
Code	Test	Anode	Cathode	EK Duration	Purpose
T1	$CaCl_2$-DW	$CaCl_2$	DW	3 Days	Effect of concentration of urea with bacteria and $CaCl_2$ (0.25, 0.5, 1) M
T2	DW-Urea with bacteria	DW	Urea with bacteria	8 Days	
T3	Measurement of Voltage	$CaCl_2$-DW- Urea with bacteria		1-11 Days	
T4	Measurement of the value of UCT and $CaCO_3$			16	
Phase 48×10^{-4}					
Code	Test	Anode	Cathode	EK Duration	Purpose
T1	$CaCl_2$-DW	$CaCl_2$	DW	3 Days	Effect of concentration of urea with bacteria and $CaCl_2$ (0.25, 0.5, 1) M
T2	DW-Urea with bacteria	DW	Urea with bacteria	8 Days

T4	Measurement the value of UCT and $CaCO_3$			16	

reagent molar concentrations. The value of undrained shear strength for the soil treated with bacterial concentration 10^7 cfu/ml and with a molar concentration of calcium chloride and urea (0.5M) is increased above the control line, raised to about 120 kPa near the anode and then the values increase toward the cathode until it gained a higher strength of about 205 kPa at the proximity of the cathode, while the molar concentration (0.25M and 1M) tests start at a lower value which is around (85 and 90) kPa respectively at the anode. Then starts to increase steadily and reach the maximum value of 145 kPa and 160 kPa for samples treated with 0.25M and 1M respectively. Also, for the soil treated with bacterial concentration 10^4 cfu/ml system, the trend was almost similar with the 10^7 cfu/ml but at a lower value of c_u that is from 60, 80, and 75 kPa to 85, 135, and 100 kPa from the anode to cathode with the molar concentration (0.25, 0.5, and 1) M respectively.

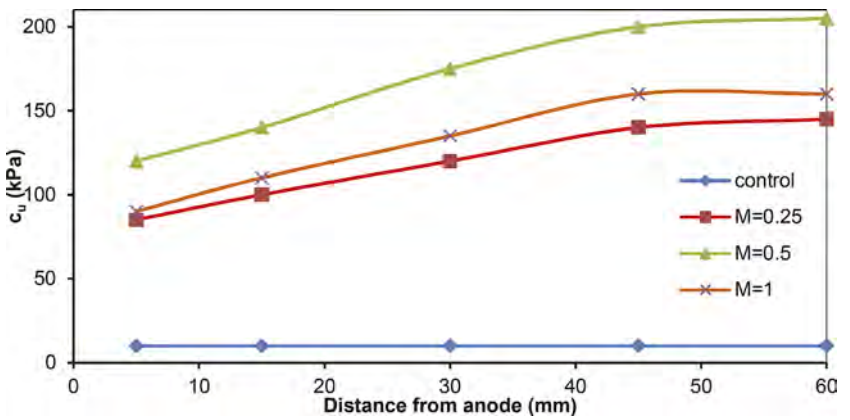

Figure 4. Undrained shear strength of soil treated with bacterial concentration 10^7 cfu/mL system with distance from the anode.

In general, this clearly shows the highest values of the undrained shear strength of all treated soils by 0.5M, whereas for the soil treated with cementation reagent molar concentration 1M, it did less than 0.5M and more than 0. 25M. Therefore, it can be concluded that the

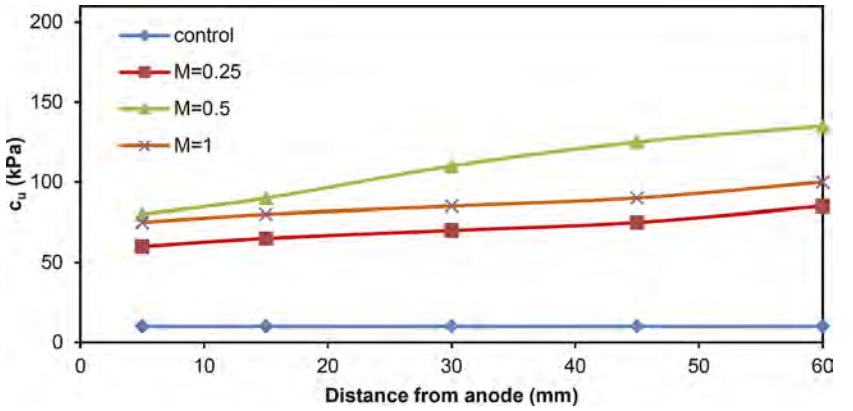

Figure 5. Undrained shear strength of soil treated with bacterial concentration 10^4 cfu/mL system with distance from the anode.

precipitation of calcite has a greater influence on the shear strength of the soil under electrokinetic stabilization treatment and will be validated with the other physical and chemical parameters later on. The soil strengthening at the cathode is attributed to the precipitation of calcium and because of the high concentration of carbonate ions (CO_3^{-2}) form cementing agent that bind the soil particles together. The high cementation reagent molar concentration and bacterial concentration that dominates the ionic concentration of the pore cause numerous electrochemical effects in the soil electrolysis, cations exchange, precipitation of salts, or secondary mineral, physical and chemical adsorption, and fabric change. All these factors are interrelated with each other and contribute to the changes in soil behavior due to electrokinetic stabilization treatment.

5 CONCLUSIONS

The following conclusions are made based on the outcomes of experimental tests:

- The undrained shear strength (c_u) of the treated soil was higher than the soft clay concerning different concentrations.
- The highest value of the undrained shear strength of all treated soils by 0.5M, whereas for the soil treated with cementation reagent molar concentration, 1M did less than 0.5M and more than 0. 25M.
- For the soil treated with bacterial concentration 10^4 cfu/ml system, the trend was almost similar with the 10^7 cfu/ml but at a lower value of c_u.
- The bearing capacity of the square footing increased with the increase of the molar concentration. Soil treated with the 0.5M test showed the highest value. However, the bearing capacity of soft soil treated with by EKs test is higher than soft soil treated with the biocementation test.

Geomembrane barrier systems for construction and rehabilitation of embankment dams

D. Cazzuffi
Cesi SpA, Milan, Italy

D. Gioffrè
University of Pavia, Pavia, Italy

ABSTRACT: The main goal of this invited lecture is to discuss the use of geomembranes in embankment dams in order to understand and to evaluate the geosynthetic barrier function in different types of applications, both for the new constructions and also for the rehabilitation of existing dams. Presently, in more than 200 embankment dams worldwide, geomembranes are in fact the main waterproofing component, including the Contrada Sabetta rockfill dam in Italy, that dates back to 1959, being recognized from the international literature as the oldest geomembrane application in dams in the world. The use of geomembranes is generally associated with other types of geosynthetics performing various functions, as geotextiles for mechanical protection and local drainage, or also as geonets for more extended drainage, thereby forming a geosynthetic barrier system. In the invited lecture, the uses of geosynthetic barriers in the construction of new dams and also in the rehabilitation of existing dams around the world are critically reviewed. Design and construction aspects are considered, as well as selection and specifications of the various types of geosynthetic materials. In particular, the issue of sustainability matters on the use of geomembranes in embankment dams compared to the use of other traditional materials (as granular and cohesive soils, metallic blankets and bituminous concrete layers) is adequately treated. Finally, the durability aspects are extensively illustrated, with particular reference to the on-site behavior of applications in dams in the Alpine region.

1 INTRODUCTION

The design of embankment dams involves an adequate seepage and stability analysis of the dam's body (see for example Zhussupbekov and Mkilima 2022). Depending on the available materials on site, the embankment dam could be conceived with a central core or with a watertight upstream face (Jappelli 2002).

In particular, the use of geosynthetics as water barrier on the upstream face became widely use in the last sixty years, starting with the first application of Contrada Sabetta dam in Italy in 1959.

The first applications of geomembranes in dams took place in new embankment dams because many of these dams, being too permeable, required a separate element to provide imperviousness. In many cases, it appeared that geosynthetic barrier systems were more economical and easier to install than traditional impervious materials such as clay, cement concrete, bituminous concrete or even metallic blankets (ICOLD 1981).

Geomembranes were used in embankment dams before they were used in concrete or masonry dams probably for two reasons: (i) because geomembrane installation on the slope of an embankment dam is similar to installation on the slopes of a pond, an application where geomembranes has been used since the late 1950s; and (ii) because installation on a gentle slope is less demanding than installation on a vertical face (Cazzuffi et al. 2010).

As already mentioned, Contrada Sabetta dam, constructed in 1959 in Italy, is considered the first example of use of a geomembrane as the only water barrier in a dam (Cazzuffi 1987).

DOI: 10.1201/9781003299127-15

Contrada Sabetta dam is a 32.5 m high rockfill dam with a crest length of 155 m. It is a dam of a special type: rocks were arranged as dry masonry, which made it possible to achieve very steep slopes, 1V:1H upstream and 1V:1.4H downstream. The geomembrane used was 2.0 mm thick and made of polyisobutylene, an elastomeric compound that is no longer used as a geomembrane today, not because of any performance problem, at least when it is covered, but essentially because modern geomembranes are easier to seam. A general cross section of Contrada Sabetta dam is shown in Figure 1 and a detailed cross section is illustrated in Figure 2. Special features of Contrada Sabetta dam included the following:

- The geomembrane barrier consisted of two layers of identical geomembranes placed on top of each other over the entire upstream face of the dam. (It is important to note that two geomembranes (or two liners of any type) placed on top of each other, without a drainage layer in between, do not form a double liner.) A total of 3900 m^2 of geomembrane were used on the 1900 m^2 upstream face. These two geomembrane layers were glued to each other along the edges.
- The lower geomembrane layer was glued using a bitumen adhesive on the 0.1 m thick supporting material made of porous cement concrete. The porous cement concrete rests on 0.25 m thick reinforced concrete slabs, resting on the dry masonry.
- The geomembrane barrier was covered by unreinforced 2 m x 2 m concrete slabs, 0.20 m thick, cast on site. The joints between adjacent slabs were left open, 1 mm wide, and were not filled by any porous material, to allow for free circulation of water and to provide some flexibility in case of settlement. There was also a sheet of bituminous paper-felt between the concrete slabs and the upper geomembrane layer to protect the geomembrane during the casting of the concrete slabs.

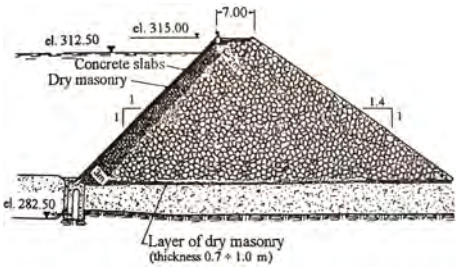

Figure 1. General cross section of Contrada Sabetta dam (modified after Cazzuffi 1987 and ICOLD 1991).

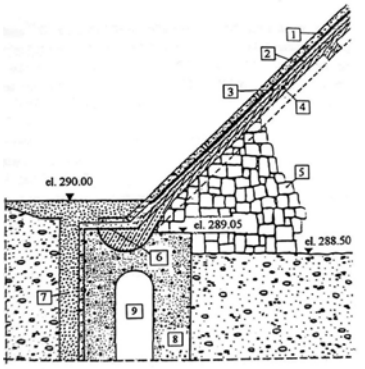

1) 0.20 m thick concrete slabs
2) one sheet of bituminous paper-felt + two sheets of polyisobutylene geomembrane (2.0 mm thick) + bituminous adhesive
3) porous concrete (0.10 m thick)
4) reinforced concrete slabs (0.25 m thick)
5) dry masonry (thickness ranging from 2.00 to 3.00 m)
6) joint be-tween plinth and upstream facing
7) plastic concrete diaphragm wall
8) concrete plinth
9) inspection and drainage gallery

Figure 2. Detailed cross section of upstream toe of Contrada Sabetta dam (modified after Cazzuffi 1987 and ICOLD 1991).

In most of the early projects, the geomembranes were installed during construction of the dam on the upstream slope and covered. The first exceptions were: (1) the first geomembrane used inside a dam was a CPE (Chlorinated Polyethylene) geomembrane used in 1970 on a 1V:0.67H slope (56º) inside a rockfill dam (Odiel dam in Spain) with upstream and downstream slopes of 1V:1.3H; (2) the first geomembrane used for repairing a dam was a 0.9 mm thick PVC (Polyvinyl chloride) geomembrane installed in 1971 at Obecnice dam, an earthfill dam in the Czech Republic; and (3) the first geomembrane used exposed on the face of an embankment dam was a 4 mm thick bituminous geomembrane installed in 1973 at Banegon dam, a 17 m high earthfill dam in France. It was also the first use of a bituminous geomembrane in a dam.

Mission dam (now called Terzaghi dam), a 55 m high rockfill dam constructed in 1960 in Canada, is a special case for both historical and technical reasons. It is a special case for historical reasons because Karl Terzaghi was the designer and because it was one of the first dams including a geomembrane. It was a special case for technical reasons because the geomembrane application was not typical. A detailed description of the construction of the dam was provided by Terzaghi & Lacroix (1964) and a description of the geomembrane installation was provided by Lacroix (1984).

Special features of Terzaghi dam relevant to the geomembrane application are the following:

- The water barrier in the dam was a 1.5 m thick clay layer covered by 2 m of rubble fill.
- Large differential settlement was expected and the clay layer was designed to be convex in order to remain in compression when settlement occurs.
- However, at the transition between the 15º slope and the quasi-horizontal area near the toe of the upstream face, the clay layer was necessarily concave.

In this 10,000 m^2 transition zone, a geomembrane was used to prevent the clay from cracking. The function of the geomembrane can be described as follows. The geomembrane, placed on top of the clay, ensures that a uniform pressure equal to the hydrostatic pressure is applied on the clay. The hydrostatic pressure being higher than the compressive strength of the clay, clay cracking is prevented. Furthermore, if some cracks develop, in spite of the normal pressure applied by the geomembrane, water does not penetrate into the cracks and, therefore, no hydrostatic pressure is applied within the cracks.

In contrast, without geomembrane, as cracks tend to develop as a result of differential settlement, water would penetrate in the cracks. The hydrostatic pressure, acting on both sides of cracks, would open the cracks and cause the cracks to propagate through the entire thickness of the clay layer, thereby impairing the clay barrier function of the clay layer.

A PVC geomembrane was selected because of its large elongation before rupture. The PVC geomembrane selected was 0.75 mm thick, which was considered, particularly in North America, to be a very thick PVC geomembrane at that time. It was smooth on one side and embossed on the other side.

Clearly, Terzaghi dam is an interesting use of a geomembrane in a dam, which can provide an example for some applications in the future. However, it cannot be considered as a precursor of modern applications of geomembranes in embankment dams.

2 EMBANKMENT DAMS

2.1 *Geomembranes and other barriers*

Until 2010, geomembranes have been used in 171 large embankment dams, according to the ICOLD database (ICOLD 2010), both for new construction and for rehabilitation purposes. (Scuero and Vaschetti 2009). In embankment dams, geomembranes are in competition with traditional barriers such as: clay or bituminous central cores, or upstream facings made of cement concrete slabs or bituminous concrete layers or even metallic blankets (Bertacchi et al 1988).

2.2 *Advantages of geomembranes*

Geomembranes are increasingly used because they have numerous advantages over traditional barrier materials: imperviousness, cost, construction, sustainability issues and practical considerations (Cancelli and Cazzuffi 1994).

Geomembranes are significantly less permeable than all other barrier materials. This geomembrane property is essential for the containment of liquids that could contaminate the ground or the ground water, but typically is not considered essential in dams. However, with the growing emphasis on water conservation due to the climatic change, it is likely that the superior imperviousness of geomembranes will be considered to be a significant asset of geomembranes in the future.

Some geomembranes can undergo large strains (e.g., 100% or more) without rupture. A geomembrane with a high elongation capability will maintain watertightness in presence of differential settlements and movements that could cause: (1) cracking of concrete slabs in concrete face rockfill dams and, in extreme cases, could cause failure of the waterstops; and (2) disruption in the connection of the bituminous facing to the concrete structures in the case of bituminous concrete face embankment dams. Concerning dams with clay core, the imperviousness of the core heavily relies on construction quality (too often influenced by weather conditions) and on the skill of the contractor. It can therefore be said that geomembranes can improve safety of embankment dams because they are engineered to maintain imperviousness in presence of events that could impair the performance of other waterproofing systems eventually used in embankment dams.

Geomembrane waterproofing barriers can provide substantial advantages in the construction of embankment dams as compared to traditional waterproofing barriers, because they avoid problems such as lack of suitable materials and deterioration of waterstops. Also, they simplify construction by eliminating the need for installing multiple lines of waterstops and by being easier to connect to ancillary concrete structures than clay cores or bituminous concrete layers.

Construction times and constraints are reduced when geomembrane barriers are used. With traditional barrier materials, the impact that the installation/construction of the face slabs, or the placement/compaction of the impervious core, can have on the overall construction schedule, and the complexity of the techniques needed to construct the waterproofing system, must be taken into consideration when evaluating times of completion. In dams with a central core (made of clay or bituminous material), a crucial point is that, being the construction of the dam body and the construction of the central core related, the constraints imposed by the weather conditions, or any disruption in the placement of the filter material, will affect the rate of construction of the entire dam body. On the contrary, installation of a geomembrane barrier system can be scheduled in function of the general schedule of construction and is not significantly affected by weather.

A variety of types of geomembranes are used in embankment dams (Table 1). Based on the ICOLD database, geomembranes have been used in a total of 171 embankment dams (ICOLD, 2010). In particular, PVC geomembranes have been adopted in 48.5% of dams, while PE (polyethylene) geomembranes (LLDPE, HDPE, CSPE, CPE) have been installed in almost 30% of dams and bituminous geomembranes have been utilized in about 12% of embankment dams.

Table 1. Embankment dams: geomembranes (GM) by types of constituent material.

Type of GM	N	%	Tot exposed	Tot covered	Unknown
PVC	83	48.5	23	57	3
LLDPE	27	15.8	0	26	1
Prefabricated bituminous	20	11.7	7	13	0
HDPE	15	8.8	3	11	1
Elastomeric	11	6.4	5	4	2
CSPE	7	4.1	3	4	0
PP	6	3.5	3	3	0
CPE	2	1.2	0	2	0
Total	171	100.0	44	120	7

PVC: Polyvinyl chloride; LLDPE: Linear Low-density Polyethylene; HDPE: High-density Polyethylene; CSPE: Chloro-sulfonated Polyethylene; PP: Polypropylene; CPE: Chlorinated Polyethylene

3 CONSTRUCTION OF NEW EMBANKMENT DAMS

For new construction of embankment dams, it is possible to define two design concepts: location of the geomembrane and type of liner system.

In an embankment dam, two positions can be considered for the geomembrane barrier: (1) the geomembrane can be at the upstream slope, covered or not; or (2) the geomembrane can be internal, i.e. located inside the dam body, either inclined inside the upstream zone of the dam, or vertical or quasi vertical, in a central position.

Based on the ICOLD database, in approximately 90% of the dams where a geomembrane is used, it is at the upstream slope and in approximately 10% it is internal. Among the geomembranes used at the upstream slope: 70% are covered, and 30% are exposed.

When a geomembrane is used on the upstream slope, it can be exposed or covered (i.e. "protected") by a layer of heavy material such as soil, concrete, etc.

The design of a dam with a liner (any type of liner) should be such that the seepage resulting from a major breach in the liner should not cause the rupture or a major distress of the dam. Therefore, the various zones that constitute a dam should comprise adequate filters to prevent internal erosion of the dam. This is particularly important when the liner is an exposed geomembrane because this type of materials can be breached accidentally. In fact, geomembranes are significantly more waterproof than concrete or clay, but they can be damaged by some mechanical actions.

If the dam does not meet the conditions indicated above and is sensitive to internal erosion in case of seepage, a possible solution consists in minimizing the rate of leakage through the liner system, even in case of a breach in the geomembrane. Two possibilities for minimizing leakage are the use of a double liner, and/or the use of a composite liner.

Even if there are some examples of use of geomembranes in a central position of an embankment dam (Cazzuffi et al 2010), the present invited lecture illustrates mainly the case of applications on the upstream face, both for exposed geomembranes and for covered geomembranes.

3.1 *Upstream exposed geomembranes*

Exposed geomembranes account for approximately 30% of the geomembranes used at the upstream slope of embankment dams, e.g. Bilancino cofferdam in Italy (Figure 3); and the geomembranes used at the upstream slope of embankment dams are approximately 90% of the geomembranes used in embankment dams.

Geomembranes exposed on the upstream face of embankment dams are subjected to a variety of potentially detrimental actions:

- Mechanical damage by ice, floating debris, rocks falling, animals, vandals, and traffic.
- Degradation by exposure to environmental agents (oxygen, UV, heat).
- Displacement by wind, wave action, fluctuations of water level, and gravity (causing creep).

Geomembranes can be used exposed if they have appropriate strength and composition to resist mechanical damage and degradation. Precautions must be taken to prevent or reduce geomembrane displacement by wind, waves and gravity. Generally, the main risk is displacement by wind. Therefore, geomembranes must be anchored against wind uplift.

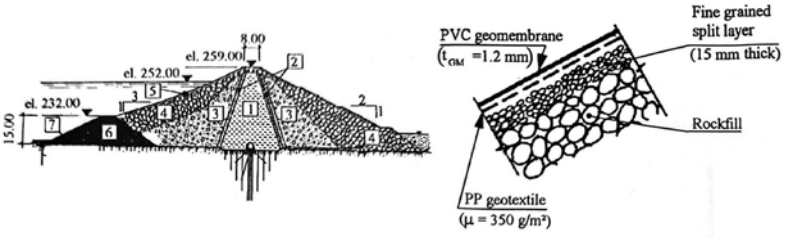

Figure 3. Bilancino zoned embankment dam in Italy, 42 m high, with a cofferdam lined with an exposed PVC geomembrane (modified from Baldovin, 1993): 1. Clayey silt core; 2. Filters, 3. Transitions; 4. Rockfill; 5. Rip-rap; 6. Cofferdam (with upstream face 1V:2H and downstream face 1V:1.5H); 7. PVC geomembrane (t_{GM} = 1.2 mm) and PP geotextile (μ = 350 g/m^3).

3.2 *Upstream covered geomembranes*

If a geomembrane is left exposed on the upstream face of an embankment dam, it could be subjected to a number of actions that could damage it. The reasons for geomembrane protection by a cover layer are:

- Protection of the geomembrane against mechanical damage (by ice, floating debris, rock falling from the sides, animals, vandals, traffic).
- Elimination of exposure to environmental agents (oxygen, UV, heat) that in some cases could cause degradation of the geomembrane.
- Prevention of geomembrane displacement by wind, wave action, gravity (causing creep).

Mechanical protection of geomembranes on slopes is typically ensured by covering the geomembrane with a layer of heavy material such as cement concrete or soil. Considering all of the potentially detrimental actions, a majority (70%) of the geomembranes used at the upstream slopes of embankment dams are covered, based on the ICOLD database.

Several systems have been used, or could be used, to cover geomembranes:

- Interlocking concrete blocks;
- Articulated concrete blocks;
- Concrete slabs;
- Shotcrete on geotextile;
- Geocells or geo-mattresses filled with concrete;
- Soil and rock protection layers.

It is important to note that improperly designed or constructed cover layers can eventually damage a geomembrane during construction or operation. Therefore, a thick needle-punched nonwoven geotextile is generally used between the geomembrane and the cover material.

The placement of the cover layer is possibly the most critical part of construction of a covered geomembrane system. Construction quality assurance activities should not stop after placement of the geomembrane. It should continue during the placement of a geotextile protection layer on the geomembrane and then, during the following placement of the cover layer.

The important role of the geotextile layer during operation is illustrated by the fact that the geomembrane was not damaged despite extensive displacement of articulated concrete blocks at L'Ospedale dam in France, that was built in 1978.

At Codole dam, always in France, a cost analysis at the design stage showed that the solution adopted was cost-effective compared to other solutions even if the geomembrane and the overlying cement concrete slabs had to be re-placed after 25 years of service. Codole dam was built in 1983 and is still in service without any further replacing of cement concrete slabs (Figure 4).

At Codole dam, the cement concrete slabs were reinforced with traditional steel bars. This proved to be a potential problem. Great precautions had to be taken during construction to avoid damaging the geomembrane with the reinforcing bars, in spite of the presence of a geotextile layer above the geomembrane.

Bovilla dam in Albania, is a 91 m high rockfill dam built in 1996 for water supply, flood mitigation and hydropower (Figure 5). The original design of a concrete face rockfill dam was changed to a geomembrane face rockfill dam for the following reasons: (1) concerns about the final quality of the reinforced concrete face and its potential for future cracking; and (2) need to reduce construction time and costs as the project was behind schedule (Sembenelli et al. 1998).

The upstream composite geomembrane installed in 1996 is the only element providing watertightness to the dam: the composite geomembrane consists of a 3 mm thick PVC geomembrane laminated to a 700 g/m^2 polyester geotextile. It was placed directly over a porous cement concrete layer constituted by gravel stabilized with cement slurry (Figure 6). The geomembrane covers the entire upstream slope, from the crest to the massive toe block, i.e. over a difference in elevation of 54 m. The upstream slope is 1V:1.55H in the upper 40% and 1V:1.6H in the lower 60%.

The geomembrane was covered with unreinforced concrete slabs that were placed on an 800 g/m^2 geotextile. The slabs are 6 m long in the slope direction and 3 m horizontally. The slabs

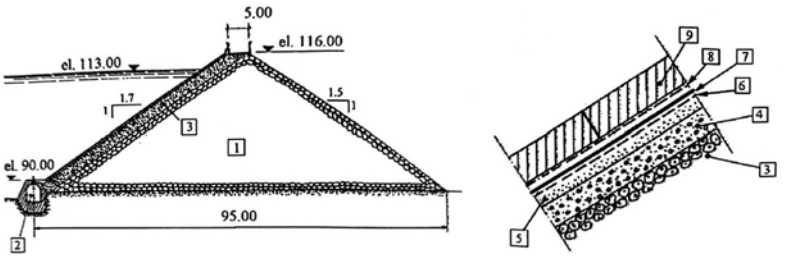

Figure 4. Codole rockfill dam in France, 22 high (modified from ICOLD, 1991): 1. Rockfill (up to 1.00 m size); 2. Inspection and drainage gallery; 3. Sand and gravel layer (2.00 m thick, 25÷120 mm grain size); 4. Gravel layer (0.15 thick, 25÷50 mm grain size); 5. Cold premix layer (50 mm thick, 6÷12 mm grain size); 6. Geotextile (μ = 400 g/m^3) bonded to geomembrane; 7. PVC geomembrane (t_{GM} = 2.0 mm); 8. Geotextile (μ = 400 g/m^3); 9. Cement concrete slabs (0.14 m thick, 4.5 x 5.0 m^2 size).

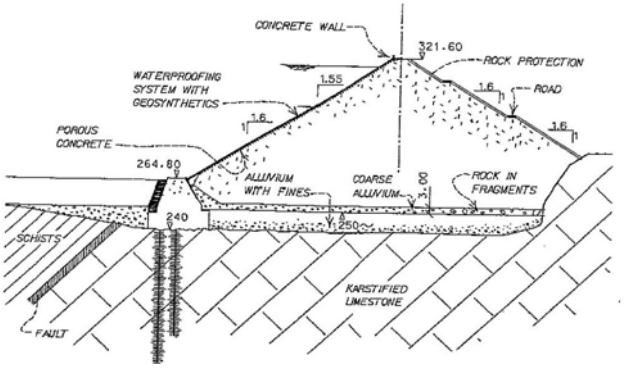

Figure 5. General main cross section at Bovilla dam in Albania.

are 0.20 m thick. The geotextile had a double function: providing anti-puncture protection to the geomembrane against casting of the slabs, and act as a light reinforcement for the slabs themselves.

Figure 6. Bovilla dam: composite geomembrane placing over the porous cement concrete layer.

The decision to adopt cast in place concrete slabs rather than prefabricated concrete blocks was taken because casting slabs was considered less aggressive on the PVC geomembrane than the placement of prefabricated concrete elements, and also considering the problems with articulated concrete blocks previously registered at L'Ospedale dam in France.

At Bovilla dam, the bottom seal of the geomembrane on the toe block was designed to be able to accept differential movements and settlements one order of magnitude larger than the estimated ones. Extra material and protection/decoupling layers were placed for this purpose over the layer of geomembrane at the seal.

La Galaube dam, 43 m high, a rockfill dam built in France in 2000, is one of the highest dam waterproofed with a bituminous geomembrane (Gautier et al,. 2002). The bituminous geomembrane, 5 mm thick, has been laid on a 0.10 m thick cold asphalt mix placed over a layer of non-bounded gravel impregnated with bitumen on the 1V:2.0H slope. The bituminous geomembrane is protected by a geotextile layer (Figure 7) and the final cover layer is constituted by a 0.10 m thick cement concrete slab reinforced with PP (Polypropylene) fibers.

The bottom anchorage is made on the concrete plinth and is of the tie-down type. Installation of 22.000 m^2 of bituminous geomembrane was completed in 2000.

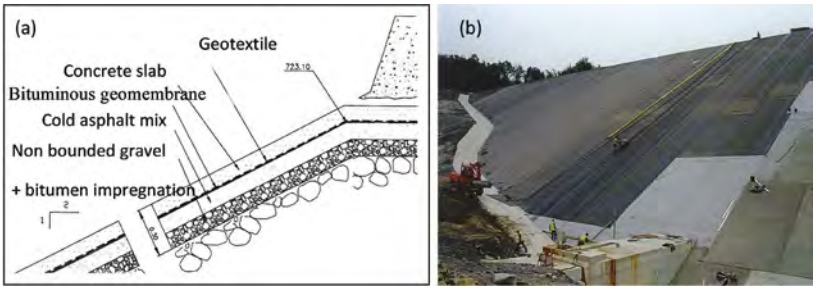

Figure 7. La Galaube dam in France: (a) typical cross section at the top (after Gautier, 2003); (b) placing of geotextile protection layer (in grey) over the bituminous geomembrane layer (in black).

Geomembrane covers using a soil layer cannot be used on the steep slopes typical of rockfill dams because they would not be stable. Soil layers should only be used on slopes less steep than 1V:2.0H, preferably on 1V: 2.5H slopes and less steep. It is essential to check the stability of the soil cover under rapid drawdown conditions, the worst conditions for static stability. In relevant areas, the seismic stability should also be checked.

At Worster dam, Colorado, USA, 22 m high, 215 m long, lined with a 1.5 mm textured HDPE (High-density Polyethylene) geomembrane, the 0.3 m thick soil cover bulged at the toe of the 1V:3.0H slope at the first drawdown of the reservoir, as it was uplifted by water entrapped between the geomembrane and an old concrete slab located a few meters behind the geomembrane.

4 REHABILITATION OF EMBANKMENT DAMS

Geomembranes have been used also for the rehabilitation of embankment dams, and in particular for cement concrete face rockfill dams and for bituminous concrete face rockfill dams.

4.1 *Rehabilitation of cement concrete or bituminous concrete face rockfill dams*

In the rehabilitation of cement concrete face rockfill dam dams or bituminous concrete face rockfill dams, the design should take into account that both are hard surfaces to which geomembranes can be attached. Therefore, the anchorage system of the geomembrane to the dam face is designed depending on the type and strength of the existing facing (cement concrete or bituminous concrete): consequently, the geomembrane is typically left exposed, and maintained to the dam upstream face by face anchorage and perimeter anchorage.

4.2 *Rehabilitation of cement concrete face rockfill dams*

For cement concrete rockfill dams, face anchorage in the past has be made by gluing or by mechanical fixations.

Gluing has been done in the case of in situ geomembranes. In a number of these applications, gluing has resulted in failure, such as at Paradela dam in Portugal and Rouchain dam in France. These failures can be attributed to the nature of the in-situ geomembranes. But, they may also be due to a fundamental conceptual mistake. Two liners should not be located directly on top of each other, unless there is a sufficient load on them to counteract water pressure. Of course, there is no load on a geomembrane glued on a rigid support. Therefore, the ICOLD Bulletin (2010) recommends that gluing "should not be continuous over the entire face to allow drainage behind the geomembrane and release of vapor pressure which would result in uplift pressure which could detach and ultimately damage the geomembrane or the sup-porting layer. Rehabilitation of cement concrete or bituminous concrete facings with a geomembrane glued on the entire surface is not recommended." In fact, gluing has been abandoned since the late 1980s.

A simple mechanical fixation consists of nailing the geomembrane to the supporting layer. This has been done for the partial repair of Heimbach concrete dam in Germany. Conceivably, a nailed geomembrane (or a geomembrane with other types of punctual anchors) could be used for the repair or rehabilitation of cement concrete face rockfill dams.

Mechanical fixations are bolted to the dam with different methods depending on the characteristics of the face. Mechanical fixations are commonly used nowadays and they have the additional advantage of allowing a drainage system behind the geomembrane.

A remarkable example of rehabilitation on the entire facing of cement concrete face rockfill dam is represented by Midtbotnvatn dam in Norway (Figure 8). In this dam, the 2.5 mm thick PVC composite geomembrane was installed in 43 days instead of 2 full summer seasons as required by the second best rehabilitation option (morainic material): this fact is quite important for applications in cold regions where the rehabilitation works could be done only in the summer season.

Figure 8. Rehabilitation of Midtbotnvatn rockfill dam in Norway: placing of PVC composite geomembrane layer over the damaged cement concrete facing.

4.3 *Repair of bituminous concrete face rockfill dams*

If a geomembrane is used to repair dams having a bituminous concrete face, the anchorage system is designed in function of the particular characteristics of the subgrade, which being not a rigid material like concrete does not always allow using the type of anchors used on concrete.

For anchoring the profiles or batten strips that provide face anchorage, typically field testing is made to verify if chemical phials or grouted anchors or deep anchors must be adopted.

Chemical phials require a stronger and not very viscous subgrade. Grouted anchors and deep anchors (Duckbill/Manta Ray type) can be used in alternative.

At Moravka, a 39 meter high earthfill dam in the Czech Republic used for hydropower, potable water supply, and flood control, an exposed PVC composite geomembrane was placed on the bituminous concrete facing that despite several repairs, including a new bituminous concrete layer, continued to exhibit important leakage (Figure 9). An asset of geomembrane systems in this type of dams is that they do not require milling of the deteriorated bituminous concrete, which on the contrary is necessary if a new bituminous concrete layer is installed.

Pull out field testing was carried out at several locations of the facing to ascertain if chemical anchors could be used to fix the tensioning profiles for face anchorage. The tests were successful, but since the resistance of the bituminous concrete could vary over the year depending on atmospheric temperature, the conventional chemical anchors were modified to ensure stability.

Two bottom perimeter seals were installed at the concrete block where the drainage gallery is located (Figure 10). The primary seal confines the drainage system of the upstream face (geomembrane system); the secondary seal confines the drainage system for water coming from foundation/abutments/failing joints in the concrete. The two drainage systems discharge in the gallery with separate discharge pipes to allow a suitable monitoring of the system.

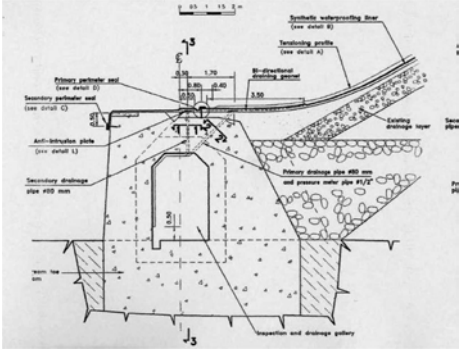

Figure 10. Moravka bituminous concrete face rockfill dam, Czech Republic: the two bottom seals.

The exposed geomembrane system was released in 2009 (Figure 11a). During the following years, the geomembrane system has resisted to important ice impact (Figure 11b).

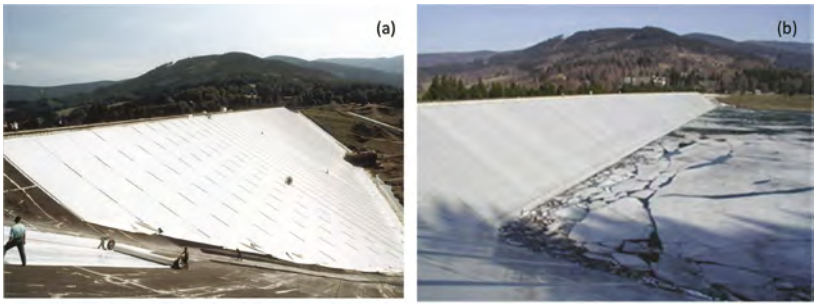

Figure 11. Moravka dam: (a) placing of PVC composite geomembrane layer 2.5 mm thick (b) heavy ice impact did not damage the exposed PVC geomembrane.

5 PERFORMANCE OF EMBANKMENT DAMS WITH GEOMEMBRANES

A typical rate of leakage per unit area observed in the case of large earthfill and rockfill dams constructed with a geomembrane liner on the upstream face and covered is of the order of 1 liter/hr/m^2 (assuming that monitoring is accurate, which is not guaranteed) for the best cases and up to 10 liter/hr/m^2 for dams that do not have the best performance. For the sake of comparison, one defect per 1000 m^2 with a diameter of 2 mm gives a calculated leakage rate of the order of 0.1 liter/hr/m^2 with a typical water head. It is possible that leakage at peripheral connections may explain the difference.

However, in the case of geomembranes anchored on a concrete face rockfill dam, the rate of leakage is of the order of 0.1 liter/hr/m^2 for the best cases. It appears that the typical leakage rate in the case of geomembranes anchored on a concrete face rockfill dam is an order of magnitude times less than the typical rate of leakage through geomembranes installed conventionally in embankment dams. This may be due to better installation on rigid surface.

5.1 *Safety in case of geomembrane failure*

Exposed geomembranes can be damaged by accidental exceptional events (vandalism, terrorism) or by repeated or occasional aggressions from the service environment (animals, ageing). Upstream geomembranes, exposed or covered, can be damaged by extraordinary causes such as earthquakes or falling aircrafts.

The design of a dam with a liner (any type of liner) should be such that the seepage resulting from a major breach in the liner should not cause the rupture or a major distress of the dam itself. Therefore, when a geomembrane liner is considered for an embankment dam, it is essential to check that the appropriate precautions have been taken.

First of all, it is important to monitor and maintain dams. Current defects in geomembranes generally have no detrimental consequences, because a geomembrane - with a small number of small punctures - is still less permeable than any other liners.

Significant defects in geomembranes, due to the exceptional causes mentioned above (earthquakes or falling aircrafts), should be repaired if they are likely to have detrimental consequences. Fortunately, it is generally easy to repair geomembranes. Damage repair, at least for geomembranes having suitable characteristics, is feasible by simple patching if in the dry, or by underwater installation. Of course, the damage repair could be easy for exposed geomembranes.

In the case of internal geomembranes (covered geomembranes), the only cause of significant damage to the geomembrane could be a major earthquake. Therefore, it is important - particularly in seismic areas - to design the dam structure accordingly and to use a geomembrane with high elongation capability and high puncture resistance, since the geomembrane could come in contact with rocks in case of malfunctioning of the protective layers. An internal geomembrane (covered case) with high elongation capability is probably the safest possible liner in case of earthquake.

In conclusion, with an appropriate dam design, and proper geomembrane selection, the geomembrane liners are very safe also in case of important earthquakes.

5.2 *Behavior of geomembranes as a function of time*

Durability is based on the weathering properties, and on the resistance of the geomembrane to specific loads during service (extreme temperatures, frost, freeze/thaw, ice, impacts by floating debris and boats, wind and waves, fauna and flora, vandalism etc.).

Taken for granted that not all geomembranes have the same behavior due to their chemistry, their basic ingredients and their manufacturing process, it is important for dam projects to select a type of geomembrane already adopted in several similar applications or eventually to design a new geomembrane that can best perform according to the type of environment in which it will be used, and that can provide adequate durability for the required application.

Standard accelerated ageing tests are available and are being used all over the world to predict the behavior of geomembranes in service. These tests, although accelerated, would however require too long time to give indication of long-term behavior.

The most practical way to ascertain if a geomembrane will be resistant in the long term to the environmental loading expected in a dam project, is to exhume samples of the same geomembrane that have already been in service, in a similar environment and project, for a period of time that should be as long as possible, ideally as long as the required service life of the geomembrane in the considered dam, and perform tests to determine to which extent their properties have changed. Testing of the physical and mechanical properties of the exhumed samples indicates if the geomembrane properties at the time of the test are within acceptable limits, and extrapolation allows the determination of the expected remaining service life.

This approach has been adopted for applications in the Alpine regions (Cazzuffi 1987; Cazzuffi and Gioffrè 2020; Cazzuffi and Gioffrè 2021; Giroud 2021), using data from several dams rehabilitated with exposed PVC composite geomembrane. The oldest reported application of exposed PVC geomembranes on dams dates back to the mid 1970s, and -since then- many dams have been rehabilitated with exposed geomembranes of the same type, which makes it possible to obtain dependable results. Furthermore, many of these dams are at high elevation (typically higher than 2000 m) where the UV radiation is relevant and the weather conditions are harsh. From this database, it has been provisionally concluded that the service life of PVC composite geomembranes in such extreme environment is around 50 years (Hsuan et al. 2008). It should be noted that geomembranes of the same type installed today are of better quality than the geomembranes installed about 40 years ago and included in the data base used to predict durability. Therefore, the durability of PVC composite geomembranes installed today may be even greater than the predicted durability of at least 50 years.

The approach just described for PVC geomembranes should be eventually used also with other types of geomembranes to evaluate if they have the appropriate durability for use in dams.

5.3 *Evaluation of the residual life of exposed geomembranes*

In order to evaluate the variation over time of the characteristics of the PVC geomembranes installed on 8 dams in Alpine regions, a remarkable number of samples have been taken some periods after application and all of them have been put through the same type of tests.

Samples have been taken both above and under the water level and in different parts of the upstream face, with the aim of studying the different behavior of the same geomembrane in different conditions of exposure.

In the determination of the life expectancy of a geomembrane, it is important to identify the more critical portion of the upstream face, as the first failure will affect negatively the whole waterproofing system. Therefore, here we will present the results of the tests made on samples exhumed above the water level, as this is the area which suffers most from the direct exposure to atmospheric agents. The results obtained are thus referred to the worse conditions for each geomembrane and this helped us to conduct a precautionary analysis of the geomembrane durability.

All the samples taken from the dams' upstream faces have been tested at the Geosynthetics Laboratory of CESI SpA in Italy. The different types of tests (Table 2) allowed the comparison among different samples during the degradation process of the geomembranes.

Table 2. Laboratory tests and reference standards for the evaluation of the determination of the long-term behavior of the exhumed PVC composite geomembrane samples.

Laboratory test	Reference standard
Plasticizer extraction	EN ISO 6427
Nominal thickness	EN 1849-2
Volumic mass	EN ISO 1183-1
Hardness (Shore A)	EN ISO 868
Cold flexibility	EN 495-5
Dimensional stability	EN 1107-2
Tensile properties	EN ISO 527-3
Water vapor permeability	EN 1931

The case of Camposecco masonry dam in Italy is particularly significant, as for this dam also the test results on virgin samples are available; knowing the material's initial conditions, the analysis is more precious as it allows to reconstruct the entire life of the geomembrane on the dam in which it has been applied for rehabilitation of the upstream face (Figure 12).

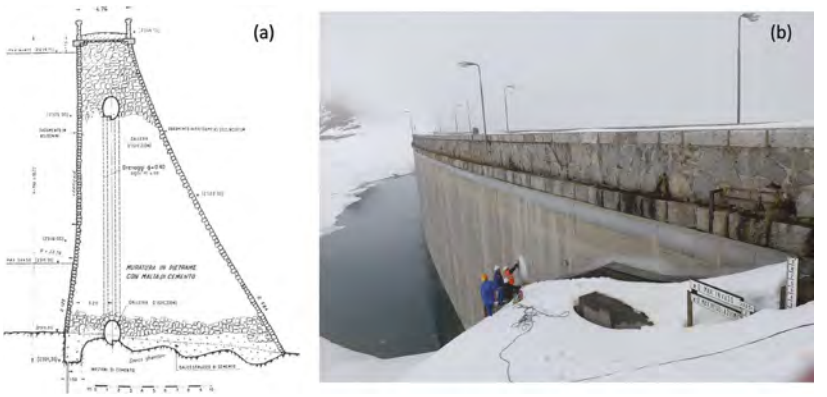

Figure 12. Camposecco dam in Italy: (a) Cross section; (b) PVC composite geomembrane sampling.

The results obtained show a constant small decrease of the plasticizers' content (Figure 13), while temperature of cold flexibility rises with time, and dimensional stability grows longitudinally and declines transversally in the years.

Mechanical parameters derived from the tensile tests show that the geomembrane get a little bit stiffer over time (Figure 14), with some increase of tensile strength and a small reduction of the correspondent strain, both in the longitudinal and in the transversal directions.

With regards to the waterproofing properties, the results of the vapor transmission tests demonstrate in general a negligible decrease of the permeability coefficient, thus a small improvement of the watertightness of the geomembranes, also due to some possible inclusion of particulates and sediments.

Long-term performance of PVC geomembranes depends on several aspects referred to the exposure environment and to the specific polymer and additive formulations. The service life

of PVC geomembranes can be predicted based on experimental results. Through a careful monitoring of the variation over time of the characteristics of the PVC geomembranes in service, it was possible to define a methodology of lifetime prediction of the geomembrane installed in dams when the results on virgin samples are available. In particular, the plasticizer content plays a fundamental role particularly in terms of variation in physical properties of the PVC geomembranes (Giroud, 1995; Giroud and Tisinger, 1993).

In order to evaluate most critical service life of the PVC geomembrane, the curve of plasticizer content versus time is extrapolated until the end-of-service-life plasticizer content is reached.

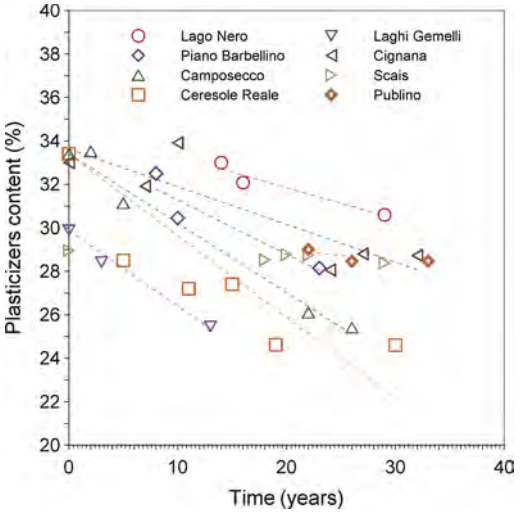

Figure 13. Plasticizers content evolution vs time for PVC geomembrane samples exhumed from different dams on Alps in Italy.

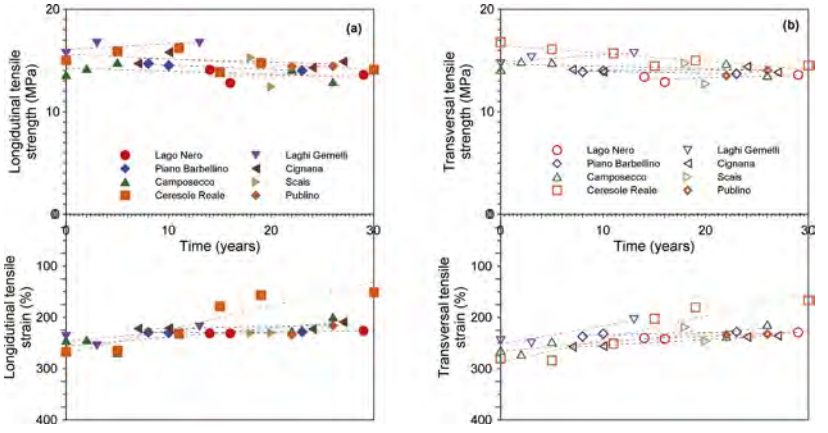

Figure 14. Tensile strength and strain evolution vs time for PVC geomembrane samples exhumed from different dams on Alps in Italy: (a) longitudinal direction; (b) transversal direction.

Based on laboratory tests (Luciani et al. 2019; Luciani et al. 2020) and on data from monitored structures, Giroud (2021) proposes, for the end-of-service-life criterion, a plasticizer content value of 17.5% for PVC composite geomembranes bonded to a nonwoven needle-punched geotextile (which are most frequently used in the considered dams).

Figure 15 shows lifetime assessment of exposed PVC geomembranes for Camposecco dam; vertical lines in Figure 15 shows that the lifetime assessment of the exposed geomembranes for Camposecco dam, assuming a linear decrease of plasticizer loss ratio over time, is approximately 48.5 years, based on the plasticizer content criterion.

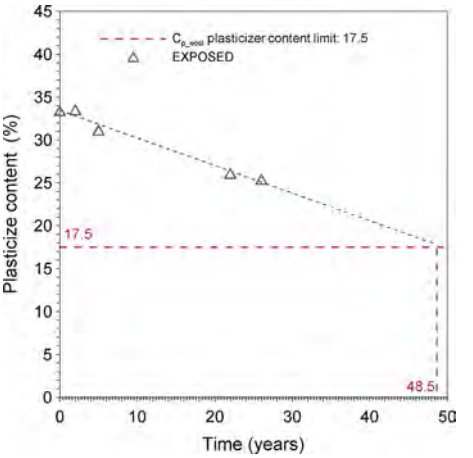

Figure 15. Camposecco dam: Lifetime assessment of exposed PVC geomembranes.

6 CONCLUSIONS

The range of possible applications of geomembranes as water barriers in embankment dams is quite wide. Geomembranes can be applied to all types of dams, in new construction and in rehabilitation.

Design and installation systems of the various components of geomembrane systems according to the type of application have been discussed in this invited lecture.

Geomembrane selection and behavior of geomembrane systems vs. time have been also investigated based on various research projects, and on results from laboratory tests and tests on exhumed samples.

Data on the performance of dams rehabilitated using geomembranes have been provided. These data show a remarkable performance of geomembranes in embankment dams, even when geomembranes are directly exposed to atmospheric agents.

Therefore, this invited lecture could contribute to demonstrate that nowadays the use of geomembranes in embankment dams, both for new constructions and also for rehabilitation purposes, is a well-established technique all around the world, provided that good design, excellent application and careful monitoring are provided.

ABSTRACT: Three-dimensional finite element analysis has been widely used in foundation design. For the efficiency of computations, simplified analysis treating the soils by series of springs were suggested in many design practice. For piled raft foundation, the coefficients of subgrade reactions and the pile stiffness are thus important to the design analysis. This paper intends to discuss the values of coefficients of pile reactions and/or pile stiffness for the embedded piled raft foundations in soft clays subjected to vertical uniform loads. Dimensionless pile displacements, pile reactions, and coefficient of pile reactions were suggested. Their correlations with the ratio of foundation embedment depth to raft size, the slenderness ratio of pile, and the ratio of pile-to-pile spacing distance to pile diameter were examined. Finally the optimized correlation diagrams were reported while a simple modelling was able to verify the suggestion.

1 INTRODUCTION

1.1 *Piled raft foundation analysis*

Piled raft foundation can provide economic and ecologic design solution to mega building structures. The load-response mechanism of such foundation can be deviated from those known for pile foundations. It has been noted that conventional pile foundation is usually designed assuming that the piles are connected to a rigid cap which can yield uniform settlements and rotations under the loads. Soil resistance underneath the cap is typically ignored. In the contrast, piled raft foundation relies heavily on the resistances of soils below the raft. To evaluate the foundation serviceability, the design of piled raft foundation requires computing the structural deformations. Overview of the available analysis methods have been suggested by Poulos (2001). The three-dimensional finite-element (FE) analysis has been known as the most powerful tool to estimate the behaviors of building foundations. The correspondent applications have been reported in numerous engineering projects on high-rise buildings (Katzenbach et al 2016). With the performance based design (PBD) guidelines, Katzenbach & Choudhury (2013) suggested that both the capacity and serviceability performances of the foundation should be taken into account in designing the piled raft foundation (or namely the combined pile raft foundation, CPRF). Figure 1 depicts the qualitative relationships of the settlement ratio (maximum settlement of CPRF to max. settlement of a single raft) versus the load ratio (the load supported by piles to the total foundation load) of the CPRF. It was suggested that both ratios at 50% should be aimed for an efficient design. Chang & Matsumoto (2017) suggested that the serviceability (*i.e.,* deformations) of the foundation is significantly important to modern design practice since the foundation load-response relations became more predictable with the advanced numerical methods, and the foundation deformations are commonly restraint first to avoid inelastic behaviors.

DOI: 10.1201/9781003299127-16

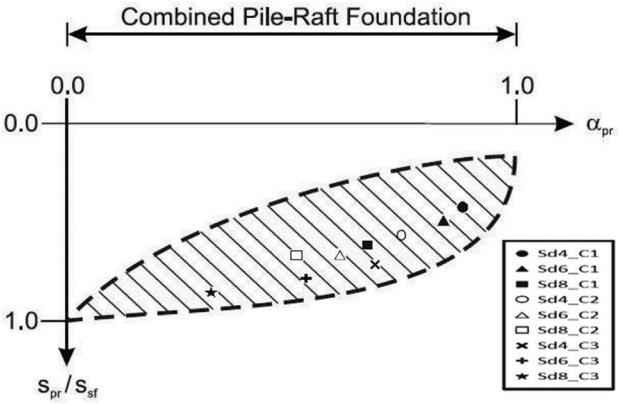

Figure 1. The qualitative relations between the settlements and the load of CPRF (after Katzenbach & Choudhury, 2013).

1.2 *Piled raft foundation analysis in Taiwan*

The current design of pile foundation in Taiwan follows the conventional methodologies. Vertical bearing capacity and uplift capacity of the single pile are analyzed first with presumed pile dimensions and bored-hole data from the field. The factors of safety at different design conditions are applied to ultimate loads in the predictions. In some cases, negative skin frictions are estimated to ensure that the piles are safe under such effects. The pile load test is required to ensure the design. Total capacity of the grouped pile is calculated using either analytical formulas suggested in the design code excluding the interferences of pile-to-pile interactions or the solutions from simplified computer-based analysis. Computer programs such as APILE, LPILE and GROUP (Ensoft, 1987-) are commonly adopted to examine the pile performance. The *t-z*, *Q-z* and *p-y* curves interpreted from the field test and/or available documents are often used for the measurements. The SAP2000 analysis is sometimes utilized by structural engineers to examine the foundation behaviors. Analytical equations suggested by Chang (1937) on single pile subjected to horizontal loads are sometimes used to check the corresponding pile performance. If the site had liquefaction induced problems, both vertical and lateral resistances of the pile will be analyzed with soil stiffness and strength reduced from the empirical liquefaction potential analysis. The soil parameter reduction coefficients suggested by JRA (1996) and AIJ (1988) are recommend for such deductions. According to the design code, lateral resistance of the pile is dominated by an allowable displacement at 10% of the pile diameter. One can refer to Chang et al (2016) for the general report.

Until now, the design of piled raft foundation (or CRPF) is rarely addressed in geotechnical engineering design code in Taiwan. The design of such foundation requires the third-party structure assessments. In order to ensure that the foundation performs safely under the loads, structural deformation analysis of the foundation became rather important. It is normally done by treating the raft as a beam or a plate attached to a series of soil and pile springs. The values of spring constants can be assumed using empirical formulas and/or engineering judgements. Therefore these springs require special attentions.

Chang et al (2022a) recently has reported the variations of the modulus of subgrade reactions for surface raft foundation subjected to short-term vertical loads. For the piled raft foundation at the ground surface, the loads carried out at the piles were found mainly dependent of the soil stiffness and the number of piles installed, however the size of the raft also would interactively affect the results (Chang et al 2022b). For mat foundations with the embedment, a technic paper on dimensionless modulus of subgrade reactions is shared at 17ARC (Chang et al 2023). This paper is aimed to discuss the similar studies for embedded piled raft foundation in clays under short-term vertical loads from three-dimensional finite element analysis. The long-term loading effects including the consolidation influences to the clays would dramatically increase the foundation settlements, therefore the pile stiffness should be further analyzed with cautions.

2 NUMERICAL MODELS

2.1 *Foundation modelling*

The numerical model of the embedded piled raft foundation is illustrated in Figure 2. A square raft with the width varying at 16, 26 and 36 meters was assumed. The thickness of the raft was 1m. Embedded depth of the raft was varying at 8 and 12m. For more realistic modelling, the concrete diaphragm wall was around the raft. The depth of the diaphragm wall was kept as 2 times of the depth for foundation embedment. Round concrete piles with 1m diameter were installed underneath the raft. The pile length was varying at 20m and 30m. The pile-to-pile spacing distance was kept at 3 and 5 times of the pile diameter. Homogeneous soft clay was assumed for the ground soil. The corresponding shear wave velocity, V_s of the soil was varying at 100, 120 and 140 m/s, respectively. Ground water table was temporarily excluded whereas the averaged Poisson's ratio of the soil was kept at 0.4.

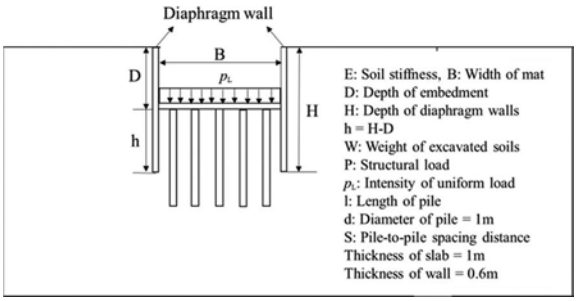

Figure 2. Foundation model of this study.

The Young's modulus of the soil, E_s were thus obtained from elasticity equations. Empirical relations suggested by Hsieh et al (2003) between the Young's modulus E_s and the undrained shear strength of the clays, S_u in Taipei was used to obtain the value of the undrained shear strength. The Mohr-Coulomb soil model was adopted. Note that the structural load, P was taken approximately as 1.5 times the weight of excavated soils. In some studies, the total load was fixed to be independent of embedment depth and size of the slab. The applied uniform load, p_L was decomposed into a series of incremental loads of 10kPa. Iterative procedure was carried out to ensure the equilibriums of the system. Table 1 summarizes the material properties and engineering parameters used in the analysis. Totally 72 numerical cases were analyzed.

Table 1. Foundation geometries, material properties and parameters of the study.

Foundation dimensions and load	FE zone: 350m×350m×150m, Mat width (B): 16m, 26m, 36m, Depth of embedment (D): 8m, 12m Depth of diaphragm (H): 2D Thickness of mat: 1m, Thickness of wall: 0.6m Pile diameter (d): 1m, Cross-section area of pile (a), Pile length (l): 20m, 30m Pile-to-pile spacing distance (S): 3m, 5m Structural load (P): 1.5W, Weight of soils excavated (W):$\gamma_s \times B^2 \times D$
Concrete	γ_c = 24 kN/m^3, E_c =30 GPa, v_c = 0.15
Soil	γ_s = 20 kN/m^3, v_s= 0.4, V_s = 100m/s, 120ms, 140m/s, E_s =57 MPa, 82Mpa, 112Mpa, S_u= 28.5kPa, 41kPa, 56kPa (E_s/S_u =2000) for soils denoted as E1, E2 and E3 soils

2.2 *Discrete mesh and boundaries*

The 3D FE analysis was made using Midas GTX NX package (Midas, 2014). Three dimensional 8-node solid elements were used to model the concrete structure and the soils. The

interface elements were implemented between the concrete and the soils. Normal and tangent stiffness of the interface elements, k_n and k_t were assigned as $10E_s$ and E_s, respectively. Ultimate adhesion of the interface elements was assumed as 2/3 of the undrained shear strength of the clay. Stage-construction feature available in Midas analysis was used. The stability of the foundation displacements was ensured with the FE dimensions at 350m×350m×150m. Essential boundaries such as the rollers were placed. Two- and three-dimensional hinges were resulted at the interfaces of these boundaries. For computational efficiency, 1/4 FE mesh was analyzed based symmetry. The computation time required for the piled raft foundation analysis are around 6~24 hours using PC with Processor 11th Gen Intel® Core™ i7-11700 @2.5 GHz. The required time was mainly found in proportion to the resulted foundation settlement.

3 GENERAL PILE BEHAVIORS

3.1 *Pile displacements*

The largest displacements of the foundations were found appeared at the center in the range of 16~231mm. The pile displacements are the same. They were mainly reduced by the increase of soils stiffness, number of piles, and the length of pile. For similar structural loads, increasing the depth of embedment and the size of mat foundation will reduce the foundation settlements. Figure 3 presents the influences of soil stiffness, the number of piles and the pile length for piled raft foundation where the raft width is 26m. The maximum pile displacements occurred at different locations of the piled raft foundation can be found in Lin (2022).

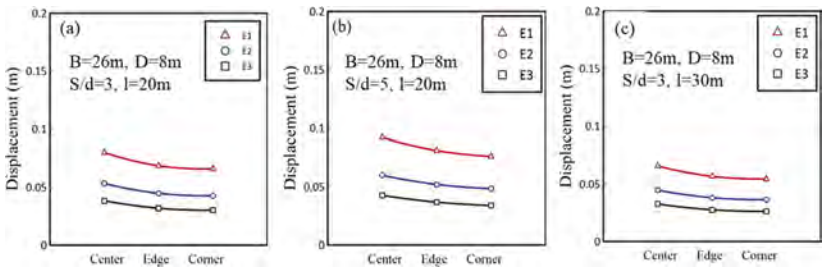

Figure 3. Foundation displacements affected by (a) soil stiffness (b) number of piles (c) pile length.

3.2 *Pile reactions*

The variations of pile reactions were found relatively insignificant in comparison with the pile displacements. The pile reactions (p) at the center pile or the pile near to the center of the foundation were found in between 989~4137kPa. The load sharing of the piles was found influenced by the soil stiffness, the raft dimension, embedment depth, number of piles, and the pile length. The influences of soil stiffness are rather smaller compared to those found at the pile displacements. Figure 4 indicates the influences of the pile reactions by soil stiffness, embedment depth, number of piles and pile length. More details of the discussions can be found in Lin (2022).

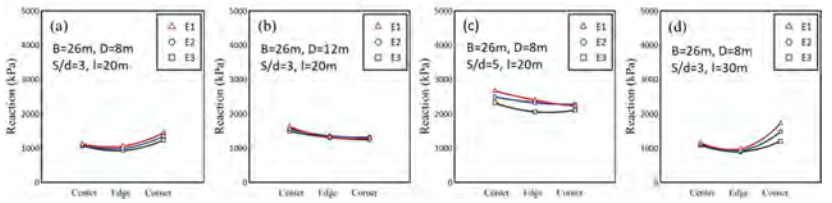

Figure 4. Pile reactions affected by (a) soil stiffness (b) depth of embedment (c) number of piles (d) pile length.

3.3 *Coefficient of pile reaction and corresponding pile stiffness*

The coefficient of pile reaction (k) is able to obtain subtracting pile reactions by pile displacement. The pile stiffness kp is calculated by multiplying k with the cross-section area of the pile. It was found that the coefficient of pile reaction (k) at the center were in the range of 8.7~136MN/m^3. Corresponding pile stiffness is about 6.8~106MN/m. It seems that the increase of soil stiffness, depth of the embedment, and the pile length will help to increase the pile stiffness. Figure 5 reveals the corresponding results. For more information, please see Lin (2022).

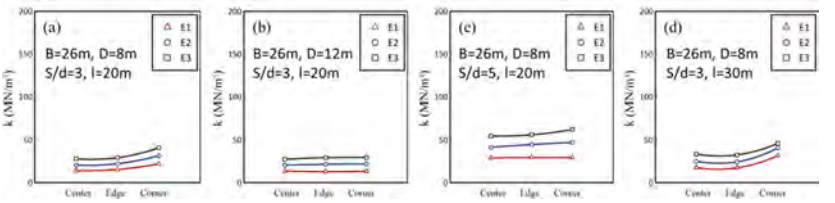

Figure 5. Coefficient of pile reaction affected by (a) soil stiffness (b) depth of embedment (c) number of piles (d) pile length.

4 DIMENSIONLESS MEASURES

4.1 *Pile displacements*

The dimensionless pile displacement in this study was defined as $\gamma_c s/E_c$ and s/B, where s is the real pile displacement. The values of 2D/B, S/d and l/d were taken as the dimensionless characters of the foundation geometry. It was found that the correlations between the dimensionless pile displacements and the dimensionless character of the foundation geometry are more scattered compared to those shown in mat foundation. Therefore the Box Plot was used to find the median values of the dimensionless pile displacements. For example, the dimensionless pile displacements ($\gamma_c s/E_c$) can be plotted against the shear wave velocities (V_s) of the soils considering the variations of raft dimensions and embedment depth. Figure 6 depicts the plots of $\gamma_c s/E_c$ versus V_s varying with the raft dimension (B) and depth of embedment (D). The corresponding plots of medians of $\gamma_c s/E_c$ versus the values of 2D/B are shown in Figure 7 separating the influences of raft dimension. Similarly, the plots for $\gamma_c s/E_c$ versus 2D/B separating the influences of the depth of embedment are shown in Figure 8.

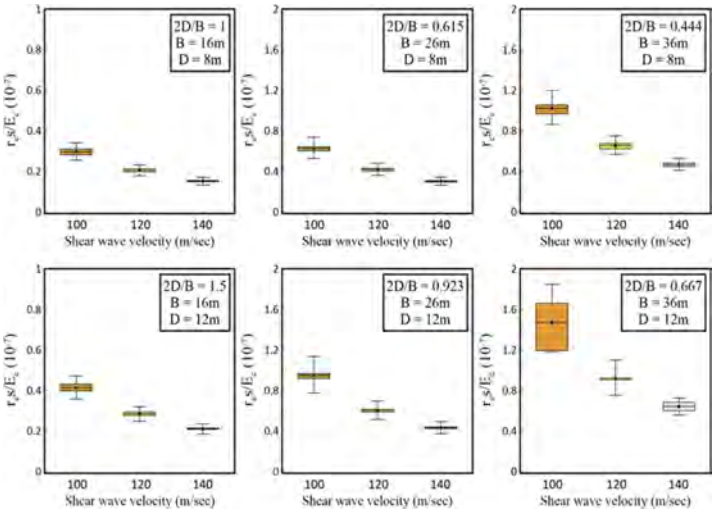

Figure 6. Box plots for dimensionless pile displacements ($\gamma_c s/E_c$) versus shear wave velocities (V_s).

For dimensionless pile displacement defined as s/B, the plots of s/B versus Vs varying with the raft dimension (B) and depth of embedment (D) can be shown in Figure 9. Again, the corresponding plots of s/B versus the values of 2D/B separating the influences of the raft dimension and the depth of embedment are depicted in Figure 10 and Figure 11, respectively. Correlations of the dimensionless pile displacements and the dimensionless character of foundation geometry (2D/B) based on different depths of the embedment were suggested owing to the number of data points presented.

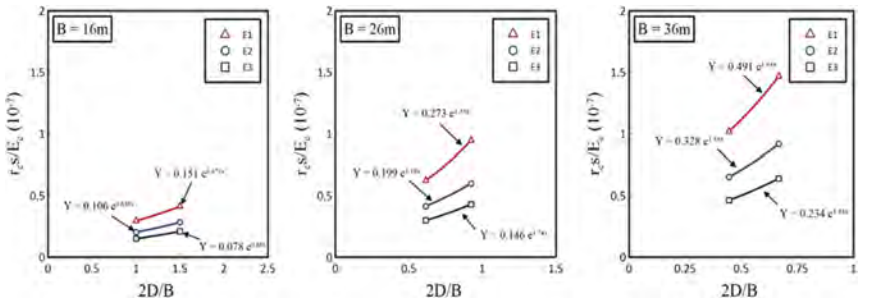

Figure 7. Correlations of dimensionless pile displacements ($\gamma_c s/E_c$) versus 2D/B for various raft dimensions.

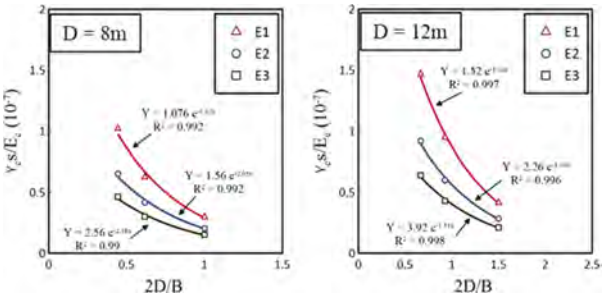

Figure 8. Correlations of dimensionless pile displacements ($\gamma_c s/E_c$) versus 2D/B for various depths of embedment.

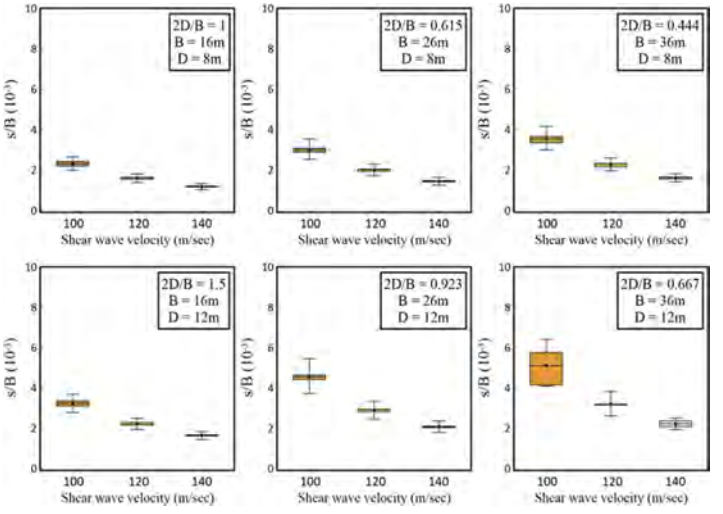

Figure 9. Box plots for dimensionless pile displacements (s/B) versus shear wave velocities (V_s).

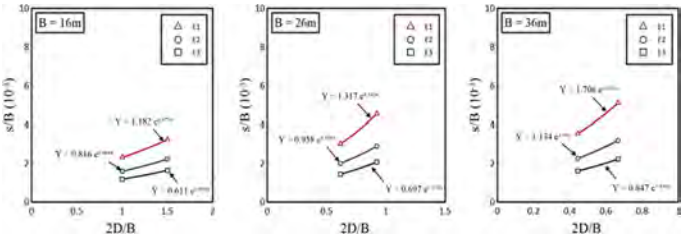

Figure 10. Correlations of dimensionless pile displacements (s/B) versus 2D/B for various raft dimensions.

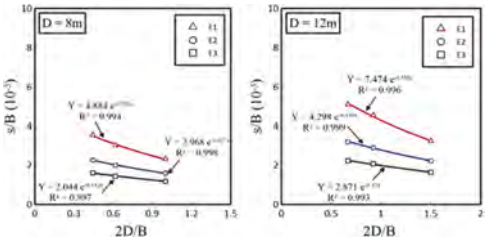

Figure 11. Correlations of dimensionless pile displacements (s/B) versus 2D/B for various depths of embedment.

The similar procedures to plot the dimensionless pile displacements $\gamma_c s/E_c$ and s/B with the dependence of shear wave velocity (V_s) of the ground soils, and subsequently obtain the correlations of the pile displacements versus other characters of the foundation geometry (e.g. S/d and l/d) can be found in Lin (2022). It was generally found that the Box plots made with the dependence of S/d and l/d would have larger deviations in terms of the height of the box and the height difference of the maximum and minimum values. Therefore they were not recommended.

4.2 *Pile reactions*

Following the above definitions of dimensionless pile displacement, the dimensionless pile reaction in this study was defined as p/E_c and $p/\gamma_c B$ respectively, where p is the pile reactions (Units in F/L^2). Figure 12-Figure 15 reveal the Box plots for p/E_c and $p/\gamma_c B$ versus the shear wave velocity of the ground soils with variations of embedment depth, and the correlations of the medians with respect to the dimensionless character 2D/B. The correlations of $p/\gamma_c B$ were not recommended owing to relatively higher deviations.

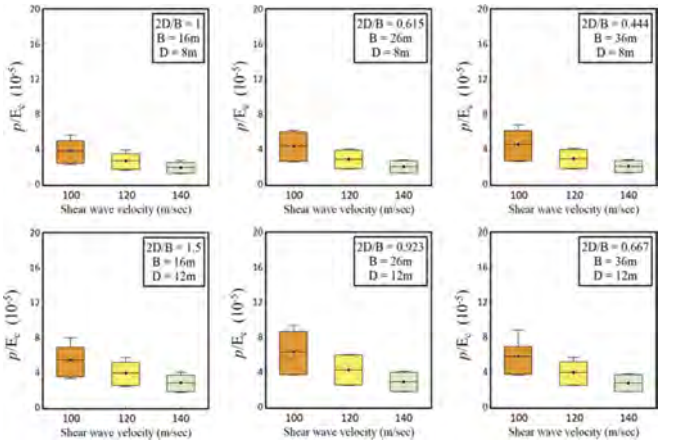

Figure 12. Box plots for dimensionless pile reactions (p/E_c) versus shear wave velocities (V_s).

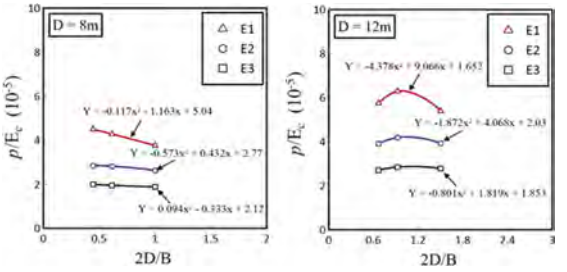

Figure 13. Correlations of dimensionless pile displacements (p/E_c) versus 2D/B for various depths of embedment.

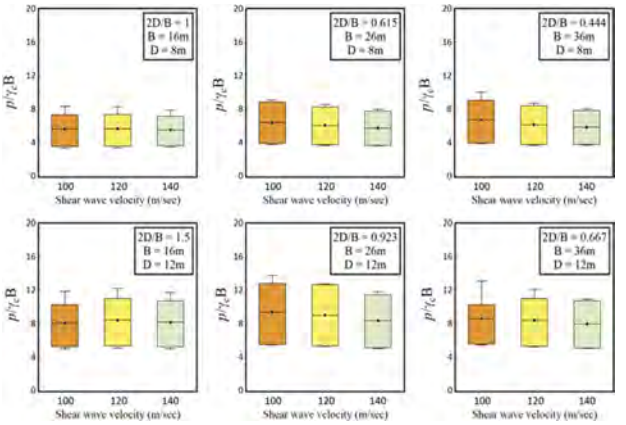

Figure 14. Box plots for dimensionless pile reactions ($p/\gamma_c B$) versus shear wave velocities (V_s).

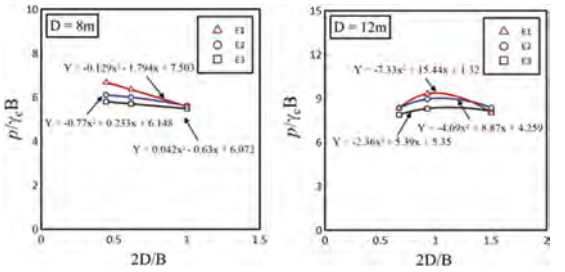

Figure 15. Correlations of dimensionless pile displacements ($p/\gamma_c B$) versus 2D/B for various depths of embedment.

4.3 *Coefficient of pile reactions*

The dimensionless coefficient of pile reactions was denoted as $p/\gamma_c s$ following the above dimensionless quantities of pile displacement and pile reaction. Similarly, the Box plots of $p/\gamma_c s$ versus V_s can be shown in Figure 16. The correlations between the dimensionless coefficient of pile reaction and the dimensionless character of foundation geometry (2D/B) at different depths of embedment are shown in Figure 17.

4.4 *Applications*

Notice that the maximum load pressure applied to the studied foundation is in the range of 240~360kPa. Therefore, if the loading condition can be approximated, engineers can use the

regression curves shown in Figures 8, 13 and 17 to estimate the pile displacement, the pile reactions and the coefficient of pile reactions based on similar soil conditions. For soil stiffness different to the suggested quantities, interpolations should be used to obtain the approximated values. For example, the pile displacement, s can be found as the procedures shown in Figure 18 considering the depth of foundation embedment is in between 8~12m. The pile reactions and the coefficient of pile reaction (or multiplying with a to obtain the pile stiffness) can be found using the similar procedure. Once the pile settlement, s and pile reactions, p are obtained, the coefficient of pile reaction, k can be also calculated as p/s.

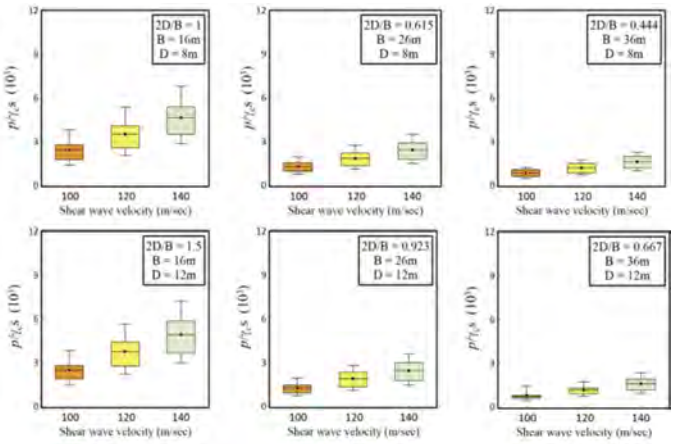

Figure 16. Box plots for dimensionless coefficient of pile reaction ($p/\gamma_c s$) vs. shear wave velocities (V_s).

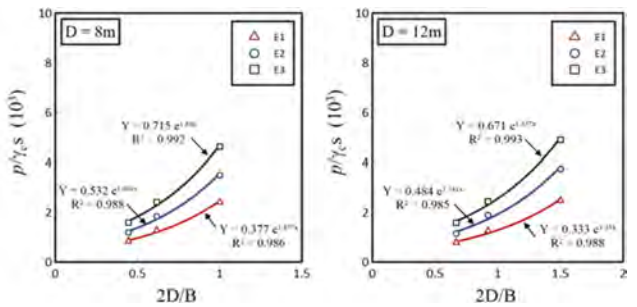

Figure 17. Correlations of dimensionless coefficient of pile reaction ($p/\gamma_c s$) vs. 2D/B for various depths of embedment.

5 CONCLUDING REMARKS

The pile displacements, pile reactions, and the coefficient of pile reactions of the embedded piled raft foundation located in soft clays subjected to vertical loads have been analyzed by 3D FE analysis. The influences of soil stiffness, raft dimension, depth of embedment (which affects the applied load), the number of piles installed, and the pile length were studied by seventy-two numerical cases. Enable to use them in routine design, the dimensionless measures were proposed first and then analyzed using Box plot. With the medians, their correlations with the dimensionless characters of the foundation geometry were examined. The correlations of $\gamma_c s/E_c$, p/E_c, and $p/\gamma_c s$ versus 2D/B were finally recommended to design practice. They are suggested as a preliminary design tool for piled raft foundations in soft clays. Further examination with the field measurements is welcomed.

ACKNOWLEDGEMENT

This paper presents a partial result of the technical project supported by Ground Master Construction Co. Ltd. in Taiwan. Sincere gratitude is expressed. The thankfulness is extended to Prof. C.H. Chen (NTU), Dr. C.D. Ou (SEAGS & AGSSEA) and Vice President Mr. C.C. Ko (MAA) for their valuable comments/suggestions in reviewing the project.

Numerical modelling of complex geotechnical problems - Three examples

Helmut F. Schweiger
Institute of Soil Mechanics, Foundation Engineering and Computational Geotechnics, Graz University of Technology, Austria

ABSTRACT: Over the last decades numerical methods have gained increasing importance in practical geotechnical engineering and have become a standard tool in geotechnical design, widely accepted by the geotechnical profession. In this presentation the application of advanced numerical models for solving practical geotechnical problems is shown whereas the examples have been chosen in such a way that different aspects are highlighted in each case. Results from fibre-optic measurements for a pull-out test of a ground anchor in soft soil could be reproduced by employing advanced constitutive models, in particular for the grout, in the bonded length of the anchor. The back-analysis of a slow-moving landslide is presented next, where the rate of deformation is influenced by water level changes in a reservoir for a pumping power plant, creep of lacustrine sediments and environmental effects such as rainfall infiltration. Finally results of modelling cone penetration testing in silts are presented.

1 INTRODUCTION

Numerical methods have proven to be an extremely powerful tool for solving practical geotechnical problems. This has been possible on the one hand because a number of commercial codes have been developed to a stage that they can be easily operated by geotechnical engineers and complex 3D models can be calculated with reasonable computational effort. On the other hand, constitutive models which are able to describe important features of soil behavior have been implemented in a robust manner in these codes. So, it seems there is no limit with respect to complexity in geometry and/or mechanical/hydraulical behavior which can be modelled today. However, it has to be emphasized that open questions in soil modelling remain and there is still no generally accepted constitutive model for soils available. Figure 1 shows an example of a finite element mesh typically used in the eighties and Figure 2 what is fairly standard today, and the progress made is obvious.

Similar developments can be observed with respect to constitutive models. It is now widely accepted that simple failure criteria such as the Mohr-Coulomb model are a reasonable choice for describing failure under drained conditions (or undrained conditions in terms of total stresses where it becomes the Tresca failure criterion) but are not sufficient to describe the mechanical behavior of soils for stress states well below failure. The latter however is the majority of applications of numerical methods in geotechnics. For this reason, all commercially available software packages offer more advanced constitutive models based on hardening plasticity formulations which consider a non-linear stress-strain behavior under working load stresses and in most cases include the behavior in the very small strain range, usually denoted as "small strain stiffness". An example for such a model which has gained some popularity in recent years is the Hardening Soil Small model (Schanz et al. 1999, Benz et al. 2009) which is implemented, in slightly modified versions, in various commercially available codes.

2 ANCHOR PULL-OUT TEST MONITORED BY FIBRE-OPTIC MEASUREMENTS

2.1 *Soil conditions, constitutive models for soil and grout and numerical model*

The test was performed on a construction site in St. Kanzian, in the southern part of Austria. The anchor was installed vertically, was post-grouted and had a free length of 12 m and a fixed length of 8 m respectively. Laboratory testing of soil samples extracted close to the test area classified the soil as clayey, sandy silt of low plasticity and the grain size distribution was approximately 70% silt, 15% clay and 15% sand. A seismic dilatometer test (sDMT) was conducted to determine the shear wave velocity and the shear modulus at small strains, $G_{0,ref}$. The soil is referred herein as "Seeton". Layers with higher sand content (denoted as sand in the following) were identified in a core drilling performed close to the location where the anchor was installed and were also observed in the sDMT. Oedometer tests and direct shear tests were performed for both soil layers. The constitutive model chosen for both soil layers is the Hardening Soil Small model (Schanz et al. 1999, Benz et al. 2009) as implemented in the finite element code Plaxis (Brinkgreve et al. 2017). Four stiffness parameters are required for this model: a secant stiffness for deviatoric loading ($E_{50,ref}$), a tangent stiffness for oedometer loading ($E_{oed,ref}$), an unloading/reloading stiffness ($E_{ur,ref}$) and the small-strain shear modulus ($G_{0,ref}$). The threshold shear strain $\gamma_{0.7}$ for $G_{0,ref}$ was assumed based on experience. These parameters are related to a reference pressure which is taken here as 100 kPa. The stress level dependency of stiffness values is controlled by parameter m. For parameter determination in-situ, laboratory test and experience have been combined to arrive at the input parameters for the Hardening Soil Small model which are summarized in Table 1.

Table 1. Material parameters for Hardening Soil Small model.

Parameter	Seeton	Sand
$E_{50,ref}$ (kPa)	6 625	16 000
$E_{oed,ref}$ (kPa)	5 300	16 000
$E_{ur,ref}$ (kPa)	48 000	48 000
c' (kPa)	10	5
φ′ (°)	29.5	32
m	0.9	0.6
ν'_{ur}	0.2	0.2
K_0^{nc}	0.51	0.43
$G_{0,ref}$ (kPa)	120 000	120 000
$\gamma_{0.7}$	0.15E-3	0.15E-3

It was expected that the grout material used in the bonded length of the anchor would behave as a nonlinear material and would, at least at higher load levels, exhibit some cracking. Therefore an appropriate constitutive model had to be employed and a model, originally developed for modelling the mechanical behavior of shotcrete, has been selected (denoted as Concrete model in the following). The model is formulated within the framework of elasto-plasticity and for deviatoric loading a Mohr-Coulomb yield surface is employed and, in the tension regime, a Rankine yield surface is assumed. The important feature of the model relevant to the analysis presented in the following is its capability to model the development of cracks by means of a so-called smeared-crack approach. This behavior in tension is linear elastic until the tensile strength is reached. Linear strain softening follows, governed by the major principal plastic strain and the fracture energy G_t (Figure 3). Once the residual strength is reached, no further softening takes place. As follows from Figure 3 the softening parameter H_t takes a value between 0 and 1.0 in the softening regime and a value larger 1.0 once the residual strength in tension is reached. This parameter will be plotted later in order to visualize the occurrence of cracks. More details on the model can be found in Schädlich & Schweiger (2014). Samples of the grout material were taken and uniaxial compressive test (UCS) and the multistage triaxial test (MST) were utilized to determine the required input parameters. However, no tensile tests were available and therefore G_t was chosen based on experience. Key parameters are given in Table 2. E is the Young'smodulus, ν the Poisson's ratio, $f_{c,28}$ and $f_{t,28}$ are the uniaxial compressive and tensile strength, $G_{c,28}$ and $G_{t,28}$ the compressive and tensile fracture energy and f_{tun} is the ratio of residual to peak tensile strength, all values for cured grout. The tendon of the anchor was modelled as a linear elastic material.

Table 2. Key material parameters for Concrete model.

Parameter	Grout Material
E_{28} (GPa)	15.5
ν	0.20
$f_{c,28}$ (MPa)	30.6
$f_{t,28}$ (MPa)	1.5
$G_{c,28}$ (kN/m)	3.06
f_{tun}	0.05
$G_{t,28}$ (kN/m)	0.01

The numerical simulation was performed using the finite element software Plaxis 2D (Brinkgreve et al. 2017). Because the anchor was installed vertically an axisymmetric model could be used. The model geometry including a detail of the anchor is presented in Figure 4. The tendon was considered only in the fixed length and prescribed displacements were applied at the tendon at the top of the fixed length. Grout was considered in the free and fixed length,

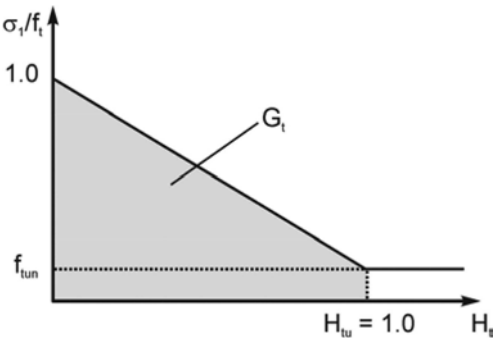

Figure 3. Normalized stress - strain curve in tension, definition of state variable H_t.

whereas pressure grouting was only assumed in the latter. The pressure grouting was taken into account in the numerical model by increasing the radial stresses along the fixed length, i.e. the earth pressure coefficient at rest (K_0) was set equal to one. In addition, the diameter of the bonded section was increased to 280 mm (borehole diameter was 178 mm) based on the amount of grout pumped into the soil.

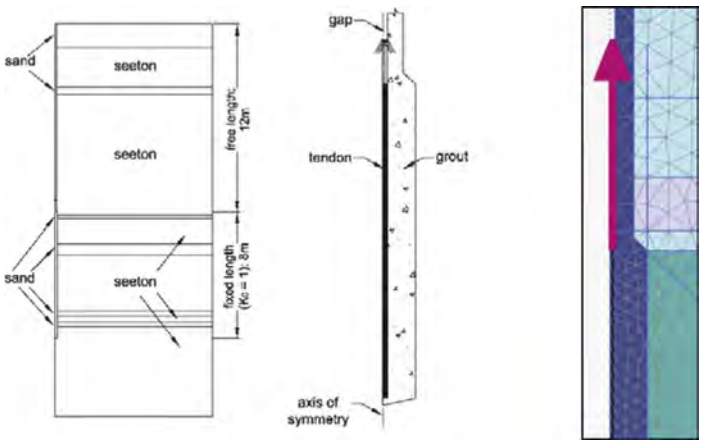

Figure 4. Numerical model: geometry, anchor detail, detail of finite element mesh.

2.2 *Results*

The in-situ measured and the numerically obtained load-displacement curves are compared in Figure 5. Only the displacements at the top of the fixed length are presented. The horizontal bars show the anchor displacement if the creep, developing during the holding stage at each load level, is subtracted from the displacement because creep effects have not been considered in the numerical analysis. Two numerical load-displacement curves are shown. The dashed line corresponds to the class-A prediction done before the test and the solid line to the numerical simulation with slightly refined material parameters after the test. The predicted load-displacement curves showed very good agreement with the in-situ one. The numerical ultimate load was approximately 1100 kN and the failure criteria of the in-situ test was achieved at 1200 kN. The class-A load-displacement curve was slightly stiffer than the in-situ curve and a better agreement was achieved with modified parameters as mentioned above. However, from a practical point of view the agreement between measurements and analysis can be considered excellent.

The numerical strain distribution along the tendon compared with the in-situ measurements, obtained by means of fibre-optic measurements (Monsberger et al. 2016), is presented in Figure 6. The numerical oscillations observed from 280 kN onwards are a result of the snap-

back instability generated when cracking in the grout starts. This is a numerical problem which is however not considered relevant for the purpose of this study. Together with the fact that measurements indicate that some cracks are closing with further loading which cannot be accounted for realistically by the applied constitutive model this leads to some deviations between numerical results and measurements, in particular for higher load levels. Because at residual state the calculated strain values are not meaningful, the tension softening parameter H_t is used as a measure to compare numerical results with in-situ cracking in the grout body. H_t is an output of the model and a value of H_t larger than 0 indicates that softening in tension has started. A value larger than 1 means that the tensile stress has decreased to its residual value (Figure 3). Figure 7 presents the evolution of H_t for selected load stages. In Figure 7 H_t is plotted along the fixed length and compared with the in-situ strain distribution in the grout. The peaks along the H_t profile indicate that cracking is, at least qualitatively, captured very well. A more comprehensive discussion of results can be found in Fabris (2020) and Fabris et al. (2021).

3 SLOW MOVING LANDSLIDE

3.1 *Problem description and measurements*

In the course of extension works for a water storage basin, a slow-moving landslide was identified next to the storage basin. The dimensions of the water storage basin are roughly 400 m in length and 100 m in width with a horizontal length of the landslide of roughly 270 m. The inclination of the slope is 30° on average and inclinometer readings suggested that the sliding surfaces would be between 20 and 40 m below ground surface. The subsurface explorations showed a sliding mass consisting mainly of weathered and sheared rock. Below the sliding mass and below the water storage basin lacustrine fine sediments, mainly silt, are present. A plan view and a layout of the slow-moving landslide and the water storage basin are shown in Figure 8.

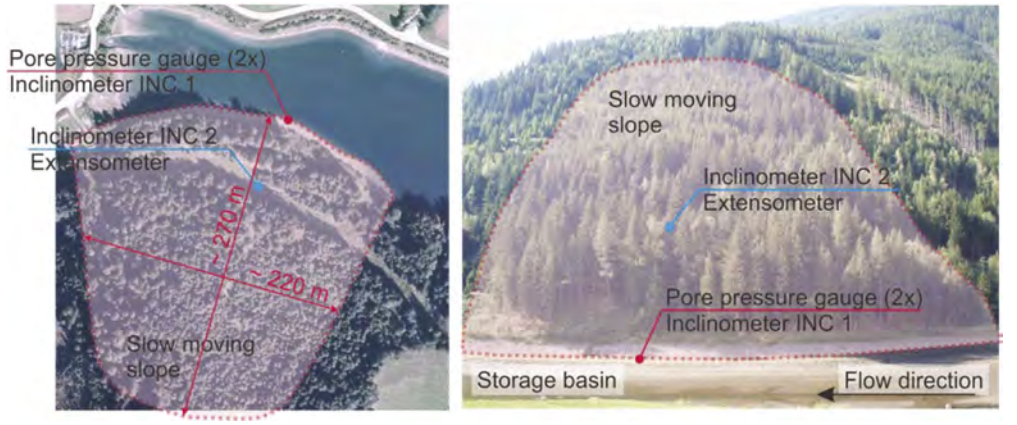

Figure 8. Layout and plan view of water storage basin and slow-moving landslide.

Due to the operation of the pump storage power plant the water level in the basin changes up to three times a day whereas the maximum level change is 7.0 m. A comprehensive monitoring system was installed including additional inclinometers and pore water pressure gauges. The pore pressure measurements showed changes in pore water pressures in the subsoil at the toe of the landslide linked to the water table changes in the water storage basin. However, it was observed that this was not a one-to-one relationship because positive and negative excess

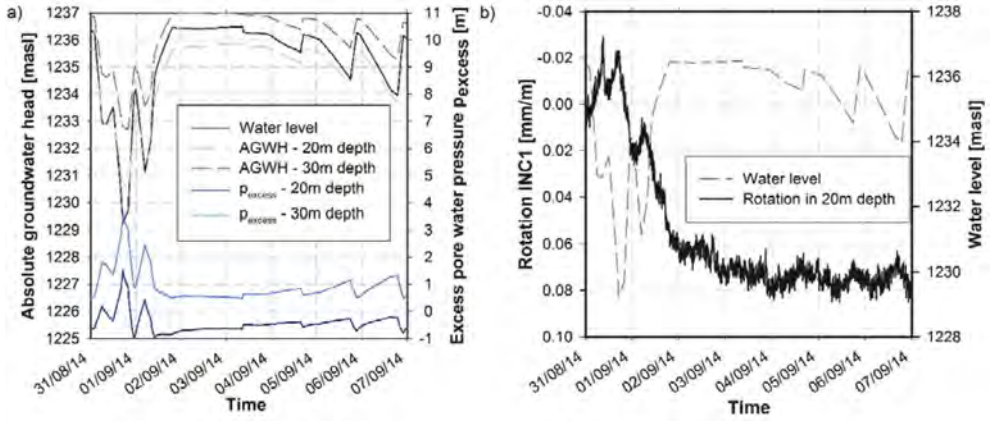

Figure 9. Excess pore water pressures due to water level changes, b) Correlation between deformation rates and water level changes.

pore pressures have been measured, i.e. the pressure level of the pore pressure measurement is above or below the corresponding water level in the water reservoir. Typical measurement results of the pore pressure gauges are shown in Figure 9. For a better understanding of the reasons for these measured excess pore water pressures a numerical study was carried out. These analyses revealed, as expected, that the magnitude of these excess pore water pressures depends on the ratio between drawdown velocity and soil permeability and furthermore on the ratio between pore water compressibility and soil skeleton compressibility (Ausweger & Schweiger, 2017). Also the presence of air bubbles in the water may contribute to this effect (Ausweger & Schweiger, 2016). In Figure 9 the excess pore water pressure p_excess is defined by the difference of measured and hydrostatic pore water pressure. Deformation measurements using in-place inclinometers revealed a correlation between deformation rates and excess pore water pressures at the slope toe. This shows that the slope deformations are influenced by the water level changes in the water storage basin, as these control the excess pore water pressures in the subsoil. A typical comparison of water level changes and rotation of the inclinometer probe in the major sliding zone is shown in Figure 9b.

3.2 *Numerical model for storage basin and results*

Preliminary numerical analyses and careful examination of the measurements indicated that water level changes alone could not explain measured displacements. Therefore a finite element model (Figure 10) was set up incorporating the water level changes from the storage basin but also environmental influences such as rainfall events assuming site specific precipitation and evaporation. Furthermore, the lacustrine fine sediments at the slope toe were modelled with the Soft Soil Creep model (Vermeer & Neher, 1999) to model the creep behavior of these soil layers (see Figure 10). To achieve appropriate initial conditions concerning the stress state and the hydraulic conditions, the geological history was modelled in a simplified way. Afterwards, one year with characteristic precipitation and water level changes was simulated (Ausweger, 2017).

The back-calculation of the pore water pressures was performed for several periods with different types of water level changes. Figure 11 shows a comparison of the measured and calculated excess pore water pressures for the two installed pore water pressure gauges PPG 1 (in 21 m depth) and PPG 2 (in 33 m depth). Furthermore, the water level in the storage basin is plotted in the diagram. From the comparison in Figure 11 it can be seen that a good agreement between calculations and measurements could be achieved. In order to identify the quantitative contribution of the different influencing factors on the total displacements, separate calculation phases were performed. In each phase a new influencing factor was considered. As

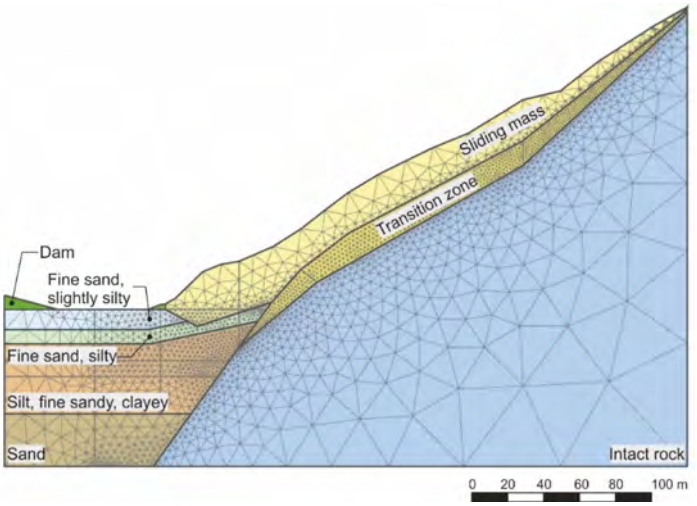

Figure 10. FE-model for numerical back-calculations (Ausweger, 2017).

an example, the results for a point in the middle of the slope are shown in Figure 12. The difference between two time-displacement curves is the influence of each additionally considered factor as indicated by the label of the curves. It follows that for the point considered the influence of water level changes is about 50% of the total displacements (difference between curve labelled "precipitation" and curve labelled "water level changes") but creep behavior of the lacustrine sediments at the base of the slope and precipitation add to the displacements. A comparison between the in-situ measurements and the total calculated displacements including all effects indicates a good agreement. The results were evaluated for several points along the slope. It could be clearly shown that the influence of the creep behavior of the lacustrine fine sediments on the deformations decreases with increasing distance from the slope toe. The influence of precipitation and evaporation is increasing in the middle and upper part of the slope and the influence of the water level changes on the slope deformations is almost constant over the entire slope. Based on the back-calculations of the slope deformations it can be argued that the water level changes are the main reason for the slope movements. However, slope movements would also occur without the storage operation but the magnitude of the deformations would be smaller.

4 NUMERICAL SIMULATION OF CONE PENETRATION TEST

4.1 *Numerical framework and constitutive model*

In-situ site investigation methods, such as cone penetration testing (CPT), are frequently used to derive hydraulic and mechanical soil properties from measured tip resistance, sleeve friction and pore water pressure via empirical correlations. However, there are uncertainties in interpretation of CPT results when e.g. partial drainage has to be considered or the soil exhibits some form of structure and bonding. The latter aspect is addressed in the following. Here numerical methods can play a significant role in obtaining a better understanding of CPT. Recent advances in the numerical simulation of large deformation problems based on a Particle Finite Element Method (PFEM, see Oñate et al. 2011) allow to model this kind of penetration problems. The simulations in this paper are carried out using the platform G-PFEM, short for Geotechnical-Particle Finite Element Method (Monforte et al. 2017a,b), which has been developed within the Kratos framework (Dadvand et al. 2010) at the Polytechnic University of Catalonia (UPC) and the Center for Numerical Methods in Engineering (CIMNE). In G-PFEM, the quasi-static linear momentum and mass balance equations are

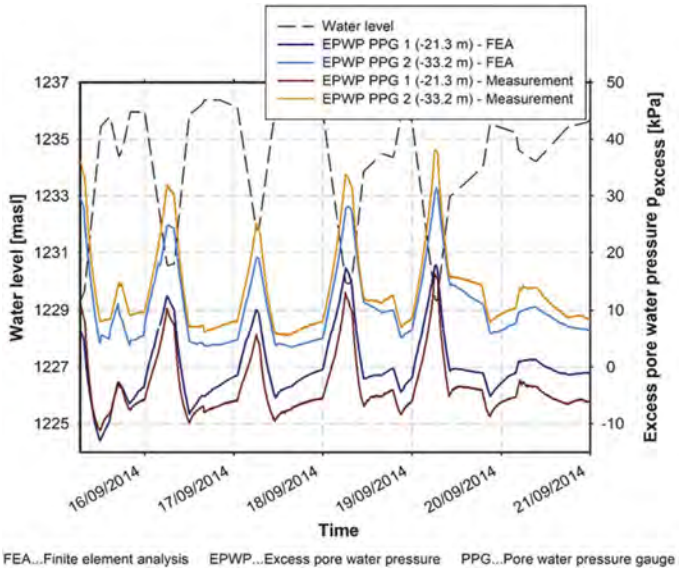

Figure 11. Back-calculated excess pore water pressures (Ausweger, 2017).

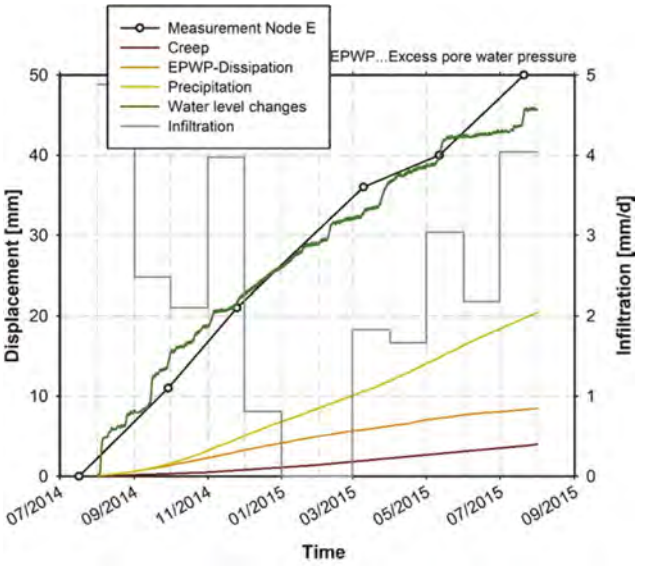

Figure 12. Displacements at node E (in the middle of the slope) due to different factors (Ausweger, 2017).

formulated for a solid and fluid phase adopting an updated Lagrangian description. The basic idea behind the PFEM is a continuous remeshing of critical regions of the domain, where new nodes can be added and old ones removed, in order to deal with large deformations and avoid excessive mesh distortion. This strategy results in an increased computational cost and therefore low order elements in combination with a mixed formulation of the problem are used. In order to avoid locking effects an additional degree of freedom, namely the determinant J of the deformation gradient is introduced on top of the displacement and water pressure fields u and p_w (Monforte et al. 2017b).

Modelling a CPT involves an ideally rigid cone that penetrates a deformable two-phase medium at a constant velocity. This leads to an axisymmetric model consisting of a rectangular

box with a height of 1.1 m and a width of 0.5 m. The cone radius R measures 1.78 cm with a tip angle of 60° corresponding to the standard geometry (base area of 10 cm²). The penetration starts from an initial position where the cone is located at a depth of 10 cm. The lateral and lower boundaries are fixed in normal direction while an overburden pressure can be applied at the top of the domain. Figure 13 shows the basic model. In this work the Clay and Sand Model (CASM) which is a state parameter based, elastic-plastic critical state (CS) model proposed as proposed by Yu (1998) is employed. [2]. The model has been enhanced in order to take into account the effects of bonding and destructuration based on the concepts presented by Gens & Nova (1993), see Figure 14. Undrained conditions have been postulated.

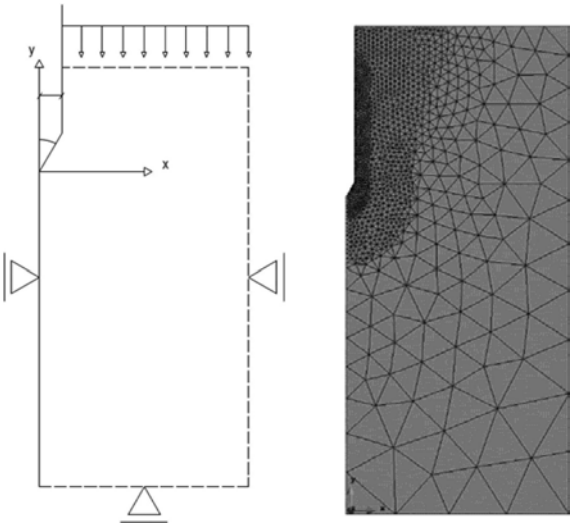

Figure 13. Axisymmetric model (left) and refined mesh during penetration process (right).

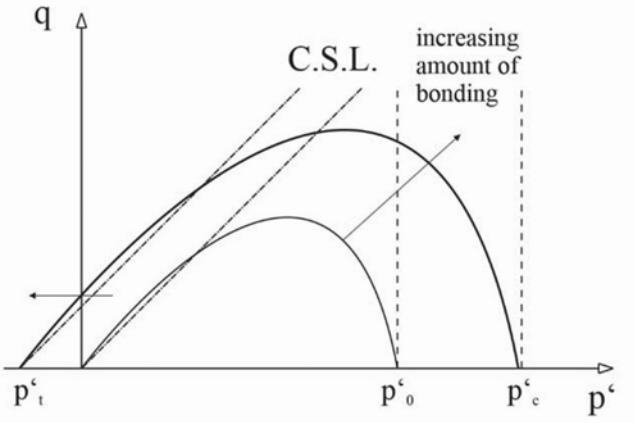

Figure 14. CASM yield surface with bonding.

4.2 *Influence of bonding and destructuration*

In this section the influence of initial bonding and destructuration occurring during the penetration process is evaluated. The parameters for this investigation are taken again for a clayey silt. The coefficient of lateral earth pressure at rest K_0 is taken as 0.5, the effective vertical stress is 160 kPa and the initial water pressure u_0 is 50 kPa. Two different degrees of initial

bonding, defined by the parameter b_0, namely 0.25 and 0.75, are chosen. In addition, different rates for destructuration, controlled by the parameter h are assumed. h = 0 denotes no destructuration at all, i.e. the bonds between particles are not destroyed during penetration whereas higher values for h indicate higher rates of destructuration. It follows from Figure 15 that bonding increases the calculated tip resistance as compared to the soil with b = 0, the higher b the higher q_c, as expected. The increase of tip resistance is significant. If destructuration is taken into account (h > 0), tip resistance decreases, and the values obtained are between the bonded and unbonded case.

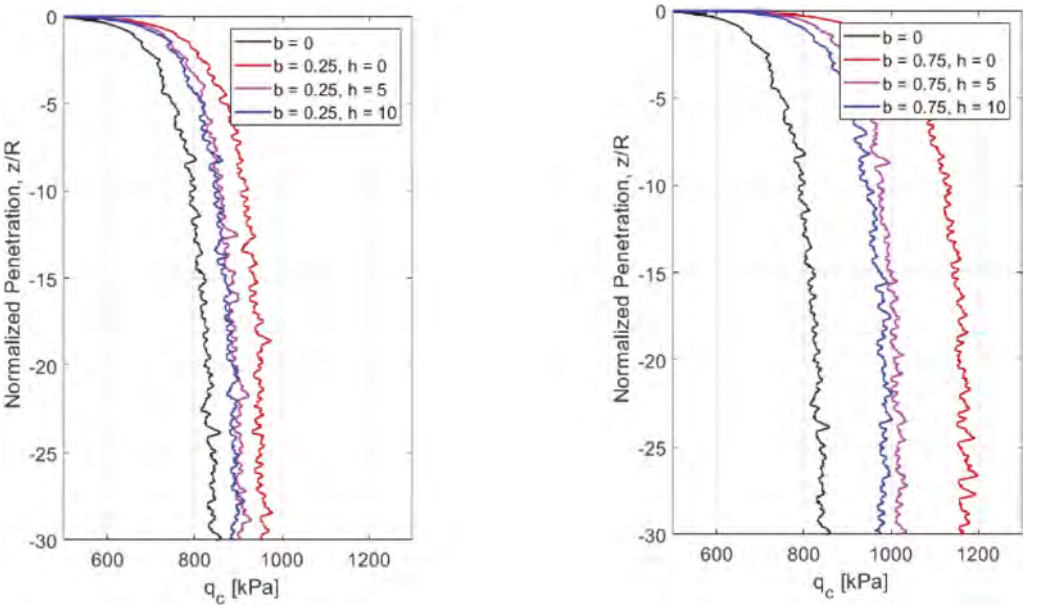

Figure 15. Calculated tip resistance q_c over normalized depth z/R for different degrees of bonding and rate of destructuration.

5 CONCLUSIONS

In this paper three examples have been chosen to illustrate that advanced numerical modelling can contribute to a better understanding of geotechnical problems. The numerical simulation of an anchor pull-out test showed that the predicted load-displacement curve and the one obtained in-situ showed very good agreement proving that accurate predictions are possible when a careful interpretation of in-situ testing and laboratory experiments using engineering judgement and experience is made. The fibre-optic sensors installed led to a better understanding of the behavior of ground anchors. The development of cracks in the grout of the bonded length could be clearly identified. By employing an appropriate constitutive model for the grout in the numerical analysis the development of cracks in the grout could be successfully reproduced in good agreement with the in-situ measurements.

The second example, namely the back-analysis of a slow-moving landslide at a water reservoir, proved that complex mechanisms contributing to slope movement, such as water level fluctuations in the reservoir, creep phenomena in soft lacustrine deposits present at the toe of the slope and environmental effects such as rainfall infiltration can be accounted for in numerical analyses. It is acknowledged that due to significant uncertainties in input parameters the solutions presented are by no means unique but still provide a better insight into the mechanical behavior of such slopes and will help the experienced geotechnical engineer in defining appropriate mitigating measures.

In the last example it is shown that G-PFEM, a finite element framework for analyzing large strain and large deformation problems, is an appropriate tool for simulating CPTu. The

constitutive model CASM has been enhanced in order to take into account bonding and destructuration. It could be clearly shown that tip resistance increases significantly with the degree of bonding and reduces with higher rates of destructuration, as expected. These results can be used for an improved interpretation of CPT results in structured soils.

ACKNOWLEDGEMENTS

The work presented on the pull-out test is part of a FFG-funded research project (Bridge-24 Nr. 858505) and the support of ÖBB-Infrastructure and ASFINAG is gratefully acknowledged. The fibre-optic measurements have been performed by the Institute of Engineering Geodesy and Measurement Systems of the Graz University of Technology (H. Woschitz). The test has been executed by Keller Grundbau (V. Račanský, R. Kulmer). Thanks are also due to Boštjan Pulko, Carla Fabris, Georg Ausweger, Roman Marte and Laurin Hauser.

Creep after surcharge unloading

C.F. Leung
National University of Singapore, Singapore

T.A. Vergote
DEME, Belgium

S.C. Chian
National University of Singapore, Singapore

ABSTRACT: Ground improvement by means of surcharge and vertical drains are often employed to accelerate the consolidation of newly reclaimed lands. However, the long-term performance of the reclaimed land is uncertain as the creep settlement of the land after unloading may exceed the stringent ground settlement limit for the operation of container port with various automated port equipment. A review of published literature reveals that existing methods have limitations on predicting the long-term ground settlement after surcharge unloading. In this article, a theoretical approach is proposed to simulate the long-term ground settlement after unloading. The approach is verified against long term soil consolidation tests subject to different over-consolidation ratios. Finally, the potential applications of the theoretical approach in practice are highlighted.

1 INTRODUCTION

The container port of Singapore is one of the busiest ports in the world. In many countries including Singapore, the container ports are built on reclaimed land underlain by soft compressible materials of the original seabed. Owing to shortage of reclaimed fills in Singapore, the Building and Construction Authority of Singapore (BCA 2008) issued guidelines that all dredged, and construction waste soils should be used for land reclamation to tackle the simultaneous problem of shortage of fill materials and disposal of construction waste soils. The above filling process would produce a highly heterogeneous and less competent fill grounds. Ground improvement employing surcharge and vertical flexible drains are typically employed to accelerate the settlement of such fill grounds and the underlying in-situ compressible soils. Figure 1a shows vertical drains being installed in the reclaimed land and Figure 1b shows the placement of surcharge to accelerate the consolidation of the fill ground and underlying compressible soil strata.

Figure 2 shows the Singapore Pasir Panjang Container port wharf front after completion. In modern days, automatic guided vehicles often operate in the wharf front area and the container stacking yard area behind the wharf front. To ensure that the automated equipment would function properly during the life of port operation (typically minimum 60 years for the case of Singapore), the mechanical engineers would specify stringent residual movement and rotation limits of the reclaimed ground after surcharge removal. As such, the long-term settlement of the reclaimed land after removal of surcharge needs to be evaluated.

Although many studies have reported the creep of soils under constant loading (Grimstad et al. 2017, Mesri 1973, Watabe et al. 2012), there are relatively few existing literatures reporting on the creep of soils after unloading of surcharge (Mesri & Feng, 1991). In view of the above, this invited lecture will present the latest research findings on creep upon unloading from the National University of Singapore. A new theoretical model will be presented in this lecture to predict the long-term ground settlement after removal of the surcharge.

2 LABORATORY TEST OBSERVATIONS

Vergote (2020) conducted an extensive series of oedometer tests to examine the creep of clay upon unloading with various over-consolidation ratios (OCR). Sample test results are shown in Figure 3. It is evident that soil creep would reappear upon stress relaxation and the clay would respond to unloading by swelling due to dissipation of suction pressures under constant effective stress. The amount of creep of the soil depends on the magnitude of OCR.

Vergote et al. (2019) compared recent constitute models of soil creep upon unloading. They reported that while the models are fitted with parameters to render near-identical compression behavior during loading, the unloading creep behavior varied widely depending on the OCR applied. They also highlighted the limitations of existing strain-based model and established that the isotache strain rate-based models are better suited as the problem of the time origin can

be overcome. However, unloading behavior is characterized by changes in the isotache relation which are not fully consistent with the loading behavior. As such, the more flexible, non-linear strain rate-based models to evaluate the unloading creep behavior should be utilized.

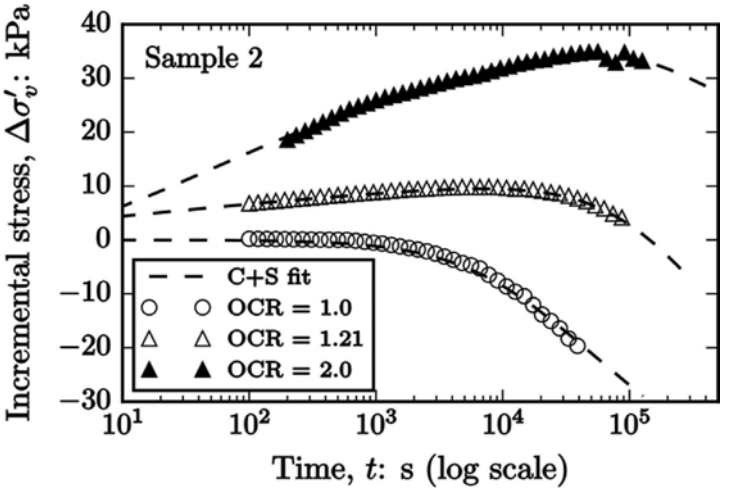

Figure 3. Effect of overconsolidation ratio to relaxation of soil, with increased swelling and reduced creep with increasing overconsolidation, after (Vergote et al., 2022).

Vergote (2020) re-analyzed the oedometer test results of Feng (1991) on creep after unloading using the strain rate-based approach, and the results are shown in Figure 4. The creep after reappearance is non-linear in e-log(t) scale (as reported by Mesri & Feng, 1991). In the present study, it can be interpreted in a consistent way using the strain rate versus accumulated strain ($\dot{e} - \Delta e$). The speed at which creep occurs, $\dot{e}$, goes down gradually with time and as more creep strain Δe occurs. For normally consolidated clay, this results in an approximately linear relation between $e - \log(t)$, but the linearity strongly depends on the selection of a time origin or a reference time. This problem does not occur if strain rate is evaluated relative to strain. Both in loading and after unloading, a linear relation can be found, which can be described by the initial strain rate, $\dot{\varepsilon}_{initial}$, as the intercept and $\hat{C}_\alpha$ as the slope (Figure 4).

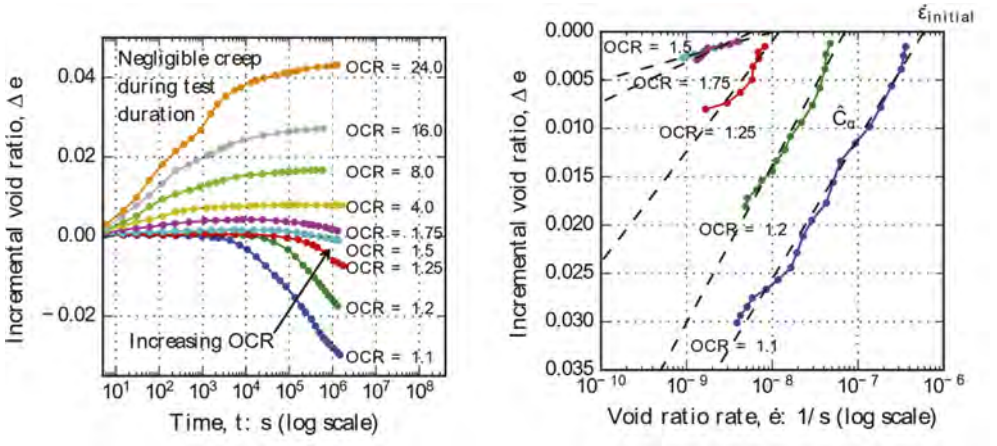

Figure 4. Reinterpretation of the oedometer tests on Berthierville clay (Feng, 1991), following a strain rate approach, after (Vergote et al., 2022).

The interpretation in $\dot{e} - \Delta e$ space linearizes the creep response aligned with the isotache approach. This is illustrated in Figure 5 whereby a normalized best-fit parameters of $\dot{\varepsilon}_{initial}$ and a rate-based secondary compression index $\hat{C}_\alpha$ for different OCR values upon loading can be obtained. The key finding is that the initial creep strain rate after unloading, and hence the secondary compression index, reduce significantly with increasing OCR. In view of this, a simple model is presented here to estimate creep after unloading.

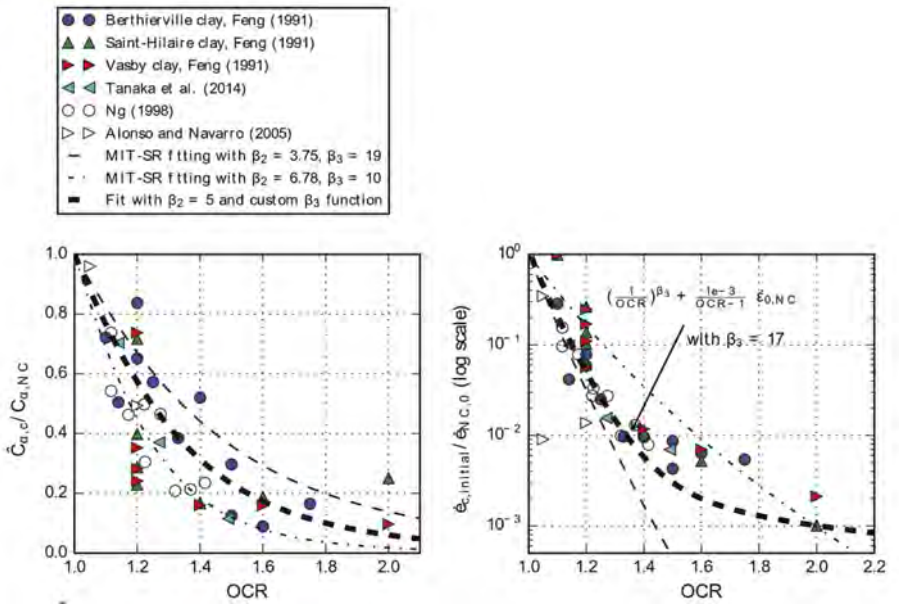

Figure 5. Normalized best-fit creep parameters after unloading for six clays, after (Vergote et al., 2022).

3 C + S MODEL

Existing models only allow to predict creep after unloading but they do not account for the soil swelling behavior. In reality, viscous swelling has a significant effect. It does not only lead to significant deformations (often larger than creep) but also affects the creep response. In view of this, Vergote et al. (2022) proposed a new model tackling creep C and swelling S independently, namely the **C+S model**, to account for this behavior. Figure 6 reveals the principle of the C+S Model. As illustrated in Equation 1, the model considers a decomposition in strain rates as:

$$\dot{e} = \dot{e}_e + \dot{e}_c - \dot{e}_s \tag{1}$$

Where $\dot{e}$ is the total void ratio rate, $\dot{e}_e$ is the elastic void ratio rate, $\dot{e}_c$ is the creep void ratio rate and $\dot{e}_s$ is the viscous swelling rate. The creep and swelling strain rates, respectively, under constant loading are expressed as:

$$\ddot{e}_c = -\frac{\dot{e} \cdot \dot{e}_c}{\hat{C}_{\alpha,c}} \ln(10) \tag{2}$$

$$\ddot{e}_s = \frac{\dot{e}_s^2}{\hat{C}_{\alpha,s}} \ln(10) \tag{3}$$

where $\hat{C}_{\alpha,c}$ and $\hat{C}_{\alpha,s}$ are the secondary compression and swelling indices, and $\dot{e}_{c,init}$ and $\dot{e}_{s,init}$ the initial strain rates for creep and swelling after unloading. These four parameters are a function

of OCR. When considering the overconsolidation, it is important to make a distinction between the applied overconsolidation due to surcharge as defined by:

$$OCR = \frac{\max(\sigma')}{\sigma'} \tag{4}$$

This definition does not consider creep induced increase in the preconsolidation pressure. This is considered within an isotache framework by considering the preconsolidation stress on the reference isotache, leading to a reference overconsolidation ratio (see Figure 7):

$$OCR_{ref} = \frac{\sigma'_{p,ref}}{\sigma'} \tag{5}$$

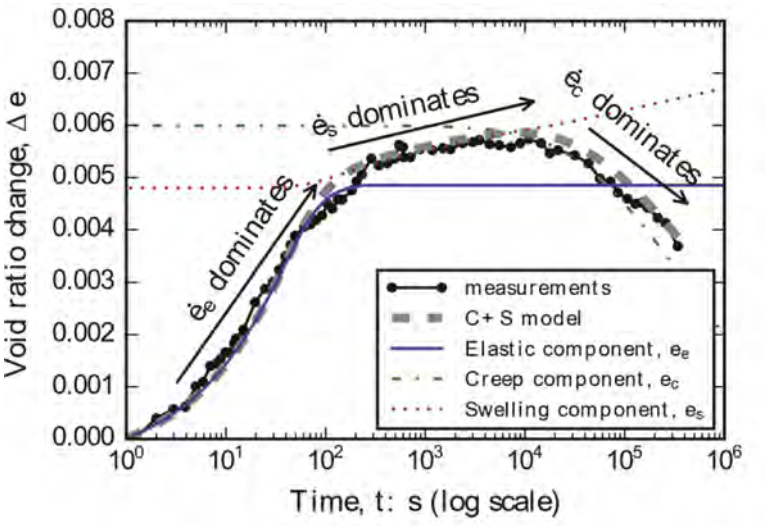

Figure 6. Principle of C + S model: decomposition of strain rates in an elastic, swelling and creep rate component, with sequential dominance of the three components as illustrated in a test at OCR = 1·49 by (Tanaka et al. 2014), after (Vergote et al., 2022).

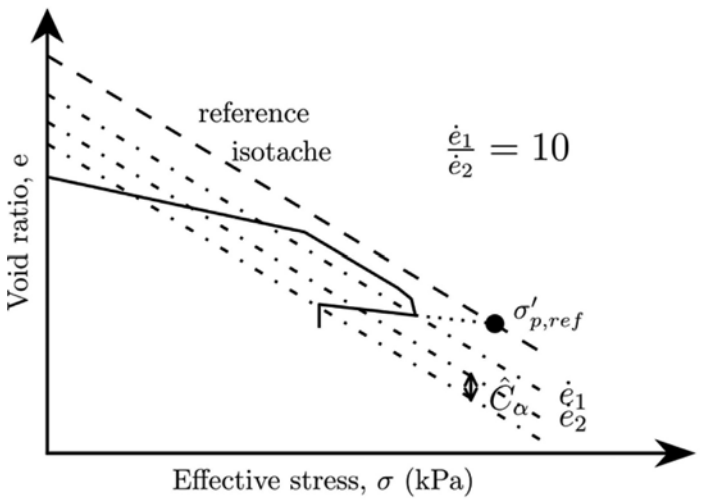

Figure 7. Reference isotache and the derivation of the reference preconsolidation pressure, after (Vergote et al., 2022).

The model is derived for constant loading and for relaxation conditions and used in calibration for previously published test results by others and new results. This was done with a Bayesian parameter updating approach using Markov Chain Monte Carlo simulation, (Hogg & Foreman-Mackey 2018). A clear relation of the normalized parameters, $\hat{C}_{\alpha,c}/C_{\alpha}$, $\hat{C}_{\alpha,s}/C_{\alpha}$, $\dot{e}_{c,init}/\dot{e}_{NC}$ and $\dot{e}_{s,init}$ can be observed. The relation is consistent among the different tests and samples implying that the normalization is appropriate for a wide range of silty and clayey soil types. These are illustrated in Figures 8 to 11. Details of the C+S Model are given in Vergote et al. (2022). A large set of test results is fit to the C+S model and the derived parameters are given in these figures. A clear relation is found between the different test results, including tests on sand, with a general reduction in the creep parameters, $\hat{C}_{\alpha,c}$ and $\dot{e}_{c,init}$ in function of the overconsolidation ratio relative to a reference isotache line, OCR_{ref}. The swelling parameters, $\hat{C}_{\alpha,s}$ and $\dot{e}_{s,init}$ increase with increased preloading and evolve in function of the overconsolidation ratio as calculated from load changes, OCR.

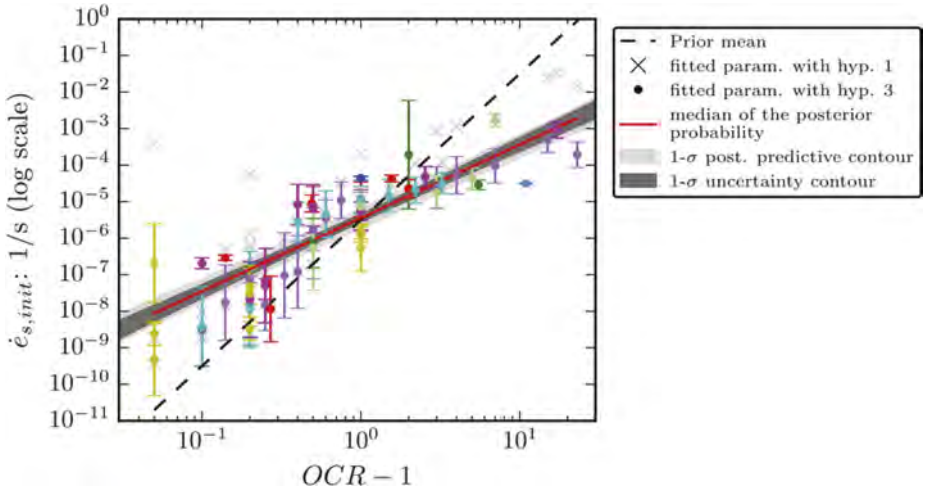

Figure 11. Increase of $\dot{e}_{s,init.}$ with increasing OCR, after (Vergote 2020).

4 DISTORTED ISOTACHE MODEL WITH SWELLING

Vergote et al. (2021) provided further evaluation to examine the validity of C+S Model from the prospective of an isotache model. In general, one can observe that (a) swelling and creep are not mutually exclusive and should be considered in the model, (b) the isotaches are non-linearly spaced, which implies that creep slows down (lower coefficient of secondary compression C_α at higher accumulated creep strain), and (c) after unloading, the isotaches are distorted. An illustration of these non-linear and distorted isotaches is given in Figure 12.

The C+S model allows to model the unloading effect under constant load or relaxation (constant volume) conditions. To simulate the real stress path of the soil in a more general application, one can integrate these features in a new isotache model that considers non-linear isotaches, distortion of isotaches after unloading and viscous swelling. The model is also hydro-mechanically coupled such that it can simulate consolidation correctly. A complex stress path is illustrated in Figure 13.

The model was validated with a constant rate of strain (CRS) compression test involving all the loading and unloading stages, constant loading stages, and relaxation stages. Thanks to the viscous swelling and distorted isotaches, a better fit to the model results was possible, with

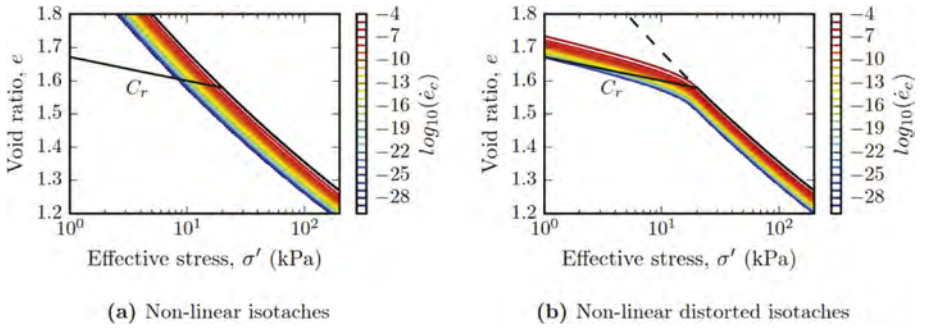

Figure 12. Increase of $\dot{e}_{s,init.}$ with increasing *OCR*, after Vergote et al. (2021).

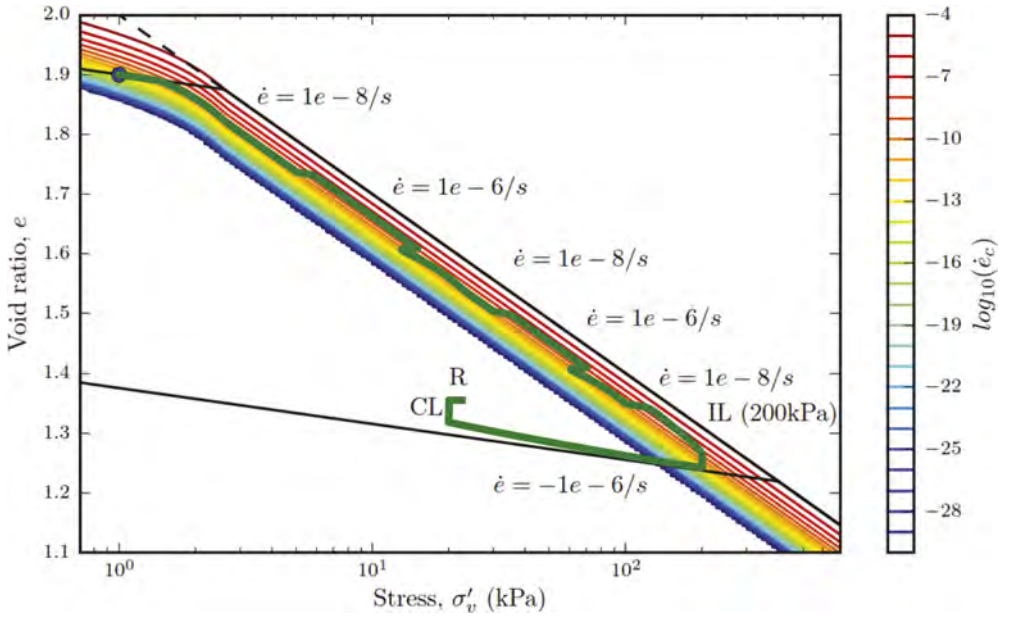

Figure 13. Increase of $\dot{e}_{s,init.}$ with increasing *OCR*, after Vergote et al. (2021).

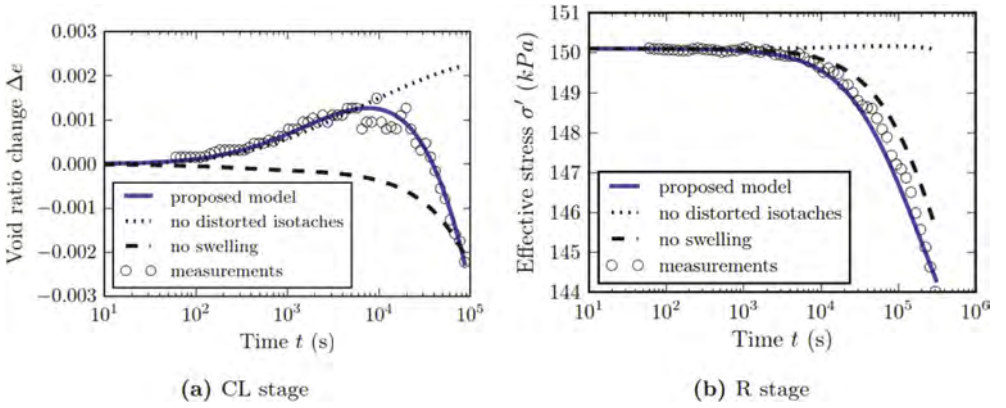
particular improvement during unloading at low to medium OCRs. Please refer to Figure 14 for illustration.

Experimental results also suggest a rate dependence in the hysteresis effect during unloading-reloading cycles. The model can simulate this, thanks to the viscous effects in the soil, as demonstrated in Figure 15.

4 INDEPENDENT EVALUATION OF C+S MODEL

Dick (2022) evaluated the C+S model for the use of long-term settlements against field data based on the InSAR field measurements. InSAR (Interferometric Synthetic Aperture Radar) is a technique to interpret radar images. The measurements allow to map the relative deformation of surfaces over time, which makes InSAR a promising alternative to field measurements. The measurements were applied to two roads in the Netherlands. He illustrated that the C+S model showed a more realistic settlement rate compared to the linear isotache model, although it still overestimated the settlement rate after 10 years employing default parameters. This was done by comparing the measured strain rate to the predicted strain rate after 10



(a) CL stage (b) R stage

Figure 14. Sequential constant load and relaxation tests after unloading at OCR = 1.2, after Vergote et al. (2021).

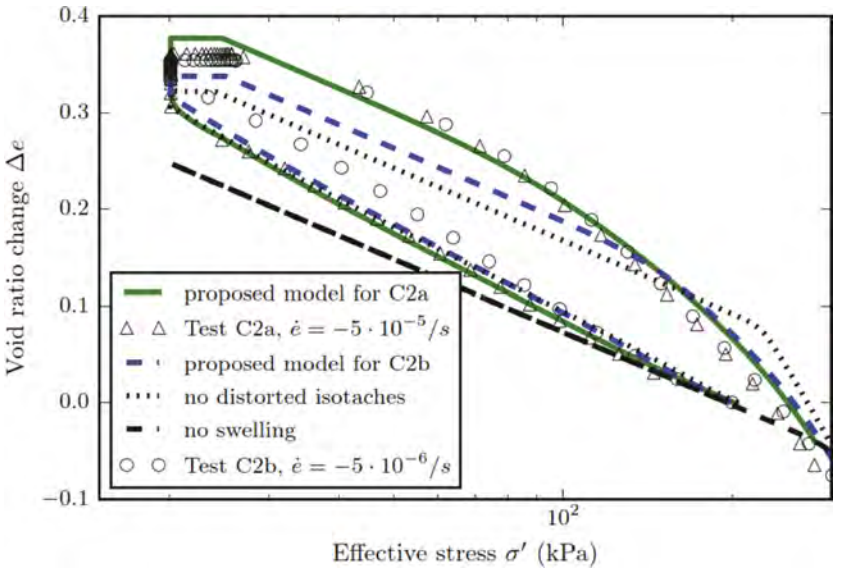


Figure 15. CRS Unloading-reloading cycle at slow and fast rate with a constant load and relaxation phase at OCR = 12, after Vergote et al. (2021).

years. The authors of this article think that it is fairly straightforward to calibrate the parameters of the model with the InSAR measurements to achieve better long-term predictions and retain a good prediction upon loading. This indicates the potential of the model to predict long term settlement of the soil.

In addition, extensive validation using compression tests on Mexico Clay show features as identified in the C+S research: viscous swelling and non-linear creep. The experimental data was used to validate multiple isotache models. The C+S model was compared to linear isotache models and predicted the actual behavior much better, especially after unloading. This can be seen in Figure 16.

5 POTENTIAL PRACTICAL APPLICATIONS OF C+S MODEL

Vergote et al (2021) demonstrated the potential use of C+S model for soil improvement designs presenting some practical phenomena to be considered including the evaluation of

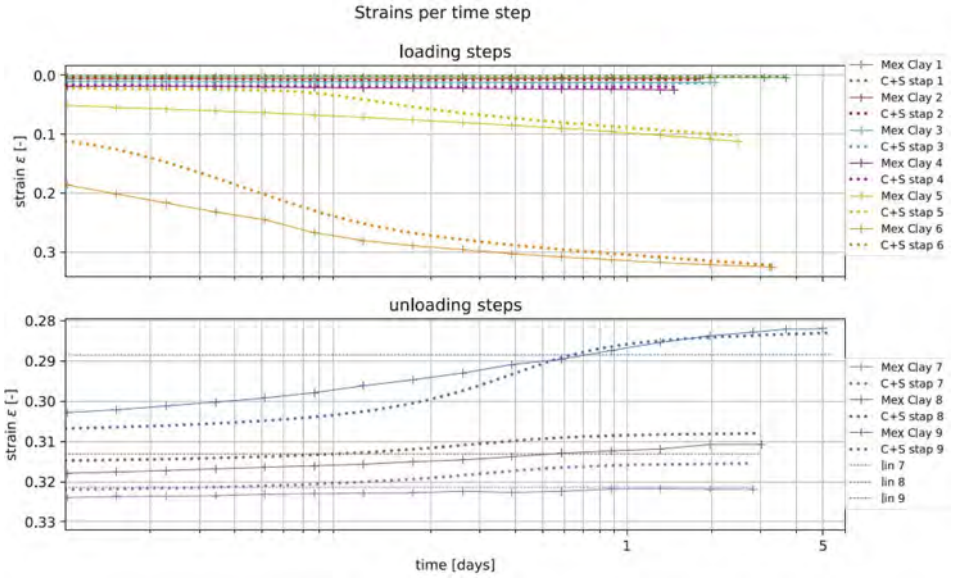

Figure 16. Strain development per loading step for the C+S model and Mexico clay data with a changed value of *cv* upon unloading, after (Dick 2022).

unloading effects. The primary goal of the model is to improve prediction after preloading with surcharge and prefabricated vertical drains (PVD) or vacuum consolidation. The amount of preload stress depends not only on the elastic response of future live loads but also on the long-term time-dependent deformations. By selecting an appropriate preloading height and preload time, the creep deformations can be reduced. Figures 17 and 18 show the effect of increase in preload and increase in preload time on the long-term response of a homogenous clay ($C_c = 0.4,\ C_r = C_c/10,\ C_\alpha = C_c \cdot 0.04$) of 20m.

For a given preload, the overconsolidation ratio will vary over depth, which should be considered in the predictions. In general, it can be observed that creep is reduced to very small values with an OCR > 1.4. Preloading beyond this level will lead to larger long-term swelling. This is function of the design life and the properties of the soil.

The viscous response during unloading is also important for other phenomena, such as long-term swelling estimations after excavation of dredging of soils that serve as foundations for tunnels, for instance for the Fehmarn Belt fixed link, see Kinslev (2021). Highly overconsolidated clays are dredged, leading to significant swelling which impose possible future stresses and deformations to the infrastructure. The current research shows that the swelling is rate-dependent and the C+S approach provides a framework to interpret this and relevant predictions.

Finally, to enable reliable practical predictions, it is important to map the uncertainty of the model to enable probabilistic predictions and reliability-based design. As part of this research, the model calibration was done with a Bayesian updating approach using Markov Chain Monte Carlo, (Foreman-Mackey et al. 2013, Hogg & Foreman-Mackey 2018, Vergote et al. 2022). This allows to create posterior predictive distributions, to derive a probability of a deformation and can be further integrated in an overall framework. An example for drivability predictions in offshore wind is given in Vergote & Raymackers (2022).

6 CONCLUDING REMARKS

This invited lecture first reports the limitations of existing theories on the prediction of soil creep settlement upon removal of surcharge. The conventional strain-based theories are

unable to simulate the laboratory oedometer test results on creep after unloading. In view of the above, a new strain rate-based approach, the C+S Model, is presented to better simulate the creep behavior upon unloading. The overall concept and principle of the model are presented in this lecture. The model can evaluate the creep and swelling phenomena separately in a rational manner. In addition, the model is verified using distorted isotache model considering swelling as well as third-party independent evaluation against existing field data on creep after unloading. Although there are still minor gaps in the verification against field data in the longer term after 10 years, the authors believe that the model can be further fine-tuned to bridge these minor gaps between theoretical and observed field data.

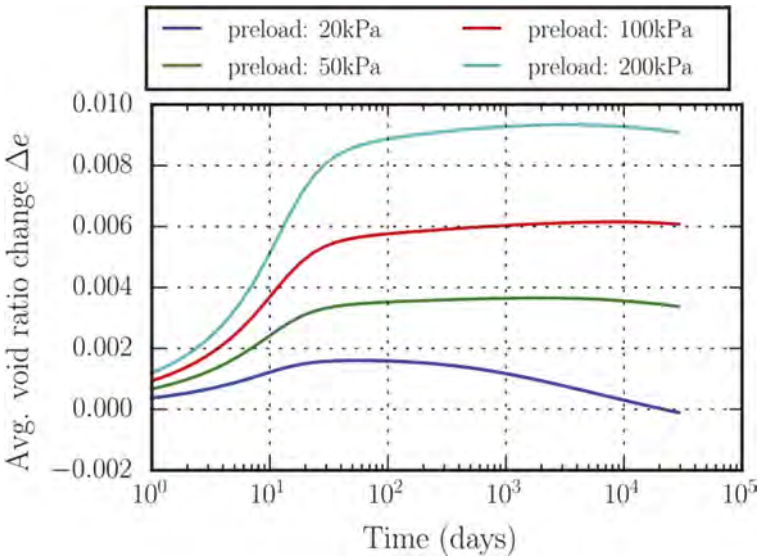

Figure 17. Model sensitivity to preload magnitude.

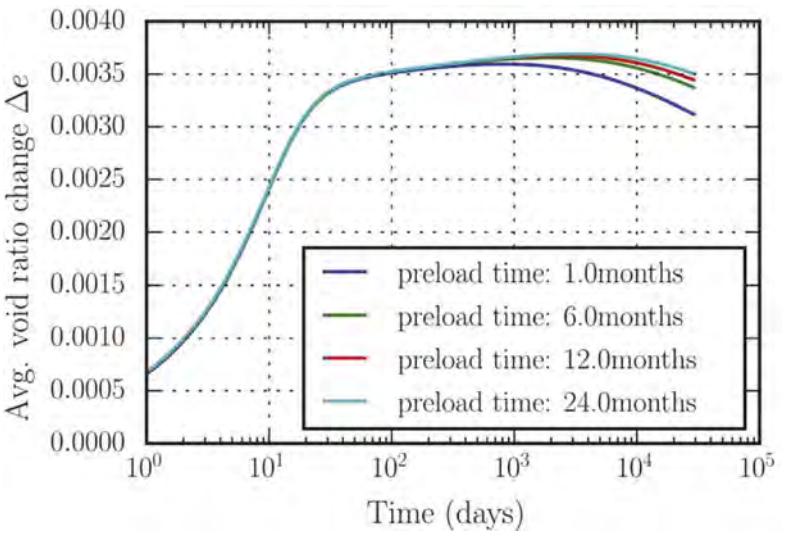

Figure 18. Model sensitivity to preload time (100kPa preload).

Further improvements to the model are planned to be made, both numerically and with availability of more experimental data. For instance, the model should be incorporated in a multi-layered, large strain, axisymmetric model to cater for end-to-end realistic consolidation predictions of land reclamations. Further, while significant experimental work has been done, the data is still rather limited, especially related to rate-dependence of unloading, the effect on reloading and the behavior of sandy soil. A large dataset of long-term field data similar to the InSAR data from the Netherlands would be particularly useful, especially if applied to a reclaimed area from the start of deployment.

Innovative geotechnical solution for base isolation

J.S. Dhanya
L. N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: Base isolation systems have been widely recognized as a promising solution for mitigating seismic hazards in buildings. This paper explores a novel solution to the problem of earthquake damage to low-rise buildings in developing countries, where traditional base isolation systems are often too costly and difficult to install. The proposed solution is a Geotechnical Seismic Isolation (GSI) system composed of geomaterials beneath the building foundation to act as a seismic filter medium, reducing the intensity of seismic waves by energy dissipation and damping. The present study focuses on using the Sand-rubber mixture (SRM) and geogrid composite as the geomaterials for energy dissipation. The study includes laboratory tests to optimize the geomaterial composition, scaled model tests, and finite element-based numerical studies to assess the performance of the GSI system under static and dynamic loading. It was observed from the element test that SRM with 30% rubber content has adequate shear strength and damping properties to be used as a foundation bed. The results from scaled model tests on a model footing placed on the GSI system show that a geogrid-reinforced GSI layer can increase bearing capacity up to three times with a significant reduction in settlement. Based on finite element studies on a symmetric low-rise framed building placed on the proposed GSI system subjected to seismic excitation, it was found that GSI is effective in reducing peak ground acceleration and decreasing the shear force and interstory drift in the building.

1 INTRODUCTION

Earthquake-resistant buildings have been a focus for the past few decades. Structural control concepts have been implemented by increasing the strength and stiffness of the structure, but damages can still occur. Though the strengthening method leads to safeguarding the structure from collapse at, the functionality of the structure after an earthquake cannot be guaranteed due to excessive damages. A different approach is to decouple the structure from the footing using base isolation techniques to reduce the intensity of the earthquake vibrations transmitted to the structure. The base isolation systems shift the natural period of the structure, reduce the magnitude of energy transferred to it, and increase damping, reducing the spectral displacement. The first rubber bearing isolator was used in 1969, and by the 1980s, seismic isolation gained worldwide popularity and has been refined over the years, using different types of bearings and materials (Kelly 2002).

Rubber bearings were the first modern-era isolation devices, followed by elastomeric bearings made of rubber and steel layers, which exhibit low damping resistance followed by friction pendulum and sliding bearings. However, the procurement and installation can be costly, making it challenging for developing nations to implement the system for regular residential buildings. A potential alternative to conventional base isolation systems involves incorporating damping into the soil up to a specific depth to partially dissipate energy within the soil before it reaches the foundation and superstructure. Compacted sand layers have traditionally been used as an energy dissipating layer. However, due to the decreasing availability of sand in the construction industry, researchers have investigated the use of waste materials such as scrap rubber tires and other polymeric waste products for geotechnical applications (Edil and

DOI: 10.1201/9781003299127-19

Bosscher1994; Ahn and Cheng 2014). Scrap tires with rubber as their primary component have been found to be particularly useful for vibration isolation (Dhanya et al. 2022, 2020, 2019; Forcellini et al.2020). A mixture of sand and shredded rubber tires, referred to as sand-rubber mixture (SRM), has been proposed as a potential solution to the problems of earthquake hazard, unaffordable and ineffective seismic isolation systems, and the rapid generation of scrap rubber tires. This mixture can be used as a vibration mitigation solution and serves as a novel seismic isolation layer, referred to as the Geotechnical Seismic Isolation (GSI) system, placed below building foundations.

In 2007, Tsang proposed using a sand-rubber mixture (SRM) as a geotechnical seismic isolation layer beneath building foundations. Studies by Tsang et al. (2012,2021), Xiong and Li (2013), and Pitilakis et al. (2015) have demonstrated that this method can reduce both horizontal and vertical shaking levels. Similar studies have examined the use of sandbags and synthetic liners as energy-absorbing layers for seismic protection, with Yegian et al. (2004), Jain et al. (2004), and Ansari et al. (2011) reporting lower accelerations compared to fixed-base structures. Pitilakis et al. (2015) noted that SRM layers are particularly effective for mid-rise buildings, reducing design shear force and displacement. Shaking-table experiments conducted by Xiong and Li (2013) and Bandyopadhyay et al. (2015) with shredded rubber-soil mixtures as isolation material placed below concrete blocks confirm the suitability of SRM for seismic isolation. Previous studies have also reported that the damping ratio of SRM increases with an increment in rubber content (Hazarika et al. 2010; Anastasiadis et al. 2012; Senetakis et al. 2012; Ehsani et al. 2015) and that it has low liquefaction potential (Hazarika et al. 2007; Kaneko et al. 2013; Mashiri et al. 2016). The high elasticity, durability, and non-biodegradability of rubber present in SRM make it a sustainable and cost-effective alternative to expensive base isolation techniques.

The previous studies on the use of SRM for seismic isolation have mainly focused on laboratory characterization of the material with varying amounts and sizes of rubber. However, there is still no conclusive study on the optimal percentage of sand-rubber shreds mixture that provides a reasonable shear modulus with a satisfactory damping ratio over a wide range of strains suitable for seismic isolation applications. Furthermore, limited studies have been reported on the use of SRM as a vibration-absorbing layer for buildings, with little emphasis on site-specific conditions and earthquakes with varying peak ground acceleration (PGA) and frequency content. Additionally, the static performance of buildings placed on the GSI system, settlement problems posed by the low stiffness of SRM, and the influence of Soil-Structure Interaction (SSI) on the performance of the base-isolated building have not been adequately addressed in previous studies.

In view of this, the current study aims to investigate the physical and mechanical response of SRM through a series of laboratory tests to determine the optimal percentage of the mixture that offers sufficient stiffness and energy dissipation capacity. Furthermore, scaled model tests were conducted to evaluate the performance of footings resting on GSI systems, with a primary focus on settlement issues in the foundation on the SRM layer. Geosynthetic reinforcement was also explored to enhance the bearing capacity and settlement performance of the GSI system. Further rigorous dynamic analysis was conducted using advanced Finite Element Method (FEM) tools to gain a deeper understanding of the response of a low-rise building resting on the proposed GSI system under seismic loading.

2 CHARACTERIZATION OF SRM AND GEOSYNTHETIC

The study utilized locally sourced river sand of uniformly angular-shaped grains from Chennai city, India. Scrap rubber tyre used in the study was obtained from a local scrap tyre-recycling unit where the steel reinforcements inside the automobile tyres were removed. The tyre base material used for the study is from heavy-duty automobiles such as lorry/trucks which have a higher proportion of natural rubber compared to other non-rubber ingredients like steel and fibres. The final shredded tyre samples are metal and textile fibre-free. The scrap tyres were fragmented into angular shaped granulated tyres of size less than 4.75 mm using the shredding

machine from the tyre-recycling unit. The tyre particles passing 4.75mm size sieve was used in the preparation of sand-rubber tyre mixture samples. For the present study, the sand and granulated rubber were uniformly hand mixed to achieve a homogenous SRM mixture as shown in Figure 1a. Gravimetric proportioning is adopted rather than the volumetric proportioning for the rubber/sand content in the SRM to attain better control and uniformity in the mixture. The physical properties of sand and the granulated rubber tyre are presented in Table 3.1. The geosynthetic reinforcement used in the study is a commercially available planar biaxial geogrid (MACGRID AR) made of glass fibre strands arranged in grid shape having an aperture size of 10 mm x 10 mm (Figure 1b) with a maximum tensile strength of 11.5 kN/m.

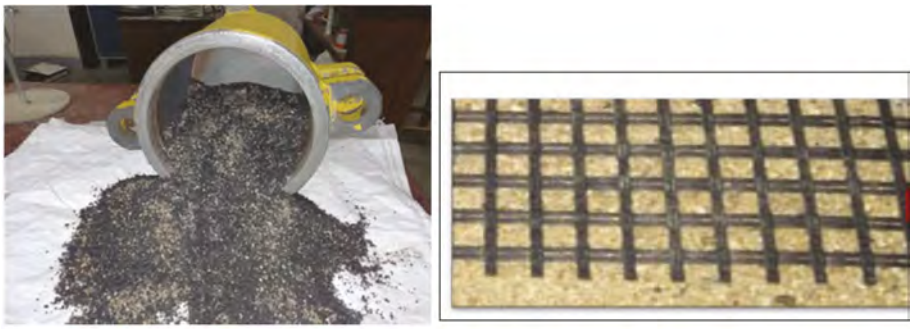

Figure 1. (a) Typical sand-rubber mixture sample (b) Geogrid used for the study.

To determine the gradation of the material, mechanical shakers were used for grain size analysis (Figure 2a). Based on the Indian standard classification system (IS: 1498 1970), the material was classified as poorly graded Sand (SP). The rubber tyre material used in this study is classified as granulated rubber tyre according to ASTM D 6270-08 (2012) since the particle size lies in the range of 425 μm – 12 mm. The granulated tyre for the present study was classified as an equivalent of poorly graded sand (SP) as per IS: 1498 (1970).

To get a better insight into the effect of rubber content on the shear strength response of the mixture, direct shear test is carried out on a standard apparatus with a shear box of 60 mm x 60 mm size. The shear strength of the mixture was normalized with respect to sand for a relative density of 85%. It can be seen from Figure 2b that the decrease in peak shear strength is gradual upto 30% rubber content, beyond which there is a steep decrease in the strength characteristics. Further, increase in normal stress was found to increase the shear strength of the mixture, this could be due to the redistribution of rubber within the voids of sand particles thereby increasing the contact surface and interlocking friction between sand and rubber particles (Foose et al., 1996; Asadi et al., 2018). Hence for the GSI system in the present study SRM with 30% rubber contend was adopted.

3 SCALED MODEL TEST ON FOOTING RESTING ON GSI SYSTEM

To shed insight into the understanding of shallow foundation performance with the presence of reinforced and unreinforced GSI layer, a series of laboratory model tests were carried out on scaled-down model footing. The study employed Wood's (2004) scaling laws of similitude to ensure similarity in both geometry and materials. A scale factor (λ) of 10 was applied to create a model footing that represents a prototype footing of 1 m x 1 m in size. The prototype footing used concrete with E of 20 GPa, while the model footing used steel with E of 200 GPa. The thickness of the model footing was calculated as 10 mm for the study.

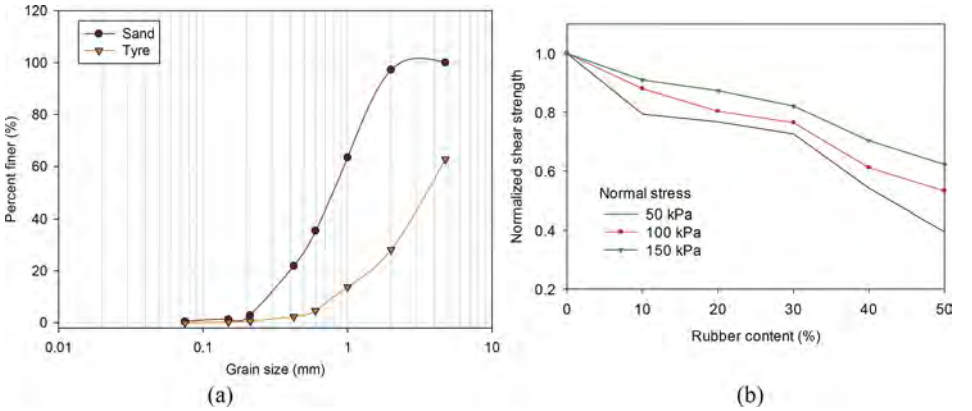

Figure 2. (a) Grain size distribution curve (b) Influence of rubber content on the shear strength of SRM (relative density- 85%).

3.1 *Experimental setup and methodology*

Experiments were conducted using a model square footing of width 0. 1 m (B) placed on top of the GSI layer composed of SRM within a sand bed tank setup (refer to Figure 3). The test tank utilized in this study was made of steel and had inner dimensions of 1 m x 1 m x1 m positioned below a 2m long and 2m high reaction frame. Pneumatic actuators were attached to the reaction frame to apply loads. A steel rod with a height of 1m connected the steel plate for the model footing to the actuator. The pneumatic actuator was used to apply vertical loading in displacement control mode. The load was measured using an electronic load cell with a capacity of 20 kN, and displacement was measured using a linear variable displacement transducer (LVDT) with a capacity of ±30 mm. Calibration of the load cell and LVDT was performed during installation by the equipment providers, and digitalized load-displacement data was automatically saved and available for analysis after testing.

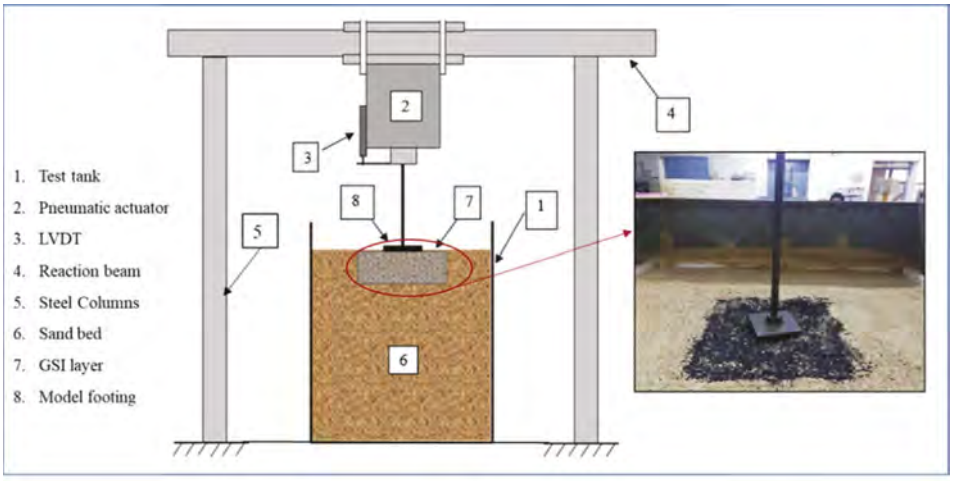

Figure 3. Schematic of the model test setup.

In all experiments, the test tank was filled with sand to a depth of 0.9 meters. A series of tests were conducted on footings resting on different layers of the GSI system to study their behavior under static loading. The first series of tests involved footings on sand beds of 0.9m depth with a relative density of 85% using the sand pluviation technique (Cresswell et al. 1999), where the

sand was poured from a fixed height. The sand was filled in 0.1 m layers and leveled before adding the next layer. Three preliminary trial tests were carried out to confirm the repeatability of load testing. The second series of tests were carried out on footings placed on the SRM-GSI layer. The already-compacted sand bed was excavated for a fixed size of 300 mm x 300 mm with the necessary thickness and backfilled with SRM. Geogrid reinforcement was added to the GSI layers below the footing to increase the bearing capacity and settlement aspect of the system. Hence, the third series of tests were carried out on footings placed on geogrid-reinforced SRM-GSI layer layers. Geogrids were placed at the top of the already compacted sand and SRM layer at a desired depth, and filling was carried out simultaneously to achieve the required relative density. The delicate strain gauges attached to the geogrids were carefully protected throughout the operation to avoid damage. The effective depth of influence is within a range of 2B from the bottom of the footing; hence the geogrids were positioned within a depth of 2B below the footing. In this study, single and double geogrids were used to reinforce the GSI system with layer thicknesses of 1B, 2B and 3B. The single layer of geogrid was placed at a depth of 0.5B, while the double layered geogrids were placed at depths of 0.3B and 0.5B with a vertical spacing of 0.2B. The model footing was placed on the level surface at the center of the GSI layer and sand-bed medium, to which a vertical compressive load was applied until the ultimate bearing pressure was observed. Readings from the load cell, LVDT and strain gauges were collected at a sampling rate of 5s.

3.2 *Response of footing resting on the reinforced and unreinforced GSI layer*

The results obtained from different series of tests are plotted as bearing pressure against the footing settlement (s) in terms of settlement ratios (s/B), as shown in Figure 4. The results revealed that the SRM-GSI layer had a larger settlement compared to the sand layer. The settlement ratio corresponding to the ultimate bearing pressure was 9% for sand and 13% for the SRM-GSI layer. The SRM-GSI layer showed initial compression due to the higher ductility of the rubber content in the mixture. However, there was no significant reduction in the bearing capacity of the GSI layer compared to sand. Interestingly, the SRM-GSI layer with a thickness of 0.5B exhibited a bearing capacity equivalent to that of pure sand. This could be because of the small difference in shear strength between the sand and SRM mixture at lower confining pressure. The bearing capacity of the SRM-GSI layer with a thickness of 1B and 2B increased, but the rate of increment in bearing capacity with settlement ratio reduced by 30% compared to the SRM-GSI layer with 0.5B width. In conclusion, the results suggest that the SRM-GSI layer has a higher settlement than the sand layer.

Figure 4.b Illustrates the load-settlement curves for a footing on the SRM-GSI layer reinforced with geogrid. The results show that the geogrid reinforcement significantly increases the bearing capacity and reduces the settlement of the footing. Additionally, the geogrid-reinforced GSI system exhibits a higher ultimate capacity and fails at higher values of settlement ratio compared to the unreinforced system. The figure reveals that the ultimate bearing capacity of the footing (at an s/B ratio of 20%) on the GSI system increases three times for double geogrids and two times for single geogrid reinforcement. The details of the influence of different parameters of geogrid reinforcement in the GSI system can be found in Dhanya et al. (2019). The studyconfirms that geogrid reinforced GSI system performs well under static loading conditions and can sustain foundation loading sufficiently with adequate bearing capacity and reduced settlement.

4 SEISMIC RESPONSE OF FRAMED STRUCTURE RESTING ON GEOGRID REINFORCED GSI LAYER

A low-rise building with shallow footing is used to numerically analyze the GSI system's dynamic performance using finite element software ABAQUS 6.14. A typical moment resisting framed structure on raft footing is chosen for numerical modeling, with the GSI layer placed below and at the sides of the raft footing. Geogrid reinforcement is added to enhance the GSI system's advantages under static and dynamic loading conditions. The study focuses on a region-specific layered soil domain in the highly seismic Indo-Gangetic plain basin the details of which are presented in Dhanya et al. (2020).

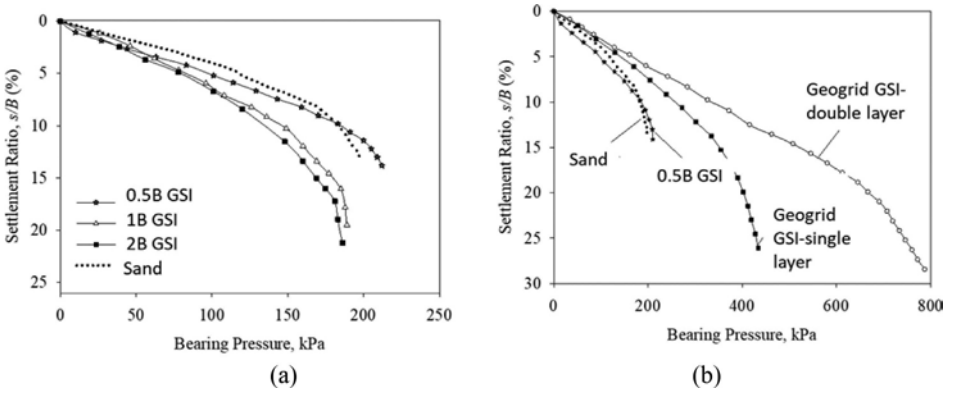

Figure 4. Bearing pressure-settlement response for the GSI system.

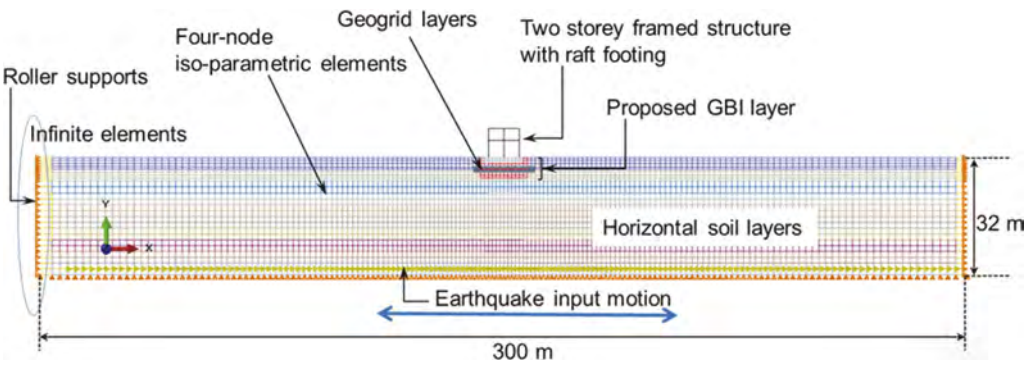

Figure 5. Finite element model adopted for the study.

A-4 type residential apartment buildings with two stories were selected to represent conventional low-rise buildings, based on the National Building Code (NBC) of India (2016). The framed structure used in the study had a height of 4.5 meters at the ground floor (including plinth level) and 3 meters at the top floor, with two equal bays each having a width of 4 m. The beams and columns in the structure were assigned cross-sections of 0.35 m x 0.4 m and 0.35 m x 0.45 m, respectively. The dead load and live load coming on the structure was calculated based on the code provision, IS 875:1987 Part 1& II (2008).

The soil domain of depth 32 m was chosen for the study. Plane strain quadrilateral grids with four-node iso-parametric elements were used to model the soil, GSI layer and footing. Soil is modelled using hypoelstic constitutive model while SRM is modelled using hyperelastic model. Elastic-perfectly plastic material constitutive behaviour was assumed for geogrids modelled using beam elements the details of which can be found in Dhanya et al. (2020). The soil domain was divided into homogenous horizontal layers. The bottom boundary was assumed to be fixed while the side boundaries were given roller supports that restrained horizontal movements but allowed for vertical movements. To simulate unbounded soil media and prevent wave reflections, infinite elements were used to create transmitting boundaries. In the dynamic analysis, the input motions under consideration consist of acceleration-time histories from two major earthquakes that occurred in the Indian subcontinent namely the 2001 Bhuj earthquake (Mw=7.7; PGA=0.1g; predominate frequency= 3.5 Hz) and 2015 Nepal earthquake (Mw=7.8; PGA=0.14g; predominate frequency= 0.2 Hz) obtained from the COSMOS Virtual Data Center as shown in Figure 6.

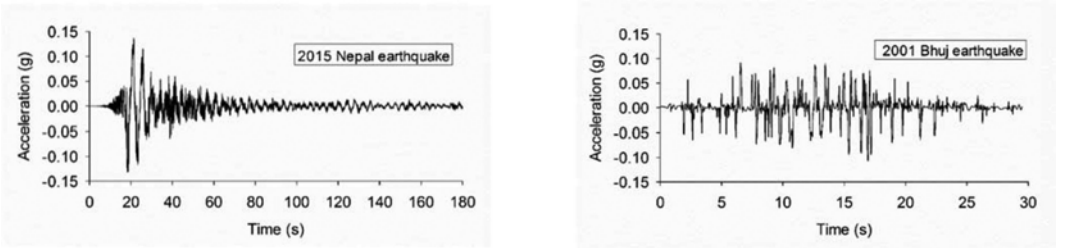

Figure 6. Acceleration-time history of earthquake input motions adopted.

4.1 *Acceleration response of the framed structure on GSI system*

Figure 7a depicts the acceleration-time history obtained at the top of the footing for the natural soil and geogrid reinforced GSI layer of thickness 0.05B when subjected to the 2015 Nepal earthquake motion. The GSI layer shows a significant reduction in the amplitude of acceleration at the footing top compared to the natural soil system. Figure 7b can provide a useful understanding of the characteristics of the acceleration response spectra (with 5% damping) for buildings resting on the geogrid reinforced GSI layer at the footing level. The graph clearly shows a reduction in spectral acceleration for the GSI system compared to the natural sol layer. This reduction is particularly pronounced in the mid-period range of 0.3 s to 1 s, whereas for periods less than 0.3 s and greater than 1 s, the reduction in spectral acceleration is less noticeable. Additionally, the presence of the GSI layer causes a slight shift in the predominant period of the system to a higher value compared to the natural soil system. This shift results in a reduction of spectral acceleration for low-rise buildings, which have a shorter natural period, such as 0.24 s in the current scenario.

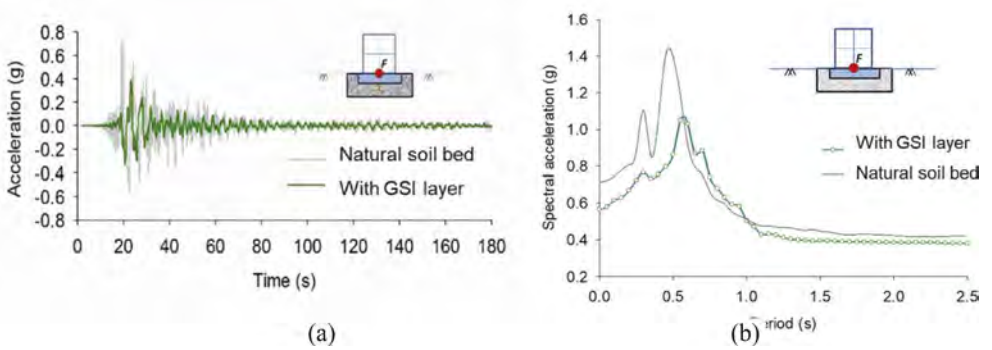

Figure 7. (a) Acceleration time history response (b) Spectral acceleration response at the footing level of the structure.

The thickness of the GSI system has a significant impact on the degree of reduction in earthquake input motion amplification. An optimal thickness of the GSI layer was determined through numerical analysis to ensure satisfactory seismic isolation for the proposed building. The GSI layer thickness was varied at 0.05B, 1B, and 2B, and the system was double-layer geogrid reinforced. The study used the scaled acceleration-time history of the 2015 Nepal earthquake (Mw=7.8) as the input motion and the results were extracted from nodes at the top of the building and footing. The reduction in the peak values of the spectral acceleration due to the presence of GSI was evident for all thicknesses of the GSI layer, as shown in Table 1. The reduction in spectral acceleration values for the GSI system indicates higher energy absorption induced by a thicker layer of the GSI system. For instance, at the top of the building, the isolation efficiency increased by 37% when the thickness of the GSI layer was

increased from 0.05B to 2B. At the footing top, an isolation efficiency of 35% was obtained, indicating that the peak ground acceleration of incoming seismic waves was reduced significantly due to the presence of the GSI layer (thickness=2B). Although the isolation effect initially increases with the increase in thickness of GSI, the isolation efficiency for 0.1B and 0.2B are more or less similar, indicating that using a 0.1B thickness of the GSI layer is enough to achieve the necessary energy dissipation. Additionally, the shift in the fundamental period of the system is more significant for thickness of GSI of 0.1B and 0.2B compared to 0.05B.

Table 1. Effect of thickness of GSI layer on peak spectral acceleration and predominant period (Scaled 2015 Nepal earthquake, Mw=7.8; PGA= 0.24g).

		Peak spectral acceleration (g)		Predominant period (s)	
Description		Footing top	Building top	Footing top	Building top
Natural soil		2.39	2.75	0.47	0.67
Geogrid reinforced GSI layer	$T_{GSI}=0.05B$	1.72	2.27	0.6	0.85
	$T_{GSI}=0.1B$	1.59	1.73	0.67	0.90
	$T_{GSI}=0.2B$	1.46	1.69	0.7	0.95

4.2 *Shear force and interstorey drift*

The effect of seismic isolation on the base shear of the framed structure was investigated and comparison was made between the fixed base structure and structures with seismic isolation, namely, while taking into account the effects of SSI. A constant scaled PGA of 0.24g was maintained for the earthquake input motions during the study. Figure 8 illustrates the base shear ratio, which represents the ratio of shear force developed in the SSI structure to that of the fixed base structure. The figure suggests that the SSI effects are advantageous for the GSI system, as it reduces the base shear when compared to the fixed base system. Additionally, the figure shows that the reduction in base shear is more significant for buildings placed on the SRM-GSI system than on the geogrid reinforced SRM-GSI system. This may be due to the decrease in soil stiffness beneath the building foundation. In contrast, the natural soil layer demonstrated a higher base shear ratio, as it is relatively stiff compared to the GSI system. For example, during the 2015 Nepal earthquake (Mw=7.8), the base shear ratio was 0.47 for the Sur system, which decreased to 0.3 for the GSIur system. Furthermore, the flexible-base provided by the GSI layer influences the SSI effects, resulting in lower base shear when compared to the fixed base system.

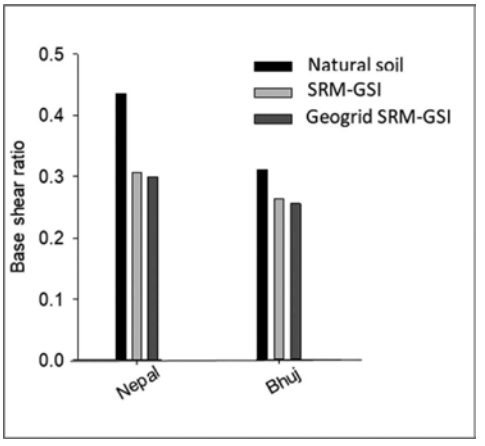

Figure 8. Base shear ratio for different earthquake input motion.

Assessing the performance of GSI isolated structures during earthquakes involves analyzing the maximum lateral displacement experienced by each floor of the building and the corresponding interstorey drift calculated as the difference in lateral deflection of the jth storey and the lateral displacement of the (j+1)th storey, divided by the storey height. The results were summarized in Table 2, which showcases the variation of maximum storey drift for the 1st and 2nd floors of the building for different ground motions (PGA=0.24g). The structure on natural soil had a higher inter-storey drift due to increased lateral displacement in comparison to SRM-GSI layer. This effect is mainly caused by the high amplitude of seismic waves reaching the structure. To further reduce the lateral displacement of GSI layers, the geogrids were introduced, which created a confining effect and restrained the structure's lateral displacement placed on the GSI system.

Table 2. Maximum inter-storey drift of the building for different earthquake motions.

	Maximum storey drift (mm)					
	Natural soil		SRM-GSI		Reinforced SRM-GSI	
Earthquake	1st floor	2nd floor	1st floor	2nd floor	1st floor	2nd floor
2015 Nepal (Mw=7.8)	9.4	10.5	7.7	8.6	6.1	6.6
2001 Bhuj (Mw=7.7)	3.6	5.1	3.2	4.5	3.0	4.2

5 CONCLUSIONS

The present study explores the use of geo-base isolation system made of Sand-Rubber Mixture (SRM) as a vibration isolation layer below the foundation system for seismic protection of buildings using element tests, laboratory model studies and numerical investigation. It was observed that the contribution of sand and rubber to the SRM material matrix is predominant at rubber content below 40% higher than which the influence of rubber matrix prevails. SRM with 30% rubber content possesses adequate stiffness, shear modulus and damping properties ideal for its use as geo-base isolation material. From the model tests, it was observed that the introduction of the proposed GSI layer between the footing and the underlying sandy strata reduces bearing capacity and increases settlement. Provision of geogrids to the geo-base isolation system was found to increase the bearing capacity by two times for single geogrid layer and three times for double geogrid layer. Further, single and double layered geogrid reinforcement reduces the settlement of GSI system up to 30% and 45% respectively. The finite element based numerical studies recommended. It is recommended to adopt the geo-base isolation system for seismic protection of low-rise symmetric buildings in the seismically active Indo Gangetic region of India with the following parameters: GSI layer with a width of 1.2B and thickness of 0.1B reinforced with two layers of geogrid having a spacing of 0.05B and length of 2B.

ABSTRACT: Microscale contacts are inherent in most geotechnical failures such as soil liquefaction, landslides and internal instability, thus study of these failures based on microscale concepts can significantly enhance our intrinsic understanding as well as the quality of prediction and designs. Despite rapidly increasing investigation on micro-mechanisms of soil failures, especially based on Discrete Element Method (DEM), cohesive behaviours of particles are usually ignored and simplified, resulting in incomplete and/or inaccurate understanding. My study aims to overcome this imperative limitation and improve our modelling capability by investigating the influence of microscale cohesive contacts on fundamental soil behaviours such as the formation of angle of repose and direct shear. Different degrees of cohesion between particles are incorporated into DEM models and the results are validated against experimental data. The results show cohesive contacts can significantly affect soil behaviour and the predicted outcomes if they are not considered properly. The prediction capability of this DEM model can be further applied to study the cohesive behaviour of geomaterials in various geotechnical problems such as soil clogging and debris flow.

1 INTRODUCTION

Soils are naturally occurring materials composed of constituent grains of varying sizes, shapes and compositions that are in contact with each other. The particulate nature of soils gives rise to complex interactions between particles such as friction and inter-particle cohesion and these particle-scale contacts play a crucial role in determining the overall behaviour of the soil including its strength, stiffness, and deformation characteristics. To understand the macro-response of soils, it is imperative to take their particulate nature and micro-scale contacts into account, and this requires the use of advanced approaches such as the discrete element method (DEM) to capture the particle-scale response. Previous studies have successfully employed DEM techniques to capture a range of complex soil responses; for instance, non-linear stress and strain responses (O'Sullivan, 2011), stress-state dependency (Lommen et al., 2014), critical-state behaviour (Phan et al., 2021), internal instability (Nguyen and Indraratna, 2020a), and many others. However, most previous studies have mainly considered cohesionless frictional materials

DOI: 10.1201/9781003299127-20

whereas cohesive contacts are ignored leading to inaccurate or incomplete analysis. This means increasing effort is needed to simulate the cohesive behaviour of soils more accurately in DEM.

The cohesive behaviour of soils, which refers to the bonding and inter-particle cohesion between soil particles, plays a crucial role in the stability of soils and their resistance to macro-scale failures such as liquefaction, landslides and slope instability (Mitchell and Soga, 2005). At the macro-scale, the classical Mohr-Coulomb theory states that the cohesive strength of soils contributes to the overall shear strength, providing resistance to sliding and shear deformation. At the microscopic level, the cohesive strength is characterised by the presence of cohesive contacts between soil particles, which mainly include van der Waal forces between fine particles (Parteli et al., 2014), electrostatic forces (Endres et al., 2021) and capillary interactions between wet particles (Wang et al., 2018). As these cohesive forces can occur individually or concurrently, the effort to consider these non-linear forces in DEM contacts can be complex and computationally intensive. In addition, measuring the micro-scale cohesive forces between individual particles in laboratory testing is arduous, which makes it more difficult to obtain accurate and reliable data to support the modelling of this behaviour. Moreover, cohesion is often dependent on several factors such as moisture contents and types of soil, making it problematic to develop a comprehensive model to accurately represent this behaviour. In a nutshell, the cohesive behaviour of soils, despite its significant influence on the performance of soils, is often ignored in DEM simulations due to difficulties in modelling and characterising this ambiguous behaviour.

To overcome limitations regarding the computational cost, it is common to use some of the well-established physics models such as the JKR (Johnson-Kendall-Roberts) and the DMT (Darjaguin-Muller-Toporov) to describe the attraction forces between two contacting particles. While JKR theory is developed to capture the short-range, strong surface forces between large and deformable bodies, DMT regime corresponds to an opposite type of materials (i.e., hard, small radius, and long-range attraction forces). Previous studies stated that cohesive forces calculated by the JKR model are closely approximated with experimental measurements by AFM for various materials (Jones, 2003). Therefore, the JKR model has been increasingly used to model fine and wet materials in which cohesive interactions dominate the macroscopic behaviour of materials considerably (Deng and Davé, 2013, Hassanzadeh et al., 2020). In this study, the JKR theory will be incorporated into the DEM contact mechanics to capture the cohesive behaviour of geomaterials.

This study aims to apply DEM model which simultaneously considers frictional (sliding) contact, rolling resistance and micro-scale cohesive forces, with a special emphasis on the modelling the cohesive behaviour of geomaterials. It will also provide a thorough investigation into the micro-cohesive effects on macro-behaviour of soils while flowing and shearing. The application of the current cohesive model is validated against experimental tests such as the angle of repose (AoR) and direct shear tests (DST). Furthermore, extensive analysis is conducted to investigate the effect of cohesive contact forces on the macro- and micro-response of soils. Based on this analysis, a linkage between micro-scale parameter and macro-scale property can be provided to obtain a better understanding of the overall soil responses.

2 DEM COHESIVE MODEL AND NUMERICAL ANALYSIS

2.1 *DEM cohesive model*

For granular materials, the Hertz-Mindlin contact model has been successfully adopted by previous studies (Zhu et al., 2007) to compute the normal and tangential contact forces in relation to elastic deformation between particles, therefore, this model will be employed in the current study. In the Hertz-Mindlin model, the respective contact forces are determined from contact stiffnesses as follows:

$$k_n = \frac{4}{3} E^* \sqrt{R^* \delta_n} \tag{1}$$

$$k_t = 8G^* \sqrt{R^* \delta_n} \tag{2}$$

where E^*,G^* and R^* are the effective Young's modulus, shear modulus, and radius of two particles respectively, and δ_n is the normal overlap or displacement. Further information to determine these input parameters is provided elsewhere (Li et al., 2005, Zhu et al., 2007).

Following most of DEM studies in the literature, spheres are commonly used owing to the modelling simplicity and contact detection efficiency. However, this simplification leads to the loss of shape effects (i.e., angularity and interlocking) and results in discrepancies between numerical and physical results. Hence, to compensate for realistic shapes in DEM, a concept of using rolling resistance model has been developed by several researchers (Ai et al., 2011) to account for a rolling resistance torque opposing the free-rolling tendency of spheres. In this study, a rolling resistance model known as elastic-plastic spring-dashpot model (EPSD2) will be used as this model has been recognised to prevent oscillatory behaviour and provide quasi-static simulations. The rotational resistance torque is a function of a rolling friction coefficient μ_r as follows:

$$\left| M_{ij}^r \right| \leq \mu_r R^* \left| F_{ij}^n \right| \tag{3}$$

For the cohesive behaviour, the cohesive model proposed by Doan et al. (2023) was used to couple the simplified Hertz-Mindlin contact mechanics and JKR theory to capture the elasto-cohesive response between particle contacts. The fundamental concept of JKR theory characterises the attractive forces between solids by an additional tensile stress at the contact boundary leading to a finite contact area even at zero load, as shown in Figure 1.

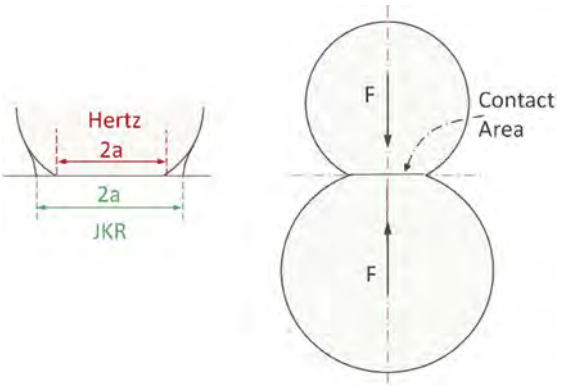

Figure 1. Schematic of the force-displacement relationship in JKR theory (refer to (Roessler and Katterfeld, 2019)).

The JKR theory used a concept of energy balance method to determine the surface attraction forces (i.e., vdW forces) based on their respective surface energies. The application of JKR has been expanding across multi-disciplinary fields to model the cohesive behaviour of powders, micro-scale particles and geomaterials (Deng and Davé, 2013, Barthel, 2008). The contact forces, deformation and radius are derived by JKR theory as follows:

$$\boldsymbol{F_{ij}^{JKR}} = \frac{4E^* a^3}{3R^*} - \sqrt{8\pi E^* \gamma_E a^3} \tag{4}$$

$$\delta_{ij}^{JKR} = \frac{a^2}{R^*} - \sqrt{\frac{2\pi a \gamma_E}{E^*}} \tag{5}$$

$$a = \frac{3R^*}{4E^*}\left[\boldsymbol{F_{ij}^{JKR}} + 3\pi\gamma_E R^* + \sqrt{\boldsymbol{F_{ij}^{JKR}} 6\pi\gamma_E R^* + (3\pi\gamma_E R^*)^2}\right] \tag{6}$$

Where as F_{ij}^{JKR} and δ_{ij}^{JKR} are the cohesive contact force and deformation according to JKR formulations; γ_E is an effective surface energy between two particles and a is the contact radius. As the computation of the contact radius a is prohibitively demanding and not easily obtained, the original JKR model is subjected to some simplifications leading to the development of the simplified JKR model (SJKR). Instead of using the surface energies, the SJKR model employs an empirical and numerical cohesive term named Cohesion Energy Density (CED), which is defined as the volumetric energy needed to separate the attractive interactions between two particles. In this SJKR model, the cohesive force is computed as a function of CED (J/m^3) and the contacting area A as follows:

$$\boldsymbol{F_{ij}^{JKR}} = CED \times A \tag{7}$$

As described by Doan et al. (2023), the term CED can be related to the surface energy which is a physical property and can be theoretically measured for any materials, as follows:

$$CED = \sqrt[3]{\frac{8E^{*2}\gamma_E}{3R^*\pi^2}} \tag{8}$$

2.2 *Numerical validation with experimental tests studying the flowing behaviour of soil (Angle of repose test)*

Prior to further developments, it is crucial to test the proposed DEM model with micro-scale cohesive forces against fundamental tests such as the angle of repose (AoR) test. The angle of repose is defined in Terzaghi (1943) as the steepest slope of angle that a soil can form without external effects such as confining pressures. The AoR test is demonstrated by numerous studies (Li et al., 2005, Derakhshani et al., 2015) to provide valuable information about the interparticle forces and friction angle of materials, both of which are critical for geotechnical designs and analysis. Previous studies have shown that the AoR is highly sensitive with the presence of cohesive forces, hence, a neglect of cohesive contacts results in an underprediction of the AoR value. Therefore, incorporating the cohesive forces in DEM contact mechanics is prominent to capture the macro-response of materials more realistically.

To simulate the AoR test, a lifting cylinder test was chosen due to its simplicity to determine the AoR of geomaterials. Sandy soils in dry and wet states were selected to study the cohesionless and cohesive behaviour of materials in the AoR test. For wet sands, the inter-particle cohesive forces mainly take on a form of liquid-bridging forces which result in the generation of capillary and viscous forces. The SJKR model was used to represent the capillary forces, while the influence of viscous force was deemed insignificant in quasi-static conditions. To simulate the AoR test in DEM, several input parameters which have been consistently provided in previous studies were collated in the Table 1 below. Additionally, as the rolling friction coefficient and micro-scale cohesive forces (i.e., calculated from the Cohesion Energy Density (CED) value) are different among materials, these values will be calibrated to match with the current experimental data. For the calibration of rolling resistance coefficient, this value varies greatly in the literature ranging from 0.1 (i.e., highly spherical particles) to 0.5 (i.e., highly angular shape), hence, this range was used in the current study. The calibration of CED parameter was based on past studies which reasonably captured the cohesive effect of various materials. In the current investigation, CED values were selected from 0 for the cohesionless state to 5 x 10^5 (J/m^3) for the cohesive state. The variations of rolling resistance coefficients and CED were summarised in Table 2.

To verify that the DEM simulations are valid, the numerical results were compared with the experimental tests conducted on wet sands from Roessler and Katterfeld (2019). It is worthy to

Table 1. The input parameters for the current DEM study.

Parameters	Value range	Value increment
Rolling friction coefficient (μ_r)	0.1 - 0.5	0.1
Cohesion Energy Density (CED) (J/m^3)	0 - 5x10^5	1x10^5

note that instead of comparing the angle of repose (AoR) values which can be highly variable and not appropriate for the characterisation of cohesive materials, the flowability of materials was selected for comparison. The flowability of wet soils was observed to be dependent on a lifting height (h) which was defined as a gap between the bottom of the cylinder and the horizontal base, hence, the flow response of soils was captured in four separate stages (i.e., h = 90 mm, 120 mm, 160 mm and 280 mm for a 375mm-high cylinder). Figure 2 demonstrates that DEM simulations can mimic the flow characteristics of materials in the experiments very well. More specifically, at the initial stage of the tests when the lifting height remains small (h = 90 mm), a solid column of materials is witnessed in both DEM and experiments without any bending or spreading of materials yet as the cohesive and frictional forces are sufficient to counteract with the self-weight of the material. This phenomenon is repeatedly observed in the physical tests by Roessler and Katterfeld (2019). Then, when the gap is increased further, the column of materials starts to collapse, leading to the further spreading of materials to form a convex slope as seen in Stage 2, 3 in Figure 2. Finally, at stage 4 when the cylinder is sufficiently lifted, a quasi-static heap of wet sand materials is formed physically and numerically. To sum up, the DEM simulations incorporating cohesive forces were in good agreement with the experimental results. For a further development, the DEM model can be improved to simulate cracks appearing in the heaps of wet sands owing to difficulties to maintain a uniform and homogenous distribution of moisture content in the experiment.

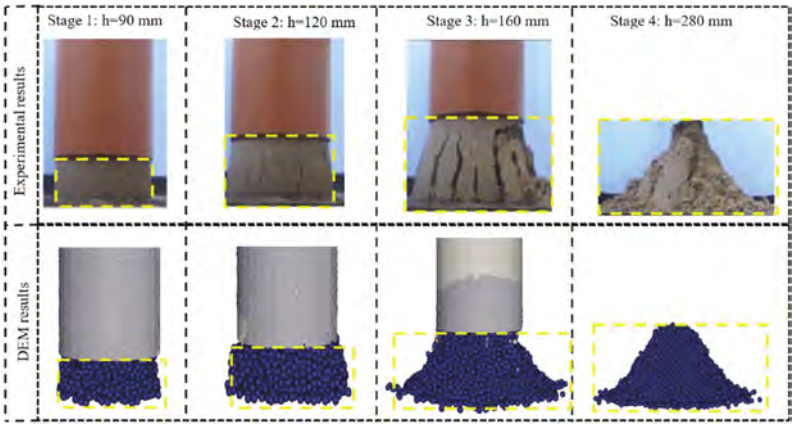

Figure 2. Comparison between DEM models and experimental tests.

The experimental tests from Roessler and Katterfeld (2019) also found out that the bending of the column of materials at different phases was reproducible and can be quantified, hence, this criteria was chosen for a quantitative comparison between DEM and experiments. The bending of material was characterised by a parameter named the relative pile diameters (d_{rel}) to compare between the diameter of the pile d_{pile} and the diameter of the cylinder ($d_{cylinder}$) (i.e., the formulation was given in Doan et al. (2023)). Figure 3 indicates that with a small lifting height h = 80 mm, the pile remains nearly vertical with 2.3 % bending in DEM results and 2.1 % bending in experiments. However, when the cylinder is lifted further, the slope of materials curves more significantly with 25.1 % of convex bending in DEM and 25% in the referenced case. By comparing the DEM results and experiments both qualitatively and quantitatively, DEM simulations represented experimental observations very well. More particularly, the DEM results also captured many important features of the cohesive behaviour of soils; for example, when cohesive forces were present, the flowability of materials was significantly hindered as compared to the free-flowing feature of cohesionless materials.

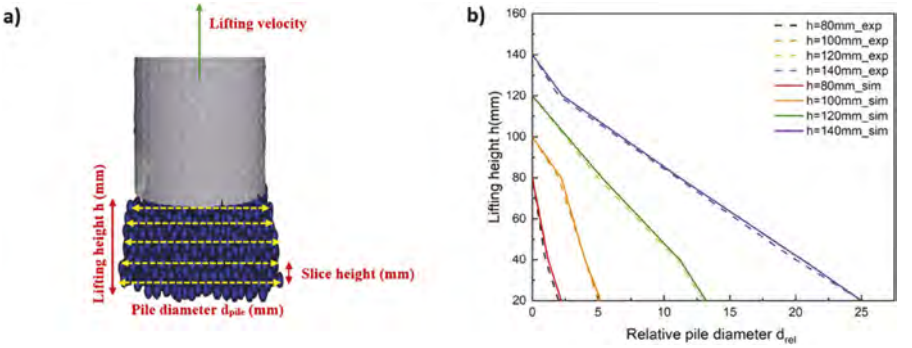

Figure 3. Quantitative comparison of the convex bending between DEM and experimental results from Roessler and Katterfeld (2019) (modified after (Doan et al., 2023)).

2.3 *Numerical calibration and comparison with experimental test for loading condition in Direct Shear Test (DST)*

After the DEM cohesive model was validated against the fundamental angle of repose test, more efforts are needed to test the capability of the cohesive model under external loading. It is critical to study the behaviour of a soil under loading conditions such as the shear strength and deformation of soil in several contexts, namely, the soil bearing capacity and settlement characteristics, the stability of slopes and retaining walls, and soil liquefaction and erosion. This study aims to investigate the underlying mechanics of the cohesive effects on the shear behaviour of soils via the use of the proposed DEM cohesive model and standardised Direct Shear Tests (DST). A validation of the current DEM model is performed by using a series of physical direct shear test to compare with the equivalent numerical results.

A series of direct shear tests were conducted using DEM simulations to capture the effect of microscopic cohesion on the shear strength of cohesive materials. The simulations were carried on a realistic grading of geomaterials with a similar particle size distribution as in the experiment as shown in . The schematic of the direct shear test (DST) is given in Figure 5.

To fill in a numerical shear box as shown in Figure 5, the number of particles was nearly 100,000 particles which by far surpassed the minimum number of 30,000-50,000 particles required for the friction angle and the dilation angle to be captured well in DEM results (Ni et al., 2000). In addition, the ratio between the length of the shear box and the maximum particle size was nearly 50 times, which exceeded the ratio of 10 times empirically defined in ASTM standards to minimize the boundary effects. Besides particle sizes, other microparameters such as the Young's Modulus, Poisson's ratio in DEM simulations were selected based on previous studies (refers to Table 3).

For comparison with experimental results, soils in cohesionless and cohesive states were used to compare with DEM results. For the dry sand without cohesion, the shear strength is primarily controlled by the sliding and rolling friction between two particles. These particle-level parameters are difficult to measure, hence they are often calibrated in numerical procedure. This study varied sliding and rolling friction to match the experimental results with experimental data. As shown in Figure 6, both experimental and numerical results exhibit a strain softening behaviour, where the shear stresses reach a peak value and then gradually decrease. A dimensionless parameter called stress ratio is used to normalise the shear stresses with the applied normal stresses. The maximum stress ratios in DEM simulations for three levels of normal stresses (i.e., 45 kPa, 90 kPa, and 133 kPa) are very close with the experimental values, confirming the accuracy of the strength parameters predicted in DEM simulations. In addition, comparison between dilative behaviour between DEM and experiments indicates a reasonable agreement confirming the predictability of DEM both in terms of strength and deformation of the cohesionless soil.

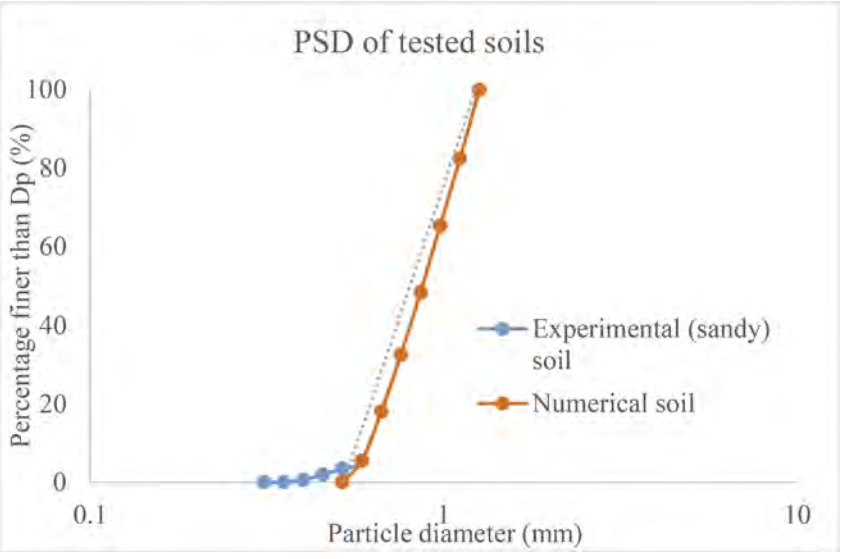

Figure 4. PSD used in DEM and experiments for the direct shear tests.

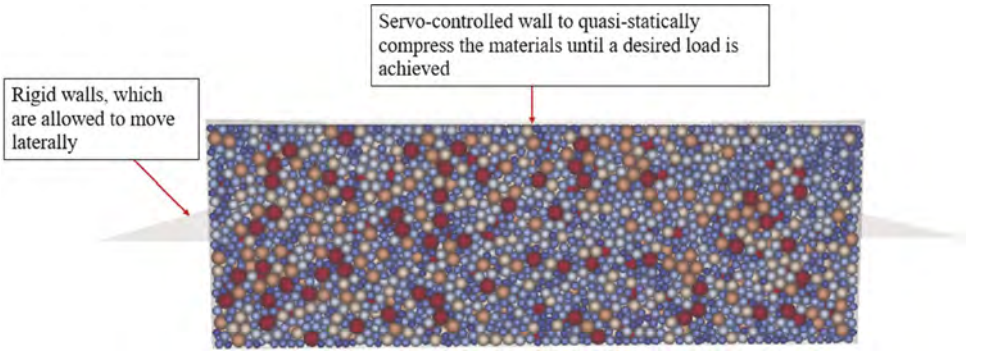

Figure 5. Direct shear test simulated in DEM.

For the cohesive state of materials, the sandy samples were mixed with a certain degree of water (i.e., moisture content 10%) to generate weakly cohesive forces arising

mainly from capillary interactions. Figure 7 demonstrates the stress-strain curves in the experiments with 10 % water content and DEM model introducing cohesive forces from CED value (i.e., CED = 4 x 10^5 J/m^3). Results from DEM simulations show a similar trend as those of the experimental observations. In general, DEM model has successfully captured the main features of the experimental outcomes, such as the peak strength and the softening response under various cohesion levels (i.e., cohesionless and weakly cohesive state).

3 RESULTS AND DISCUSSION

After completing the calibration process where the DEM results were reasonably validated against fundamental experiment tests such as the Angle of Repose (AoR), and the Direct Shear Test (DST), this section will discuss some of the insights obtained from DEM analysis to demonstrate the effect of micro-scale cohesion on the macro- and micro-responses of soils.

3.1 *The cohesive effect on the macro-response in AoR test*

Figure 8 shows a three-dimensional plot indicating an interactive role between micro-scale friction and cohesion on the angle of repose. It shows that with increasing cohesion levels (from 0 to $5x10^5$ J/m^3), AoR values increase proportionally regardless of the rolling friction value. More importantly, without the effect of cohesion, the AoR is only able to increase up to 31°, however, with the presence of CED values, the AoR values can reach a higher value ranging from 40° to 45°. This finding is supported by experimental observations presented in (Mason et al., 1999, Mitarai and Nori, 2006) implying that the angle of repose of partially saturated materials is generally higher than a cohesionless dry system, nonetheless, these studies did not study how various cohesion levels (i.e., moisture content) affect the forming of this angle. This study also discovers that the numerical AoR values can increase up to 45°, which falls within the range of AoR values for cohesive materials (Beakawi Al-Hashemi and Baghabra Al-Amoudi, 2018). The reason for this rising AoR can be linked to the effect of cohesive forces on the flowing behaviour of soils as with the cohesive presence, the additional tensile forces prevent the separation between particles and consequently, hinder the flowing capacity of the materials.

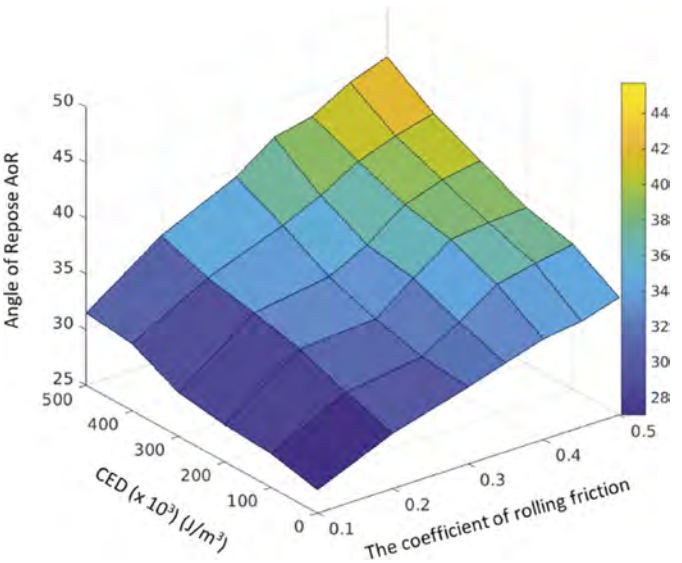

Figure 8. The effect of micro-scale cohesive forces (determined from CED values) on AoR value.

Besides AoR values, the overall porosity is a significant consideration to reflect the microstructure and the compactness of the pile, which is also dependent of micro-scale parameters such as inter-particle cohesion and friction. To compute the porosity value, this study developed a Python program incorporating Monte-Carlo algorithm to approximate the void fraction (i.e., or porosity) within a specific volume of materials. Figure 9 shows the changes of porosity with cohesion and rolling friction levels as when the cohesive and frictional forces increase, the porosity increases as well. For instance, with a given value of rolling friction (for example, 0.1), the porosity value increases from 0.586 to 0.6 when cohesion value CED

increases from 0 to $5x10^5$ (J/m^3). This tendency is due to a fact that when cohesive forces are present, the micro-structure of materials is seen gradually separated with large voids and chain-connected connections (Rognon et al., 2007, Xu et al., 2007). The increased porosity with cohesion content has been observed experimentally by (Gratchev et al., 2006, Goudarzy et al., 2021), indicating that when cohesive fines are present, the structures become separated with open micro-fabrics.

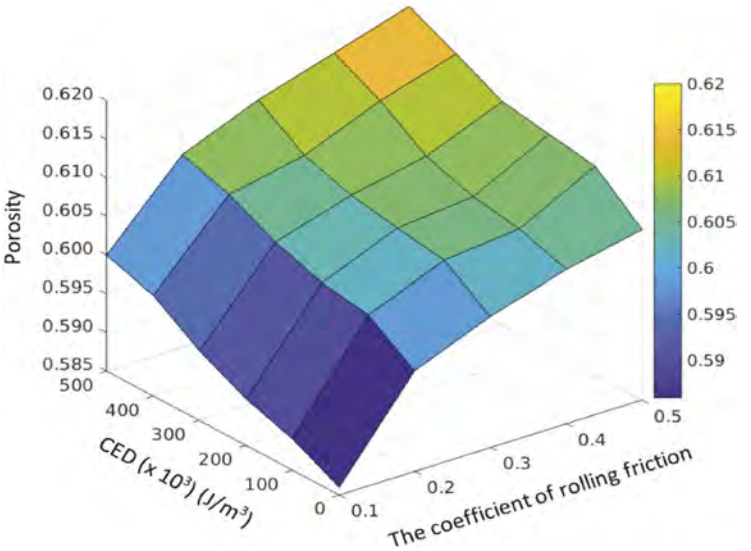

Figure 9. The cohesive effect on the porous structure of the AoR pile.

3.2 *Effect of cohesive contact on the micro-mechanical response of AoR via the analysis of coordination number*

The coordination number CN (i.e., refers to the number of neighbours per particle) is determined with respect to the total number of contacts (n_c) and number of particles (n_p) as follows:

$$CN = \frac{2n_c}{n_p} \tag{9}$$

Figure 10 demonstrates that the coordination number, which is with the spatial arrangement of the particles, was negatively dependent on the values of cohesion and rolling friction coefficients. In the case of cohesive materials as CN values decrease with increasingly cohesive particles (i.e., CED increased from 0 to 5 x 10^5). The similar tendency is also observed in the case of cohesionless material (CED = 0), the CN value experiences a reduction from 8 to 7.3 when the particles become more rotationally resistant. When the values of cohesion and rolling friction are both high, the CN value continuously reduces to reach a small value between 6 and 7. This means when cohesive forces or frictional forces dominate, the system becomes less densified with fewer contacts per particles.

To gain insights into how the cohesive and rolling resistant forces impact the coordination number, the balance of all external and internal forces acting on particles is analysed. According to Yu et al. (2003), cohesionless granules commonly have an average of six contacts per particle to counterbalance the gravitational forces. However, when both cohesion and rolling friction increase, the coupled effect of cohesive and frictional forces is sufficient to resist the driving force of gravity, allowing stability to be achieved with fewer particle-to-particle contacts, as few as two per particle, as demonstrated by Xu et al. (2007).

3.3 *Particle-scale insights into the movement of individual particles in the AoR test*

This study also attempts to track the kinetic energy and the total displacement of particles which have not been provided in previous studies and explores how cohesive forces affect the materials at the particle-scale level. Figure 11a compares the kinetic energy between the cohesionless and cohesive systems and reveals that the with cohesive forces, the KE of the system reaches a smaller peak. In addition, the cohesionless samples peak and stabilise at an earlier stage than the cohesive

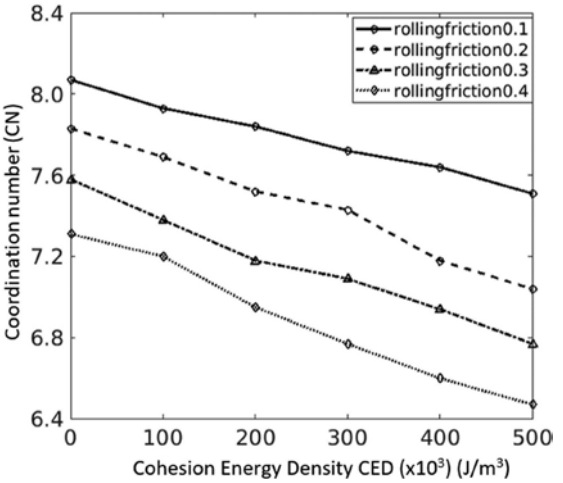

Figure 10. The cohesive influence on the internal fabric of AoR test.

samples, indicating that more time is required for the cohesion-induced materials to dissipate the kinetic energy. This is because as the level of cohesion increases, the interparticle forces become stronger and the particles tend to move together as agglomerates instead of as individual units. As a result, cohesive particles exhibit a more gradual and less brittle response, with a delay in the initiation and dissipation of kinetic energy compared to non-cohesive particles. This is shown in the Figure 11a that the non-cohesive materials take about 17s to reach a stable state, while the cohesive materials need more than 19s to stabilise. Moreover, Figure 11b captures the total displacement of particles with and without cohesion in the forming of the angle of repose AoR. The

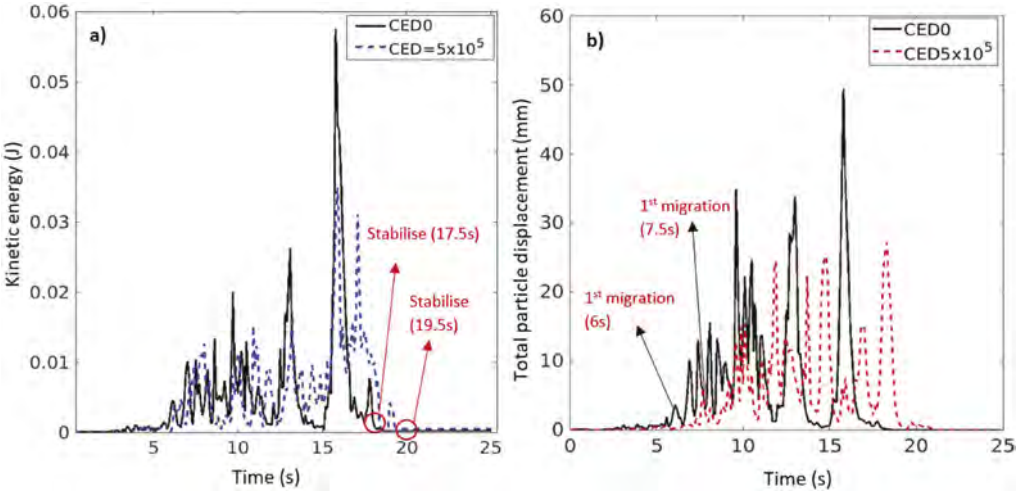

Figure 11. Particle-scale analysis in the AoR test in terms of a) kinetic energy KE and b) particle displacements.

cohesionless particles (i.e., black solid line) experience a much higher displacement (i.e, around 49 mm) than the displacement that the cohesive materials can make (i.e., 35 m). In addition, similar with the evolution of kinetic energy, cohesive samples experience a delay in the migration and stabilisation, compared to the cohesionless samples. Hence, this signifies a less brittle response when cohesion is included.

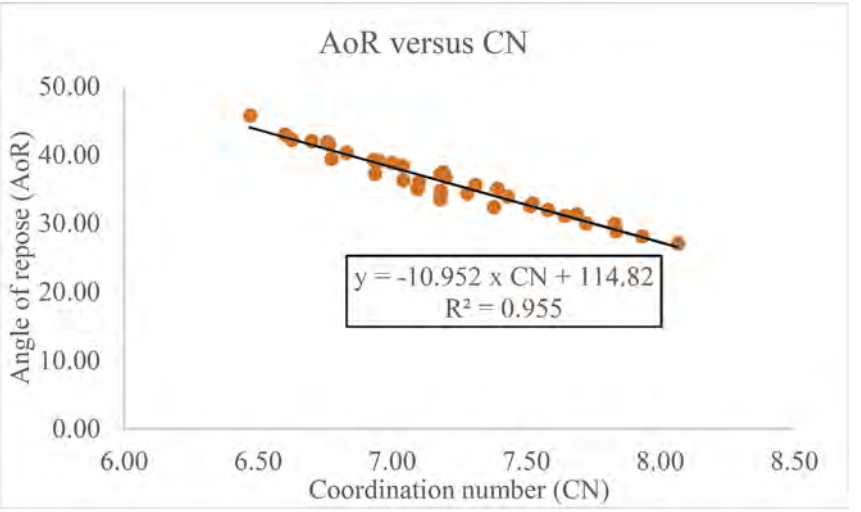

Figure 12. Quantitative relationships between AoR and CN for varying cohesion and rolling friction levels.

3.4 *Linkage between macro-parameters and micro-parameters*

The current study has revealed that both the angle of repose (AoR) and the micro-scale coordination number (CN) are directly affected by the particle-scale parameters such as the cohesion and friction effects. With the data available, this study attempts to propose a linkage between the macro-parameter AoR and the micro-parameter CN for materials for all cohesion and rolling friction levels. The correlations between the AoR and CN values are depicted very well by the fitted regression lines, with an error rate below 5% as shown in Figure 12. Moreover, the proposed equation demonstrates an inverse relationship between AoR and CN, which means a higher CN leads to a lower AoR, indicating increased stability of the slopes. In fact, a higher CN implies that the particles are more densely packed and have more contacts with their neighbours, resulting in a more stable structure. This stability is then reflected in a lower angle of repose. This explanation is also applied in the case of increasing cohesive and frictional forces, the system becomes looser (i.e., smaller CN) and the angle of repose can reach a higher slope without sliding (i.e., higher AoR).

3.5 *The cohesive effect on the strength-deformation behaviour in DST shear test*

Figure 13 shows the evolution of shear stress as observed in DEM simulations during shear tests on cohesionless (CED = 0) and cohesive state of soils with varying levels of cohesion. Compared to the non-cohesive dry sand samples, cohesive effects contribute to an enhanced shear strength, which becomes more pronounced with increasing cohesion levels. For example, when the cohesion energy density CED is low (i.e., CED < 5 x 10^5), the stress-strain curve in the simulations experiences a slight upward shift, reflecting the higher peak shear stresses and residual stresses, which is quite similar with the behaviour of wet samples with 10 % water content from experiments. However, this shift is minimal as the capillary forces, also known as the weak apparent cohesion, have a limited effect on soil strength under external loading.

Figure 13 also shows the dilation characteristics influenced by the cohesive effects in soils in the direct shear test. The results indicate that when cohesive forces increase, the samples displace more substantially in the vertical direction. The reason for this effect is that the addition of cohesion causes particles to behave as agglomerates or clumps, resulting in a larger dilation angle and

a higher friction angle. In order words, with the addition of cohesion, agglomerated particles are mobilised by a larger force and hence, the soil exhibits a greater resistance to shearing.

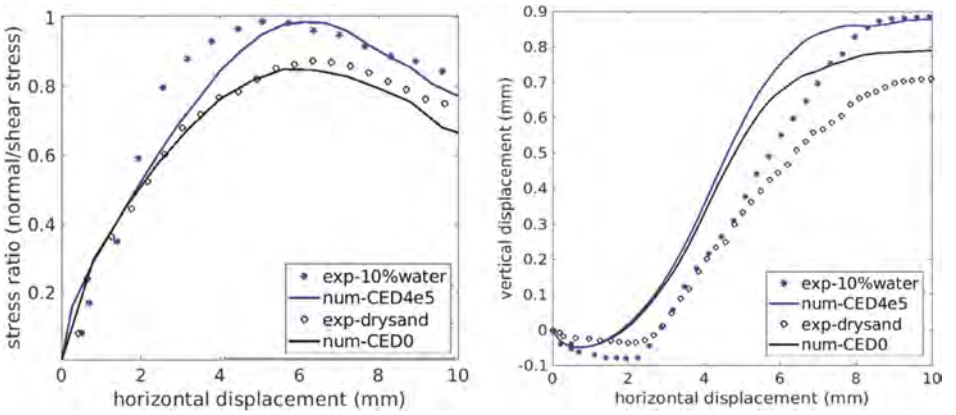

Figure 13. The development of shear stress and vertical movement under varying cohesion levels in DEM a) shear stress versus horizontal displacement at a normal stress 45 kPa, b) vertical displacement versus horizontal displacement.

4 CURRENT CHALLENGES AND FUTURE STUDIES

Although significant efforts have gone to modelling particle contacts in the past years, yet the current state of DEM contact models, especially considering cohesive behaviour still remains considerable challenges that prevent predictions from higher accuracy. Some of them can be pointed out, thus suggestions for future studies as follows:

1. As the generic formulation of the JKR contact radius is mathematically challenging, the simplified JKR (SJKR) model takes on a circular form as proposed in Hertzian theory. More computational efforts are needed to solve the equation of the real contact radius in cohesive contact model, so that more accurate load-deformation behaviour of various materials can be simulated.
2. The cohesion forces provided by JKR model will diminish when the normal deformation δ_n reaches negative values, therefore, this model is applicable to model the short-range attraction forces between particles, whereas the separation distance is minimal, rather than the long-range attraction forces.
3. The current JKR model was developed to extend the Hertz theory to capture the elaso-cohesive contacts, while solutions for modelling visco-elastic and plastic effects are still incomplete. As visco- and elasto-plastic behaviours often exhibit in soils, significant efforts are required to develop more detailed and realistic contact models for DEM simulations.

5 CONCLUSIONS AND PRACTICAL IMPLICATIONS

Advanced numerical DEM studies were conducted to investigate the mechanism and the influences of micro-scale cohesive contacts on the macro-behaviour of soils. Varying degrees of cohesion between particles were incorporated to study the cohesive behaviour of soils under different conditions such as the free-flow and shear. Critical findings of this study can be collated as follows:

1) The cohesive behaviour of soils, despite its significant influence on the stability of soils, remained considerable ambiguity in terms of its microscale mechanism and effects. The current extensive investigation using DEM study to examine the cohesive effect of material found out that when the cohesive effect was ignored, it can lead to the underestimation of the angle of repose. In fact, the AoR value was reported as a function of the micro-scale cohesion since the higher the cohesive forces, the higher AoR values.

2) The results also revealed that increasing cohesion levels led to a higher apparent porosity regardless of the level of friction. Such a response of increasing porosity can be attributed to the tendency to form chain-connected structures, as well as large agglomerates among cohesive particles.
3) The empirical relationships ($R^2 > 0.98$) between the macro-scale AoR and micro-scale coordination number CN were established for the first time considering different levels of cohesion. The equations demonstrated the inverse relationship between AoR and CN, meaning that a higher CN signified a smaller AoR value. As when CN increased, the gravity-induced densification process was enhanced significantly and particles were more vulnerable to moving, leading to a smaller AoR value.
4) This study also demonstrated that not only the interparticle cohesive effects were dominant in the free-flowing condition, but also they can significantly alter shear behaviour of soil under loading. When cohesion was present, the shear strength of the cohesive samples was significantly higher than that in cohesionless state, and this feature was expected to become more pronounced with increasing cohesion levels.
5) Moreover, with the presence of cohesive forces, the samples experienced a greater degree of expansion in the vertical direction (i.e., dilation) than the cohesionless samples. This is because the addition of interparticle cohesion linked particles into agglomerates through increased particle connections and bridging, which were mobilised by a larger dilation angle and friction angle.
6) The practical implication of this study is to promote a better understanding of the micro-cohesive effect on soil behaviour and to use this understanding in geotechnical designs and analysis. For instance, the strengthening effect of the interparticle cohesion on the shear strength of materials can provide significant values to ground improvement in practical applications if they are appropriately combined with frictional components.

ACKNOWLEDGEMENT

This research was supported by Transport Research Centre (TRC, UTS), and the Australian Government through the Australian Research Council's Linkage Projects funding scheme (project **LP160101254**). Technical and financial support from industry partners including SMEC, Sydney Trains, ACRI and Coffey are greatly appreciated. Moreover, the contents of this paper include some critical outcomes that have been published previously. They have been cited where warranted, and the copyright clearance from the original sources has been granted to the authors to reproduce with kind permission.

ABSTRACT: The temperature effects on foundations and structures. The results of calculations of ground bases and structures on temperature influences and loads are given. Conclusions on the obtained results with suggested recommendations are also made in work.

Keywords: temperature, numerical analysis, mosaics, loads

1 INTRODUCTION

Kazakhstan is located in a climatic region with seasonally frozen ground. During the calendar year the temperature varies seasonally from negative to positive values. Temperatures can reach -45 °C in winter and +45 °C in summer. Soil types vary across Kazakhstan due to its large size and varied landscape (Shakhmov et al. 2015; Zhussupbekov at al. 2013; Zhussupbekov at al, 2012; Shakhmov et al. 2016). Many buildings and constructions have been built in Kazakhstan due to urban growth, such as Astana, Almaty and Shymkent. There are also many infrastructure projects such as roads, railways and bridges. Kazakhstan is located at the crossroads between east and west, and historical economic and cultural ties run through this area. Kazakhstan is also a participant in international infrastructure projects such as the Silk Road, One Belt, One Road, and others. The China-Western Europe Westward Project, also known as the New Silk Road by land, is a Chinese initiative to create a network of transport and logistics links between China and Western Europe. One element of this project is the construction of a road that will connect the western and eastern parts of Kazakhstan. The road will be made of cement concrete, which is one of the strongest materials for road construction. It has a high compressive and bending strength which allows it to withstand heavy loads and retain its properties for a long time (Usenov et al. 2022; Kuvakov et al. 2016). But the operation of these rigid roads has resulted in problems with the occurrence of deformation and defects. Defects and deformations such as longitudinal and transverse cracks, through and surface cracks, spalling and warping(blow-up) of boards are common on the road.

2 RESEARCH METHOD

2.1 *Numerical analysis of various temperature stress-strain state of highways in the "Lira" program*

The LIRA-CAD 2017 software package (LIRA-CAD 2017 PC) is a multifunctional software package for calculating, researching and designing structures for various purposes.

PC LIRA-CAD 2017 is successfully used in the calculations of construction, mechanical engineering, bridge construction, nuclear power, oil industry and in many other areas where methods of construction mechanics are relevant.

The software complexes of the LIRA family have a more than 40-year history of creation, development and application in scientific research and practice of design of structures. The software systems of the LIRA family are continuously being improved and adapted to new operating systems and graphical environments. The newest representative of the LIRA family is the LIRA-CAD 2017 PC.

In addition to the general calculation of the object model for all possible types of static loads, temperature, deformation and dynamic effects (wind taking into account pulsation, seismic effects, etc.), the LIRA-CAD 2017 PC automates a number of design processes: determination of calculated combinations of loads and forces, assignment of structural elements, selection and verification of sections of steel and reinforced concrete structures with the formation of sketches of working drawings of columns and beams.

PC LIRA-CAD 2017 allows you to study the overall stability of the calculated model, check the strength of the cross-sections of elements according to various theories of destruction. The LIRA-CAD 2017 PC provides an opportunity to perform calculations of objects taking into account physical and geometric nonlinearities, to simulate the process of erecting a structure taking into account the installation and dismantling of elements.

PC LIRA-CAD 2017 supports information communication with such systems as AutoCAD,ArchiCAD, Allplan, Hypersteel, as well as PC MONOMACH-CAD, FOC-PC.the template file B1ProcA4.dot to the template directory. This directory can be found by selecting the Tools menu, Options and then by tabbing the File Locations. When the Word programme has been started, open the File menu and choose New. Now select the template B1PROCA4. dot and start by renaming the document after clicking Save As in the Files menu.

2.2 *Initial data*

The road was originally taken from the southern regions of Kazakhstan. This region has the highest temperatures in summer. This causes the concrete slabs to warp. In particular, dozens of cases of road warping are recorded every year in these regions. The road consists of 4 lanes of which 2 in the forward direction and 2 in the reverse direction. The slabs are 5 metres long and 25 cm thick.

3 RESULTS

The results for temperature phenomena at 50 degrees Celsius are shown below.

4 CONCLUSION

According to the results obtained on the temperature loads of the central bank of the plates, isofields and VAT plots were identified with the following values: the expansion of concrete by 50 m was 30 mm, while the deformation of the plates during warping was 92 mm. The maximum mosaics voltage according to Mx 1.93e-009 t* m/ m, according to Mu 105 t * m/ m. When pinched on both sides, the maximum mosaics are stressed by Mx 184 t * m/m,

Figure 1. Isofield of movements along the X axis (mm).

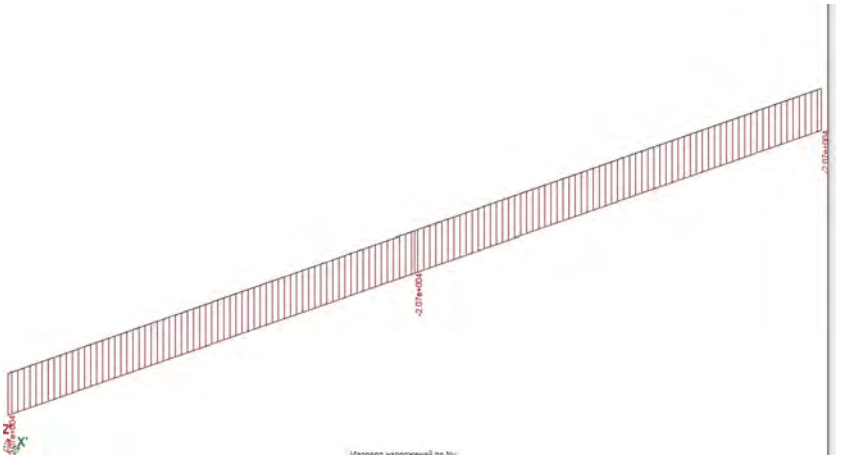

Figure 2. Mx plot.

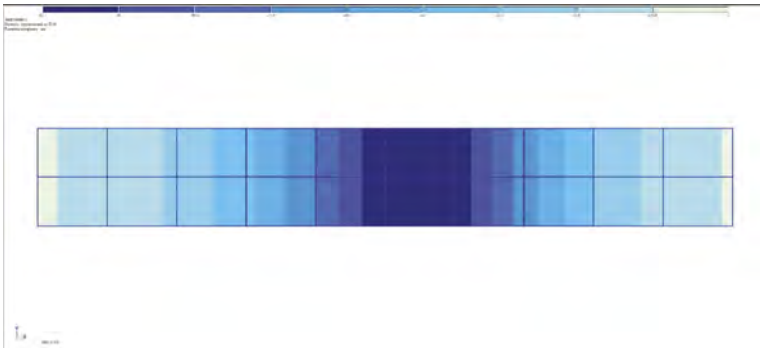

Figure 3. Isofield of movements along the X-axis (mm) with double pinching.

by Mu 231 t * m/m. The mosaic voltage according to Nx is 2.07e-004, and 4.57e-004 (t/m2) with double pinching (Figures 1–10).

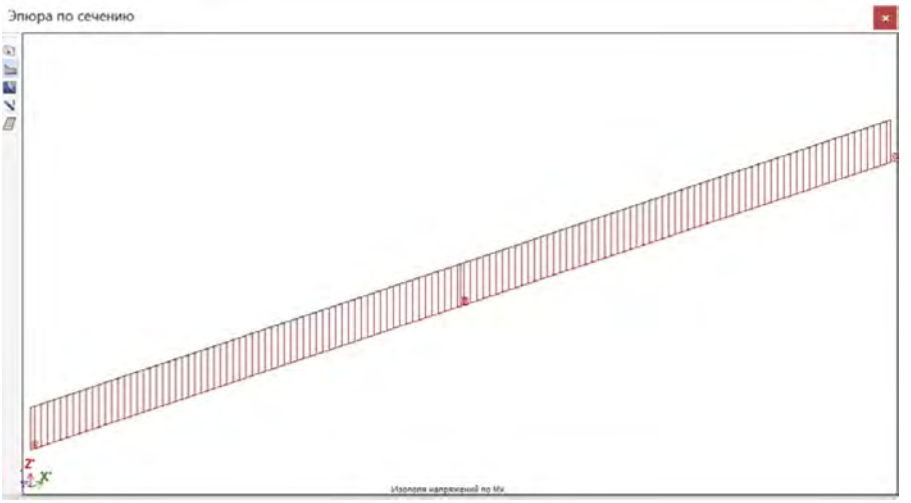

Figure 4. Mx plot.

Behavior and modeling of silt-clay transition soils

V.N. Kaliakin
Department of Civil and Environmental Engineering, University of Delaware, USA

P. Anantanasakul
Department of Civil and Environmental Engineering, Mahidol University, Nakhon Pathom, Thailand

ABSTRACT: Natural soil deposits are often composed of particles of different sizes and base minerals. Such variations generally preclude characterization of natural soils into a single soil type such as a gravel, sand, silt or clay. The mechanical behavior of such soils can vary quite considerably spatially within a soil deposit. The soil formation process involves variable particle size distribution from one location to another. This gives rise to the creation of an array of soils that transition from one general soil type to another within essentially similar deposits. Such materials are thus commonly referred to as transition soils and are very abundant in the world. The effect of non-plastic silt content on the behavior of silt-clay soils is not fully understood. This is due to a lack of laboratory tests that isolate silt content from clay mineral type, pre-consolidation histories, loading direction, and loading rate. This paper gives an overview of the experimentally measured behavior of silt-clay transition soils and their characterization using the Generalized Bounding Surface constitutive model.

1 INTRODUCTION

In many parts of the world, natural soil deposits often consist of particles having different sizes and base minerals. Such variations often preclude characterization of natural soils into a single soil type such as a gravel, sand, silt or clay. Instead, such deposits must be characterized as some combination of these four basic soil types. Although natural soils having similar origins typically have similar base materials, the nature of their formation process often results in particle size distributions that vary spatially from one site to another. This results in an array of soils that, within essentially similar deposits, transition from one general soil type to another. Very often, the mechanical behavior of such "transition" soils can vary rather significantly.

Present in several metropolitan areas of the world (e.g., London, greater Bangkok, Shanghai, the islands of Hong Kong, the San Francisco Bay area) are large deposits of silt-clay transition soils. Since a rather significant amount of geotechnical activities are ongoing in these areas, it is imperative for geotechnical engineers to understand the behavior of such soils in which the gradation gradually changes, thus producing essentially different soil types. An improved understanding of the stress-strain, volume change and strength characteristics of silt-clay transition soils will thus allow for more accurate analysis and more robust design of geostructures constructed on such soil deposits.

2 PREVIOUS EXPERIMENTAL STUDIES

Pertinent to better understanding the behavior of silt-clay transition soils are the results of experimental studies performed on low-plasticity silts (Penman 1953; Parry & Nadarajah 1974; Fleming & Duncan 1990; Brandon et al. 2006; Nocilla et al. 2006). One characteristic exhibited by such soils is a sensitivity of undrained stress-strain characteristics to sample disturbance and testing conditions.

DOI: 10.1201/9781003299127-22

A relatively small number of researchers have studied the stress-strain and strength behavior of silt-clay transition soils (Seed et al. 1964; Lupini et al. 1981; Stark et al. 1994; Yin 1999; Cola & Simonini 2002; Yin 2002; Nocilla et al. 2006; Anantanasakul et al. 2012; Wang & Luna 2012; Wong et al. 2017; Anantanasakul & Roth 2018; Anantanasakul et al. 2023). Based on the results of these studies it has generally been concluded that with high silt contents of low clay contents, silt-clay transition soils become less plastic, as quantified by lower values of the plasticity index. The behavior of such soils, which are often characterized as being low-plasticity silts, has been observed to be intermediate between that of clay and fine sand (Penman 1953; Fleming & Duncan 1990; Brandon et al. 2006; Nocilla et al. 2006).

Compared to soils that are primarily clays, silt-clay transition soils are less compressible under both one-dimensional and isotropic consolidation. Such behavior was observed when testing both isotropically (Yin 1999; Cola & Simonini 2002; Anantanasakul & Roth 2018) and anisotropically (Parry & Nadarajah 1974; Anantanasakul et al. 2012) prepared specimens.

Increases in silt content result in stiffer stress-strain response, larger undrained shear strength and effective friction angles (Stark et al. 1994; Yin 2002; Nocilla et al. 2006; Anantanasakul et al. 2012, Anantanasakul & Roth 2018). At higher silt contents, silt-clay transition soils often exhibit dilative volumetric response during shearing under drained conditions (Yin 1999; Brandon et al. 2006). This precludes a straightforward determination of undrained shear strength in a manner similar to clays.

Relatively few studies have investigated the effect of overconsolidation ratio (OCR) on the response of silt-clay transition soils (Henkel 1956; Hvorslev 1960; Ladd & Foott 1974; Fleming & Duncan 1990; Wang & Luna 2012; Anantanasakul & Roth 2018). With increasing OCR, less ductile stress-strain response with more pronounced peak strength has been observed in silt-clay transition soils. In these studies, under drained conditions, the soils exhibited increased dilative volumetric response. The magnitude of such response varied considerably among the different soils tested.

The only study that systematically investigated the effect that variations in silt content have on the mechanical behavior of silt-clay transition soils was that performed by Anantanasakul & Roth's (2018). In this study, the same base clay, specimen preparation procedure, testing methods and conditions were used. Only the amount of silt present in a test specimen was systematically varied. Since the results of this study will be used to illustrate the numerical simulation of silt-clay transition soils, some additional details pertaining to this study are next presented.

3 EXPERIMENTAL STUDY WITH VARYING DEGREES OF OVERCONSOLIDATION

3.1 *Information on soils tested*

In their study, Anantanasakul & Roth (2018) employed two base soils, namely kaolin clay and a non-plastic silt. The silt consisted of ground silica, sieved to obtain a specific particle-size gradation. Three laboratory-prepared soils were studied. In the subsequent development, the pure kaolin clay will be referred to as "Soil 1". The other two soils were created by mixing Soil 1 with different amounts of non-plastic silt. These two silt-clay mixtures will be referred to as Soils 2 and 3.

Table 1 lists the clay (grain diameter < 0.002 mm), silt (0.075 mm > grain diameter > 0.002 mm) and sand (4.75 mm > grain diameter > 0.075 mm) contents of the three soils. The tested silt-clay soils contained small amounts of sand-sized particles (sand contents equal or less than 2%). The effects of such particles on the mechanical response of silt-clay soils were deemed negligible. Table 1 also lists the liquid limits, plastic limits and plasticity indices for the three soils tested. The liquid limits and plasticity indices decrease with increases in the amount of non-plastic silt. According to the Unified Soil Classification System (USCS), Soils 1, 2 and 3 can be classified as MH, ML and ML, respectively.

3.2 *Specimen preparation*

Proper amounts of dry kaolin powder and base silt were mixed with water to produce slurries at water contents twice the liquid limits of the three tested soils. The mixing of slurries was carried out in a commercial-grade stand mixer. The slurries were one-dimensionally consolidated in the double-draining consolidation tank at an effective vertical stress of 150 kPa. Following consolidation, cake samples, 250 mm in diameter and 170 mm high, were obtained from the tank. It is worth mentioning that the consolidation pressure of 150 kPa was employed to produce soil samples which were adequately stiff and could be handled in the subsequent testing procedures without significant disturbance. Cylindrical specimens, 71 mm in diameter and 142 mm tall, were carved from the cake samples and installed into the axisymmetric triaxial apparatus.

Table 1. Properties of soils tested.

Soil Property	Soil 1	Soil 2	Soil 3
Clay content (%)	74	49	30
Silt content (%)	24	50	69
Sand content (%)	2	1	1
Liquid limit (%)	55	42	30
Plastic limit (%)	35	31	24
Plasticity index (%)	20	11	6
Specific gravity	2.64	2.64	2.65

3.3 *One-dimensional compression tests*

A series of one-dimensional consolidation tests was performed on the three soils tested. Table 2 summarizes the initial void ratios (e_0) of the specimens prior to the compression tests, the values of the compression indices (C_c) and, recompression indices (C_r) indices, and the measured preconsolidation pressures (σ'_p) are presented in Table 3.

Table 2. Values obtained from one-dimensional consolidation tests.

Soil Parameter	Soil 1	Soil 2	Soil 3
Initial void ratios (e_0)	0.95	0.77	0.65
Compression index (C_c)	0.290	0.220	0.130
Recompression index (C_r)	0.090	0.040	0.015
C_r/C_c	0.31	0.18	0.12
Preconsolidation pressure (kPa)	160	125	140

3.4 *Consolidated-undrained triaxial tests*

Consolidated-undrained triaxial tests were performed on isotropically consolidated specimens of Soils 1, 2 and 3. These CIUC tests were of deformation control type with an axial strain rate of 0.01% per minute. The triaxial specimens were consolidated at a maximum isotropic effective stress (σ'_0) of 400 kPa. Upon completion of primary consolidation at this stress level, triaxial specimens of Soils 1, 2 and 3 were normally consolidated. In some tests, the specimens were then unloaded to appropriate confining stresses (σ'_c) of 200, 100 and 50 kPa so as to achieve OCRs of 2.0, 4.0 and 8.0 prior to undrained shear.

Based on the results of their experimental study, Anantanasakul & Roth (2018) concluded that the amount of non-plastic silt present rather significantly affected the behavior of silt-clay transition soils. During undrained shearing, such soils exhibited stiffer stress-strain response with increasing silt content. Figure 1 presents graphical evidence that confirms this conclusion for OCR equal to 2.0. Similar trends were observed for the normally consolidated specimens, as well as for ones with OCR equal to 4.0 and 8.0.

The undrained shear strengths and effective friction angles increased with increases in the amount of silt. This was attributed to the increased friction and interlocking among the angular silt particles.

With increasing silt content, in specimens with OCR equal to 1.0, 2.0 and 4.0, the excess pore pressure changes increased, suggesting an increased contractive tendency. However, as evident from Figure 2, this trend reverses for OCR equal to 8.0 in that now the excess pore pressure becomes more negative with increasing silt content, the pore pressure, indicating an increased dilative tendency.

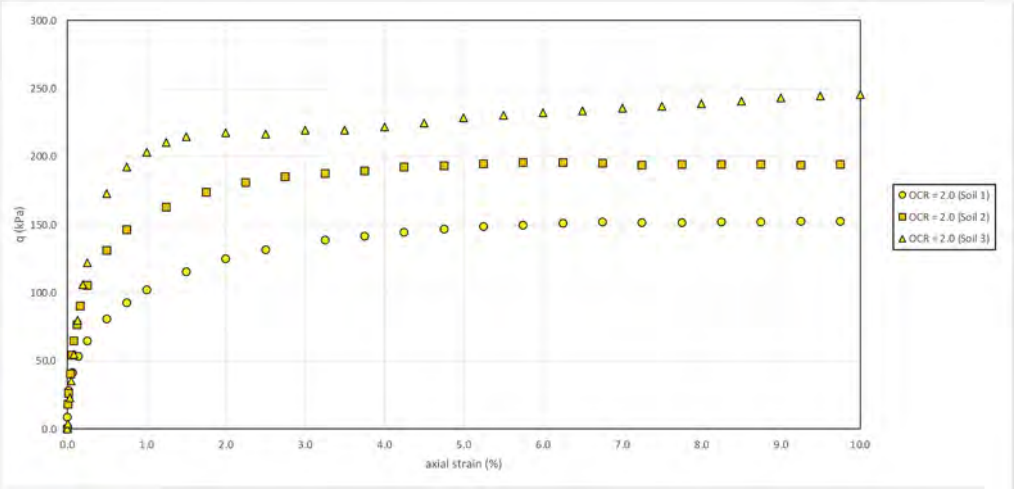

Figure 1. Comparison of experimental principal stress difference-axial strain response for OCR=2.0.

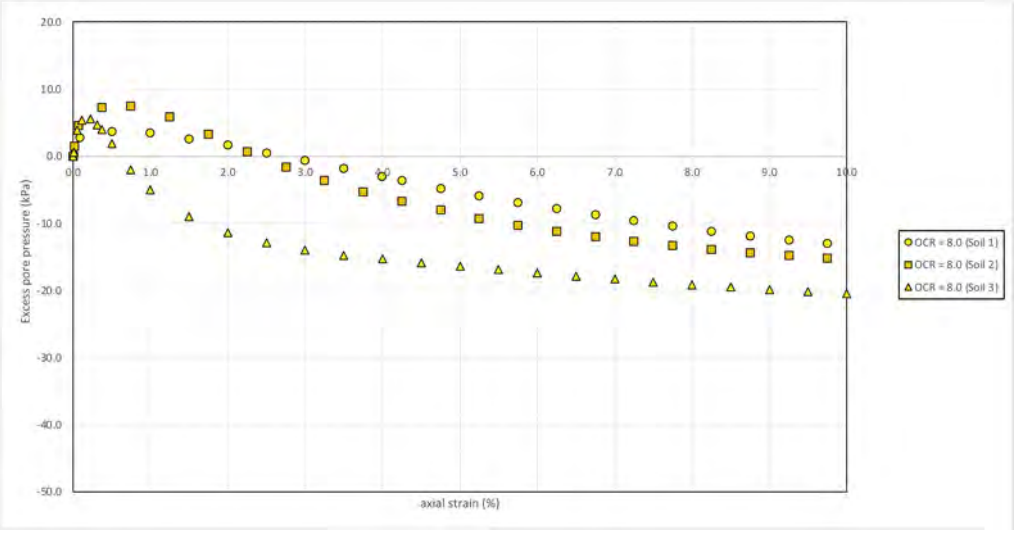

Figure 2. Comparison of experimental excess pore pressure-axial strain response for OCR = 8.0.

The discussion next turns to the the numerical simulation of the silt-clay transition soils tested by Anantanasakul & Roth (2018). Before discussing specifics associated with these simulations, it is timely to briefly review some general aspects related to the mathematical modeling of the response of clays.

4 MATHEMATICAL MODELING OF RESPONSE

Several constitutive models based on classical elastoplasticity theory have been proposed to simulate the behavior clay. A significant milestone in the development of such models was the advent of the critical state theory of soil mechanics (Schofield & Wroth 1968). This theory served as the basis for several isotropically hardening elastoplastic formulations such as the Modified Cam Clay model (Roscoe & Burland 1968) and its variants. Perhaps the biggest drawback of such models is that plastic response is restricted to only those stress states lying on the yield surface; states within the surface are purely elastic. As a consequence, models based on classical elastoplasticity predict excessively "stiff" elastic response for overconsolidated clays; in addition, such models cannot accurately predict hysteretic plastic strains or accumulated excess pore pressures generated by cyclic loading. Finally, the simulations developed using such models are counter to the results of experimental studies indicate that as a saturated cohesive soil is loaded, it continuously develops both elastic and inelastic strains without a distinct yield state that delineates elastic from inelastic response (Roscoe & Burland 1968; Wong & Mitchell 1975).

Beginning in the 1960's one class of "unconventional" constitutive models developed to overcome the aforementioned shortcomings associated with standard elastoplastic models employed kinematic hardening in addition to purely isotropic hardening. In such models, the overall hardening is said to be anisotropic. Extended elastoplastic formulations utilyzing kinematic hardening of a family of "nested" surfaces were developed (Iwan 1967; Mrŏz et al. 1978). Each such surface translates independently in a purely kinematic fashion. The combined effect gives rise to a piecewise linear hardening behavior for the material as a whole.

Although nested surface models have demonstrated flexibility in simulating the complex monotonic response of clays (Darve et al. 1986), their numerical implementation tends to be complicated (Vermeer & De Borst 1984). This shortcoming was overcome by developing models based on the bounding surface in stress invariant space (Dafalias 1979a), which can be viewed as a modification of certain nested surface models (Mrŏz et al. 1978). Bounding surface models involve only two surfaces, namely a current loading surface and an outer "bounding" surface (Figure 3). The intermediate loading surfaces are implicitly defined on the basis of the proximity (δ) of the current stress point to a properly defined "image" stress point on the bounding surface. The prominent features of a bounding surface formulation are 1) the existence of inelastic deformations for stress states within an outer ("bounding") surface, and 2) the existence of a smoothly varying plastic modulus. These features represent definite advantages over classical rate-independent yield surface elastoplastic formulations, especially for "softer" materials such as cohesive soils (Dafalias 1986).

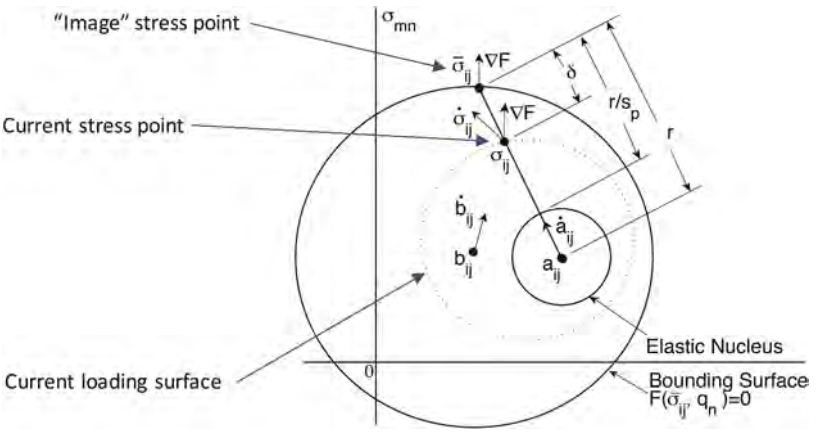

Figure 3. Schematic illustration of a general bounding surface in stress space.

Dafalias (1979a) qualitatively presented a direct bounding surface formulation for rate-independent isotropic soil elastoplasticity for the case of zero elastic range and in conjunction with implied loading surfaces; this model was also extended to include a quasi-elastic range (Dafalias 1979b). The latter model combined the attractive features of simplicity and good predictive capabilities when applied to clays. It was subsequently formulated within the framework of stress invariant space in conjunction with a critical state failure criterion (Schofield & Wroth 1968), which included a three-invariant formulation (Dafalias & Herrmann 1982; Dafalias et al. 1982). This form of the model was synthesized (Dafalias & Herrmann 1986) and then subsequently simplified (Kaliakin & Dafalias 1989).

Dafalias (1982a) was the first to discuss the issue of anisotropy in conjunction with bounding surface models. This led to the progressive development of an anisotropic, rate-independent bounding surface models for cohesive soils (Anandarajah & Dafalias 1986; Liang & Ma 1992).

Dafalias 1982a,b first presented the theoretical basis for a time-dependent version of the bounding surface model for isotropic cohesive soils. This model was subsequently refined, implemented, formally presented and verified (Kaliakin & Dafalias 1990a,b).

Realizing that previous anisotropic time-dependent bounding surface formulations (Al-Shamrani & Sture 1998; Voyiadjis & Kim 2003) were overly complex, Ling et al. (2002) proposed a somewhat more rational model that reduced the total number of parameters without compromising predictive capabilities (Ling et al. 2002, 2003).

Jiang et al. (2012) extended the anisotropic model of Ling et al. (2002) to include a non-associative flow rule, which is typically required in order to more accurately simulate the response of soft cohesive soils that exhibit softening.

The predictive capabilities of bounding surface models for cohesive soils have typically been assessed by comparing numerical results with data obtained from laboratory tests. The majority of these tests were performed under axisymmetric triaxial compression and extension stress states. In a few instances, more complex stress states were considered. This included the centrifuge modeling of the filling and emptying of an oil storage tank (Shen et al. 1986), the simulation of a caisson-retained sand island in the Canadian Beaufort Sea (Kaliakin et al. 1990), sundry simulations of field soils (Jiang et al. 2013), and simulation of complex field excavations in soft soils (Hung et al. 2014; Ling et al. 2016).

5 THE GENERALIZED BOUNDING SURFACE MODEL

Although all of the aforementioned models for cohesive soils were based on the concept of a bounding surface in stress space, they improved upon earlier versions of such models, enhanced the predictive capabilities of earlier models by expanding their features, or accomplished both of these tasks. Missing from the earlier development of bounding surface models for cohesive soils was any attempt to *synthesize* the many previous forms of these models. Such a synthesis has now been realized through the Generalized Bounding Surface Model (GBSM) for cohesive soils (Kaliakin et al. 2018). The GBSM also improves upon many aspects of previous models for cohesive soils and expands the scope of the model to thermo-hydro-mechanical analyses.

In its most general form, the GBSM for cohesive soils is a fully three-dimensional, temperature and time-dependent model that accounts for both inherent and stress induced anisotropy. To better simulate the behavior of cohesive soils exhibiting softening, the model employs a non-associative flow rule. The microfabric-inspired rotational hardening rule associated with the model was developed after a thorough review of past modeling practice. Finally, the shape hardening function used in the GBSM was developed simplifying earlier versions without compromising the model's predictive capabilities. Details pertaining to the GBSM, an investigation of the associated parameters, as well as a discussion describing how potential limitations of the model have been overcome are given in (Kaliakin et al. 2018; Nieto-Leal et al. 2020; Nieto-Leal et al. 2021).

The GBSM has been shown to accurately simulate the stress-strain and strength characteristics of different clays for various stress conditions (e.g., Kaliakin et al. 2018; Nieto-Leal et al. 2021). However, its applicability for cohesive soils with different clay and silt contents and thus

levels of plasticity has not been investigated in a systematic manner. Due to the availability of experimental results obtained from a series of consolidated-undrained triaxial tests on silt-clay transition soils by Anantanasakul & Roth (2018), the present simulations were undertaken.

5.1 *Identification of applicable model parameters*

Since the specimens tested by Anantanasakul & Roth (2018) were all isotropically consolidated, only isotropic forms of the GBSM apply to the present simulations. This reduces the number of applicable model parameters. The isotropic forms employing an associative and non-associative flow rule are referred to herein as the GBSMia and GBSMin forms, respectively, of the model.

Since Anantanasakul & Roth (2018) only tested the aforementioned specimens in axisymmetric triaxial compression, those parameters controlling the response of the GBSM in extension are immaterial. Consequently, the number of model parameters reduces further.

The model parameters associated with the GSBMia and GBSMin forms of the model, as restricted to response in axisymmetric triaxial compression, are grouped by their type as follows: the critical state parameters λ, κ and M_c, the elastic parameter Poisson's ratio (ν), the surface configuration parameters R and N_c (the latter only applies to the GBSMin form of the model), the projection center parameter C, the elastic nucleus parameter s_p, and the shape hardening parameters h_c and a.

5.2 *Determination of parameter values for silt-clay transition soils*

The values of λ and κ were determined from the values of C_c and C_r, respectively, listed in Table 2. With increasing silt content, the values of λ decreased from 0.146 to 0.058; the κ values likewise decreased from 0.045 to 0.007. Table 3 lists the values of λ and κ determined for each of the three soils tested.

Assuming no effective cohesion, the friction angle (ϕ') for each of the three soils was determined from the maximum effective stress ratios (σ'_1/σ'_3), as measured in the CIUC tests on both normally consolidated and overconsolidated specimens. The slope of the critical state line associated with axisymmetric triaxial compression (M_c) is then determined from the following expression:

$$M_c = \frac{6\sin\phi'}{3 - \sin\phi'} \tag{1}$$

With increasing silt content, the values of M_c increased from 0.770 to 1.440. Table 3 lists the values of M_c determined for each of the three soils tested.

Table 3. Values of model parameters used in present simulations.

Model Parameter	Soil 1	Soil 2	Soil 3
λ	0.146	0.105	0.058
κ	0.045	0.015	0.007
M_c	0.77	1.07	1.44
ν	0.18	0.23	0.30
R	2.35	2.20	2.45
C	0.50	0.60	0.55
s_p	1.00	1.50	1.50
h_c	1.75	4.00	4.00
a	3.25	2.25	3.25
N_c	n/a	0.950	n/a

To determine the values of Poisson's ratio, isotropically consolidated drained (CIDC) triaxial compression tests, each with an unload-reload cycle, were performed on normally consolidated

specimens of the silt-clay soils (Anantanasakul & Roth 2018). In these tests, deviator stresses in the vertical direction were applied up to levels equal to 50% of the anticipated maximum principal stress differences $(\sigma_1 - \sigma_3)_{max}$. The specimens were later unloaded to 25% of the maximum value and then reloaded. The Poisson's ratio values were computed from the corresponding changes in axial strains $(\Delta\varepsilon_1)$ and volumetric strains $(\Delta\varepsilon_v = \Delta\varepsilon_1 + 2\Delta\varepsilon_3)$ during reloading as follows:

$$\nu = -\frac{\Delta\varepsilon_3}{\Delta\varepsilon_1} = -\frac{\Delta\varepsilon_v - \Delta\varepsilon_1}{2\Delta\varepsilon_1} \tag{2}$$

where ε_3 is the minor principal strain. Table 3 lists the values of Poisson's ratio so determined for the three soils tested, which ranged from 0.18 to 0.30.

Values of the surface configuration parameter R ($R \geq 2$) were determined by primarily matching the effective stress paths of the normally consolidated specimens of the three soils tested. Suitable values for the projection parameter C ($0 \leq C < 1$) were determined primarily by matching the effective stress paths of tests on overconsolidated specimens with the OCRs of 2.0, 4.0 and 8.0. The values R and C so determined are listed in Table 3.

Values for the "elastic nucleus" parameter s_p ($s_p \geq 1$) were determined by matching the principal stress difference ($q = \sigma_1 - \sigma_3$)-axial strain (ε_1) response for the aforementioned overconsolidated specimens. When $s_p = 1$, the elastic nucleus reduces to a point and plastic strains are predicted within the entire bounding surface. Stiffer q-ε_1 response can be simulated by using s_p values greater than unity. This was the case for Soils 2 and 3 (see Table 3). Figure 4 better illustrates the meaning of the parameters R, C and s_p.

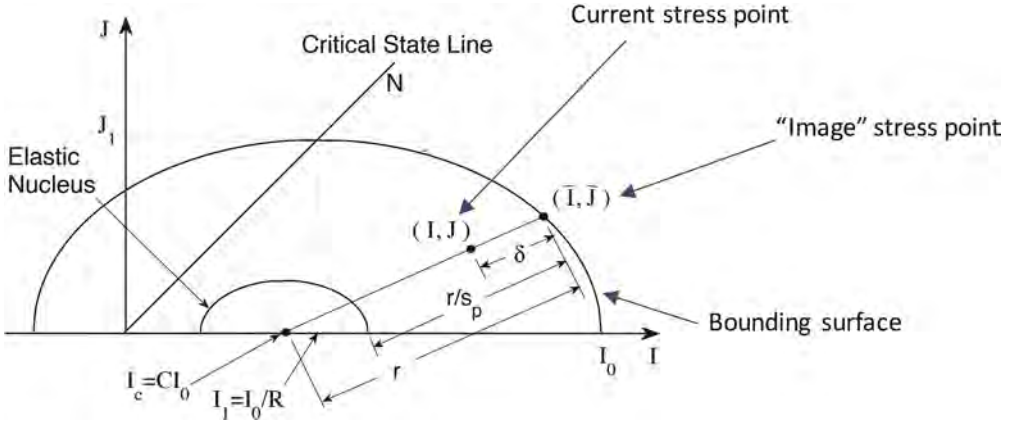

Figure 4. Schematic illustration of elliptical bounding surface in space of stress invariants.

Accurate simulation of Soil 2 required the use of the GBSMin form of the model. The non-associative flow rule used in this form requires the value of the parameter N_c that is used to define the shape of the plastic potential surface. The value of this parameter (0.950) was primarily determined by matching the q-ε_1 curves for specimens with OCRs of 2.0, 4.0 and 8.0.

The values of the shape hardening parameters h_c and a are only active in simulation of tests on overconsolidated specimens. The values of h_c were determined by matching the q-ε_1 curves for specimens with OCRs of 2.0 and 4.0. Finally, the values of a were determined by matching the q-ε_1 curves and effective stress paths for specimens with OCR equal to 8.0. With increasing silt content, the values of h_c increased from 1.75 to 4.0. The values determined for a did not follow this trend. Table 3 lists the values of the shape hardening parameters determined for the three soils tested.

6 SIMULATION OF BEHAVIOR OF SILT-CLAY TRANSITION SOILS

The constitutive relations associated with the GBSM, along with such enhancements as local iteration, sub-stepping and radial return (Herrmann et al. 1987) have been incorporated into

a modular system of FORTAN-77 subroutines. This system consists of a master subroutine clay_UD that is supported by numerous lower-level subroutines. Implementation of the GBSM in such a manner facilitates simple and inexpensive incorporation into existing and new computer programs for the analysis of geo-structures.

For purposes of assessing the characteristics of the GBSM and for simulating experimental results, a means for predicting the results of simple homogeneous tests must be made available. The Fortran-90 computer program CALBR8 (Kaliakin 1992) has been developed for this purpose. CALBR8 evaluates the constitutive relations, as applied to a homogeneous specimen, subjected to arbitrary homogeneous stress, strain and temperature histories, under either drained or undrained conditions. Although CALBR8 has been written to evaluate the time- and temperature-dependent constitutive relations, the formulation can also be used to perform time-dependent and isothermal analyses (Burmister).

In the subsequent figures, the experimental results of Anantanasakul & Roth (2018) are depicted by discrete symbols. The simulations obtained using the GBSM are depicted by solid, dashed, and dot-dashed lines.

6.1 *Simulation of the behavior of Soil 1*

Using the parameter values listed in the second column of Table 3 in conjunction with the GBSMia form of the model, the behavior of Soil 1 was simulated. Figure 5 shows the simulated effective stress paths for the OCRs of 1.0, 2.0, 4.0 and 8.0. The simulated q-ε_1 response is shown in Figure 6. Finally, Figure 7 shows the simulated excess pore pressure-ε_1 response.

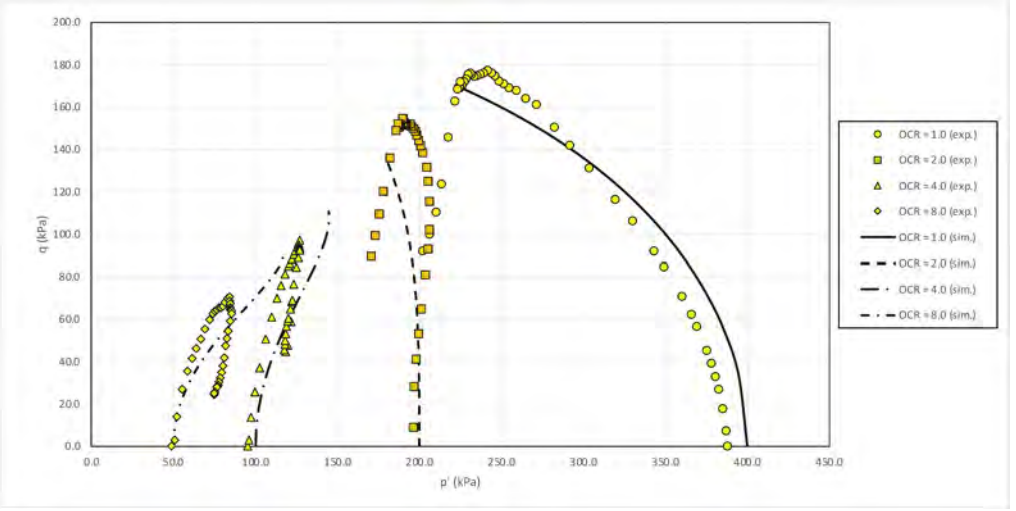

Figure 5. Comparison of simulated and experimental effective stress paths for Soil 1.

Although no single q-ε_1 is simulated exactly, as seen from Figure 6, an overall "best-fit" of the q-ε_1 has been realized. The simulated excess pore pressure-ε_1 for OCRs of 1.0, 2.0 and 4.0 is quite accurate (Figure 7). In the case of OCR equal to 8.0, the excess pore pressure is somewhat over predicted.

6.2 *Simulation of the behavior of Soil 2*

Using the parameter values listed in the third column of Table 3 in conjunction with the GBSMin form of the model, the behavior of Soil 2 was simulated. Figure 8 shows the

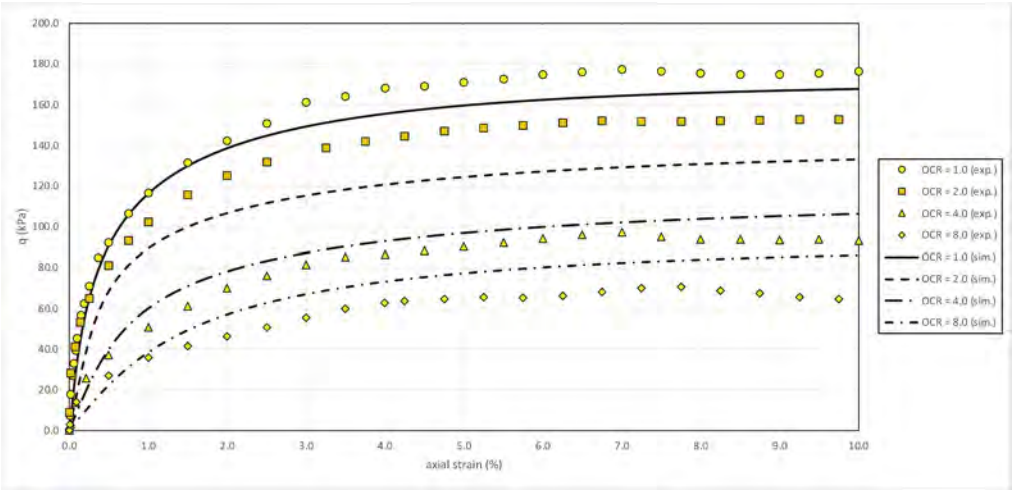

Figure 6. Comparison of simulated and experimental principal stress difference-axial strain response for Soil 1.

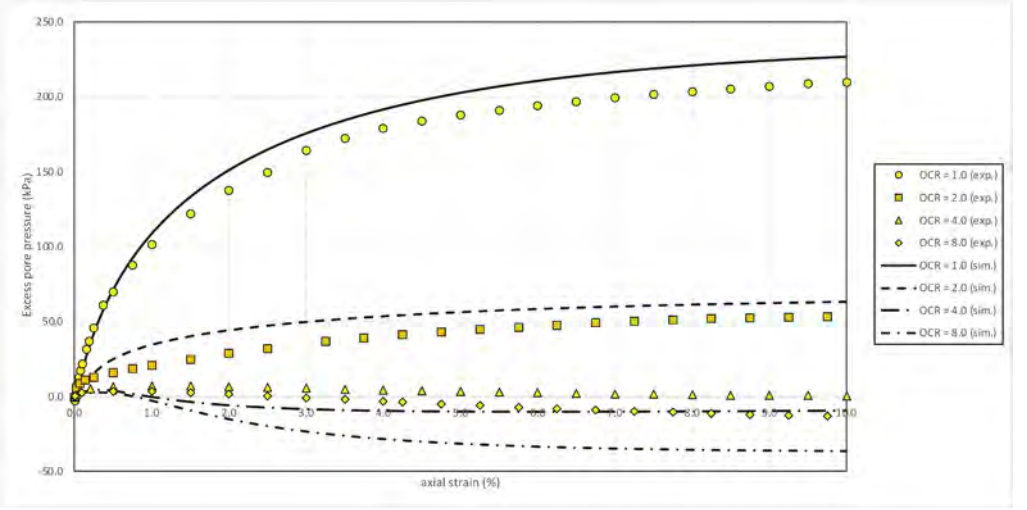

Figure 7. Comparison of simulated and excess pore pressure-axial strain response for Soil 1.

simulated effective stress paths for the OCRs of 1.0, 2.0, 4.0 and 8.0. The simulated q-ε_1 response is shown in Figure 9. Finally, Figure 10 shows the simulated excess pore pressure-ε_1 response.

Initially, the response of Soil 2 was simulated using the GBSMia form of the model. However, the GBSM employs a critical state failure criterion that predicts a constant value of undrained shear strength even as the shear strains continuously increase. As such, the reduction in strength after failure that was exhibited by Soil 2 at high strains could not be simulated. This shortcoming was partially reduced through the use of the GBSMin form of the model. The non-associative flow rule allows for some reduction in strength with continued straining (Nieto-Leal et al. 2018). However, as evident from the simulations of Soil 2, the use of a non-associative flow rule is not a panacea in such simulations.

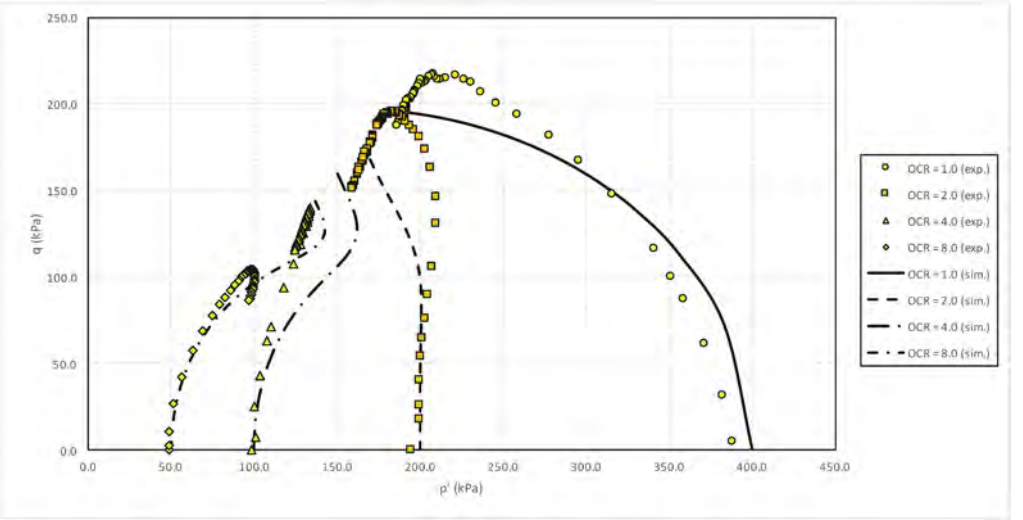

Figure 8. Comparison of simulated and experimental effective stress paths for Soil 2.

As evident from Figure 9, an overall "best-fit" was again obtained for the simulated q-ε_1 response. With the exception of the case for OCRs 1.0 and 8.0, the overall excess pore pressure response was simulated rather accurately (Figure 10).

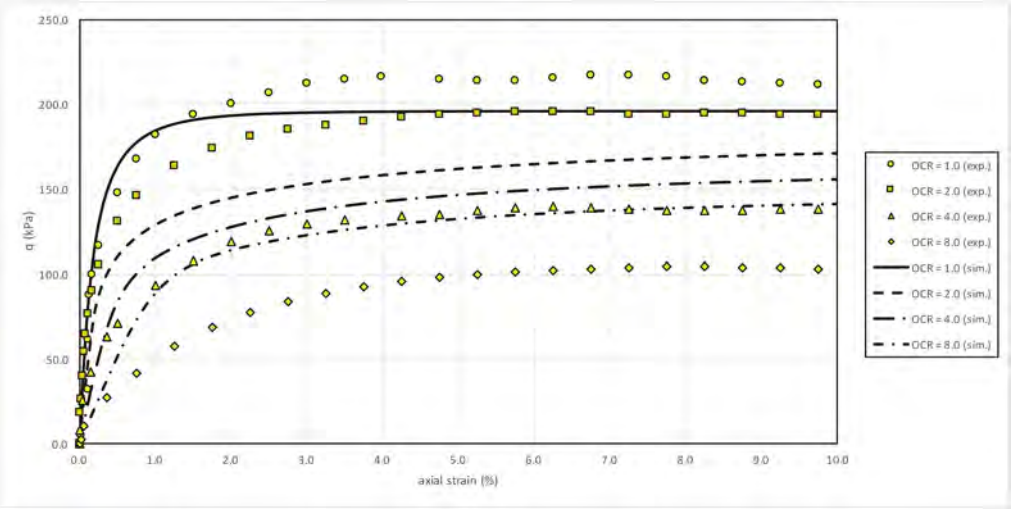

Figure 9. Comparison of simulated and experimental principal stress difference-axial strain response for Soil 2.

6.3 *Simulation of the behavior of Soil 3*

Finally, using the parameter values listed in the fourth column of Table 3 in conjunction with the GBSMia form of the model, the behavior of Soil 3 was simulated. Figure 11 shows the simulated effective stress paths for the OCRs of 1.0, 2.0, 4.0 and 8.0. The simulated q-ε_1

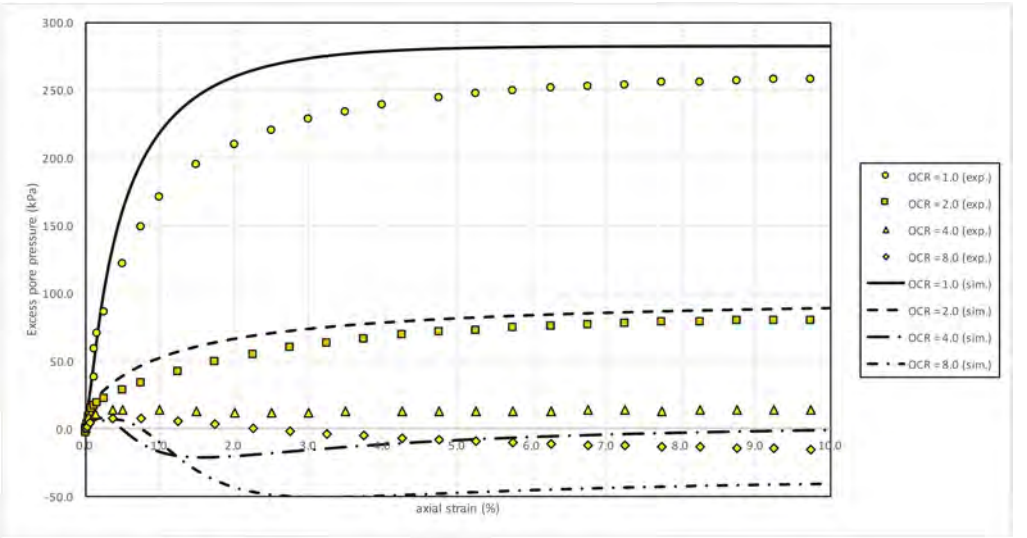

Figure 10. Comparison of simulated and excess pore pressure-axial strain response for Soil 2.

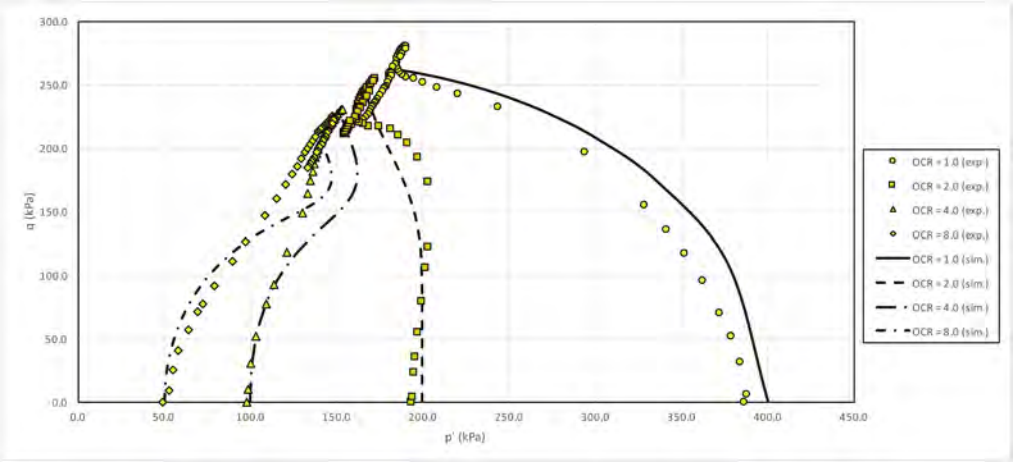

Figure 11. Comparison of simulated and experimental effective stress paths for Soil 3.

response is shown in Figure 12. Finally, Figure 13 shows the simulated excess pore pressure-ε_1 response.

Although Soil 3 contained the largest amount of non-plastic silt, the GBSM simulations obtained for this soil were the most accurate. This is particularly evident in the simulated q-ε_1 (Figure 12) and excess pore pressure-ε_1 response (Figure 13).

7 CONCLUSIONS

The Generalized Bounding Surface Model for cohesive soils was employed to simulate the stress-strain, pore pressure change and strength characteristics obtained from CIUC triaxial tests on normally consolidated and overconsolidated silt-clay transition soils. The soils employed in this study employed the same base clay but systematically varied the amount of non-plastic silt content. It was observed that the isotropic forms of the GBSM, once calibrated properly, was able to simulate the undrained response of silt-clay soils with widely varying silt

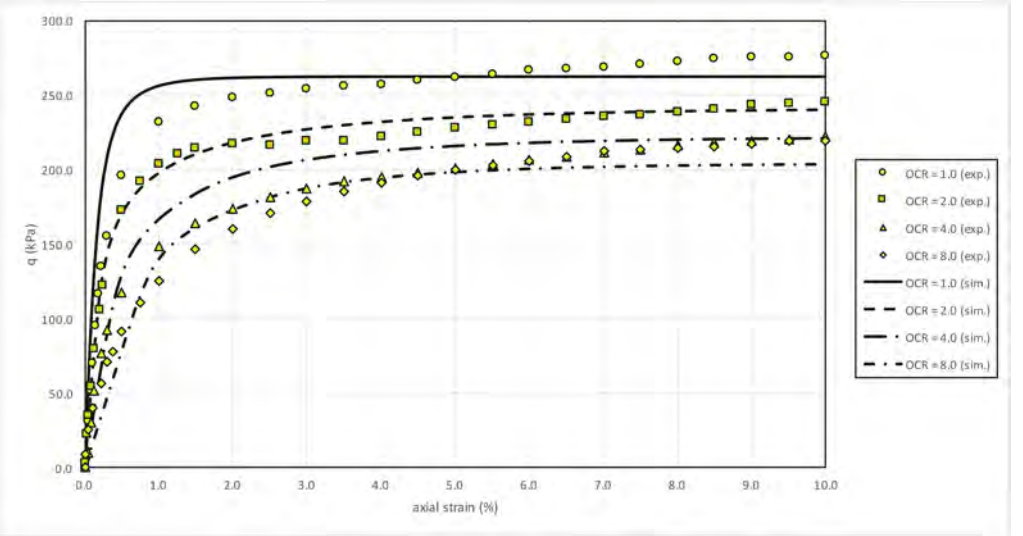

Figure 12. Comparison of simulated and experimental principal stress difference-axial strain response for Soil 3.

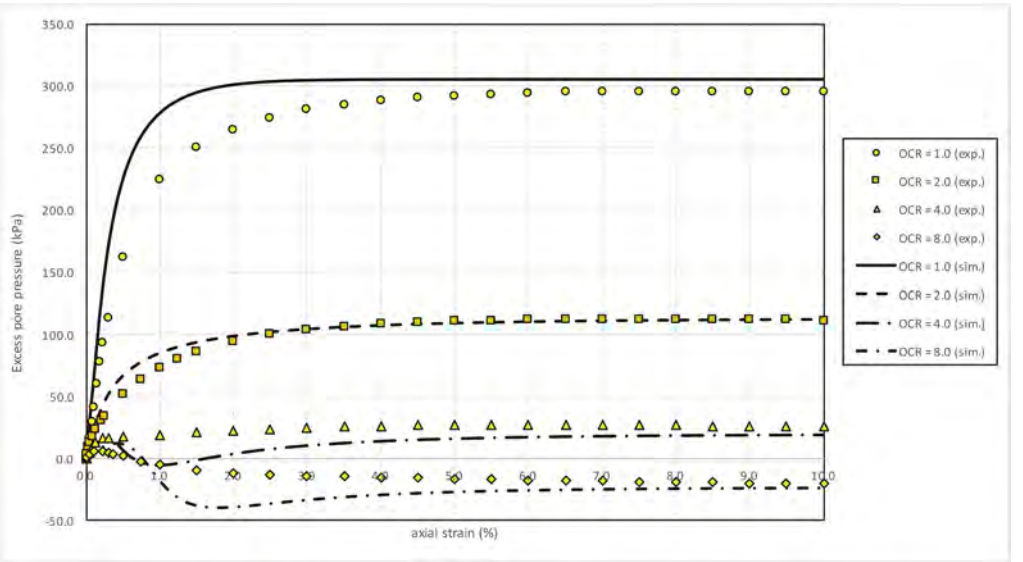

Figure 13. Comparison of simulated and excess pore pressure-axial strain response for Soil 3.

contents and thus values of plasticity index with reasonable accuracy. The trends of material behavior with respect to variation in the silt content can reasonably be simulated. The accuracies of numerical predictions were highest for the soil with highest non-plastic silt content and lowest plasticity index. The model was less accurate, where the experimental stress-strain relations and undrained shear strengths were sometimes over-estimated, for the soils with lower silt contents and with moderate and high OCR values. In the case of Soils 1 and 2, the simulated excess pore pressure-axial strain response was over-predicted.

The reason for such over-predictions may, in part, be attributed to the use of a single elliptical bounding surface (Figure 2). For overconsolidated stress states on the "dry" (or left) side of critical, the predicted effective stress path is unrealistically "pulled" upward. This often results in

prediction of a high peak shear strength and stiff stress-strain response prior to failure. Although this issue has been investigated in detail and a remedy proposed (Nieto-Leal & Kaliakin 2014), this issue may need to be re-visited when simulating the response of silt-clay transition soils.

Finally, the values of several of the model parameters used to simulate each of the three silt-clay transition soils were determined by best matching the associated experimental results. Ideally, however, the values of at least some of these parameters should be determined from index properties, from volume content of non-plastic silt present in a soil, etc. This can, however, only be realized with additional systematic experimental studies of silt-clay transition soils. These should consider time and rate effects, as well the effect of anisotropy.

Application of vertical drains and vacuum preloading for stabilising soft ground for transport infrastructure

Cholachat Rujikiatkamjorn
Professor, Transport Research Centre, University of Technology Sydney, NSW, Australia

Buddhima Indraratna
Distinguished Professor and Director, Transport Research Centre, University of Technology Sydney, NSW, Australia

ABSTRACT: Demand for the development of transportation infrastructure built on soft clays soils has increased in the past decades because of the rapid surge in population density along the coastal belts of many countries. Acceptable ground conditions are also becoming limited. Due to these reasons, ground improvement is pertinent and required as an essential part of infrastructure development. The application of prefabricated vertical drains with vacuum and surcharge preloading can be one of the economical techniques for transportation infrastructure projects. Consoldiation of soft soil by applying a surcharge alone can become lengthy. The application of prefabricated vertical drains (PVDs) with vacuum can reduce the waiting period significantly by decreasing the drainage path length in the radial direction. In this paper, factors affected the performance of the system including (a) drain spacing and partially penetrating drains, (b) smear zone, (c) vacuum systems, (d) application of numerical analysis for multi-drain system, (e) the optimum time for switching off vaccum pump, are discussed with their advantages and limitations.

1 INTRODUCTION

The application of preloading prior to the construction of transport infrastructure is one of the most effective and economical methods for reducing long-term deformation and increasing soft soil shear strength (Johnson 1970). To accelerate the consolidation, prefabricated vertical drains (PVDs) with or without vacuum pressure can be applied with surcharge. The consolidation time can be decreased via (a) shortened radial drainage path facilitated by PVDs and (b) apparent increased preloading pressure due to vacuum pressure (Kjellman, 1948; Qian et al. 1992). The combined vacuum and fill can further increase embankment stability through the reduction of surcharge height and the inward lateral displacement due to suction (Indraratna et al. 2005).

2 APPLICATION OF PVDS: DRAIN SPACING AND PARTIALLY PENETRATING DRAINS

In current practice, prefabricated vertical drains (PVDs) are comprised of a plastic strip with flow channels protected by filter geosynthetics jacket to prevent silt intrusion (Rixner et al. 1986). To reduce environmental footprint, bio-degradable vertical drains were introduced (Lee et al. 1994). Indraratna et al. (2018) showed that the performance of the biodegradable drains is similar to synthetic drains as the influence of the drain degradation becomes minimal at the end of the consolidation. PVD shapes can be either rectangular (100mmx4mm) for a typical fill surcharge or circular for the application of vacuum preloading (35-50mm diameter). They are often installed in a triangular or square pattern using installation machine. The spacing and installation depth range from 0.8-2.5m and 3-30m, respectively.

DOI: 10.1201/9781003299127-23

Partially penetrating vertical drains option where PVDs are installed within impermeable soil layer (Figure 1) can often be observed in practice when (a) the influence of an embankment loading is restricted within a shallow depth of soft clay layer, (b) vacuum consolidation to prevent any leak to bottom permeable layer (Hart et al. 1958; Zeng and Xie 1989; Zhu and Yin 2000; Ong et al. 2012; Geng et al. 2011). Geng et al. 2011 showed that PVD length could be reduced by 10% without considerably affecting consolidation time.

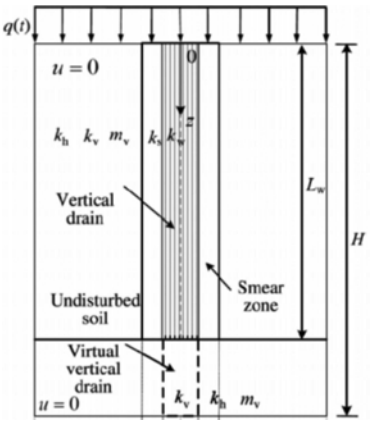

Figure 1. Partially penetrating drain (Geng et al. 2011, Permission obtained from CGJ).

3 ROLE OF SMEAR ZONE

During the installation process of PVDs, surrounding soil properties are disturbed, such as permeability and compressibility. The characterisation of smear zone can be determined using large-scale laboratory testing, back calculation of time-settlement curves and recently soil samples collected after the PVDs installation (Bergado et al. 1991; Indraratna and Redana, 1997; Miura & Chai, 1999; Sharma and Xiao 2000; Hird and Sangtian, 2002; Basu et al. 2007, Sathananthan et al. 2006; Pothiraksanon et al. (2008); Saowapakpiboon et al., 2011; Ghandeharioon et al. 2012; Indraratna et al. 2015; Parsa-Pajouh et al. 2014; Choudary et al. 2016; Sengul et al., 2017). Indraratna et al. (2015) showed that the extent of the smear zone can be determined using a variation of permeability, soil compressibility, or water content. Overlapping of the smear zone can be evidenced due to multiple drains installation (Figure 2). Depending on the installation method and the condition of soil, the extent of the smear zone can vary from 1.3 to 7 times the equivalent mandrel diameter. Based on the observation, Rujikiatkamjorn and Indraratna (2014) incorporated the change of soil compressibility and permeability in a smear zone into an analytical model for a unit cell. The proposed theory was validated with field data from a selected case study in the town of Ballina, New South Wales, Australia.

4 APPLICATION OF VACUUM AND SURCHARGE PRELOADING

After the removal of load application, treated soils become over-consolidated upon the construction of permanent structures (Almeida et al. 2000; Bergado et al. 2002; Indraratna et al. 2000). For conventional fill application, PVDs are often installed through entire clay strata or beyond the loading influence zone imparted by an embankment fill. In an area where embankment's instability is an issue due to soil at a shallow depth having very low shear strength or significant height of surcharge, vacuum in combination with fill preloading can become a desirable option (Cognon et al. 1994; Chu et al. 2000). Apparent preloading pressure created by suction can speed up consolidation process as staged construction can be minimised (Shang et al. 1998; Shen et al. 2005). Vacuum pressure can propagate at the greater depth via PVDs which are often installed within low permeable layer to minimise vacuum loss. Due to the isotropic consolidation effects,

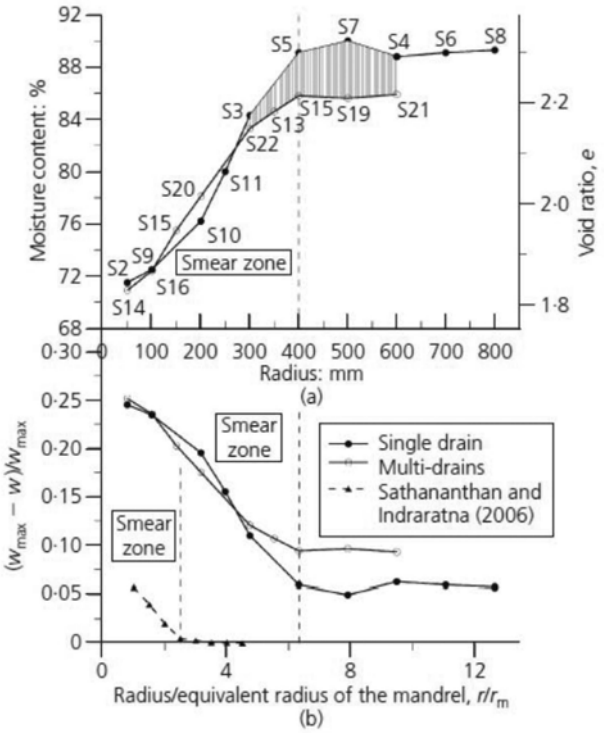

Figure 2. Water content and void ratio variation (Indraratna et al. 2015 with permission obtained from ICE).

the lateral displacement can be controlled using the combination of fill and vacuum preloading (Chai et al. 2008; Indraratna et al. 2012). The systems to apply vacuum pressure can be divided into 2 major systems, namely, membrane and membraneless system.

For the membrane system, the working platform made of a sand layer is placed before an installation of PVDs (Figure 3). Afterwards network of horizontal drainage connected to vacuum pumps is laid, followed by a membrane. The edges of the membrane are submerged under the peripheral bentonite trench. Quality assurance prior to the placement of the fill needs to be performed to prevent any leakage of the membrane. To prevent any leakage at the peripheries of the treated areas due to the presence of an intermittent permeable layer, bentonite slurry walls are often installed to provide vertical impermeable wall adjoining the treated area.

The second approach to apply vacuum pressure is the membranless system (Figure 4). The system is no longer required the membrane as individual drains are connected directly to vacuum pumps via horizontal pipes. Recently some efforts have been made to improve the connection between PVDs and the horizontal pipes to ensure minimum leakage and better propagation of vacuum preloading (Cai et al, 2017; Sun et al. 2017). This system allows smaller portion of an improved area to be treated. The applied vacuum pressure can range from 40-85 kPa. Additional field instrumentation, such as vacuum gauges and in-drain piezometers, is often required to assess the performance of the system.

5 FINITE ELEMENT MODELLING OF VERTICAL DRAINS IN SOFT GROUND UNDER SURCHARGE COMBINED WITH VACUUM PRELOADING

Due to the shape of embankments applicable for transport and port infrastructure, finite element analyses under plane strain condition can be adopted to predict or assess the consolidation behaviour of soft soil beneath an embankment (i.e. multi-drain analysis). Hird et al. (2002);

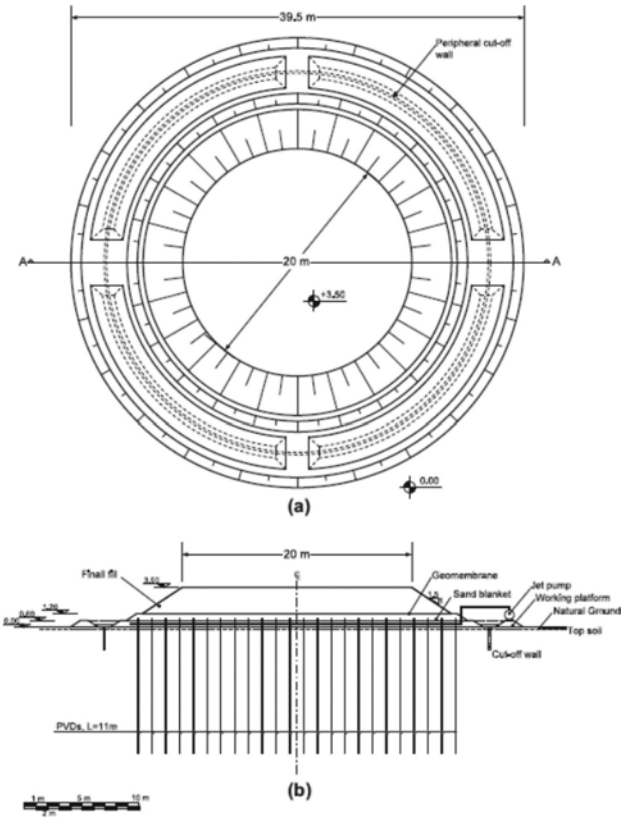

Figure 3. Typical circular embankment plan and cross-section for membrane system (Indraratna et al. 2016 with permission from Computers and Geotechnics).

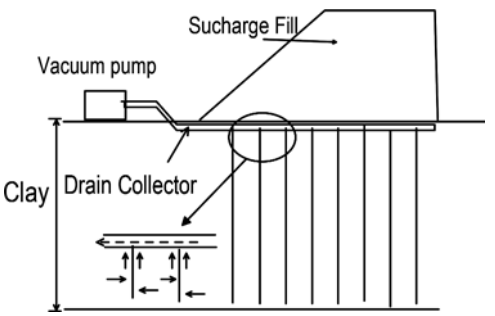

Figure 4. Typical cross section for membraneless system (Indraratna et al. 2015b with permission).

Indraratna and Redana (2000); Chai et al. (2001) showed that conversion techniques are required to ensure the equivalence between axisymmetric (in-situ) and plane strain condition. The equivalent soil permeability in the PVDs zone can be determined based on the drain spacing, in-situ soil permeability, smear zone and the length of the drain. The PVDs zone in finite element modelling can be represented by single equivalent soil permeability with no drain elements. On the other approaches, Hird et al. (2002); Indraratna and Redana (2000) present the permeability conversion by maintaining the geometry of the unit cell. An entire consolidation curve under axisymmetric condition can be captured under equivalent plane strain analysis. In

this approach, individual drains surrounded by smear zone can be modelled explicitly in the analysis. Another advantage of this method is to simulate more realistic consolidation under vacuum preloading. It allows the decayed propagation of the vacuum pressure along the drain and captures inward lateral displacement due to suction (Indraratna et al. 2005).

6 OPTIMUM TIME PERIOD FOR VACUUM PRELOADING APPLICATION

Application of vacuum and fill preloading can further shorten consolidation time. However, extended period of the vacuum application can become uneconomical due to the excessive operation cost of vacuum pumps. Based on laboratory observation supported by field observation at the Port of Brisbane reclamation project in Australia, Kianfar et al. (2015) showed that removal of the vacuum pressure can be decided upon the pore pressure response. In the field, settlement and pore pressure dissipation rates are required through an array of field instrumentation to terminate vacuum pressure (Figure 5)

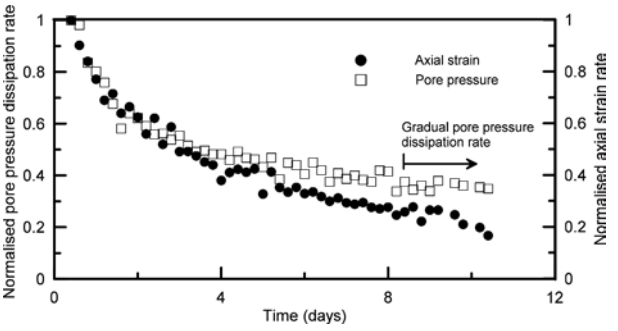

Figure 5. Determination of removal time of vacuum pressure (Kianfar et al. 2015 with permission from CGJ).

7 TIME-DEPENDENT SOIL AND DRAIN PROPERTIES WITH SPECIAL REFERENCE TO BIODEGRADABLE PVDS

In order to analyse the radial consolidation responses due to vertical drains, the unit cell theory representing a single drain surrounded by a soil annulus in axisymmetric condition (3D) was originally proposed by Barron (1948), Richart (1957), Hansbo (1981). Their theories are based on several assumptions including (a) small strain theory, (b) larminar flow (Darcy's law), (c) constant compressibility and permeability, and (d) constant PVDs properties e.g. drain discharge capacity. Indraratna et al. (2011) and (2012) demonstrated that for case studies dealth with larger clay thickness or the application of vacuum preloading, predictions based on conventional redial consolidation theory often deviate from the field observations. Since 2000, several studies have made an attempt to incorporate some features into radial consolidation theory. Indraratna et al. (2017) showed that large strain solution considering non-Darcian flow and variation of compressibility and permeability should be adopted when the vertical strain due to preloading is expected to be more than 15%.

From an environmental point of view, the use of biodegradable natural drains helps to minimise the carbon footprint and improve the environmental sustainability of future infrastructure developments. They also offer a more cost-effective alternative to polymer PVDs and assist rural industries (e.g. jute) in developing Asian nations. The use of biodegradable drains in soft ground is not entirely new. The very first PVD used in Sweden was made of cardboard, while jute drains were trialled in Singapore in the 1970s. This phenomenon of degradation tends to reduce the efficiency of natural drains overtime. Recently, Indraratna et al. (2016) considered the time depedent degaradability of natural

PVDs made from jute, coir and straw in their analytical solution. Figure 6a shows the results of a recent pilot project in Ballina, Australia (2013-2016) where plastic and biodegradable PVDs were installed and monitored in the same condition. It is evident that the settlement and excess pore pressure induced by these two types of PVDs are almost identical, which indicates insignificant influence of biodegradation on soil behaviour. However, this novel type of PVDs can also experience a rapid degradation when subjected to adverse environmental conditions such as surface soils where cellulose degrading bacteria are very active, which can hence hamper considerably the consolidation progress of soil. For example, Figure 1b represents experimental data where an over-degradation of drains causes the dissipation of excess pore pressure severely deviated from the case of normal PVDs. A novel numerical approach where the biodegradation of PVDs is incorporated into the governing equations of soil has been developed, and the results show a good agreement with experimental observation (Figure 6). This finding clearly indicates that attention to biodegradation properties of these fibre drains is seriously needed especially when using them in adverse soil conditions.

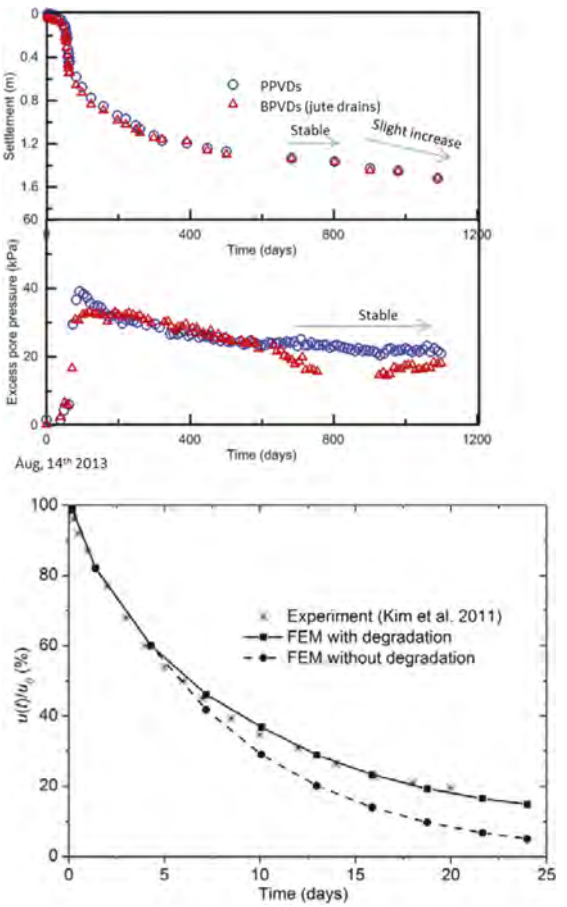

Figure 6. A) Compare the performance of PPVDs and BPVDs in Ballina field and b) Influence of drain degradation on soil consolidation (laboratory observation compared to FEM model) (Indraratna et al. 2018 with permission from Computers and Geotechnics).

8 CONCLUSIONS

In this paper, factors affecting the performance of vacuum preloading with vertical drains were explained and discussed. Salient findings can be summarized as follows:

- Performance of the biodegradable drains is similar to synthetic drains as the influence of the drain degradation becomes minimal at the end of the consolidation.
- PVD length could be reduced by 10% without considerably affecting consolidation time.
- Depending on the installation method and the condition of soil, the extent of the smear zone can vary from 1.3 to 7 times the equivalent mandrel diameter.
- In an area where embankment's instability is an issue due to soil at a shallow depth having very low shear strength or significant height of surcharge, vacuum in combination with fill preloading can become a desirable option.
- Finite element analyses under plane strain condition can be adopted to predict or assess the consolidation behaviour of soft soil beneath an embankment (i.e. multi-drain analysis) with appropriate conversion techniques.
- Removal of the vacuum pressure can be decided upon the pore pressure and time settlement responses.

ACKNOWLEDGEMENT

This research was funded under Australian Research Council (ARC) Linkage scheme s as a collaboration a In this paper, several universities (University of Wollongong, University of Newcastle, Imperial College, London and the University of London) and industry partners (Menard Oceania, Soilwicks, Douglas partners, Coffey geotechnics, National Jute Board of India). The contributions from past research fellows and students including Dr Kirti Choudhar, Prof Geng Xueyu, Dr Ali Ghandeharioon, Dr I Redana, Dr Darshana Perera, Dr Rui Zhong, Dr Pankaj Baral, Dr Kourush Kianfar, is very much appreciated. Most of the content of this paper has already been published in the Canadian Geotechnical Journal, Jorunal of Geotechnical Engineering, ICE, Journal of Geotechnical and Geoenvironmental Engineering, ASCE, Computers and Geotechnics.

Preservation and restoration of monuments: The authenticity principle in geotechnical interventions

C. Tsatsanifos
Pangaea Consulting Engineers Ltd., Athens, Greece

ABSTRACT: Generally, the authenticity principle has been discussed for the superstructures of historic monuments and not for their foundations. Interventions on the foundations or on the embankments on which some monuments have been built have not usually been deemed necessary, while there are many examples where either the type of the foundation or the embankment was developed in some special way according to regional characteristics, or the foundation or the embankment itself is of historic heritage. In this paper case studies of geotechnical interventions for the preservation and restoration of monuments are presented and discussed and questions are posed regarding the application of the authenticity principle.

1 INTRODUCTION

The principles on the conservation and restoration of monuments were initially set at the 1st and 2nd International Congresses of Architects and Technicians of Historic Monuments held in Athens (1931) and Venice (1964) respectively, which adopted the so-called "The Athens Charter" and "The Venice Charter".

"The Athens Charter" introduced the word anastylosis as defining the conservation method which intends to keep the authenticity of the monuments: "*In the case of ruins, scrupulous conservation is necessary, and steps should be taken to reinstate any original fragments that may be recovered (anastylosis), whenever this is possible; the new materials used for this purpose should in all cases be recognizable*".

Later on, in "The Venice Charter" it was stated that "*The process of restoration is a highly specialized operation. Its aim is to preserve and reveal the aesthetic and historic value of the monument and is based on respect for original material and authentic documents … Where traditional techniques prove inadequate, the consolidation of a monument can be achieved by the use of any modern technique for conservation and construction, the efficacy of which has been shown by scientific data and proved by experience*".

The authenticity principle was concluded in "The Nara Document on Authenticity", drafted by the participants at the Nara Conference on Authenticity in Relation to the World Heritage Convention, held at Nara, Japan, in November 1994. Accordingly, the authenticity should be determined in a manner respectful of cultures and heritage diversity to include any variation of the regional tradition of conservation of heritage.

2 THE AUTHENTICITY PRINCIPLE IN GEOTECHNICAL ENGINEERING

The authenticity principle has been discussed for geotechnical historic monuments (superstructures) like retaining structures, earth/rock fill dams, embankments etc. However, the foundations of historic monuments were not considered as one of the elements that constitute historic monuments and have been changed and modified without any concern for authenticity. The same

DOI: 10.1201/9781003299127-24

applies for the embankments on which some monuments have been built in some special way according to regional characteristics, or for the foundation ground. In these cases, the type of the geotechnical structure might be preferred to keep its originalities.

Based on the above, the International Scientific Committee on the Analysis and Restoration of Structures of Architectural Heritage under ICOMOS (ISCARSAH) had proposed and was accepted to include heritage structures in the ISO 13822:2010 Bases for design of structures – Assessment of existing structures. ISO 13822:2010 has expanded the heritage structure to include foundation as a part of the structure. Furthermore, in paragraph of I.5.3 of the Annex I: Authenticity of Foundation it is stated: *From the point of view of conservation, foundations are not different from the rest of the structure and should be assessed and rehabilitated taking into consideration their heritage value. This involves the requirement to identify their authenticity and character-defining elements.* (Iwasaki et al., 2022).

The foundation ground has not been considered with respect to authenticity, because, over the years of the life of the monument, disrupting natural and anthropic agents introduce changes in the prevailing geotechnical conditions of the site. These agents may strongly affect the foundation system of the monument, or the ground on which the monument has been built, requiring major interventions in order to strengthen the foundation of the structure or the ground. In such cases, the full compliance with the authenticity and anastylosis principles is not possible.

The authenticity principle can be somehow violated in the case of interim or temporary remedial measures.

3 METHODS OF GEOTECHNICAL PRESERVATION AND RESTORATION OF MONUMENTS

The International Society for Soil Mechanics and Geotechnical Engineering promoted, over 30 years ago, an ad hoc Committee on the Preservation of Monuments and Historic Sites, initially numbered TC19 and currently TC301, to study methods of conservation of monuments and historic sites. The committee focuses on the organisation of symposia and workshops with the aim to exchange and compare experiences and to collect case histories of preservation of monuments, as well as well as on the preparation of a set of guidelines on conservation and preservation of monuments and historic sites. However, as stated in the objectives of TC301, considering that each monuments is a "unicum" and taking into account the concept of "integrity", it is rather difficult to apply approaches based on guidelines to the preservation of monuments and the effort is devoted to:

- Framing of the special requirements and constraints to be considered in any rehabilitation intervention on Monuments in order to preserve their cultural and historical integrity;
- Geotechnical methodologies suitable for the interventions on Monuments and Historic sites.

Poulos (2005) and (Ulitsky, 2005) attempted a division of the methods for the geotechnical restoration of monuments, into two broad categories:

i. "Hard" methods, which rely on changes on the foundation of the monument or on the application of some form of direct force to the foundation, like:
– Repair of the existing foundation or strengthen it by its extension,
– Provide additional supports,
– Underpin the foundations by means of piles constructed through the body of the foundation,
– In case of pile foundations extend the pile caps or rafts to provide additional bearing capacity and stiffness,
– In case of uneven settlements application of force by anchor stressing, additional loading, jacking of the foundation on the "low" side.

ii. "Soft" methods, which rely on processes improving the subsoil or produce corrective foundation movements by inducing appropriate ground movements, like:
– Soil extraction and underexcavation,

– Dewatering or inducing changes in the pore water pressures by local injection of water or by electro – osmosis,
– Compensation grouting,
– Removal of soil support,
– Improve the subsoil (cementation, silication, chemical and electro - chemical strengthening, high pressure grouting capable of stabilising the soil mass, deep soil mixing, soil nailing, rock anchoring etc.),
– Isolation or separation trenches between new and existing building – monument.

From the above methods only the isolation or separation trenches seem to fully comply with the authenticity and anastylosis principle. The "hard" methods alter the foundation system, while the other "soft" methods alter the subsoil conditions.

4 CASE STUDIES

4.1 *Retaining walls*

4.1.1 *The treasures retaining wall and the retained upslope at the Ancient Olympia (Egglezos and Karnavezos, 2014)*

The retaining wall of the treasures of the Sanctuary of Olympia (Figure 1a) is the northern part of the sanctuary's enclosure and retains the slope of the Kronian hill. The material of construction of the domes of the wall is bioclastic limestone. A provincial road passes upstream of the wall.

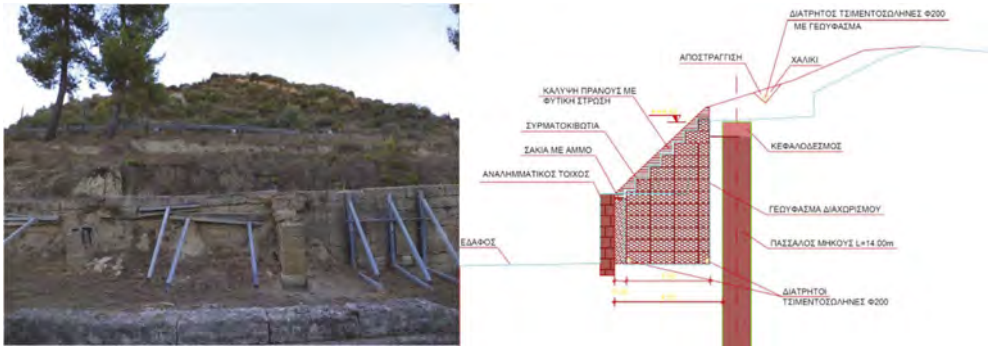

Figure 1. (a) Photo of the Treasures Retaining Wall. (b) Final phase of the restoration measures behind the ancient retaining wall.

The wall was probably constructed in the second half of the 4th century. Many landslides occurred and consecutive repairs, up to and including Roman imperial times. After the destruction of the Sanctuary of Olympia, possibly in 426 A.D., landslides and floods slowly covered with alluvial all the ancient monuments, including the retaining wall of the Treasures, which came to light again during the excavations of the German Archaeological Institute in the years 1875-1881.

The earth pressures and the roots of the trees on the slope have caused deformation of the original geometry of the wall and have damaged blocks of the wall. A detailed field reconnaissance has been conducted, which concluded that there is sliding (or near sliding condition), with the failure surface passing under the wall, the crest under the upstream road and the toe on the northern boundary of the foundations of the Treasures.

Based on these findings, a detailed geotechnical analysis has been conducted in order to investigate the current stability of the retaining wall and the upstream slope. The results of the analysis concluded that:

i. The area of Kronion hill upstream of the road is in a state of surface instability, consistent with the macroscopic observations.
ii. There are no general instabilities under static conditions; however, the safety factors for the historical earthquake loading are marginally inadequate and absolutely inadequate taking into account high water level behind the slope, as well as the regulatory earthquake. Local instabilities upstream of the wall occur systematically for all analysed cross-sections and for all load states (even in the case of static conditions – a favourable case).

To increase the stability of the whole system, the following measures have been designed (Figure 1b):

a. A pile diaphragm (piles Ø120 every 2.40m) to stabilize the upstream slope against sliding.
b. Relief of earth pressures on the wall by placing gabion boxes and sand bags between the wall and the piles.
c. Construction of a drainage system to relieve the wall from the adverse action of the water (surface flowing stormwater upstream of the piles and water moving underground within the soil mass of the slope at the base of the gabions).
d. Cover with topsoil of the restored slope.
e. Reinforcement of the temporary metal retaining structure during the construction phase of the project, to safely take over any additional loads on the wall from the operation of the construction equipment.

According to the authors, the design of the stabilisation measures achieves, at a reasonable financial cost, the desired safety of the upstream slope against an existing slip, the reduction of the earth pressures on the ancient retaining wall (and therefore the wall is not required to act as the main retaining structure of the slope), the possibility of carrying out restoration works of the monument, according to its final restoration design, with safety for employees, as well as the future safe passage of visitors along the base of the slope. In addition, it contributes to the safety of antiquities that extend along the base of the wall (foundations of the Treasures), to the stability of the upstream road, as well as to the prevention of relatively deep slipping surfaces, which could, under certain conditions, emerge, having their crest on the hill upstream of the road.

Regarding the retaining structure, the proposed solution is fully compatible with the authenticity principle; however, the initial ground conditions as well as the loading conditions of the monument are changed (these "initial" conditions have changed many times in the past due to excavations and Kladeos river deposits). Hence, one could argue that the solutions does not totally respect the authenticity principle, since it should reinstate the ground behind the wall. But, maybe this is the only solution to solve the monument without any direct action on it.

4.1.2 *Angkor monuments (Iwasaki et al., 2022)*

The Baphuon Temple

The Baphuon temple was built in mid11th century in Angkor Thom and was dedicated to the Hindu God Shiva. In the late 15th century, the temple was converted to a Buddhist temple.

In 1943, the northeastern side of the slope of the temple failed as a result of excessive water penetration due to rainfall. Figure 2a shows the original structure of a stone masonry retaining wall with thin layers of crushed laterite chips, of 1–2 cm in thickness, embedded in compacted sandy layers for possibly drainage of infiltrated water, extending 4m to 5m behind the wall.

École Française d'Extrême-Orient (EFEO) had started the restoration work in 1958 and tried to reconstruct the original structure but failed when the fill mound reached at 5m in height. They tried three times to replicate the original structure, but in vain. As a result, the stone masonry retaining wall was substituted by a reinforced concrete retaining wall as shown in Figure 2b. The original stones were reused to cover the front face of the concrete wall.

West causeway of Angkor Wat

The west causeway of Angkor Wat is the gateway that overpasses the 190m wide moat, as shown in Figure 3a. The causeway consists of earthen embankment between two stone masonry retaining walls consisting of lateritic blocks. The original structure of retaining wall

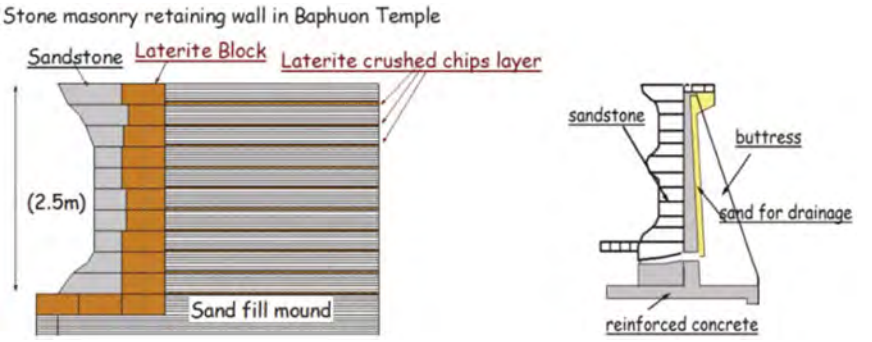

Figure 2. (a) Original masonry retaining wall, (b) Reinforced concrete.

is shown in Figure 3b. After the failure of the causeway in 1952 as a result of infiltration of water due to heavy rain, EFEO performed restoration work for the southern side of the retaining structure using reinforced concrete as shown in Figure 3c.

Figure 3. (a) Retaining wall structure of the west causeway of AngkorWat (south side). (b) Original structure, (c) RC-retaining wall (EFEO) and (d) RC-retaining wall (Sophia Univ.).

The second phase of the restoration work for the northern side of the west causeway of Angkor Wat has been studied by Sophia University as shown in Figure 4d. It is a modification of the EFEO design, using again a concrete retaining structure. The backfilled soil behind the masonry wall is excavated first and the reinforced concrete retaining wall is placed behind the existing retaining wall. The existing weathered and decayed lateritic blocks are anchored to the RC wall and maintained as it is.

In the EFEO design the original wall was removed, the concrete retaining structure was built and the blocks of the original wall were reinstated in front of the concrete wall. In the University of Sophia alternative there was no intervention on the original wall except the anchoring of the blocs on the RC wall.

Prasat Suor Prat

Prasat Suor Prat consists of 12 towers and located on the east side of the Royal Plaza, Angkor Thom. The towers are constructed almost exclusively of lateritic blocks with sandstone accessories and door/window jambs.

N1-tower has inclined 4–5 degrees northward from the vertical, representing the largest inclination in all towers of Prasat Suor Prat. Further to the inclination, its foundation was spreading outwards in all directions.

It was difficult to identify the reason why the tower was inclined and spread out. Therefore, it was decided to dismantle the upper structure as well as the foundation to excavate archaeological trench. The base of the tower is 10m by 10m on a filled mound with lateritic masonry retaining structure.

Figure 4a shows N-S section of foundation of the N1 tower. The surrounding retaining wall was inclined to the north by 0.4m settlement for 10m width. The basement of the retaining structure at the north side was found to have settled and slid outwards as shown in Figure 4a. The vertical weight had caused compression of the fill as well as outward spreading.

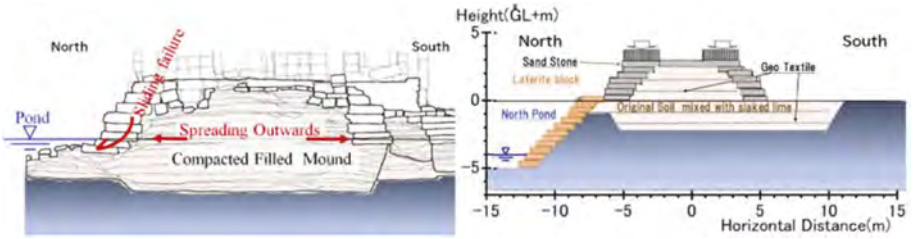

Figure 4. (a) Trenched section of N1 tower. (b) Restoration of foundation of N1 tower.

The Japanese Government for Safeguarding Angkor Team (JSA) had introduced a traditional technology of slake lime mixed with the original sand, which improves the strength characteristics with geo-textile to increase the tension strength of the fill. Adding about 10% of the slaked lime to the original soil resulted in increasing strength with durability against water submersion (Figure 4b).

In all the case studies presented by Iwasaki et al. (2022) practically there was a complete reconstruction of the monuments. In the first two cases new structural members were introduced, but covered with the original blocks of the wall and, consequently, not visible to the visitor, and the original soil was used for backfilling. We could say that the authenticity and anastylosis principles were applied for the visible parts of the monuments (reassembly of existing but dismembered parts), though the material used for integration is hidden and not identifiable.

In the case of the N1 Tower of Prasat Suor Prat the reconstruction did not use new structural members. The original blocks of the wall as well the original soil were used, the latter being compacted with the addition of slake lime (a traditional method) but also with geotextile to increase the tension strength of the fill. At the end, one could say that the authenticity and anastylosis principles were applied for the restoration of the monument, though the addition of geotextile does not conform to them, but it is hidden and not identifiable.

4.2 *Foundations*

4.2.1 *The National Bank of Greece administration building and the acharnian gate of the Ancient Athens circuit wall (Tsatsanifos and Pasqualin, 2013)*

The archaeological excavation prior to the construction of the new administration building of the National Bank of Greece (NBG) at the centre of modern Athens brought to light important antiquities concerning the approach to the Acharnian Gate of the ancient Athens circuit wall.

The preservation and the exhibition of the antiquities were prerequisites for constructing the building at this site. This, combined with the other operational prerequisite that the building should have underground floors formulated a serious geotechnical problem, requiring innovative solution to be overcome.

The building was designed taking into account these requirements. Figure 5a shows a drawing of the building with the antiquities preserved in the ground floor – basement.

The solution involved the temporary excavation and support under the antiquities without any interference with them. Figure 6a shows the plan of the whole temporary support system, i.e. that for the excavation walls and that for the antiquities.

The "Berlin" type wall was used for the temporary support of the vertical slopes of the excavation. This is a rather flexible support system consisting of vertical steel beams (2 steel ∏ or, sometimes, bored reinforced concrete piles), earth anchors and shotcrete.

The method of the forepoles (horizontal micro piles) was used for the support of the antiquities and horizontal steel beams were welded to the steel piles under the forepoles, in order to act as their support after the excavation of the ground under the fore poles (Figure 6b). To ensure the good contact of the fore poles and the steel beams, shotcrete was applied. Finally, steel tube trusses were used for the lateral support of the system.

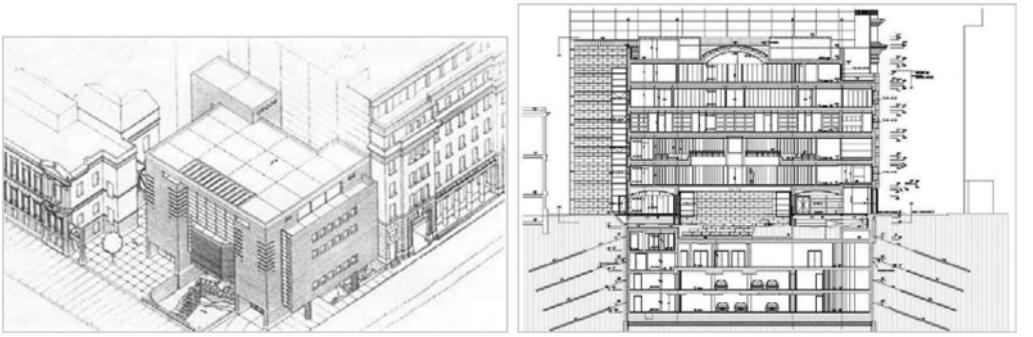

Figure 5. (a) Drawing of the NBG Administration Building with the antiquities preserved in the ground floor – basement. (b) Cross section with the underground floors below the antiquities.

Figure 6. (a) Plan of the temporary support system for the construction of the building. (b) Construction of the fore poles under the antiquities.

In the next stage the ground under the fore poles was excavated and a layer of shotcrete, reinforced with steel wire mesh was applied. The final step was the concreting of the roof slab of the 2nd basement, just under the fore poles supporting the Acharnian Gate.

The method applied did not affect the antiquities or their foundations. Hence, from this point of view the solution is fully compatible with the authenticity principle; however, the initial ground conditions have changed: the monument is resting on a concrete slab instead on the original ground. So, one could argue that the solutions does not totally respect the authenticity principle. But, this is the only solution to retain the monument in place without any direct action on it. The other solution, which has been applied in a number of cases in Greece is the total dismantling of the monument and its re-erection at a different site or on top of the new structure.

4.2.2 *Foundation strengthening of the AEB Bank building in Budapest (Sata, 2003)*

This is again an example where underground space was required under a historical building. The AEB Bank chose a two-storied historic building for its headquarters in Budapest (Figure 7a). The renewal, re-utilisation and enlargement of the building should follow the original architecture. An underground garage had also to be constructed, requiring the deepening of the foundation level. In this case underpinning for strengthening the foundation of the building was used.

The main concern was to minimize the settlements to acceptable for the historic structure levels. It was achieved by inducing a pre-stressing force between the wall and the piles, which acted against the gravitational force of the wall.

In this case, the method has changed completely the foundation of the structure, hence the authenticity principle, regarding the foundation, has not been respected. But again for a building of this size and for the requirement of creating a basement floor, this was the only solution.

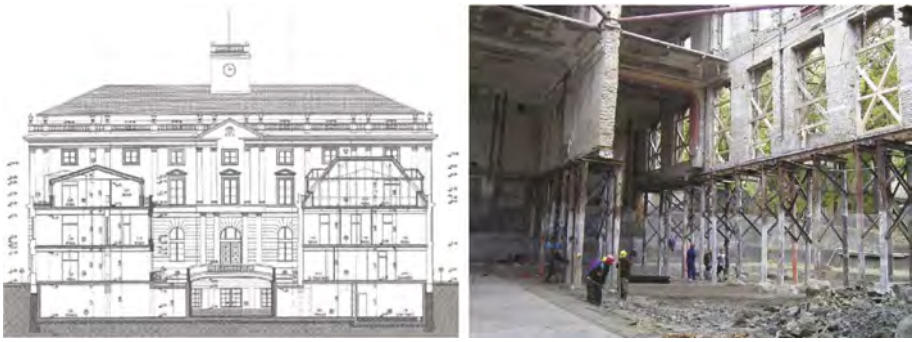

Figure 7. (a) Architectural section of the renewed AEB Bank in Budapest. (b) The building "in the air".

4.2.3 *Underpinning. The cases of the 1st High-School Building of Thessaloniki and the Catholic Church in Giannitsa (Tsotsos and Naskos, 1995)*

According to the authors the problems of the building was the result of the higher applied stresses, compared to the estimated bearing capacity of the ground, combined with the differentiation of the water content under the building, which led to swelling or settlement in different parts of the foundation.

The restoration consisted of seven pairs of micro-piles, along the problematic area and the underpinning of the old foundation with an equal number of perpendicular to the walls beams connected to the pile heads (Figure 8). The whole operation of this intervention was done from the outside and there was no disruption of the operation of the church.

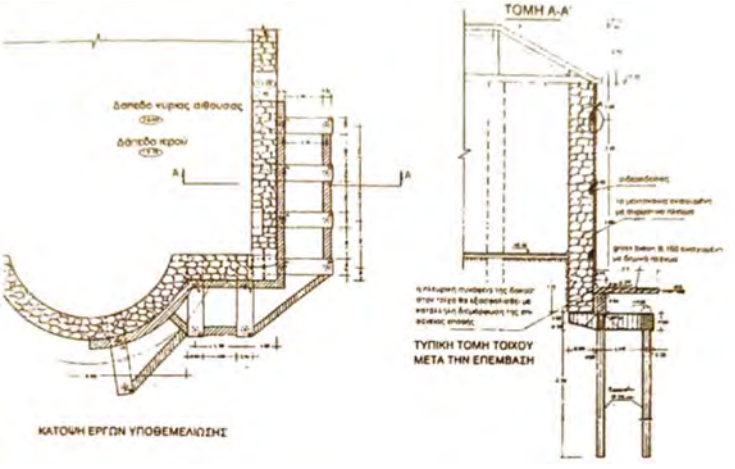

Figure 8. Schematic presentation of the underpinning works in the northeastern part of the Church.

In this case, the method has changed part of the foundation of the structure, hence the authenticity principle, regarding the foundation, has not been respected. However, there was no intervention in the superstructure of the monument.

4.3 *Interventions on the foundation ground*

4.3.1 *The leaning Tower of Pisa (Burland et al., 2003)*

The most famous example of the contribution of geotechnical engineering in the restoration of a monument is that of the Leaning Tower of Pisa, where the soil extraction method has been applied.

The tower is founded on weak, highly compressible soils and its inclination has been increasing inexorably over the years to the point at which it was about to reach leaning instability (about 5.5 degrees to the vertical, see Figure 9).

Since the internationally accepted conventions for the conservation and preservation of monuments and historic sites provided that any intrusive intervention on the Tower had to be kept to an absolute minimum, permanent stabilisation schemes involving propping or visible support were unacceptable and in any case could have triggered the collapse of the fragile masonry. After a careful consideration of a number of possible approaches, the International Committee for the Safeguard and Stabilisation of the Tower of Pisa, appointed by the Italian Government, adopted a controlled removal of small volumes of soil from beneath the north side of the tower foundation (underexcavation).

This technique provided an ultra-soft method of increasing the stability of the tower, which is completely consistent with the requirement of architectural conservation.

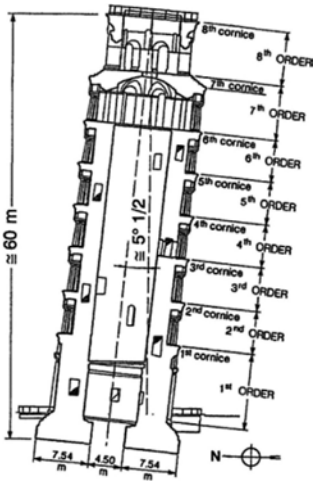

Figure 9. Cross section of the leaning Tower of Pisa.

Different physical and numerical models have been employed to predict the effects of soil removal on the stability. The preliminary underexcavation intervention, only undertaken once the Commission was satisfied by comprehensive numerical and physical modelling together with a large scale trial, has demonstrated that the tower responds very positively to soil extraction. The final underexcavation has attained the target of reducing the tilt of the tower by half a degree, i.e. to bring the tower "back to future" to the time just before the excavation of the catino in 1838.

The application of the method did not change the foundation of the tower; however it changed the subsoil, if we consider the soil extraction as change. The Pisa Tower intervention is the case with the highest respect of the authenticity and anastylosis principles.

4.3.2 *Design of the Stabilisation of the NW wing of the Stavronikita Holy Monastery (Arvanitakis and Monokroussos, 1988)*

The Stavronikita Monastery lies on the northern coast of the Athos peninsula, at the top of a rocky outcrop about 40m above sea level.

The monastery was built in the 16th century and has undergone many additions since then. However, the 1932 Ierissos earthquake cracked many parts the walls of the monastery over the steep slopes, as well as the rock formation, while the 1978 Thessaloniki earthquake accelerated the phenomenon of new cracks on the walls and in the rockmass and widening of their apertures. The cracks in the rockmass resulted in rockfalls, underexcavations and general stability problems.

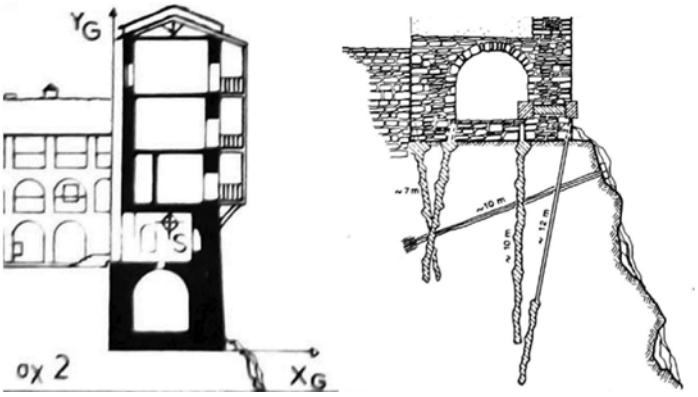

Figure 10. (a) Cross section at the problematic area. (b) Stabilisation measures.

The stabilisation measures proposed by the designers consisted of micropiles, through the existing foundation of the walls, combined with rock anchors in order to increase the stability of the rock slope, as shown in Figure 10a and 10b.

In this case study the method applied for the restoration do not respect the authenticity and anastylosis principles either for the foundation of the monument or for the rockmass; however it seems that it was the only visible solution for the preservation of the monuments.

4.4 *Temporary or permanent Burial of antiquities (Tsatsanifos, 2017)*

Many antiquities have being found during the excavations for the reconstruction of an old 3 storey and a basement building at the Plaka area of central Athens, consisting of parts of marble roman baths and "siroi" (large storage earthen jars in the ground) of the Byzantine era (Figure 11).

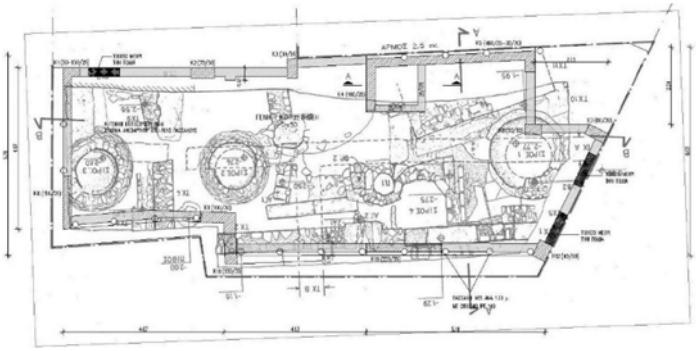

Figure 11. Plan of the foundation of the building at Cherefontos with the antiquities found (Tsatsanifos, 2017).

After the detailed archaeological investigations, the archaeological service decided that the antiquities could be buried and the new structure be built over them. However, since the burial of any ancient monument is considered as intervention to the monument, some rules should be followed, particularly the Articles 9, 10, 11, 12, 13, 14 and 15 of the Venice Charter.

In this particular case the new building will have a raft foundation and the burial would be performed using well graded sand with less than 5% fines.

This is a case where the authenticity and anastylosis principles were fully respected; however, not for us but the future generations.

5 CONCLUSIONS

From the case studies presented from different parts of the world it seems that the full compliance with the authenticity principle is relatively easy for the superstructure of the geotechnical monuments but it is very difficult regarding the foundations of the monuments. However, considering that in almost all the cases the foundations are not visible, we can violate the principle of authenticity and apply any available method in order to succeed in the stability of the monument.

The serious problem arises when we are discussing about the foundation ground. Can the foundation ground been considered as a monument itself? Maybe not. We have accepted that natural and anthropic agents may have reduced the shear strength or increased applied stress leading to bearing capacity failures of the monument on it. For example the rock outcrops, on which many of the Mount Athos monasteries have been built, during the 1,000 years life of the monasteries, have undergone weathering, fracturing, earthquake loading etc. and now they cannot support the structures on them. Hence it is imperative to apply some retaining measures on them. On the other hand the actions of the foundation ground on the monument have been changed and, as D' Agostino said, the stabilizations measures should not modify the soil - structure relation.

Finally, it seems that the soil extraction as well as the support of the monument well below its foundation are the methods with the highest respect of the authenticity and anastylosis principles.

ABSTRACT: This paper presents a study on strength anisotropy in a sandy material with anisotropic fabric formed by press loading. Two series of DS-CD tests (direct shear tests under CD condition) were performed using a developed DS apparatus with a double-jack system. To maintain anisotropic fabric in a sample, a freezing technique was developed. Shear strength of samples in the active shear zone was found to be stronger than that of the passive zone, and the results could be expressed well by an ellipse equation with tilting coordinates of an angle measuring 15° to the horizontal line. To find a reason for the inclination of the axis of strength ellipses, a 2D-DS test was performed by a developed 2D-DS device. The direction of the main shear zone of a sand sample measuring 15° coincided well with that of the ellipses' coordinates, which should be taken into consideration when shear strength from a DS-CD test should be used in a safety analysis of a soil structure.

1 INTRODUCTION

Aiming to evaluate shear strength of a compacted weathered granite with anisotropy for such as safety analyses of an embankment, two series of CDDS tests (direct shear tests under CD condition) on sandy soil samples, in which the inherent anisotropy was induced by press loading, were performed using an improved DS apparatus in this study (Mochizuki *et al.*, 2021).

The first directive articles for research on shear strength anisotropy, it is said, was presented by (Bjerrum, 1973) in the 'State of arts reports' in the 8th-ICSMFE conferences, in which a concept of "an extension mode (TE)" for the shoulder part of a slope, "a simple direct shear mode (SDS)" for the middle part and "a compression shear mode (TC)" for the toe part was presented. After that, Bjerrum's discussion became a road map for the following study of shear strength anisotropy.

The most reliable test data on undisturbed clay samples from Osaka city, Japan were presented by (Mikasa, Takada and Oshima, 1987) using the original type of Mikasa's DS apparatus ((MIKASA, 1965), see Figure 1). Test results on clay samples against the N-S surface showed similar trends of anisotropy on shear strength as those on ones of remolded clay. They compared them to those of the E-W direction, and the possibility of secondary loading of tectonic force in the E-W direction on the Osaka layers was found. Whereas (Nishimura, Minh and Jardine, 2007) tried to quantify the anisotropy of London clay using a torsional triaxial test. An introduction of anisotropic shear strength into stability analysis of a slope was tried by (Shogaki and Kumagai, 2008).

DOI: 10.1201/9781003299127-25

The fabric characteristics and anisotropic nature of granular materials was systematically studied by (Parkin, Gerrad and Willougby, 1968), (Arthur and Menzies, 1972), (Oda, 1972) and (EL-Sohby and Andrawes, 1973), which demonstrated the significance of anisotropic fabric also in cohesionless soils. Regarding the anisotropy of sandy material, however, less publications were published as a study on sand anisotropy appears to be much more difficult to prevent deterioration of anisotropic fabric than that of clay during sampling or forming of them for shear tests.

In this study, to overcome the difficulty to maintain anisotropic fabric induced by press loading a freezing technique was introduced, in which an improved DS apparatus was used ((Ishikawa *et al.*, 2009), see Figure 2). It was found that the test results could be expressed well by an ellipse equation with tilting coordinates of an angle measuring 15° for the strength anisotropy of the sandy material. In order to discuss the inclination of the axis of ellipses, a 2D-DS tests (two-dimensional direct shear tests) were performed using a newly developed 2D-DS device (Ohfuji, Ueno and Mochizuki, 1999).

2 TEST CONDITIONS AND PREPARATION OF SAMPLES WITH ANISOTROPIC FABRIC

2.1 *Improved direct shear apparatus and used material*

Progress of a DS (direct shear) apparatus in Japan was totally different from that in Europe or USA. Figure 1 shows a cross-sectional sketch of the main part of Mikasa's original DS apparatus developed in 1965 (MIKASA, 1965). Vertical stress is applied from the bottom of a sample, the reaction force is supported by the rollers installed at the upper plate, which prevents the upper shear box to lean during shearing. And the resulting function enables performing a CV (constant volume) test as well as a CD test (Takada, 1993). The apparatus was adopted in a code of the Japan Geotechnical Society since 1979 (JGS0561 (Japan Geotechnical Society, 1979)) and has been used widely in Japan.

One shortcoming of the Mikasa's DS apparatus, however, is growing evitable friction between a sample and the shear box wall when performing CD tests on dense sands, which tends to give unexpected over-prediction of shear strength. To eliminate such problems, (Ishikawa *et al.*, 2009) developed a new DS apparatus with a double-jack (DJ) system on the upper shear box, shown in Figure 2. Accuracy of test results on Toyoura sand (standard sand in Japan), was proved to present almost equivalent results obtained by triaxial CD tests.

2.2 *Test conditions for CD_{DS} tests and preparing test samples*

Table 1 shows the main properties of the material used for specimens, which was made from strongly weathered granite with 20% of fine grains from Tokushima, Japan. It is normally used

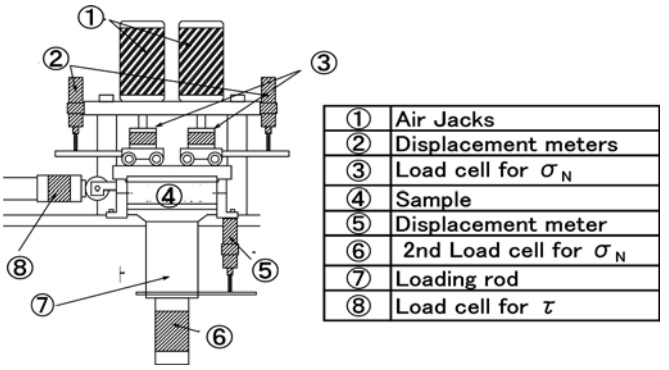

Figure 2. A newly designed DS_{DJ} apparatus with double-jack system (Ishikawa *et al.*, 2009).

for construction of dike, road embankments, earth dams etc. The material was sieved with a 1.2 mm mesh and mixed well. Then, the material was weighted measuring 1 kg each by the quartering method, and water was added to be its optimum water content measuring 14%, which was found from a preliminary compaction test. After forming a sand layer of about 1 cm thickness with 1kg of material in a strong box measuring L52×W19.5×H18cm the layers were pressed with a static load of 600 or 1,200 kN/m^2 for one minute to each layer, which compressed into a 0.5 cm layer of a specimen. Twenty times of press loading was repeated to produce a specimen with about 10 cm thickness, which simulated a road embankment construction by heavy roller weight.

Table 1. Main properties of sand material.

γ_s (g/cm^3)	2.634
d_{max} (mm)	1.2
Sand (%)	79
Silt (%)	8
ρ_{dmax} (g/cm^3)	1.87
w_{opt} (%)	13.4

After the forming of a specimen with twenty sub-layers, the plate for loading was clicked by handy vices to prevent it from heaving. As an anisotropic fabric formed in soil specimen was not free from disruption due to sampling or forming into a sample, a freezing technique to a sample was developed for these tests. The specimen in the strong box was moved into a freezer at a temperature of minus 45 °C. Here, they are referred to as "a 600 kN/m^2 sample or 1,200 kN/m^2 sample" in this paper. The surface of which was covered with aluminum foil to prevent the sublimation of water. Table 2 shows test conditions. The procedure of a CDDS test followed the Japanese code of JGS0561.

Table 2. Test conditions (DS-CD test).

Shear test conditions	
Drain condition	CD
Melting temperature (°C)	21 (15 min)
Time for consolidation (min)	20
σ_N (kN/m^2)	50, 100, 150, 200, 250, 300
Rate of shear (mm/min)	0.25
Shear angle, θ (°)	Active zone: 0, 30, 60, 90 Passive zone: 90, 120, 150, 180
γ_d (g/cm^3)	1.74

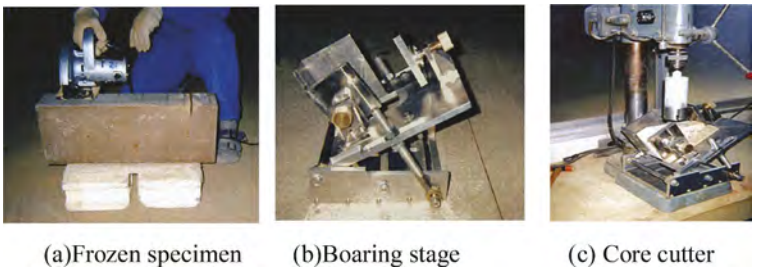

Figure 3. Process of sampling from a frozen specimen.

Then, a frozen specimen was cut into seven blocks of L7×W19.5 ×D10 cm (Figure 3(b)), and cutting direction were designated for each test on a frozen block. Then, a frozen block was moved to a newly designed coring stage (Figure 3(c)).

Figure 4 shows the definition of shearing angle, δ, of a sample, which is d fined against the shearing direction of a sample to the horizontal stratification, in which a zone of δ=0° to 90° is referred to as the active shear zone, and that of δ=90° to 180° is the passive shear zone. A sliced sample measuring about 2.5cm in height was brought into a cutter-ring of φ60×20 mm by a pre-determined press slowly to avoid deterioration of a sample due to over-loading, and a frozen sample was set into a shear box. Then, the sample was heated up to its melting point of 21 □ for 15 min by a band heater around the shear box, that condition was found in a preliminary test. The samples were sheared loading a designed vertical stress, σ_N under CD condition.

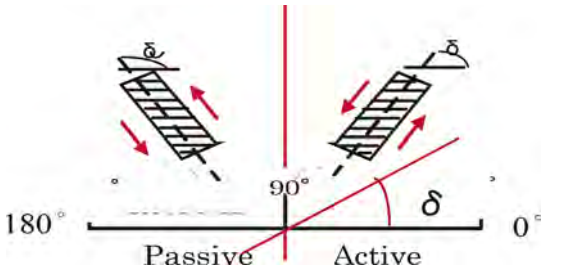

Figure 4. Shearing angleδand Active/Passive zone.

3 TEST RESULTS

Figure 5(a) shows τ (shear strength)∼ D and Δh∼ D relations of CDDS tests sheared to δ = 0° direction for 1,200 kN/m^2 samples. Here, D is horizontal displacement and Δh is a change of height (or volume) of a sample due to dilatancy. Curves of $\tau \sim$ D show a distinct peak strength even though the vertical stress, σ_N, increased. Figure 5(b) shows test results of those sheared to δ=90° direction. Test results of samples of δ = 90° direction did not exhibited such distinct peak strengths.

Figure 6(a) shows test results of 1,200 kN/m^2 samples sheard to different angles of δ under the vertical stress of σN=100kN/m^2. The $\tau \sim$ D curves sheared to $\delta = 0 \sim 60^\circ$ (the active zone) exhibited distinct peak strengths, though samples of δ=90, 120, 150° (the passive zone) did not show such clear peak strengths. These results suggest that 'inherent fabric in a sample' was destructed more during shearing in the passive zone under CD condition than that in active zone.

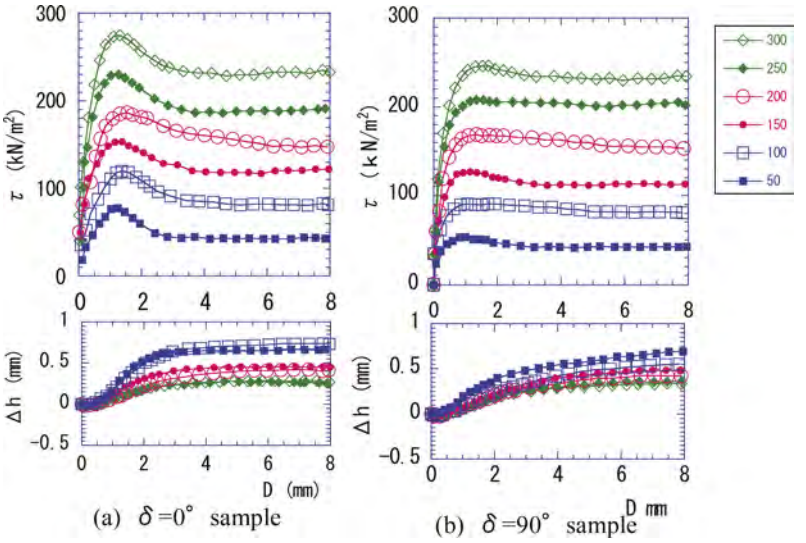

Figure 5. $\tau \sim D$, $\Delta h \sim D$ diagrams of CD_{DS} tests for 1,200 kN/m^2 samples.

Figure 6(b) shows test results of 1,200 kN/m^2 samples tested under the vertical stress of σ_N=200 kN/m^2, which did not exhibit such distinct difference of peak strengths even for δ=0, 30, 60° samples.

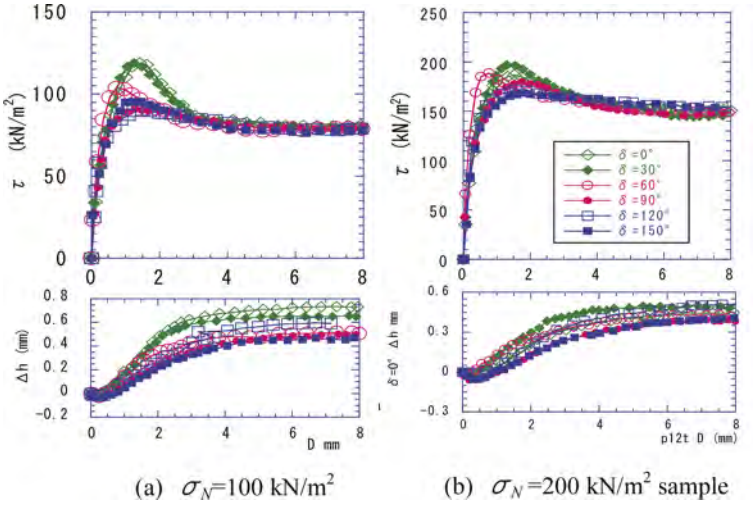

Figure 6. $\tau \sim D$, $\Delta h \sim D$ diagrams of CD_{DS} tests for 1,200 kN/m^2 samples with different angles of δ.

It suggests that anisotropic fabric in samples under σN=200 kN/m^2 was destroyed during shearing more than that in a sample under σN=100 kN/m^2. "An intention ratio of anisotropic fabric/σ_N" will be an index for shear strength of a sample with anisotropic fabric.

4 DISCUSSION OF TEST RESULTS

4.1 *Strength ellipses for anisotropy*

From discussions in the foregoing section, the strength of a sample with anisotropic fabric was found to depend on stress condition and the shearing direction of a sample, δ. When test results of strength anisotropy are introduced into safety analysis of soil structure, formulation of test results of strength anisotropy is a preferable technique. The formulating test data will also work effectively to take an average of data in such a case with un-evitable fluctuating errors. After several preliminary trials, an ellipse equation was found to express the test results of strength anisotropy of samples.

Figure 7(a) shows the resulting elliptical curves for 600 kN/m^2 samples. It should be noted that the axis of ellipses tilted measuring β= -15° to the horizontal coordinate of the chart (in the passive zone: see Figure 7(a)), therefore, the direction of the long axis of ellipses was measuring θ=+15°(=δ-β), and that of the short axis was measuring 105°(θ). The results of CDDS tests are well expressed by the ellipsoidal curves, though some scatters of the test data are detected. It should be noted that the degree of flatness of the ellipses decreases along with increases of vertical stress.

Figure 7(b) is a chart of test data for 1,200 kN/m^2 samples. Results of CDDS tests showed successfully being represented in ellipses, inclined at an angle measuring 15° to the horizontal coordinate. However, the trend of the elliptical curves was different from that of clay samples with the maximum shear strength at θ=45°.

Shear strength, τf in Equation (1), being a formula of ellipse, was calculated in the following processes:

$$\tau_f = \sqrt{\left[a^2\cos^2(\delta-\beta) + b^2\sin^2(\delta-\beta)\right]} \quad \text{Here, } \theta = \delta - \beta \tag{1}$$

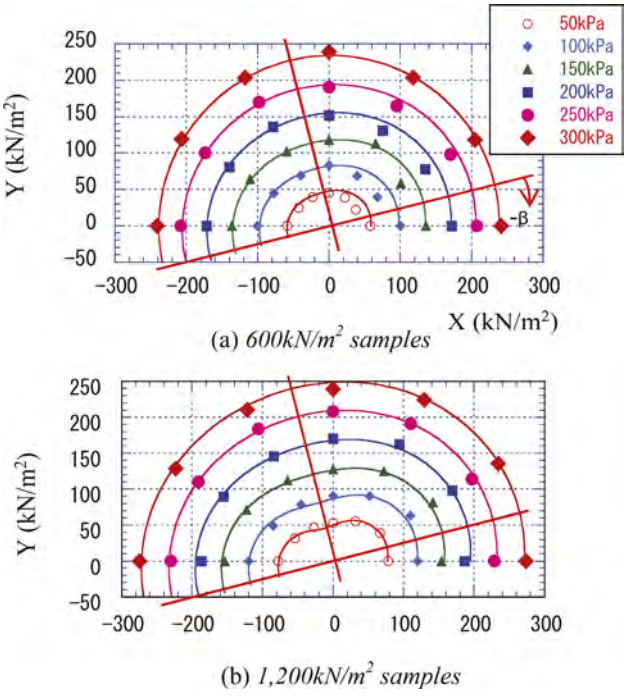

Figure 7. Results of CD_{DS} tests and ellipses of strength anisotropy.

An equivalent radius of the ellipse, Re, is found from Equation (2), and a ratio of flatness, A1 or A2 of an ellipse is calculated from Equation (3), in which parameters, 'a' and 'b' are a short or a long radius of an ellipse, which were found from test data of δ=0° or 90° samples, respectively for the first approximation of the parameters in this study. Then, Re was calculated by Equation (2), and test results were plotted in a polar chart. Then, shear strength, τf is calculated by Equation (4), which was transformed from Equation (1) using parameters, A and Re instead of parameters, a and b.

$$\text{Equivalent radius of an ellipse: } R_e = \sqrt{[a \times b]} \tag{2}$$

$$\text{Ratio of flatness of an ellipse: } A_1 = \frac{(a - R_e)}{R_e} \text{ or } A_2 = \frac{(R_e - b)}{R_e} \tag{3}$$

$$\tau_f = R_e \sqrt{\left[(1+A)^2 \cos^2(\delta - \beta) + (1-A)^2 \sin^2(\delta - \beta)\right]} \quad Here,\ \delta - \beta = \theta \tag{4}$$

4.2 *Discussion on the inclination of the primary axes of ellipses to the horizontal coordinate*

In Section 3, the primary axes of strength ellipses were found to be inclined measuring β= -15° to the horizontal line (in the passive zone). To introduce the effect of strength anisotropy into an analysis of soil structures such as road embankments etc., it is necessary to find a reason about the inclination of the axes of the ellipses.

With this view, the development of the shear zone in a sand sample during a DS test was observed using a newly developed 2D-DS device, a sketch of which was shown in Figure 8 (Ohfuji, Ueno and Mochizuki, 1999). A double jack system was installed on the upper plate of the shear box to keep it horizontally with a constant condition of total vertical force, σ_N. The front surface of the shear box was covered with separated crystal-glass plates to observe the deformation of a sample. The density of sand (ρ_d) was 1.655g/cm^3 and the size of the sample was L30×H20×D4 cm. Photos were taken at each scheduled interval, and the photo image analyzer was used to detect shear zone in a sand sample of Toyoura-sand (Japanese standard sand).

Figures 9(a) ~ (d) show areas where shear strains, γ_{xy}, being over 10% in a sample at each displacement of a 2D-DS test, which exhibited progress of expanding shear zones over 10%. The peak strength of a test was detected at D=10 mm (Figure 9(c). Additional broken lines in the figure were drawn to show the direction of β= -15° to the horizontal (in the passive zone). The direction of the shear zone to the horizon in the sample was found to coincide well with the inclination angles of the axis of strength ellipses, which is a reason for the inclination of strength ellipses in Figure 7.

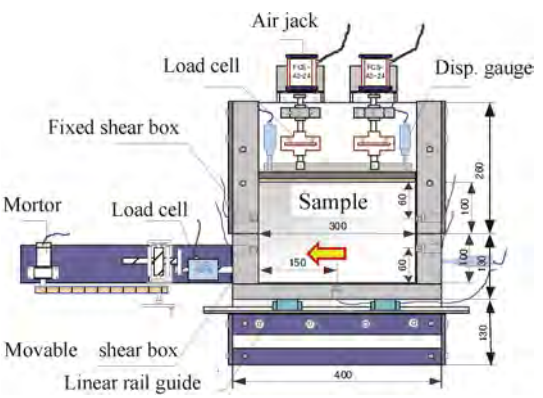

Figure 8. Sketch of a developed 2*D-DS* device (Ohfuji, Ueno and Mochizuki, 1999).

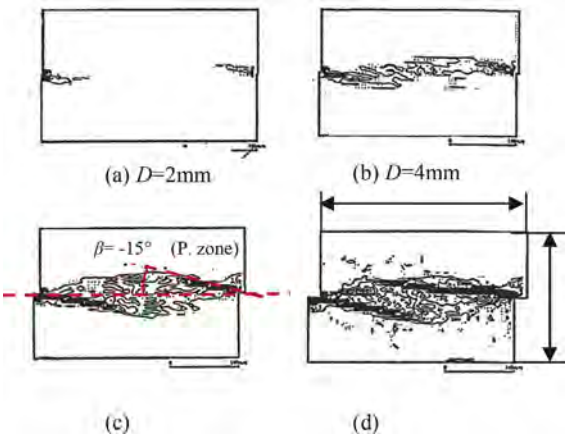

Figure 9. Expanding of a zone over 10% of γ_{xy} (Ohfuji, Ueno and Mochizuki, 1999).

It is concluded that an inclined angle measuring θ=15° (θ=δ - β) of the axis of strength ellipses to the horizontal coordinate must be revised when results of DS tests will be used in safety analysis of soil structures. Someone may think it is a particular kind of a negative problem in a DS test, however, it is not, as the only way to observe strength anisotropy in sandy materials is not test data of a triaxial test, but those of a DS test using the improved DS apparatus with double-jack system.

5 CONCLUSIONS

This paper presented an experimental study on shear strength anisotropy in a compacted sandy material. Two series of CDDS tests (direct shear tests under CD condition) were performed using an improved DS (direct shear) apparatus. To avoid deterioration of the anisotropic fabric of a sample, which was formed by press loading of 600 kN/m^2 and 1,200 kN/m^2, a freezing technique was introduced. The samples and test method were chosen to simulate the construction of an actual road embankment. The main conclusions reached in this study are as follows:

(1) A freezing technique of a sample was attributed to preventing deterioration of the anisotropic fabric induced by press loading in a sandy sample. An improved DS apparatus with a double-jack system worked effectively to observe strength anisotropy in sandy samples under CD condition.
(2) Samples in the active shear zone of δ=0°to 60°showed distinct and high peak strengths, whereas those in the passive zone of δ=90°to 150°showed un-clear peak and low strengths.
(3) Strength gap of δ=0° samples to that of θ=90° samples became smaller along with the increase of vertical stress, σ_N, which was caused by the induced anti-anisotropy behavior or destruction of anisotropic fabric during shearing under CD condition.
(4) It was found that the results can be expressed well by an ellipse equation with tilting coordinates of an angle measuring β= -15° (in the passive zone) to the horizontal coordinate.
(5) Progress of increasing of the shear zone in a sand sample was observed using a newly developed 2D-DS device, and the primary shear zone developed to a direction measuring β= -15° to the horizon in the sample was found, which coincided well with the inclination of the primary axes of strength ellipses for a sample with strength anisotropy induced by press loading. It suggests that the axes inclination of strength ellipses must be revised when the results of the strength anisotropy observed by DS tests will be used in safety analysis of soil structures.

ACKNOWLEDGEMENT:

The authors would like to express the appreciation to Prof. Victor Kaliakin (University of Delaware, *USA*) who discussed and gave much advice to our study. The authors also express our gratitude to Mr. J. Hujisawa for his laboratory works in this study.

Consideration of the methods determining a characteristics length of concept model using the new parameter D_{rmv} for volcanic sandy soil

R. Nakajima, K. Sako, S. Ito & R. Kitamura
Kagoshima University, Kagoshima Prefecture, Japan

ABSTRACT: This study investigated the characteristic length (D_{cha}) as a parameter of the concept model for estimating unsaturated seepage behaviors. We aimed to improve the practicality of the model. The model was proposed by Sako and Kitamura (2006) to derive the seepage behavior of unsaturated soil. D_{cha} is a parameter used to determine the pore size distribution in soil specimens. The methods for determining the parameters for each soil were discussed herein. In this study, a new parameter D_{rmv} was proposed to determine D_{cha}. The characteristics of this parameters were analyzed for volcanic sandy soil. The results indicated $D_{rmv} < 10^{-3}$ mm for volcanic sandy soil and D_{rmv} were related to the uniformity coefficient, U_c. The validity of this method was verified by comparing the D_{rmv} calculation with the experimental data for volcanic sandy soil sampled at a natural slope in Kagoshima Prefecture, Japan.

1 INTRODUCTION

The soil-water characteristic curve (SWCC) is an essential characteristic of the soil that controls water infiltration characteristics in unsaturated soil and has been employed to simulate the saturated-unsaturated seepage analysis. As soil water retention tests to obtain SWCCs are complicated and time-consuming, various models have been proposed to estimate SWCCs. Sako and Kitamura proposed a conceptual model for unsaturated seepage behavior using statistics and probabilities (Sako and Kitamura., 2006). In this model, the pore size distribution was correlated with the grain size distribution and void ratio. The SWCCs and unsaturated hydraulic conductivity were derived using the estimated pore size distribution and characteristic length, D_{cha}, which is a crucial parameter for deriving the pore size distribution. However, the value of characteristic length must be modified depending on the soil type. In previous studies, equations for D_{cha} have been proposed and methods for determining D_{cha} for each soil type have been discussed. This study proposed a method for determining D_{cha} for volcanic sandy soil. In this study, D_{rmv} was introduced as a new parameter to determine D_{cha}, which was calculated for 30 samples of volcanic sandy soil. The parameters were characterized and their relationship with the properties of the grain size distribution was also discussed. A method for determining D_{cha} using D_{rmv} was proposed in this study. The validity of the method was verified by comparing D_{rmv} calculation with the experimental data for volcanic sandy soil.

DOI: 10.1201/9781003299127-26

2 OUTLINE OF THE CONCEPT MODEL FOR UNSATURATED HYDRAULIC PROPERTIES AND CALCULATION PROCESS

2.1 *Outline of the concept model for unsaturated hydraulic properties*

A soil element with a few soil particles, called an Elementary Particulate Body (EPB) is shown in Figure 1. The EPB can be modeled as shown in Figure 2. The pore structure in the EPB was modeled using a pipe with diameter D_v and the inclination angle θ. The soil particles in the EPB were modeled by other impermeable parts. D_v and θ were also adapted as random variables to model the complex pore structure of the soil.

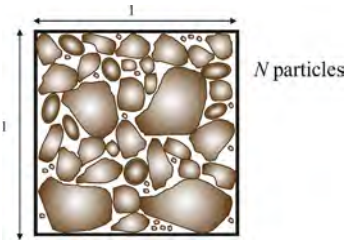

Figure 3. Random packing of particles in unit volume.

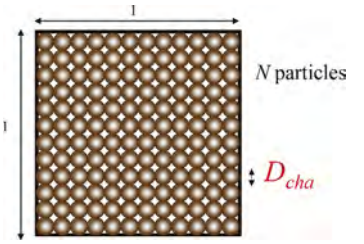

Figure 4. Packing of uniform sphere in unit volume.

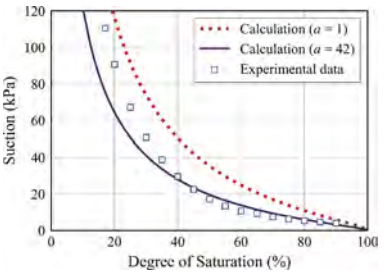

Figure 5. SWCCs obtained from experiments and calculations.

The volumetric water content (W_v) and suction (s_u) were expressed as follows:

$$W_v = \frac{e(d)}{1+e} = \frac{1}{1+e}\int_0^d \int_{-\pi/2}^{\pi/2} \frac{V_p}{V_e - V_p} \cdot P_d(D_v) \cdot P_c(\theta) d\theta \, dD_v \tag{1}$$

$$\text{and} \quad s_u = \gamma_w \cdot h_c = \frac{4 \cdot T_s \cdot \cos\alpha}{d}. \tag{2}$$

Here, V_e and V_p denote the volumes of the EPB and pipe in Figure 2, respectively. $P_d(D_v)$ and $P_c(\theta)$ denote the probability density functions of the pipe diameter (D_v) and inclination (θ), respectively. d denotes the maximum diameter of pipes filled with water. γ_w, h_c, T_s, and α are the unit weight of water, pressure head, surface tension, and contact angle of the meniscus at a contact point of the soil particle, respectively.

In this model, the characteristic length D_{cha} was defined as the particle size representative of the soil. Nakajima et al. (Nakajima, R. et al., 2019) pointed out that D_{cha} varies depending on the soil type and proposed a new equation for D_{cha}, as follows:

$$D_{cha} = \left\{ \sum_{i=a}^{n} \frac{1}{D_{s,i}^3} \cdot f_s(D_{s,i}) \cdot \Delta D_{s,i} \right\}^{-\frac{1}{3}}. \tag{3}$$

Here, $D_{s,i}$, $f_s(D_{s,i})$, $\Delta D_{s,i}$, a, and n denote the i-th grain size, probability density function of grain size distribution, interval increment, minimum value of the integration range of $f_s(D_{s,i})$, and number of divisions (n = 360), respectively.

Since the grain size distribution can be expressed as a log-normal distribution, the probability density function of the grain size distribution $f_s(D_s)$ in Equation (3) can be expressed as

$$f_s(D_s) = \frac{1}{\sqrt{2\pi} \cdot \zeta_s \cdot D_s} \cdot \exp\left[-\frac{\ln(D_s - \lambda_s)^2}{2 \cdot \zeta_s}\right], \quad (4)$$

where, D_s, λ_s, and ζ_s, are the grain size, distribution parameter, and integral range of $f_s(D_s)$ from ($\lambda_s - 4\zeta_s$) to ($\lambda_s + 4\zeta_s$), respectively.

The principle behind Equation (3) can be expressed as follows: Figure 3 shows the random packing of soil particles per unit volume. The N soil particles of random shape and size are packed with a dry density of ρ_d. Figure 3 is modeled as shown in Figure 4. It shows a simple N uniform particles per unit volume. The dry density is equal to that shown in Figure 3. D_{cha} is the diameter of a uniform particle. The value of a in Equation (3) is a parameter related to integration range of $f_s(D_{s,i})$. The optimum value of a is calculated using experimental data of SWCC. Consequently, the D_{cha} is determined for each soil.

2.2 *The calculation process of the concept model*

This section describes how to determine D_{cha} and derive SWCC using Equation (3). The SWCC experimental data of Kushira soil (ρ_s = 2.48 mg/m^3) from volcanic sandy soil were obtained using the simplified evaporation method. Figure 5 shows the SWCC values obtained from the experiments and calculations. The calculation results overestimated the experimental data by a dotted line with a value of a = 1 in Equation (3). This resulted in D_{cha} being 0.85 % finer by weight, denoted as $D_{0.85}$. The equation assumed that particles of random sizes and shapes are uniform particles of equal numbers. A significant number of fine particles resulted in the size of the uniform particles being underestimated. The size of D_{cha} was adjusted by increasing the minimum value of a of the integration range of $f_s(D_{s,i})$. Reducing the integral range of $f_s(D_{s,i})$ from the smallest particles reduces the effect of the fine particles. The solid line shows that the results are close to the experimental data when a = 42. D_{cha} was 3.56% finer by weight, indicating that the grain size of $D_{3.56}$ influences the SWCC of Kushira soil. Using this calculation process, the parameter D_{cha} was determined for each soil. However, to derive a valid D_{cha} experimental data is needed. This study proposed a method to determine D_{cha} for volcanic sandy soil by introducing D_{rmv} as a new parameter. D_{rmv} was calculated for 30 for volcanic sandy soil samples. The characteristics of the parameters are discussed in the following section.

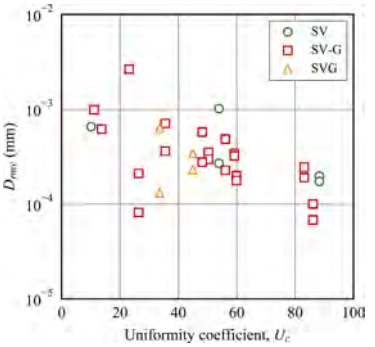

Figure 6. Relationship between D_{rmv} and uniformity coefficient, U_c.

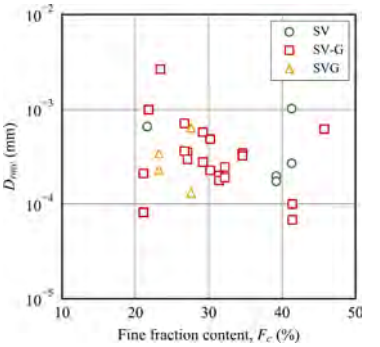

Figure 7. Relationship between D_{rmv} and fine fraction content, F_c (%).

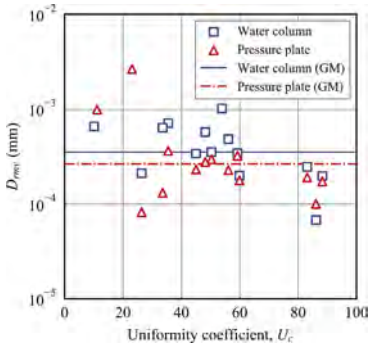

Figure 8. Relationship between D_{rmv} and uniformity coefficient, U_c classified by the test methods.

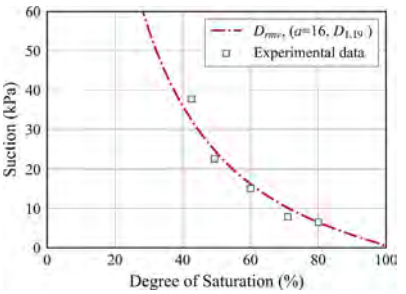

Figure 9. Calculation result and experimental data. (Higashimata soil).

3 NEW PARAMETER AND ITS CHARACTERISTICS

D_{cha} is determined by adjusting the size of D_{cha} and narrowing the $f_s(D_{s,i})$ from the finest particle size. The maximum diameter of the particles removed for determining D_{cha} is defined as D_{rmv} and can be expressed as follows:

$$D_{rmv} = \exp\left[\lambda_s - \left\{4\zeta_s\left(1 - \frac{2}{n}\right) \times (a-1)\right\}\right]. \quad (5)$$

The value of a can be determined without the results of the experimental data if the D_{rmv} is known for each soil. This making it possible to calculate D_{cha} for each soil acceding to Equation (3). In this study, the D_{rmv} was calculated for 30 SWCCs experimental datasets of volcanic sandy soil to obtain the characteristics of D_{rmv}. The soils were classified as sand of volcanic fine fraction nature (SV), sand of volcanic fine fraction nature with gravel (SV-G) and gravelly sand of volcanic fine fraction nature (SVG) according to the Japanese Geotechnical Society (2015). The SWCC experimental data were obtained using pressure plate, water column, centrifuge, and simplified evaporation methods.

The relationship between D_{rmv} and the properties of grain size distribution, such as uniformity coefficient, U_c, and fine fraction content, F_c (%) (percentage of particles with diameter less than 0.075 mm), are discussed. Figure 6 shows the relationship between D_{rmv} and uniformity coefficient U_c. Although the value of SV-G varies, the larger the uniformity coefficient, the smaller the value of D_{rmv}. Most of the value of D_{rmv} were in range $D_{rmv} < 10^{-3}$ mm. Figure 7 shows the relationship between D_{rmv} and F_c (%). The larger the fine fraction content, the smaller D_{rmv} trend to be. However, there is more variation compared to the relationship with the uniformity coefficient.

Owing to the differences in the soil-water retention test results, the D_{rmv} for each experiment is discussed. Of the 30 SWCCs experimental data, 14 were obtained using the pressure plate method and 14 using the water column method. Figure 8 shows the relationship between D_{rmv} and uniformity coefficient, U_c, classified by the soil-water retention test methods. The geometric means (GM) of D_{rmv} were calculated using each test method. Based on the results, the relationships were clarified by classifying the test methods. The geometric means of D_{rmv} for the water column and pressure plate methods were 3.53×10^{-4} mm and 2.64×10^{-4} mm, respectively. For volcanic sandy soil it was suggested that the geometric mean of D_{rmv} for each test method could be used to determine D_{cha}.

4 EVALUATION OF THE VALIDITY OF THE METHOD USING A NEW PARAMETER

A soil water retention test was conducted using pressure plate method to verify the validity of the new method. Volcanic sandy soil collected from natural slopes in Kagoshima, Japan was

used (from now on, this will be referred to a "Higashimata soil") (ρ_s=2.51(mg/m^3). Higashimata soil is classified as Volcanic gravelly sand with fine fraction (SG-V). The void ratio e of the sample was set to 0.98. The initial water content was set to 33.4 %. Figure 9 shows the experimental data and calculation results. The dash-dot line shows the result using the geometric mean of D_{rmv} for pressure plate methods, which is $D_{rmv} = 2.64 \times 10^{-4}$ mm. Using the geometric mean of D_{rmv} and Equation (5), a = 16 was obtained. D_{cha} was calculated to be 1.19% finer by weight ($D_{1.19}$) from Equation (3). The calculated values of SWCC were close to the experimental data. Therefore, an appropriate D_{cha} can be obtained by using the geometric mean of D_{rmv}. The SWCCs can be estimated without soil-water retention tests for volcanic sandy soil.

5 CONCLUSION

In this study, a new method to determine the D_{cha} was proposed using the parameter D_{rmv}. The D_{rmv} values were calculated for 30 volcanic sandy soil samples. The characteristics of the parameters were discussed. A soil-water retention test was conducted to verify the validity of the method. The result indicated a relationship between D_{rmv} and the uniformity coefficient. However, D_{rmv} was found to be less than 10^{-3} mm for volcanic sandy soil. This relationship was clarified by separating the test methods. The geometric mean was calculated for each test method. The methods using the geometric mean could determine D_{cha} The calculation results were close to the experimental data for volcanic sandy soil. Appropriate D_{cha} can be obtained by using the geometric mean of D_{rmv}, and the SWCCs can be estimated without soil-water retention test results for volcanic sandy soil.

Y-Y' Calculus: From soil consolidation to other physical sciences

Sudhir K. Tewatia
Adama Science & Technology University, Ethiopia

Kanishck Tewatia
Loyalist College, Toronto, Canada

Anttriksh Tewatia
Hughes Systique, Gurgaon, India

One Line Summary: Originated from Soil Consolidation, its breakthrough in Calculus to start a new era in physical sciences wherever Newton-Leibniz Calculus applies, gets complicated or fails.

ABSTRACT: Advancements in soil consolidation are discussed and further improvements proposed with particular reference to *Tewatia's Y-Y'* Calculus that is known as Settlement versus Rate of Settlement Approach in consolidation. A branch of calculus named as *Y-Y'* (or *y versus dy/dx*) is suggested (as compared to the common *X-Y', x versus dy/dx, dy/dx versus x* or *Newton-Leibniz* branch) that solves some complicated/unsolved theoretical and practical problems in physical sciences (Physics, Chemistry, Mathematics, Biology and allied sciences) and engineering in amazingly simple and short manner, particularly when independent variable *X* is unknown and *X-Y'* Approach can't be used. Complicated theoretical and practical problems in *1D, 2D, 3D* Primary and Secondary consolidations with non-uniform gradual loading and irregular shaped clays are solved with elementary school level *Y-Y'* Approach. Some particular cases from soil consolidation that are basically creep and diffusion equations in isolation and in combination with each other are taken for comparison with heat and electricity transfer. The *Y-Y' Approach* can similarly be applied in wave equations and other fields wherever normal calculus works or fails.

1 INTRODUCTION

The *Y-Y' Calculus* was invented by Tewatia in 1998 and used in various theoretical and practical problems of soil consolidation [1-20]. In common calculus, differential equations are used for solving problems mostly as below

$$y = f(x); y' = dy/dx = f_1(x) \text{ or } x = f_2(y'); y'' = d^2y/dx^2 = f_3(x) \text{ or } x = f_4(y'') \quad (1)$$

That means differential equations are used as a function of x or vice versa. Very less practice is there to use it as a function of y instead of x. A new approach in calculus, named as *Y-Y'* (or *y* versus *dy/dx*), is suggested (as compared to the common *X-Y'* or *x* versus *dy/dx* or *Newton-Leibniz Approach*) that solves some complicated/unsolved theoretical and practical problems in physical sciences (Physics, Chemistry, Mathematics, Biology and allied sciences) and engineering in amazingly simple and short manner, particularly when independent variable x is unknown and *X-Y'* Approach can't be used. Similar happened in consolidation where all researchers were using δ-t or δ-σ plots; where, δ is settlement, t is time and σ is pressure in primary and secondary consolidation equations. The solution failed when σ or t is unknown at the instant of load increment and it was the common case in the field. Terzaghi [21-22] gave the average loading time concept for continuous uniform loading that, however, was very rough assumption and not true (Figure 1).

DOI: 10.1201/9781003299127-27

The numerical/computer or exact solutions of this problem were suggested by researchers like Leo [23] but they are complicated or require some extra (initial/boundary etc) conditions to be known and fail in case of non-uniform ramp loading and arbitrary shaped clayey soils. A rough (not exact) example is *Pissa* tower where its assumed that it has been sinking due to secondary consolidation since its construction in stages about 8-9 centuries ago so exact time of final/present load increment is not known. However, time settlement data of last 100 years is known. If one wants to predict its past and future settlements due to secondary consolidation and wants to determine the coefficient of secondary consolidation using creep or secondary consolidation equation

$$\delta = a\ log(t) + b \tag{2}$$

then time of load increment (8-9 centuries back), t, should be known. However, its very simple by following $Y\text{-}Y'$ equation [3, 15]

$$\delta = a\ log(d\delta/dt) + b \tag{3}$$

In field, the settlement is due to complex phenomenon like primary and secondary consolidations intermix, non-uniform gradual or ramp loading, multiple stratified layers with different consolidation properties, complex drainage boundaries, unknown initial settlement, time and pressure at the time of load increment etc. In such situations $Y\text{-}Y'$ approach gives easy solutions of some theoretical and practical problems.

Terzaghi [21,22] defined Soil Mechanics as "The Application of the laws of mechanics and hydraulics to engineering problems dealing with sediments and other unconsolidated accumulations of solid particles". That means Geotechnical engineering used laws and mathematical analogies from other physical sciences. Perhaps, Coulomb was the first scientist to use mechanics in soil in slope analysis in 1776. Primary consolidation is basically a *diffusion* (heat) equation [24,25] applied by Terzaghi from thermodynamics to soil mechanics and Secondary consolidation is creep equation of physics, where settlement proceeds linearly with logarithm of time at constant effective stress. Therefore, new developments in consolidation theory on account of $Y\text{-}Y'$ Approach will be beneficial to (diffusion) thermodynamics, electricity, mass transfer etc. For example equations of one, two, three dimensions; radial and combined *radial +vertical* ($R+V$) consolidations are derived very easily without partial differential equations in $Y\text{-}Y'$ approach, similar should follow in other disciplines on similar mathematical analogies. In this paper advancements in soil consolidation are discussed from this point of view with some examples. $Y\text{-}Y'$ calculus (alone or in combination with $X\text{-}Y'$ calculus) can be used not only in creep and diffusion equations but in several other problems also like wave equation etc in all physical sciences and engineering wherever normal calculus works or fails.

2 Y-Y' CALCULUS IN CREEP OR SECONDARY CONSOLIDATION

Illustration, procedure and advantages of new method; generation of δ-t data and its comparison with actual data are given by solved examples [3, 6, 15].

Question 1: Because of secondary consolidation, the rate of settlement of a structure after *1* years is *10 mm/year*. Find the rate of settlement after 3 years.

Answer: In $Y\text{-}Y'$ calculus, product of time and rate of settlement is constant in secondary consolidation. Therefore, the rate of settlement after 30 years will be (10*1/3) i.e. 3.3 *mm/year*.

3 Y-Y' CALCULUS IN COMPRESSIBILITY CHARACTERISTICS

This is similar to previous section as in case of creep except for, t is substituted by σ' and α is substituted by compression index, C_c [3,6,15,17]. In the previous section a method was suggested for obtaining δ-t data of present, past and future from limited δ-$d\delta/dt$ or δ-$dt/d\delta$ data. In this section a method is suggested for obtaining δ-σ' data of present, past and future from limited δ-$d\delta/d\sigma'$ or δ-$d\sigma'/d\delta$ data. Fastest rapid loading methods for vertical, radial and *3D* consolidation are possible only when $Y\text{-}Y'$ Approach is used [17].

4 DERIVATION OF BASIC THEORETICAL EQUATIONS OF CONSOLIDATION

In consolidation literature, equations have been derived, solved and used from simple to more difficult sequence; One dimensional (Vertical), Radial, Combined (*V+R*) and the *3D* consolidation equation (in Cartesian coordinates) does not exist. To show the simplicity and beauty of *Y-Y'* approach let's move from most difficult to simplest one.

4.1 *Carrillo [26] type equations for 3D consolidation in cartesian coordinates*

Using *Y-Y'* Calculus (*Figure 2*), Tewatia [9,10] derived

$$(1 - U_{xyz}) = (1 - U_x)(1 - U_y)(1 - U_z) \tag{4}$$

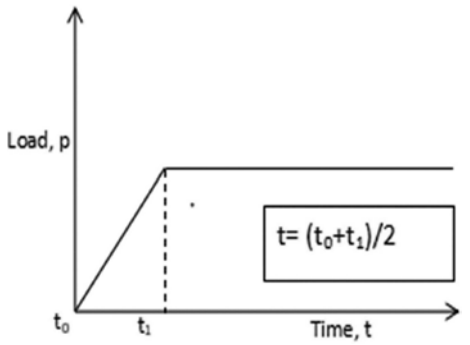

Figure 1. Uniform ramp loading.

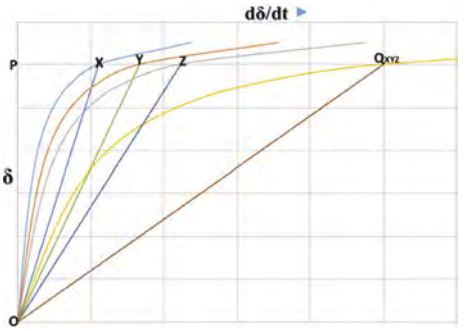

Figure 2. Derivation of *3D* consololidation Eq (4).

Where, U_x, U_y, U_z are degrees of consolidation when drainage is allowed in *X*, *Y* and Z directions only individually and U_{xyz} is the degree of consolidation due to combined drainage in *X*, *Y* and *Z* directions, simultaneously. Eq 4 can be easily modified for *N* number of drainage (Q4), just not *3* only. When the drainage is allowed in radial and vertical directions, it is called combined *vertical+radial* consolidation and Eq 4 reduces to Carrillo's [26] Eq 5

$$(1 - U_{rv}) = (1 - U_r)(1 - U_v) \tag{5}$$

4.2 *Barron's Radial consolidation Equation [27]*

Thiem's [28] *Eq* for flow of water in confined aquifer is used and we get Barron's *Eq 6* [3,16,27]

$$U_r = 1 - e^{-\frac{8}{F_n}T_r} = 1 - e^{T_{rn}} \tag{6}$$

$$F(n) = \frac{n^2}{n^2 - 1}\ln(n) - \frac{3n^2 - 1}{4n^2} \tag{7}$$

Where, F_n is a function of n ($= d_e/d_w$); d_e is the diameter of influence and d_w is the diameter of the drain well. A new variable T_{rn} ($=8T_r/F_n$) is introduced that contains family of U_r-T_r curves for different values of n (in Eq 6) in a single curve [3,16-19].

4.3 *Vertical consolidation Equation*

Similar to radial consolidation, one dimensional or vertical consolidation equation was derived as [16]

$$U = 1 - e^{-T} \tag{8}$$

Newly derived *Eq 8* is somewhat similar to *Eq 9*, later (exponential) part of Terzaghi's *Eq 10* and it does not compare well with first parabolic part of Terzaghi's *Eq 11*.

$$U = 1 - \frac{8}{\pi^2}\varepsilon^{-\frac{\pi^2}{4}T} \tag{9}$$

$$U_v = 1 - \frac{8}{\pi^2}\sum_{N=0}^{N=\infty}\frac{1}{(2N+1)^2}\exp\left(-\frac{(2N+1)^2\pi^2}{4}T\right) \tag{10}$$

$$T = \frac{\pi}{4}U^2 \tag{11}$$

Citing this new derivation and mismatching with initial portion and quoting other researchers Mei and Chen [29] observed that Initial conditions and Boundary conditions of the Terzaghi's [21-22] one dimensional consolidation equation conflict with each other. Therefore, the classical initial-boundary value problem of the equation is not well-posed. However, the exact reasons for this are left to the future researchers and in next articles *Y-Y'* approach is carried out to various other problems of consolidation based on Terzaghi's *Eq 10*.

5 ADVANCED THEORETICAL EQUATIONS OF COMBINED (*V+R*) AND *3D* CONSOLIDATIONS WITH NON-UNIFORM RAMP LOADING AND ARBITRARY SHAPE OF DRAINING CLAY

5.1 *For combined vertical and radial consolidation*

Tewatia [3,9,10,16,17,19] derived

$$\delta = \frac{4H^2}{\pi^2\lambda c_v}\left(\frac{d\delta}{dt}\right) + \delta_{100} \tag{12}$$

Following is the theoretical equation of above experimental *Eq 12*

$$U_{rv} = 1 - \frac{8}{\pi^2}\exp\left(-\frac{\pi^2\lambda T_v}{4}\right) \tag{13}$$

Where,

$$\lambda = 1 + \frac{32k_rH^2}{\pi^2k_vd_e{}^2F_n};\ \frac{c_r}{c_v} = \frac{k_r}{k_v} \tag{14}$$

Installation of vertical drains accelerates the time factor for vertical consolidation within a fixed time by λ times.

Question 2: A clay layer *10m* thick with vertical drains is sandwitched between *2* sand layers. Given: $c_v = 0.6\ m^2/yr$, $c_r = 1.2\ m^2/yr$, $d_e = 1.06m$, $d_r = 0.1m$. Find % settlement of clay in *0.42 years* by ***a***. *Conventional method* and ***b***. *Using Eq 13*.

Solution: $n = 1.06/0.1 = 10.6$, $F_n = 1.634$ using *Eq 7*

a. *Conventional Method*: $U_r = 0.9$ by *Eq 6* (*1st part*), $U_v = 0.12$ by *Eq 10*, $U_{rv} = 91.2\%$ by *Eq 5*.
b. *Using Eq 14*: $\lambda = 89.3$, $U_{rv} = 91.2\%$ by *Eq 13*.

Note: U_{rv} by new method is directly found without using *Eq 6, 10 or 5*.

5.2 *Theoretical Equation of 3D consolidation in cartesian coordinates using Y-Y' Approach*

In *Cartesian co-ordinates* [30]

$$\frac{\partial u}{\partial t} = c_x \frac{\partial^2 u}{\partial x^2} + c_y \frac{\partial^2 u}{\partial y^2} + c_z \frac{\partial^2 u}{\partial z^2} \tag{15}$$

Where, t is time; u is pore pressure; in X, Y and Z directions c_x, c_y, and c_z are the coefficients of consolidation, respectively. Solution of Eq 15 does not exist in literature. However, Tewatia [3,9,10] easily obtained it using *Y-Y' Approach* as

$$U_{xyz} = 1 - \frac{8}{\pi^2} \sum_{N=0}^{N=\infty} \frac{1}{(2N+1)^2} \exp\left(- \frac{(2N+1)^2 \pi^2}{4} \lambda T_v \right) \tag{16}$$

$$\lambda = 1 + \frac{k_y H^2}{k_z B^2} + \frac{k_x H^2}{k_z L^2} \tag{17}$$

Where, k_x, k_y *and* k_z are the permeability's of soil in *X (Length L), Y (Breadth B) and Z (Height H)* directions. *Eq 16-17* (like *Eq 12-14*) can be applied in step and non-uniform ramp loading with unknown time of load increment and can determine that unknown time also.

5.3 *Arbitrary drainage*

A new factor, $\lambda c_H = \lambda c_v / H^2$ is defined [3, 6,19]. The λ_{cH} is the property of in situ clay of definite shape, size and drainage conditions that can be determined in the field itself by *Eq 18* along with δ_{100}) by observing the trend of settlement for some time without knowing any history, shape, size and drainage conditions [3,6].

$$\delta = \frac{4}{\pi^2 \lambda_{cH}} \left(\frac{d\delta}{dt} \right) + \delta_{100} \tag{18}$$

6 SOME PARALLEL ANALOGIES/EXAMPLES IN DIFFUSION EQUATIONS OF PHYSICAL SCIENCES (SAY, THERMODYNAMICS, ELECTRICITY)

Question 3: A solid body of Length L, Breadth B and Height H was allowed to cool for a sufficient time (theoretically infinite) from Temperature $T°C$ to $0°C$ in a an ice box at $0°C$ ice temperature. Total ice melted to $0°C$ water was *100 ml* due to latent heat gained from the body while it cooled. Now suppose, in t minutes time:

1. Total ice melted when the body was insulated along H and B and heat conduction was allowed only along length L from the two ends was *20ml*.
2. Total ice melted when the body was insulated along L and B and heat conduction was allowed only along Height H from the two ends was *80ml*.
3. Total ice melted when the body was insulated along L and H and heat conduction was allowed only along Breadth B from the two ends was *50ml*.

Find the total ice melted in t minutes when the heat conduction is allowed along L, H and B simultaneously (from all *6 faces*) and no insulation is provided.

Solution: Consolidation *Eq 4* is used directly; where, $U_L = 20/100 = 0.2$, $U_H = 80/100 = 0.8$, $U_B = 50/100 = 0.5$. $(1-U_{LBH}) = (1-0.2)(1-0.8)(1-0.5) \Rightarrow U_{LBH} = 0.92$, means *92ml* ice will melt.

Question 4: 5 Electrical wires of different conductivity or resistance are connected to two capacitors with charge or voltage difference U. When connected individually they drain charge 10, 20, 30, 40 and 50% U, respectively, in time, t. How much % charge they will drain in time, t, when all are connected together in parallel? Voltage difference is not constant, it drops as current flows.

***Solution*:** Its similar to *Q3*. From *Eq 4*:

$(1-U_{12345})=(1-U_1)(1-U_2)(1-U_3)(1-U_4)(1-U_5)=(1-0.1)(1-0.2)(1-0.3)(1-0.4)(1-0.5)$
$=0.9\times0.8\times0.7\times0.6\times0.5=0.15120$. => $U_{12345} = 0.84880 = 84.88\%$

Question 5: In *Question 3*, *case 1*, it took *10 minutes* for *20ml* ice to melt. How much time will be taken for *40 ml* ice to melt? If the length of rod, *L* is *2m*, what is diffusivity coefficient of the body conducting heat, κ?

***Solution*:** This is parallel to one dimensional consolidation *Eq 10* and for *U=40%, Eq 11 is valid*. $U_1 = 20/100 = 0.20$; $U_2 = 40/100 = 0.40$; $t_1 = 10$ *minutes*

$$\frac{T_1}{T_2} = \frac{t_1}{t_2} = (\frac{U_1}{U_2})^2 \Rightarrow \frac{10}{t_2} = (\frac{0.2_1}{0.4})^2;$$

That gives, $t_2 = 40$ *minutes*. From *Eq 11: T=0.032* for $U = 0.20$ at $t = 10$ *min*, h = length of drainage path for heat conduction = $L/2 = 2/2$ for double drainage = *1m*. $T = c_v\, t/h^2 = \kappa\, t/h^2$ => $\kappa = 0.0032\ m^2/min$.

It is noted that c_v = coefficient of consolidation, is diffusivity coefficient in consolidation, while in heat equation diffusivity coefficient is κ, that is parallel to c_v in mathematical analogy.

Question 6: In *Question 3*, if κ is same along *L*, *B* and *H*. Find *B* and *H*.

***Solution*:** $T = \kappa\, t/h^2$ => $h = (\kappa t/T)^{0.5}$; For *U=0.8, T=0.567* from *Eq 9* => $h = (0.0032\times10/0.567)^{0.5} = 0.2375$; $H = 2h = 0.475m$. For *U=0.5, T=0.2* from *Eq 10* => $h = (0.0032\times10/0.2)^{0.5} = 0.16$; $B = 2h = 0.32m$

Question 7: A solid body of Length *L=2m*, Breadth *B=0.32* and Height *H=0.475m* was allowed to cool from Temperature *T°C* to *0°C* in a an ice box at *0°C* ice. Total ice melted to *0° C* water was *100 ml*. Diffusivity coefficient, $\kappa = 0.0032\ m^2/min$ is same in *X, Y* and *Z* directions, Find time *t* in minutes when *80ml* ice will melt. The body is draining from all *6 faces*.

***Solution*:** This is the case of *3D* drainage of heat in *Cartesian Coordinates* and *Eq 16-17* are applicable. $U = 80/100 = 0.8$, λT from *Eq 16 is 0.567*. As κ is same in all directions, so thermal conductivity is also same in all directions. Hence, in *Eq 17;* $k_x=k_y=k_z$.

$\lambda = 1 + (H/B)^2 + (H/L)^2 = 1 + (0.475/0.32)^2 + (0.475/2)^2 = 1 + 2.203 + 0.056 = 3.259$. $T = 0.567/3.259 = 0.174 = \kappa t/h^2$, where, $h = H/2$ in double drainage of heat. $t = (0.174/0.0032)(0.475/2)^2 = 3.07$ *min*.

When flow was in *H* direction alone, it was *10 min*, so the time to achieve *80%U* was reduced by λ *(=3.259)* times by addition of heat flow in *L* and *B* directions.

Similar examples may be taken in Electricity (where charge is diffused, producing current), mass transfer etc. One interesting example is *Hubble's law*, where plot of distance versus the speed of galaxies is straight line and slope of that is Hubble constant. Plot of settlement versus rate of settlement in Radial (and later part of vertical) Consolidation is also a straight line (like Eq 23) the slope of which is c_r, the coefficient of radial consolidation [3]. The straight line starts from the beginning and reduces the experimental time to the minimum possible (zero theoretically). Creep examples are found in various engineering and physics. Spreading of communicable diseases like Corona etc is also a diffusion where *Y-Y'* Approach may also have some application. In consolidation, *Y-Y'* Approach is used mostly on *diffusion* and *creep* equations but it may be tried in wave equations also and in all fields.

7 ADVANCEMENTS IN VERTICAL CONSOLIDATION DUE TO Y-Y' APPROACH

7.1 *Terzaghi's Eq 10 is resolved in 3 parts [1,3,15,17,19,31]*

(Figure 3-4): (1) Parabolic *Eq 11* for *0-40% U*, (2). Transition (*Eq 20*) from Parabolic to Exponential for *40-60% U*, (3). Exponential *Eq 9* for *60-100% U*. *U* versus *dU/dT* plot is a symmetrical *S* shaped curve on semi-log plot (Figure 3), having point of inflection at *50%U*.

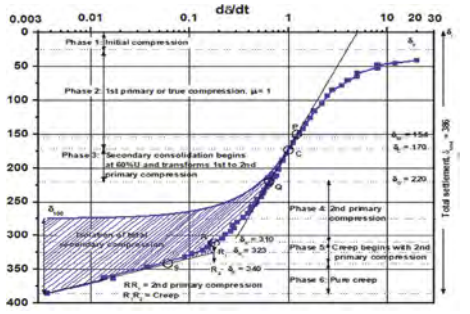

Figure 3. Symmetrical *S-Curve* & 6 Phases.

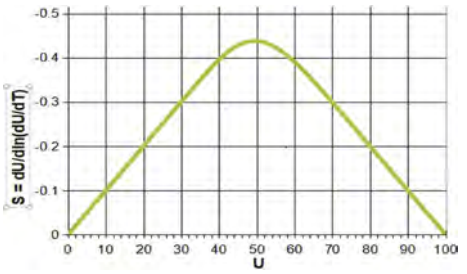

Figure 4. *U* versus Slope of Symmetrical *S-Curve*, *S*.

$$S = U \text{ for } 0 < U < 40\%;\ S = 1 - U \text{ for } 60 < U < 100\%;\\ S = 3.82\left(U - U^2 - 0.1353\right) \text{ for } 40 < U < 60\% \tag{19}$$

$S_{max} = 0.438$ at $U = 0.5$ or *50%* on *ln* scale on *X-axis*. $S_{max} = 1.009 \approx 1$ at $U = 0.5$ or *50%* on log_{10} scale on *X-axis* The slope of this *S-curve*, *S*, varies linearly with *U* from *0-40%* and *60-100%*. *S* has a parabolic relationship with *U* from 40-60% *U*, called transition zone (Figure 4). The equation of transition zone is

$$3.82(U^2 - U - 0.1353)U'' + (U')^2 = 0 \tag{20}$$

Eq 20, does not contain any *T* or *x* term; all variables are in terms of *U, U', U''* only in a simple manner; its *Y-Y' Approach*. Earlier, Eq 10 was resolved in 2 parts only; parabolic Eq 11 from *0-60%U* and Exponential *Eq* 9 from *60-100%U*.

7.2 *Six phases of consolidation (Figure 3)*

The six phases occur due to intermixing of Initial Compression and Secondary compression with 3 parts (parabolic, transition and exponential) of primary compression of *Eq* 10. They are (1) Initial Compression (2) First Primary Compression (3) Transition from first primary compression to second primary compression (4) Second Primary compression (5) Transition from second primary compression to creep and (6) Creep. They are quantitatively isolated in *Figure 3*. In inorganic soils, usually, first primary compression (and transition) part gives *true* c_v. Earlier, only Initial, Primary and Secondary (three) phases of consolidation were known.

7.3 *Fastest method for determination of c_v [1,3,15,17,19,32]*

It can be evaluated at *50% U* only by *Eq 21* (*Figure 3-4*) as compared to minimum *70% U* in other faster methods for the determination of c_v.

$$c_v = -\frac{0.8033\left(\frac{d\delta}{dt}\right)_{50} H^2}{s_{50}} \tag{21}$$

The c_v, δ_0 *and* δ_{100} can be evaluated without knowing the time, settlement and pressure at the instant of load increment, just by observing the δ *versus* $d\delta/dt$ plot for sometime, starting from any arbitrary settlement, δ.

7.4 *The Y-Y' approach gives a simple condition for true c_v:*

In soils following Terzaghi's vertical consolidation theory the product of time and rate of settlement at *50%* consolidation divided by the slope of the tangent at the point of inflection

in *semi-log$_{10}$* plot of *settlement versus rate of settlement* equals *0.245*. In that case, *Eq 21* gives *true* c_v.

$$\mu = \frac{t_{50} \times (\frac{d\delta}{dt})_{50}}{0.245 \times s_{50}} \tag{22}$$

where, μ is a fuzzy logic varying between 0-1, that determines the trueness of c_v [3, 4, 15,31]. Closer is c_v to the *true* c_v, closer is μ to 1. The *true* c_v is devoid of any effect of secondary consolidation. Before the advent of *Y-Y' Approach*, comparison of the calculated values of hydraulic conductivity with the measured ones was required to get the trueness of c_v.

7.5 *From δ-(dδ/dt) Plot, Determination of Instantaneous* c_v, δ_0 *and* δ_{100} *[1, 3, 15]*

$$\delta = \frac{4H^2}{\pi^2 c_v}(\frac{d\delta}{dt}) + \delta_{100} \tag{23}$$

$$c_v = -\frac{4H^2}{\pi^2 m} \tag{24}$$

Eq 23 is straight line in the form: $y = m\,x + c$, where, H is the drainage path, c is intercept on *y-axis* and m is slope. The *δ-(dδ/dt)* plot is a straight line having an intercept on δ axis, $c = \delta_{100}$ and slope, $m = (4H^2)/(\pi^2 c_v)$. The c_v can be evaluated from *Eq 24*.

8 CONCLUSIONS

The *Y-Y'* Calculus is powerful mathematical tool to be used where *X-Y'* calculus fails or becomes complicated. It can be used alone or in combination with *X-Y'* calculus. Analysis and advancements of consolidation problems is carried out with it while comparing it with *X-Y'* calculus in solving the problems. However, consolidation consists of mainly diffusion and creep equations but *Y-Y'* calculus can be used in wave equations and other field also. Soil Consolidation paves the way and marks the beginning of new era in physical sciences and engineering with novel mathematical analogies developed through *Y-Y' Calculus*. Terzaghi's definition of Soil Mechanics, at least in soil consolidation, needs to be re-evaluated.

ABSTRACT: Hydraulic conductivity is an important geotechnical engineering property as it is linked to the performance of many geo-structures. This study used a recently compiled granular soil database (CG/KSAT/7/1278) to evaluate the best fit probability density functions for important parameters in the database. The Loglogistic function was found to be the best-fit probability density function for the parameters from CG/KSAT/7/1278 investigated in this paper. The grading entropy parameters (un-normalised) were used to develop a chart that highlights trends from the effect of changes of the gradation parameters on the estimated soil permeability.

1 INTRODUCTION

Hydraulic conductivity (k) is a fundamental soil mechanics parameter that is closely linked to many geotechnical problems, such as seepage, settlement, and slope stability (e.g. Lambe & Whitman 1969, Taylor 1948). Simple predictive models for k calibrated using laboratory data are often used (e.g. Chapuis 2012).

Feng (2022) assembled a coarse-grained soil database CG/KSAT/7/1278, which consists over 1200 measurements of k (see Feng 2022 and Feng et al. 2023 for full details of the assembled database including the original data-sources). Feng (2022) examined various empirical and semi-empirical transformation models for k of granular soils.

The aims of this study are: (a) Identify the best-fit PDFs for important parameters using CG/KSAT/7/1278; (b) Examine the influence of statistical outliers on the choice of best-fit PDFs from (a) and (c) Investigate if the grading entropy theory can offer insights into the variation of the soil permeability data from CG/KSAT/7/1278. For further details on the establishment and statistical analysis of the database see the thesis of Feng (2022) and Feng et al. (2023).

2 DATABASE STUDY

2.1 *Identifying potential outliers*

In this work the following procedure for identification of potential outliers was adopted: (i) datapoints with a computed standardized residual not within the range of -2 to 2 (cf. Montgomery et al. 2007), or those with a computed leverage value greater than three times the computed mean

DOI: 10.1201/9781003299127-28

leverage (cf. Velleman & Welsch 1981) were identified for all calibrated regression models (see Feng 2022 for a full list of the calibrated models); and (ii) if a datapoint from (i) was identified as an outlier for greater than 75% of the calibrated models it was deemed to be a statistical outlier. This analysis results in 22 datapoints out of 1278 in the CG/KSAT/7/1278 database (approximately 2%) being classified as statistical outliers (a similar procedure for identification of statistical outliers was adopted in Feng et al. 2021, Feng et al. 2022, and the procedure outlined in this paper is also used in Feng et al. 2023 for analysis of CG/KSAT/7/1278).

2.2 *Probability Density Functions (PDFs)*

The best fitting PDFs for the key parameters from the database CG/KSAT/7/1278 were evaluated using the Akaike Information Criterion (AIC) (Akaike 1974) before and after the removal of the statistical outliers as identified in Section 2.1. The AIC is computed as:

$$AIC = -2\log\left(L(\hat{\theta})\right) + 2K_i \tag{1}$$

where $L(\hat{\theta})$ is the 'likelihood function', and K_i is the number of parameters in the PDF fitted to the data. The trialled PDFs were: 'Lognormal', 'Exponential', 'Weibull', 'Loglogistic' and 'Gamma' (Feng and Vardanega 2019 carried out a similar study for a fine-grained soil k database: FG/KSAT-1358), were fitted to the void ratio (e), aperture diameter through which 50% of the material would pass (D_{50}) and k data from CG/KSAT/7/1278. In the following analysis the k data was analysed in the form of the intrinsic permeability K (length^2).

Figures 1–3 show probability plots where the aforementioned PDFs are fitted to the e, D_{50} and K data from CG/KSAT/7/1278 with and without the identified statistical outliers included. Tables 1 and 2 record the computed AIC for the PDFs trialled. The results show that the 'Loglogistic' function is the best-fit PDF for all parameter examined in database either before or after the removal of the identified statistical outliers. The 'Loglogistic' function can be expressed as (e.g. Johnson et al. 1994):

$$f(x|\mu,\sigma) = \frac{e^z}{\sigma x(1+e^z)^2} \text{ , where } z = \frac{\log(x)-\mu}{\sigma} \tag{2}$$

where, μ = mean of the logarithmic values, and σ = scale parameter of the logarithmic values. Table 3 compares the fitted parameters of the best-fit PDFs ('Loglogistic') for the key parameters of the studied database with and without the identified statistical outliers. The effect of outliers on the fitted PDFs was deemed to be negligible.

Table 1. Computed AIC for the fitted PDFs for CG/KSAT/7/1278 (best fits shown in bold).

n =1278	Exponential	Lognormal	Weibull	Loglogistic	Gamma
e	1140	-628	-599	-801	-716
D_{50} (mm)	3810	2800	3313	2762	3524
K (mm^2)	-16736	-25291	-25108	-25388	-24269

Table 2. Computed AIC for the fitted PDFs for CG/KSAT/7/1278 with identified outliers removed (best fits shown in bold).

n =1256	Exponential	Lognormal	Weibull	Loglogistic	Gamma
e	1131	-716	-656	-880	-791
D_{50} (mm)	3582	2610	3127	2565	3331
K (mm^2)	-17532	-24883	-24701	-24972	-23946

Table 3. Best fit PDF (Equation 2) for key parameters of CG/KSAT/7/1278.

Fitted parameters	with the outliers included (n = 1278)			with outliers removed (n = 1256)		
	e	D_{50} (mm)	K (mm^2)	e	D_{50} (mm)	K (mm^2)
μ	-0.59	-0.71	-12.49	-0.59	-0.74	-12.48
σ	0.18	0.69	1.74	0.17	0.67	1.66

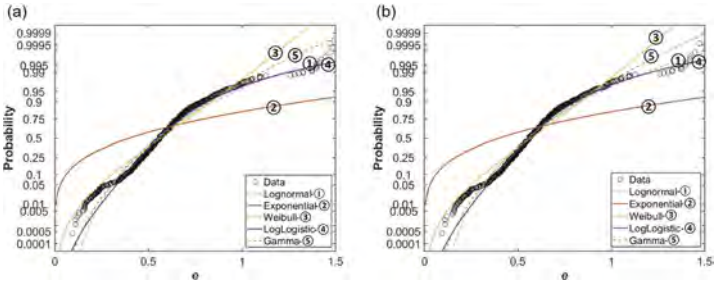

Figure 1. (a) Probability plot with PDFs fitted to data of e from CG/KSAT/7/1278 (n =1278), (b) Probability plot with PDFs fitted to data of e from CG/KSAT/7/1278 with identified statistical outliers removed (n =1256).

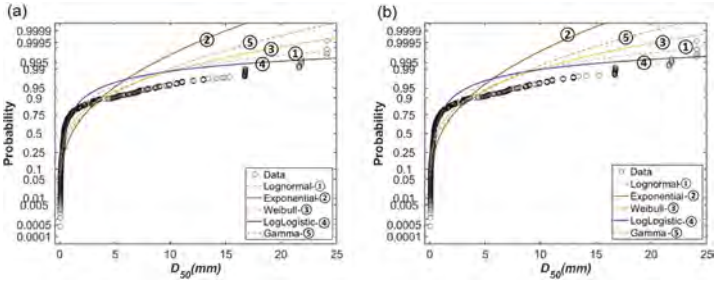

Figure 2. (a) Probability plot with PDFs fitted to data of D_{50} (mm) from CG/KSAT/7/1278 (n =1278), (b) Probability plot with PDFs fitted to data of D_{50} (mm) from CG/KSAT/7/1278 with identified statistical outliers removed (n =1256).

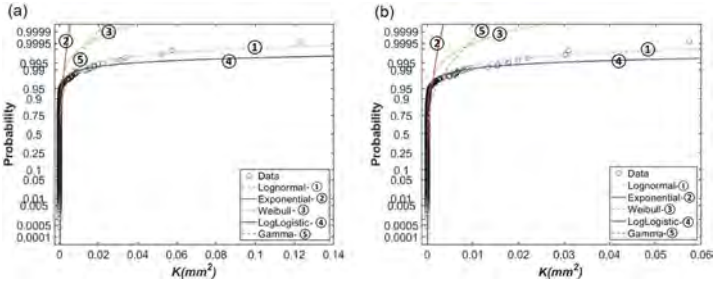

Figure 3. (a) Probability plot with PDFs fitted to data of K (mm^2) from CG/KSAT/7/1278 (n =1278), (b) Probability plot with PDFs fitted to data of K (mm^2) from CG/KSAT/7/1278 with identified statistical outliers removed (n =1256).

3 GRADING ENTROPY

The grading entropy approach was presented to investigate granular soil dry bulk density (e.g. Lőrincz 1990) and has subsequently been used to study a range of geotechnical problems (e.g. Lőrincz et al. 2005, Imre et al. 2009, Imre et al. 2012 and McDougall et al. 2013). Lőrincz

et al. (2005) and Imre et al. (2009) give a detailed introduction of the framework (which characterizes disorder in soil particle size distributions) and full derivation of grading entropy parameters. The grading entropy S of a soil mixture is given by (form of the equations are shown as in Singh 2014, pp. 324-328):

$$S = S_0 + \Delta S \tag{3}$$

where S_0 = base entropy:

$$S_0 = \sum_{i=1}^{N} x_i \log_2 C_i \tag{4}$$

where N = number of fractions, x_i = relative frequency of fraction i, C_i = number of elementary statistical cells contained in fraction i. The entropy increment ΔS is:

$$\Delta S = -\sum_{i=1}^{N} x_i \log_2 x_i \tag{5}$$

the base entropy S_0 and the entropy increment ΔS helps explain the relative spread of the grain sizes and explains the relative distribution of the particles. The normalised grading entropy coordinates A and B are:

$$A = \frac{\sum_{i=1}^{N} x_i(i-1)}{N-1} \tag{6}$$

$$B = -\frac{\sum_{i=1}^{N} x_i \log_2 x_i}{\log N} \tag{7}$$

Feng et al. (2019) used the normalised grading entropy parameters (A, B) to assess the hydraulic conductivity for a granular soil mixture. O'Kelly & Nogal in their discussion of Feng et al. (2019) proposed the addition of the e alongside A and B for hydraulic conductivity prediction (Feng et al. 2020). O'Kelly & Nogal (2020) applied their three-parameter approach to test data on a wider range of granular materials than was presented in Feng et al. (2019, 2020). Feng et al. (2021) then investigated the influence of using the grading entropy parameter (S) along with the percentage air voids to assess asphalt concrete hydraulic conductivity using a large database. Imre et al. (2021) used the un-normalised grading entropy coordinates and determined iso-lines for the saturated k.

The grading entropy parameters for data from CG/KSAT/7/1278 were calculated with the width of the elementary cell (d_0) assumed to be 2^{-22}mm following Imre et al. (2009). Figures 4 and 5 present the normalised and non-normalized grading entropy diagram for the database CG/KSAT/7/1278. Figure 4 shows that the permeability levels exhibit an increasing trend with higher S_0 value and lower ΔS value. Such variation of permeability level is less distinct on the normalised grading entropy diagram (Figure 5). It was observed that datapoints with lower permeability level (i.e. categories 'very low', 'practically impermeable') mostly are aggregated around the A = 2/3 on the normalised grading entropy diagram, which according to Lőrincz (1990) represent mixtures with the maximum density for a given fraction number N, concerning a fixed distribution type (e.g., fractal distribution, non-fractal distribution).

4 CONCLUSIONS

Some statistical analysis of the coarse-grained soil database CG/KSAT/7/1278 has been presented in this paper. The main findings from this study are:

(a) the 'Loglogistic' function is the best fit PDF (of those trialled) for the e, D_{50} and K data from CG/KSAT/7/1278.
(b) The influence of the identified statistical outliers was found to be minimal on the best fit PDFs.

(c) On the normalised grading entropy diagram (A versus B), the K categories are less distinguishable than on the un-normalised grading entropy diagram (ΔS versus S_0) for the studied data.

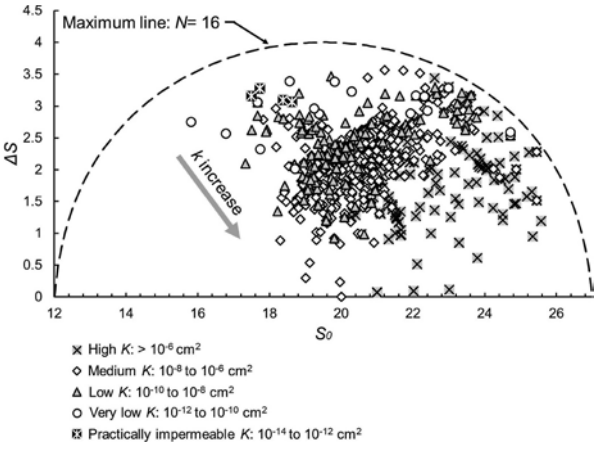

Figure 4. Grading entropy diagram; K categorization based on the categorization system given in Lambe & Whitman (1969, p. 288).

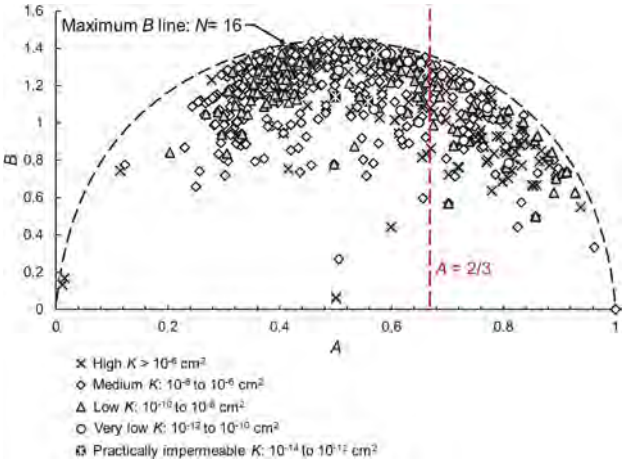

Figure 5. Normalised grading entropy diagram; K categorization based on the categorization system given in Lambe & Whitman (1969, p. 288).

Preparing CO_2 hydrate-bearing sand specimens using dissolved gas and its properties

S. Kimoto
Osaka Sangyo University, Osaka, Japan

Y. Yoshida
Toyota Tsusho Corporation, Tokyo, Japan

ABSTRACT: Various projects related to gas hydrate, such as methane hydrate resource development and carbon dioxide underground storage using gas hydrate, are attracting attention. Various laboratory tests have been conducted using artificially prepared hydrate-containing sand samples to investigate the mechanical properties of gas hydrate-containing ground. In this study, we focused on the hydrate formation process and morphologies, and prepared CO_2 hydrate-bearing sand specimens by the dissolved gas method. In addition, undrained triaxial compression tests were performed using the prepared specimens. From the test results, hydrate-bearing specimens with the value of hydrate saturation ranged from 3.4% to 8.8% were made. The stress-strain behavior and the effective stress path were almost the same as that of the hydrate-free specimen.

1 INTRODUCTION

Various laboratory tests have been carried out on the mechanical properties of gas-hydrate-containing ground. Since the data of the mechanical test using the natural hydrate-containing samples collected by the pressure core is limited, various mechanical tests using the gas hydrate-containing specimens artificially prepared are carried out. Several methods can form hydrates artificially in ground materials in a laboratory. The most commonly used method is the partial water saturation method, which can prepare a specimen with high hydrate saturation in a short time (Waite et al., 2009). However, the formation process may be different from that in nature because it produces hydrates in excess gas condition. In this study, we attempted to prepare sand specimens containing CO_2 hydrate by the dissolved gas method. In this method, the formation process is similar to that in nature in the sense that hydrate is formed from the gas aqueous solution in excess water condition. In addition, undrained triaxial tests were conducted for understanding the mechanical properties.

2 TESTING PROCEDURE

2.1 *Dissolved gas method and testing apparatus*

In the dissolved gas method, hydrate is formed by passing a saturated CO_2 aqueous solution through the specimen and cooling it to the temperature in the hydrate stable region. In this method, hydrate is formed by utilizing the fact that the gas solubility in the presence of hydrate decreases with decreasing temperature. Figure 1 shows the temperature dependence of CO_2 solubility in each phase at 2.0 MPa. As shown in the figure, the solubility of CO_2 decreases at low temperatures in the presence of hydrate, so the excess dissolved gas precipitates as hydrate. To

increase the hydrate saturation rate, it is important to cool the CO_2 saturated aqueous solution to increase gas concentration.

A schematic view of a low-temperature and high-pressure triaxial apparatus (Iwai et al. 2018), used in this study is shown in Figure 2. In this study, a circulation tank (No. (13) in

Figure 2) was newly added as a cooling system for the containers and routes involved in the preparation and water flow of the CO_2 aqueous solution indicated by the red line in the figure.

2.2 *Sample preparation*

Toyoura sand with a water content of 16.0% is used as the host soil. The specimen is molded to a diameter of 35 mm and a height of 70 mm and frozen for 24 hours. The initial void ratio is 0.75. After the specimen is placed in the cell, the void is replaced with a saturated aqueous CO_2 solution under the conditions of a temperature of 8 °C or 20 °C and a pressure of 2.8 MPa. After that, hydrate is formed by continuing to pass the aqueous solution from the lower part (tank (4) in Fig. 1) to the upper part (tank (3) in Fig. 1) of the specimen while keeping the specimen temperature at 1 to 4 °C and the gap pressure at the upper part of the specimen at 2.8 MPa. Table 1 shows the preparation conditions for the specimen. The tests were conducted with different the cooling temperature and the water flow time. Case-MD represents a case where a monotonic loading test and a thermal dissociation test are performed, and Case-D represents a case where only a thermal dissociation test is performed.

After hydrate formation, in the series of Case-MD, shear is performed under undrained conditions at a pore pressure of 10 MPa, a cell pressure of 12 MPa, and a strain rate of 0.1%/min. After that, the pore pressure is adjusted to 2.8 MPa and the cell pressure is adjusted to 3.3 to 4.8 MPa, and the temperature of the cell water is raised from 1 °C to 20 °C in an isotropic state to dissociate the hydrate in the specimen. CO_2 hydrate equilibrium curve and temperature-pressure paths is shown in Figure 3.

2.3 *Calculation of hydrate saturation*

After the test is completed, the CO_2 gas generated from the specimen is collected and the hydrate content is calculated from the volume. In order to consider the amount of dissolved gas, the hydrate content was calculated from the difference from the recovered gas volume of Case-D0 and Case-MD0, in which hydrate formation process were not carried out after replacing the void with an aqueous solution. To describe the hydrated contest in the pore space, hydrate saturation, S_r^H, is defined as the ratio of hydrate volume to void volume. The recovery volume and the calculated hydrate saturation, S_r^H, is shown in Table 1. The value of hydrate saturation, S_r^H, ranges from 3.4% to 8.8%.

3 TEST RESULTS

Figure 4 shows the change in the amount of water flow of the aqueous solution and the change in the hydraulic conductivity during the hydrate formation process. It was confirmed that the hydraulic conductivity decreased with the passage of the aqueous solution. This is the effect of solid hydrate blocking the flow path of the aqueous solution. In Case-MD1 and MD3 using an aqueous solution saturated at 8 °C, the decrease in hydraulic conductivity was remarkable. The reason why the hydraulic conductivity increases and decreases repeatedly in Case-D4 is that the water flow is continued while the obstruction is cleared each time by the backflow of the aqueous solution. Figure 5 shows the pore pressure-temperature relationship and axial strain-temperature relationship during dissociation by thermal stimulation. With the hydrate equilibrium curve as the boundary, the interstitial pressure increased sharply, and at the same time, the axial strain increased significantly in the expansion. This is because CO_2 gas was generated by the dissociation of hydrate.

Figure 6 shows the stress-strain relationships and effective stress paths in the shear process. No change in mechanical properties was confirmed with or without hydrate formation. The increase in strength due to the inclusion of hydrate has not been confirmed under the hydrate saturation, S_r^H, of 3.4 %.

4 CONCLUSIONS

In this study, CO_2 hydrate-bearing sand specimen was prepared by the dissolved gas method. From the test results, hydrate was formed in the void of sand specimen and the value of hydrate saturation ranged from 3.4% to 8.8%. From the triaxial tests, the increase in strength due to the inclusion of hydrate has not been confirmed. Hydrates may be formed in the void of sand grain and did not affect mechanical properties in the range of hydrate saturation.

Reconstruction of isotropic Cam-clay model based on finite deformation theory

Y. Abe, S. Yamada & T. Kyoya
Tohoku University, Sendai, Japan

ABSTRACT: This study reconstructs isotropic Cam-clay model based on multiplicative decomposition of the deformation gradient. The aim of the reconstruction is a formulation considering the existence of the state boundary surface in Cauchy stress – specific volume space, which is a basic experimental fact of Cam-clay model. For this purpose, we define a hyperelastic strain energy function per unit volume in the intermediate configuration and formulate using zeta stress and Eshelby-zeta stress derived by considering the non-negativeness of plastic dissipation. This study also constructs an implicit stress update algorithm for the model and derives the tangent modulus consistent with the algorithm to incorporate the proposed model into a finite element analysis code. Moreover, this study demonstrates the significance of the proposed model by comparing an existing model using Kirchhoff stress, and verifies the stress update algorithm.

1 GENERAL INSTRUCTIONS

In the framework of finite deformation elastoplasticity, several researchers (Borja et al. 1998, Yamakawa et al. 2010) have formulated the Cam-clay model using multiplicative decomposition of the deformation gradient and a hyperelastic constitutive law. However, these pioneering works have not fully considered the volume change of the intermediate configuration. Due to this, the formulations in the previous studies cannot guarantee the existence of the state boundary surface, which plays an important role in the derivation of the Cam-Clay model.

Therefore, this study reconstructs the isotropic Cam-clay model that can explain the existence of state boundary surface using zeta and Eshelby-zeta stresses, which are derived by considering the volume change of the intermediate configuration in terms of the non-negativeness of plastic dissipation with referring to Bennett et al. (2016). To verify the validity of the proposed model, numerical analysis using a finite element analysis code that implements the constructed model is performed.

2 FORMULATION OF THE ISOTROPIC CAM-CALY MODEL BASED ON FINITE DEFORMATION THEORY

2.1 *Definition of main kinematic quantities*

The formulation is given in the framework of finite deformation elastoplasticity based on the multiplicative decomposition of the deformation gradient. The deformation gradient is multiplicatively decomposed into elastic and plastic components $\boldsymbol{F} = \boldsymbol{F}^e\boldsymbol{F}^p$.

The elastic left Cauchy-Green tensor $\boldsymbol{b}^e \left(= \boldsymbol{F}^e(\boldsymbol{F}^e)^T\right)$ referring to the current configuration can be spectrally decomposed as follows:

DOI: 10.1201/9781003299127-30

$$\boldsymbol{b}^e = \sum_{\alpha=1}^{3} (\lambda_\alpha^e)^2 \boldsymbol{n}_\alpha \otimes \boldsymbol{n}_\alpha \tag{1}$$

where $(\lambda_\alpha^e)^2$ and $\boldsymbol{n}_\alpha$ are the eigenvalues and eigenvectors of $\boldsymbol{b}^e$, respectively. $\varepsilon_\alpha^e = \ln \lambda_\alpha^e$ is defined as the elastic principal logarithmic strain.

The elastic logarithmic volume strain $\varepsilon_{\mathrm{v}}^e = \varepsilon_\alpha^e \delta_\alpha$ ($\delta_\alpha = 1$) and the elastic logarithmic shear strain $\varepsilon_{\mathrm{s}}^e = \sqrt{2/3 \varepsilon_{\mathrm{dev},\alpha}^e \varepsilon_{\mathrm{dev},\alpha}^e}$ are defined as invariants of the elastic principal logarithmic strain. Note that $\varepsilon_{\mathrm{dev},\alpha}^e = -\left(\varepsilon_\alpha^e - (1/3)\varepsilon_{\mathrm{v}}^e \delta_\alpha\right)$ is the elastic deviatoric principal strain.

2.2 *Hyperelastic constitutive law and plastic flow rule*

To formulate using the hyperelastic constitutive law, a special form of the hyperelastic model proposed by Houlsby et al. (2005) is applied to the elastic part. A hyperelastic strain energy function per unit volume in the intermediate configuration $\bar{\Psi}$ is defined as follows:

$$\bar{\Psi} = \tilde{\kappa}^* p_r \exp\left[\frac{1}{\tilde{\kappa}^*}\left(\varepsilon_{\mathrm{v}}^e + \frac{3}{2}\tilde{\mu}\left(\varepsilon_{\mathrm{s}}^e\right)^2\right)\right] \tag{2}$$

where $\tilde{\kappa}^*$ is the swelling index in the $\ln \mathrm{v} - \ln p^\zeta$ plane and there is a relationship $\tilde{\kappa}^* = \tilde{\kappa}/(1-\tilde{\kappa})$ using the swelling index $\tilde{\kappa}$ in the $\ln \mathrm{v} - \ln p$ plane. p_r is the reference stress and $\tilde{\mu}$ is the dimensionless shear modulus. A hyperelastic constitutive law is defined as follows:

$$\zeta = 2\frac{\partial \bar{\Psi}}{\partial \boldsymbol{b}^e}\boldsymbol{b}^e \tag{3}$$

where $\boldsymbol{\zeta}$ is defined as $\boldsymbol{\zeta} = J^e \boldsymbol{\sigma}$ and referred to as zeta stress.

To satisfy the non-negativeness of plastic dissipation, the plastic velocity gradient tensor $\boldsymbol{l}^p \left(= \boldsymbol{F}^e \dot{\boldsymbol{F}}^p (\boldsymbol{F}^p)^{-1} (\boldsymbol{F}^e)^{-1}\right)$ is specified by the associated flow rule as follows:

$$\boldsymbol{l}^p = \dot{\gamma}\frac{\partial f}{\partial \xi} \tag{4}$$

where $\dot{\gamma}\,(\geq 0)$ is the plastic multiplier. ξ is defined as $\xi = \zeta - \bar{\Psi}\boldsymbol{I}$ and referred to as Eshelby-zeta stress.

2.3 *Hardening rule and yield function*

To make the normal consolidation line straight on the $\ln \mathrm{v} - \ln p^\zeta$ plane, the isotropic hardening rule is given by using the yield mean stress p_{c}^ξ and the plastic logarithmic volumetric strain $\boldsymbol{\varepsilon}_{\mathrm{v}}^p$:

$$p_{\mathrm{c}}^\xi = p_{\mathrm{c0}}^\xi \exp\left[\tilde{\theta}^*\left(\varepsilon_{\mathrm{v}}^p - \varepsilon_{\mathrm{v0}}^p\right)\right] \tag{5}$$

where $\tilde{\theta}^* = 1/(\tilde{\lambda}^* - \tilde{\kappa}^*)$. $\tilde{\lambda}^*$ is the compression index on the $\ln \mathrm{v} - \ln p^\zeta$ plane and has the relationship $\tilde{\lambda}^* = \tilde{\lambda}/(1-\tilde{\kappa})$ with the compression index $\tilde{\lambda}$ on the $\ln \mathrm{v} - \ln p$ plane. Note that the subscript 0 indicates the initial value.

The yield function of the modified Cam-Clay model is adopted in the Eshelby-zeta stress space

$$f(\xi, p_{\mathrm{c}}^\xi) = \frac{p^\xi}{p_{\mathrm{r}}}\frac{\left(\mathrm{M}^\xi\right)^2 + \left(\eta^\xi\right)^2}{\left(\mathrm{M}^\xi\right)^2} - \frac{p_{\mathrm{c}}^\xi}{p_{\mathrm{r}}} \tag{6}$$

where p^{ξ} and η^{ξ} are the mean stress and stress ratio with respect to the Eshelby-zeta stress, respectively. M^{ξ} is expressed as $M^{\xi} = (1 - \tilde{\kappa})M$ using the critical state constant M in the Cauchy stress space.

This study formulates the constitutive model by describing the above basic lows/rules using principal values and axes of several tensors. For finite element analysis, an implicit stress updating algorithm is developed and tangent modulus consistent with the algorithm is derived.

2.4 *State boundary surface*

The state boundary surface can be obtained from the above basic laws/rules as follows:

$$\ln v = \ln N - \tilde{\lambda} \ln \frac{p}{p_r} - \frac{\tilde{\lambda} - \tilde{\kappa}}{1 - \tilde{\kappa}} \ln \frac{M^2 + \eta^2}{M^2} + (1 - \tilde{\lambda}) \frac{\eta^2}{6\tilde{\mu}} \tag{7}$$

i.e. the specific volume v is uniquely determined for the current Cauchy stress during yielding.

3 NUMERICAL ANALYSIS EXAMPLES

3.1 *Comparison with existing model: Isotropic compression*

In this verification, a soil is isotropically compressed with initial specific volume varying from 2.7 to 2.4 in increments of 0.1. Figures 1a and 1b indicate that in both the Eshelby-zeta stress - specific volume and Cauchy stress - specific volume spaces, the normal consolidation line of the proposed model is uniquely determined regardless of the difference in the initial specific volume. In contrast, Figures 1c and 1d illustrate that the normal consolidation line of the

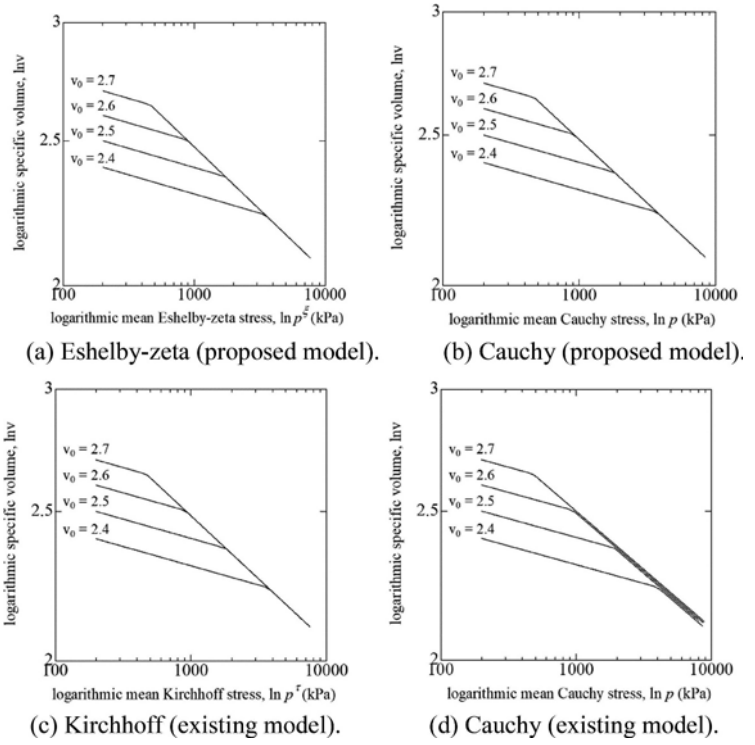

Figure 1. Mean stress - specific volume relationship.

existing model is uniquely determined in Kirchhoff stress - specific volume space, but not in Cauchy stress - specific volume space.

3.2 *Comparison with existing model: Drained and undrained triaxial compression shear*

In this verification, a drained triaxial compression shear is first applied to a normally consolidated clay until the axial strain reaches 50% under constant lateral pressure in a uniform deformation field. Next, undrained shear is performed separately, setting the initial specific volume to the specific volume when the axial strain reaches 50% in the drained triaxial compression shear.

Since the specific volume is constant during undrained shear, the specific volumes at the critical states of the two analyses coincide under such conditions. The stress states at the critical state of the two models are compared. Figures 2a and 2b indicate that the critical states for the drained triaxial compression and undrained shear coincide in both Eshelby-zeta and Cauchy stress spaces in the proposed model. On the other hand, as shown in Figures 2c and 2d, in the existing model, the critical states for both tests coincide in the Kirchhoff stress space, but not in the Cauchy stress space. This difference emerges depending on the existence of the state boundary surface in Cauchy stress - specific volume space.

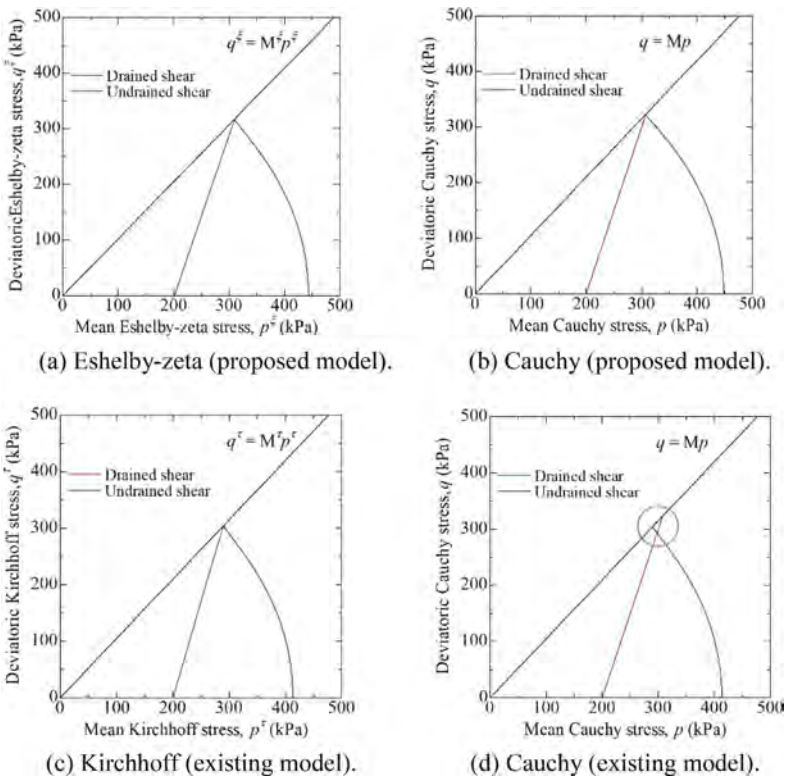

Figure 2. Mean stress - shear stress relationship.

4 CONCLUSION

This study has formulated the isotropic Cam-Clay model based on the multiplicative decomposition of the deformation gradient and using zeta and Eshelby-zeta stresses so that the model has the state boundary surface. Comparison with the existing model using Kirchhoff stress shows the necessity of the state boundary surface in the Cauchy stress - specific volume space.

Critical state parameters for a saturated lateritic clay

D.B. Akinniyi & M. Bagheri
Coventry University, UK

ABSTRACT: The critical state soil mechanics is the most useful framework for understanding responses of different soil type to mechanical stress. For lateritic soil, widely distributed soil in the tropics and well recognized for its rich composition in oxides of iron and aluminum (sesquioxide), its mechanical behaviour has not been well studied within this framework. Therefore, a good understanding of the compressibility and shear strength properties of the lateritic soil would improve the designs of structures built on it. This paper presents experimental data from isotropic compression and consolidated undrained triaxial tests on saturated samples of lateritic soil from Nigeria. The data from these tests are presented and interpreted within the critical-state framework. Effects of sesquioxide composition on the compressibility and dilatancy is reported and discussed.

1 INTRODUCTION

The critical-state concept is a very important framework for interpreting the behaviour of saturated soils (Schofield & Wroth, 1968). When a soil undergoes shearing, it reaches a state where it continues to deform at constant stress and constant void ratio. This state is the critical state and for most soils, the critical state is reached at large strains above 25%. The conventional understanding is that when a soil is sheared to such a large strain i.e. above 25%, the effects of fabric on the soil behavior should have been erased. Therefore, the strength parameters obtained at this critical state is independent of soil fabric and is unique for each soil type (Atkinson, 1993). The determination of the critical state line for a soil can aid the interpretation of its mechanical behavior especially during shearing. For instance, a soil specimen whose initial state lies above the critical state line in the v-ln p' compression plane is considered wet/loose and according to critical state soil mechanics, a strain-hardening and contraction behavior is expected during drained shearing. For soil specimen whose initial state falls below the critical state line in the same plane, a strain softening and a dilative behavior is expected during drained shearing (Atkinson, 1993).

The critical state theory has been used to interpret the mechanical behavior of many soil type and their unique parameters has been determined (Ng & Chiu, 2001 & 2003; Wheeler & Sivakumar, 1995; Gan & Fredlund, 1996). However, for lateritic soil, a type of soil that is found in many region of the world, there are very few studies investigating its behavior within the critical state framework. Although, there has been several studies on the mechanical behavior of the lateritic soil (Ng et al., 2019; Otalvaro et al., 2015; Futai & Almeida, 2005; Toll, 1990), still there is a wide variation in the shear strength parameters available in the literature. While most authors stop shearing the test at a small strain between 1% and 5%, others adopt the Mohr Coulomb theory for interpretation of the shear result. In Africa, unconfined compression test is one of the most common shear test conducted on lateritic soil and the maximum shear strain is generally less than 10% (Owolabi & Aderinola, 2014; Ola, 1978;). In Brazil, some authors conducted undrained and drained triaxial testing on both compacted and intact lateritic soil specimen (Fagundes & Rodrigues, 2015; Futai et al. 2004). However, majority of these authors studying lateritic soil adopted Mohr-Coulomb theory rather than the critical state framework. As such, the strength parameters in the literature are mostly peak state parameters which are dependent on the initial fabric, (water content and

DOI: 10.1201/9781003299127-31

sample preparation technique) of the specimen. To understand the behavior of lateritic soil more explicitly, determining unique critical state parameters is therefore important.

Furthermore, the lateritic soil is also well recognized for its rich composition in oxides of iron and aluminum (sesquioxide) (Gidigasu, 1976). The soil, even though a fine material, contains large particles which results from the aggregation influence of its sesquioxide content (Zhang et. al., 2014). Thus, the lateritic soil is a highly structured material depending on the quantity of the sesquioxide content. Previous researchers working on highly structured soil found that the critical state may be impossible to reach even if shearing exceeds 25%. According to previous researchers (Ferreira & Bica, 2006; Martins et al. 2001), the fabric of highly structured soil maybe difficult to erase and therefore no unique parameter may be determined and determining critical state parameters may be unrealistic. There are very few authors who have sheared the lateritic soil to such large strain, therefore, it is still not clear if critical state parameters could be determined for lateritic soil.

In this paper, a compacted and saturated lateritic clay from Nigeria undergoes isotropic compression and undrained shearing test at three different confining stresses. The results were interpreted within the critical state framework, a critical state line and its parameters were determined.

2 TEST MATERIAL

Disturbed sample of lateritic clay from Southwest, Nigeria was collected and tested in this study. Large aggregates in the collected samples were broken down and the soil was sieved through 2mm ASTM standard sieve. Particles larger than 2mm were discarded and not used for the determination of the geotechnical index properties and the shearing test. The index properties of the soil were determined following the ASTM standard (ASTM, 2011). Due to possible aggregation as a result of the sesquioxide content in lateritic soil, wet sieving and hydrometer method were used to determine the particle size distribution and a sodium hematophospate was added to the solution as dispersant to separate soil aggregates. The coarse and fine fractions of the tested soil are 42% and 58% respectively. Details of other index properties of the soil are summarized in Table 1. The soil was classified as a sandy lean clay (CL) (ASTM D2487, 2011). The sesquioxide content in the tested soil was determined using X-ray fluorescence test and quantified to be 38%.

3 SPECIMEN PREPARATION AND TEST PROGRAMME

A total number of 6 specimens was prepared for the isotropic compression and undrained shearing tests using static compaction method. Each specimen was compacted in 10 layers at 19% compaction water content to a dry density of 74% of the proctor maximum. Specimen uniformity was ensured by adopting the under-compaction method of preparation proposed by Ladd (1978).

Two series of tests were carried out in a triaxial apparatus, the first series is isotropic loading and unloading tests to obtain the compressibility parameters. The second series is consolidated undrained (CU) shear test to investigate the shear behaviour and obtain the critical state strength parameters. For the shear test, normally consolidated specimen and over-consolidated specimen were tested in order to understand the influence of stress history on the shear behaviour of the tested material. The normally consolidated specimen were sheared at three different confining stresses (50, 100 and 200 kPa). The over-consolidated specimen were sheared at 50kPa confining stress after been loaded and unloaded to achieve over-consolidation ratio of 5 and 7. Details of the test are summarized in Table 2.

4 TEST PROCEDURES

After specimen preparation, a porous stone was placed underneath and on top of the specimen and carefully placed on the base pedestal of the triaxial apparatus. The specimen was flushed with

CO_2 and de-aired water respectively, then back pressure was applied to fully saturate the specimen. The minimum back pressure used in all the test was 250 kPa and minimum B value achieved for all the saturated specimen is 0.97. There was no measurement of volume change during saturation.

For the isotropic loading test, the following confining pressures were applied in stages: 15, 25, 50, 100, 200, 300, 400 kPa. Unloading was done at 250 and 350 kPa respectively to take the specimen back to 50 kPa given a OCR value of 5 and 7 respectively. After isotropic compression test, consolidated undrained shearing test was carried out. After bringing each specimen to the design effective stresses, drainage valves were closed after the excess pore water pressure has been dissipated, then an undrained shearing test was performed. The strain rate was 0.04 mm/min during the shearing process.

5 DISCUSSION OF RESULTS

5.1 *Isotropic loading and unloading*

Figure 1 shows the response of the lateritic specimen to isotropic loading and unloading. At first, a gradual change in specific volume is observed as the effective mean stress increases. Then, a yield point is reached and the specific volume begins to reduce abruptly. The yield stress corresponding to the yield point is estimated to be 80 kPa using Casangrande's graphical method. At 100 kPa effective stress, the specimen is unloaded in stages to 50 kPa and a very slight increase in the specific volume is observed. The specimen is compressed again

from 50 kPa in stages to 300 kPa effective mean stress and then unloaded back to 50 kPa. A post yield isotropic normal compression line (NCL) is determined and its slope (usually denoted as λ) is estimated as 0.07. The slope of the unloading curve is also estimated to be 0.013. The value of λ obtained in this study is compared with the saturated compressibility of some other compacted lateritic soils reported in the literature and summarized in this study are summarized in Table 3. It is clear that the compressibility of lateritic soils varies significantly with particle sizes. The lateritic soil in this study have the least compressibility even though it contains significant amount of clay compared other soils in the Table 3.

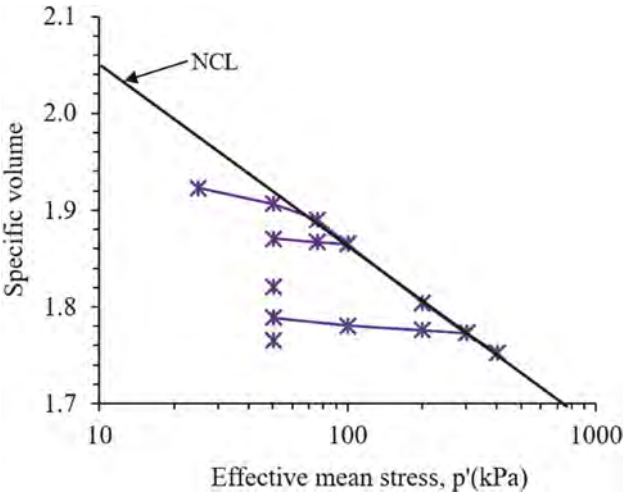

Figure 1. Isotropic compression behavior of the tested specimen.

The reason for this low compressibility of the lateritic soil in this study may be due to the influence of its 38% sesquioxide composition. The sesquioxide content in most lateritic soils is not often quantified, thus, comparing compression behavior may be misleading. The sesquioxide enhances aggregation, hence larger particles are formed and specimen may behave as a coarse grained material (Zhang et al., 2016).

Table 3. Comparison of compression index of compacted lateritic soils.

Lateritic soil types	λ	Parent rock
Sandy lean clay (this study)	0.08	Granitic (Igneous)
Gravel (Toll, 1990)	0.11	Basalt (sedimentary)
Clayey silt (Otalvaro et al., 2015)	0.16	Paranoá (meta-sedimentary)
Clayey sand 1 (Bennatti et al., 2013)	0.15	Colluvium (sedimentary)
Clayey sand 2 (Futai & Almeida, 2005)	0.18	Gneiss (sedimentary)

Figure 2 shows the initial condition of the specimen before shearing. It is noted that all the normally consolidated (NC) specimen lies close to the NCL line determined during isotropic compression. The over-consolidated specimens lies farther away from the NCL compared to the NC specimens.

5.2 *Shear behavior of the normally consolidated specimen*

Figure 3a shows the stress-strain relationship during undrained shearing of the lateritic specimens at three confining stresses. At 50 kPa confining stress, the deviator stress increases monotonically with the axial strain and no sign of softening is observed till the end of the test. The behavior at

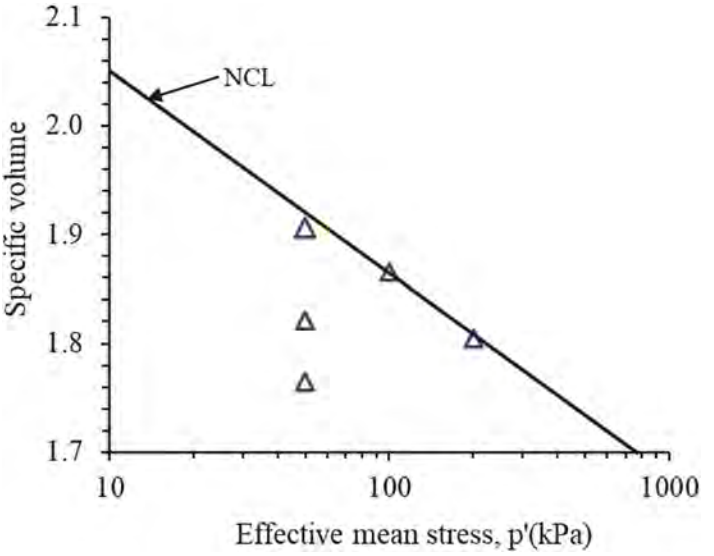

Figure 2. States of all saturated specimens before shearing.

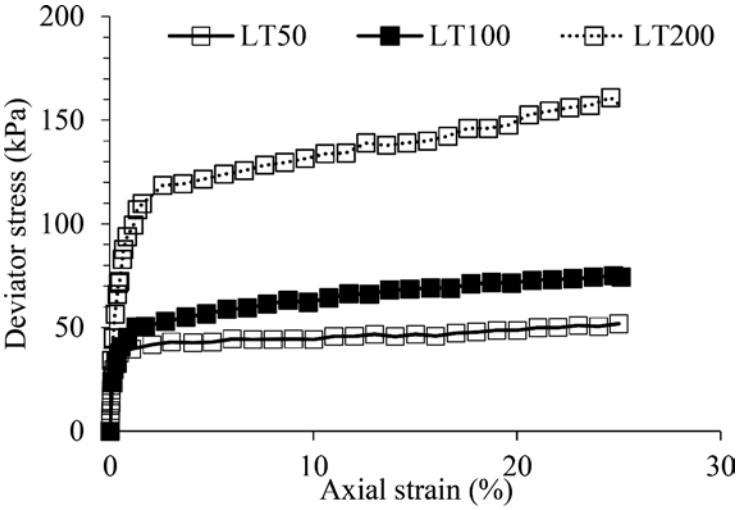
50 kPa is generally referred to as a strain hardening behaviour and this is consistent with the critical state framework for normally consolidated specimen. At 100 kPa and 200 kPa confining stress, a similar strain hardening behaviour with no evidence of softening is observed. As expected, maximum deviator stress increases with confining stress. It can also be observed that the deviator stresses at the three confining stresses are still changing slightly towards the end of the test suggesting a true critical state has not been reached. However, the rate of increase in deviator stress at 50 and 100 kPa towards the end of the test has reduced significantly. The behaviour of the studied soil may be due to the influence of the sesquioxide content which may enhance aggregation of particles (Zhang at al., 2004). Due to aggregation, the fabric of the soil may require larger shear strain to fully reach critical state.

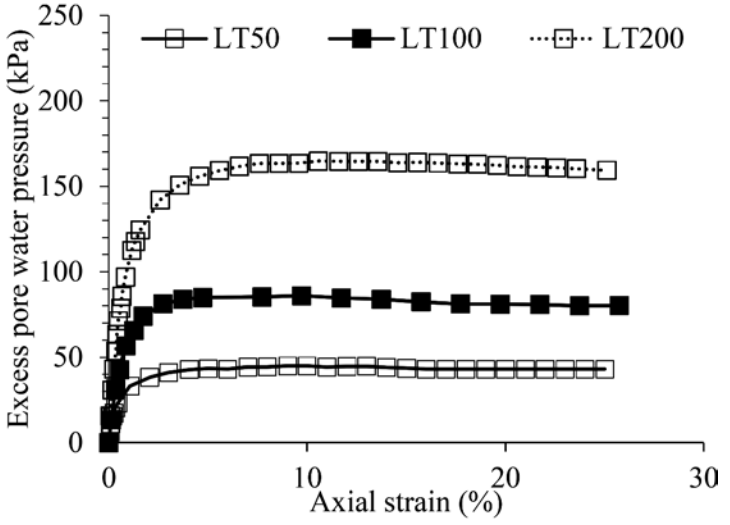
Figure 3b shows the relationship between the excess pore water pressure and the axial strain during the undrained shearing test at all confining stress. At 50 kPa, the specimen shows initial build-up of positive excess pore water pressure, it reaches a peak and then a slight drop from peak is observed till the end of the test. The initial build-up of the pore pressure indicate that specimen exhibit a contractive tendency while the slight reduction indicates a dilative tendency. At other confining stresses, similar behavior observed at 50 kPa is observed in all the specimen. A barreling type of failure was observed in all the specimen after testing. All these observations are consistent with critical state framework for soils sheared at normally consolidated state (Atkinson, 1993).

5.3 *Shear behavior of the over-consolidated specimen*

The stress strain relationship of the over-consolidated specimen sheared at confining stress of 50 kPa is shown in Figure 4a. All the specimen showed a strain hardening behaviour despite having different stress histories. It can be seen that the deviator stress increases monotonically with the axial strain and no peak nor sign of softening is observed. As expected, the maximum deviator stress increases with increasing OCR. Most of the specimen are still showing significant change in deviator stress at the end of the state. This indicates that the specimen have not reached the critical state. Lateritic soil may require shearing to a larger strain (above 25%) in order to reach a true critical state. In Figure 4b, the relationship between the excess pore water pressure and the axial strain is shown. It can be seen that positive excess pore water pressure was initially generated in all the specimen. As shearing continues, a reduction in pore water pressure is observed in all the specimen but only the specimen with OCR of 1 and 5 appears to have reached a plateau at the end of the test.



(a)



(b)

Figure 3. (a) Triaxial stress strain and (b) Pore pressure vs strain responses from undrained tests for the normally consolidated saturated lateritic specimen.

5.4 *Phase transformation behaviour*

Figure 5 shows the stress paths of the normally consolidated lateritic specimen during undrained shearing in the q – p′ plane. For all the specimen, the effective mean stress initially reduces (showing a tendency of contraction), then at a later stage, a turning point is reached and phase transformation occurs. Under subsequent shearing, the effective mean stress increases (showing a tendency of dilation, accompanied by an increase in deviator stress) and soil state finally reaches the CSL. The initial contraction is likely attributed to the collapse of large inter-aggregate pores. The subsequent dilative behaviour is due to re-arrangement and interlocking of the large-sized aggregates. Futai & Almeida (2004) also observed a phase

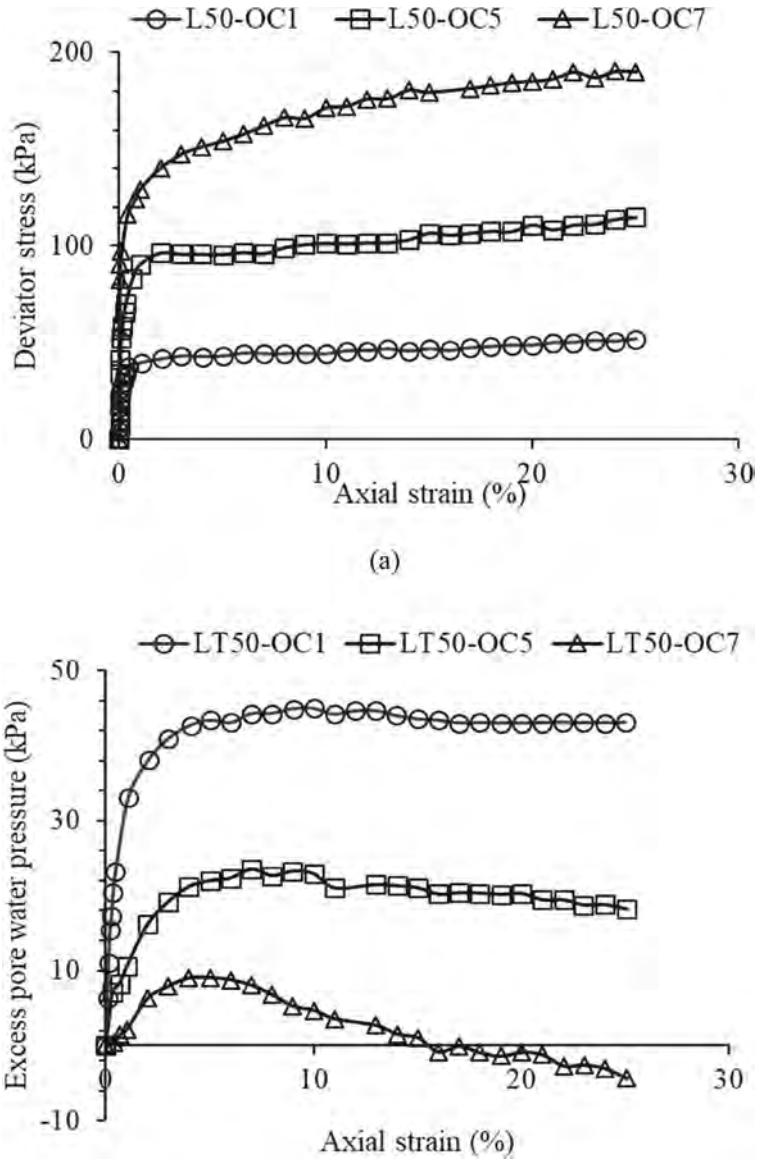


Figure 4. Influence of stress history on the shearing response of the studied lateritic soil (a) stress strain and (b) pore pressure vs strain responses from undrained tests.

transformation behaviour on a saturated and compacted lateritic clay from Brazil. This is likely due to the effect of the aggregates giving the specimen a behaviour typical of coarse-grained material.

Figure 6 shows the stress paths of the specimen at OCR of 1, 5 and 7 during undrained shearing in the q – p′ plane. At 50 kPa confining stress, the effective mean stress of the specimen at OCR of 1 initially reduces indicating a tendency of contract. Under subsequent shearing, the effective mean stress increases (showing a tendency of dilation, accompanied by an increase in deviator stress) and soil state finally reaches the CSL. For the specimens at OCR of 5 and 7, the effective mean stress initially increases indicating a tendency of dilate. Under subsequent shearing, the effective mean stress decreases (showing a tendency of contract, accompanied by an increase in deviator stress).

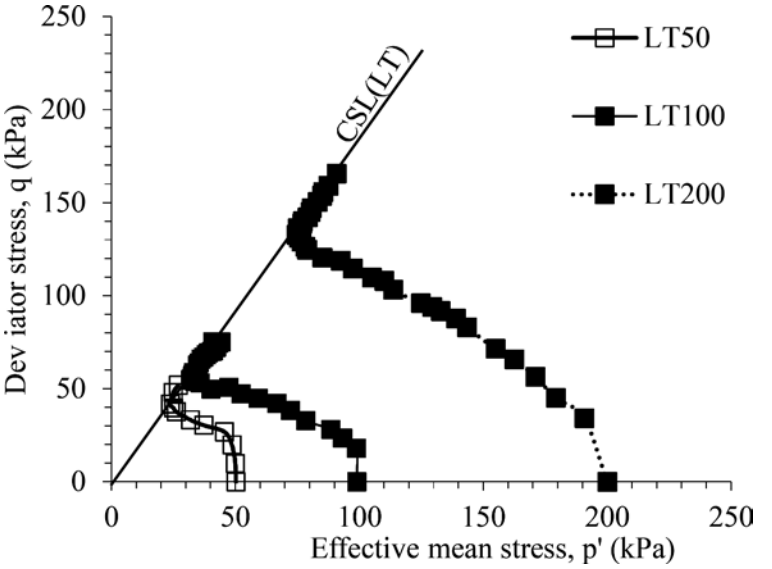

Figure 5. Stress paths of normally consolidated saturated lateritic specimen in q - *p*' space.

According to the stress path shown in Figure 7, the final states of all specimens fall on a single line. The slope of the critical state line, M (commonly referred to as the stress ratio of the critical state) line, is estimated to be 1.73. The corresponding critical state angle of internal friction φ′ is 42° for the studied specimen. The high friction angle is due to the influence of large particles and aggregates in their microstructure.

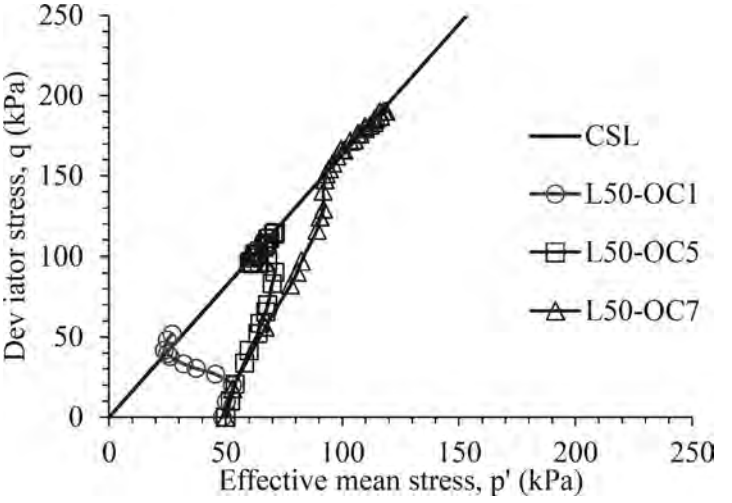

Figure 6. Stress paths of the saturated lateritic specimen at different stress history in q - *p*' space.

Figure 8 presents the stress path of the specimen in the v-ln p' compression plane. The effective mean stress of the normally consolidated specimens shift to the left at the end of shearing indicating a reduction in effective mean stress. On the other hand, the over consolidated specimen shifts to the right indicating an increase in the effective mean stress after shearing. For all the specimen tested in this study, a unique line is determined which is parallel to the slope of the NCL. This line is the critical state line in the compression plane. The slope of the CSL (λ) in this plane, the specific volume (Γ) at p'=1kPa were determined. These two parameters are

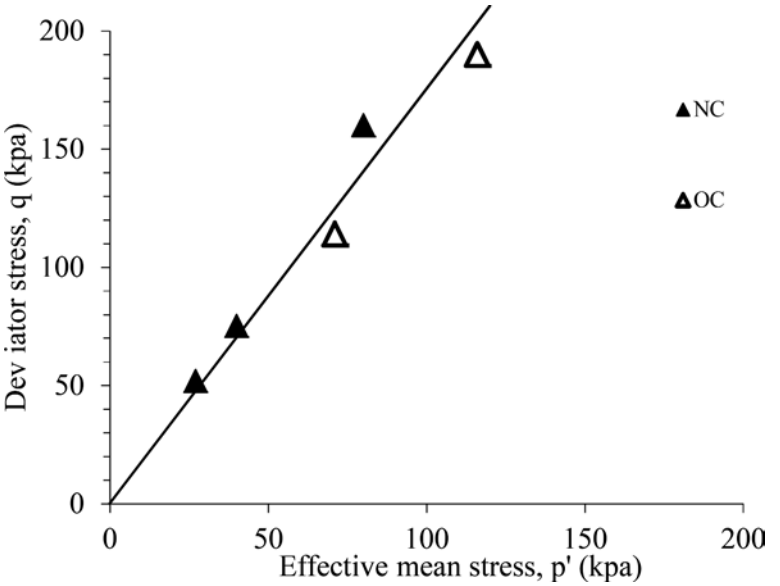

Figure 7. The critical state line of the studied lateritic soil in q – p' space.

critical state parameters and are unique to the soil tested in this study. The critical state parameters obtained for the saturated lateritic specimen tested in this study are summarized in Table 4. These parameters are useful for interpreting the behaviour of lateritic soils.

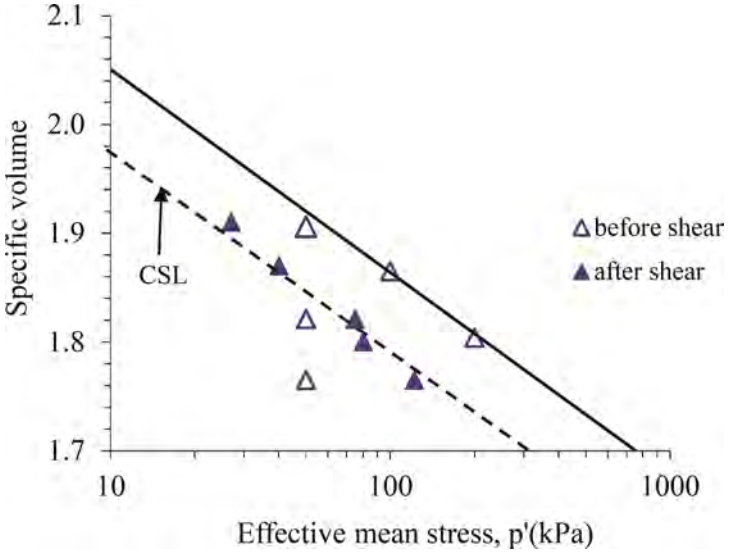

Figure 8. States of all saturated specimens before and after shearing in v – ln p' space.

6 CONCLUSION

In this study, the critical-state parameters for a saturated sample of a lateritic clay were experimentally determined using the conventional triaxial test apparatus. Isotropic compression and consolidated undrained shearing test were carried out on both normally consolidated and

Table 4. Summary of the critical state parameters obtained in this study for the tested lateritic specimen.

*CSL parameters	Lateritic Soil
λ	0.07

N	2.05
M	1.733

* where M is the slope of the projection of the critical-state line in q– p' space, Γ and N are the intercept of the CSL and NCL respectively (at p' = 1 kPa in the v – ln p' space), λ and M are the slope of the projection of the critical-state line in v – ln p' space and q – p' space respectively.

over consolidated specimen. Specimen were fully saturated with a back pressure not less than 200 kPa. At the end of shearing, most of the specimen did not reach the true critical state as the deviator stress is still increasing at the end of the test. Unlike most clays where the critical state is often reached at about 25% axial strain, the lateritic soil needs to be sheared to a larger strain in order to erase the effects of fabric on the strength parameters. The behaviour of lateritic soil is attributed to the influence of its highly aggregated microstructure which is due to the influence of its sesquioxide content. Even though a true critical state was not reached by some of the specimen, critical state parameters were still derived at the end of the test. The test results have shown that the slope of the NCL and CSL lines for the saturated lateritic specimens are parallel to each other. The parameters of M and λ have been determined and it was found that the lateritic clay has a larger friction angle which is not typical for a sandy clay material. The large friction angle is therefore attributed to the influence of its sesquioxide content which enhances formation of large grain sizes through aggregation of soil particles. The intercept of the critical state line in the compression plane was also determined which is unique to the studied soil. Considering the variability in the microstructure of different lateritic soil owing to the presence of sesquioxide, it is impossible to generalize the critical state parameters in this study for all lateritic soil. Therefore, the result of this study could be useful for interpreting lateritic specimen with similar grain size distribution and sesquioxide content.

Liquid limit and density of high plastic clays

J. Frankovska & M. Brcek
Slovak University of Technology in Bratislava, Slovakia

ABSTRACT: Laboratory tests to determine the limits of the liquid and plastic are by far the most widely used index tests and are often adopted to assess the mechanical behaviour of clay. The laboratory investigation results for determining liquid limits using the Fall-cone method and method based on Casagrande-type devices for high-plastic clays were analysed. The density of the soil particles was determined by the pycnometer method by fluid displacement and the pycnometer method by gas displacement. Helium was used as the measurement gas. Significant differences were observed based on the laboratory method used. The range of differences in the geotechnical properties of high plastic clays was 10 to 30 %. The impact of the testing methods on the intrinsic properties of high plastic clays is analyzed in the paper.

1 INTRODUCTION

The basic physical properties of soils also referred to as intrinsic properties, are those that we need to describe and classify soils. These are mainly grain size and consistency (Atterberg) limits for fine-grained soils. The descriptive properties are constant for a given soil, independent of stress, strain, time, etc. Geotechnical parameters that characterise the physical state of the ground (state parameters) and are not constant for the soil are, for example, the soil's moisture content and bulk density in its natural state. Fine-grained soils it is mainly the consistency of the ground. Thus, the initial condition of the soil (soil in its natural state) can be characterised by two sets of geotechnical parameters: descriptive and state parameters. The basic physical properties of soils are also referred to as intrinsic properties in geotechnical engineering. Based on these, significant physical, strength-strain or hydraulic properties of soils, which are the geotechnical parameters of strength, compressibility or coefficient of filtration, can be determined by using appropriate correlations in cases where direct field or laboratory tests are not possible. These geotechnical parameters directly enter analytical or numerical models in the design of geotechnical structures.

Consistency limits include liquid, plasticity and shrinkage limits. These limits are also called Atterberg limits after the Swedish engineer Albert Atterberg, who defined them in the early 20th century and published their determination in 1911. They are important characteristics of fine-grained soils because they determine their geotechnical properties. Atterberg limits are empirically determined moisture contents that represent changes in soil behaviour. The liquid and plasticity limits provide important information on the character of fine-grained soils and are determined by relatively simple laboratory tests.

Atterberg limits are extensively used to identify, describe, and classify fine grained soils and as a basis for preliminary assessment of their mechanical properties.

The consistency limits depend on the mineralogical composition and the more smectites the soil contains, the greater the value they reach (Mitchell & Soga, 2005, Tiwari & Ajmera, 2011). Consistency limit values for selected clay minerals are given in Table 1.

Eurocode 7 and STN 72 1014 define two methods for determining the liquid limit: the Casagrande method and the fall cone method. The cone penetration method is based on the measurement of soil penetration by a standardized cone of a specified mass. It has been used in

DOI: 10.1201/9781003299127-32

Table 1. Consistency limits based on clay minerals (Mitchell & Soga, 2005).

Mineral	Liquid limit (%)	Plasticity limit (%)	Shrinkage limit (%)
Montmorillonit	100 – 900	50 – 100	8.5 – 15
Kaolinite	30 – 110	25 – 40	25 – 29
Illite	60 – 120	35 – 60	15 – 17

Scandinavia since 1915 (Bjerrum & Flodin, 1960). Two types of cones are recommended for determining the liquid limit. They differ in the angle of the cone, its mass and the depth of penetration at which the liquid limit is determined. They are designated the British cone (30°/80 g) and the Swedish cone (60°/60 g). Based on the results of a study comparing the results in five laboratories in Europe: TCD Ireland, BAW Germany, RGD Netherlands, SGI Sweden and BRE UK, it was shown that the two cone types give essentially the same values of flow limit for geotechnical practice (Farrell et al., 1999).

Density of solid particles - specific gravity can be defined as the density that expresses the mass per unit volume of the solid phase of a soil, i. e. excluding pores, voids and fractures.

It is determined in the laboratory most commonly in a Gay-Lussac type pycnometer (a container with a special stopper that has an accuracy of volume determination to the thousandth of a millilitre) with a volume of 50 ml or 100 ml. In the case of problematic soil types (e.g. expansive soil) or where higher accuracy requirements are required, the specific gravity is determined in a gas pycnometer, most commonly using helium.

2 MATERIALS

Tests were performed on 22 specimens of high plastic clays. Test samples of fine-grained soils were taken on bentonite deposits, the Western Carpathians, Slovakia (Kopernica, Stará Kremnička - Jelšový potok, Lutila I, Stará Kremnička III, Bartošová Lehôtka II, Lastovce and Kuzmice). All samples were classified as clays with very high and extremely high plasticity.

3 METHODS

3.1 *Liquid limit determination*

Two methods: the Casagrande method and the fall cone method, were used for the liquid limit determination. The British cone (30°/80 g) was used for cone penetration testing. The sample preparation is the same for both methods. However, the amount of soil required to perform the test is greater for the cone test, which requires about 200 g of soil.

3.2 *Density of solis particles determination*

Two methods were compared for the determination of density (bulk density) - using a Gay-Lussac pycnometer with water and gas (helium) pycnometer (type ULTRAPYC 1200e, Quantachrome Instrument, procedure according to ASTM D6093-97:2011, DIN 18121-2:2010). The equipment allows the determination of the volume of the solid phase of the soil. The gas pycnometer method uses the property of expansion and compression of gases with pressure change at a constant temperature. Helium is a suitable gas for use because it is an inert gas and because of the small size of the molecules, which makes it capable of penetrating even the smallest pores and capillaries of an apparently compact material. The values of the resulting specific gravity of soils are most often in the range of 2400 to 3000 $kg.m^{-3}$. The measurement duration is limited by the time required to reach thermal stability.

4 RESULTS

4.1 *Liquid limits of high plastic clays*

For fine-grained soils with a liquid limit of 30% to 50%, the results of testing using the two methods are comparable (Frankovská & Dananaj, 2006, Farrell et al., 1999). For soils with w_L higher than 50 %, the liquid limit determined by the cone method is lower than the liquid limit determined by the Casagrande method (Figure 1).

The variance of the values of the liquid limit determined by the two methods increases linearly with increasing liquid limit value and reaches a difference of 70% for soils with a liquid limit up to 350%.

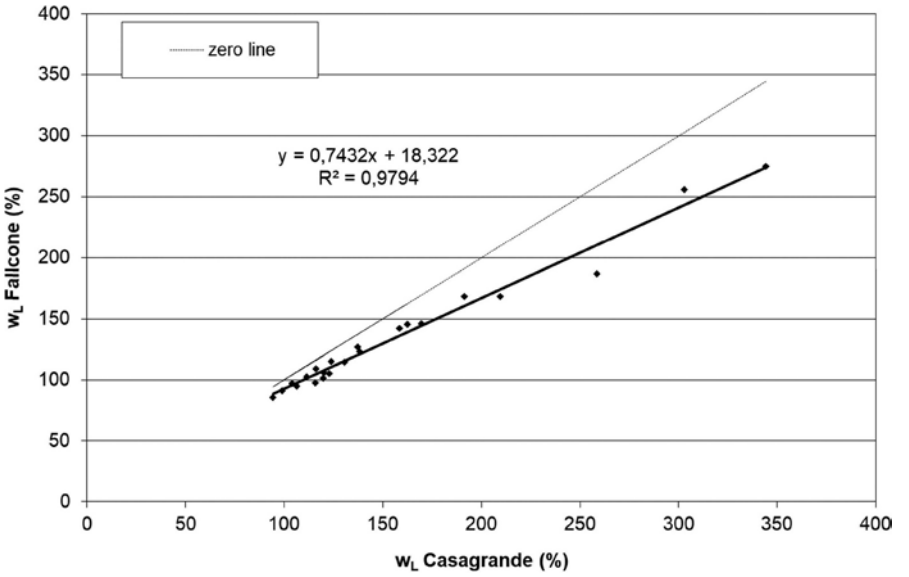

Figure 1. Casagrande and fall cone methods for soils with w_L > 90%.

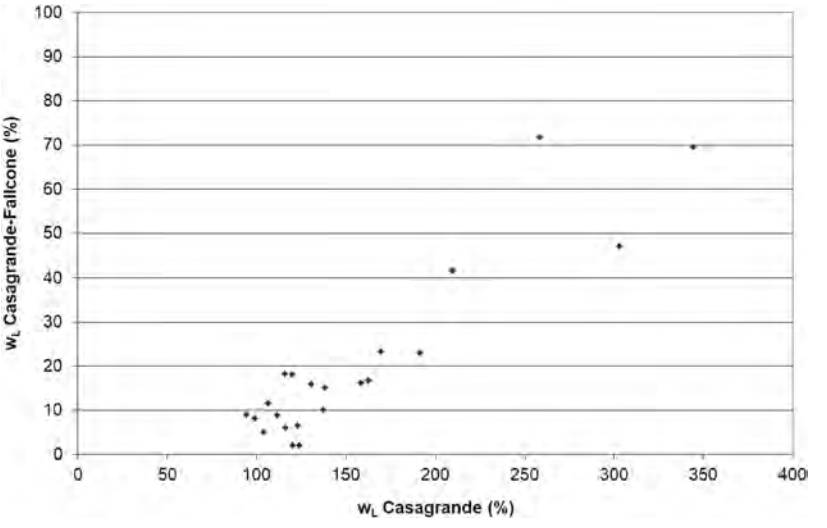

Figure 2. Differences between liquid limits determined by Casagrande and fall cone methods.

The cone test is not faster, but it is more reliable because the test mechanism depends directly on the static shear strength of the soil. Casagrande's method introduces a dynamic element to the test that does not depend on the shear strength in the same way for all soil types. The unconfined shear strength of soils at the yield stress decreases as the yield stress increases, which is the reason for the different yield stress values determined by the Casagrande and cone methods.

Results obtained by the fall cone method have been proven to be more consistent and less liable to experimental and personal errors than those obtained by the Casagrande method. Comparing the time necessary for the test, both methods are equally time-consuming. The estimate of liquid limit either by the cone test or by the Casagrande´s method, requires very good laboratory skills.

4.2 *Results of density measurement*

For twelve bentonite test samples, significant differences were found in the results - evaluation of the solids particle densities due to the methodology used.

The resulting values ranged from 2.63 g/cm^3 to 2.83 g/cm^3 for the water pycnometer determination and from 2.31 g/cm^3 to 2.39 g/cm^3 for the helium ultrapycnometer determination.

5 CONCLUSION

Both the liquid limit of the soils and the density of solid particles depend mainly on the mineralogical composition of the soils. The correct determination of the liquid limit is important because of the use of this basic geotechnical parameter of soils for correlations with other parameters characterizing the strength, compressibility and hydraulic properties of soils, which directly enter the computational models for the design of geotechnical structures.

Experimental investigations based on laboratory tests of samples of highly plastic soils from different locations in Slovakia have indicated significant differences in the values of the liquid limit determined by the Casagrande apparatus and the 80g/30° cone, ranging from 10 to 70 % for soil samples with a liquid limit above 90 %.

A significant difference was also found for the determination of the solid particle density of highly plastic soils. The indication of the method used for the determination of the liquid limit of the soils in the geotechnical investigation report or is therefore necessary.

Effect of different pore structure in sandy soil on monotonic and cyclic shear behavior

M. Nakano & T. Sakai
Nagoya University, Nagoya, Aichi, Japan

ABSTRACT: This study investigated the effect of pore structure due to suffusion on the behavior of soil specimens by replacing some of the fine-grain content of the specimens with a chemical fertilizer that dissolves in water. In monotonic shear behavior, the fertilizer-replaced samples showed a greater degree of plastic compression in early shear. In cyclic undrained shear behavior, the fertilizer-replaced sample exhibited more shear strain development with fewer cycles. It can be inferred that the pore structure due to the dissolution of fertilizer in water has a different soil structure from that of the basic specimens.

1 INTRODUCTION

Internal erosion, a phenomenon in which fine particles move and flow out of river levees and earth-fill dams due to seepage, is one of the causes of instability of these structures. Ishimaru et al. (2020) categorized and organized previous studies on internal erosion based on the Initiation-Continuation-Progression-Breach/Failure process described by Foster & Fell (1999). Some studies to investigate the Breach/Failure process, i.e., the cause of instability of levees, have been conducted by triaxial tests simulating suffusion, which was shear tests using specimens with fine-grain removed beforehand (e.g., Kodaka et al. 2016), or shear tests by revised triaxial apparatus reproducing suffusion from the specimen (Ke & Takahashi 2014, Prasomsri & Takahashi 2020)

The objective of this study is to investigate the effect of pore structure due to fine-grain loss on the behavior of soil specimens by replacing some of the fine-grain content of the specimens with a chemical fertilizer that dissolves in water, and then to provide basic data for research on suffusion. In the future, we aim to describe the soil skeleton structure of soils with the same specific volume but different pore structure based on the mechanical behavior of soils.

2 PHYSICAL PROPERTIES OF THE SAMPLES USED IN THE TEST

The samples used in the tests were three types of Tohoku silica sand: 'basic sample', 'fine-grain-removed sample', and 'fertilizer-replaced sample'. Figure 1 shows the grain size distribution for the basic and fine-grained samples, and Table 1 shows their physical properties.

Table 1. Physical property of sand.

	Particle density ρ_s(g/cm^3)	Maximum void ratio e_{max}	Minimum void ratio e_{min}
Basic sample	2.650	0.885	0.486
Fine-grain-removed sample	2.650	0.908	0.486

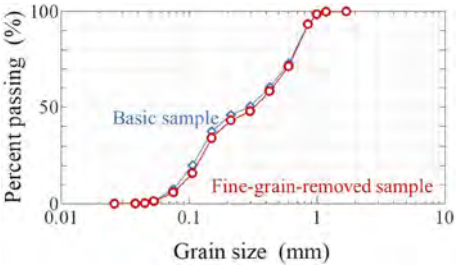

Figure 1. Grain size distribution.

DOI: 10.1201/9781003299127-33

The fine-grain removal sample is a sample removed 5% fine fraction of 106 μm or less in grain size from the basic sample. The fertilize-replaced sample is obtained by adding 5% of fertilizer grains of 106 μm or less in grain size to the fine-grain removal sample. The grain size distribution is the same as that of the basic sample. When the fertilizer is fully dissolved by water, the distribution is equal to that of the fine-grain removal sample.

3 SPECIMEN PREPARATION FOR THE THREE SAMPLES AND TESTING METHODS

The specimens were cylindrical specimens with a diameter of 50 mm and a height of 100 mm. The basic and fertilizer-replaced samples were prepared by air-dropping method to achieve a relative density *Dr* of 80%. On the other hand, the fine-grain removal sample was *Dr* of 60%. The reason for this is that the *Dr* of the fertilizer replacement sample is 60% when the fertilizer is sufficiently melted in water.

Each specimen was set in a triaxial apparatus and saturated by water flow to ensure that the B-value was greater than 95%. After isotropic consolidation was completed at an isotropic pressure of 98.1 kPa, various shear tests were conducted. The saturation process time for the fertilizer-replaced specimens was 2 hours and 30 minutes. It was confirmed that the fertilizers in the specimens were completely dissolved during this water flow time by preliminary experiments. Both the fine-grain-removed and fertilizer-replaced specimens had *Dr* of 60% after saturation process, but the pore structure is considered to be different in the specimens.

4 EXPERIMENTAL RESULTS

4.1 *Shear behavior of specimen simulating suffusion*

Figure 2 shows the undrained shear behavior for the basic sample and the fertilizer-replaced sample. The fertilizer-replaced sample simulated that the basic sample with a *Dr* of 80% has a *Dr* of 60% due to suffusion. Fertilizer dissolves to form pore space, which represents suffusion.

The basic sample exhibited remarkable hardening behavior with plastic expansion, with a maximum deviator stress *q* of approximately 1600 kPa. On the other hand, the fertilizer-replaced specimen also exhibited hardening behavior with plastic expansion, but the maximum *q* was below 600 kPa. A significant reduction in strength occurred due to suffusion. Figure 3 shows a comparison of drainage shear behavior. The basic sample shows more pronounced plastic expansion and a clear peak of *q* (approximately 450 kPa). On the other hand, the fertilizer-replaced sample did not show a clear peak, and the maximum *q* was about 330 kPa.

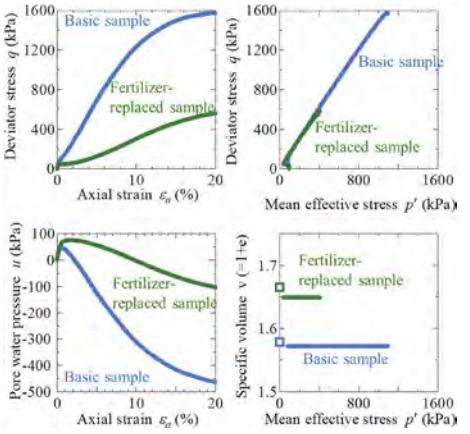

Figure 2. Undrained shear behavior for the basic sample and the fertilizer- replaced sample.

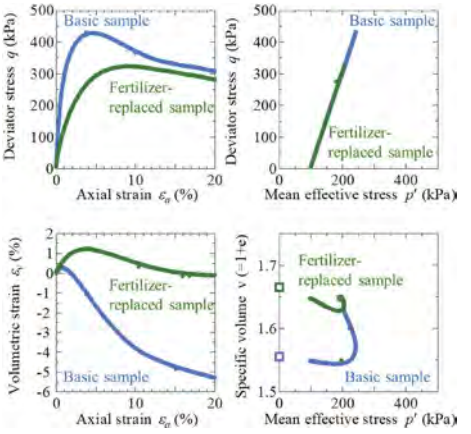

Figure 3. Drained shear behavior for the basic sample and the fertilizer- replaced sample.

4.2 *Comparison of fine-grain-removed and fertilizer- replaced samples - Monotonic undrained shear test*

To investigate whether the voids created by the dissolution of fertilizer by water supply created a special soil skeleton structure, a comparison was made between the fine-grain removal sample and the fertilizer replacement sample, which had the same *Dr* and particle size distribution.

Figure 4 shows the undrained shear test results. For $q \sim \varepsilon_a$, the fertilizer-replaced specimens had lower q and lower maximum q than the fine-grain-removed specimens. The mean effective stress p' in the early shear phase decreased and the positive excess pore pressure u increased, which means larger plastic compression. The excess pore pressure in the fine-grain-removed sample was higher in the latter half of the shear period.

Figure 5 shows the drained shear test results. For $q \sim \varepsilon_a$, the fertilizer-replaced sample had a smaller initial stiffness and a slightly larger peak than the fine-grain-removed sample. The dilatancy properties showed that the fertilizer-replaced sample exhibited a large compression in the early shear phase, followed by expansion, but did not exhibit negative volumetric strain throughout the shear phase. On the other hand, the fine-grain removal sample showed a small positive volumetric strain at the beginning of shearing and negative the latter half of the shear period.

Both undrained and drained shear behavior showed differences between specimens, with different pore formation and soil structures.

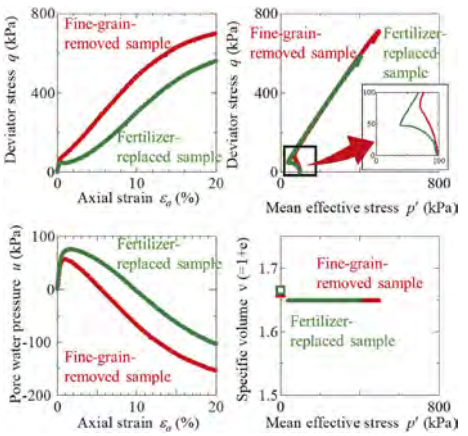

Figure 4. Undrained shear behavior for the fine-grain-removed sample and the fertilizer-replacedsample.

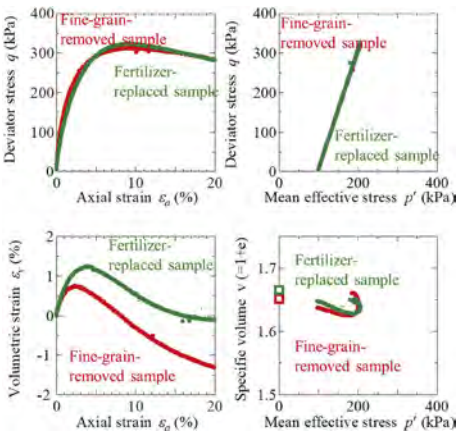

Figure 5. Drained shear behavior for the fine-grain-removed sample and the fertilizer-replaced sample.

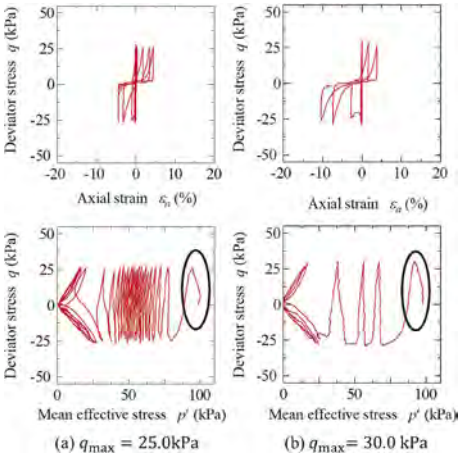
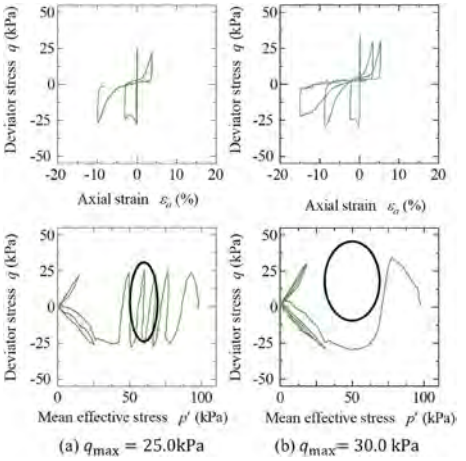
4.3 *Comparison of fine-grain-removed and fertilizer- replaced samples - Monotonic undrained shear test - Cyclic undrained shear test*

The difference between both specimens was also investigated in cyclic undrained shear tests. The stress amplitudes were 25.0 kPa and 30.0 kPa.

Figures 6 and 7 show the undrained cyclic shear results for the fine-grain-removed and fertilizer-replaced samples, respectively. Both samples liquefied more easily as the amplitude increased, and the strain gradually increased after liquefaction. However, for the same amplitude, the fertilizer-replaced sample liquefied more easily and showed greater strain development after liquefaction. This is because the p' of the fertilizer-replaced sample decreased more significantly during the first iteration (black circles in the figure). This may be due to the greater reduction in stiffness and shear resistance of the fertilizer- replaced specimens.



Figures 6. The undrained cyclic shear results for the fine-grain-removed samples.



Figures 7. The undrained cyclic shear results for the fertilizer-replaced samples.

5 CONCLUSIONS

In this study, the effects of different pore structures on monotonic and cyclic shear tests of sand specimens were investigated using a triaxial compression test apparatus. The following conclusions are drawn.

1) The fertilizer in the fertilizer-replaced sample was dissolved with water to reproduce the sample with suffusion. When undrained shear was performed on these samples, the maximum q decreased compared to the basic sample.
2) In monotonic undrained shear behavior, the fertilizer- replaced samples showed a greater degree of plastic compression in early shear. In drained shear, the fertilizer- replaced specimens had lower initial stiffness and greater positive volumetric strain. It can be inferred that the pore structure due to the dissolution of fertilizer in water has a different soil structure from that of the basic specimens.
3) In cyclic undrained shear behavior, both samples were more prone to liquefaction as the stress amplitude ratio was increased. However, the fertilizer-replaced sample exhibited more shear strain development with fewer cycles.

We have not found evidence that fertilizer-induced pore formation is the same as actual pore formation due to suffusion. However, it is suggested that the pore formation in the sample from which the fine particles have been removed, i.e., the fine-grain-removed sample, is not the same as the actual pore formation. This should be taken into account when conducting future experiments to reproduce suffusion.

Progressive formation of concentrated seepage path in gap-graded sand due to suffusion and its influence on permeability change

R. Kido & Y. Higo
Kyoto University, Kyoto, Japan

ABSTRACT: Suffusion, which is classified as one of internal erosion, causes change in physical and hydraulic properties of soils during permeation, while the mechanism of permeability change for sands due to suffusion is not sufficiently clear. In the present study, permeability tests of gap-graded sand are performed by increasing levels of hydraulic gradient. During the tests, X-ray micro CT is applied to observed internal structure of sand specimens, and then the progressive formation of concentrated seepage path caused by suffusion is visualized by image analysis. It is found that permeability of gap-graded sand increases until a concentrated seepage path completely goes through the sand along a direction of seepage due to suffusion.

1 INTRODUCTION

Degradation and failure of soil structures, such as embankment subsidence, are often caused by the generation and development of microcavities due to internal erosion, in which particles are expelled by seepage forces and other actions. In general, internal erosion can be classified into four types: 1) pile or crack internal erosion, 2) backward internal erosion, 3) internal contact erosion and 4) suffusion (internal stability of a soil, or volume erosion) (Fry, 2012). In this study, suffusion, i.e., the internal erosion in which only fine particles are expelled from the pore spaces composed of coarse grains due to the seepage flow.

Once a suffusion occurs and develops, the physical and hydraulic properties of the soil change. Such changes in soil properties are caused by the formation of concentrated seepage path and clogging in the process of changing the grain size distribution and void ratio. Some studies observed internal structural changes in soil caused by suffusion using Scanning Electron Microscopy (SEM) (Sato and Kuwano, 2018) and X-ray micro Computed Tomography (CT) (e.g., Nguyen et al., 2019). They focus on the change in pore structure and its associated settlement caused by suffusion, while the mechanism of permeability change of the eroded sand is not sufficiently clear.

In the present study, permeability tests of gap-graded sand are performed by increasing levels of hydraulic gradient. X-ray micro CT is applied during the tests to observed inner structure of sand specimens, and then the progressive formation of concentrated seepage path caused by suffusion is visualized by image analysis. The influence of the formation of concentrated seepage path on the permeability change due to suffusion is discussed.

2 EXPERIMENTAL METHODS

2.1 *Materials and specimen preparation*

Figure 1 shows the test apparatus used in the present study, which was developed to conduct permeability test, triaxial compression test and X-ray micro CT scan. The downward seepage flow is applied by the water head difference between the upper tank connected to the top of the specimen and the lower tank connected to the bottom of the specimen. The lower tank has an outlet hole to maintain a constant water level, and the water flow rate from this hole is

DOI: 10.1201/9781003299127-34

measured by a gravimeter. The triaxial cell is made by an acrylic that allows us not only to support the loading force, but also to obtain high resolution images using X-ray micro CT apparatus, KYOTO-GEO μXCT (TOSCANER-32250mhdk).

Two levels of confining pressure, 10 kPa and 50 kPa, were applied to the specimen during the permeability test. The permeation was performed at a specified level of hydraulic gradient for three hours and then, the inner structure of the specimen was visualized using the X-ray micro CT. Such permeation and visualization were repeated with a step-by-step increase of the hydraulic gradient. The rest specimen was made dried and the mass of the dry sand was measured to calculate the mass of the eroded sand particles after completing the permeability test. In the present study, Erosion Rate (ER) is defined as a ratio of the amount of fine particles in the specimen before the permeability test to that of eroded fine particles after the permeability test. Water flow rate was measure by 10 seconds and permeability was calculated based on Darcy's law.

2.2 *Test apparatus and test methods*

Silica sand No. 3 was used for the coarse particle and silica sand No. 8 was used for the fine particle. These sand materials were mixed with a weight ratio of 7:3, similar to Ke and Takahashi (2014). The fine content F_c is 12.87%. A maximum void ratio and a minimum void ratio of the mixed sand is 0.782 and 0.390, respectively.

Silica sand No. 3 and No. 8 were mixed to obtain a relative density D_r of 30% as the mixed sand. Desaturated water with a water content of 3% was added to the mixed sand to make an uniform specimen by a moist tamping method. A perforated plate with a diameter of 34.9 mm, a thickness of 5.0 mm, a hole diameter of 1.0 mm, and a hole center spacing of 2.0 mm was placed at the top of a pedestal. The hole diameter of the perforated plate is large enough to allow only silica sand No. 8 to pass through. The moist-mixed sand was compacted in ten layers to make the specimen with a diameter of 35.0 mm and a height of 70.0 mm. After placing a porous stone and cap with bearing on the top of the specimen, the specimen was saturated by passing desaturated water through the specimen using a double-suction method.

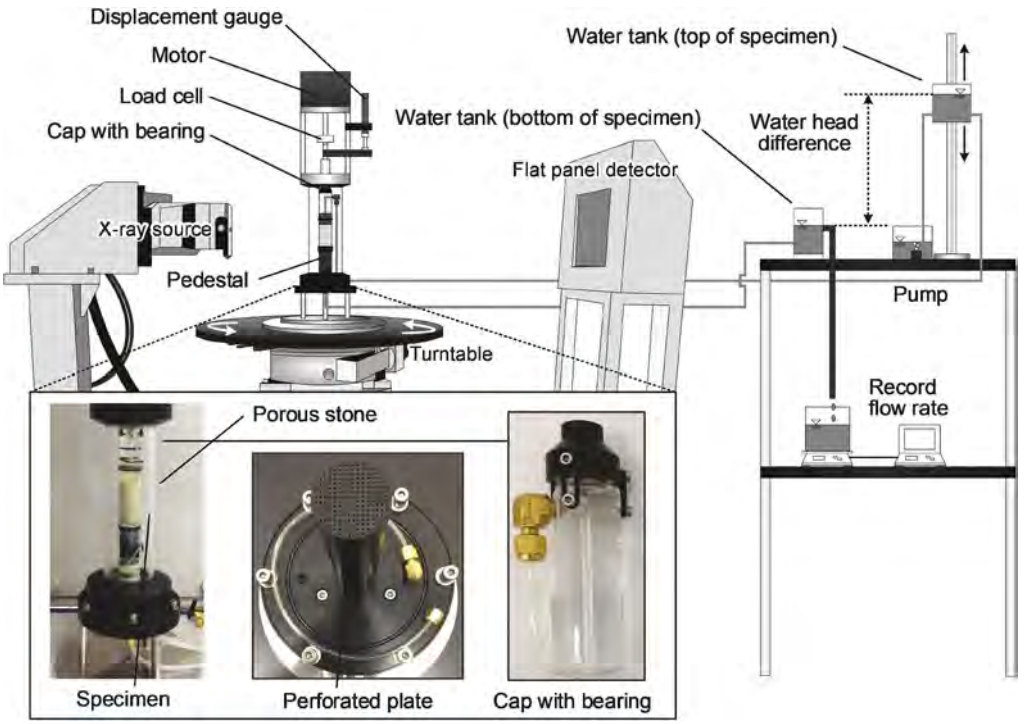

Figure 1. Apparatus of permeability test.

3 RESULTS AND DISCUSSIONS

3.1 *Change in permeability*

Test cases are listed in Table 1. The change in permeability and appearance of tube connected to the bottom of the specimen after the permeability test are shown in Figure 2. In Case 1, the permeability is kept almost constant at i=4, and then the permeability is increased monotonically with an increase of hydraulic gradient. In this process, the amount of eroded fine particles is increased as shown in Figure 2b. In other words, permeability is increased due to suffusion. As shown in Table 1, Case 3 shows smaller value of ER than Case 2; namely, a larger amount of fine particles is eroded in Case 3 than Case 2. Nevertheless, the permeability of Case 3 becomes higher than that of Case 2 beyond i=12.

3.2 *Development of local concentrated seepage path by suffusion*

Since the specimen is in an almost water-saturated condition, water fills the pore spaces where fine particles are expelled when suffusion occurs. Such pore spaces will locally occur and then connect with each other forming a concentrated seepage path, through which water will selectively flow. In the present study, the progressive formation of the seepage path in the specimen during permeability test is visualized using image analysis techniques.

Figure 3a shows a procedure of image analysis. At first, a binary image for pore water phase is obtained by a simple threshold method using a three-dimensional image processing software VGstudioMax3.1 (Volume Graphics). The binary image includes voxels of the pore water phase related to the seepage path, absorbed water around soil particles of silica sand No. 3, and partial volume effect (Higo et al., 2014). In order to extract the voxels for the pore water phase related to only the seepage path, Morphology analysis (Kido et al., 2020) that performs two kinds of image processing, i.e., Erosion and Dilation, is performed.

Figures 3b-3d show the concentrated seepage path at each hydraulic gradient visualized by the image analysis. In Case 1, the pore water phase is limited until i=4, and then it progressively increases with an increase of hydraulic gradient, forming a concentrated seepage path that goes through from top to bottom of the specimen. The similar tendency for development of such a concentrated seepage path is also observed in Case 3. On the other hand, it is found from Figure 3c that the concentrated seepage path for Case 2 is locally formed at the lower part of the specimen.

Table 1. Permeability test cases.

Case	σ_3 (kPa)	e_0	ER (%)	Hydraulic gradient i
Case 1	10	0.66	11.33	4, 8, 12
Case 2	50	0.67	6.08	4, 8, 12
Case 3	50	0.66	4.56	4, 8, 12, 16

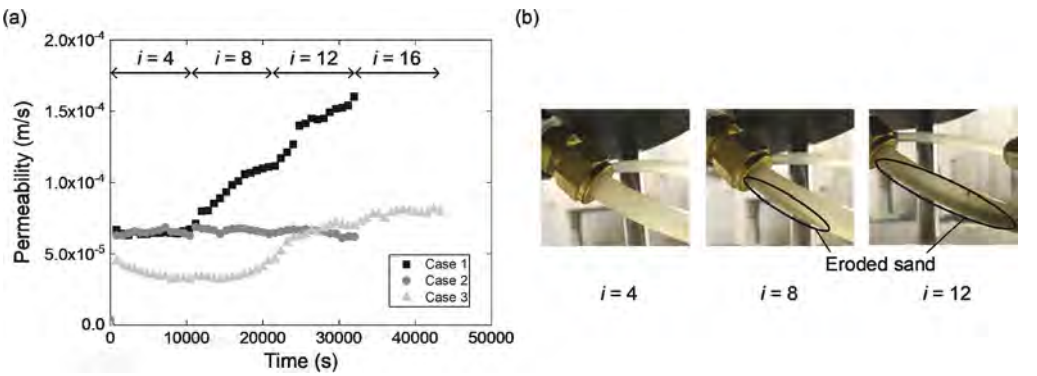

Figure 2. Results of permeability test: (a) permeability change and (b) eroded sand for Case 1.

3.3 *Effect of suffusion on permeability change*

The permeability change is compared with the tendency for the development of the concentrated seepage path. For Case 2, the seepage path is limited at the lower part of the specimen and the permeability is not changed. These results probably indicate that the suffusion occurs mainly at the lower part of the specimen, and the fine particles clogged in the middle part of the specimen that becomes a bottleneck, resulting in almost constant permeability. A reduction of permeability for Case 3 up to i=8 may be also caused by such clogging phenomenon because the seepage path is only seen in the bottom part of the specimen. On the other hand, the values of permeability for Cases 1 and 3 tend to gradually increase with an increase of hydraulic gradient. In this process, a clear concentrated seepage path is progressively formed for both the two cases.

The above results confirm that permeability of gap-graded sand increases until a concentrated seepage path completely goes through the sand along with a direction of seepage due to suffusion.

4 CONCLUSIONS

Permeability tests of gap-graded sand were conducted, and pore water phase in specimens at each level of hydraulic gradient was observed using X-ray micro CT and image analysis. The progressive formation of concentrated seepage path caused by suffusion was successfully visualized. It was found that permeability of gap-graded sand increases until a concentrated seepage path completely goes through the sand along a direction of seepage due to suffusion.

Evaluation of density of consolidated clay during desiccation using X-ray CT scanner

M. Tanaka, T. Kawamura & T. Umezaki
Shinshu University, Nagano, Japan

ABSTRACT: X-ray CT imaging was conducted for a consolidated clay in air-dry test, which is defined as the element test. It was found that the distribution of CT values in the specimen was not uniform during desiccation. Then the representative CT value, CT^*, of the entire specimen was computed during the desiccation process, during which the specimen transitioned from saturated to unsaturated state. The relations of w–CT^* and ρ_t–CT^* can be evaluated as bilinear relations, which bend near the shrinkage limit, w_s. Before or after w_s, there are conditions where the value of CT^* is the same even though the values of w and ρ_t are different. The relationship of ρ_t–CT^* during clay desiccation differs from that of solid materials and aqueous solutions.

1 INTRODUCTION

X-ray CT scanner is widely used for medical and industrial purpose. It is also used for geotechnical engineering purpose, for example, to visualize movement of soil particles and changes in density in a given region. The authors have studied to evaluate the state change of soil due to shrinkage and freezing, respectively, by using an X-ray CT scanner (Computerized tomography scanning equipment NAOMi-CT, RF Co., Ltd.). This scanner is 650 mm in width, 310 mm in depth, and 300 mm in height does not require shielded space to avoid X-ray exposure. Therefore, it can be transportable and is expected to be employed in not only laboratory tests but also outside work.

In this paper, X-ray CT scanning was conducted for the consolidated clay specimen during desiccation. The state change of the whole specimen from the saturated condition of the two-phase structure of soil particle and pore water to the unsaturated condition of three-phase structures adding pore air was discussed. The representative CT value for the entire specimen in the element test was generated from CT images using image analysis and averaging, and wet density was evaluated using CT value.

2 REPRESENTATIVE CT VALUE OF WHOLE SPECIMEN IN ELEMENT TEST

Image analysis for CT images and averaging procedure were conducted, to calculate the representative CT value of not local part of the specimen but the whole specimen. Figure 1 shows a flow diagram for calculating the representative CT value. The diagram consists of three phases. In phase (a), one vertical cross sectional CT image was captured for each CT scanning. The CT image is converted to local CT values within the specimen, which are subsequently translated to pixel values. In phase (b), the CT image was binarized using a threshold determined by the CT value at the border between air and the specimen. Then the part of air was eliminated from the CT image and the cross section of only the specimen was extracted as the target area. In phase (c), the CT-value distribution of the specimen was output. The CT values were averaged and finally, the representative CT value, CT^*, of the whole specimen, was calculated.

DOI: 10.1201/9781003299127-35

3 SAMPLES AND TEST PROCEDURE

Air-dry test was performed on NSF(C) clay specimen (soil particle density ρ_S = 2.723 g/cm^3, liquid limit w_L = 57.5%, plastic limit w_P = 35.7%, and shrinkage limit w_S = 37.6%). The value of w_s is larger than that of w_p. Toyoda et al. (1996) compared the shrinkage limits and the plastic limits of 17 soils. Results show that the values of w_s in seven soil samples were $w_s \geq w_P$. After de-airing slurry sample (water content, $w \approx 2\ w_L$), one-dimensional consolidation was performed at the fixed pressure. The consolidation time was determined using the 3t method and four saturated consolidated clay samples (w_0 = 0.87–0.89 w_L) were prepared. Then, cylindrical specimens (initial diameter and height, d_0 =3.5 cm and h_0 =5.0 cm) was fabricated using a trimming method with a thin wire saw. The specimen was placed on a glass plate and an air-dry test was performed in a thermostatic chamber with a room temperature of 23°C ± 1°C. X-ray CT scanning and measuring the specimen mass, height, and diameter were conducted at a fixed interval. And the values of water content, w, volume, V, void ratio, e, degree of saturation, S_r, and wet density, ρ_t, were calculated.

4 TEST RESULTS AND DISCUSSIONS

Table 1 shows the distribution of CT values in the vertical cross sectionals of the specimen during the air-dry test and the representative CT value, CT^*, derived from the process shown in Figure 1. The air-dry test is defined as the element test. However, it was found that the distribution of CT values within the specimen was not uniform during desiccation. Red color points, where CT value is larger than about 30,000, increase with elapsed time. The CT value in the specimen increases from the side area due to desiccation. However, at t = 360 min, w is almost equal to the shrinkage limit, and then red points decrease, as shown in Table 1(c)–(e).

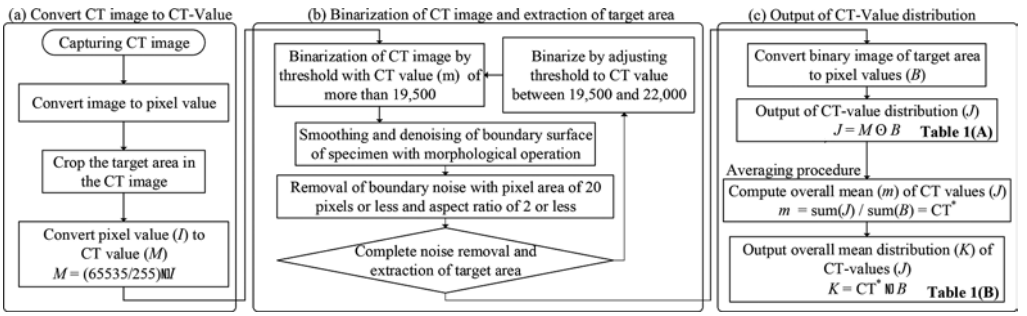

Figure 1. Flow diagram of extraction of CT value from CT image.

Figure 2 shows the relation of w–e. The relation decreases through S_r = 100% line, which is the normal shrinkage line. Then, when w gets lower than w_s, the value of e approaches a constant value, and the volume does not decrease even if moisture decreases. Because the volume is constant in $w < w_s$, it is assumed that the soil structure is formed.

Figure 3 depicts the relation of w–S_r. The value of S_r is about 100% until the value of w decreases to w_s and the saturated condition is maintained. When the value of w becomes smaller than w_s, the relation becomes almost a unique straight line through the origin, S_r = 0%, and the specimen becomes unsaturated and finally dry. Based on the findings of vacuum evaporation tests for six different types of reconstituted cohesive soil, Umezaki et al. (2013) reported that the relations of w–e and w–S_r bend near w_s.

Figure 4 shows the relation of w and CT^* of the whole specimen. The relation is not a straight line, but can be evaluated as bilinear relation, which bends near w_s. This is a similar tendency to the relations of w–e and w–S_r. When the value of w decreases under the saturated condition, CT^* increases and becomes maximum near the shrinkage limit, w_s. The initial and maximum values of CT^* are about 29,000 and 31,000, respectively. Then the value of w decreases further, the specimen transitioned to the unsaturated condition. During the

Table 1. CT-values distribution and representative CT value of consolidated clay in the air-dry test.

(a) t = 0 min (Initial) (w = 50%)	(b) t = 180 min (w = 44%)	(c) t = 360 min (w = 38% ≈ w_s)	(d) t = 540 min (w = 32%)	(e) t = 720 min (w = 26%)

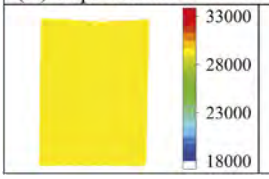

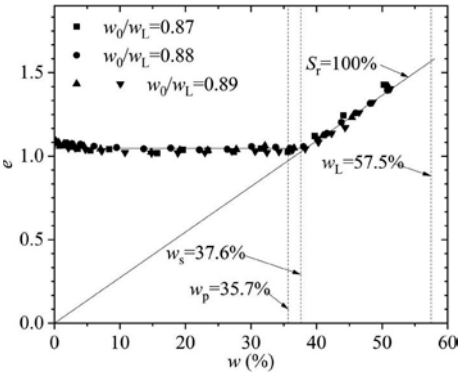

Figure 2. Relation of w and e.

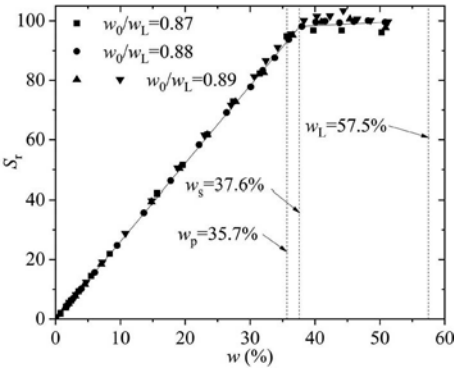

Figure 3. Relation of w and S_r.

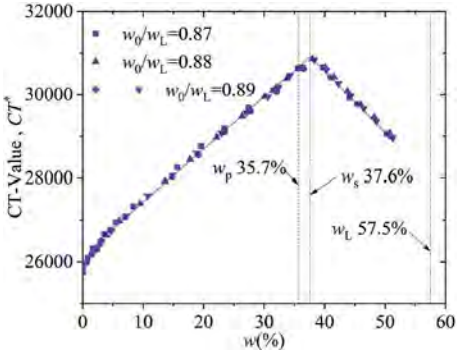

Figure 4. Relation of w and CT^*.

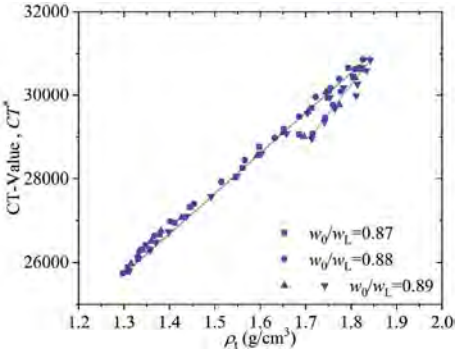

Figure 5. Relation of ρ_t and CT^*.

process, the value of CT^* decreases and becomes minimum at dry condition. The minimum value is about 25,500. There are the conditions where the value of CT^* is the same before or after w_s even if the values of w are different. The shrinkage limit is considered to be a particular point concerning degree of saturation and soil structure.

Figure 5 shows the relation of ρ_t and CT^*. The relation is not a straight line, but can be evaluated as bilinear relation, which is one straight line in saturated condition from the initial to w_s and another straight line in unsaturated condition from w_s to dry condition, as well as w–e, w–S_r, and w–CT^* relations. Furthermore, as well as the w–CT^* relation, before or after the shrinkage limit, there are the conditions where the value of CT^* is the same even though the values of ρ_t are different. The inclination of two straight lines is larger than in the saturated condition.

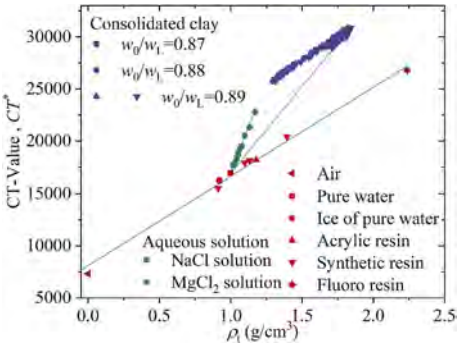

Figure 6. Relation of ρ_t and CT^* for synthetic resin, aqueous solution, and consolidated clay.

Figure 6 shows the relation of ρ_t and CT^* and added the measured values of other homogeneous samples: air, pure water, ice of pure water, solid materials of synthetic resin and aqueous solutions. Three distinct types of synthetic resin and two different types of aqueous solutions with varying concentrations of NaCl and $MgCl_2$ were employed. The CT values of pure water and aqueous solution were measured by pouring them into a glass container. Except for clay, CT value distributions were almost uniform for all materials, and the procedure in Figure 1 was not used. The relation of ρ_t and CT^* for homogeneous samples except for clay becomes a straight line as widely known. The relationship for aqueous solutions is a different straight line with pure water as an initial point. The relation for consolidated clay differs from the others and becomes bilinear. The source of the relationship under saturated conditions appears to be pure water. It is considered that the reason why the relation of ρ_t and CT^* of clay during desiccation becomes bilinear is the influence of soil structure.

5 CONCLUSIONS

X-ray CT imaging was performed for the consolidated clay in the air-dry test, which is defined as the element test. The representative CT value, CT^*, of the whole specimen was calculated during desiccation and state change of clay was discussed. The main conclusions are as follows.

(1) The relations of w–CT^* and ρ_t–CT^* are not straight lines, but can be evaluated as bilinear relations, which bend near w_s.
(2) Before or after the shrinkage limit, there are the conditions where the value of CT^* is the same even though the values of w and ρ_t are different.
(3) The relation of ρ_t and CT^* during desiccation of clay differs from the other homogeneous samples of solid materials of synthetic resin and aqueous solutions. The origin of the relation in saturated clay seems to be pure water.

ACKNOWLEDGMENT

The X-ray CT scanner was presented by RF Co., Ltd. Mr. Kazumi Kodaira, a researcher in RF Co., Ltd., supported the image analysis. Mr. Kouya Matsuda, a former student of Shinshu University, supported a part of the air-dry test. The authors are deeply grateful to them.

Closed-form solution for the consolidation of unsaturated soils considering semi-permeable boundary

L.S. Zhao & S.L. Shen
MOE Key Laboratory of Intelligence Manufacturing Technology, Department of Civil and Environmental Engineering, College of Engineering, Shantou University, Shantou, China

W.H. Yuan
Department of Civil and Environmental Engineering, College of Engineering, Shantou University, Shantou, China

ABSTRACT: The consolidation of unsaturated soils is commonly encountered in real practice. In contrast to saturated soils, the additional air phase in the void of the soil stratum complicates the consolidation process of unsaturated soils. In this study, a closed-form solution was established for the consolidation of unsaturated soils considering a semi-permeable boundary. A series of cases were conducted to show the characteristics associated with the consolidation of unsaturated soils commonly happened in in-situ projects. Compared with the existing analytical solutions, the derivation process is much simpler without using complicated mathematical methodologies. The proposed solution is verified to be accurate by comparing it with an analytical solution in the literature. This study reveals that, with a semi-permeable boundary, there exist some impeded effects on the excess pore water and air pressures at corresponding boundaries. The excess pore water and air pressures closed to the semi-permeable boundary exhibit an impeded feature.

1 INTRODUCTION

The consolidation of unsaturated soils is commonly encountered in real practice (Chiu et al., 2003; Ho and Fatahi, 2016; Huang et al., 2021; Lei et al., 2001; Ng et al., 2016). In contrast to the saturated soils (Terzaghi, 1943), the additional air phase in the void of the soil stratum complicates the consolidation process of unsaturated soils. This feature may cause a large discrepancy when approximating the settlement associated with the consolidation process (Huang et al., 2020; Li et al., 2021). In recent decades, researchers made a great effort in the consolidation of unsaturated soils (Lo et al., 2021; Wang et al., 2017; Wang et al., 2020). For instance, Ho et al. (2016) considered the permeable characteristics both in horizontal and vertical directions and proposed a new model under the 2D plain strain assumption. Wang et al. (2019) took the partial drainage boundary conditions into account and the proposed models are more flexible in the real application. Moradi et al. (2019) extended the governing equation from a one-layer system into a multi-layer system.

These analytical solutions were commonly applied to verify the numerical solutions and were used to study the influence of parameters with physical meanings through a parametric study. Nevertheless, plenty of these analytical or semi-analytical solutions were based on ideal boundary conditions, which have remarkable differences from the scenarios in real practice. The boundary in real practice cannot be absolutely permeable or impermeable due to the movement of fine particles towards the boundaries and the variation of temperature at the ground surface. The semi-permeable boundary condition describes the partial drainage properties at the

DOI: 10.1201/9781003299127-36

boundaries and can mitigate the discrepancy between the predictions and the measurements in real practice. With the scholars' great efforts, some great progress has been made in the consolidation of unsaturated soils considering semi-permeable boundary conditions. (Wang et al., 2017) used Laplace transform and Crump's method to solve the consolidation problem with semi-permeable boundary conditions. Huang and Zhao (2020) further evaluated the different permeable properties for both water and air phase at boundaries and presented a general analytical solution. To obtain corresponding analytical solutions, some complicated mathematical algorithms were inevitable to be introduced into these methods. Such as Laplace transform and inverse Laplace transform (Zhao et al., 2020), Crump's method (Wang et al., 2017), conjugate complex number (Niu et al., 2021), etc. This is reasonable when dealing with complex mathematical problems. However, this may decrease the widespread application of these proposed analytical or semi-analytical solutions by engineers in real practice.

Thus, the present study aims to propose an analytical solution considering partial drainage boundary conditions with simple mathematical derivation, which is more user-friendly in real practice. Besides, the proposed solution will be validated by comparing it with other solutions considering impeded boundary.

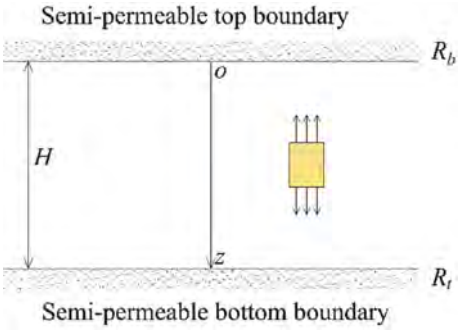

Figure 1. One dimensional consolidation of unsaturated soil layer with a semi-permeable boundary.

2 MATHEMATICAL MODELLING

Figure 1a illustrates a soil stratum of unsaturated soil with semi-permeable upper and lower boundary conditions. The thickness of the soil layer is H and the parameters, R_t and R_b, which are related to the semi-permeable boundary will be discussed later. The flows of air and water were assumed in the vertical direction only. To obtain the analytical solution considering the semi-permeable boundary properly, some assumptions were made to facilitate the derivation. Most of these assumptions are aligned with those assumptions made in the consolidation theory of unsaturated soils.

According to Fredlund and Hasan (1979), the governing equations for the consolidation of unsaturated soils can be expressed as follows,

$$\frac{\partial u_a}{\partial t} + C_a\left(\frac{\partial u_w}{\partial t}\right) + C_v^a\left(\frac{\partial^2 u_a}{\partial z^2}\right) = C_\sigma^a\left(\frac{\partial q}{\partial t}\right) \tag{1}$$

$$\frac{\partial u_w}{\partial t} + C_w\left(\frac{\partial u_a}{\partial t}\right) + C_v^w\left(\frac{\partial^2 u_w}{\partial z^2}\right) = C_\sigma^w\left(\frac{\partial q}{\partial t}\right) \tag{2}$$

where C_a, C_v^a, C_w, C_v^w, C_σ^a, C_σ^w are parameters used to get neat and uniform forms of Equations (5) and (6). These six parameters can be written as the following formulas based on the consolidation properties of unsaturated soils.

$$C_a = \frac{m_2^a\left(u_a^0 + u_{atm}\right)}{\left[\left(m_1^a - m_2^a\right)\left(u_a^0 + u_{atm}\right) - n(1 - S_r)\right]} \tag{3}$$

$$C_v^a = \frac{k_a R\Theta}{gM\left[\left(u_a^0 + u_{atm}\right)\left(m_1^a - m_2^a\right) - n(1 - S_r)\right]} \tag{4}$$

$$C_w = \left(\frac{m_1^w}{m_2^w} - 1\right) \tag{5}$$

$$C_v^w = \frac{1}{m_2^w}\left(\frac{k_w}{\gamma_w}\right) \tag{6}$$

$$C_\sigma^a = \frac{m_1^a\left(u_a^0 + u_{atm}\right)}{\left[\left(m_1^a - m_2^a\right)\left(u_a^0 + u_{atm}\right) - n(1 - S_r)\right]} \tag{7}$$

$$C_\sigma^w = m_1^w / m_2^w \tag{8}$$

3 BOUNDARY CONDITION

To meet the real drainage feature at boundaries of unsaturated soils, some researchers made a great effort to develop the theory of partial drainage boundary. As stated by Huang et al. (2020), there exist two hypotheses about partial drainage conditions. One is about time-dependent boundary conditions which are used to show the change of drainage properties at boundaries with time (Zhou et al., 2017). The other one is associated with an additional impeded layer at the boundary (Wang et al., 2017, Zhao et al., 2019). The current study is based on the assumption with impeded layers and they can be written as:

Top boundary

$$\frac{\partial u_a(0,t)}{\partial z} - \frac{R_a^t}{H} u_a(0,t) = 0 \tag{9}$$

$$\frac{\partial u_w(0,t)}{\partial z} - \frac{R_w^t}{H} u_w(0,t) = 0 \tag{10}$$

Bottom boundary

$$\frac{\partial u_a(1,t)}{\partial z} + \frac{R_a^b}{H} u_a(1,t) = 0 \tag{11}$$

$$\frac{\partial u_w(1,t)}{\partial z} + \frac{R_w^b}{H} u_w(1,t) = 0 \tag{12}$$

where R_a^t, R_w^t, R_a^b, R_w^b are four parameters related to the impeded layers at the top and bottom boundaries. Some researchers related these parameters with the permeability ratio and thickness ratio between the impeded layer and the target unsaturated soil layer. This hypothesis is reasonable and has explicit physical meaning. It should be noted the initial condition is assumed as a uniform distribution, which was adopted by many researchers.

4 CLOSED SOLUTION

In this study, the separation of the variable method was adopted to obtain the closed-form solution. The solution related to the governing Equations (1) and (2) can be written as,

$$\phi_i(\bar{z}, T) = \sum\nolimits_{m=1}^{\infty} A_m Z^m(\bar{z}) f_i^m(T) \ (i = \ 1, 2) \tag{13}$$

where $Z^m(\bar{z})$ is the eigenfunction associated with the depth of the soil layer. $f_i^m(T)$ is generalized Fourier coefficients with the variable of time factor T. A_m are coefficients related to $f_i^m(T)$, which can be obtained on basis of the initial distribution of excess pore pressures.

The excess pore water and air pressures can be calculated as,

$$\bar{u}_a(\bar{z}, T) = \frac{e_{21}\phi_2(\bar{z}, T) - \phi_1(\bar{z}, T)}{e_{12}e_{21} - 1} \tag{14}$$

$$\bar{u}_w(\bar{z}, T) = \frac{e_{12}\phi_1(\bar{z}, T) - \phi_2(\bar{z}, T)}{e_{12}e_{21} - 1} \tag{15}$$

where e_{21} and e_{12} are parameters related to the properties of unsaturated soils and can be calculated using the coefficients in Equations (1) and (2). Once, the average degree of consolidation for both water and air phases subjected to instantaneous loading can be obtained according to the consolidation theory proposed by Fredlund and Hasan (1979).

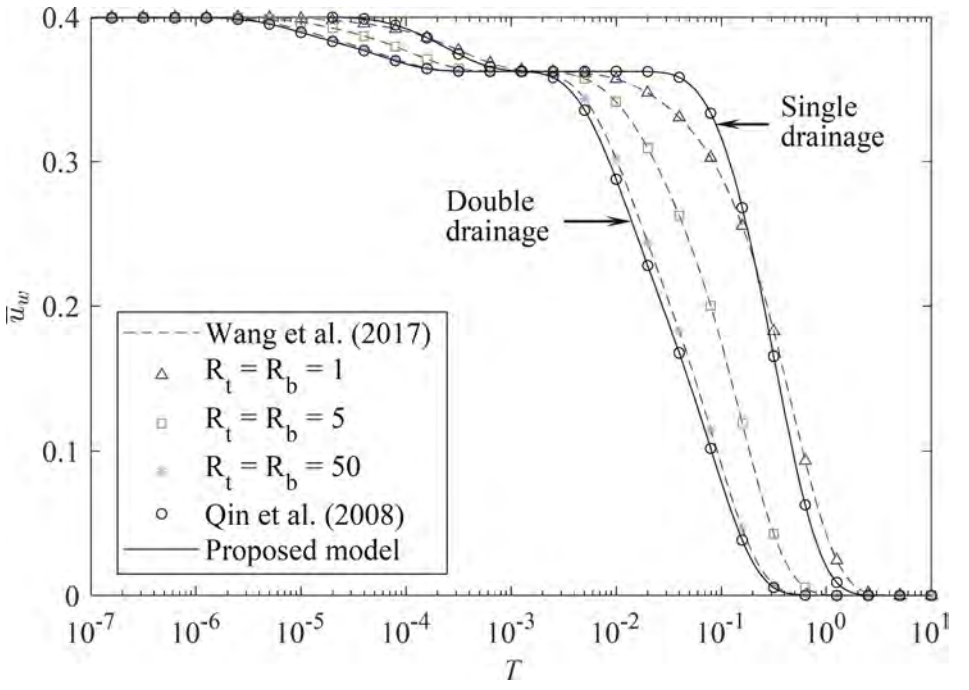

Figure 2. Normalized excess water pore pressures versus time compared with existing analytical solutions.

5 CASE STUDY AND VALIDATION

In this study, the following case was used to validate the accuracy of the proposed analytical solution for unsaturated soils with impeded boundaries. The thickness of the unsaturated soil stratum is assumed as 10 m, the initial porosity is 0.50 and the initial degree of saturation is 80%. The hydraulic conductivity for the water phase, k_w, and air phase, k_a, are $10^{-1\circ}$ m/s and 10^{-9} m/s, respectively. The coefficient of volume change with respect to a change in net normal stress under K_0 loading is m_{1k}^s. The coefficient of volume change with respect to a change in matric suction under K_0 loading is m_2^s. The coefficients of volume changes are: $m_{1k}^s = -2.5 \times 10^{-4} kPa^{-1}$, $m_2^w = -2.0 \times 10^{-4} kPa^{-1}$, $m_{1k}^w = -0.5 \times 10^{-4} kPa^{-1}$, $m_2^s = -1.0 \times 10^{-4} kPa^{-1}$. In the cases presented by Wang et al. (2017), the uniform initial distributions of excess pore air and pore water pressures were assumed as 5 kPa and 40 kPa, respectively. To prove the reasonableness of the proposed solution, Figure 2 presents the variations of excess pore water pressure at the depth of

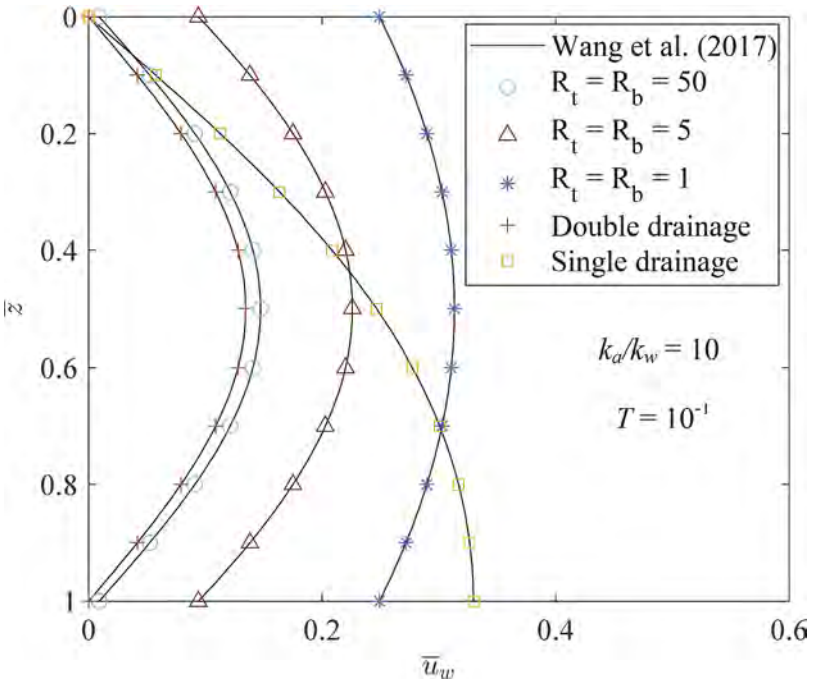

Figure 3. Isochrones of excess water pore pressures compared with existing analytical solutions.

8 m considering different semi-permeable boundary conditions. The analytical solutions presented by Wang et al. (2017) with the same semi-permeable boundary conditions were plotted in these two figures as well and they are identical to the proposed solutions. Furthermore, this figure shows another two scenarios with ideal double drainage ($R_t = R_b = \infty$) and single drainage ($R_t = \infty$, $R_b = 0$) and they are the same as the solutions obtained from the analytical solution proposed by Qin et al. (2008). To further validate the proposed analytical solution, the isochrones of excess pore water and air pressure are shown in Figure 3. At the time step of $T = 10^{-4}$, Figure 3 shows the influence of the semi-permeable boundary on the isochrones of excess pore water pressures at $T = 10^{-1}$. In the same way, the results were compared with the existing analytical solutions in the literature (Lei Wang et al., 2017). The above discussion indicates the accuracy of the proposed analytical solution from different aspects.

6 CONCLUSION

In this study, an analytical solution is presented to show the consolidation characteristics of unsaturated soils considering semi-permeable boundary conditions. The present work reveals a simple derivation process involving semi-permeable boundary conditions. The solutions illustrate that the semi-permeable boundary can impede the dissipation of excess pore pressures at the corresponding boundary and can increase the excess pore pressures to some certain value. The permeability ratio between the air and water phases has the main impact on the consolidation of the air phase and the early stage of consolidation for the water phase.

ABSTRACT: Many steep slopes are associated with deep groundwater table so they are located within unsaturated zone. Therefore, it is important to incorporate the unsaturated soil properties in the analysis of slope and design of slope preventive measures. The main property of the unsaturated soil is Water Retention Curve (WRC) describing the relationship between suction and water content. Many researchers developed technologies and methods in the determination of WRC which are associated with certain theory and assumption. The establishment of WRC can be performed using direct and indirect method. This paper focuses on the comparison of three different laboratory testing methods as direct methods to generate WRC. In addition, the paper summarizes the advantages and disadvantages of different methods in the determination of the air-entry value which is the important variable of WRC. The estimation of WRC using indirect method is presented as the practical approach for rapid determination of WRC.

Keywords: Rainfall-induced landslides, unsaturated soil, water retention curve, air-entry value

1 INTRODUCTION

In classical soil mechanics (e.g., excavation and foundation), geotechnical problems have been solved based on the saturated shear strength principles from Terzaghi (1936). This is admissible because of its conservative approach. Saturated condition can only be found below the groundwater table. For residual soils, unsaturated conditions need to be considered (Satyanaga and Rahadjo, 2020). Unlike saturated soil, an unsaturated soil has negative pore water pressures (Rahardjo et al., 2016). Therefore, understanding on unsaturated soil mechanics is required in solving geotechnical issues.

The water retention curve (WRC) describes the relation between the water content and the suction of the unsaturated soil (e.g., Satyanaga et al., 2017). The determination of WRC is merely done in the laboratory whereby the mathematical modelling is of huge importance to reduce the efforts in the laboratory. The WRC is highly depended on the soil type, but it has usually the form of a sigmoid function. The water content can be displayed as degree of saturation, gravimetric water content or volumetric water content. The soil suction has a range between nearly 0 and 10^6 kPa (Rahardjo et al., 2019). The boundary effect zone is the zone between zero suction and the air-entry value (AEV) (Satyanaga and Rahardjo, 2019). Basically, this zone represents the capillary fringe of groundwater in an unsaturated soil. The

*Corresponding author: alfrendo.satyanaga@nu.edu.kz

DOI: 10.1201/9781003299127-37

transition zone is the zone between the AEV and the residual condition. The air-entry value marks the suction where air begins to penetrate into the largest pores. The determination of the AVE can be done deterministic (Zhai & Rahardjo, 2012) or graphically (Zhai et al., 2020). On the WRC, the AEV is the interception of the tangent at the point of the maximal water content and the tangent at the point of the maximum gradient called inflection point.

This paper focuses on the comparison of different laboratory test methods as direct methods and different estimation methods to generate WRC. The scope of works includes the WRC testing in laboratory using Tempe cell, pressure plate, Fredlund cell, modified triaxial cell.

2 APPLICABLE THEORY

Laboratory experiments deliver a series of data for defining the WRC. For a practical usage, simple mathematical description of the WRC is needed. This description are empirical formulations, which can be fitted at most exactly to the measured data. Over the past century, investigators presented a whole variety from simple to sophisticated mathematical models. Statistical assessment from Sillers and Fredlund (2001) with the Akaike Information Criterion (AIC) and Leong and Rahardjo (1997) with a residual analysis concluded that Fredlund and Xing (1994) model as the best model in best fitting WRC data. Therefore, the model from Fredlund and Xing (1994) (Equation 1) was used in this study.

$$\theta(\psi,\ a,\ n,\ m) = C(\psi) * \frac{\theta_s}{\left\{ ln\left[e + \left(\frac{\psi}{a}\right)^n \right] \right\}^m} \tag{1}$$

whereas *a,n ,m* are unknown fitting parameters, ψ is the matric suction (u_a - u_w), θ_s is the saturated water content, *e* is the natural number (≈2.72) and $C(\psi)$ is a correction factor defined as follow:

$$C(\psi) = \frac{ln\left(1 + \frac{\psi}{\psi_r}\right)}{\left[ln1 + \left(\frac{1'000'000}{\psi_r}\right) \right]} + 1 \tag{2}$$

The parameter ψ_r is a fitting parameter related to the residual suction. However, Leong and Rahardjo (1997) favour to use C(ψ) = 1 and this was applied in this study as well. The fitting parameters a,n and m are empirical in nature and they can be fitted with the method of the least squares whereas the parameters need to be reasonable (Fredlund & Xing, 1994). Parameter *a* is related to the AEV and basically defines the "position" of the curve. Parameter *n* expresses the ratio of drain of a soil and could be regarded as slope of the SWCC. Parameter *m* is related to the residual stage of the curve and is an indicator for the logarithmic symmetry of the curve. Zhai and Rahardjo (2012) proposed deterministic approach (Equations 3 and 4) to calculate AEV.

$$\psi_{AEV} = a * 0.1^{\frac{3.72 * 1.31^{m+1} * \left(1 - e^{-\frac{m}{3.67}}\right)}{n * m * \ln(10)}} \tag{3}$$

for correction factor = 1

$$\psi_{AEV} = a * 10^{\frac{\theta_i - \theta_s}{s_1}} \tag{4}$$

for correction factor is not equal to 1

where the parameters *a, m* and *n* are the fitting parameters from D. G. Fredlund and Xing (1994). The parameter s_1 is the slope, θ_i the volumetric water content at the inflection point a_f and θ_s the saturated residual water content.

To avoid time consuming and expensive laboratory experiments, some researchers came up with estimations for the SWCC. Such estimations can also be useful for planning the laboratory experiments (i.e., define the suction to be measured). M. D. Fredlund et al., (2002)

presented an estimation based on the grain-size distribution. This method is implemented in the software SoilVision and it is rather difficult to calculate by hand but it delivers reasonably reliable results for sands and silts. However, it has some weaknesses for clays, tills and loams.

A straight forward estimation for plastic soil is proposed by Zapata (1999) and further developed by Perera et al., (2005). This method is based on the grain-size distribution and the plasticity index (PI). The method predicts WRC based on a weighed Plasticity index, *wPI* for non-plastic soils (Equation 5), respectively. Equations 6 to 8 can be used to determine WRC of plastic soils.

$$wPI = PI * P_{200} \ (expressed\ as\ a\ decimal) \tag{5}$$

$$a = 32.835\{ln(wPI)\} + 32.438 \tag{6}$$

$$n = 1.421(wPI)^{-0.3185} \tag{7}$$

$$m = -0.2154\{ln(wPI)\} + 0.7145 \tag{8}$$

The parameter *a, n, m* and ψ_r representing the fitting parameters from the Fredlund & Xing equation in Equation 3 and 4 where ψ_r = 500.

3 APPLICABLE THEORY RESEARCH METHODOLOGY

The soil used in the laboratory test was obtained from a borehole at Orchard Boulevard site located at the central of Singapore which is a part of residual soil from Bukit Timah Granite. In this study undisturbed samples from a depth between 6 to 7 meters were used. The index properties tests were performed based on ASTM standard. The grain-size distribution was determined based on ASTM D422-63. The tests to obtain Atterberg limits were performed based on ASTM D4318-00. The specific gravity was carried out based on ASTM D854-02.

Three sets of WRC tests were determined in the laboratory with three different methods (Satyanaga et al., 2019): (i) Tempe cell and pressure plate; (ii) Fredlund cell and (iii) modified Triaxial device. The Tempe cell in Figure 1 was used for measurement of WRC at suction < 100 kPa. A 1 bar high entry disk was used in this experiment. A schematic diagram of a cross sectional view of Tempe cell is shown in Figure 2. The pressure plate (Figure 3) was measurement of WRC at suction > 100 kPa. A 5-bar high entry disk was applied in this experiment. The image of the open pressure plate is shown in Figure 4. A cross sectional view of pressure plate is shown in Figure 5.

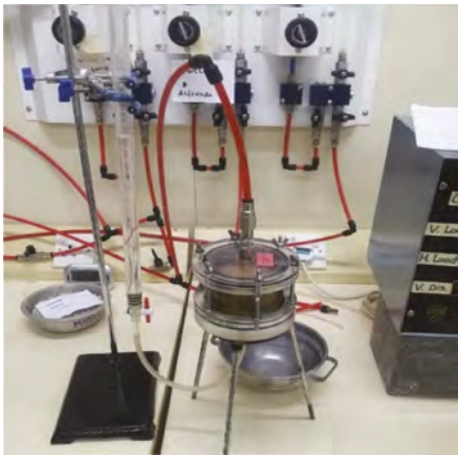

Figure 1. Tempe cell set up during WRC testing.

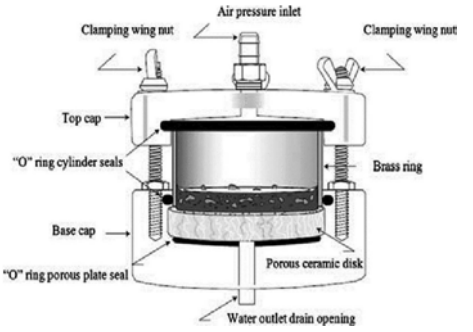

Figure 2. Cross sectional view tempe cell from Satyanaga et al. (2021a).

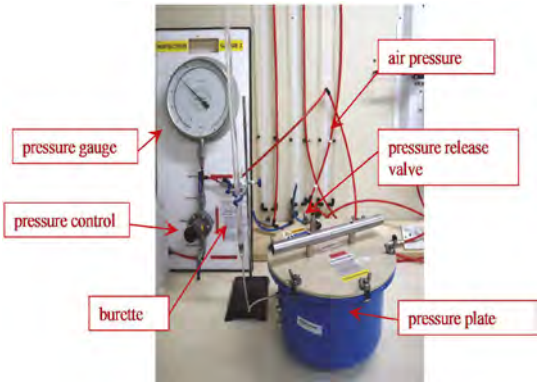

Figure 3. Pressure plate set up during WRC testing.

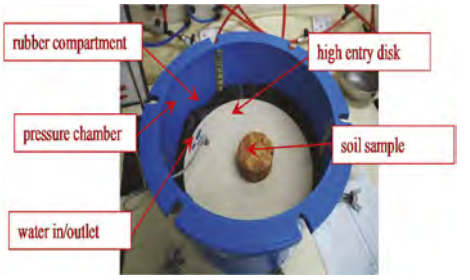

Figure 4. Open pressure plate during WRC testing.

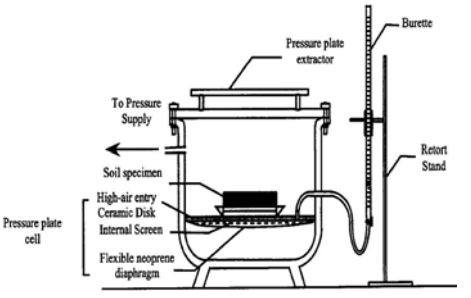

Figure 5. Cross sectional view pressure plate from Satyanaga et al. (2021b).

The previous WRC estimation from M. D. Fredlund et al. (2002) was used to define the applied matric suction, based on the grain-size distribution. The following suction stages were applied in the measurement of WRC: 1 kPa, 2 kPa, 5 kPa, 10 kPa, 20 kPa, 25 kPa, 50 kPa, 75 kPa, 90 kPa for Tempe cell testing and 200 kPa, 300 kPa, 400 kPa for pressure plate testing. The high entry disc (or porous ceramic disc) was connected via a tube to a burette filled with de-aired and distilled water. The purpose of this connection was to keep the disc during the experiment saturated. Air pressure was applied from the top of the cell. The matric suction resulted from the difference between the applied air pressure and the piezometric head in the burette. The equalization was controlled by measuring the mass of the sample by weighting the closed cell.

The Fredlund cell set up during the WRC testing is shown in Figure 6. A 5-bar high entry disk was applied in the experiment. The set-up of the open Fredlund cell is shown in Figure 7. A schematic diagram of a cross sectional view is shown in Figure 8.

Figure 6. Fredlund cell set up during WRC testing.

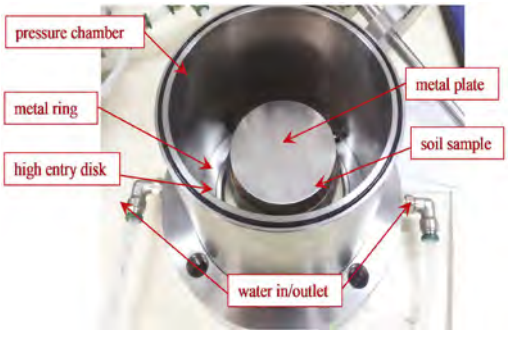

Figure 7. Open Fredlund cell before WRC testing is started.

The different suction stages were estimated according to the findings of the first suction measurements of the Tempe cell. The following suction stages were used in the measurement of WRC: 5 kPa, 10 kPa, 25 kPa, 50 kPa, 75 kPa, 100 kPa, 150 kPa, 200 kPa, 300 kPa, 400 kPa and 500 kPa. Before the testing, the water volume tube was calibrated for determining. the following correction factors. They are the ratio between mass water and the height in the tube, and the volume change in the tube which can directly be converted into water mass or water volume. Air pressure was applied from the top of the cell. The matric suction resulted from the difference between the applied air pressure and the piezometric head in the volume tube. The equalization was controlled by reading the volume change.

The modified triaxial device for the WRC testing is shown in Figure 9. A 5-bar high entry disk was applied in this experiment. The image of open cell is shown in Figure 10.

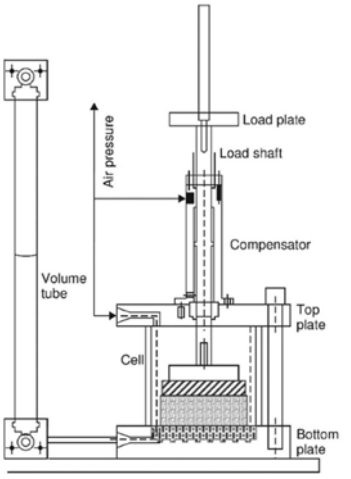

Figure 8. Cross sectional view Fredlund cell (after Fredlund et al., 2012).

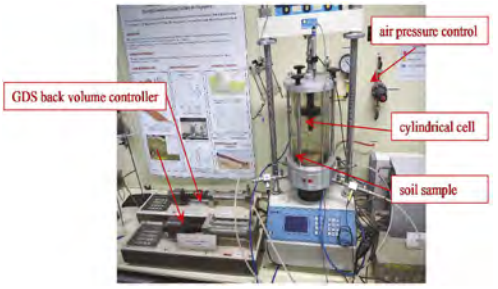

Figure 9. Modified triaxial apparatus set up during WRC testing.

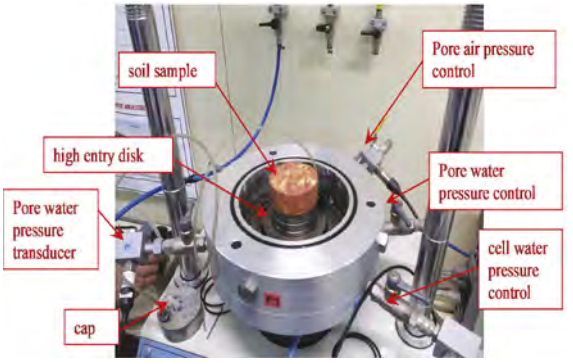

Figure 10. Open triaxial apparatus prior to WRC testing.

The different suction stages were estimated according to the findings of the suction measurements of the Tempe cell and Fredlund cell. The following suction stages were used in the measurement: 10 kPa, 25 kPa, 50 kPa, 75 kPa, 100 kPa, 150 kPa, 200 kPa, 300 kPa, 400 kPa and 500 kPa. Soil suction could be applied to the sample by reducing the pore water back pressure and keeping the air pressure on 490 kPa. As soon as no significant change in the back pressure volume change was observed, the sample was regarded as equalized, and the soil suction could be increased. The different readings were done automatically by transducers attached to the air pressure control, pore water pressure and cell pressure control. Since the

specimen was from a depth of 6 to 7m, confining pressure of 90 kPa was applied to the specimen to simulate the conditions in such depth.

4 RESULTS AND DISCUSSIONS

The WRC from direct and indirect method are displayed in Figure 11. The duration of WRC test using Tempe cell and pressure plate are around 5 weeks. Totally, 175 measurements were made at 8 different matric suctions. The curve was fitted with Fredlund and Xing (1994) by the sum of the least square with the correction factor $C = 1$ on the degree of saturation points. In order to get reasonable results, the fitting parameter were limited with the values $a = 500$, $n \leq 6$ and $m \leq 6$. Following parameter were determined a = 500, n = 0.716, m = 2.475, θ_s = 49%. The duration of WRC test using Fredlund cell are around 6 weeks. Totally, 152 measurements were made at 11 different matric suctions. a = 500, n = 1.048, m = 0.974, θ_s = 51%. The duration of WRC test using modified Triaxial cell test are around 5 weeks. Totally, 6 different matric suctions were measured. a =500, n = 1.030, m = 1.472, θ_s = 50%. The estimation based on Zapata resulted in following SWCC. a = 131, n = 0.548, m = 0.070, θ_s = 50%, C_r = 500. The estimation based on Fredlund & Wilson was done with the software SoilVision and resulted in following SWCC. a = 583, n = 0.722, m = 0.988, θ_s = 50%, C_r = 500.

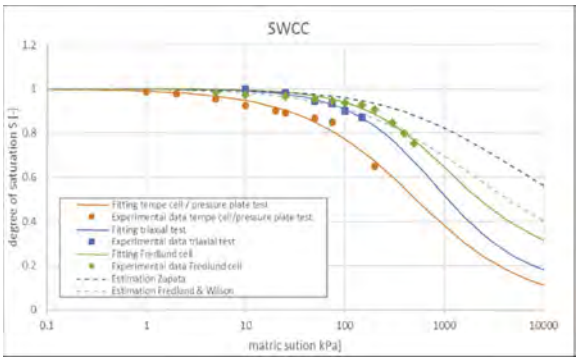

Figure 11. Overview of determined and estimated SWCC.

Figure 11 shows that different methods result in different curves. It shows that the application of confining pressure has a significant influence on the SWCC. The water content is higher on the same suction when confining pressure is applied. The two estimations perform up to 200 kPa quite well compared with the experimental data from the Fredlund Cell and the triaxial test. It seems that estimation based on Perera et al. (2005) overestimates the data. However, both curves seem to be too flat. This has a significant influence on the bending point and therefore on the AEV and on higher suctions.

As the determination of the WRC with the Fredlund cell could be done without any problems, this WRC is assumed to be the most accurate. Therefore, the air entry value (114 kPa) was determined based on Zhai and Rahardjo (2012). In order to show the variability and uncertainties, which comes with the AEV determining with a fitting by Fredlund and Xing (1994) and C=1, the AEV of different methods and different parameters were analyzed. Then, the comparisons of AEV were made with the following methods: (i) Determination (Zhai & Rahardjo, 2012)/ graphically estimation (Vanapalli et al., 1998); (ii) Fitting methods: least square / R^2 / least absolute deviation/sum of weighted least squares; (iii) SWCC determination/estimation: Tempe cell & Pressure plate / Fredlund cell / Triaxial device / Zapata estimation / Fredlund & Wilson estimation; (iv) Fitting degree of saturation / volumetric water content; (v) Fitting limits. The obtained value above (114 kPa) and the applied approach (i.e., determination from the Fredlund & Xing fitted saturated water content based on a least square fitting with given limits) were regarded as standard. The AEVs were analyzed by

varying one element. The AEV was determined mathematically. The other, more classical, approach is a graphical estimation and is described by Vanapalli et al. (1998). The AEV is the interception of the tangent at the point of the maximal water content (i.e., S=1) and the tangent at the inflection point (a_f). The method is illustrated in Figure 12, whereby the dotted line is the function of the slope. The determined AVE from graphical method is 143 kPa. All the different AEV are summarized in Figure 13.

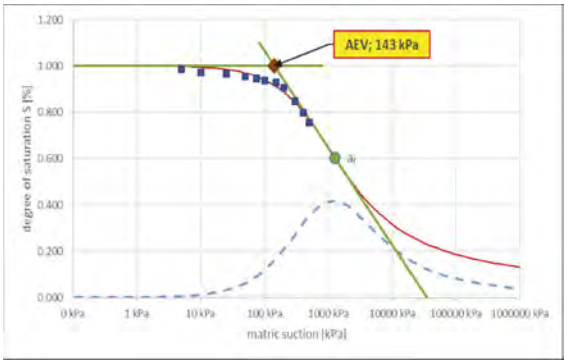

Figure 12. Determination of AEV based on graphical method.

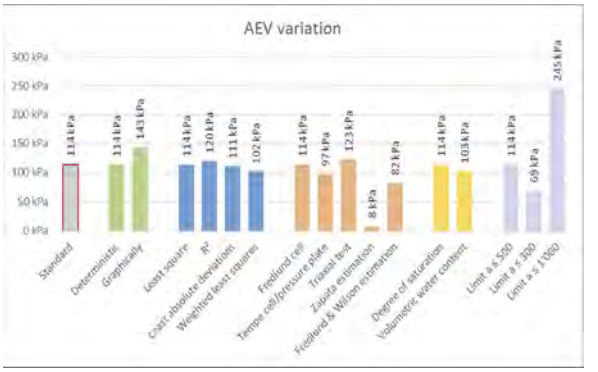

Figure 13. AEV from different method.

5 CONCLUSIONS

The following conclusions can be deduced from this study

- The biggest influence on the AEV seems to have a variation of the limits, whereby as described above, the variation is much higher if the AEV is determined mathematically.
- There is a significant difference between determining the AEV mathematically and graphically.
- The variation due to different fitting methods is the smallest and does not have an influence on the shape of the SWCC.
- With different laboratory methods, the AEV varies. Whereby an applied confining pressure results in a higher AEV.
- The estimation methods in this study underestimated the AEV. The shape of the SWCC estimated by Perera et al. (2005) cannot lead to a reliable estimation of the AEV.
- The AEV determined based on a volumetric water content fitting is smaller than the AEV obtained from a degree of saturation fitting.

ABSTRACT: Missing soil parameters are common in soil investigation and published literature due to the fact that undisturbed soil samples used in a laboratory test cannot be used for another testing as the soil has been disturbed and no longer representative of the actual field condition. The issue of missing soil parameter is further exacerbated in the event of high heterogeneity of the ground, where soil parameters obtained from a specific depth in the ground may not be reflective of another depth in the same borehole. Therefore, soil parameters without direct measurements have to be inferred from other available soil parameters. This is the part where machine learning becomes useful. However, many machine learning models do not handle missing data automatically. This paper presents the attempt to modify existing machine learning algorithms to achieve the ability of filling missing values in soil datasets.

1 INTRODUCTION

1.1 *Nature of geotechnical engineering*

In the modern geotechnical engineering, sophisticated numerical software and wide range of insitu and lab testing are available to model the behavior of soil. However, in practice, soil parameters needed for numerical modelling are often inadequate for design. Comprehensive site investigation to complete these missing parameters may also be constrained due to time and cost limitations. Sometimes, despite carrying out what was deemed sufficient site investigations, design engineers may occasionally encounter cases where adjacent boreholes may provide ground conditions that are not consistent. This highlights the essence of the key challenge in geotechnical engineering: Inadequate, incomplete and sometimes conflicting information.

Inadequate information may be a result of too few boreholes with wide spacing at an unexpectedly heterogeneous site. Too few lab tests provisioned for each borehole may also surface such issues of inadequate information. Incomplete information can arise from the limited undisturbed samples at each depth interval. Design engineers would have to decide whether to conduct a triaxial, oedometer, vane shear or shearbox test. Different tests can produce slightly different results for the same parameter. In making matters worse, large variation in soil proile and properties between adjacent boreholes can lead to conflicting information when

DOI: 10.1201/9781003299127-38

determining the ground profile and properties. All these issues with information can have significant repercussion to numerical modeling of geotechnical problems.

1.2 *Overcoming limited soil information*

In order to overcome cases of limited soil data, design engineers resort to making certain assumptions and interpolation of missing soil parameters based on the typical values for similar soil. For design engineers with rich depository of records from past projects and literature, an alternative is to acquire complementary information from trends and relationships of these local and global soil databases. This is known as machine learning, or in broader terms, data driven methods.

In data driven approach, decisions are made based on data, rather than intuition. Machine learning is an attempt to make machines learn from experience. In the recent years, such use of data-driven methodologies in research and field trials have been adopted, especially to characterise soil properties in site investigation (Ching and Phoon, 2014; Christensen et al., 2021; Javadi and Rezania, 2009; Wang and Liang, 2020; Xiao et al. 2021; Shen et al., 2023; Lo et al. 2023).

In this paper, the focus would be on the use of data driven machine learning, where learning is based on data, to fill missing soil data in site investigation.

2 MISSING VALUE IMPUTATION

2.1 *Database*

Data from a total of 77 compressibility related publications were compiled to form the database. The 12 parameters collated were: compression and recompression indices C_c and C_r, initial void ratio e_0, initial moisture content w_0, specific gravity G_s, plastic limit PL, liquid limit LL, plasticity index PI, percentage of sand, silt, clay as well as fines (silt + clay) content.

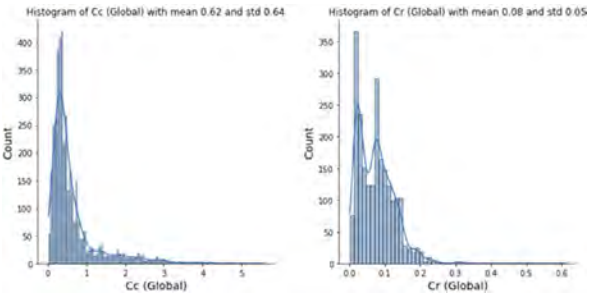

Figure 1. Histograms of input parameters.

Figures 1 and 2 show the histograms of the compressibility indices and input parameters collated, respectively. These publications were selected having provided sufficient information with respect to both oedometer test results as well as sample properties and conditions. These scope of these papers therefore largely included the evaluation and investigation of empirical correlations between compression indices and soil properties, detailed oedometer analyses of soils with varying compositions or structural conditions, and reviews of the classifications and engineering properties of a particular soil. For conciseness, the full list of these publications would not be listed in the references. They are available upon request from the authors.

Table 1 presents the missing percentages of missing data for each input parameter in the C_c and C_r training set. Missing values have to be filled by imputation in order for machine learning to be carried out in order for input parameters to be complete for proper design in numerical modeling. In machine learning, parameters are often referred to as features.

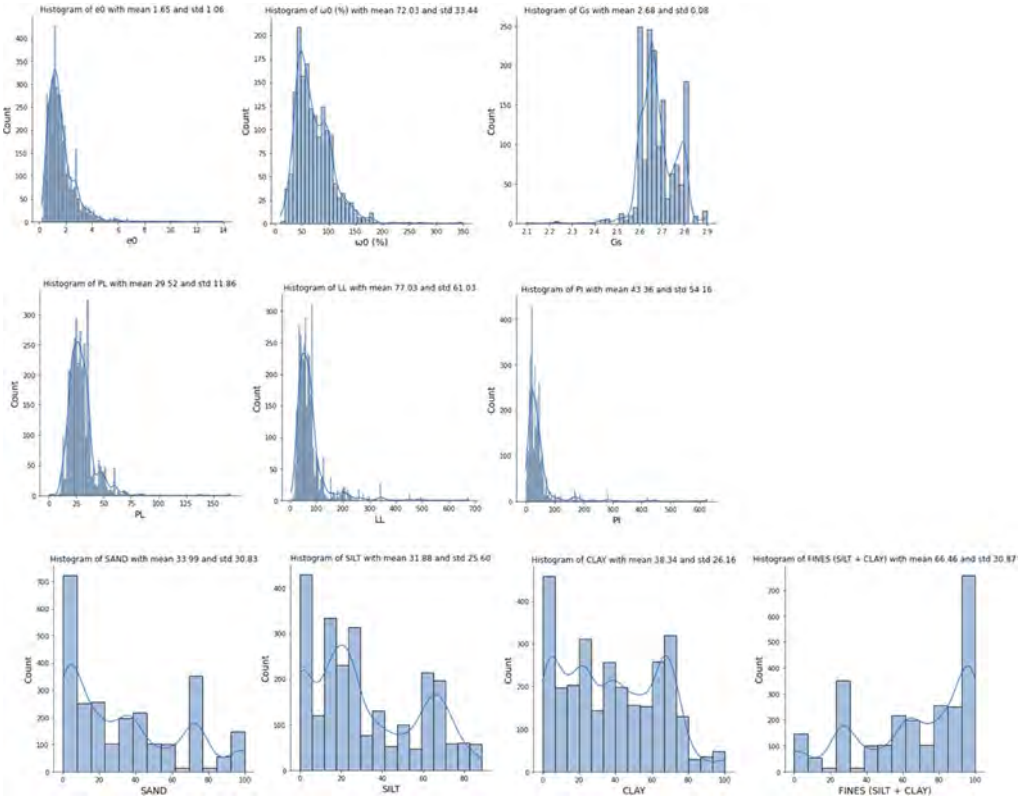

Figure 2. Histograms of compressibility indices.

Table 1. Percentage of missing data (by feature) in training set.

Features	% of missing data	
	C_c	C_r
e_0	10.0	2.6
w_0	30.1	13.0
G_s	80.3	18.7
PL	30.5	11.6
LL	24.7	11.6
PI	30.5	11.6
Sand	68.7	0.9
Silt	71.0	8.3
Clay	55.2	8.3
Fines	68.4	0.7

2.2 *Machine learning model*

Our machine learning analysis adopts the XGBoost model as it is capable of handling missing values relatively better than the other models due to a built-in algorithm. Conventional machine learning approaches may simply neglect the row of data with missing inputs, resulting in a small dataset to work with. In XGBoost, Chen and Guestrin (2016) described the sparsity-aware split finding in the approach. When searching for the best split, XGBoost first

considers the non-missing values. Then, the missing values would be classified into one default direction, either left or right. The optimum default direction is determined by the one that gives the maximum gain in the similarity score after classifying the missing values into that direction.

XGBoost (eXtreme Gradient Boosting) is a tree boosting method originated from "Gradient Boosting" introduced by Friedman (2001). XGBoost predicts the results using K additive regression trees. The decision function can be written in following form:

$$\hat{y}_i = \sum_{k=1}^{K} f_k(x_i),\ f_k \in \mathcal{F}$$

where f is a regression tree in the functional space $\mathcal{F}$.

The objective function of XGBoost consists of 2 terms: loss term (l) and model complexity term (Ω):

$$L(\phi) = \sum_i l(\hat{y}_i, y_i) + \sum_k \Omega(f_k)$$

where $\Omega(f_k) = \gamma T + \frac{1}{2}\lambda \|w\|^2$. T is the number of leaves, w is the vector of scores on leaves, γ and λ regularization hyper-parameters. The objective function is minimized in an additive manner.

Figure 3 shows an example of predicting whether someone likes a hypothetical computer game using XGBoost regressor.

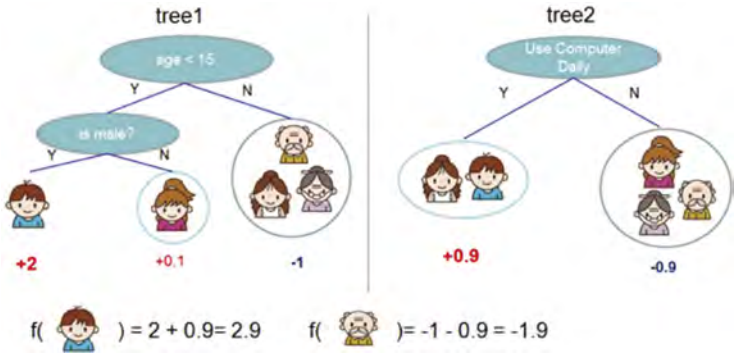

Figure 3. Example of XGBoost regressor (Chen & Guestrin, 2016).

2.3 *Imputation methods*

According to Rubin (1976) and Little & Rubin (1987), missing data can be classified into 3 mechanisms: missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). For MCAR, the probability of data missing is independent of any data. An example is a data logger missing a data point due to random connection problem. For MAR, the probability of data missing is independent of that feature, but is dependent on other features. For example, a data logger produces more missing value on a soft ground. For MNAR, the probability of data missing is dependent on the value of the missing data. An example is a data logger that always fails to record large numbers. In this study, the missing data issue is akin to the MAR assumption. Three imputation methods were considered: 1) mean and median, 2) KNN, and 3) iterative imputation.

Mean and median use the mean or median value of a certain feature to fill in any missing value in that feature. They are the simplest and fastest imputation method. However, the distribution of the features and the relations between features are often distorted after imputation.

KNN imputation fill in missing data using the weighted average k-Nearest Neighbors approach (Troyanskaya et al., 2001). Euclidean distance is used to measure the distance between 2 samples. Stekhoven & Buhlmann (2012) proposed a cross-validation KNN method to determine k. The original dataset is first imputed using mean imputation, and is then introduced with artificial missing values. After that, KNN imputation is conducted using a range of k values, the error between the imputed and the complete dataset is obtained for each k. Repeat the above steps for l times, and k is determined by the value that has the lowest average error across the l repetitions.

Iterative imputation is a multivariate imputation method. Each feature with missing values are predicted using the remaining features. Some popular iterative imputation methods include MissForest (Stekhoven & Buhlmann, 2012) and MICE (van Buuren & Oudshoorn, 1999). Since the focus of this study is not to measure the uncertainty caused by missing values, multi-imputation method like MICE is not adopted.

For each method considered, the performance of the unimputed (for XGBoost) and imputed datasets (via the various imputation methods) were assessed in terms of cross validated mean squared error (CVMSE). The option giving the lowest CVMSE was then adopted as the optimal dataset for that model, and would be selected to undergo further evaluation through the feature selection process. An example of this assessment is shown in Figure 4, where the original dataset still resulted in the best performance for C_c prediction on a untuned XGBoost model against the various imputed datasets. OriginalData refers to the original dataset with missing data. Bayesian_sample_asc refers to iterative imputation using Bayesian Ridge Regression; the order of imputation is from features with fewest missing values to most. Bayesian_desc refers to iterative imputation using Bayesian Ridge Regression; the order of imputation is from features with most missing values to fewest. et_asc adopts iterative imputation using extra tree; the order of imputation is from features with fewests missing values to most. mf_asc adopts Miss-Forest imputation; the order of imputation is from features with fewest missing values to most. knn refers to K-Nearest Neighbors imputation. cvknn is the cross-validated KNN. Median is filling the missing data with the median value, while mean is fills the missing data with the mean value.

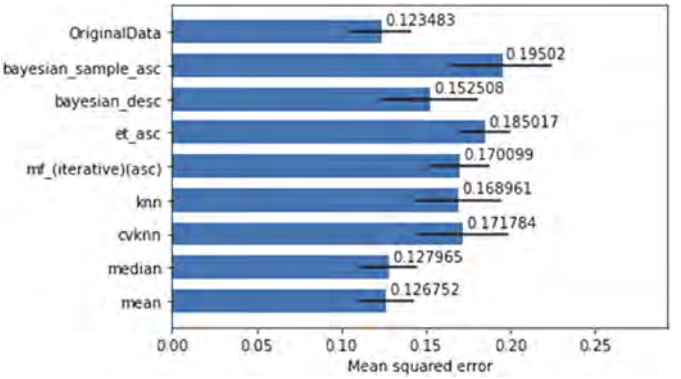

Figure 4. Comparison of unimputed (for XGBoost) and imputed (via various imputation methods) datasets.

According to findings from Figure 4, the imputation methods performed appear to provide no significant improvement on the performance of the model. Some imputation methods have shown to cause an increase in the means squared error instead. This suggests that the XGBoost model can already handle the missing values reasonably well and suitable for use in this database with the soil parameters mentioned earlier.

3 CONCLUSION

Missing soil parameters is a common issue in practice, which can hamper good quality numerical modeling of geotechnical problems. Data driven machine learning techniques can enable statistically robust and efficient filling of missing soil parameters. XGBoost was adopted in this study which showed its ability to fill these missing soil parameters with low mean squared errors comparable or better than existing imputation methods. Therefore, design engineers new to imputation approaches may consider attempting techniques similar to XGBoost as a start to overcoming issues with missing soil parameters in their modeling.

ACKNOWLEDGEMENT

Clay soil deformations under regime long-term triaxial compression taking into account initial defects

I.T. Mirsayapov & N.N. Aysin
KSUAE, Kazan, Russia

ABSTRACT: The arrangement of deep pits leads to a change in the stress-strain state of the soil mass within the radius of the zone of influence. When entering the zone of existing buildings, there is a need for an assessment and geotechnical forecast of the behavior of the soils under foundations of existing buildings and structures. At the same time, it is necessary to take into account existing and new defects and cracks in soils. For determine the main dependences of clay samples deformation characteristics with existing defects experimental studies with triaxial compression of samples with cracks and without cracks were carry out. Based on the results of the study, new data were obtained on the effect of defects in soil samples on the deformation of clay soil. Based on the research results, the dependences of the main deformation characteristics of clay soil are constructed.

1 INTRODUCTION

Constructing a deep pit located in a built-up area makes necessary to perform a geotechnical forecast (assessment) of the impact of construction on the change in the stress-strain state of the surrounding soil mass, including the foundations of the surrounding buildings. The geotechnical forecast of the impact should take into account the technological settlement of the foundations of the surrounding buildings from the "wall in the soil" device. At the same time, it is necessary to take into account the horizontal movements of the enclosing structure of the pit and the unloading of the subgrade from the excavation in the pit, loads from the newly erected structure or additional loads from the reconstructed structure and other factors, taking into account the sequence of the underground part of the structure, using analytical and numerical calculation methods. Depending on the category of technical condition of existing buildings, the permissible additional settlement of buildings is 20-50 mm. At the same time, the unevenness of the settlements is no less, sometimes even more dangerous. Pronozin et al (2019, 2020) considered the amount of additional stresses in the structure of the building with uneven settlement.

The process of destruction and development of nonlinear deformations of clay soil under triaxial compression is accompanied by the formation and development of micro- and macrocracks in the planes of ultimate equilibrium. Micro- and macro-cracks in the soil structure affect the deformation and strength of the soil under prolonged loading. Melnikov et al. (2021) studied the change in the physical and mechanical characteristics of the soil under the building when the structure of soil changes.

Emil Soból et al. (2020) studied 15 different Warsaw clays. The collected data allowed the authors to create empirical models describing the characteristics of rigidity with high reliability. Combined empirical models allow us to estimate the value of the shear modulus of a connected soil in a wide range of shear deformations with high accuracy. As a result of the study, it was found that the maximum shear modulus increases with the average effective pressure. The plasticity number had a negligible effect on the G_{MAX} value, and depends on the effective stress p' and the void ratio e. Shear deformation had the greatest impact on the shear

DOI: 10.1201/9781003299127-39

modulus and normalized shear modulus degradation curves. With an increase in both plasticity and effective stress, the nonlinear threshold strain shifted to a higher shear strain. However, the average effective stress (p') had a noticeably smaller effect on the elastic range of shear deformation than the plasticity index (P_I).

Clay soils have pronounced rheological properties, which vary depending on the degree of damage to the structure with initial defects and damages. A relatively small number of works study the influence of defects in the form of micro- and macro-cracks on the rheological properties of soils. The issues of changing the strength and deformability of clay soils with initial defects and damages under prolonged regime static loading have not been practically studied (Xianzhang 2017, Kutergin 2015, Hussein 2020, Mirsayapov 2020, Mirsayapov & Koroleva 2019).

When designing and building, it is necessary to avoid uneven settlement. In the article by Heng Zhang et al. (2021), an analytical solution based on the Laplace integral transformation method has been developed for predicting long-term uneven settlement of buildings on soft soil foundations. The methodology is based on Laplace integral transformation and the theory of viscoelasticity. It combines an analytical solution with a finite element method for a solution taking into account the sequence of construction and loading. The accuracy of the analytical solution based on the integral Laplace transform is confirmed by the monitoring results.

In clay soils under triaxial compression, stresses and deformations vary depending on the stress level, the ratio of vertical and horizontal stresses, the duration of the load, the trajectory and the size of the initial structural defects (Wang Y. 2017, Hicher P. Y. 2016, Hu C. & Liu H. 2015, Wang Y. 2017, Mirsayapov, I.T. & Koroleva, I.V. 2019). Therefore, the stress to strain ratio is not constant, and changes, even if one of these quantities does not change over time and the other (stress or strain) changes. In connection with the above, there is a need to establish patterns of changes in the strength and deformability of clayey soils, taking into account changes in long-term loading modes and the influence of existing defects and damages

2 MATERIALS AND METHODS

Complex modeling of the stress-strain state and numerical studies have made it possible to establish that the construction of a deep pit with a depth of 13.0 m with vertical walls without proper fastening in the immediate vicinity of the building led to simultaneous vertical and horizontal movement of the soils of the foundations of the building. There were a lot of shear lines of the soil mass under the foundations (Figure 1), indicating the achievement of the first limit state of the foundations and the formation of cracks in the soil mass.

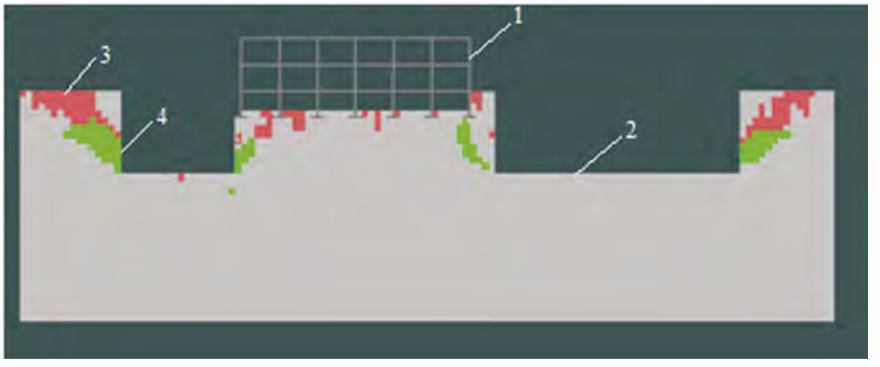

Figure 1. The general condition of the soil after digging the pit to a depth of 13 m: 1 – existing building, 2 – deep pit, 3 – the zone of soil failure, 4 – the zone of soil starching.

To assess the further behavior of the soil, it is necessary to establish the physical, mechanical and deformation characteristics of the soil, taking into account the cracks and defects that

have appeared. For this purpose, this stress-strain state of the soil was recreated in laboratory conditions. The tests were carried out on a true triaxial compression device with rigid walls. The device was developed at the department (Mirsayapov et al 2012, 2015). The soil sample loaded using mechanical levers, which ensures constant pressure when the sample is deformed. The tests were carried out at the same lateral pressure. Vertical σ_1 stresses were applied to the sample with a given step.

Artificially prepared samples of clay soil were used for testing, having the shape of a cube with dimensions of 10 x 10 x 10 cm, with the specified characteristics: density p = 1.91 g/cm^3; humidity W = 0.2. To determine the effect of the formation and development of defects on the strength and deformation of clay soil, artificial cracks of two types were created (Figure 2) with the line with the diameter 0.8 mm: 1 – one crack in the assumed ultimate equilibrium surface of the soil; 2 – in the form of two intersecting cracks in two surfaces of ultimate equilibrium.

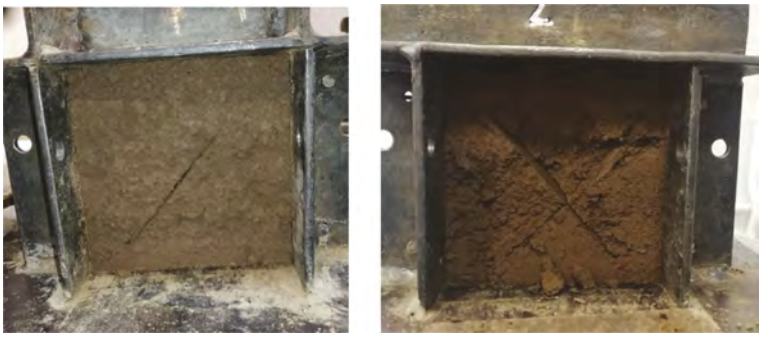

Figure 2. Samples with cracks in the equilibrium planes: a) with one crack; b) with two intersecting cracks in two equilibrium planes.

The design of the equipment includes five loading dies, which are displaced in pairs relative to each other. It is assumed that during loading, only the main stresses are applied to the edges of the soil sample, and the shear stresses are equal to zero. Movements, coaxial with the applied loads, were measured by indicators. The values of deformations were determined by calculation. At the initial stage, the soil sample was subjected to comprehensive compression $\sigma_1 = \sigma_2 = \sigma_3$ = 160 kPa. After stabilization of axial deformations at constant values of lateral stresses $\sigma_2 = \sigma_3$ = 160 kPa, a vertical load was applied to the sample. Each loading stage was sustained, then the next load level was applied until the ultimate deformation was reached.

3 RESULTS

Within each block of regime long-term static loading, there was an increase in linear vertical deformations, shear deformations, as well as a change in the intensity of shear deformations, the modulus of vertical deformations and the shear modulus, indirectly characterizing the change in the strength and deformation characteristics of soils during loading.

At the stage of comprehensive compression lateral deformations grow more intensively than vertical ones. The maximum value of lateral deformations is reached at the moment when vertical deformations make up 25-30% of the maximum deformations during fracture. A noticeable increase in vertical linear deformations begins at $\sigma_z > 0.3\ \sigma_{ult}$. In the blocks of regime long-term loading, there was an increase in vertical deformations both at the stage of comprehensive and at the stage of deviatory loading. Analysis of the development schedule of vertical deformations shows that they develop throughout the tests with varying intensity. At this interval of deviatory loading, the maximum vertical deformations were in samples with two cracks, the minimum deformations were in samples without cracks.

Horizontal deformations ε_x and ε_y also developed throughout the long-term deviatory loading with different intensity. The highest value of horizontal deformations is observed in

samples with two cracks, the minimum deformations are observed in samples without cracks. The results of experimental studies show that the biggest values of the intensity of shear deformations were in samples with one crack and the minimum values of the intensity of shear deformations in samples without cracks.

At the stage of deviatory loading, the linear modulus of *AER* vertical deformations, the shear modulus and the volumetric modulus of deformations decreased on all blocks of regime loading. The most intensive decrease in the modulus of vertical deformations occurred in samples without cracks. In the samples with one and two cracks, the decrease in the modulus of vertical deformations occurred more smoothly than in the samples without cracks. The same situation can be seen with the volumetric modulus of deformations. Due to the fact that the initial cracks led to a more intensive growth of all components of deformations, the decrease in the volume modulus of deformations was smooth with an increase in the stress deviator.

Numerical modeling, taking into account the results of laboratory studies, showed that the construction of a three-storey underground parking in a deep pit led to a further deterioration of the geotechnical situation:

- vertical and horizontal movements of soils in the foundations increased to 42.5 mm and 23.7 mm;
- the zone of the first limiting state of the soil under the foundations has spread in the axes A-D, 9-15;
- the forces in the elements of the frame increased up to 60%.

4 DISCUSSIONS

The construction of a deep pit with a depth of 13 m with vertical walls without proper fastening in the immediate vicinity of the building caused horizontal movement of the subgrade. There were signs of deformations of the reinforced concrete frame of the building between the axes A-B due to additional settlement of the foundations of the columns of the frame of the building due to the horizontal movement of the walls of the deep pit, which led to simultaneous vertical and horizontal movement of soils outside the deep pit, i.e. the soil under the foundations of the building. A cracks appeared in the concrete floor of the basement floor along the wall along the A axis with an opening width of up to 6 mm at a distance of 1 m from the inner surface of the wall along the A axis, while the vertical movement of the floor in the wall area was about 20 mm. There were also cracks with an opening of up to 1 mm in the interplate seams of the basement floor and vertical cracks with an opening of up to 0.5 mm in the support zone of the basement floor crossbar (between axes A-B). In the future, these defects were further developed and other defects appeared, which indicates the continuation of the development of deformations of the soil under the foundations of the building. The technical condition of the foundations and the building at the moment is difficult to predict and requires research taking into account the development of additional deformations of soils in the pit and beyond.

5 CONCLUSIONS

The performed experimental studies of clay samples in a cubic stabilometer under conditions of long-term regime static loading and numerical calculation of building deformations allowed us to establish the following basic patterns of behaviour of clay soils under load:

1. The rate of crack development depends on the rate of change of the vertical stress deviator and the change in the lateral pressure.
2. The initial defects of clay soil samples in the form of one or two cracks located in the ultimate equilibrium surfaces led to an increase in vertical, horizontal deformations and the intensity of shear deformations, regardless of the loading regime, compared with samples without initial defects.

3. The numerical studies performed on the basis of the calculation model showed that the construction of a deep pit with a depth of 13 m led to simultaneous vertical and horizontal movement of the soils of the foundations of the building. There were a lot of shifting lines of the soil mass under the foundations. The results of geotechnical monitoring for 4 months confirmed the results of numerical studies.

ABSTRACT: By a novel approach, this paper simulates the mechanical behaviors of clays under constant stress ratio compression tests using three-dimensional Discrete Element Method (DEM), and different cement contents and principal stress ratios (CSR $= \sigma_3/\sigma_1$) are included. The DEM remolded/structured clay sample is generated using spheres of a certain grade, which characterize an assembly of bonded/unbonded clusters of the highest level, and the cluster crushing is further employed to simulate the structural degradation and gradual deformation of clays. The simulation results qualitatively agree with available experimental observations. As the CSR increases, the deviator strain decreases while the structural yield stress increases generally on the macro scale; and the fabric anisotropy of total contact normal and ratios of inter-cluster bond breakage and cluster crushing all decline, and the contact force chains tend to be more uniformly distributed on the micro scale. The structural yield surface enlarges with the increasing cement content.

Keywords: remolded and structured clays, discrete element method, constant stress ratio compression test, structural yield stress, clay cluster crushing

1 INTRODUCTION

Due to the physico-chemical reactions in sedimentary environments, the precipitated amorphous or crystalline cementitious (e.g. free oxides, soluble salts) bridges gradually connect the clay particles, which creates an open-type microstructure with multilevel water-stable clusters (aggregates) in the structured (i.e. natural, artificial cemented) clays [Liu et al. 2012, Nguyen et al. 2017, Jiang et al. 2017], as presented in Figure 1. The interaction between multilevel clusters instead of clay platelets controls the structural strength as well as macro behaviors of clay (Figure 1e). Taken the microstructural properties into account, many researchers explored the mechanical behaviors (e.g. compressibility, fabric anisotropy, rate-dependence, overconsolidation, swelling, etc.) of clays using various micro numerical approaches, including Discrete Element Method (DEM), molecular dynamic simulations and micromechanical method. These published studies facilitate the understandings of inter-particle complex physico-chemical forces [Anandarajah & Chen 1994, 1997] and aggregation process [Boton et al. 2014, Liu et al. 2015] in clays. However, most of them were mainly performed based on the clay platelets of various shapes for remolded state (i.e. rigid/flexible line segments in two-dimensional (2D) simulations [Anandarajah 2000, Khabazian et al. 2018]; and flat cuboid, flat ellipsoid, irregular flat polygon and clumps for them in three-dimensional (3D) simulations [Yao & Anandarajah 2003,

DOI: 10.1201/9781003299127-40

Katti et al. 2009, Ebrahimi et al. 2014, Luo et al. 2021, Jaradat & Abdelaziz 2019]), and cannot consider the cluster characteristics of structured clays, which needs further explorations.

Only a few studies were carried out based on the rigid or flexible clay clusters. Hattab & Chang (2015) proposes a micromechanical modeling technique for clay behaviors by regarding clay as an assembly of rigid spherical clusters, in which the deformability of individual cluster as well as intra/inter-cluster cementations cannot be considered. Suzuki & Matsushima (2015) further utilized a variety of irregular clusters with different shapes, voids and flexibilities to simulate clay sediments with a more realistic microstructure by DEM, in which the deformation (destruction) of individual cluster can be simply quantified by interparticle movements within it, while the cluster number is limited by computational efficiency and the cementation effect remains unknown.

On this basic, this paper breaks out clay platelet-based modeling frame, and proposes a novel DEM approach by considering cementation mechanism and multilevel clusters characteristics of structured clay. A 3D micro contact model accounting for various physico-chemical interactions between spherical clusters is adopted. The remolded/structured clay sample is regarded as an assembly of unbounded/bonded clusters of highest level following certain grade, and the cluster crushing is employed to simulate the gradual structural destruction and deformation in clays. The proposed numerical approach was utilized to investigate the macro/micro-mechanical behaviors of remolded and structured clays of three cement contents under constant stress ratio compression tests, which can coincide with relevant laboratory results qualitatively.

The cluster feature observed by scanning electron micrographs (SEM) of clays and its schematic: (a) mix-clayey material composed of 35% kaolinite and 65% montmorillonite [Hattab & Chang 2015]; (b) (c) natural marine clay in Guinea [Liu et al. 2012]; (d) natural Zhanjiang clay and Zhanjiang clay with free iron oxides removed [Zhang et al. 2016]; (e) schematic of natural clay structure based on multi-level clusters (modified from [Tan & Kong 2001]).

2 DEM SIMULATION PROGRAM

2.1 *Contact model for clay and cluster crushing execution in DEM*

By using well-graded spheres as a simplification on the clay clusters of highest level, a 3D micro contact model for clay was adopted, and the cluster crushing was implemented. Details will be given in other relevant studies, and here only the crucial information are elaborated.

In this contact model, two cutoff distances (i.e. physico-chemical cut-off distance d_{pc}, and mechanical cut-off distance d_{mc}) [Anandarajah 2000] are taken into account in the inter-cluster contact detection criterion (i.e. gap $\leq d_{pc}$ for contact) and bond formation criterion

(i.e. gap $\leq h_0^b = g_c R_b$ for bond formation). At the inter-cluster contact, the bridged bond force and three micro phyisco-chemical forces (i.e. diffused double-layer repulsive force F_{DDL}, van der Waals attractive force F_{VD}, and Born mechanical repulsive force $F_B = f(E_p, d_{mc}, \text{gap})$) are considered in the normal direction. Based on the Hamaker-de Boer and Gouy-chapman theories, the physico-chemical forces $F_{VD} = A \cdot f(\beta, R, d_{mc}, \text{gap})$ and $F_{DDL} = f(\beta, \kappa, \psi_0, R, d_{mc}, \text{gap})$ between two coarse spheres are calculated respectively as power and exponential functions by the Derjaguin approximation [Jiang et al. 2013], which meet the classical DLVO colloid stability theory. While in the tangential/rolling/twisting directions, only the Born mechanical and bond forces are calculated. Note that, the rational assignments of two cutoff distances are crucial, which need to consider several factors, i.e. the significant (long/short term) range of each physico-chemical force, relative magnitude of repulsive barrier/attractive valley for normal net force and the DEM computation efficiency. Generally, d_{mc} ranges in 0.5nm ~ 2nm [Yao & Anandarajah 2003, Jaradat & Abdelaziz 2019, Luo et al. 2021], and d_{pc} is 3 ~ 5 times the electrical double-layer thickness $1/\kappa$ [Anandarajah 2000, Bayesteh & Mirghasemi 2013]. On this basis, Figure 2 illustrates the variations of three physico-chemical forces and their net force in the normal direction with proper values of relevant parameters, which coincide with the numerical investigations by Lu et al. (2008), Jaradat & Abdelaziz (2019) and Luo et al. (2021). As presented, F_{VD} and F_{DDL} begin to act when inter-cluster separation gap decreases to d_{pc} from infinity, and for gap less than d_{mc} these two physico-chemical forces are assumed to remain contant and F_B begins to dominate.

Cluster crushing is further executed every certain steps to simulate the gradual deformation of local stable aggregates in the remolded clay and successive bond breakages between multi-level clusters in the structured clay. Based on the investigation of Ciantia et al. (2015), the cluster crushing criterion of structured clay is established by using correction factors (i.e. A_k and B_k) to identify the influences of cluster size and bond strength/size on the cluster crushing strength. The broken cluster is deleted and replaced by two or fourteen (bounded by the median diameter d_{50}) non-overlapping tangent spherical sub-clusters with different smaller sizes. The remaining bonds associated with the broken cluster are all removed automatically by default [De Bono & Mcdowell 2014].

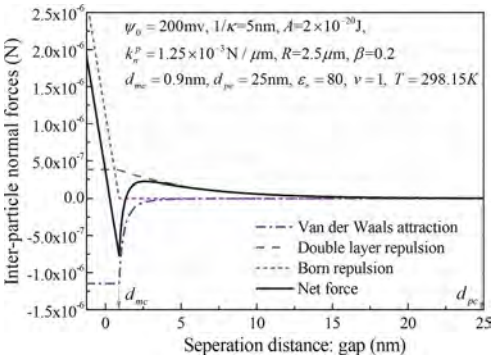

Figure 2. Variations of inter-particle physico-chemical and net forces.

2.2 *Sample preparation and DEM programs*

Based on the SEM observations [Lu et al. 2008] and numerical studies of clay cluster [Hattab & Chang 2015], the adopted DEM assembly is composed of 20870 clay clusters of highest level, with the diameters uniformly ranging from 4.8 um to 16.5 um given d_{50} of 10um, as presented in Figure 3. The clay sample was accomplished by the following step in PFC3D. (1) A homogenous and loose cubic assembly with the target void ratio of 1.50 was generated by the multi-layer under-compaction method [Jiang et al. 2003]. (2) A vertical stress of 12.5kPa was then applied to the top and bottom walls with the side walls stationary to reproduce an in-situ stress state (i.e. 'k_0' state), and the void ratio was 1.25 after precompression. (3) For the structured clay sample, the bonds at inter-cluster contacts were finally assigned when the gap

is smaller than $g_c\lambda_b R$. The cement content (cc) can be geometrically calculated based on inter-particle separation distance (gap), bond radius coefficient λ_b (i.e. ratio of bond radius R_b to the common particle radius R) and critical bond thickness coefficient g_c (i.e. ratio of the critical bond thickness h_0^b to bond radius R_b). In the DEM study four cement contents were considered, including cc = 0% (i.e. remolded clay) and cc = 2.5%, 5% and 10% (i.e. structured clay) by varying the bond radius coefficient λ_b only. The values of contact and crushing parameters are illustrated in Table 1, among them the proper parametric values for physico-chemical forces are essential to obtain the high void ratio.

In the subsequent step-loading stage, six rigid walls were servo-controlled to maintain a constant ratio of the minor and major principal stresses (i.e. CSR $=\sigma_3/\sigma_1$). A series of constant stress ratio compression tests on four clay samples were simulated, including CSR= 0.3, 0.35, 0.4, 0.5, 0.6, 0.7, 0.9 (i.e. anisotropic compression) and 1.0 (i.e. isotropic compression).

Table 1. Micro parameters for the remolded and structured clays.

Particle parameter	Intercluster effective modulus E_p (MPa)	70	Bond parameter	Compressive bond strength σ_c^b (Mpa)	25
	Normal-to-shear stiffness ratio ξ_p	1.5		Tensile-to-compressive strength ratio η_σ	2.5
	Intercluster frictional coefficient μ	0.5		Critical bond thickness coefficient g_c	0.1
	Electrical double-layer thickness $1/\kappa$ (nm)	5		Bond radius coefficient λ_b	0.429/ 0.506/ 0.597
	Surface electric potential ψ_0 (mv)	10	Crushing parameter	Reference cluster diameter d_0 (um)	10
	Hamaker constant A (10^{-20}J)	7.5		Reference cluster crushing strength $\sigma_{d,0}$ (GPa)	1.25
				Cluster size effect index m	0.25
	Contact radius coefficient β	0.1		Correction factor by bond strength/size A_k	2.57e2
	Physico-chemical cutoff distance d_{pc} (nm)	25		Correction factor by cluster size B_k	10
	Mechanical cutoff distance d_{mc} (nm)	0.9		Minimum cluster crushing size $d_{\lim}$ (um)	2.5

3 ANALYSES OF SIMULATION RESULTS

3.1 *Macro mechanical behaviors*

In this section, the macro mechanical behavior of numerical clay samples are first analyzed and compared with experimental data for remolded, natural and artificial cemented clayey soils.

Figures 4a and 4c present the compression curves of remolded and structured clay (cc = 5%) samples under different constant stress ratios respectively, which qualitatively agree with the laboratory results by Shi et al. (2015) and Jiang et al. (2017) (Figures 4b and 4d). Due to the gradual microstructure evolution (e.g. cluster deformation, inter-cluster displacement, variation of water film thickness, etc.), the void ratio of remolded clay exhibits an almost uniform decrease without a distinct consolidation yield point, and its magnitude increases with the increasing CSR when the same effective mean stress p is reached (Figure 4a). In comparison, the apparent structural yield characteristic can be observed in the structured clays, and the yield stress p_y (determined by the bi-linear method, as depicted in Figure 5(a)) increases basically as CSR increases (Figure 4c). For the structured clay, initially only elastic deformation occurs and the beneficial contribution of cementation make the variation of void ratio negligible. While beyond the yield stress, plastic deformation associated with cementation degradation (i.e. structure damage) gradually accumulates, and thus the void spaces of inter/intra-cluster reduce significantly. At the ultimate state, the compression curves under different CSRs tend to be parallel.

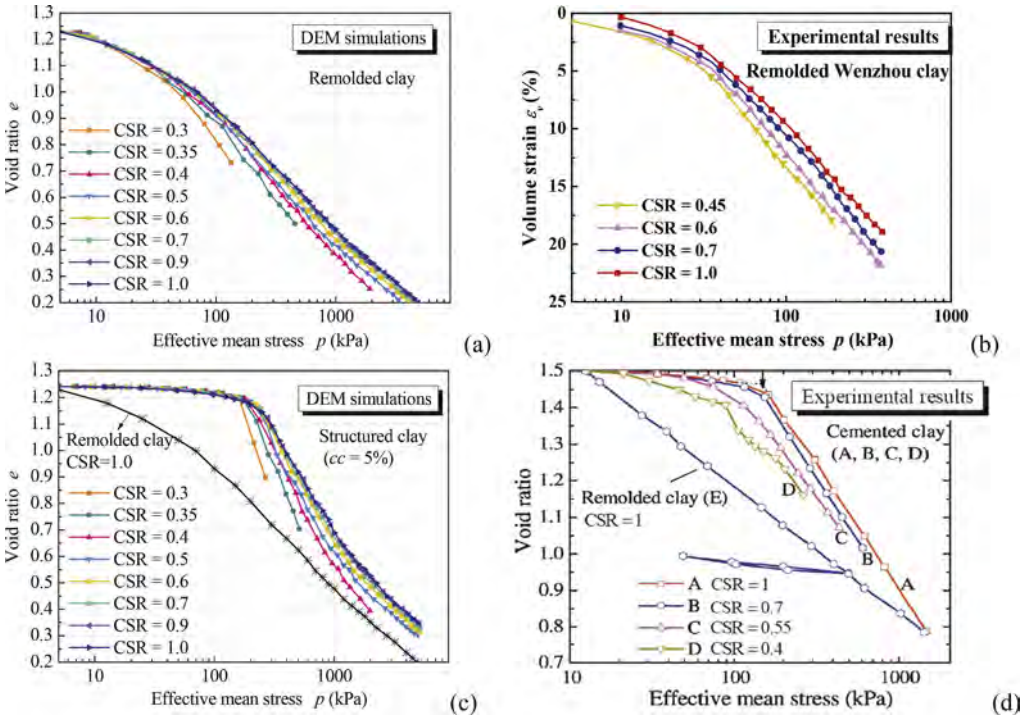

Figure 4. Compression curves under different CSRs: (a) DEM results of the remolded clay; (b) experimental results of the remolded Wenzhou clay [Shi et al. 2015]; (c) DEM results of the structured clay (cc = 5%); (d) experimental results of the artificial cemented clay [Jiang et al. 2017].

To study the cementation effect, Figure 5a provides the isotropic compression (i.e. CSR = 1.0) curves as well as their unloading-reloading curves at p = 500kPa of each clay sample, and Figure 5b further gives the structural yield surface of all structured clays. As shown, increasing the cement content can lead to an increase in the yield stress aas well as an enlargement of structural yield surface. In addition, at a high stress level, the void ratio of structured clay is gradually approaches that of remolded clay, and their ultimate void difference suggests the residual cementation effect (i.e. the incompletely destroyed cementations and the cumulative fabric changes), whose magnitude also tends to increase with the increasing cement content. Moreover, it can be observed from the unloading-reloading curves that (Figure 5a), the higher the cement content is contained (i.e. the stronger the clay structure is), the more the elastic

deformation accumulates during loading, and thus the more distinct the swelling exhibits. These features are basically consistent with the experiment observations of natural clays [Adachi et al. 2008, Delage 2010] and artificial cemented clays [Miura et al. 2001, Kamruzzaman et al. 2009, Nguyen et al. 2017]. Note that, the simulated increasing yield stress cannot be exactly captured as CSR ranges from 0.7 to 1.0 (i.e. the yield surfaces rotate anticlockwise slightly), as described in Figures 4c and 5b,which can be explained by the slight initial anisotropy of 'k_0' generated clay samples.

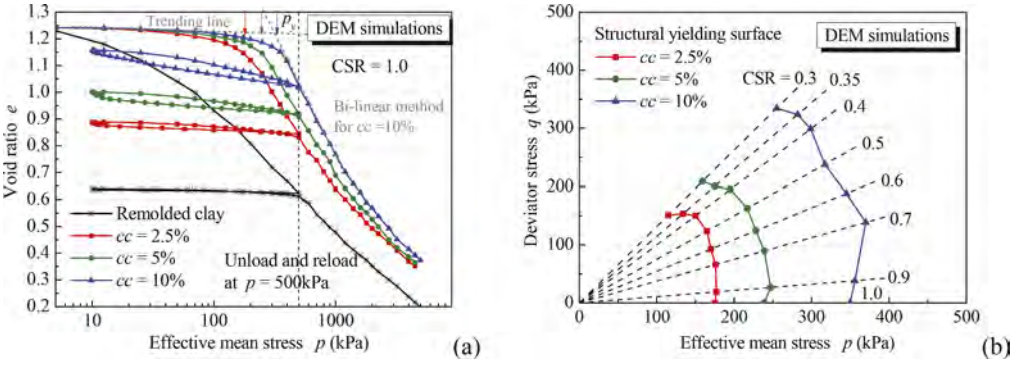

Figure 5. Yielding in the DEM structural clay samples with different cement contents: (a) isotropic compression (CSR = 1.0) curve and its unloading-reloading curve; (b) structural yielding surface.

Figure 6a and 6b present the deviator strain versus log p relationships of remolded and structured clay (cc = 5%) samples respectively under different CSRs. These figures reveal that, the higher the CSR is, the lower the deviator strain incurs (its irregularity at CSR = 0.9 is attributed to the initial anisotropy, as aforementioned) by the remolded and structured (at post-yielding stage) clays at the same effective mean stress. Similar behavior can be found by the experimental researches of cemented Bangkok clay [Bergado et al. 2006], as given in Figure 6c.

3.2 *Microstructure evolutions*

The microscopic information, including the inter-cluster bond breakage, cluster crushing, contact force chain and contact orientation, will be analyzed and linked to the macro features.

Figure 7 illustrates the evolutions of inter-cluster bond breakage and cluster crushing ratios in structured clay samples (cc = 5%) under different CSRs, as a reflection of the microstructure degradation. It can be observed from Figures 4c and 7 that, at each CSR condition, the macro structural yielding corresponds to the stress state in which the significant inter-cluster (at highest level) broken bonds commence (Figure 7a), while the start point of distinct cluster crushing (i.e. bond breakages between sub-level clusters) lags behind it slightly (Figure 7b). Hence, the phenomenon that the higher the clay cluster level is, the easier the inter-cluster bonds break can be simulated by a set of rational parameters (Table 1). These figures also reveal that the broken bond ratio of multilevel clusters decreases with increasing CSR in structured clays.

In addition, to study the cementation effect, Figure 8 provides the evolutions of inter-cluster bond breakage and cluster crushing ratios in three structured clays under isotropic compression test (i.e. CSR = 1.0), as well as their normalization curves by p/p_y. As presented, given a specific p beyond p_y, the ratios of broken bond between highest-level clusters and themselves crushing all decrease with the increasing cement content, while their normalizations in different structured clays all coincide approximately.

To visualize the microstructure, Figure 9 illustrates the cluster distribution and contact force chains for the remolded and structured (cc = 5%) clay samples under CSR = 0.4, 0.6 and 0.9. As observed from Figures 9a and 9c, the deviator strain, the total number of clay cluster and the

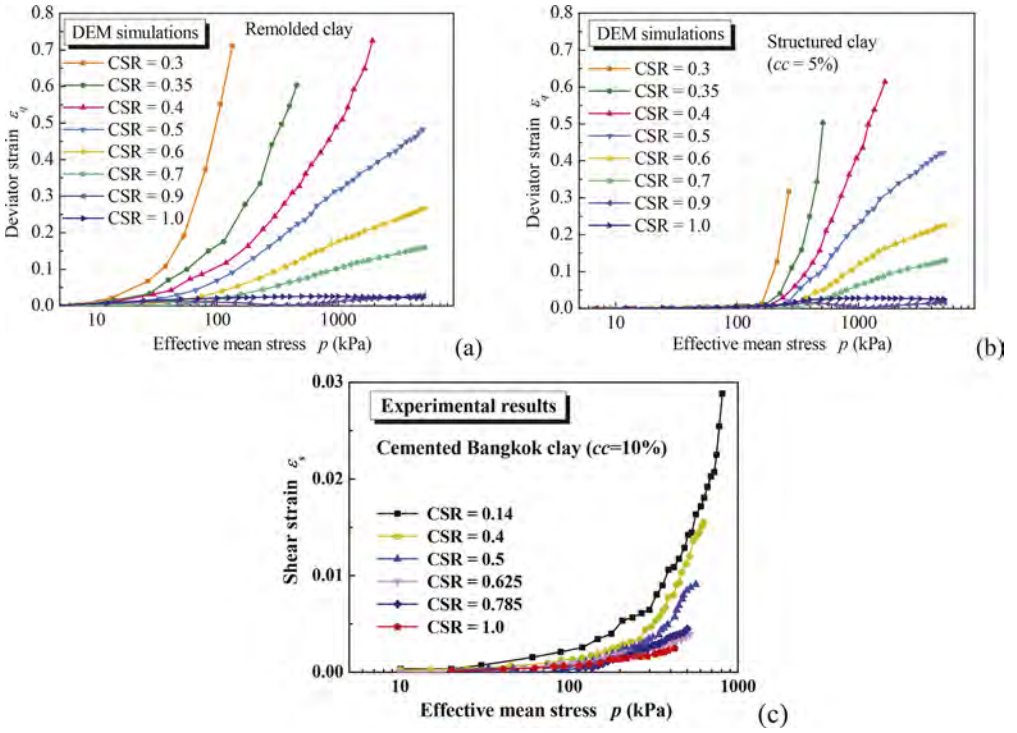

Figure 6. Deviator strain evolution under different CSRs: (a) DEM results of the remolded clay; (b) DEM results of the structured clay (cc = 5%); (c) experimental results of cemented Bangkok clay [Bergado et al. 2006].

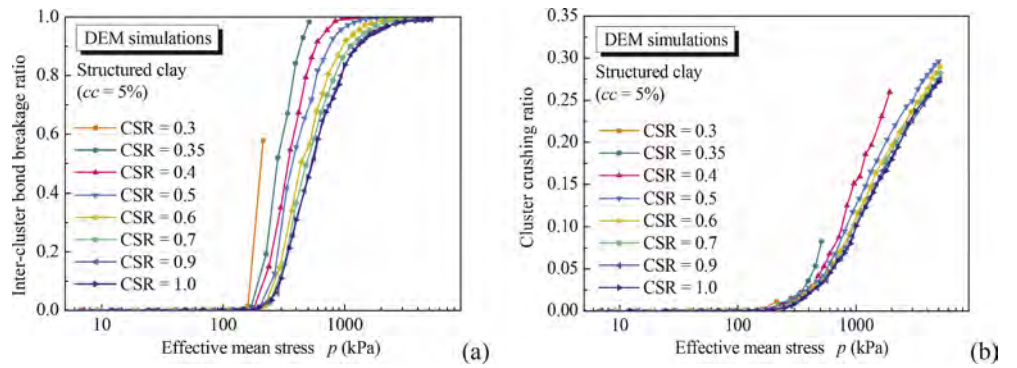

Figure 7. Structural degradation in the DEM structured clay (cc = 5%) samples under different CSRs quantified by: (a) evolutions of inter-cluster bond breakage ratio; (b) evolutions of cluster crushing ratio.

proportion of smaller clusters all increase significantly with the decrease of CSR (or cement content). Due to the structural resistance, the coarser strong contact force chains in the structured clay are more distributed than those in the remolded clay, as described in Figures 9b and 9d. Moreover, as CSR increases from 0.4 to 0.9, the distribution of stronger contact force chains tends to be from mainly along the vertical to more uniform in all directions.

To quantify the variation of contact orientation during loading, the fabric anisotropy curves of total contact normal as well as the contact orientation rose diagrams of CSR = 0.4 /0.6 /0.9 at p = 1000kPa (i.e. projected onto the xy, xz and yz planes) in remolded and structured (cc = 5%) clay samples are given in Figure 10. For the deviator fabric of contact normal, its initial small value of around 0.06 suggests the slightly initial anisotropy of clay samples after 'k_0'

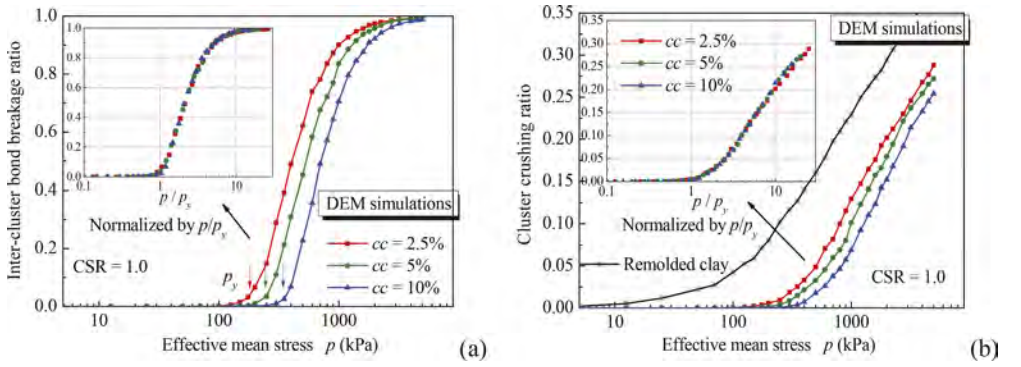

Figure 8. Structural degradation in the DEM structured clay samples with different cement contents (under CSR = 1.0) quantified by: (a) evolution of the inter-cluster bond breakage ratio and its normalization by p/p_y; and (b) evolution of the cluster crushing ratio and its normalization by p/p_y.

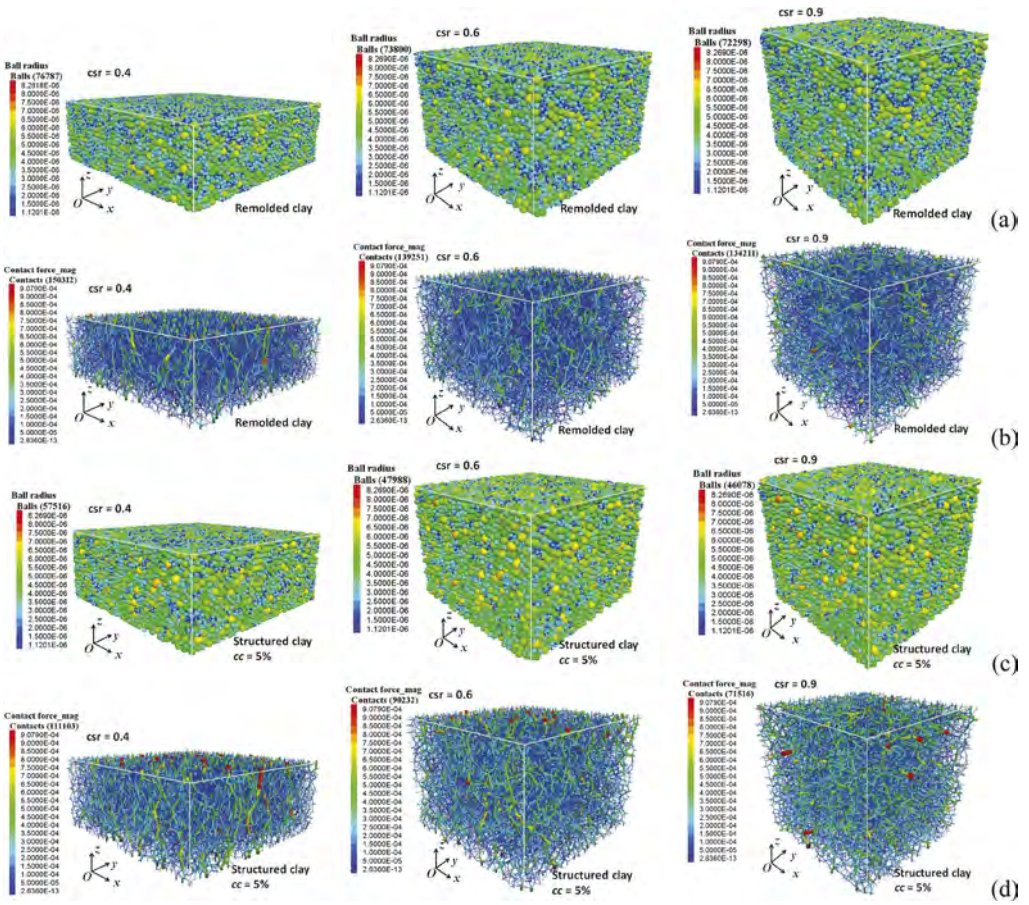

Figure 9. DEM micro observations under CSR = 0.4/0.6/0.9: (a) (b) cluster composition of deformed sample and contact force chain in the remolded clay; (c)(d) cluster composition of deformed sample and contact force chain in the structured clay (cc = 5%).

precompression, and it keeps almost constant until reaching the structural yielding state for the structured clay, suggesting the significant fabric resistance. Beyond the structural yielding, the micro bonds gradually degrade, and thus the fabric anisotropy of contacts is affected obviously by the stress anisotropy of different CSR compression tests. That is, the deviator fabric of total contact normal gradually decreases when the stress ratio is high (i.e. CSR $\geq$ 0.5), while it tends to first increase and then decrease as CSR < 0.5. It can be also observed from the rose diagrams that, the clay samples are approximately isotropic in the *x*-*y* direction, while some degree of anisotropy is exhibited in *x*-*z* and *y*-*z* directions. The final steady fabric anisotropy of clay samples with different cement contents is similar, which reduces with the increasing CSR.

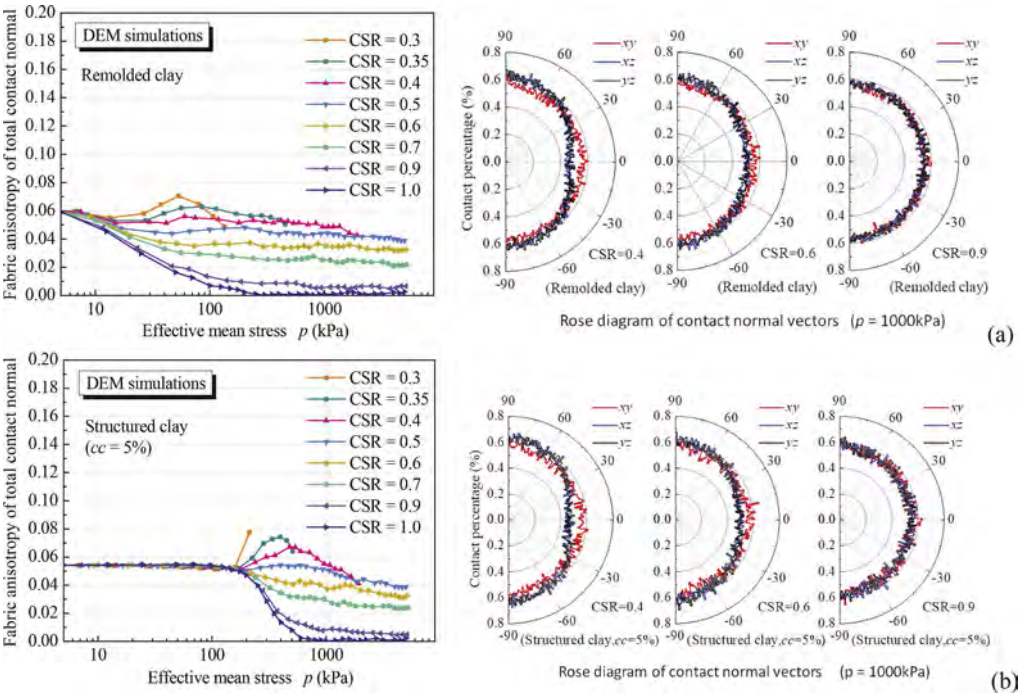

Figure 10. DEM results of fabric anisotropy of contact normal under different CSRs and contact orientation rose diagram under CSR =0.4 /0.6 /0.9: (a) for remolded clay; (b) for structured clay (*cc* = 5%).

4 CONCLUSIONS

This paper investigates the influences of cement content and stress ratio on the macro/micro-mechanical behaviors of remolded and structured clays under CSR compression conditions by utilizing a novel 3D numerical approach. The main conclusions can be drawn as follows:

(1) The DEM materials incorporating the proposed contact model as well as cluster crushing can capture the mechanical characteristics of clay in the CSR compression tests. For structured clays, the distinct structural yield stress can be captured, and its ultimate void difference from the remolded clay suggests the residual cementation effect, which all increase with the increasing cement content. The yield stress basically raises as CSR increases except CSR = 0.7 ~ 1.0, which is mainly due to the initial anisotropy of 'k_0' generated clay samples.

(2) With the increasing CSR (or cement content), the deviator strain, the broken bond ratio of multilevel clusters and the proportion of smaller clusters all decrease significantly. The final steady fabric anisotropy of clay samples with different cement contents is similar, which decreases with the increasing CSR.

ABSTRACT: Kathmandu Valley, the capital of Nepal, is a highly populated and rapidly urbanised area of the country built upon lacustrine and fluvial origin deposits. Because the valley deposit is located in an earthquake-prone zone with a long history of catastrophic earthquakes, it is vulnerable to numerous geohazards like liquefaction. Although a few localized geotechnical studies have been conducted in the valley, holistic understanding, modelling, and geotechnical soil characterisation are seldom documented. This study attempts to characterize the Kathmandu soil based on geotechnical properties using statistical analysis approach. We have collected and analysed more than 400 geotechnical investigation reports and bored 10 test locations. Statistical analysis and representation of index properties, consolidation parameters, shear strength, SPT-N value, and shear wave velocity have been assessed in this paper. These findings can aid structural and foundation engineers in studying foundations, cost estimation of geotechnical investigations, and planning and implementing various civil engineering projects.

Keywords: Geotechnical properties, Characterization, Statistical analysis, Index properties, Shear strength, Kathmandu Valley

1 INTRODUCTION

The capital city of Nepal, Kathmandu, is located in the valley and is the largest city in the country, serving as an important center of politics, business, and tourism. It is considered the cultural and economic hub of Nepal, and is home to numerous UNESCO World Heritage sites, including temples, palaces, and stupas. The valley's rich history and cultural heritage, combined with its vibrant city life, make it an essential destination for anyone visiting Nepal. It is located in central Nepal and is the most populous metropolitan area in the country.

Kathmandu Valley is characterised by lacustrine and fluvial deposition in origin with a maximum thickness of 650 m (Sakai, 2001). The deposited sediments consist of interbedded clay, silt, sand, and gravel (Mugnier et al., 2011) with a temporal and spatial variable shallow groundwater table (Shrestha et al., 2016).

DOI: 10.1201/9781003299127-41

The valley's urbanisation has been fast, and all of the urban communities exhibit rapid expansion on their peripheral (Chaulagain et al. 2016). Additionally, the Kathmandu Valley is located in an earthquake-prone zone with a long history of deadly earthquakes. Being formed of lacustrine sediments with a strong capability for amplifying seismic waves, the valley is highly susceptible to damage if not given proper care during geotechnical investigations or subsoil characterisation of the site.

Subsoil characterisation is vital for geotechnical and geological designing associated with earthworks, structure foundations, forecast and comprehension of natural hazards, and environmental issues (Ahmed et al., 2020). Due to inadequate or incompetent subsurface characterisation and assessment of soil strength, possible foundation-related failures or structure collapses may occur. As a result of the variety and variance in subsurface conditions, thorough geotechnical evaluations of a building site are required in designing earthworks and structural foundations (Oyeyemi et al. 2017).

This research aims at collecting and analysing more than 400 previous geotechnical investigation data from different projects and boring 10 SPT-N boreholes with laboratory experiments. Statistical analysis and representation of index properties, consolidation parameters, shear strength, SPT-N value, and shear wave velocity have been assessed in this paper. This study can help urban planning, preliminary and feasibility studies, and land-use policies. It also assists the geotechnical engineers beforehand to plan the comprehensive geotechnical investigation based on the provided geotechnical map and soil properties data.

2 GEOLOGY

Surrounded by mid-height mountains and drained by a river system called Bagmati, a bowl-shaped Kathmandu Valley has a more or less flat terrain except for a few gorges created by the river network. As a deep sediment-filled ancient lake, the valley deposit mainly consists of materials transported from the peripheral mountains. Figure 1 shows the geological map of the valley deposit (redrawn after Dhital (2015)). The sediment deposits are mostly a mixture and alteration of clay, silt, sand, and gravel layers (Subedi et al. 2021) and relatively shallow groundwater table (Shrestha et al., 2016). Moreover, materials in the northern side of the valley are riverbed stratified deposits of all soil types. In contrast, alluvial fan facies are evident in the south end. Additionally, middle part of the valley is mostly thick layers of black clay and organic mud. All this makes it clear that relatively coarse material (i.e., coarse silt, sand, and fine gravel) deposited areas in the Kathmandu Valley are particularly prone to liquefaction (Okamura et al., 2015; Sharma et al., 2019) (Subedi & Acharya 2022).

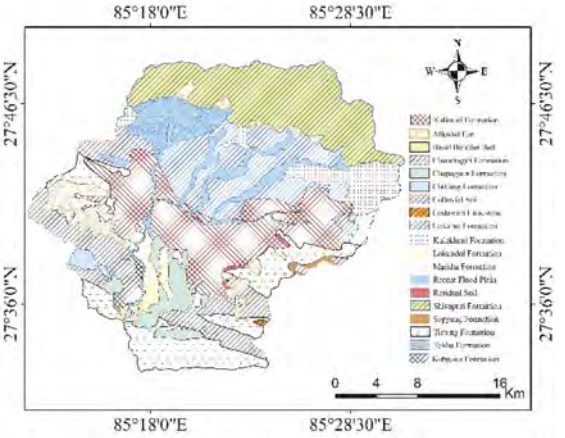

Figure 1. Geological formation map of Kathmandu Valley redrawn after Dhital (2015).

3 DATABASE

In Kathmandu Valley, the standard penetration resistance test (SPT) is the most often utilised in-situ test. In Nepal, other approaches such as the cone penetration test (CPT) have not been deployed due to resource and technical constraints (Sharma et al. 2019). Thus, for this study, most of the data include borehole logs prepared for a different purpose. The uncorrected SPT numbers are corrected using the strategy proposed by Robertson and Wride (1998). For this study, both primary and secondary data were used. As primary data, geotechnical investigations (boreholes and SPT test) were conducted at ten different locations in Kathmandu Valley, five boreholes from the core city area and five from the 2015 Gorkha earthquake-induced liquefaction zones. As secondary data, about 400 soil investigation reports for various projects, including residential and public buildings, bridges, slope stability works etc., were collected. The total number of boreholes collected for this study were more than 1500. All these boreholes were up to 20 m from ground surface.

4 RESULT AND DISCUSSION

4.1 *Stratigraphy*

The geotechnical investigations reveal that the top 20m of soil in the valley contains a complex and stratified profile. A depth up to 20m was considered for this study as this depth is good enough for the shallow foundation for residential buildings and low story commercial or public buildings. Mostly grey to dark, silty sand and clayey silt are abundant throughout the valley, with wide variations in soil characteristics. Up to 1m depth, organic clay, fine sand beds, and peat layers are commonly termed a crust layer on the surface. Dark grey sandy silt dominates the majority of the investigation locations just under the crust layer. Below this layer comes silt with low plasticity followed by silt with medium plasticity; the resultant layer is often composed of stiff clay with low-to-medium plasticity. Typical soil profiles with SPT-N values are presented in Figure 2.

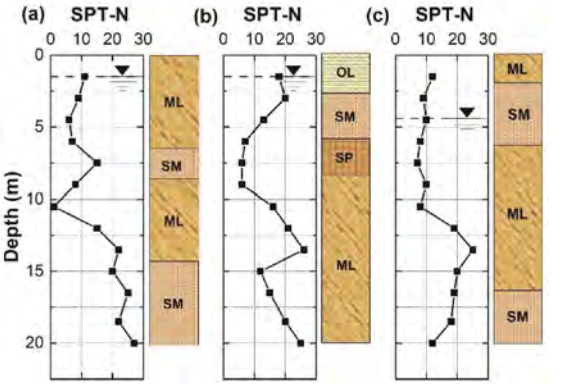

Figure 2. Typical stratigraphy profiles observed GWT and SPT of (a) Manamaiju, (b) Ramkot, and (c) Tundikhel.

4.2 *Statistical analysis*

The soil in Kathmandu Valley is diverse and layered at shallow depths. The heterogeneity results from lithological variation, natural soil variability, and exposure to varying overburden forces in different places. Thus, if the probability distribution for any measurable characteristic is known, it is critical to do statistical analysis to identify their geotechnical properties. According to prior research, the normal distribution fits most of the index, consolidation, and shear strength parameters of many natural soils (Kim et al., 2012). As a result, the current analysis used the standard distribution to provide a general characterisation for Kathmandu

soils. The number of data (n), minimum value, maximum value, mean value (μ) and standard deviation (σ) were calculated for each soil property. The list of geotechnical properties, number of data, minimum and maximum value with μ and σ are summarised in Table 1.

Table 1. Variability and statistical representation of Geotechnical properties of Kathmandu soils.

Property	Number of Data (n)	Min.	Max.	Mean (μ)	Standard deviation (σ)
Bulk density, γ (kN/m^3)	166	9.8	22.34	18.14	1.83
Specific gravity, G_s	302	1.89	2.89	2.59	0.15
Natural water content, w_n (%)	455	5.38	98	39.94	20.08
Plastic limit, PL (%)	239	15.2	50.98	29.12	7.84
Liquid limit, LL (%)	239	22.8	69.12	44.29	11.29
Plasticity index, PI (%)	239	1.73	34	15.13	6.26
Standard penetration test, SPT (N)	1167	0	50	15.5	11.14
Undrained shear strength, C_u (kPa)	119	1.3	178.48	61.50	33.65
Cohesion, C (kPa)	102	0	29	11.63	7.11
Friction angle, ϕ (°)	120	6.2	40	22.60	8.42
Coefficient of consolidation, C_v (cm^2/s)	67	0.0002	1	0.18	0.271
Shear wave velocity, V_s (m/s)	108	65	432	208.37	88.72
Primary wave velocity, V_p (m/s)	26	246	1677	999.58	449.29

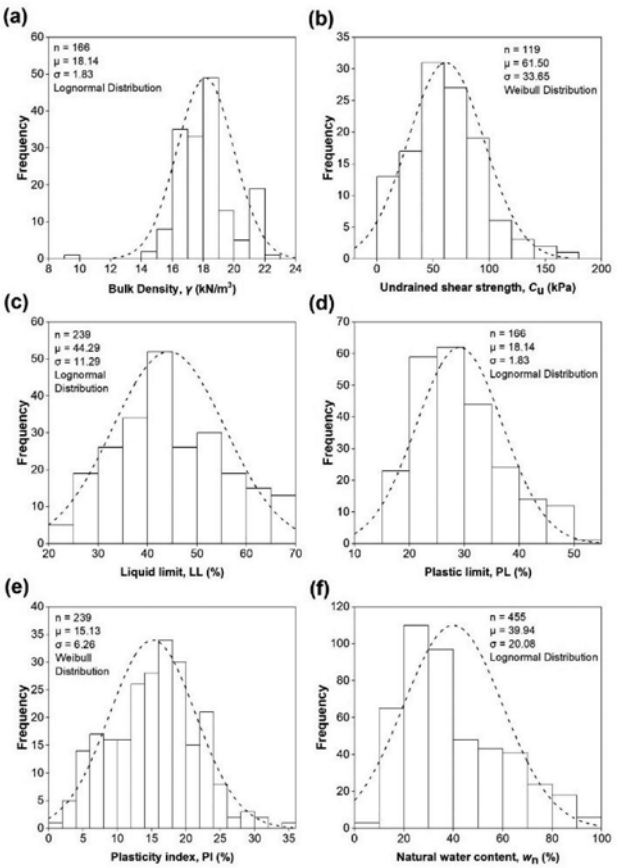

Figure 3. Histogram and distribution function of the Kathmandu soil properties (a) γ, (b) $C_{u,}$ (c) LL, (d) PL, (e) PI, and (f) w_n.

As illustrated in Figure 3, the statistical details and histograms were created with depth to determine the variance of soil properties with depth.

4.3 *Particle size distribution*

The percentage of various sizes of soil particles was determined utilising particle size analysis. The particle size distribution graph shown in Figure 4 shows that silty sand is abundant in Kathmandu soil. In addition to this, two sets of grain size curves showing the particle size distribution ranges for most liquefiable and potentially liquefiable soils proposed by Tsuchida and Hayashi (1972) are also plotted. The majority of the gradation curves are seen to fall inside the border of possibly liquefiable soil. It strongly suggests that the soil in Kathmandu is highly susceptible to liquefaction considering high GWT.

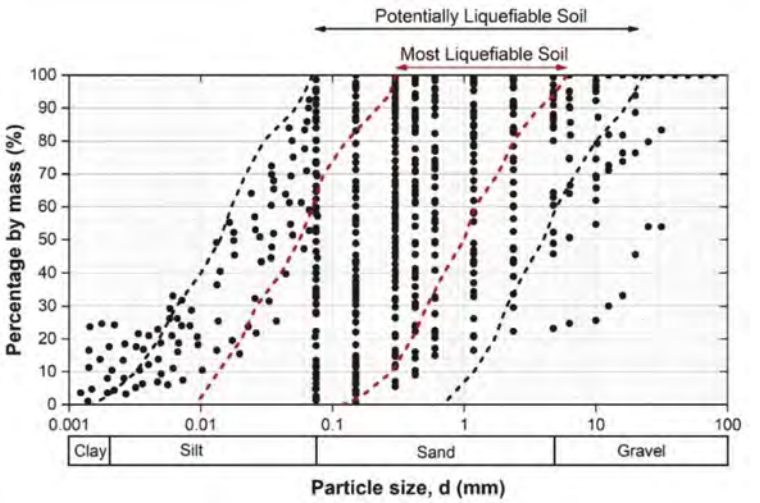

Figure 4. Particle size distribution with a range of Liquefiable soils given by Tsuchida and Hayashi (1972).

4.4 *Index and strength properties*

The SPT-N values of soil layers lying in the central part were found less than the outer part of the valley. It might be due to the presence of hard rock in the outer part of the valley. Most of the shallow depth soil is silt and silty sand. The SPT-N values of about 85% of the borehole test data were found less than 20, and more than 50% have SPT-N values less than 10 in shallow depth in the core area of the valley. The average SPT-N value of Kathmandu soil at depths 1.5m, 3m, 6m, 9m and 15m were 12, 15, 18, 20 and 23, respectively, with overall μ=15.5 and σ=11.14. Typical SPT profiles at three different locations in the study are presented in Figure 2, whereas the variation of SPT-N with depth for Kathmandu Valley is shown in Figure 5(a).

Specific gravity (G_s) is a critical parameter in evaluating the engineering behaviour of the soil. The value of G_s is used to calculate the void ratio, compressibility coefficient, degree of saturation and other soil parameters. In general, a higher value of G_s indicates mineral soil and higher strength. In the study area, the value of the specific gravity of soil is between 1.89 to 2.89 (μ=2.59, σ=0.15) (Figure 5(b)). The low specific gravity (<2.5) might be attributed to the organic soil at the top. The average value of G_s as 2.59 indicates the high presence of silty sand in the valley.

The fines content (FC) of sandy soils is critical in the engineering design of geotechnical buildings, particularly in earthquake-prone areas. The quantity of FC in soil has

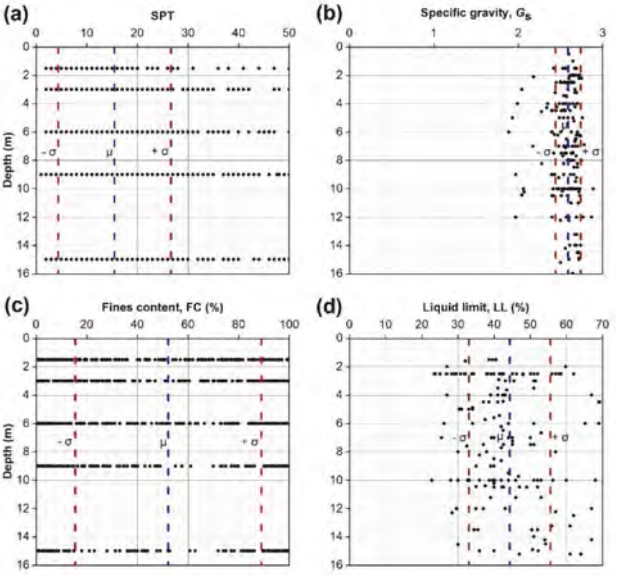

Figure 5. Index and strength properties of soil vs. depth: (a) SPT, (b) G_s, (c) FC, and (d) LL.

a considerable effect on its relative density and liquefaction potential. The variation of FC with depth in Kathmandu soils is shown in Figure 5(c). The value of FC ranges from 0 to 100 %, with a mean of 52.24 and standard deviation of 36.69. Sand and silt with low FC might be attributed to liquefaction at several locations in Kathmandu Valley during 2015 Gorkha, Nepal, even though the peak ground acceleration (PGA) earthquake (~0.18g) was much smaller than that expected (i.e. 0.30g).

The lowest water content at which soil transitions from a plastic to a fluid state is the liquid limit (LL). More than 40% of the borehole locations considered in this study have less or equal 35% with μ=44.29 and σ=11.29. Sandy soil with LL less than 35 indicates the high probability of liquefaction (Bray and Sancio, 2006). The variation of LL with depth is presented in Figures 5(d).

5 CONCLUSIONS

Following are the major conclusions of this study:

1. From ground surface to a depth of around 20 metres, the Kathmandu Valley has a complicated and layered profile. The majority of the gathered database exhibited lithological heterogeneity. The valley was primarily composed of clayey silt and silty sand. Fine sand beds, organic clay, and peat layers were prevalent in the 1 m top layers.
2. After analysing particle size distribution and the Plasticity chart, it was evident that Kathmandu soil deposits are very susceptible to liquefaction.
3. The SPT values of soil layers lying in the central part were much lesser than the outer. It might be due to the presence of hard rock bedding in the outer part of the valley. About 85% of the borehole test data had SPT less than 20, and more than 50% have SPT less than 10 in shallow depth in the core area of the valley. Most of the samples had a moisture content ranging from 20 to 40% with an average of 39.94%, whereas the specific gravity value was mainly between 1.89-2.89 with an average value of 2.59.
4. More than 40% of the boreholes locations taken for this study had a liquid limit (LL) less or equalled 35% (μ=44.29). Most of the soils in this study possessed undrained shear strength at failure (Cu) ranging from 30 to 90 kPa. After plotting a total of 120 ring shear

tests, cohesion was found from 0 kPa to 20 kPa (μ=11.63 kPa), and friction angle varied from 6.2° and 40° with an average of 22.6°. It was observed that most of the soil samples had a shear wave velocity lesser than 360 m/s, which indicates the extensive presence of stiff soil.

The analytical findings apply to future research and studies on the subsurface state of the Kathmandu Valley and civil engineering techniques. This work is the first comprehensive investigation on the geotechnical characterisation of Kathmandu soil to the authors' knowledge. It will have a substantial impact on land use planning. These study findings might help prioritise sites with geotechnical concerns or high total costs for civil engineering projects. It may aid in selecting more appropriate foundation types and building designs, as well as in the forecasting of changes in geological engineering conditions and the prediction of hazardous geological events. Finally, despite the abundance of boreholes in the Kathmandu valley, direct shear wave observations are pretty rare. To better understand the Kathmandu soil's geotechnical properties, more investigations and studies are required to obtain more accurate results.

ABSTRACT: In this paper, the grading entropy method is applied together with advanced interpolation methods in order to establish empirical relationships between grading entropy coordinates and minimum dry density of sands. Three databases consisting of 94 samples (in total) of artificial mixtures of natural sands with fractal or continuous grain size distributions were used to evaluate three different types of empirical relationship. Whilst some databases have been previously published, recently acquired data has also been considered. The results show that there is a strong relationship between grading entropy coordinates and the minimum dry density.

1 INTRODUCTION

The experimental works by Kabai (1968, 1972, 1974) in relation to the dry density of sands from the Danube river concluded that the ratio of the minimum to the maximum dry density was basically constant, although it decreased as the soil became slightly plastic. Lőrincz (1986) also observed that a mixture of spheres with various radii can be denser if the radii values are selected from a larger size interval. Consequently, the dry density of the soil increases with the maximum particle diameter d_{max}. Furthermore, if the number of size fractions (N) in a sand mixture increases density is also expected to increase. Lőrincz (1986) tested both fractal and gap-graded grain size distribution with fixed N between 1 and 5 using grading entropy coordinates and found that the minimum dry density had a minimum value at around $A = 2/3$ (A is the relative base entropy, one of the grading entropy coordinates). This minimum value

DOI: 10.1201/9781003299127-42

occurred for gap-graded mixtures. The aim of the present study is to extend the findings of these pioneering works with new experimental work (referred to as the new Óbuda-Bochum database) as well as other theoretical work by Imre et al (2009, 2011, 2013 and 2017). A key aspect is that a relationship between grain size distribution and dry density cannot be generally determined empirically due to the large number of possible grading curves hence an interpolation technique is used (Imre et al, 2009, 2017) to assess the success of various statistically derived PSD-density relationships in terms of grading entropy coordinates. The grading entropy concept is described in detail by Lőrincz (1986) and characterises any grading curve using an abstract system of N fractions. Each fraction (which may represent the weight of material collected in a given sieve during an experimental test) has a diameter (d) range that doubles in size (e.g. $d_0 \leq d < 2d_0$, …, $2^{22}d_0 \leq d < 2^{23}d_0$, $2^{23}d_0 \leq d < 2^{24}d_0$, where d_0 may be 2^{-22} mm, the size of a silica tetrahedron). The relative frequencies of the fractions fulfil that:

$$\sum_{i=1}^{N} x_i = 1, x_i \geq 0, N \geq 1 \tag{1}$$

where the integer variable N is the number of the fractions between the finest and coarsest non-zero fractions, and x_i is the relative frequencies of fraction i (i.e. it may be the mass percentage retained in each sieve) The grading entropy can be separated into the base entropy (S_0) and the entropy increment (ΔS), defined as follows:

$$S_0 = \sum x_i S_{0i} = \sum x_i i \text{ and } \Delta S = \frac{-1}{\ln 2} \sum_{x_i \neq 0} x_i \ln x_i \tag{2}$$

where S_{0i} is the i^{th} fraction entropy ($=i$). The normalised forms of S_0 and ΔS are the relative base entropy (A) and the normalised entropy increment (B), respectively:

$$A = \frac{(S_0 - S_{0min})}{(S_{0max} - S_{0min})} \text{ and } B = \frac{\Delta S}{\ln N} \tag{3}$$

where S_{0max} and S_{0min} are the entropies of the largest and smallest fractions, respectively. Any grading curve can be represented as a point in terms of the non-normalised or normalised entropy coordinates. The inverse image of the maximum line of the diagram (critical values of the map) is the optimal line. The optimal point or grading curve has finite fractal distribution with the following relative frequencies:

$$x_1 = \frac{1}{\sum_{j=1}^{N} a^{j-1}} = \frac{1-a}{1-a^N}, \; x_j = x_1 a^{j-1} \tag{4}$$

where a is the root of equation (5) as defined by Imre, et al (2009):

$$y = \sum_{j=1}^{N} a^{j-1}[j - 1 - A(N-1)] = 0 \tag{5}$$

The optimal grading curve with finite fractal distribution is a kind of mean grading curve of the grading curves for a given A. The inverse image of a regular value of the diagram with a given A and B ordinate is an "N-3 dimensional sphere" in the N-1 dimensional, closed simplex. The mean grading is the optimal one related to the given A.

2 MEASUREMENTS AND DATABASE - MINIMUM DRY DENSITY

The soils and testing methods are described in Imre, et al (2009, 2013, 2017). For this preliminary study three different databases were used. They are here referred to as the (i) Lőrincz, (ii) Kabai

and (iii) Óbuda-Bochum databases, respectively. For the present analysis 50, 23 and 21 data samples were used from the databases (i), (ii), and (iii), respectively. In all databases, artificial mixtures of sand with different gradations were tested for dry density according to DIN 18126, and using various sample sizes. Values of the minimum solid volume ratio (s_{min}) were evaluated in terms of these dry density tests. The rationale for using such databases is as follows:

The Lőrincz (1986) database includes mixtures with optimal gradings with particle sizes varying between 0.07 and 4 mm with different values of relative base entropy (A); the Kabai (1972) database includes continuous data considering a slightly different value of d_0; the Óbuda-Bochum database (with data produced from ongoing research) includes unpublished results consisting of optimal gradings with $A = 2/3$. In summary, the databases have been chosen/developed in order to consider a wide range of particle sizes and distributions.

3 RESULTS AND ANALYSIS

In order to assess the effectiveness of using the grading entropy coordinates to estimate the minimum solid volume ratio (s_{min}), three types of empirical equation were tested on the basis of the experimental data. These are as follows:

$$s_{min} = C_3 S_0^{C_1} \Delta S^{C_2} \tag{6}$$

$$s_{min} = C_3 S_0^{C_1} (\Delta S + 1)^{C_2} \tag{7}$$

$$s_{min} = C_1 S_0 + C_2 \Delta S + C_3 \tag{8}$$

According to the results shown in Table 1 and Figure 1, the fitting parameters for each of the equations used were similar and it may be argued that additional statistical tests are required. The evaluation of these relationships must also be made within the context of their range of validity (which differs for each of the databases used). Note that despite its relative simplicity, Equation 8 provided the best fit for all databases. Similarly, amongst the three databases used, the Lőrincz database produced the best R^2 values.

4 SUMMARY AND CONCLUSIONS

The grading entropy method was applied using some experiments made on artificial mixtures of natural sands with fractal or continuous grain size distribution to determine a relationship between grading curves and dry density values in terms of solid volume ratio. Results indicated that there is a strong relationship between grading entropy coordinates and density. Despite its simplicity a fully linear relationship provided the best fit. Results however are dependent on the database used and must also be considered within the context of their range of validity.

A linear relation was found for the tested fractal distributions or continuous mixtures which supports the idea raised in Edwards' Statistical Mechanics approach that the dry density and the entropy are closely related. Therefore, by means of further research, a link between minimum solid volume ratio and the statistical mechanics approach (Baule et al. 2016) may be established. Further research is also suggested on gap-graded mixtures

Determination of shear and deformation parameters of coarse-grained soils

E. Kucova & J. Frankovska
Slovak University of Technology in Bratislava, Slovakia

ABSTRACT: The determination of soil properties is highly affected by its spatial variability. Furthermore, in many cases, it is impossible to extract undisturbed soil sample for laboratory testing. Regarding coarse grained soils, their mechanical parameters are mostly determined directly in situ as conventional shear and oedometric apparatus do not have the capacity for its measurement. In Slovakia, the dynamic penetration test is one of the most widely used field tests for these purposes. The test is primarily used for testing the resistance of coarse-grained soils, but using proper correlations, it is possible to determine other selected properties, including deformation modulus and angle of shear strength. These parameters can also be tested in the laboratory with a large-scale shear box and oedometric apparatus. In this article, the analysis of the results of deformation modulus and angle of shear strength measured in situ and in laboratory is presented.

1 INTRODUCTION

In geotechnical engineering, soil and rock properties are essential knowledge for the design of structures. However, the determination of these properties is more complicated than the determination of manmade materials properties due to their natural condition. In many cases, geotechnical engineers are met with the situation, when it is hard to obtain undisturbed representative samples for laboratory testing and therefore, many soil/rock tests are conducted directly in the field.

In Slovakia, besides common field tests used in engineering-geological survey (Schnaid 2009, Marchetti 2006, Yu 2000), the dynamic penetration (DP) is frequently used for soil testing. It is used for investigation of the soil resistance against the dynamic penetration of the rod. The test is primarily intended for testing of coarse-grained soils, because of the less friction between the soil particles and the penetration rod. Using appropriate correlations, it is possible to derive specific geotechnical parameters: relative density (I_D), angle of shear strength (ϕ_{ef}), deformation modulus (E_{def}) of coarse-grained soils. To obtain these properties, there exist many correlations published in foreign and domestic literature (EN 1997-2:2007, DIN 4094-3:2002, STN 72 1032:1997, Matys et al.1990). However, these correlations should be chosen with caution as not all of them are direct (do not represent direct relation between DP results and property), thus the applicability of them may vary.

Regarding the relation between DP results and soil property, foreign standards (EN 1997-2:2007, DIN 4094-3:2002) mention mostly the direct correlations between the results of the number of blows and relative density. Correlations for mechanical properties (e.g., ϕ_{ef} and E_{def}) are expressed indirectly. It means that in the foreign standards ϕ_{ef} and E_{def} are derived from I_D. The applicability of these correlations was discussed by Vrettos & Papamichael (2018), who concluded that the correlations are reliable for determining the medium density. Furthermore, they observed that the accuracy for determination of other geotechnical parameters is questionable, and they recommended using direct correlations.

Direct correlations for mechanical parameters of coarse-grained soils are published in the Slovak literature (STN 72 1032:1997, Matys et al.1990). These correlations are derived from

DOI: 10.1201/9781003299127-43

the results of dynamic penetration resistance (q_{dyn}), which considers the friction on the rod and the change in rod´s weight with increasing depth, therefore, is considered as more reliable (Vrettos & Papamichael, 2018).

Other important factor, necessary for choosing appropriate correlation, is soil composition and genesis of the soil. The fact is that from all the available correlation in Slovakia only some correlations specify type or genesis of the soil. This creates significant gap for evaluation of geotechnical properties (especially the mechanical ones) from DP test. The genesis of soil is critical for the evaluation of geotechnical properties, especially in gravels, where mechanical properties are affected by interlocking forces between grains. In general, it is known that between angular grains the interlocking is greater, which means better geotechnical parameters than in the soils with round particles.

On the other hand, in Slovakia there exist some recommended values of mechanical properties for coarse-grained soils (STN 73 1001:1989) assessed from comparable experience. But, in previous study, comparing them with field test results, we found out that these values are a bit optimistic for fluvial gravels, therefore cannot be completely followed.

In order to analyze the mechanical properties of fluvial coarse-grained material, this paper presents results from a series of heavy dynamic penetration tests performed in fluvial soils near Bratislava, the capital of Slovakia. These results were consecutively used for the determination of mechanical properties of coarse-grained soils by applying selected direct correlations. The results are furthermore compared with the results of laboratory tests to analyze mechanical properties and assess the applicability of selected correlations.

2 GEOLOGY AND TESTING METHODS

In our study, we analyzed the results of mechanical properties of coarse-grained soil collected from the field and laboratory testing. The field test was performed in southwestern Slovakia near the capital city. This area is characterized by the large deposits of quaternary fluvial coarse-grained soils. In the past, these deposits were accumulated by the Danube River in form of river terraces. The most represented soils in the area are well (GW) and poor (GP) graded gravels, that are occasionally intersected with layers of fine-grained gravel (G-F, GC). The grains of fluvial gravels are well rounded with smooth round or cylindrical shapes with size of 1-5 cm.

These soils were tested by heavy dynamic penetration (DPH). Penetrations were performed to depths of 7-25 meters. Groundwater was observed at depths of 0.4 - 4 meters below the surface. The investigation shows that the area is mostly represented by medium dense to dense poor-grade gravels (GP), alternatively by layers of sandy soils - see typical geological profile (Figure 1). During the execution of DPH tests (example of DP test recording is shown in Figure 1), the number of blows N_{10} were recorded, from which the dynamic penetration resistance q_{dyn} (MPa) was subsequently derived. Afterwards, using selected correlations (Table 1), the mechanical properties of coarse-grained soils were derived from the q_{dyn} results.

Table 1. Correlations for determination of mechanical properties.

Soil property	Correlations	Soil	Coefficients	
Angle of shear strength (°)	$\varphi_{ef} = p \times (q_{dyn})^r$	Fine grained sand	p	24
		Gravely soils	r	0.16
Deformation modulus (MPa)	$E_{def} = n \times (q_{dyn})^m$	Silty sand	n	2.0
			m	0.83
		Fine-grained sand	n	3.5
			m	0.83
		Medium/ coarse-grained sand	n	5.5
			m	0.83
		Gravely sands	n	8.8
			m	0.83

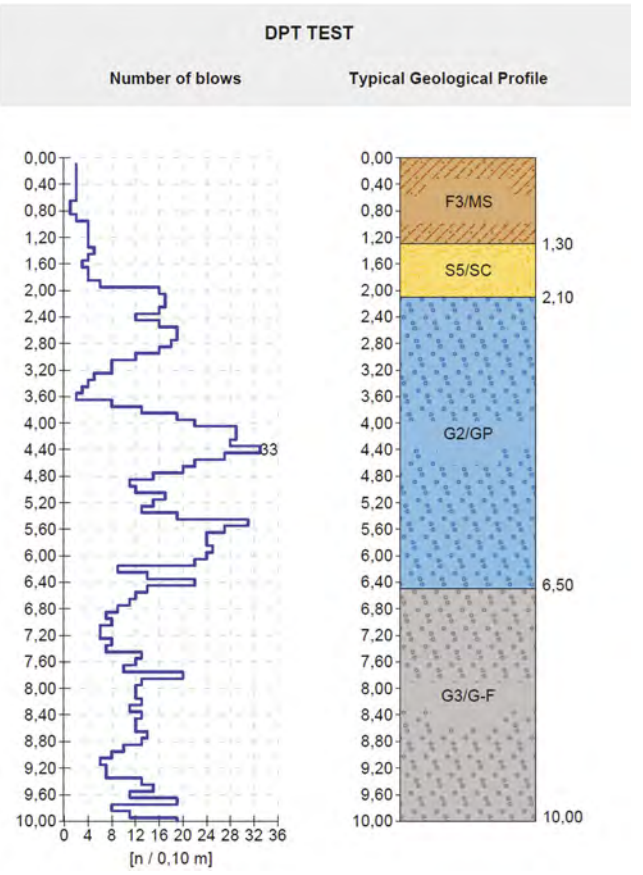

Figure 1. Typical geological profile with DPT results in tested area.

For comparison, mechanical properties of dense poor-graded gravel were also tested in labo-ratory. Shear parameter (ϕ_{ef}) was tested by using large-scale shear box machine with shear box of 300 x 300 x 200 mm and maximal horizontal displacement 60 mm. Two series of tests with normal stress of 50 kPa, 100 kPa, 150 kPa and 200 kPa were conducted on this machine. First series of tests were performed with shear velocity of 1 mm/min, while for second series of tests the shear velocity was set to 0.25 mm/min.

Before testing of shear parameters, it is important to determine the relative density of coarse-grained soil as it affects the shear strength of the sample. During our tests, we used dense gravel meaning that the sample had bigger shear strength and effect of initial shear strength, caused by grain interlocking, was observed.

Second parameter, deformation modulus, was tested on the large-scale oedometric test. The oedometric test was simulated by using the triaxial apparatus and Proctor test mold, which allowed us to test coarse-grained soil with maximum grain size of 16 mm. The soil was filled into a Proctor mold with a diameter of 150 mm and height of 125 mm. To obtain a dense sample, gravel was compacted in three layers according to the rules for the Proctor test. The mold with the soil was placed in a triaxial apparatus in which different load stages were simulated in two load cycles. The maximum applied load for the test series was 0.6 MPa.

3 RESULTS

The paper analyzes the results of mechanical properties of dense poor-graded gravel of fluvial origin obtained from field and laboratory testing. Firstly, during the field testing there were

collected about 110 results of q_{dyn} for poor-graded gravel. Consecutively, mechanical properties (e.g., ϕ_{ef} and E_{def}) were derived from these results and afterwards were statistically processed (Figure 2). For further analysis the mean values were used.

Secondly a series of laboratory tests were performed on dense poor-graded gravel using large-scale shear box test and large-scale oedometric test. For the evaluation of ϕ_{ef}, a series of shear tests with different maximal load were carried out on the dense gravel soil sample. The result of the shear test is a diagram of shear strength, which shows its development against horizontal displacement. In order to determine the angle of shear strength, the maximum values of shear strength from each load step were overlayed by straight line that indicates the angle (Figure 3).

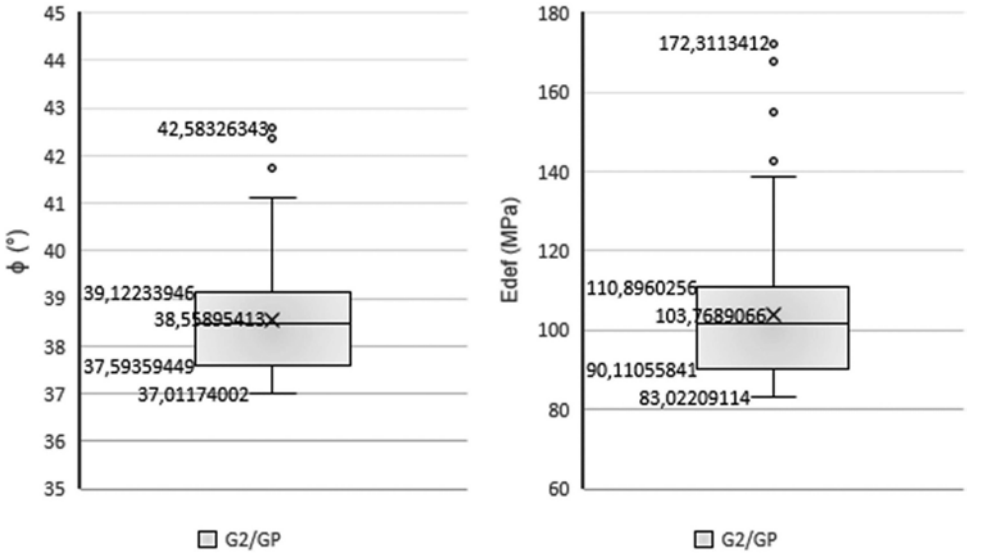

Figure 2. Statistical evaluation of mechanical properties derived from DP results.

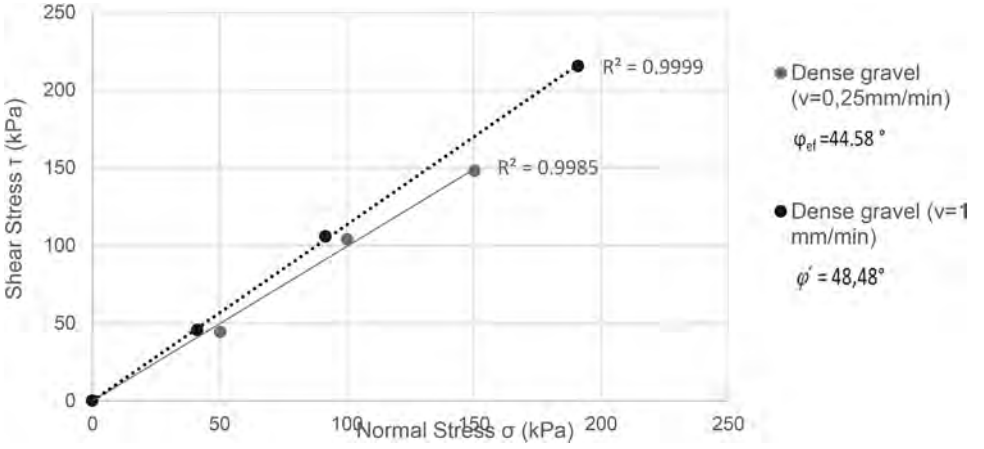

Figure 3. Angle of shear strength of dense poor-graded gravel measured in laboratory.

Furthermore, 3 compressibility tests of poor-graded gravel were carried out in the laboratory using a large-scale oedometer to determine the deformation modulus of dense gravel soil sample. During the test, the gravel was gradually loaded with a normal stress from 25 kPa to 600 kPa. Subsequently, the sample was unloaded. In total, 5 loading and 2 unloading stages with a duration of 1 hour were simulated in one loading cycle. Figure 4 shows the results of compressibility tests of poor-graded gravel.

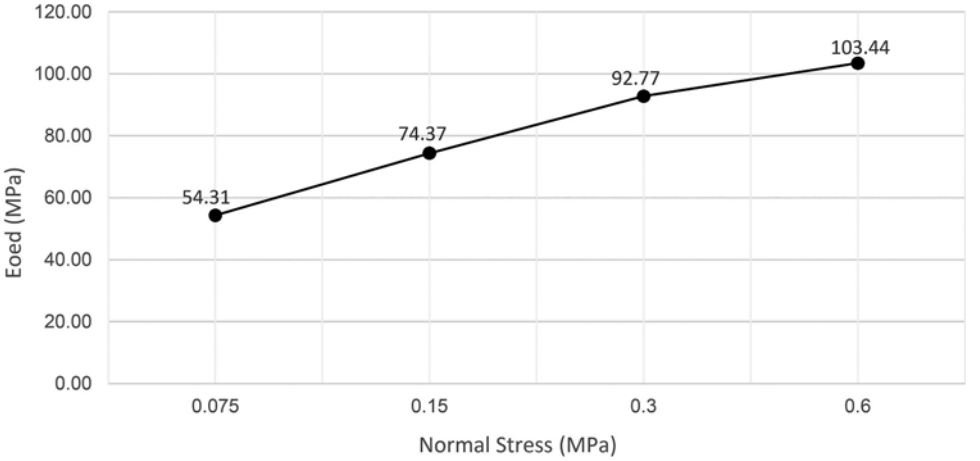

Figure 4. Deformation modulus of dense poor-graded fluvial gravel.

4 DISCUSSION

The results of the shear and oedometric tests were compared with the results of the mechanical properties derived from the dynamic penetration tests. The angle of shear strength derived from DP test using the selected correlation (Table 1) is 38.6°. Compared to the results of large-scale shear tests (Figure 2), the value is lower. However, applied correlation considers the type and class of coarse-grained soils, but do not consider its genesis (grain shape), which also affects the evaluation of geotechnical properties. Tested soil was coarse-grained soils of fluvial origin with rounded grains that have a smaller tendency for grain interlocking. Thus, this could be a cause of the lower values measured in the field.

The deformation modulus of dense gravels (Figure 4) shows a good match only for the loading step of 0.6 MPa. Nonetheless, the chosen correlation between DP results and E_{def} is more critical and gives lower values. On the other hand, in Slovak literature there exist other correlations that gives more optimistic values (STN 72 1032:1997, Matys et al.1990). However, it should be emphasized that the chosen correlations do not consider the genesis of the soil, therefore we cannot determine the accuracy of the results. In contrary, during laboratory tests, it is necessary to know the relative density of the soil, which significantly affects the determination of strength parameters. Since it is more difficult for coarse-grained soils to achieve the natural relative density, different results can be measured by laboratory tests.

5 CONCLUSION

Determining the properties of soils and rocks is a key aspect in the design of geotechnical structures. However, their determination is largely influenced by spatial variability (Pohl, 2011), and therefore in many cases it is difficult to take a representative and undisturbed sample suitable for further laboratory testing. For this reason, many tests are carried out directly in the field (Schnaid, 2009). In Slovakia, dynamic penetration (DP) is one of the most widely used field tests for the exploration of coarse-grained soils. Using appropriate correlations, it is possible to derive selected geotechnical parameters including angle of shear strength (ϕ_{ef}) and deformation modulus (E_{def}). In the laboratory, these parameters can only be determined using large-scale oedometric and shear tests, as standard tests do not have a capacity for testing soils with a large fraction of grains (Pavlík & Račanský, 2019). In laboratory conditions, it is difficult to restore original density of coarse-grained soil, especially gravels. Therefore, in most cases, field testing is used.

In this article, we present the determination of mechanical properties of coarse-grained soils from DP results using selected correlations. Coarse-grained soils in the Southwestern part of Slovakia were tested by heavy dynamic penetration. Using selected correlations, the mechanical parameters of poor-graded gravels were derived. The poor-graded gravel was further tested in the laboratory using large-scale oedometric and shear tests.

A series of shear and oedometric tests were carried out on dense gravel. A large-scale shear apparatus, (shear box dimensions 300 x 300 x 200 mm), was used for the tests. For the tests, 2 normal speeds of horizontal displacement were set – 0.25 and 1 mm/min. The angle of shear strength derived from the DP results using selected correlation is 38,6°. Compared to the results of large-scale shear tests, the value is lower. Given that tested soil is fluvial gravel with rounded grains, the smaller results of the angle of shear strength can be explained by the lateral pushing of grains during dynamic penetration.

Furthermore, a series of compressibility tests were carried out in the laboratory using a large-scale oedometer. The large-scale oedometric test was simulated by a combination of a triaxial device and a Proctor cylindrical mold with a diameter of 150 mm and a height of 125 mm. The soil samples were subjected to two loading cycles with a maximum normal stress 600 kPa. The deformation modulus (103.44 MPa) of dense gravel obtained during maximal loading stage shows a good match with the mean value (103,77 MPa) of the deformation modulus derived from DP tests. The chosen correlations for the derivation of ϕ_{ef}f and E_{def} do not consider the genesis of the soil, so the accuracy of the results is uncertain.

On the other hand, dynamic penetration is relatively often used for soil exploration in Slovakia. Therefore, it is worth to reevaluate and reconsider the use of existing correlations regarding the genesis of soils, since many of the used correlations do not take it into account.

Shear wave evolution in granular materials - role of wave oscillation direction

J. Liu

M. Otsubo
Public Works Research Institute, Tsukuba, Ibaraki, Japan

R. Kuwano
Institute of Industrial Science, The University of Tokyo, Tokyo, Japan

ABSTRACT: This study investigates the influence of S-wave oscillation direction on the evolution of S-wave signals in granular materials using the flexible boundary cubical cell and disk-shaped shear plates, by which S-waves with a fixed propagation direction and varied oscillation directions can be generated and received. Comparisons of wave signals show that S-wave oscillation direction can reflect the inner fabric of granular materials. In addition, strong directivity of particle orientation within the depositional plane was observed to have obvious influence on S-wave propagation.

1 INTRODUCTION

Shear wave (S-wave) propagation, as the most versatile and portable method to obtain the small-strain stiffness of soils, has been widely used in both laboratory testing (e.g. bender element and shear plate) and field investigation (e.g. cross-hole and surface waves) to monitor and characterize soil seismic behaviors (Minsu et al. 2014). S-waves are transverse waves, meaning that the direction of oscillation of a S-wave is perpendicular to its propagation direction. Some previous studies successfully made use of S-waves to characterize the small-strain stiffness anisotropy of soils in both principle and oblique directions by changing S-wave propagation directions (Bellotti et al. 1996; Fioravante et al. 2001). However, little attention has been paid to the effects of S-wave oscillation direction on the received wave signals, thus the measured S-wave velocities (V_s). In addition, accurate determination of S-wave traveling time is still a challenge.

In this contribution, the disk-shaped piezoelectric shear plate was used to conduct S-wave propagation tests in granular materials, by which the plate can generate and receive S-waves with various oscillation directions and the same propagation direction. The effects of oscillation direction on the S-wave signal evolution and the determination of S-wave traveling time are discussed.

2 TESTED MATERIALS

Discussions in this contribution are based on the results of tests on two granular materials: Toyoura sand (TS) and wild rice (WR). Their physical properties are listed in Table 1, and images of each material are provided in Figure 1. TS grains are sub-angular in shape, whereas WR grains are elongated, having their aspect ratios be about 0.16 as detailed in Liu et al. (2022).

DOI: 10.1201/9781003299127-44

Apart from natural TS, the WR was introduced in this research to explore some extreme fabrics of granular materials. Referring to Figure 1, the image of WR, obtained from micro-computed tomography (μCT), reveals that no obvious air voids exist inside the grains.

Table 1. Physical properties of tested materials.

Material	Median particle size (D_{50}) mm	Specific gravity (G_s)	e_{max}	e_{min}
Toyoura sand (TS)	0.24	2.64	0.943	0.574
Wild rice (WR)	11.27 (major axis)	1.47	0.951	0.612

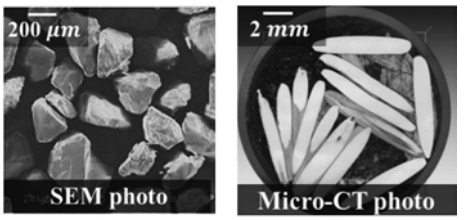

Figure 1. Images of tested materials: (a) Toyoura sand (TS) and (b) wild rice (WR).

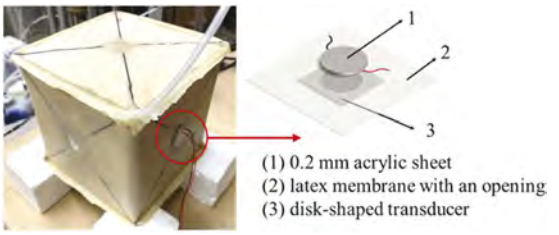

Figure 2. Flexible boundary cubical cell and transducer attachment method (Liu et al. 2022).

3 APPARATUS AND TESTING PROGRAM

3.1 *Flexible boundary cubical cell and specimen preparation*

The TS and WR were air-pluviated vertically (Z-axis) into the cubical cell (Figure 2) and tamped using a wooden hammer layer by layer for ten layers. In particular, another WR specimen was prepared by arranging the major axes of rice particles parallel to the Y-axis within the horizontal plane (Figure 3a), which is referred to as the unidirectional particle orientation specimen. Accordingly, the WR specimen prepared by the air-pluviation followed by tamping is referred to as the random particle orientation specimen (Figure 3b). All three cubical specimens had a dimension of 125 × 125 × 125 mm at dense states and were isotropically confined by the negative pressure of 50 kPa. At the center of each membrane face, a circular opening with a diameter of 20 mm was cut before the specimen preparation, and a 0.2 mm thick acrylic sheet was pasted inside the opening. The disk-shaped S-wave transducers were attached to the sheet directly by double-sided adhesive tape. By rotating a pair of transducers at the same axis (Figure 4), S-waves with a fixed propagation direction but various oscillation (shearing) directions were inserted and received.

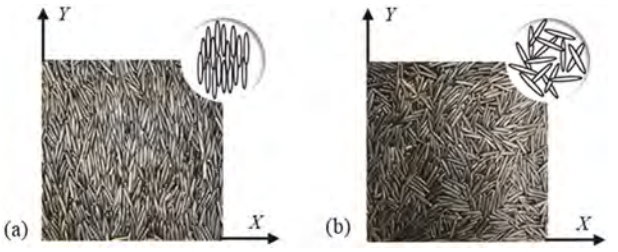

Figure 3. WR specimens with different particle orientations in XY plane: (a) dominated in Y-axis and (b) random.

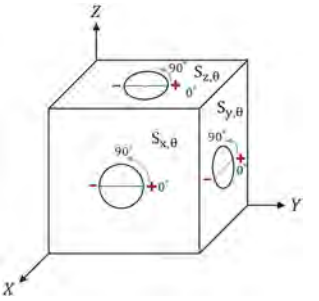

Figure 4. Change of oscillation direction of transducers.

3.2 *S-wave measurements*

A single period of sinusoidal pulse with a double amplitude voltage of 140 V was used to generate S-waves from the transmitter transducer. The input frequency f_{in} = 10 kHz was selected for the TS specimen, while f_{in} = 5 kHz was chosen for the two WR specimens. The first peak of the received S-wave was considered for the following discussions.

4 EXPERIMENTS RESULTS

4.1 *S-wave evolution in the vertical propagation direction (Z-axis)*

In the TS and WR specimens with random particle orientations, particles were assumed mostly oriented within the horizontal plane after the air-pluviation and tamping in the Z-axis. There is little difference in the S-wave arrival times when S-waves propagated in the Z-axis regardless of their oscillation directions (Figures 5a and 5b), confirming that Z-axis is the axis of symmetry according to the cross-anisotropy assumption of granular materials. However, in the WR specimen with dominated particle orientation along the Y-axis, a discontinuous change of the first major peaks can be observed (Figure 5c) when the oscillation direction was rotated from 20° to 40°. The possible explanation for this is that the WR particles can rotate easier in the XZ plane compared with the YZ planes, where elongated particles orientating along the Y-axis resist against rotation or oscillation in the YZ plane. S_{zy} is faster than S_{zx}, indicating greater stiffness in the YZ plane.

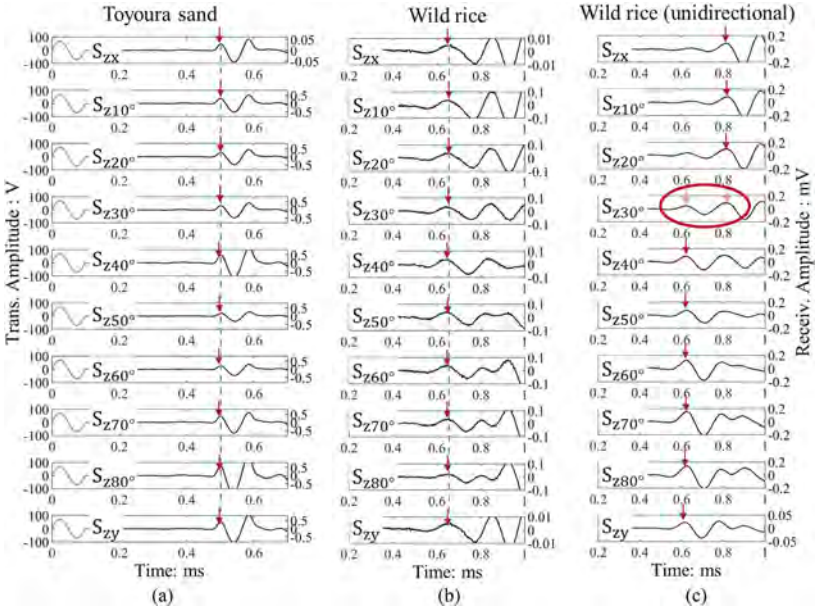

Figure 5. S-wave evolution Z-axis (vertical) propagation direction in: (a) Toyoura sand specimen, (b) wild rice specimen, and (c) wild rice specimen with unidirectional particle orientation.

4.2 *S-wave evolution in the horizontal propagation direction (X- or Y-axis)*

Figure 6a shows the S-wave evolution in the Y-axis propagation for the TS specimen (a similar response was observed for the case of propagation in the X-axis); there is a little difference in the arrival times of S-waves when the oscillation direction was varied systematically, indicating a small degree of anisotropy. Referring to Figure 6b, a discontinuous change in the arrival times of the first major peaks occurred (same for the X-axis propagation) when the oscillation direction was varied from 40° to 60°. Similarly, such phenomena may be explained by the change of dominant particle orientation within vertical planes. A gradual change of the

first arrivals of S-waves was observed in the WR specimen with dominant particle orientation in the Y-axis (Figure 6c). Liu et al. (2022) reported that for the same material with unidirectional particle orientation, S-wave travels the fastest when the propagation direction coincides with dominant particle orientation. Therefore, the gradual change in Figure 6c may result from the consistency of the S-wave propagation direction and the dominant particle orientation within the XY plane.

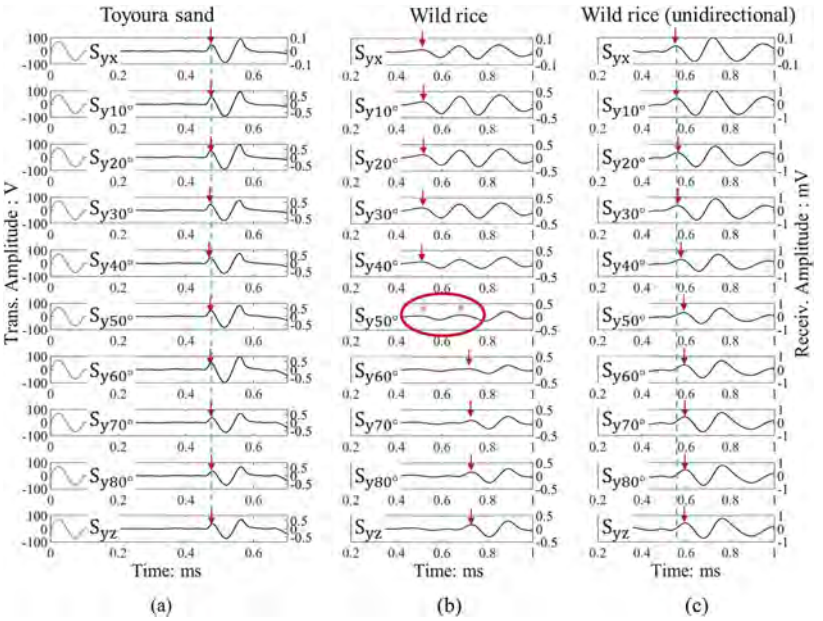

Figure 6. S-wave evolution in Y-axis (horizontal) propagation direction in: (a) Toyoura sand specimen, (b) wild rice specimen and (c) wild rice specimen with unidirectional particle orientation.

5 CONCLUSIONS

This study investigated the significance of the S-wave oscillation direction. S-waves of the TS and WR specimens with different particle orientations within the horizontal plane were measured using the flexible boundary cubical cell equipped with disk-shaped shear plates. S-waves with a fixed propagation direction but systematically varied oscillation directions were successfully measured. The S-wave oscillation direction does reflect the inner fabric of granular materials to some extent. In addition, particle orientation has an obvious influence on the S-wave propagation.

Influence of initial defects on the strength of clay soil under triaxial compression

I.T. Mirsayapov & I.V. Koroleva
Kazan State University of Architecture and Engineering, Kazan, Russia

ABSTRACT: Clay soil is the most fragile element of the "building above – ground part – foundation – soil base" system. This is especially important in cases where the base has received deformations during operation and micro- and macro-shear zones have formed in the soil, but the building is not subject to demolition. This loaded soil has different physical-mechanical characteristics than the data obtained from the geotechnical surveys results before the building construction start. The authors carried out studies of changes in the soil strength, which has a "history of loading". A soil sample with a disturbed structure was first loaded in a triaxial compression device of a cubic shape, and then destroyed in a stabilometer. Data were obtained on the change in soil strength depending on time and the influence of humidity on this process. Analytical equations have been developed that describe the process of changing the soil strength with a loading history.

Keywords: clay soil, triaxial tests, soil model, cracks in the ground, loading history

1 INTRODUCTION

In modern construction, a person uses high-strength concrete, steel and other materials for the supporting frame of the building, while the strength and deformability parameters of these materials are determined in advance at the stage of their manufacture. However, the strength and modulus of deformation of the soil base is significantly less than that of the materials from which the main structures of the building are made. Clay soil is the most fragile element of the "above-ground part of the building – foundation – soil base" system, while the safety of the building depends most of all on its reliability. This is often written about (Travush et al, 2019, Petrukhin, 2010). This is especially important in cases where the base has received deformations during operation, but the building is not subject to demolition. This loaded soil has other physical and mechanical characteristics, different from the data obtained from the results of engineering and geological surveys before the construction of the building (Mirsayapov & Aysin, 2019, Mirsayapov & Sharaf, 2017). However, there is very little research on this. The aim of the work is to study the effect of initial defects and damage on the soil strength under triaxial loading and to develop calculation methods. To achieve this goal, experimental studies of soils "without loading history" and "with loading history" were carried out in cubic and stabilometric triaxial compression devices according to the scheme of an unconsolidated undrained (UU) test (Leong et al, 2013, Nguyen et al, 2018). Theoretical studies of the influence of defects and damages on the change in the strength of clay soil from the point of view of fracture mechanics have been carried out.

2 LABORATORY TESTS OF CLAY SOIL

Under laboratory conditions, clay soils with a disturbed structure were tested, including two stages of loading. At the first stage, a "loading history" was created. At this stage, the sample

DOI: 10.1201/9781003299127-45

either underwent destruction, that is, it reached the limiting vertical or horizontal deformation for its size from the effect of an external static load, or only a few loading steps were applied in a cubic triaxial compression device with dimensions of 100 mm x 100 mm x 100 mm. It should be noted that the "load history" was created both by static (Series 1 and Series 2) and cyclic loads (Series 3). The value of all-round reduction in Series 1 was 100 kPa, in Series 2 – 300 kPa, and in Series 3 – 100 kPa, while the amplitude of the cycle – 100 kPa, and the number of cycles applied to the sample was 30 and 50. At the second stage, a cylindrical sample with a height of 76 mm and a diameter of 38 mm was cut out of the cube and subjected to static destruction in a stabilometer according to the "crushing" scheme. Unconsolidated-undrained loading (UU) was used. To evaluate the influence of the "loading history", tests only in a stabilometer were carried out without the first stage. Loading regimes are shown in Figure 1.

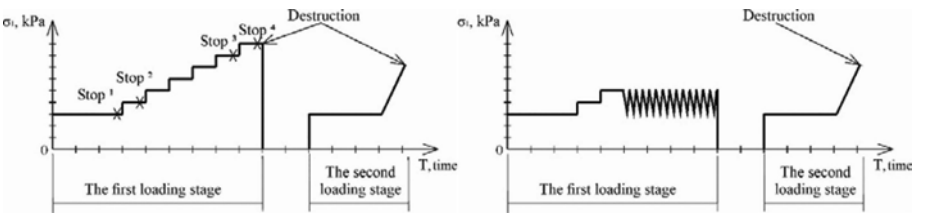

Figure 1. Loading regimes: Series 1 and Series 2 (left), Series 3 (right).

The initial characteristics of the disturbed clayey soil are shown in Table 1.

Table 1. Initial characteristics of clay soil.

Characteristic	Designation, Unit	Arithmetic mean value

Soil density	ρ, g/cm^3	1.95
Angle of internal friction at W	φ,^{o}	20.6
Specific adhesion at W	C, kPa	67.5

The test results are shown in Figure 2. For the "zero" regime, a three-axis test without a "loading history" is taken.

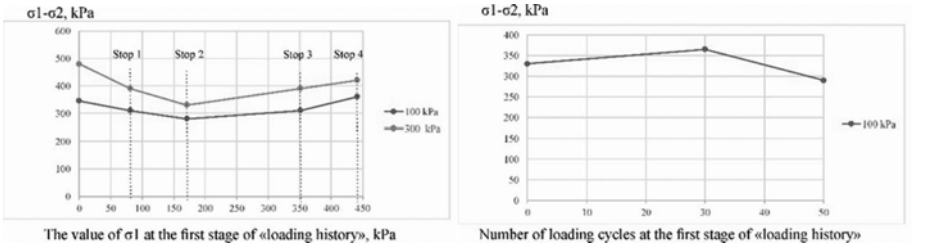

Figure 2. Change in the strength of a clay soil sample: Series 1 and Series 2 (left), Series 3 (right).

The test results made it possible to establish that, depending on the magnitude of the load and the number of cycles applied at the "load history" stage, a clayey soil sample of a disturbed structure can demonstrate an increase in the bearing capacity (strength), for example, Series 3 – after 30 cycles, the strength of the soil increased by 15% and Series 1 Stop 4 – up to 5%, and its decrease by 20%. This process is explained by the formation and

accumulation of defects in the body of the soil sample at the first stage and further softening at the second stage or hardening at the first stage and a further increase in strength at the second, depending on the magnitude of the applied load or the number of cycles that create the "loading history".

Tests of the first stage made it possible to set the soil to varying degrees of structural change. The first sample (Stop 1) had additional soil compaction by 3% in the integral volume.

Based on the results of experimental studies, it is assumed that under triaxial regime loading of a soil sample, various zones (Figure 3) of the stress-strain state arise, i.e. with a gradual increase in load, compacted zones are formed in the form of pyramids of various sizes and shapes, depending on the loading mode: from above, in the lower part of the sample and at the side faces. The sample deformation occurs due to the movement of these pyramids as rigid bodies. In these compacted zones, there is no deterioration in the physical and mechanical characteristics of soils, but their improvement (increase in density, φ and c). Negative processes that reduce the physical and mechanical characteristics of the soil are localized in the zone between these "pyramids" and the soil in this zone is subjected to simultaneous separation and shear with the formation of micro- and macro- cracks in the limiting equilibrium plane, which is used by the authors when developing a theoretical model.

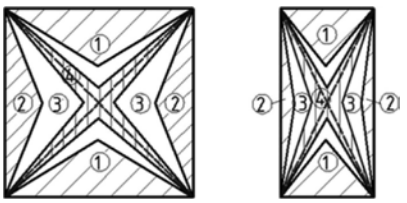

Figure 3. Location scheme of local zones of different density in the sample: 1 – vertical compacted pyramids; 2 – compacted pyramids at the side faces; 3 – zone of uniform stress state; 4 – zone of dilatancy.

3 THEORETICAL RESEARCH

According to the results of studies previously presented by the authors (Mirsayapov & Koroleva, 2011, Mirsayapov & Koroleva, 2015, Mirsayapov & Koroleva, 2016), in a cubic sample, during loading, soil compaction occurs at the first stages, and then zones of formation of limit equilibrium planes appear, and with further loading, shear zones and the shear of one part of the soil relative to another, while on strength and deformation are affected by soil moisture and load application time. Based on the above model and the results of experimental studies, the strength condition under triaxial regime compression is represented as:

$$4 \cdot [\ \sigma_V(t,N,t_1) \cdot A_{sh} \cdot cos\ \alpha_1(t,N,t_1) + \tau_V(t,N,t_1) \cdot A_{sh} \cdot sin\ \alpha_1(t,N,t_1)\ ] \geq \sigma_1 \cdot A_1 \qquad (1)$$

where $A_{sh}=b^2/(4cos\alpha_2(t,N,t_1))$ is the surface area of the side faces of the pyramid; $A_1=b^2$ is the area of the cube face; $\alpha_1(t,N,t_1)$ is the time-varying slope of the limit equilibrium area; $\alpha_2(t,N,t_1)$ is the time-varying angle of inclination of the shear area; $\sigma_v(t,N,t_1)$ are normal stresses; $\sigma_d(t,N,t_1)$ are dilatant stresses; $\tau_V(t,N,t_1)$ are shear stresses on the area of limit equilibrium.

Thus, the strength of the soil both on the first and on the second loading blocks depends on the change in the angle of internal friction, specific adhesion and the angle of inclination of the limit equilibrium plane.

The initiators of the formation of microcracks are structural defects - pores and shrinkage microcracks. Micro- and macrocracks in the planes of limit equilibrium develop unstably: the stages of nucleation, accumulation of submicrocracks, their transformation into micro- and macrocracks and abrupt development to a critical value are distinguished.

The process of crack development can be conditionally divided into three periods.

The first period - soil loosening - begins with the appearance of submicroscopic cracks after the appearance of limit equilibrium planes. Cracks occur at the pores or in the continuation of shrinkage microcracks (structural defects). At this stage, the crack sizes are small and it is most correct to speak of the formation of local plastically deformed areas. These locally plastically deformed areas near pores or shrinkage microcracks unite many submicrocracks, which are localized in certain zones of the structure, and then gradually form a loosening chain, preparing the microcrack path. In the initial stage of loading, several loosening zones are formed distributed throughout the volume. Loosening chains turn into microcracks only at a certain concentration of submicrocracks in a certain characteristic volume of the soil structure. The formation of large-sized microcracks or macrocracks occurs only in those areas where the deformation energy is sufficient to unite individual links of the loosened soil. In other, less stressed areas, individual microfractures are gradually excluded from the chain process of damage accumulation due to a decrease in stress concentration in the places where microcracks form. As the load increases, submicrocracks and microcracks grow and join, gradually turning into large microcracks. This stage can be called incubation. The duration of the incubation stage depends on the level of applied load: the higher the load level, the shorter the incubation period.

The second period begins when one of the microcracks, which is in the most unfavorable conditions, grows into a macrocrack. At the front of a developing macro-crack, a zone of plastically deformed material (loosening zone) is always formed, and a further increase in length occurs due to this end zone. The processes of material loosening in the end plastic zone and the formation of a new macrocrack section alternate. The development of a macrocrack is preceded by a relatively long period of loosening of the material in the end plastic zone. Then, depending on the stress level, a macrocrack develops by means of a stable or abrupt advance by the length of the loosening zone. This process is then systematically repeated. The second period ends when the macrocrack reaches a critical size. In the future, the crack develops unstably due to the deformation energy of the calculated volume of soil.

The duration of the third period is usually negligible compared to the previous ones, and it appears on the descending branch of the soil deformation diagram. The transition between stages is abrupt and represents a link in a continuous chain. Each period has its own crack development mechanism, but there are basic processes.

The criterion of "breakaway" (the beginning of the increase in length) is the condition of critical opening of the crack tip:

$$\delta(x, t, l) = \delta_{cr} \tag{2}$$

The development of a crack occurs stepwise by the value Δl_n as the stress increases until the total length reaches the value d_0:

$$\Delta l_n = l_0 \cdot c_0(t) \cdot (1 + \chi_0) \div (\pi \cdot K_0) \cdot ln\ (cos\ ek\alpha) \tag{3}$$

where $c_0(t) = 2K_0 \cdot \varepsilon_2/(1 + \chi_0)$; $\chi_0 = (3 - \nu_0)/(1 + \nu_0)$; $K_0 = E(\tau_1)/(2(1 \cdot \nu_0))$ is bulk modulus of soil deformation; Δl_n is crack length increment (increment of the elementary zone of plastic deformation at $\varepsilon_{gr} \geq \varepsilon_{gr,u}$).

After this, the development of a macrocrack begins. In this case, it is assumed that cracks develop in stages as deformations at the apex reach a critical value. The crack length increment Δl_n at each stage is determined from the condition:

$$\sum \left[\Delta W_i - \Delta W_r \left(\frac{\Delta W_i}{W_r} \right)^{\beta} \right] = const = W_{pl} \tag{4}$$

According to the results (Zaretskii, 2002), failure occurs when the degree of microcrack damage in the limiting equilibrium zone reaches a critical value. Therefore, the decrease in soil strength occurs mainly due to a decrease in cohesive forces.

Using the technique proposed in (Panasyuk et al. 1976), after transformations and simplifications, we obtain the function of soil strength reduction (specific cohesion) during regime loading:

$$\eta(t,\tau_1) = m(t,\tau_1)\cdot\lambda(t,\tau_1)\times\sqrt{\frac{K(\tau_1)}{K(t)}\cdot\frac{1}{1+\mathrm{K}(\tau_1)\cdot C(t,\tau_1)}}. \quad (5)$$

Then the specific cohesion between particles, taking into account the time factor, will be represented as:

$$\mathrm{C}_0(t,\tau_1) = \mathrm{C}_0(\tau_1)\cdot m(t,\tau_1)\cdot\lambda(t,\tau_1)\times\sqrt{\frac{\mathrm{K}(\tau_1)}{\mathrm{K}(t)}\cdot\frac{1}{1+\mathrm{K}(\tau_1)\cdot C(t,\tau_1)}}. \quad (6)$$

where $C(t,\tau 1)\chi_0 = (3-\nu_0)/(1+\nu_0)$ is measure of soil volumetric creep; $C_0(\tau_1)$ is initial value of specific soil cohesion at "zero" loading; $m(t, \tau_1)$ is soil strengthening function due to the restoration of water-colloidal bonds; $\lambda(t, \tau_1)$ is strengthening function due to the restoration of the structural bonds of the soil, taking into account the combination of different blocks in the process of two stages of loading.

The functions $m(t, \tau)$ and $\lambda(t, \tau)$ take into account the effects of delaying the development of micro and macro cracks and the effects of self-hardening and self-healing of clay soil due to the restoration of structural and coagulation bonds in the process of creating a "loading history".

4 CONCLUSION

Studies have been carried out on changes in the strength of soil having a cyclic and static "loading history". Data were obtained on the change in soil strength depending on the number of loading cycles, as well as the level of deviatoric load at the first stage of loading, taking into account the accumulation of structural defects in the form of micro- and macro-cracks and their self-healing.

A computational model of clay soil under triaxial compression has been developed, which makes it possible to take into account the "loading history", the processes of hardening and restoration of structural bonds, as well as dilatancy from the point of view of fracture mechanics.

Design aspects of a soil improvement in saturated clay - requirements for the material properties of an innovative composite

C. Boley & P. Pratter
Institute for Soil Mechanics and Geotechnical Engineering, Bundeswehr University Munich, Germany

ABSTRACT: Clayey soils represent a challenge in geotechnical engineering worldwide, which is dealt with using soil improvements. In particular, the choice of a suitable soil improvement method requires expertise already in the design phase. In addition to the planning aspects that must be considered for foundations in saturated clayey soils, the results of laboratory tests on an innovative composite material are presented. The research focuses on an innovative composite material made of gravel and polymer, whose mechanical and hydraulic properties are suitable for dealing with the difficult soil conditions in saturated clayey soils. Among other things, it is shown that the load-bearing capacity of the composite material is comparable to concrete, but the material has an effective pore space and remains permeable. These drainage properties are a great advantage in soils otherwise characterized by low permeability.

1 INTRODUCTION

The challenges of foundation work in saturated clay are the low load-bearing capacity of the soils and the settlement behavior. Basically, the permeability of the soils is of central importance. Experience has shown that permeability of saturated clay lies in the range from very low to practically impermeable. In geotechnical engineering, the challenges associated with saturated clay are met with

- foundation work that allows large settlements over many years, for example a spread foundation with a rigid raft foundation,
- or soil improvements.

For soil improvement, ground column technologies are used in many cases and transmit the load from the structure through the surrounding soil by side friction or lateral confinement in a comparatively flexible way. Alternatively, the load is transmitted into the deeper load-bearing soil layers by rigid vertical support elements. The different ground column technologies are presented in detail by Han (2015). The challenges and risks associated with foundations in saturated clay are pointed out by several researchers, for example Gyger et al. (1996) or Yazdani et al. (2021). Thus, driving of displacement piles into a cohesive soil causes large excess pore pressures close to the pile and at the pile-soil interface (Bałachowski & Konkol 2021, Sagaseta & Whittle 2001, Simonsen & Sørensen 2016). This increase in pore water pressure can be counteracted with an adapted design and vertical drainage (Suleiman et al. 2016, Kirstein & Wittorf 2013).

This research focusses a composite material that is semi-rigid and represents a load-bearing behavior between the above-mentioned flexible and rigid behavior. The innovative composite material has a load-bearing capacity comparable to that of concrete, but nevertheless features excellent drainage properties.

2 COMPOSITE MATERIAL

Composites are combinations of materials, where the individual constituents retain their separate identities. These separate constituents act together to give the necessary mechanical strength or stiffness to

DOI: 10.1201/9781003299127-46

the composite material (Jose et al. 2012). In this research work synthetic polymers and gravel are used. The polymers form a strong adhesive bond with the gravel and are waterproof so that an application below the groundwater level is possible. Characteristics of the intact adhesive bond of the composite material are the grain-to-grain contacts of the gravel and the polymer menisci that form on it, as well as the wetting of the entire grain surface with the polymer, see Figure 1. The polymer menisci can develop because the pore space of the gravel is not completely saturated with the polymer and air voids remain. These air voids are mainly linked and form the effective pore space, which is available for the flow processes (Fuchs et al. 2017) and significantly determines the permeability. Figure 1 (b) shows a microscopic image of the composite material. The areas with polymers are highlighted in yellow, by image processing/segmentation, and the effective pore space is marked in blue.

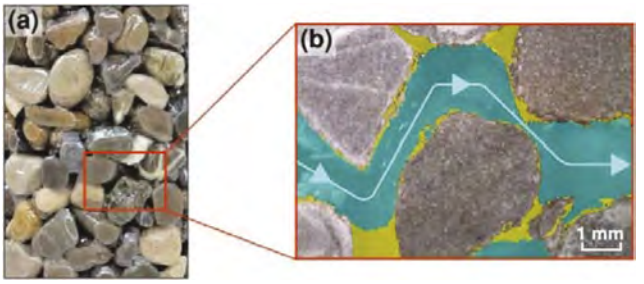

Figure 1. Composite material (a) and microscopic analysis of the pore space (b).

2.1 *Hydraulic properties*

The hydraulic properties were determined in a cylindrical permeameter with a rigid wall and at a constant hydrostatic pressure head. The test specimens were pure gravel and the composite material with different mass fractions of polymer. The mass fraction of polymer was continuously increased in three steps. At least nine individual tests were carried out for each composite material. Figure 2 shows the essential hydraulic properties. With increasing mass fraction of the polymer, the permeability of the material decreases since more pores are now filled with the polymer and less effective pore space is available for flow processes (Anagnostopoulos 2005). Although the permeability is reduced, the composite material still has a high permeability of 6.7E-03 m/s, see Figure 2. compared to pure gravel, the addition of polymer has reduced the permeability by less than one power of ten.

Consequently, soil improvement with composite material in the normally very low to practically impermeable clay, less than 10E-09 m/s (Terzaghi et al. 1996), creates a drainage path that contributes significantly to the reduction of pore water pressure.

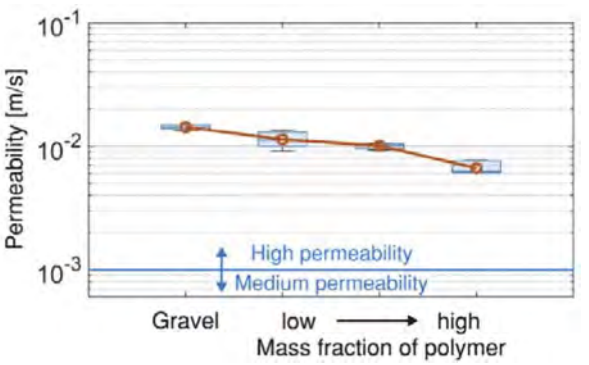

Figure 2. Permeability of pure gravel and composite material depending on the mass fraction of the polymer.

2.2 *Mechanical properties of the composite material*

Previous work with grouting material has shown that the shear behavior of grouted bodies can be correctly described using the nonlinear failure criterion according to Hoek-Brown (Boley et al. 2019). In addition to the principal stresses, the Hoek-Brown failure criterion uses the uniaxial compressive strength σ_{ci} and the material constants s, a, and m_b. The material constants depend on the geological strength index *GSI* and the disturbance factor *D* (Hoek & Brown 2019).

The results of the uniaxial compression tests show the load-bearing capacity of the composite material can increase up to 12 MPa, equal to the strength of concrete. As a grouting material, polymers can have a compressive strength of this size and even significantly higher, as the compressive strength tests by Shi et al. (2010) demonstrate. Material with a strength in this order of magnitude must be tested using rock mechanical testing equipment.

For compact and intact rock, the parameters are chosen to $s = 1$ and $a = 0.5$. The laboratory tests have shown that these values can also be used for the grouted body. The Hoek-Brown constant m_b of the composite material is determined by curve fitting from the data of the uniaxial compression tests and triaxial tests. For a composite based on polymer 01 and gravel, m_b was determined to 7.7 (R^2 0.99).

$$\sigma_1' = \sigma_3' + 11.9\ (MPa) \cdot \left\{ \left(\frac{7.7 \cdot \sigma_3'}{11.9\ (MPa)} \right) + 1 \right\}^{0.5} \tag{1}$$

The high cohesion value of 3.3 MPa can be verified by analyzing the microstructure of the composite material, see Figure 1 (b). The gravel grains are held together by the polymer, because the entire surface of the gravel, except for the grain-to-grain contact points, is wetted with the polymer and polymer menisci are formed.

In contrast to cohesion, the addition of the polymer causes a reduction in the angle of friction. In the example, the angle of friction is reduced from 39° to 35°. The decline is due to the full-surface wetting of the grains with polymer and the associated loss of grain roughness. The angle of friction and the cohesion in this example were evaluated for a normal stress of around 5.0 MPa, see Figure 3.

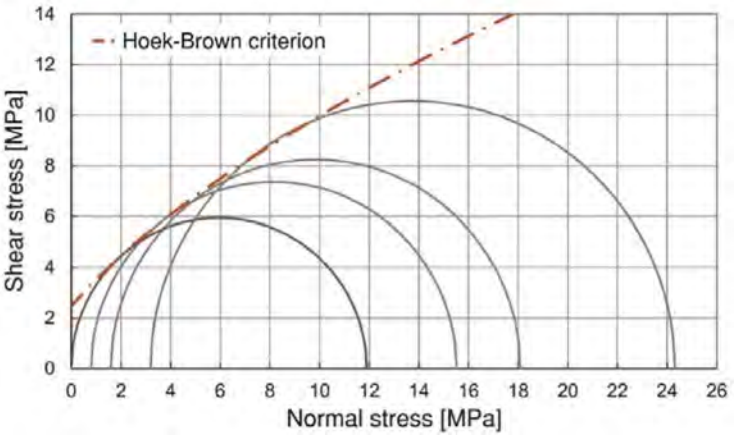

Figure 3. Fractional envelope according to Hoek-Brown for the composite material.

3 CONCLUSIONS

Based on the results of the research work, the innovative composite material has potential for application as a soil improvement. Thus, even the difficult ground conditions in saturated clay can be handled with it. Essentially, the findings of the present research work can be summarized as follows:

- The composite material has an effective pore space through which water can drain.
- Even for a high mass fraction of polymer, the composite material, with a permeability coefficient of 6.7E-03 m/s, can be classified as high permeable.
- The final strength of the high permeable composite material can be increased up to 12 MPa.
- Material behavior can be described as being well approximated by the Hoek-Brown failure criterion.
- The increase in cohesion is due to the adhesive and cohesive forces of the polymer, see polymer menisci in the microscopic analysis in Figure 1 (b).
- In contrast to cohesion, the addition of polymer causes a reduction in the angle of friction.

The presented research work is part of a currently ongoing research project. Furthermore, the research work focuses on the detailed numerical simulation of the composite material, by using the discrete element method, and on aspects from construction practice, such as durability and workability. Basically, the composite material appears to be suitable for permanent ground improvement.

New method of mechanical research of soils and use of it in design practice

A.N. Alekhin
A.N. Alekhin Ural State University of Railway Transport, Yekaterinburg, Russian Federation

ABSTRACT: Soil base is a basic, often the most pliable, load-bearing element of the building. Not being, as a rule, a constructive element of the building (except maybe artificially created reinforced soil massifs geomassifs) soil base takes on entire load from building, affecting operational and strength parameters of the building. This situation certainly requires inclusion of a soil base model into computer model of the building. In this case the problem of determining the mechanical parameters of a physically nonlinear soil from in-situ tests arises, because laboratory tests for these purposes are complex and on various reasons their results are unreliable The paper presents an algorithm of the method of determination of the design mechanical soil parameters for the physically nonlinear Botkin model. Examples of practical application of the method for the design of real objects are given.

1 INTRODUCTION

In the 1940s Russian scientist Botkin experimentally determinated and investigated physically nonlinear type of deformation for non-rocky soils (clays and sands); then this fact was confirmed by other geotechnicians (Klein, Kriegel, Alekhin). Currently researches on various aspects of this fundamental reality are being actively and successfully developed. One of the most important aspect is development of methods for determining design parameters of nonlinear soil model from in-situ test data including geometric nonlinearity as well as soil rheological properties. If the question of geometric nonlinearity, which importance for soil deformation has not yet been fully elucidated, is solved rather simply, mainly by a small adjustment of formulas for relative strains, while very complex but important investigations of rheological properties with physical nonlinearity is now beginning at some laboratories, maybe effective in-situ method will allow for rheological theory to be corrected taking into account initial stress state in soils; application of this method will also may help to asses more accurately geometric nonlinearity influence, for example, at designing neighboring buildings. Thus, the validity to solve problem of using in-situ test data was predetermined both by unique physical properties of nonrocky soil itself as specific kind of solid medium with specific internal bonds and fixed of soil structure initial stress state (both of them are inevitably destroyed during sampling) and by soil mathematical model with complex nonlinear relationships. At present Botkin's model is the only systematically and consistently verified, including practical application of physically and geometrically nonlinear soil model. Moreover, so far this is the only soil model with complex nonlinear relationships for which it was possible to develop a convenient method for determining true values of design mechanical parameters from in-situ test data that much increase reliability and accuracy of geotechnical design. The general principles of the proposed method, in particular the method of solving revers unstable problems can be applied for determining mechanical parameters of other types of physically nonlinear models. Below algorithm for the determination of mechanical parameters of physically nonlinear soil model in relation to the Botkin's model is presented. As for the way of derivation of constitutive relations for the Botkin's model as well as the formula of less general physically linear Young-Hook's model are referred to the, so called, phenomenological form obtained as a result of approximation of data

DOI: 10.1201/9781003299127-47

of actual and presentable in general parameters of the stress-strain state (SSS) of mechanical tests on deformation. Phenomenological difference between physically linear (Hooke) and physically nonlinear (Botkin) deformation types of a solid medium is shown at Figure 1.

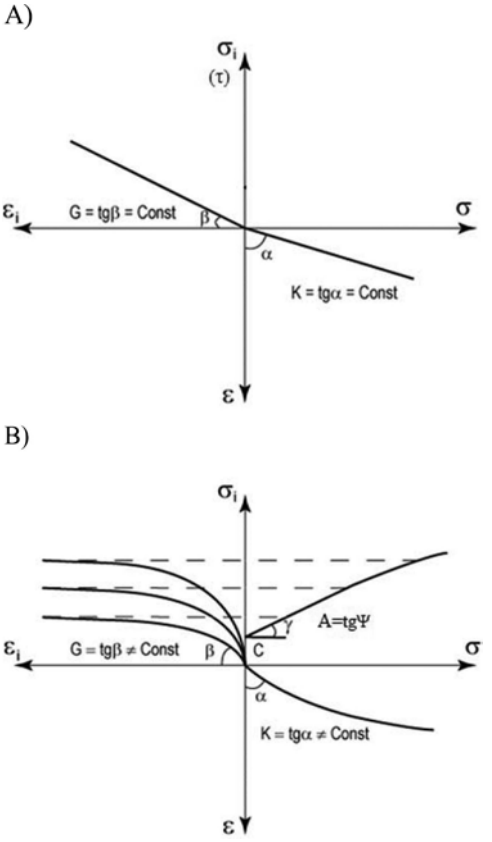

Figure 1. A) physically linear type of deformation (solid materials and rocks) B) physically nonlinear type of deformation (non-rocky soils: sands and clays); K and G – bulk modulus and shear modulus respectively; σ and ε – first invariants of the stress and strain tensors (bulk deformation); σ_i and ε_i – second invariants of the stress and strain deviators shape deformation).

2 METHODOLOGY

Main and defining difference between the less general Hooke's type of deformation salient for solid materials (primarily for metals and rubber) in relation to the more general Botkin's type of deformation salient, as was shown by Botkin for non-rocky soils (clays and sands) is in independence of stiffness and corresponding stiffness characteristics on the SSS for linear type and in their significant dependence on the SSS and also on the initial SSS for nonlinear type of deformation, especially for nonrocky soils. That is why in contrast to the stiffness constants E (Young-Hooke/s modulus) and ν (Poisson's ratio), which are convenient for determining and using for solid materials, but absolutely unsuitable for soils due to serious insurmountable problems with their definition and application, Botkin proposed simple and at the same time physically substantiated, but objectively nonlinear (with SSS parameters) formulas for stiffness characteristics, that are more convenient for soils and at the same time more fundamental for the phenomenon of solid medium deformation and hence for soil mechanics theory: for bulk modulus $K=\sigma^{1-\sigma}/A_0$ and for shear modulus $G=(A\sigma+C)/(B+\varepsilon_i)=(\sigma U-\sigma_i)/B$; here $\sigma_U=A\sigma+C$ is Mises-Botkin's criterion for soil strength which is a private version and analogue to the classical Coulomb's version of soil strength criterion, and A, B, C, A_0, α are model constants which must be determined from test data. But true values of these parameters that

allow to do geotechnical design with required accuracy both for naturally and artificially formed soil massifs can be determined only from in-situ test data since they depend on initial structural and stress states due soil physical nonlinearity. Of the complexity of nonlinear formulas describing deformation of non-rocky soils determination it is possible to determine soil design mechanical parameters values for nonlinear model only by special methods for solving inverse weakly conditioned problems, namely by minimizing discrepancy between the actual S_{fi} and numerically simulated soil displacements S_{mi}. Algorithm of the developed method was developed by analog with the method of academician Tikhonov applied for solving some nontrivial geophysical problems. In the case of determining a set of soil mechanical parameters $z_k = \{A, B, C, A_0, \alpha\}$ the objective minimization function has general form:

$$min\rho_{\alpha zk}\left[\sum_{i=1}^{n}\left(S_{mi}-S_{fi}\right)^2\right] \tag{1}$$

Here i is number of pressure stage, n is total quality of stages; to rationalize the procedure the regulatory factor α can be used in the form of a procedure or of a function that must optimizes a search for a global minimum at any stage of minimizing procedure.

The specific implementation of this method depends on the type of resolving relations of the problem being solved and on the features of physical problem being analyzed. In presented method parameters are determined by minimizing residual discrepancy $\rho\alpha_{zki}$ according to general formula (1) after applying in procedure previously determined true values. In this procedure values of S_{mi} are determined as a result of solving direct stable problem and values of S_{fi} are determined from standart in-situ static tests with usual accuracy (loading of soil by round shtamp and pressuremeter test). High speed of computational procedure is also of great importance for the efficiency of the method. Determination of true values of parameters of Botkin's model must begin on its key parameter B since this parameter though soil resistance to shape-shear deformation G affects directly soil strength. Integration on compressible zone of vertical relative soil deformations ε_z made it possible to obtain formula for vertical soil settlement with linear dependence on the parameter B:

$$S = \sqrt{3}B/2\int_0^1 y_z d_z \tag{2}$$

(Here y_z is a function of vertical stresses in soil massif which due to Henky's relations depends on mechanical soil parameters. Hypothetical representation of actual settlements (marked with individual index "f") as one of variant of numerically simulated settlements (marked with common index "m"): $S_m=F\ (p,\ A_m,\ B_m,\ C_m,\ A_{m0},\ \alpha_m) \rightarrow$ (formal rename indexes from the common index "m" to the individual index "f") $S_f=F\ (p,\ A_f,\ C_f,\ B_f,\ A_{f0},\ \alpha_f)$ allowed to write the ratio $S_f/S_m=B_f/B_m$, that after use it in formula (1) made it possible to derive statistically valid formula for true value of the parameter B: $B_f=B_m\Sigma S_{fi}/\Sigma S_{mi}$. Thus, algorithm of the method is actually based on the comparing two identical functions with different values of their identical parameters. Another very effective procedure using the regulating factor α in the form of technically meaningful interval of 100 for soil internal friction angle φ was used to determine true values of parameters A and C, connected with this angle by Botkin-Malyshev's formulas:

$$A=\frac{\sqrt{2(3+\mu^2)\mathrm{SIN}\varphi}}{3+\mu\mathrm{SIN}\varphi};\ C=\frac{\sqrt{2(3+\mu^2)\mathrm{COS}\varphi}}{3+\mu\mathrm{SIN}\varphi}\ c; \tag{3}$$

here φ and c are soil strength parameters on Coulomb's version of soil strength. These formulas made it possible to use the simplest minimization procedure with single result being obtained by looking over different angle values of angle φ.

To determine true values of parameters A_0 and α was used well-known Himmelblau's program Flexiplex for search global minimum on two parameters.

3 RESULTS AND CONCLUSION

Using physically nonlinear Botkin's model several geotechnical objects were designed and built in Ekaterinburg, namely: strip foundations of 6-storey neighboring buildings instead of pile foundations, retaining wall close to 9-storey building and spread-slab foundation of

35-storey high-rise building (see Figure 2a and 2b). In all these cases Botkin's soil model with design parameters values from in-situ test data were used for design of foundations. At all cases the cost of geotechnical constrictions was about $1 million less than the cost in original project on the base of Hooke's linear theory and with significant increase in reliability of the design solution on the base of true soil model: for example, in the case of 35-storey high-rise building on eluvial hard silty-argillaceous loam and sandy loam actual settlements differ from design one for about 25%, that is discrepancy coincides with discrepancy due to replacing in design real soil by ideal continuous medium.

Figure 2a. High-rise buildings in Ekaterinburg city: left building on the spread slab foundation is $1 cheaper than others of the same kind.

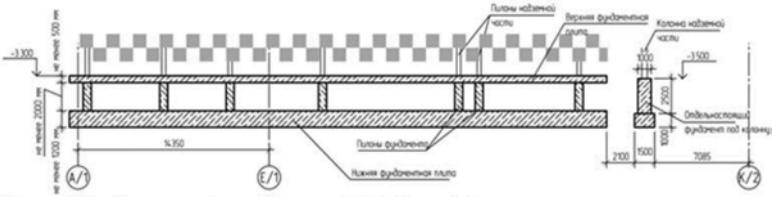

Figure 2b. Cross section of spread slab foundation.

ABSTRACT: In Quito, Ecuador, landslides present a significant threat to communities settled on hillsides and ravine slopes, and geotechnical data is needed to assess slope stability. Saturated hydraulic conductivity is a key input parameter for mechanistic modelling of rainfall infiltration and the pore water pressure conditions that can trigger landslides. This paper presents field data of in-situ saturated hydraulic conductivity by working with communities to conduct field measurements on the cemented volcanoclastic soils found in Quito. The new field data is then compared with predictions from recently established geodatabases of hydraulic conductivity obtained from laboratory tests on fine-grained and granular soil.

1 INTRODUCTION

Rapid urbanisation is predicted to increase landslides worldwide in the coming decades (e.g. Holcombe *et al.* 2016 & Ozturk *et al.* 2022). However, slope stability assessment and urban landslide risk reduction presents a challenge in regions with limited financial and technical resources for geotechnical data gathering and meeting slope design standards (e.g. Anderson & Holcombe 2006, 2013). In Quito, Ecuador, landslides often occur in the volcanic ash Cangahua soils that are found in the inter-cordillera valley from southern Colombia to central Ecuador at altitudes of 2200 to 3000 metres (Winckell & Zebrowski 1992). This is a multi-hazard environment in which rainfall can trigger cascading landslides, debris flows, and floods. Hydraulic conductivity (k) is an important soil parameter for geotechnical engineers. Saturated hydraulic conductivity (k_{sat}) is used to calculate rainfall infiltration and saturated groundwater seepage and to derive unsaturated hydraulic conductivity, for example using the Millington–Quirk formulation (Millington & Quirk 1959) in slope hydrology and stability models (e.g. CHASM, see Wilkinson *et al.* 2002).

To support the investigation of rainfall infiltration and landslide initiation, this study has the following aims: (i) present new field data of k_{sat} obtained via citizen science activities; (ii) compare the new data with values predicted from previously established transformation models. The study is part of the Tomorrow's Cities project on urban disaster risk reduction (see Galasso *et al.* 2022 for a discussion of the aims of the wider project).

2 MATERIAL AND METHODS

2.1 *Geological setting of the study site*

The study site is part of the Conocoto Giant Landslide (CGL) located on the eastern flank of the Puengasí anticline, uplifted by a segment of the Quito reverse fault system, in the southwestern part of the Metropolitan District of Quito. This relict landslide is estimated to have occurred between 165ka to 10ka and has a 3700 metre semi-circular scarp (Noroña Muñoz 2021). The deep colluvial strata are comprised of Cangahua – a volcanic ash soil produced by partial diagenesis of fine explosive volcanic material cemented primarily by amorphous clayey material, silica, iron oxides or calcite (see Vera & Lopez 1992, for a detailed description of Cangahua).

2.2 *Soil sampling and index testing*

In collaboration with community residents, undisturbed soil samples were taken from a continuous Cangahua material layer. The soil samples were denoted as S1 and S2 from 200mm and 500mm sample depths respectively. Granulometric analysis and SUCS classification were carried out on both samples, following the standard ASTM D2487 (ASTM 2011). To carry out the soil classification tests of the soil samples (using ASTM 2017a), the laboratory used the material that passed through Sieve No 40 (see ASTM D6913 for the ASTM sieve sizes) (ASTM 2017b).

2.3 *Estimation of saturated hydraulic conductivity using a double ring experiment*

In this study ASTM D3385 (ASTM 2018) was used to measure k_{sat} at the sampling point located on the ridge of the CGL, in collaboration with community residents. The experiment was carried in a half-metre deep pit during the rainy season. The double ring system was filled with water for two hours to allow saturation conditions to develop. A long-term test was then carried out in which infiltration measurements were taken every 15 minutes for 2 hours, and then every 24 hours for the following three days. The soil conditions were assumed to be near saturation. For natural Cangahua, O'Rourke & Crespo (1988) indicated a natural degree of saturation (S_r) ranging from 32% to 56%.

3 TEST RESULTS

The k_{sat} measurements obtained from the field testing show an order of magnitude range (Table 1). The soil samples (S1 and S2) collected for this study have a SUCS classification of type CL (following ASTM 2011), with a predominance of fines (see Tables 2 and 3). Table 3 also shows the computed specific surface area per volume (S_A) which can be computed using the soil grading curve (see Chapuis & Légaré 1992, Feng 2022).

Table 1. Double-ring infiltrometer test results for three-day experiment.

Time (min)	0	60	90	120	150	1590	3030
Infiltration (cm)	0	0.4	0.2	0.2	0.2	9.4	5.8
k_{sat} (m/s)	0	4.72×10^{-6}	3.61×10^{-6}	2.78×10^{-6}	2.50×10^{-6}	1.09×10^{-6}	6.71×10^{-7}

Table 2. Laboratory grain size analysis results.

S1	35	37	23	110.57
S2	25	32	20	113.95

4 ESTIMATIONS OF HYDRAULIC CONDUCTIVITY

Feng (2022) reported a new database CG/KSAT/7/1278, with over 1200 k measurements on soils with over half of the soil grain particles larger than 0.075mm in diameter (i.e. coarse-grained soils). Equations (1a) and (1b) are a k transformation model calibrated using CG/KSAT/7/1278:

$$K = 1.693 \times 10^{-2} e^{2.283} / {S_A}^2 \tag{1a}$$

$$k_{sat} = K(\gamma_w / \mu_w) \tag{1b}$$

where K = intrinsic permeability of the porous medium (mm^2 in Equation 1a, and m^2 in Equation 1b), e = void ratio, S_A = specific surface area per volume (1/mm), k_{sat} = saturated hydraulic conductivity (m/s), μ_w = dynamic viscosity of the permeant = 1.002×10^{-3} kg/(m.s) (Kestin *et al.* 1978, assuming a testing temperature of 20°C) and γ_w = unit weight of the permeant = 9.81 (m/s^2) × 998 (kg/m^3) (density value from Kestin *et al.* 1978, assuming a testing temperature of 20°C).

Feng & Vardanega (2019) assembled a fine-grained soil database FG/KSAT-1358, which contains over 1300 k measurements soils with more than half of the particles smaller than 0.075mm in diameter and with a measurable w_p (i.e. fine-grained soils). The FG/KSAT-1358 database was used to develop a transformation model of the form presented in Feng & Vardanega (2019) and further refined in Feng *et al.* (2022) (after removal of statistical outliers), shown as Equation 2:

$$k_{sat} = 1.86 \times 10^{-9} (w / w_L)^{4.226} \tag{2}$$

where k_{sat} is in units of m/s and w/w_L = the water content ratio (where w = the water content).

By using Equations 1a, 1b and 2, predictions of k_{sat} for S1 and S2 for a range of porosities (n) quoted in various publications were made and compared with the test results. Tables 4 and 5 summarise the predicted k_{sat} values. For all the calculations, S_r is taken as equal to 1.0 and specific gravity (G_s) is taken as 2.585 (the average value from the data in O'Rourke & Crespo (1988)).

	$e = n/(1-n)$	S_A (1/mm)	k_{sat} (m/s)	e	S_A (1/mm)	k_{sat} (m/s)
This study	0.905	110.57	1.08×10^{-5}	0.646	113.95	4.70×10^{-6}
Podwojewski & Germain (2005) (n = 40%)	0.667	110.57	5.36×10^{-6}	0.667	113.95	5.05×10^{-6}
Crespo (1987) (n = 43%)	0.754	110.57	7.11×10^{-6}	0.754	113.95	6.69×10^{-6}
Crespo (1987) (n = 56%)	1.273	110.57	2.35×10^{-5}	1.273	113.95	2.21×10^{-5}

Table 5. k_{sat} at 20°C predicted using Equation 2.

Reference	S1 (w_L = 37%)			S2 (w_L = 32%)		
	$e = n/(1-n)$	w (%)	k_{sat} (m/s)	e	w (%)	k_{sat} (m/s)
This study	0.905	35	1.47×10^{-9}	0.646	25	6.54×10^{-10}
Podwojewski & Germain (2005) (n = 40%)	0.667	25.8	4.05×10^{-10}	0.667	25.8	7.47×10^{-10}
Crespo (1987) (n = 43%)	0.754	29.2	6.82×10^{-10}	0.754	29.2	1.26×10^{-9}
Crespo (1987) (n = 56%)	1.273	49.2	6.22×10^{-9}	1.273	49.2	1.15×10^{-8}

Compared with the measured k_{sat} data from the field testing (Table 1), the coarse-grained soil hydraulic conductivity transformation model (Equation 1) gives a significantly better prediction of k_{sat} than the fine-grained soil hydraulic conductivity transformation model (Equation 2). This may be because that while the Cangahua soil samples tested have a measurable w_P, the data in FG/KSAT-1358 are mostly pure laboratory fine-grained clays and silts and thus might not be representative for the samples testing in this work which contain a combination of fine and coarse material (see Table 2).

5 SUMMARY

This paper has presented the results of a citizen-science based project to assess saturated hydraulic conductivity in data-limited locations where rainfall-triggered landslide hazard assessment is required. New field k_{sat} measurements were made using a double-ring infiltrometer. The new data were compared with predictions from two transformation models developed from databases of coarse-grained and fine-grained soils. The field values are closer to the predictions from the coarse-grained transformation model – this is possibly because Cangahua is not a pure clay and comprises a large component of coarse-grained material.

ABSTRACT: The paper describes the terrain of the landslide-prone area and the geological condition and factors affecting stability. Reflected the results of the research of the physical and mechanical properties of the constituent soils.

Keywords: soils, physical and mechanical properties, subsidence, Kara-Mart village, Kugart river basin, landslide

1 INTRODUCTION

The structure and state of the mountain massive is changing under the influence of endogenous and exogenous factors, arising naturally or under the influence of the structure of man-made structures. Based on the statistical data, it can be observed that landslides are mainly for an untouched massif accompanied by natural factors in mountainous areas. The terrain, seasonal changes in the hydrological and climatic conditions of the area, the physical and mechanical properties of the constituent soils are the main factors affecting the stability of the slopes [Shakhmov, 2015; Shakhmov, 2012; Shakhmov, 2016; Kuvakov, 2022]. With the transition from winter to summer and an increase in air temperature, leading to intensive melting of snow cover, expected precipitation and seismic activity in the spring-summer period, landslides are expected to intensify in the south of the republic. At the moment, out of the data of the Ministry of Emergency Situations of the Kyrgyz Republic, 1204 landslide areas threaten settlements, objects with a possible descent, which make up 80% of all landslides in the republic. The beginning of the Kugart river basin and their numerous tributaries start from the southwestern slopes of the Ferghana Range. In the river basin, 529 landslides have been described and systematized, of which 260 landslides were formed on slopes close to the northern exposure. A total of 225 landslides pose a threat to settlements, various objects of social and cultural life and infrastructure. Landslides have a large capture depth, reaching 20m. On the territory of the Suzak region, about 80% of the territory belongs to mountain structures, and 20% to flat relief types. The map-scheme for predicting emergency situations shows the location of areas of possible activation of landslide processes (Figure 1).

DOI: 10.1201/9781003299127-49

Figure 1. Location of areas of possible activation of landslide processes in the Suzak region.

It should be noted that the Kugart river basin covers many landslide-prone areas, and according to previous static studies, the number of landslides in the river section was established. Kugart has a close correlation with the amount of total annual precipitation (Figure 2) [Beksultanov, 2013].

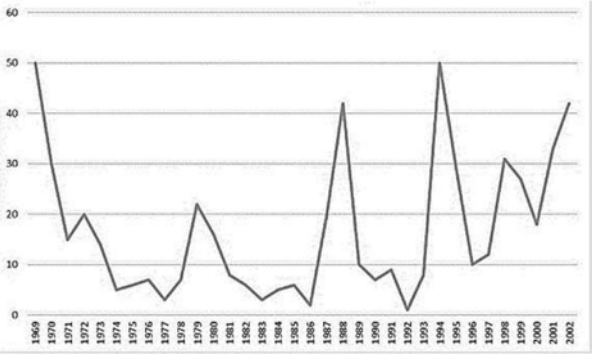

Figure 2. The number of landslides in the Kugart river basin by years.

he landslide-prone areas of the Karamart village are one of the most dangerous, located in the Kugart river basin.

2 METHODOLOGY AND RESULTS OF THE RESEARCH

In the research of soil properties, well-known state standards were used: 30416-96 - Laboratory tests. General provisions, 51-84 - Physical characteristics, 12248-96 - Strength and deformability, 12536-79 - particle size distribution. The physical and mechanical properties of soils were determined in laboratory conditions (specific gravity, density, moisture in nature, porosity, plasticity number, cohesion and angle of internal friction.) [Beksultanov, 2013].

3 MAIN RESULTS

The average relative error is 5%, which complies with the regulatory requirements specified in state standards. As a result of laboratory studies, averaged physical and mechanical data were obtained, which are shown in Table 1.

Table 1. The number of officially reported plague cases in the world.

№	pit	weight	Density	natural humidity	porousness	Plasticity number	cohesion	Angle of internal friction
1	P-1	2,71	1,78	21,5	46,2	12,2	0,033	21
2	P-2	2,72	1,72	20	42,3	12,4		
3	P-3	2,71	1,76	21	45,4	10,6		
4	P-4	2,73	1,61	19,5	44,8	11,6		

Based on the results of a visual inspection of the site, identified that subsidence lines (20 cm) with a length of 79 meters were. (Figure 3)

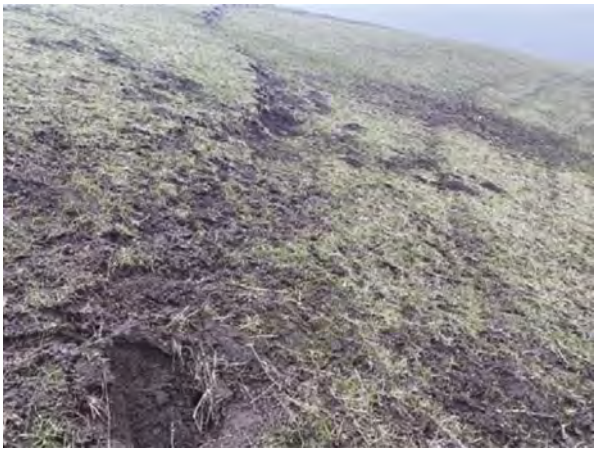

Figure 3. Line of subsidence on the surface of a landslide slope.

Also, as a result of the research of subsidence, we obtained averaged following data. Similar researches were carried out by the open joint-stock company "KYRGYZGIIZ" Osh branch [Mombekov, 2017], the results of which are shown in Figure 4.

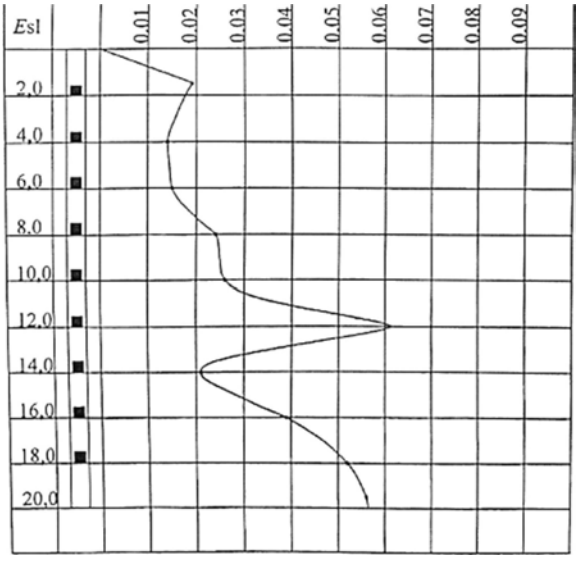

Figure 4. Graph of change in subsidence values depending on the depth of occurrence.

4 CONCLUSIONS

The obtained indicators of physical and mechanical properties are within the normal range, except for porosity. We can notice a high porosity, which reaches up to 45 As can be seen in Figure 4, the subsidence index increases with depth and shows a maximum subsidence value of 0.06 mm at depth. According to the results of the study by vertical electrical sounding, soils of semi-solid loam, moist loam and loam with gravel inclusions were identified. Note that up to 25 meters of depth, the corrosive activity is both low and medium, and the electrical resistivity varies from decreases from 120 to 10 Ohm-m. Taking into account the data obtained, it is necessary to carry out a number of measures for the geomechanical assessment of slope stability taking into account various factors. On the basis of a visual research, lines of slope subsidence were identified, which can serve as manifestations of landslide processes.

Development of innovative designs of drainage pipes that increase their stability in difficult geotechnical conditions

F.G. Gabibov
Azerbaijan Research Institute of Construction and Architecture, Baku, Azerbaijan

H.B. Salayeva
Azerbaijan University of Architecture and Civil Engineering, Baku, Azerbaijan

ABSTRACT: Studies of drainage pipes with different cross-sections have been carried out. Designs of drainage pipes with cross sections constructed using cycloid shapes have been developed. Analytical and model studies have shown increased stability of the arches of these pipes. The latter makes it possible to achieve a sharp reduction in the risk of loss of stability of drainage pipes under complex static, seismic and dynamic loads.

1 INTRODUCTION

Application in the practice of industrial, urban, transport and hydraulic engineering horizontal tubular drains are a combination of drainage pipes with loose filter sprinkles. The structural forms of tubular drains and their main elements are determined by the hydrogeological and hydrochemical features of the drained area, and also depend on the layout of the protected structures, their purpose and conditions of work. Ceramic, asbestos cement, polymer, concrete and reinforced concrete pipes are used as drainage pipes. The studies of Tulaev (1980), Abramov, Degtyarev & Korinchenko (1976), Storozhuk (1987), Razumov (1988), Gabibov & Salaeva (2022 a,b) and others are devoted to the constructions of horizontal tubular drainage. The monographs of Prevo (1964), Babin, Bykov & Volokhov (1979), Vinogradov (1980), Borodavkin & Sinyukov (1984), Dimov & E.M.Bogushevskaya (2010) are devoted to the calculation of horizontal pipeline (including closed drainage).] and others. Many computer programs have been developed to calculate horizontal pipelines Awoshika & Tokano (1972), Trautman & O'Rourke (1985). Currently, a very urgent task for engineers is to identify the most stable cross-sections of horizontal drainage pipes, which are often laid in difficult ground conditions.

2 INVESTIGATION OF NATURAL AND ARCHITECTURAL ANALOGIES TO IDENTIFY THE MOST STABLE DRAINAGE PIPE SECTIONS

To identify the most rational and stable vaults for drainage and collector pipes, it is undoubtedly useful to use natural analogies found in mining and underground construction, as well as analogies from the experience of designing and constructing vaults, domes and arches of famous architectural structures. In mining and underground construction, one of the costly items is fixing the arch of the workings to prevent its collapse. In order to reduce the material costs associated with carrying out this kind of work, various forms of workings were proposed at different times, ensuring the formation of a "natural balance" vault.

Thus, in the work of Stajevsky (1986), the results of field and experimental studies of the stability of underground workings, depending on the shape of their cross-section, are presented. It has been established that workings with a cross-section close in shape to a triangle and with walls deviated from the vertical by an angle $\alpha \leq 15 \div 30^{\circ}$ have their own high load-bearing capacity, and if necessary, they require insignificant costs to strengthen them.

DOI: 10.1201/9781003299127-50

A significant increase in the strength of soils and rocks in the vicinity of the triangular section is due to the fact that in the zones adjacent to the apex of the triangle, the vertical and horizontal stress components reach significant values that have very close numerical values (the effect of all-round compression).

Protodyakonov (1931) notes: "Based on observations of old abandoned drifts, the fastening of which has long rotted and has not been renewed, and over which, with the appropriate lateral rocks, a natural vault is formed, which holds for years and decades without further fixing, it was decided to achieve directly obtaining the same vault." Further in the work it is noted: "... the drifts have the form of a very high arch ..." and "... can stand for many years without repair."

Kilesso (1983) cites the fact that there are triangular drifts, which are without any repairs from the IV century BC.

To the conclusion that the production cross section close to the triangular are the most optimal for large depths, based on field data and results of calculations, came and the authors Baryshnikov, Mashukov & Pirlya (1982). Figure 1 shows the arches of natural equilibrium.

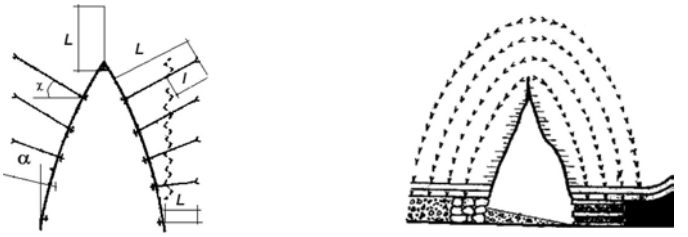

Figure 1. Vaults of natural equilibrium: *a)* – a vault obtained experimentally; *b)* – a vault in an abandoned tunnel.

The history of the development of arched structures in the general history of construction reflects the process of changing the relationship between the growing material and cultural needs of people and the growing possibilities of meeting these needs.

The arch as a load-bearing structure, simultaneously perceiving and transmitting the load, has brought its unique charm to our days through millennia. As Buettner & Hampe (1983) note: "It was already known to the architects of antiquity that if a stone beam was given an arched shape, then it acquires new bearing properties that can significantly increase the overlapped span with the same building material."

Torroja (1961) gives the following characteristic of the arch as a bearing element of a building structure: "From the point of view of stress distribution, the arch is the biggest find in the history of classical architecture. Even today, it has not lost its significance, although humanity has been getting used to the idea for quite a long time that it is the arch that is the element that increases the strength of the structure."

In the era of ancient Greek civilization, "false arches" were mostly erected. The most famous and oldest arched structures are the gateway arch and the arched vault, preserved from the Mycenaean culture. We find these curved systems with a continuous arched line of protruding cantilever elements in almost all ancient cultures.

In numerous works on the history of construction equipment by scientists of the past and modern specialists, the evolution of arched structures is described in detail. Adler (1926) points out that "even before the appearance of arched structures in ancient Greece, they were already known to the Etruscans living in the territory later conquered by Ancient Rome. Therefore, it is the Etruscan arches that can be considered the forerunners of Roman arches and vaults."

The desire of the masters of Gothic cathedrals to reduce the mass of structures and preserve the load-bearing capacity of arched structures led to the creation of giant lattice arched loops (Figure 2). In the arched loops obtained by medieval architects, who at that time solved not only artistic but also design problems, empirically, in vertically interacting paired arches, elements of modern reloid structures are viewed.

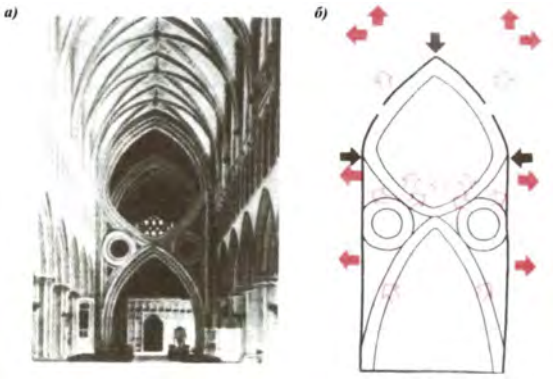

Figure 2. Reinforced arched hinges of the Cathedral in Wales (Great Britain), the end of the XII century: *a)* – type of arched hinges of the cathedral; *b)* – the scheme of the arched loop.

3 DEVELOPMENT OF DRAINAGE PIPES WITH ARCHES OF INCREASED STABILITY

The design of the drainage pipe (Figure 3) in cross-section in the form of a Reulot triangle, which has a bottom part 1 and side parts 2, has been developed. There is a perforation 3 along the entire surface of the drainage pipe. One of the corners 4 of the cross-section of the pipe is located in its upper consolidated part. Ground water passing through the protective drainage sprinkling, through the perforation of the bottom 1 and side parts 2 of the drainage pipe, enters its inner cavity and flows to the collector along a given slope. Compared to pipes with a circular cross-section, the considered design has higher indicators of stability, strength and water absorption capacity Gabibov, Habibova & Hasanov (2017).

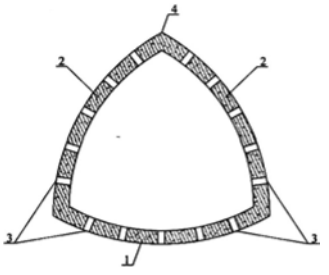

Figure 3. Drainage pipe with a peppered cross section in the form of a Reulot riangle with an angular arch: 1 – bottom part of the pipe; 2 – side parts of the pipe; 3 – perforation; 4 – upper arch corner of the pipe.

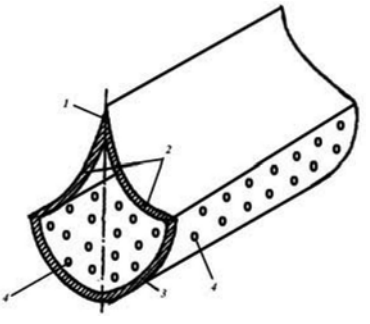

Figure 4. A drainage pipe with a clapboard formed by the intersection of hyperbolas; 1 – canopy; 2 – hyperbolas; 3 – semicircular lower part of the pipe; 4 – perforation.

Model studies Gabibov, Bogomolov & Salaeva (2022) show that the greatest stability is observed in the development with a vault in the form of half an astroid. A new design has been developed (Figure 4) of the drainage pipe, in which the arch 1 with intersecting hyperbolas 2 practically corresponds to half of the astroid. At the same time, in the lower semicircular part 3 of the pipe section, due to perforation 4, during the period of elevated groundwater level, pressure micro-streams will occur, which will erode the formed silty deposits.

4 CONCLUSIONS

1. Natural and architectural analogies have shown that triangular and arched arches are the most stable;
2. A new design of a drainage pipe with a cross-section in the form of a Reulot triangle with an angular arch has been developed, relating to cycloidal structures and increased stability;
3. Based on model studies, it was revealed that the arches in the form of half of the astroid are the most stable, in this regard, a new design of a drainage pipe with a vault in the form of intersecting hyperbolas has been developed, which practically corresponds to half of the astroid.

Dangerous geological processes and reasons of the development of landslides. (on the example of the landslides of the Zarafshan oasis, Uzbekistan)

F.A. Ikramov & M.M. Yakubov
Samarkand State Architectural and Civil Engineering Institute, Samarkand, Uzbekistan

ABSTRACT: Violation of the stability of the massifs, dangerous geological processes (land-slides, land-slips, subsidence, suffusion, karst) are widely developed in the mountain and foot-hill areas (Urgut) of the Zarafshan oasis, Republic of Uzbekistan. Especially, in recent years, due to abundant of atmospheric precipitation earthquakes and active human intervention in the environment create emergency situations and are accompanied by large material losses, often by human losses.

The main reason of the development and descent of landslides is the over moistening of loan at the contact with bedrock surface and groundwaters, as well as, the formation of land-slides caused by seismic effects. At present, more then 20 landslide hazardous and 60 potential landslide plots are under observation. In the zone of acting landslides, there are 57 children's recreation camps within the mountains and foothills areas.

Ongoing permanent observations for especially dangerous five landslide, located in the Urgut district (the villages: Sayguss, the Guss Upper, the Guss Lower, the Aktash Upper, the Aktash Lower, the Khodjaabdal village) of the Samarkand region of Uzbekistan. The above – mentioned landslides were activated by the landslide that came about and were provoked by a forced explosion on November 13, 1994. The results of long – term observations testify, that heavy rainfall and as wall as high seismic activity have a huge effect on the formation of land-slides. Landslides are most intensively developed along high-way. This makes it clear, that developing of mountainous and foothill areas without pre-liminary studies to determine the degree of stability of the slopes and the implementation of protective recommendations becomes one of the main factors in the formation of land-slides.

1 INTRODUCTION

1.1 *Dangerous geological process (as landslides)*

There are wide develops in mountain and plain areas in the Republic of Uzbekistan. Their displacing near the populated stations, different national economic objects now ever makes extraordinary situation, and it is accompanies by huge financial waits, and frequently by human loses.

Handstand's phenomena and theirs study with registration of the seismic dangerousness of our region id being very important. For solving global problems, which is arises in the result of landslides, it is necessary right value of the development reasons of landslides and effective elaboration of the engineering methods of protection, and also projecting construction against landslides.

The practice which is direct against landslides testifies with most obvious about the reasons of mistaken value and methods of the solving facts which is connected natural phenomena, often just with fallings out from the field of vision of engineers.

DOI: 10.1201/9781003299127-51

2 CONFORMITY OF DEVELOPMENT LANDSLIDES OF THE GEOLOGICAL PROCESS

Wide development and originality of displaying form of landslides and other dangerous forms of the geological process in the mountain and plain areas creates definitizes difficulties on the mastering of the territory. Mostly intensive they develop in last 2-3 thousands years, that is connected not just with intensive influence of the natural landslides factors, but with active interference of human in natural environment.

Regional conformity of displacing of landslides as in previous years, was formed for huge landslides by geological structural peculiarities of the lot, and for not so dup drifts, smelting and collapses, on the slopes of the motor-ways characters of the dropping out of precipitations.

One of the factors which is determines intensity of development and displacing landslides are atmosphere precipitations which are promotes humidity of the soil on the slopes, and increases debits of the ground water. A whole development of dangerous geological process in connected with wide spreading on the slopes of loess rock's, is under humidity characterizes with instant distorting with transitional structure in the liquid condition.

3 BASIC INFORMATION ABOUT INVSETIGATION OF THE LANDSLIDES

At present there are 20 landslides is being under the observation, and 60 potentially landslides lots. In the zone of the active landslides there are 57 children camps in the bound of the mountains and plain areas.

Nowadays we are keeping the observation of the five particularly dangerous landslides, which is in the Urgut district (of the village Sayguss, Upper-Guss, lower-Guss, upper-Actash, lower-Actash, Khodjabdal) of the Samarkand region of the Republic of Uzbekistan. Above mentioned landslide was activated with came down landslide which was provoke by the compulsory explosion on the 13th of November 1994.

3.1 *Sayguss landslide*

Landslide area is situate on the right bank of the middle flow of river Sayguss, which is timed to the diluvial slope with the steepness up to 30 degree, from the Northern- Western exposition. The height of the slope is 150-200 meter, the shape of slop is in the plan of building, in the profile is buildingly-concaved. The leigh of dislocation zone is 3 000 m2, breadth is 12 000 m, area of zone is 36 000 m2, development zone of the landslides is 8 000 m2.

In the lower part, slope is pass to the alluvial terrace, which is follows along both sides of the basic river-beds, 80-110 m wide. In the upper part, slope pass in to the gently watershed. On the character of breaking up the slope conditionally may devoid on to two parts.

The erosional cut from 1 to 3 m, is services as a natural board, between them.

Southern part of the slope is smoothed, with separate bares of the carbonated rocks. In the geological structure of the slope there are limestones of the Devonian age, which is covered from surface with the scaffolding loamy soil, with capacity in the upper part to two meter in the middle part to the 8 m and in the lower part 5 m.

3.2 *Landslide actash (upper)*

The lot is situated on the left side of Actashsay. In the geomorphological attitude the lot is situated on the diluvial slope with the steepness of 30-35 degree with height to 200 meter from the Northern-Western exposition.

At the limits of the landslides slope in the relief of the spreading under of rocks is clean stands out two hollow-figurative drops, which is divided by the doomily figurative block, capacity of the cover on the domes does not rise to 2 meters.

The 1st drop was noted in the Eastern part of the lot, and in the upper part of the slope, which is limit by the wall of frustration of the landslides, there is a spring which is wedge in the center. The spring was timed to the zone of the break. The breadth of the hollow on the lot to 40-50 meters.

The 2nd drop in the relief of the under spreading rock there is a control line in the upper part of the slope of the landslide crack, which is displayed after the compulsory explosion. Lower on the slope there is an observation of the drop. In the middle part of the slope there is an observation of the supply with watered crash, which is under the control by regime springs. Breadth of the zone dropping zone to 190 m.

3.3 *Guss landslide*

Landslide area is situated on the Northern slope of mountain range of the Chakil-Kaliyan and joins to the Guss. The buildings of the villages are locates on the gently-wavy surface of the alluvially-diluvial train on the absolute note from 1050 to 1160 meters. The body of the landslides lot-on the note from 1100 to 1250 meter.

Development of the landslides process on the slope is continued and displays more intensive in the rainy period, and still keeps the threat for the dwelling buildings which is under this landslides, of the village Guss.

4 THE RESULTS OF THE ENGEENERIAN -GEOLOGICAL INVESTIGATIONS AND PHYSICS-MECANICAL QUALITY OF THE SOILS LANDSLIDES (MASSIFS) SOLID MASS

As the engineer-geological results show, that the lithology of the locality landslides massifs is very similar. For definition of physics-mechanical qualities of the soils of covered deposits on the lot goes hole, with depth from 1,5 to 5 meter, with the selection of the assay. In the geological construction of the slope hire is limestone of the Devonian age, floored from the surface of the cover of losses with capacity in upper part to 2 meter, in the middle part to 8 meter in the lower (part) to 5 m (picture number 1).

Loamy soils by their structure are easy, middle, dusty of being definition in face metric structure of slope undifferenced. Maintenance of dusty particles with depth gradually increase with 60-62% till 70-75%, maintenance of clayey particles with depth are decrease gradually from 4-8% till 22-23%.

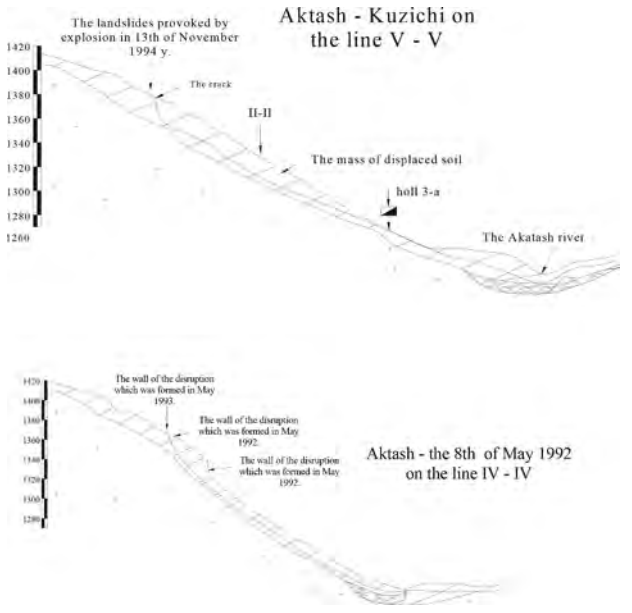

Figure 1. Engineering - geological cuts (rips) of the lots: (upper) Aktash, (Lower) Aktash, Aktash - Kuzichi.

The volume mass of rock at the break part of slope has less meaning 14,1-15,7 kH/m 3, than in natural bed 15,7-16,3% kH/m3, it testifies about some its loosen by moving of landslides. The porous of landslide soil is equally 48,7-52%. The coefficient of filter of break soil consist 0,026-0,06 m/day, with differ of feebly water stability at the first minute. After water saturation it soaks till 70% mass of soil. The soils of unbreak slope have porous 48,3-50,2% at 5 minute wets only 5% mass of soil.

Underground waters at the research lot (Saygus) everywhere accustomed to a contact of covered loamy soils with root brads. The depth of bed underground waters is changes and depends from relief's roof root's brads. At the down part of slope in the place of projection timely water flowing is wedged in spring to 0,001-0,5 l/sec.

Specific coupling under the natural humidity makes up 0,014-0,065 Mpa under the angle of the inside friction 27-32 degree, under the water-saturation - specific coupling 0,0015-0,22 Mpa, and angle of the inner (inside) friction 21-25 degree.

5 REASONS AND CONFORMITY OF DISPLAING OF THE LANDSLIDES

Peculiarity and places of displacing of the dangerous geological process is determines by the geological-tectonically structure of the region's area.

The basic reason of development and getting down of the landslides is being the presence of over humidity of the loamy soil on the contact with rooted rocks, surfaced and underground water, and also formation of the landslides, which was evoke by the seismic action, provoked by explosion.

The surface of the side served for the irrigation of the wooden-road-metal of deposit on contact with over humidity of the loamy soil.

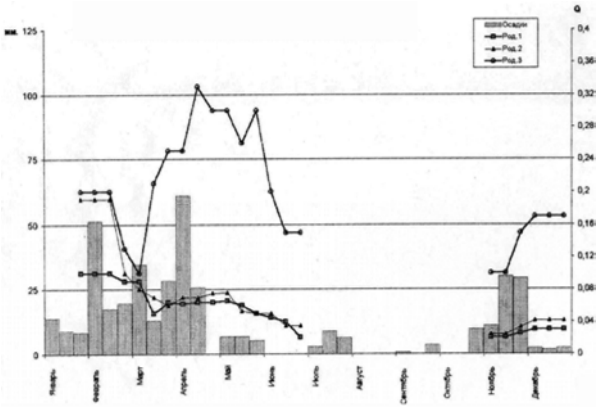

Figure 2. Graphic of subordination of springs (courses) from the amount of the atmospheric – precipitations (Lower) Aktrash 1998.

The formation and similar of landslides coming at the period of rains at the ending of months February and May. At the picture (2,3) derived graphs of dependence of amount falling precipitations up to months and water's expenditure of spring (the landslide Aktash). As you see from graphs (pic 4) the amount of landslides and their similar are confirming by facts of Samarkand meteoritical station. Last year at the first quartier falling precipitations consisted 146,1 and 173 mm.

At the landslides lots putted 30 dephonometers and at the main landslide crack putted 12 tensiometers. The value of displacement from tensiometers consisted about 9-62 mm.

At the result of observing topo geodesic repress, at the landslides gradually shows the formation mound of getting out at the down part of zone arty crack. Negative meaning of

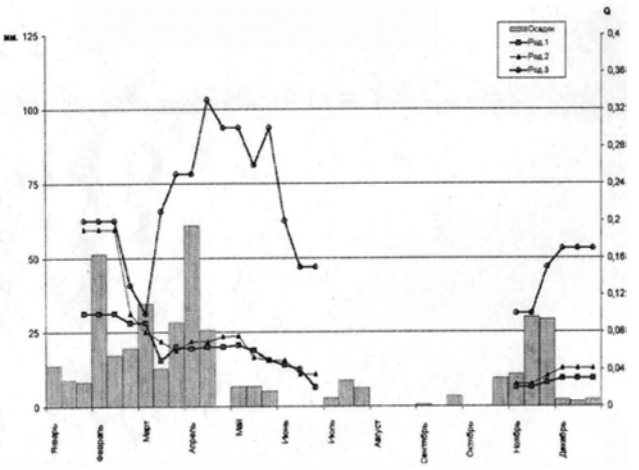

Figure 3. Graphic of subordination of springs (courses) from the amount of the atmospheric – precipitations (Lower) Aktrash 1999.

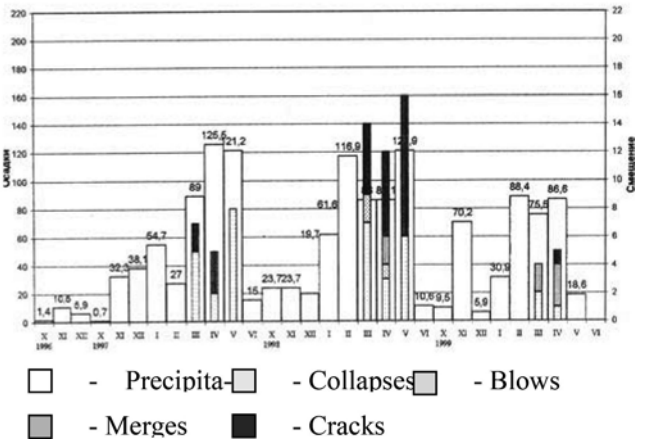

Figure 4. Graphic of subordination of the amount of landslides from the amount of atmospheric – precipitations. Samarkand Region meteorological station of the Yangiariq.

vertical reaper's moving able to evidence about the possible forming of the crack on the depth and gradually precipitate of the surface.

6 CONCLUSIONS AND ADOPTED ENGINEERING DECISIONS

The results of long observing tells, that big influence on appear of landslides gives economical activity of human. Analyze of landslides appearing tells that more 50% registrational landslides was appear by influence of building and exploitation different buildings.

More intensive landslides are develop along of auto roads. It gives notion, that mastering of mountainous and around mountainous districts without preliminary investigations by definition of degree of stability of the slopes and execution of the protection recommendations, is being one of the main factors of formation of the landslides.

At the same time, high elevated seismic activity of exploratory zone, is aggravates the dangerous of the catastrophic consequences from their influence.

On the basis of results which was spend on research works. There is an establishment four particularly dangerous landslides blocks, the capacity of the displacement mass which is makes up from 30 thousand m3 to 250 thousand m3.

In the case of displacement of the whole landslides massif the river-bed of the Say can be covered on the height 6-7 m with formation of the flooding zone on the horizon 1230 m. in the dangerous zone.

There are 44 economy (farms) of the landslides dangerous. For the dangerous landslides liquidation was recommended:

1. Unloading the unsteady mass of the slope, with the following planning and porching - terracered where are the landslides develops- the capacity of flow 150-300 thousand m3 with the straightforward direction on the house-construction.
2. After completion of the unloading in the middle part of the slope for it interception of the subterranean waters on the contact of the soils and clay it is necessary to drain ditch and restore of the exists drain-pine as a natural drains.
3. There are recommendation for construction of the water-fall of extinguished walls, the regulate dam for challenge of the landslides mass from the settlement under the formation of the huge landslides-streams.

Semi experimental Thermo-Hydro-Mechanical model for maximum shear modulus of unsaturated soils

Shaya Banar
Ph. D. Candidate, Department of Civil Engineering, Sharif University of Technology, Tehran, Iran

Fardin Jafarzadeh
Associate Professor, Sharif University of Technology & President of Iranian Geotechnical Society, Tehran, Iran

ABSTRACT: Soils in geotechnical engineering are in different mechanical and environmental conditions. What is very important in evaluating unsaturated soils is the study of environmental processes that occur in the soil. Due to the fact that soils are exposed to different climatic conditions in different seasons, its temperature and matrix suction are variable. Also, the study of soil stiffness behavior in dynamic conditions is one of its important parts. Therefore, in this paper, an attempt is made to provide a semi-experimental model for evaluating the maximum shear modulus of unsaturated soils under different temperatures and mechanical conditions, using Thermo-Hydro- Mechanical principles and various laboratory results. Laboratory results are used to validate the proposed model.

1 INTRODUCTION

Shear modulus is a key parameter to evaluate the dynamic response of geotechnical structures under various loading (i.e. machine vibration and earthquakes). Near-surface soils can be placed in different climate conditions and therefore these soils can be placed in different hydraulic and temperature conditions. Soils in different seasons behave differently due to the changes in matric suction or temperature. One of the influencing parameters on the value of maximum shear modulus (G_{max}) of unsaturated soils is matrix suction and net normal stress. For this reason, the evaluation of the maximum shear modulus in Thermo-Hydro-Mechanical (THM) conditions becomes important.

The value of the maximum shear modulus represents the elastic behavior of the soil in small strains and the effect of sliding between the soil particles is negligible, and its deformation occurs due to the elastic behavior of the soil (Hardin & Kalinski 2005). One of the important parameters for evaluating the shear modulus is the amount of shear strain level. For measuring the shear modulus different laboratory and in-situ methods are used. Most of the maximum shear modulus measurements have been done by researchers using laboratory methods such as bender element, resonant column or triaxial tests that can be conducted in small strains.

Initial studies (Hardin 1978) show that effective stress and pre-consolidation stress are principle parameters on shear modulus in saturated and dry soils (Equation 1). In the next step, researchers' studies on unsaturated soils show that the matric suction and net normal stress have a significant effect on the maximum shear modulus. Considering that measuring the maximum shear modulus in unsaturated soils requires advanced laboratory equipment. In addition, there is a long time (a couple of days or weeks) to reach equilibrium for unsaturated soils, so various researchers have given empirical and semi-empirical relationships to evaluate the shear modulus.

DOI: 10.1201/9781003299127-52

$$G_{\max} = AP_a\left(\frac{P'_c}{P'}\right)^k\left(\frac{P'}{P_a}\right)^n \quad (1)$$

where A and n = stress-dependency fitting parameters, vary for different soils; P'_c = mean pre-consolidation stress, P' = mean effective stress; P_a = atmospheric press.; k = hardening parameter.

In the last decade, more researchers try to understand the effect of temperature on soil behavior. By continuing the studies on the maximum shear modulus of unsaturated soils, the researchers found that temperature has a significant effect on the maximum shear modulus (Vahedifard et al. 2021, Zhou et al. 2015). So far, very limited studies have been done to measure the maximum shear modulus of unsaturated soils in non-isothermal conditions. But these results show that temperature has a significant effect on the shear modulus. In fact, with the increase in temperature, the shear modulus of the soil has decreased, which depends on various factors that will be discussed below.

For this reason, this research tries to evaluate the effect of THM factors on the shear modulus by providing a comprehensive model. In this model, the effect of various factors such as effective stress, pre-consolidation stress, degree of saturation, net normal stress, and temperature on the shear modulus has been seen. Finally, the evaluated value of the maximum shear modulus is compared with the results available in the literature for validation.

2 BACKGROUND

The maximum shear modulus, G_{max}; is considered in shear strains smaller than $\gamma < 10^{-5}$. Considering the importance of shear modulus evaluation, researchers have presented different experimental relationships in different conditions. In the first step (Hardin 1978) evaluated the effect of factors such as soil porosity, stress history, plastic index, and effective stress. In the next step, other researchers (Hardin & Black 1968, Vucetic & Dobry 1991) presented several relationships to evaluate the shear modulus in dry and saturated conditions.

Soil behaves differently in environmental and seasonal conditions. For this reason, researchers investigated the shear modulus of unsaturated soils in the next step. In these studies, the degree of saturation (or matric suction) and net normal stress were identified as parameters affecting the dynamic behavior of the soil (Banar et al. 2019, Mancuso et al. 2002, Inci et al. 2003, Sawangsuriya et al. 2009). Also, various researchers have tried to provide an experimental model to determine the shear modulus (Khosravi & McCartney 2012, Ghayoomi et al. 2017). In each of these models, the degree of saturation and net normal stress were considered important soil components in hydraulic conditions. Also, effective soil stress is considered the main parameter of soil mechanical behavior. In addition, all these models are suitable for isothermal conditions, and they never consider the effect of temperature on their models. Uchaipichat & Khalili 2009 confirms that temperature affects pre-consolidation stress. As the temperature increases, the pre-consolidation stress decreases (Salager et al. 2008). Various studies in this field show that temperature affects the volume change behavior of soil. It is evident that the tendency of highly overconsolidated soils to expand and normally consolidated to contract, is common for both saturated and partially saturated soils. Temperature effects on compressibility indexes are investigated, where no specific trend is identified in saturated (Campanella & Mitchell 1968, Di Donna & Laloui 2015) and unsaturated conditions (Uchaipichat & Khalili 2009, Coccia & McCartney 2016).

3 PROPOSED MODEL

In this study, an attempt is made to evaluate the maximum shear modulus value of silty soil in different Thermo-Hydro-Mechanical (THM) conditions by presenting a semi-experimental model. There are limited studies to understand the G_{max} in different THM conditions especially for unsaturated soils. In this semi-empirical model, the effect of three factors of temperature,

degree of saturation and mechanical stress loading on the maximum shear modulus is obtained. In the following, the presented model is validated using the results in previous studies.

3.1 *Semi-empirical model in Thermo-Hydro-Mechanical*

Liu et al (2021) has been proposed a fully coupled constitutive model for the Thermo-Hydro-Mechanical behavior of unsaturated soils. In this model, they consider three constitutive variables: 1- Bishop's effective stress (Equation 2) 2- Modified suction (Equation 3) 3- Temperature (T).

Liu et al (2021) employed four yield surfaces to govern the plastic behavior in Thermo-Hydro -Mechanical conditions: 1-Loading surface (LS) 2- Temperature Surface (TS) 3- Suction Increase (SI) 4- Suction Decrease (SD). LS yield surface is the extension of the Loading collapse (LC) yield line in the Hydro-Mechanical (HM) model of Wheeler et al. (2003) to non-isothermal conditions. Also, thermal contraction deformation of normally consolidated soils and lightly over-consolidated soils are attributed to LS yield surface. The thermal expansion corresponds to an elastic behavior while the thermal contraction corresponds to an elastoplastic behavior. Also, the transition temperature between thermal expansion and contraction increases with an increasing consolidation ratio. Thus, the transition temperature can be defined as the yield temperature. The third and fourth yield surfaces, suction increase/decrease are the extensions of SI/SD yield lines in the HM model of Wheeler et al. (2003) to non-isothermal conditions.

$$\sigma_{ij}^{*} = (\bar{\sigma}_{ij} - u_a) + s \times S_{r.} \tag{2}$$

$$s^{*} = ns \tag{3}$$

where $\overline{\sigma}_{ij}$= total stress tensor, u_a= pore air pressure, s=matric suction, S_r= degree of saturation, n=porosity.

Liu et al (2021) have offered that the hardening of the LS is jointly controlled by the sum of the hardening caused by yielding on the LS itself and the couple hardening produced by yielding on the TS. Also, and hardening in LS controlled by double-hardening mechanism for unsaturated soil introduced by wheeler et al. (2003) which is related to the yielding on SI/SD (Equation 4). Therefore, the hardening of the LS can be presented as follows:

$$\frac{dp_c}{P_c} = \frac{1}{\lambda - \kappa}(d\varepsilon_{VL}^{p} + d\varepsilon_{VT}^{p}) + k_1 \frac{ds_r^{p}}{\lambda_s - \kappa_s} \tag{4}$$

where λ_s= slope of the primary drying/wetting lines in the S_r-*ln S**, κ_s= slope of the scanning lines in the S_r-*ln S** plane, k_1= control the coupled movement of the LS and TS when yielding on only SI, dS_r^{p} = Plastic degree of saturation increment, $d\varepsilon_{vl}^{p}$ = plastic strain increment by mechanical loading, $d\varepsilon_{vt}^{p}$= Thermal plastic strain when yielding occurred on the TS during the heating process, v = Specific volume, P_c = Preconsolidation stress at room temperature, λ = Slope of normally consolidated line in the v-*lnP* plane, and κ= Slope of swelling curve in the v-*lnP* plane.

To drive the hardening Equation 4 can be integrated from the initial conditions into general values of these parameters (Equation 5). Then both sides can be divided by P' to yield a definition that was used in Hardin's Equation (Equation 6). Then Equation 6 directly insert into Equation 1 to define the general formulation of G_{max} in different THM conditions. Equation 7 can be split into three dimensionless terms: 1- Represent the hardening because of mechanical loading (first bracket) 2- Represent the thermal softening (second bracket) 3- Represent the hardening because of changes in saturation (third bracket). *k, k', k''* are the hardening fitting parameters that are related to the mechanical, hydraulic, and thermal conditions respectively.

$$\ln\left(\frac{dp_c^{*}}{P_c^{*}}\right) = \frac{\Delta e_L^{P} + \Delta e_T^{P}}{\lambda - \kappa} + \frac{k_1 \Delta s_r}{\lambda_s - \kappa_s} \tag{5}$$

$$\frac{P_c^*}{P'} = \frac{P_{c_0}^*}{P'} \exp\left(\frac{\Delta e_L^P}{\lambda - \kappa}\right) \exp\left(\frac{\Delta e_T^P}{\lambda - \kappa}\right) \exp\left(\frac{k_1 \Delta s_r}{\lambda_s - \kappa_s}\right) \tag{6}$$

$$G_{\max} = AP_a \left(\left[\frac{P_{c_0}^*}{P_n} \exp\left(\frac{\Delta e_L^P}{\lambda - \kappa}\right) \right]^k \times \left[\exp\left(\frac{\Delta e_T^P}{\lambda - \kappa}\right) \right]^{k'} \times \left[\frac{P_n}{P'} \exp\left(\frac{k_1 \Delta s_r}{\lambda_s - \kappa_s}\right) \right]^{k''} \right) \left(\frac{P'}{P_a}\right)^n \tag{7}$$

4 VALIDATION AGAINST EXPERIMENTALLY MEASURED DATA

4.1 *Soil type and specimen preparation*

Zhou et al. 2015 used the Completely Decomposed Tuff (CDT) to measure shear modulus at various shear strains, matric suction, and temperature. For the present study, the result of the small strain shear modulus of CDT soil is used to verify the model that is proposed. The index tests of this soil are according to Table 1 (Zhou et al. 2015). The Soil-Water Retention Curve (SWRC) at 20°C of this soil is shown in Figure 1. After the soil is statically compacted, its initial suction value is approximately equal to 95 kPa. Then this sample reaches 1, 150, and 300 kPa respectively in different hydraulic paths. Also, these samples reach equilibrium at different temperatures of 20°C and 60 °C.

Finally, after the soil sample reaches equilibrium, dynamic loading is performed on it using a modified triaxial test that has the ability to control matrix suction and temperature, and the value of the shear modulus in different strains is obtained. What is used in the current research is the results of the maximum shear modulus which is in the strain range of 0.003 %, which is considered in the range of small strains.

Table 1. Index tests of CDT soil.

Index test	Measured value
Standard compaction tests	
Max Dry density: kg/m^3	1760
Optimum water content: %	16.3
Grain size distribution:	
Percentage of sand: %	24
Percentage of silt: %	72
Percentage of clay: %	4
Specific gravity	2.73
Atterberg limits:	
Liquid limit: %	43
Plastic limit: %	29
Plasticity index: %	14

4.2 *Model parameters*

A parametric evaluation was performed to highlight the behavior of the model during the THM condition. Soil specimen had the following initial conditions: P_n=100 kPa, e_0 =0.573, s_0 =95 kPa, P'= 100 kPa, λ_s=0.254, κ_s=0.0251, λ=0.055, κ=0.005, and P'_c= 500 kPa. The value of P_n does not change during the tests. The changes in P' define based on the Bishop effective stress (Equation 2).

Soil matric suction changes from the initial condition (i.e. 95 kPa) to 1, 150, and 300 kPa. For measuring the differences in the degree of saturation in different hydraulic path use the SWRC curve. Differences for T=60 °C are similar to the T= 20°C. There is little difference between the degree of saturation in different temperatures (Uchaipichat & Khalili 2009). Also, in the non-isothermal condition, the value of λ and κ are constant and the changes of these parameters due

to the temperature effect are negligible. For measuring the changes of Δe_t^p result of normal isotropic compression test has been used. Also, for measuring the Δe_t^p the data of the non-isothermal normal isotropic compression test has been used (Uchaipichat & Khalili 2009).

Figure 2 provide a comparison between measured G_{max} value and those predicted using the Thermo-Hydro-Mechanical shear modulus in this study (i.e. Equation 7). The fitting parameters A, n, K, K', K'', and K_1 provided the most reasonable estimates and are summarized in Table 2 for the CDT soil.

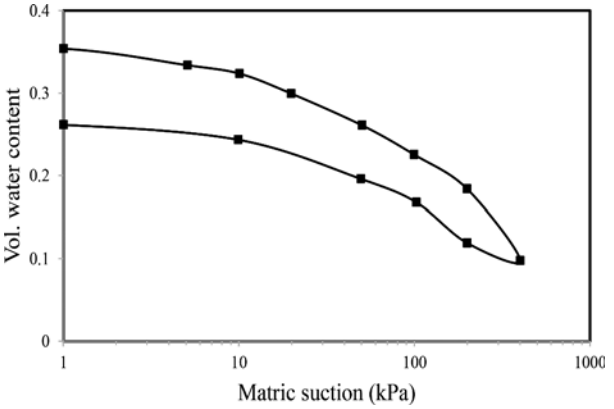

Figure 1. Soil-Water Retention Curve of CDT soil at 20°C (Zhou et al. 2015).

Table 2. Fitting parameters value.

Fitting parameters	Value	
	T=20°C	T=60°C
A	0.9	0.9
n	1.5	1.4
k	2.9	2.85
k'	0.2	0.1
k''	0.1	0.15
k_1	0.3	0.5

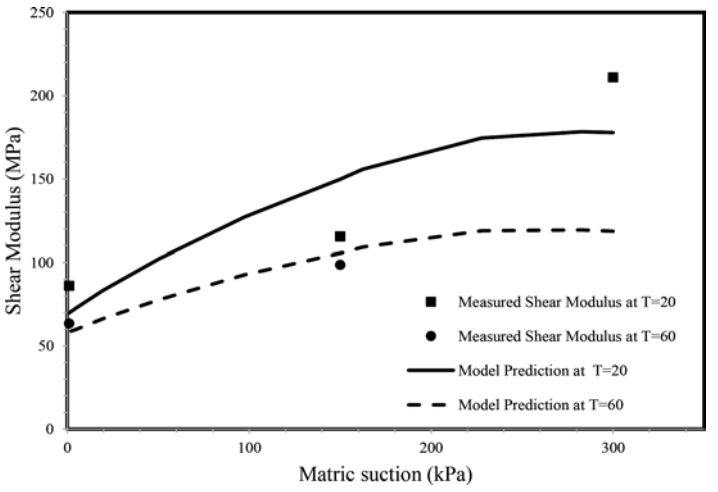

Figure 2. Comparison between the measured value and model prediction.

5 CONCLUSION

A new model was presented to represent the effect of Thermo-Hydro-Mechanical conditions on maximum shear modulus (G_{max}). Most of the previous models were in the isothermal condition and the effect of temperature was not considered. The effect of various parameters like net normal stress, degree of saturation, pre-consolidation pressure, effective stress, and temperature are considered in this model. The model was found to fit the trends in the available G_{max} data in the literature. There are limited studies to measure the G_{max} of soils at various suction and temperature, so further experimental tests are required to validate the proposed model for different conditions.

Liquefaction potential in the upper reaches of River Ravi, Pakistan

Sohail Kibria
Head R&D, NESPAK, Lahore, Pakistan

Tahir Masood
Managing Director, NESPAK, Lahore, Pakistan

Sadaf Saeed
Principal Engineer, NESPAK, Lahore, Pakistan

ABSTRACT: Pakistan has several regions of seismic activity, having low to high seismic potential. Similarly, a variety of soil deposits exist in the country; some of which are known to have significant liquefaction potential. Liquefaction potential of a certain site is generally a trade-off between the state of denseness of saturated sand deposits and the peak ground acceleration (PGA) at that site. River Ravi flowing through the Punjab province, has its flood plain in the upper Punjab. The soil deposits in its flood plain consist of fine sand with variable silt content (upto to 15%). The PGA in these plains ranges from 0.16 to 0.24g with an average of 0.20g for 475 years return period earthquake having 10% probability of exceedance in 50 years. At an important project site located in the upper reaches of river Ravi, recently loose Sand deposits were encountered up to 10-12m depth below the ground level. Light to moderately heavy structures were planned over the site. The evaluation of free-field liquefaction potential using the Cyclic Stress Approach based on SPT blows (Youd, Seed et al., 2001) with due adjustment for the moment magnitude of 6, indicated sands to be liquefiable up to 12 m depth. The mitigation of liquefaction risk at this site consisted of providing long R.C. drilled shafts (ignoring skin friction in the upper 10 to 12 m zone) under the moderately heavy loads and providing earthen platforms (raising the ground level) under the light structures. A Factor of Safety of 1.1 was taken as the threshold of liquefaction in terms of ratio of the cyclic stress ratio required to cause liquefaction to the one induced by earthquake of average PGA of 0.22g. The project structures stand constructed safely at the site. This paper provides a complete account of the process of evaluation of liquefaction potential and its effective mitigation using simple means. These type of mitigation measures can be adopted for the structures in similar ground and seismic conditions.

1 INTRODUCTION

The project site under discussion lies at India-Pakistan border in the northern Punjab in Pakistan. It is of great religious importance to a particular community of people. The facilities included light to moderately heavy buildings and a 772m long bridge.

The site is located between rivers Chenab and Ravi, about 100 m away from a tributary of Ravi on its right bank. The area is underlain by thick alluvial deposits consisting of clays, silts and sand lain by the Chenab and Ravi rivers, which flow from northern to southern sides of the project area.

2 SEISMIC Z ONATION OF PUNJAB

The Punjab plains are located near the foothills of the Himalayan range, which is seismically very active. The main active tectonic features of the Himalayan range are Main Boundary Thrust (MBT) and Riasi thrust which are passing at the closest distance of about 93 km and 80 km, respectively northeast of the project area. Both these features have potential to generate damaging earthquakes and can cause appreciable ground motion at site.

DOI: 10.1201/9781003299127-53

The part of Punjab Plain, in which the Project site is located, shows low to moderate level of seismicity which is associated with the faulting in the Basement rocks covered by the alluvial deposits.

As per Seismic Zoning Map of Pakistan included in the Revised Seismic Provisions (2007) of Building Code of Pakistan, the project falls in Zone-2B having PGA varying from 0.16 to 0.24g. This Seismic Zoning Map is based on the probabilistic evaluation of tectonic and seismicity data of the region and represents ground motion having 10% probability of exceedance in 50 years (i.e. for a return period of 475 years). Building Code of Pakistan Seismic Provisions (2007) show that the project area falls on the contour value of 0.22g on PGA contour map.

The de-aggregation of the probabilistic seismic hazard analysis for the project area shows that the most critical seismic source is a magnitude 6 earthquake occurring at a distance of 10 km from the site in the Punjab plain. The liquefaction analysis is based on this most critical seismic source.

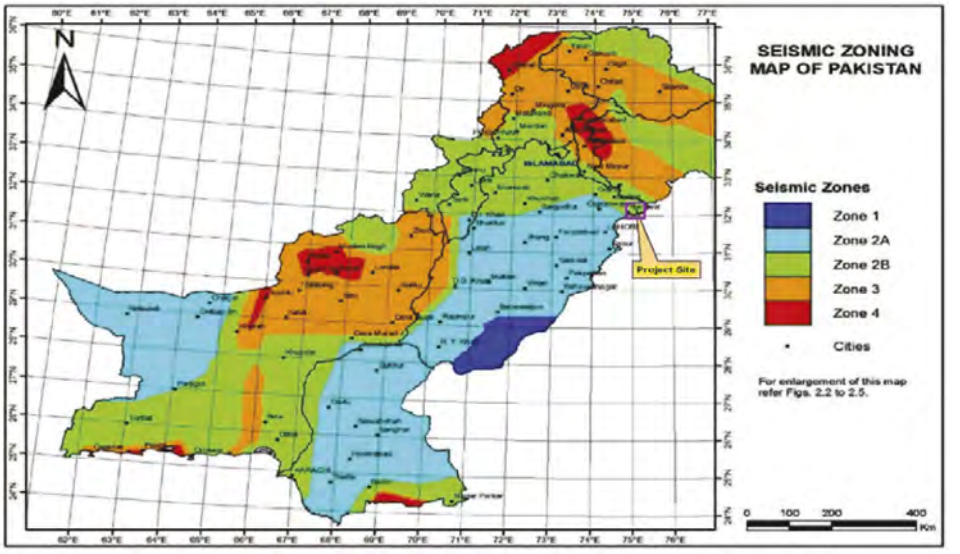

Figure 1. Seismic zoning map of pakistan.

3 GEOTECHNICAL STUDIES AND SITE CONDITIONS

Two (2) boreholes up to a maximum depth of 40 m and four (4) boreholes up to a maximum depth of 50 m below River Bed Level (RBL) were executed by using straight rotary drilling method along the proposed alignment of bridge over river Ravi. In addition, twelve boreholes up to 20m depth were drilled at structural facilities sites. Four boreholes of 10 m depth were also drilled at minor facilities sites.

3.1 *Bridge site*

At bridge site, the on-site soils comprised silty sand/poorly graded sand/poorly graded sand with silt, in very loose to medium-dense state as per SPT-N value were present from river bed level (RBL) to maximum depth of 15 m. This was followed by lean clay/silty clay, in very stiff to hard state as per SPT-N values, measured up to maximum depth of 34 m. This layer was followed by silty sand/poorly graded sand with silt, in dense state from 34 m to maximum investigated depth of 50 m. Groundwater table was encountered in all the boreholes at depth varying from 1.0 to 3.3 m below RBL.

3.2 *Main facilities sites*

At the sites for main facilities, silt/silty sand, in very loose to loose state was present to a depth of 4 m below Natural Surface Level (NSL). Silty sand/poorly graded sand with silt, in loose to

4 SPT-BASED LIQUEFACTION POTENTIAL EVALUATIONS OF SITE

When saturated sand deposits are subjected to earthquake-induced shaking, pore water pressure in the soil progressively builds-up with each loading cycle, which eventually leads to the significant loss of effective shear strength. Total liquefaction is the extreme manifestation of this phenomenon. At the commencement of soil liquefaction, the effective stress in the soil becomes zero and pore water pressure in the soil becomes equal to the initial static effective stress, i.e., the present total stress becomes zero.

Keeping in view the site subsurface conditions, the liquefaction potential of the subsurface strata was determined using Seed's cyclic stress approach based on SPT (Youd et al, 2001,

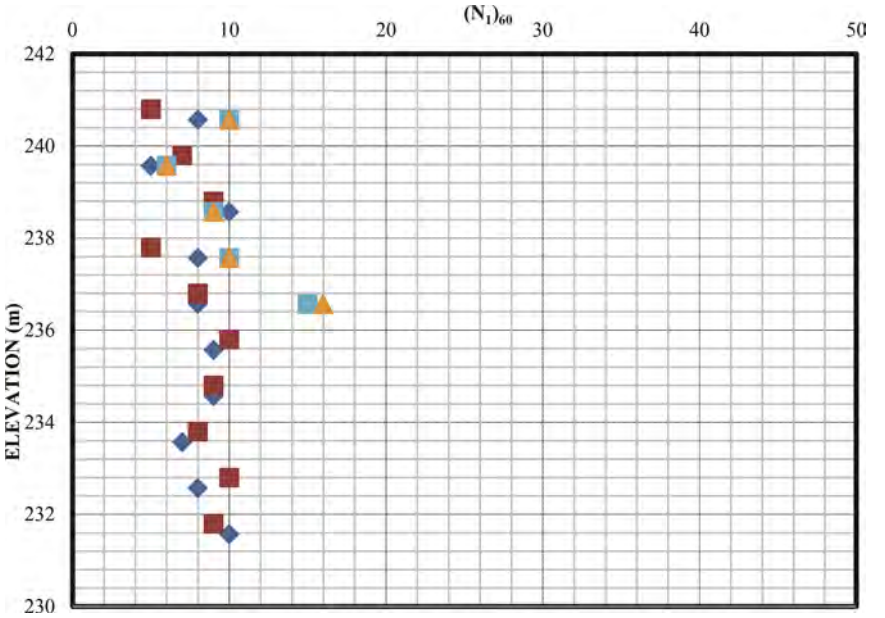

Figure 7. Corrected SPT blows at minor facilities sites.

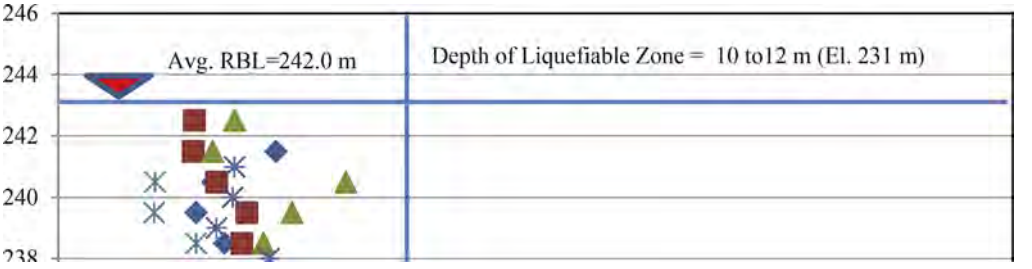

Figure 8. Bridge site – FOS.

Rauch, 1997) for free-field condition. Factor of Safety (FOS) of 1.10 was kept as the acceptance criterion against the risk of liquefaction; FOS being the ratio of cyclic stress required to cause the liquefaction using soil resistance to the cyclic stress ratio induced by earthquake. PGA value of 0.22g has been used in the liquefaction evaluations. Liquefaction analysis have been carried out considering all borehole data for the three categories of structures. The results are shown in Figures 8, 10 and 11.

FOS against liquefaction is defined as $(CRR_{7.5}/CSR).MSF.K_{\sigma}.K_{\alpha}$

$$CSR = \tau_{av}/\boldsymbol{\sigma}'_{v0} = 0.65 r_d [\boldsymbol{\sigma}_{v0}/\boldsymbol{\sigma}'_{v0}][a_{max}/g]$$

$$r_d = 1.0 - 0.00765z \quad \text{for } z \leq 9.15\text{m}$$

$$r_d = 1.174 - 0.0267z \quad \text{for } 9.15\text{m} < z \leq 23\,\text{m}$$

$$CRR_{7.5} = \left[1/\left(34-(N_1)_{60}\right)\right] + \left[(N_1)_{60}/135\right] + \left[50/\left[10\,.\,(N_1)_{60}+45\right]^2\right] - [1/200]$$

$$(N_1)_{60cs} = \alpha + \beta.(N_1)_{60}$$

where
$\alpha = 0$ for FC ≤ 5%
$\alpha = \exp[1.76 - (190/FC^2)]$ for 5% < FC < 35%
$\alpha = 5.0$ for FC ≥ 35%
$\beta = 1.0$ for FC ≤ 5%
$\beta = [0.99 + (FC^{1.5}/1{,}000)]$ for 5% < FC < 35%
$\beta = 1.2$ for FC ≥ 35%
to calculate MSF from M_w, use equation below or Figure 9.

$$MSF = (M_w/7.5)^{-2.56}$$

$$K_\sigma = (\sigma'_{v0}/P_a)^{(f-1)}$$

for relative densities between 40 and 60%, $f = 0.7$–0.8;
for relative densities between 60 and 80%, $f = 0.6$–0.7

$$K_\alpha = \tau_{st}/\sigma'_{v0}$$

where
a_{max} = peak horizontal acceleration at ground surface;
$CRR_{7.5}$ = cyclic resistance ratio for $M_w = 7.5$ earthquakes;
g = acceleration of gravity
H = thickness of layer in meters
NSL = Natural Surface Level in meters
RBL = River Bed Level in meters
γ_b = Bulk Density in kN/m^3
c = cohesion in kPa
Ø = angle of internal friction in degrees
CSR = cyclic stress ratio induced by earthquake
CRR = cyclic stress ratio required to resist liquefaction for magnitude 7.5 earthquake
r_d = stress reduction coefficient
FOS = Factor of safety
z = depth below ground surface in meters
$(N_1)_{60cs}$ = SPT blows considering clean sand effect
$(N_1)_{60}$ = Corrected SPT blows
α and β = coefficients, that are functions of fines content, used to correct $(N_1)_{60}$ to $(N_1)_{60cs}$;
FC = Fine sand content in percentage
σ_{v0} = total vertical overburden stress
σ'_{v0} = effective vertical overburden stress
MSF = Magnitude Scaling Factor to adjust the clean-sand curves to magnitudes smaller or larger than 7.5, to convert CRR (M7.5) to CRR [Figure 9]
M_w = Magnitude of earthquake
K_σ = Correction Factor for Effective Overburden Pressure larger than 100 kPa
P_a = Atmospheric pressure and f is the function of site conditions, including relative density, stress history, aging, and over consolidation ratio
K_α = Correction Factor for pre-existing shear stress in the ground
τ_{st} = Static shear stress
f = exponent estimated from site conditions used in calculation of *K*s

5 MITIGATION OF LIQUEFACTION POTENTIAL

Separate considerations of the liquefiable behavior have been made for various structure categories, for assigning different mitigation measures.

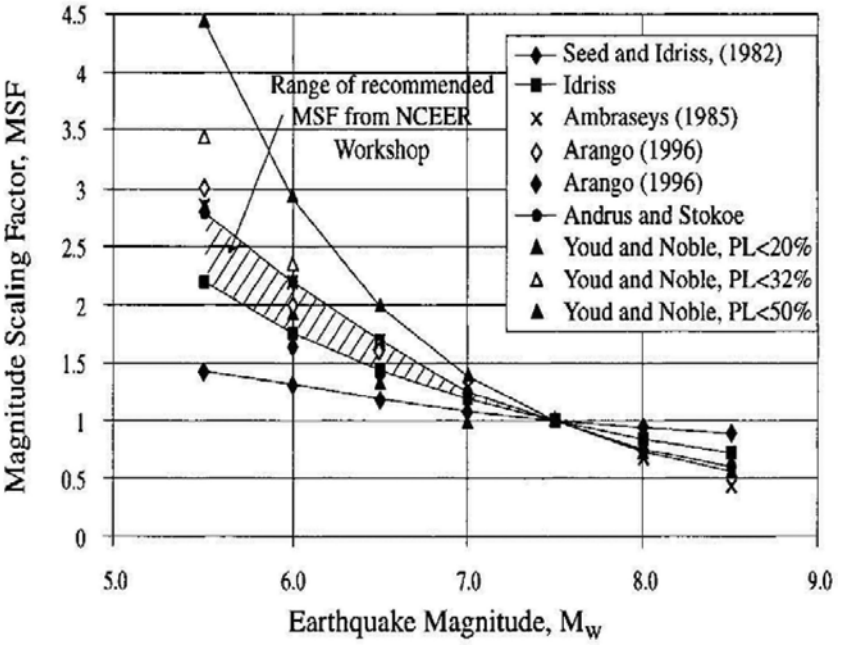

Figure 9. Magnitude scaling factors derived by various investigators (Reproduced from Youd and Noble 1997a).

Keeping in view the specific loading requirements, scour conditions, liquefaction potential of subsoil and the strata encountered at the foundation level 1500 mm diameter and 48m, drilled shafts have been provided for supporting the bridge. The shaft friction has been ignored in the upper 10 to 12 m zone to simulate liquefaction of the upper soil deposits.

All buildings of main and minor facilities have been constructed on a raised platform comprising 1 to 3.5 m thick select fill placed over existing ground. Liquefaction analyses had been carried out for all the structures with natural condition as well as placed over NSL upto Finished Floor Level (FFL) with fill. The cyclic stress ratio induced by the design earthquake has been effectively.

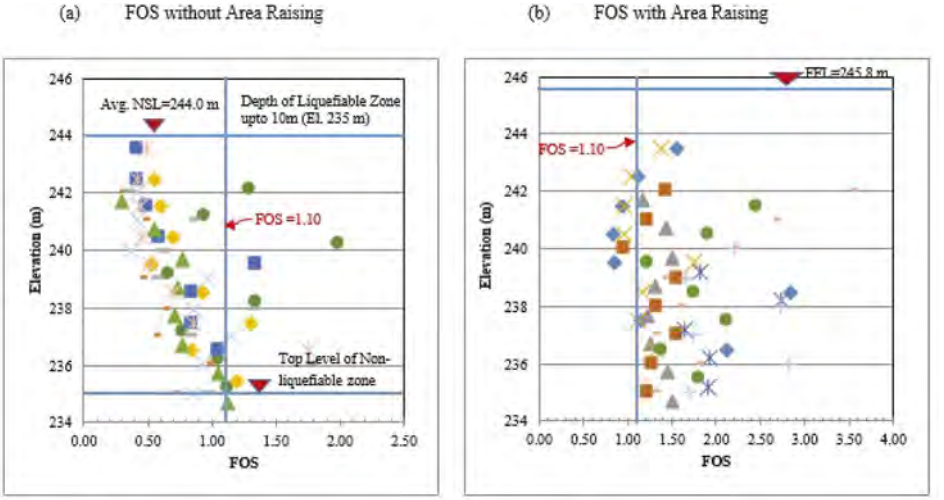

Figure 10. Main structures – FOS before and after raising NSL to FFL.

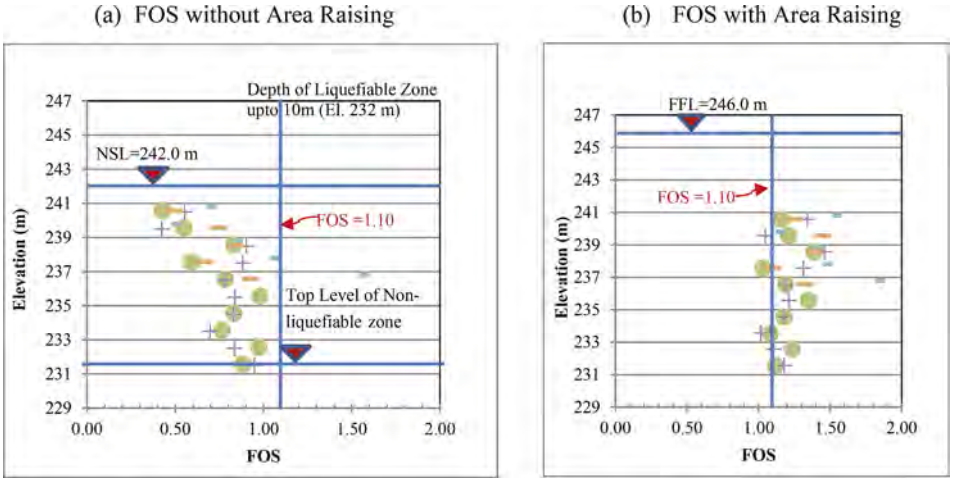

Figure 11. Minor facilities – FOS before and after raising NSL to FFL.

Deep foundations have also been provided for those main facilities where FOS was less than 1.1 and shallow foundations have been provided for other structures. The minor structures have been constructed on a raised platform comprising upto 4.0 m thick select fill placed over natural ground as shown in Figure 8. The results show FOS value as more than 1.1 after raising the area.

6 CONCLUSIONS & RECOMMENDATIONS

1. Sand deposits in the upper reaches in the north of Pakistan of river Ravi are liquefiable, under the expected seismic activity in the area, under free-field condition.
2. Drilled shafts serve as a good solution to mitigate liquefaction potential under the moderately heavy structures, whereas provision of earthen platforms works effectively by lowering the cyclic stress ratio generated by earthquake.
3. The conclusions and mitigation measures adopted at this site can be utilized for other structures too with similar ground conditions; subject to independent evaluations.

U.Z. Shermukhamedov & A.R. Abdullayev
Tashkent State Transport University, Tashkent, Uzbekistan

ABSTRACT: The paper deals with theoretical issues of determining the design resistance of soils. The main postulates of the well-known theory of the ultimate stress state condition are analyzed. The results of theoretical solutions presented by the authors of the article are given.

Keywords: Ultimate stress transmitted to the ground, Design soil resistance, Contact stresses, Shear surface deflection angle, Methods for determining the design soil resistance

1 MAIN INFORMATION

1.1 *Introduction*

The design soil resistance R is the safe pressure transmitted to the soil base through the foundation. At the same time, it is assumed that, the expected settlement of the base at such a pressure should not exceed the calculated allowable settlement for this structure S_u. It is known that the theoretical solution for determining the design resistance of soils is based on the joint solution of the equation of the plane stress state problem proposed by Flaman and the Mohr-Coulomb strength theory. The solution to this problem was obtained by N.P. Puzerevsky [1].

1.2 *Theoretical foundations for determining the magnitude and criteria for the design resistance of soils*

At present, this expression in a modified form is included in the normative documents SNiP. The main idea of this theory is that the ultimate stress state under the foundation is allowed only along its edges with a depth of its development up to $z \leq B/4$. The second, more realistic way to determine this important criterion is through the results of plate load tests. In this case, the calculated soil resistance is determined within the boundaries of the linear dependence of the graph $f(s,P)$ (Figure 1).

Below we consider a method for determining this important characteristic according to the theory of soil strength proposed by the authors based on expression (1) of the theory of limit equilibrium [3]

$$\sigma_u = cM_c + 2b\gamma M_\gamma + q_2 M_g \tag{1}$$

Where $M_\gamma = \frac{\pi * \left(\frac{\beta}{360}\right) tg^2\theta^*}{cos^3\theta^* k_a}$; $M_g = \frac{tg\theta^*}{cos^3\theta^* k_a}$ and

DOI: 10.1201/9781003299127-54

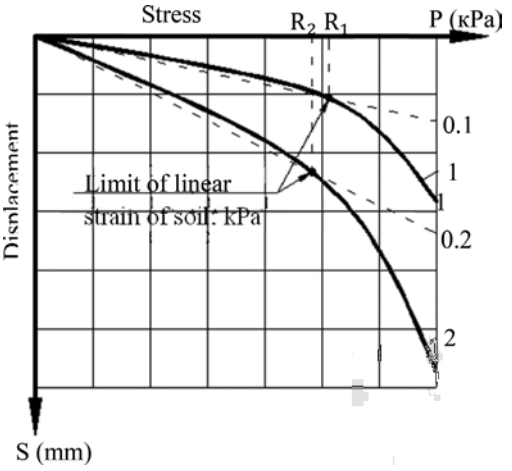

Figure 1. The relationship between the pressure under the stamp and its vertical movements: 1-soil of natural moisture and 2-in a water-saturated state.

$$M_c = \frac{1}{cos^4\theta^*(tg\theta - tg\varphi)}$$

In accordance with this theory, along the edges of the foundation of higher rigidity, contact stresses of a parabolic shape arise with a maximum at its edges:

$$\sigma_z = \frac{2\sigma_m}{\pi\sqrt{1 - \left(\frac{kx}{(b-a)}\right)}} \tag{2}$$

where $0,94 \leq k \leq 0,99$ is the coefficient regulating the maximum boundary stresses. Condition $\sigma_z = \sigma_u$ is satisfied for $(b-a) \leq x \leq b$ and condition $\sigma_z = \sigma_{min} -$ for $x = 0$, a is determined from condition $z \leq 2b/4$ (Figure 2)

$$a = \frac{b}{vtg\varphi^*}$$

where is v = (5 - 10) the scaling factor characterizing the depth of plastic zones propagation; $\varphi^* = \theta^*$- angle of deviation of the shear platform.

From the equilibrium condition corresponding to the limit state condition, we determine the average stresses under the base of the foundation

$$N = 2\sigma_m(b-a) + 2\sigma_u a \tag{3}$$

On the other hand, from equation (2) for x = (b - a) and $\sigma_z = \sigma_u$ we determine the value of σ_m

$$\sigma_m = \sigma_u \frac{\pi\sqrt{1 - \left(\frac{kx}{(b-a)}\right)^2}}{2} = \sigma_u \frac{\pi\sqrt{1-k^2}}{2} \tag{4}$$

For x = 0

$$\sigma_{xmin} = \frac{2\sigma_m}{\pi} \tag{5}$$

Finally, substituting σ_m (4) into expression (3), we get the allowable load on the foundation

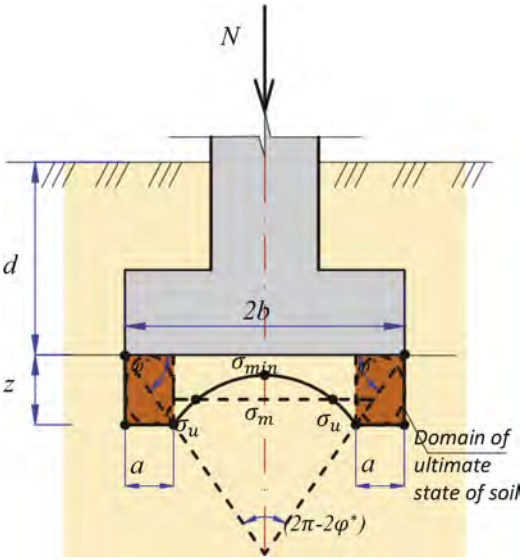

Figure 2. Design scheme for determining values of calculated soil resistance.

$$N = 2\sigma_m(b-a) + 2\sigma_u a = \sigma_u\left[\pi\sqrt{1-k^2}(b-a) + 2a\right]$$

Dividing both parts of the equation by the width of the foundation, we determine the value of the calculated soil resistance

$$R = \sigma_u \frac{\left[\pi\sqrt{1-k^2}(b-a) + 2a\right]}{2b} = \sigma_u \frac{\left[\pi\sqrt{1-k^2}\left(b-\frac{a}{b}\right) + 2\frac{a}{b}\right]}{2} \tag{6}$$

where

$$m = \frac{a}{b} = \frac{1}{vtg\varphi^*}$$

Contact stresses, considering the ultimate stress state arising along the edges, are determined by the following expression (2)

$$\sigma_x = \frac{2\sigma_m}{\pi\sqrt{1-\left(\frac{kx}{(b-a)}\right)^2}} \tag{7}$$

2 EXAMPLE

Determination of the value of the calculated soil resistance. The ultimate stress transferred to the soil is $\sigma_u = 500$ kPa. The foundation width is $2b$ = 1.4 m. The angle of deflection of the shear surface is $\varphi^* = 50^0$, $v = 10$ and $k = 0,96$, then

$$\theta^* = \kappa(atg\xi + \varphi) = 1,1(atg0,23 + 37) = 1,1 * 50 = 55$$

$$a = \frac{b}{vtg\varphi^*} = \frac{0,7}{5 * 1,19} = 0,12m$$

$$R = \sigma_u \frac{\left[\pi\sqrt{1-k^2}(b-a)+2a\right]}{2b} = 500\frac{3,14(0,7-0,12)\sqrt{1-0,96^2}+0,24}{1,4} = 266 \text{ kPa}$$

3 CONCLUSIONS

1. The well-known theory for determining the design resistance of soils, proposed by N.P. Puzerevsky [1] is based on the theory of plane stress state and Mohr-Coulomb theory of strength.
2. In the proposed theory for determining the design resistance of soils, the expression of the ultimate load $\sigma_u$on the soil and the function of contact stresses for rigid foundations proposed by the authors are used.
3. The expression proposed by the authors does not depend on the stress state of the mass in the active region of the base deformation and is a certain function of the limit stress state.

Optimal design scheme and probabilistic analysis of soil-water characteristic

Zhang Xuejuan, Tan Xiaohui, Fei Suozhu, Dong Xiaole & Xiao Ying
Hefei University of Technology, Hefei, China

ABSTRACT: Soil-water characteristic curve (SWCC) is an important curve in unsaturated soil mechanics. A SWCC can be obtained by curve fitting for a group of data points of suctions and water contents. The lower and the higher part of suction can be measured by the osmotic method and the filter paper method, respectively. Based on the results of a lot of laboratory tests of suctions and water contents of clay, four combinations of data points measured from the osmotic method and the filter paper method are employed to perform the curve fitting for SWCC. Results show that the statistics of SWCC parameters can be accurately obtained by curve fitting all data points of the osmotic method plus only one data point with high suction of the filter paper method. This finding can save a lot of laboratory effort for the measurement of SWCC of unsaturated soils.

1 INSTRUCTION

Soil water characteristic curve (SWCC) is a primary curve to study the behavior of unsaturated soil in geotechnical engineering (Han et al. 2016; Zhai et al. 2017). It is used to characterize the relationship between matrix suction and water content of soils.

There are many methods to measure the SWCC (Nam et al. 2010). However, most SWCC tests can measure soil suction range only in a limited range. It is difficult to obtain a SWCC in the whole suction range by a single test method. Therefore, some scholars proposed to use the combination of several SWCC test methods to obtain the SWCC in the whole suction range. For example, the osmotic method and the filter paper method were usually adopted to measure the low suction part and the high suction part of a SWCC, respectively (Tan et al. 2020).

Although the osmotic method and the filter paper method are simple to operate, measurement of one suction requires at least 10 days using these two methods (Nam et al. 2010), which is very time-consuming. Therefore, reducing the number of suction measurement can save the laboratory workload greatly (Li et al. 2017). Generally speaking, accuracy of the curve fitting of a SWCC decreases with the decrease of the number of data points of (ψ, w) (Ren et al. 2020). According, reducing the number of data points of (ψ, w) without decreasing the accuracy of the curve fitting of SWCC is a very important issue for investigating the behavior of unsaturated soils.

To this end, the osmotic method and the filter paper method were adopted to measure the low and the high suction part of SWCCs of clay in Hefei, China, respectively. Sixty-three groups of SWCCs were measured. Four combinations of data points (all data points of the osmotic method plus different selection of data points of filter paper method) are employed to perform the curve fitting for SWCCs. Statistics of SWCC fitting parameters of different combinations of data points were compared, and an optimal test design for obtaining a SWCC is proposed.

2 MATERIALS AND METHODS

2.1 *Properties of tested soil*

Sixty-three soil columns were collected in a construction site in Hefei, China. These soil samples are all drilled from the same unsaturated clay layer, which is about 10 m below the

DOI: 10.1201/9781003299127-55

ground surface. Basic properties of the soil are measured in the laboratory and their values are listed in Table 1.

Table 1. Basic properties of the tested soil.

Index	Water content w_0 (%)	Density ρ_0 (g/cm^3)	Specific density G_s	Plastic limit ω_P (%)	Liquid Limit ω_L (%)	Plastic index I_P
Value	23.4	2.03	2.73	26.0	53.0	27.0

2.2 *Measurement of the low suction part of SWCC - osmotic method*

The suction range measured by the osmotic method is 0 – 1500 kPa. The principle and operation steps of the osmotic method in details can be found in the reference (Shen et al. 2013). In the paper, as one of the materials used in the osmotic method, the suction of the polyethylene glycol (PEG) solution was setting as 0, 3, 8, 22, 65, 200, 550 and 1600 kPa, respectively. The relationship between the suction of the soil and the concentration of PEG solution can be expressed as follows:

$$PEG = \frac{90}{\sqrt{11/\psi + 1}} \tag{1}$$

2.3 *Measurement of the high suction part of SWCC - filter paper method*

The filter paper method is used to measure the SWCC within the high suction part of 1500 kPa – 30000 kPa. The principle and operation steps of the filter paper method can be found in the reference (Li et al. 2017). In order to obtain different suction points, the water content of the soil sample is set in the range of 13% – 23.5% in the paper. The relationship between the suction of the soil (ψ) and the water content of filter paper (w) can be expressed in Equation (2):

$$\begin{cases} \log \psi = 5.493 - 0.0767w & (w \le 47\%) \\ \log \psi = 2.470 - 0.0120w & (w > 47\%) \end{cases} \tag{2}$$

2.4 *SWCC fitting model and data combination scheme*

There are many SWCC fitting model (Brooks & Corey 1964; van Genuchten. 1980; Fredlind & Xing 1994), among which the van Genuchten model (VG model) is popularly used in Geotechnical engineering. The expression of the VG model is shown in Equation (3):

$$w = \frac{w_s - w_r}{[1 + (\psi/a)^n]^m} + w_r \tag{3}$$

where w, w_s, and w_r are the water content, the saturated water content, and the residual water content, respectively; a, n, and m are model parameters. The parameter a is related to the air entry value of soil. The parameter n is related to the pore size distribution of soil and control the gradient of the curve. The relationship between m and n is considered as m=1-1/n. ψ is matrix suction.

As described in Sections 2.2 and 2.3, eight and three data points of (ψ, w) were measured using the osmotic method and the filter paper method, respectively, for obtaining one SWCC. To obtain an optimal test design for these data points, four combination schemes of these data points are used for the curve fitting of SWCCs. The four data combination schemes are illustrated in Table 2.

Table 2. Data combination schemes for fitting SWCCs.

No.	Osmotic method	Filter paper method
1	All data points	All data points
2	All data points	No data points
3	All data points	The lowest suction point
4	All data points	The highest suction point

3 RESULTS AND DISCUSSIONS

3.1 *SWCCs of the four data combination schemes*

According to Table 2, four data combination schemes were adopted for fitting a SWCC. Therefore, a total of 63 groups of SWCCs were obtained, and each group has 4 SWCCs. Take any two groups (e.g., Group 1 and 2) for example, the comparison of four SWCCs corresponding to the four data combination schemes are shown in Figure 1, in which the squares and the circles represent the data points measured by the osmotic method and filter paper method, respectively. It is apparent that the combination of all data points controls the shape of the whole SWCC, but the data points of the osmotic method or filter paper method can only control the lower or higher part of the SWCC. Therefore, data combination 1 is necessary for accurately obtaining the entire SWCC.

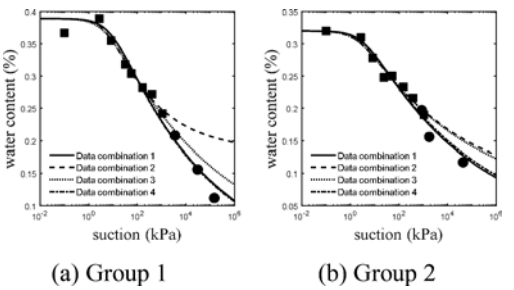

Figure 1. Comparison of SWCCs.

It can also be observed from Figure 1 that all the curves are close to each other for the low suction part of SWCCs, and the curves gradually diverge when the suction increases. For the entire suction range, the SWCCs of data combinations 1 and 4 are nearly overlapped, but the SWCCs of data combinations 2 and 3 are far from those of data combinations 1 and 4. Similar phenomena can be observed for the rest groups of SWCCs, which are not shown here. This indicates that data combination 2 (i.e., the osmotic method) and data combination 3 (i.e., the osmotic method plus the smallest suction point of the filter paper method) are not suitable for accurately measuring the SWCC. On the contrary, the data combination 4 can be obtained the SWCC accurately. Therefore, by using data combination 4 to replace data combination 1, only the highest suction data need to be measured using the filter paper method, which can greatly save the laboratory test time and effort.

3.2 *Statistical characteristics of SWCC parameters*

To further compare the features of the four data combination schemes, the statistical characteristics of SWCC parameters of each data combination of all the 63 groups of SWCCs are calculated and compared. The frequency distribution histogram and the corresponding fitted distribution curve of the four data combination schemes for the 63 SWCCs are shown

in Figures 2 and 3 for parameter a and parameter n. It is apparent that parameters a and n obey lognormal distribution for all the four data combinations. The mean and coefficient of variation (COV) in these figures are the statistical values of SWCC parameters a and n. The skewness and the kurtosis represent the degree of asymmetry and steepness of parameters frequency distribution, respectively.

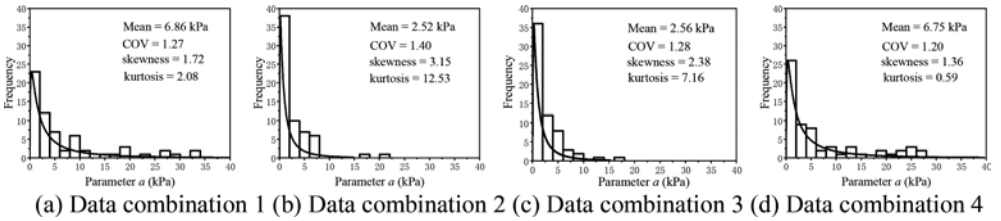

Figure 2. Probability distribution curve of parameter a.

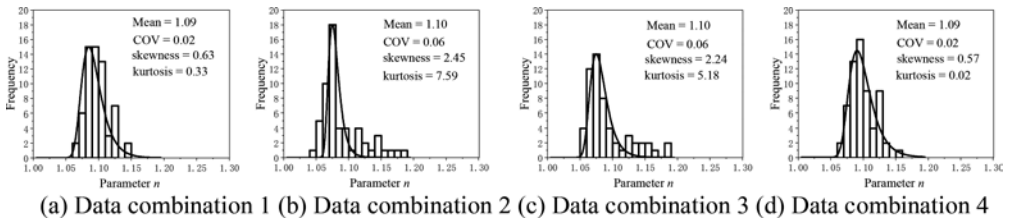

Figure 3. Probability distribution curve of parameter n.

For Figures 2 and 3, the sub-figures (a) and (d) are similar both in shape and in the values of statistics. On the contrary, the shapes and statistics of sub-figures (b) and (c) are apparently different from those of sub-figures (a) and (d). This proves again that data combination 4 can be used to substitute data combination 1 for obtaining the SWCC.

4 CONCLUSIONS

The osmotic method and filter paper method are adopted together to measure the data points of suction and water content. Many groups of data points of unsaturated clay in Hefei were measured for obtaining the SWCCs, and four data combination schemes for data points of the osmotic method and the filter paper method are investigated to select an optimal test design which can save the laboratory test effort without decreasing the accuracy of the SWCC fitting. Results show that data combination 4, including all data points of the osmotic method and the highest suction point of the filter paper method, is a best choice for obtain the entire SWCC accurately and efficiently.

Determination of elastic-visco-plastic parameters of soils based on the results of torsional shear tests

Z.G. Ter-Martirosyan, A.Z. Ter-Martirosyan, V.V. Sidorov & A.S. Almakaeva*
NRU MGSU, REC Geotechnics, Moscow, Russia

ABSTRACT: The article considers the possibility of determining soil viscosity parameters that are used for rheological soil models. These models allow to take into account the development of deformations over time and to describe the deformation curve with a high degree of accuracy. Nine shear tests were carried out on a torsional shear device at three normal stresses: 100, 200 and 400 kPa. The shear proceeded at a constant rate of 0.1138°/min and a constant vertical pressure. The soils for shear tests were selected from the construction site of the city of Moscow and are loams of a solid consistency. According to the results of laboratory experiments, the parameters of the strength and viscosity of the soil were determined. Using the new universal rheological model of Ter-Martirosyan A.Z. plots of shear stress versus time $\tau = f(t)$ were obtained. The authors in the article compare the experimental curves obtained from the results of the torsional shear test and the analytical curves obtained on the basis of the rheological model.

Keywords: shear stress, consolidation, torsional shear, viscosity, soil rheological model

1 INTRODUCTION

Clay soils, as a rule, are multiphase systems consisting of soil particles and pores filled with water and air. Clay soils have extremely low permeability coefficient. The application of loads on the soil base of a structure, composed of such soils, leads to the development of deformations in time. This is due to two processes: primary filtration consolidation which occurs due to the squeezing of water from the pores and secondary consolidation or, in other words, creep, which occurs due to the rheological properties of the soil skeleton and depends on the interstructural bonds of the particles. Both of these processes occur simultaneously in clayey soils but if filtration consolidation ends when the pore pressure increment is zero then secondary consolidation does not end with it but can proceed after a sufficiently long time. As a rule, the settlements of the construction are of a damping nature which is explained by the compaction of the soil under load. However, if shear deformations occur the creep process may redevelop. Such soil behavior is called elastoviscoplastic and models that describe the behavior of soils with regard to viscosity are called rheological. One of the main input parameters of such models is the viscosity parameter η. Rheological models make it possible to describe the soil behavior during shear with a high degree of accuracy and to obtain curves that almost completely repeat the curves based on experimental studies of soils.

The purpose of this article is to present the possibility of obtaining a viscosity parameter that allows you to more accurately describe the curve of dependence of shear stresses on time $\tau = f(t)$, in addition to the strength and deformation properties of soils. To determine the effective shear stresses laboratory tests were carried out on a torsional shear device. The experiments were carried out in accordance with the current regulatory document GOST R 59937-2021 Soils. Method for laboratory determination of strength characteristics by ring shear.

2 LITERATURE REVIEW

The formation of rheology as a separate science was initiated by the research of Bingham Yu. (1922) who was the first to introduce the term "rheology" and who made valuable studies of the rheological properties of liquids and dispersed systems. But the prerequisites for the formation of rheology as a science appeared long before that when Newton proposed the law of viscosity (internal friction) for liquid and gaseous media.

In 1874, L. Boltzmann used a linear relationship between stresses and strains and proposed the theory of hereditary creep deformation. According to this theory, stresses will depend not only on the deformation at a given point in time but also on the previous history of deformation. The theory of Boltzmann L. was further developed in the works of Volterra V.

In 1948, Yu.N. Rabotnov invented the theory of plastic heredity of creep deformations for solids and extended the Boltzmann-Volterra theory to the area of nonlinear creep.

Rheology studies have become important in solving soil mechanics problems associated with long-term loads leading to the accumulation of significant creep deformations. A great contribution to the development of soil rheology was made by the works of Terzagi K., Khvorostlev M., Tsytovich N.A., Vyalov S.S., Goldstein M.N., Casagrande A., Florin V.A., Meschan S.R., Reiner M., Maslov N.N., Ter-Stepanyan G.I., Zaretsky Yu.K., Ter-Martirosyan Z.G. and etc.

First of all, research on rheology spread in clayey soils. The first mention of the creep of clay soils is in the well-known work of Terzaghi K. (1925) [1]. The first results of long-term tests of clay soils were carried out on an annular shear device and were described by M. Khvorslev in 1937-1939. He tried to apply Newton's law for ideally viscous liquids to soils. However, later studies of the rheological properties of clay soils showed that soil flow is observed not under any load, as in a viscous Newtonian fluid but under a certain one, so Bingham's theory of viscoplastic flow began to be applied to soils. Experimental evidence of the applicability of his theory to soils was obtained by Maslov N.N. However, the theory of viscoplastic flow describes the process of steady flow at a constant speed while soils tend to change the flow speed. A modified Bingham law which takes into account the nonlinear relationship between stress and soil flow velocity was proposed by Vyalov S.S. in 1959.

Further studies by Vyalova S.S., Casagrande A., Goldstein M.N. et al. 1950 - 1970 which were summarized in the monograph by Meschyan S.R. [2] it was proved that the behavior of soils under long-term loads is more consistent with the creep of solids because similar stages of creep develop in the soil, namely damped creep, creep at a constant rate and progressive creep.

Rheology developed most intensively in the mechanics of frozen and permanently frozen soils where the soil due to the presence of water and ice in it was considered as a classical rheological body. Researches of Tsytovich N.A. [3] in frozen soils made it possible to discover the property of fluidity. In 1950 - 1955 Vyalov S.S. found that frozen soils are characterized by all manifestations of classical creep, i.e. damped and undamped deformations can develop in soils under load and the creep curve describing them has all the typical stages of creep development: unsteady creep, plastic-viscous flow, and progressive creep [4]. As a result of his research, Vyalov S.S. Introduced the term "ultimate strength" which means the stress before exceeding which progressive creep does not occur leading to destruction.

For the first time, the Boltzmann-Volterra theory was applied to soils by Florin V.A. in 1958 [5]. He developed a generalized theory of soil consolidation which could take into account primary and secondary consolidation taking into account hereditary creep. Maslov G.N. continued further research on this topic. [6, 7].

Reiner M. [8] in his book considered the basic simplest models of Hooke, Saint-Venant and Newton and described methods for determining the rheological properties of real materials.

Research Vyalova S.S. and Pekarskaya N.K. in 1966 showed that in the process of creep of clay soils the shear resistance under long-term loads is always less than the instantaneous one. Therefore, the researchers divided the instantaneous strength at the beginning of the application of loads, temporary strength which can destroy the soil in a certain period of time and long-term strength below which the resistance does not decrease.

Goldstein M.N. thought [9] that the soil has two types of bonds between particles: brittle and viscous which are destroyed when the soil is deformed. However, new viscous contacts

are formed at the site of broken bonds due to which creep damping occurs. This process is called soil hardening. If the stage of progressive creep begins during shear then soil softening occurs which was also noted in the works of Vyalov S.S., Goldstein M.N., Maslov N.N., Ter-Stepanyan G.I., Meschan S.R. and Ter-Martirosyan Z.G. [10-13].

To describe the behavior of soil under load, taking into account creep, rheological soil models are used. The simplest rheological model describing the purely viscous behavior of a material represented by a liquid or gas is Newton's law which relates shear stress to a change in strain rate:

$$\dot{\gamma}_i = \tau_i / \eta(\sigma_m, t), \tag{1}$$

where $\eta(t)$ – variable shear viscosity.

To describe the behavior of solids more complex two- or more-component models should be used. These models include the Maxwell body, the Kelvin-Voigt model, the Bingham-Shvedov model, etc. As a rule, they are combinations of the simplest models: an elastic body (Hooke model), a plastic body (Saint-Venant model) and a viscous body (Newton model).

The model of a viscoelastic body with stress relaxation which is called the Maxwell body is a series-connected elastic and viscous elements. Thus, under loading the body can elastically deform and flow at the same time. Mathematically, the model looks like this:

$$\dot{\varepsilon} = \frac{\dot{\sigma}}{E} + \frac{\sigma}{\eta}, \tag{2}$$

A model that describes the strain-relaxing behavior of a viscoelastic material also known as the Kelvin-Voigt model describes elastic strains over time that increase when a load is applied and decrease when it is removed, as well as the creep of a material under constant stress. In the scheme of the Kelvin–Voigt model the elastic and viscous elements are connected in parallel:

$$\sigma(t) = \varepsilon E(t) + \dot{\varepsilon}\eta(t), \tag{3}$$

The study of the rheological properties of concentrated clay suspensions led Bingham and Green to postulate a viscoplastic body [14]. This model is characterized by the fact that at stresses less than the critical σ_T, it does not deform and obeys Hooke's law and when this stress is exceeded it flows like a Newtonian fluid:

$$\sigma = \varepsilon E \text{ at } |\sigma| \prec |\sigma_T|, \tag{4}$$

$$\sigma - \sigma_s = \varepsilon\eta \text{ at } |\sigma| \succ |\sigma_T|, \tag{5}$$

Investigating the rheological properties of solutions, Shvedov proposed a model of a plastic-viscous material in which stress relaxation will proceed according to an exponential law up to a certain value of residual stress [15]. Mechanically, the model is a parallel connection of the elements of the Maxwell body and the Saint-Venant body with an elastic spring connected in series to them:

$$\eta\dot{\varepsilon} = (\sigma - \sigma_s) + \frac{\eta}{E}\sigma, \tag{6}$$

The Bingham equation is a degenerate Shvedov body. Comparing Equations (4), (5) and (6) it is possible to obtain the Bingham-Shvedov equation which can describe the behavior of the soil.

The rheological equation of the hardening material Rabotnov Yu.N., applicable to soils, has the following form:

$$\dot{\gamma} = \tau/(G \cdot t) \tag{7}$$

where G – soil shear module.

In the dissertation [16] Ter-Martirosyan A.Z. proposed a new universal rheological equation obtained on the basis of the Timoshenko model to describe the rate of shear deformation of a hardening and softening clay soil in the form:

$$\dot{\gamma} = \frac{\tau - \tau^*}{\eta_0}\left(\frac{e^{-\alpha\gamma}}{a} + \frac{e^{\beta\gamma}}{b}\right) + \frac{\dot{\tau}}{G} \tag{8}$$

where τ^* – ultimate shear stress;
τ – effective shear stress;
η_0 – initial viscosity;
γ – shear strain rate;
$\dot{\tau}$ - initial shear stress;
α, β, a, b – parameters of hardening and softening of clay soil determined by the results of the experiment.

Using Equation (8), the authors of [17] made graphs of the dependence of shear stresses on time $\tau = f(t)$. The parameters for the rheological model were obtained from simple shear tests. The results of comparing the experimental and analytical curves showed good convergence because Equation (8) allows one to accurately describe the double curvature of the graphs obtained experimentally on a simple shift device.

3 METHODS

In this work, a modification of the torsional shear device developed by Ter-Martirosyan Z.G. was used to test soils. This modification was combined with a certified and calibrated control and measuring device manufactured by LLC NPP Geotek which includes a set of pneumatic loading device GT 2.0.7 10 kN and control units. The general view of the installation is shown in Figure 1.

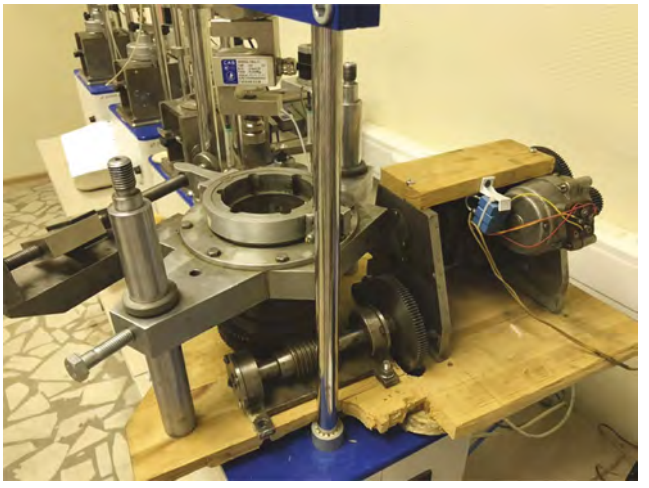

Figure 1. General view of the torsion shear device.

This device performs a kinematic torsional shear by rotating the lower part of the soil sample box at a predetermined speed. Shear resistance is measured with a horizontal force transducer connected by a lever to the top of the soil sample box and preventing it from

rotating with the bottom. The engagement of the sample which excludes its rotation inside the box during torsional shear is provided by blades located in the side parts, in the upper and lower parts of the box. A view of the box with blades is shown in Figure 2.

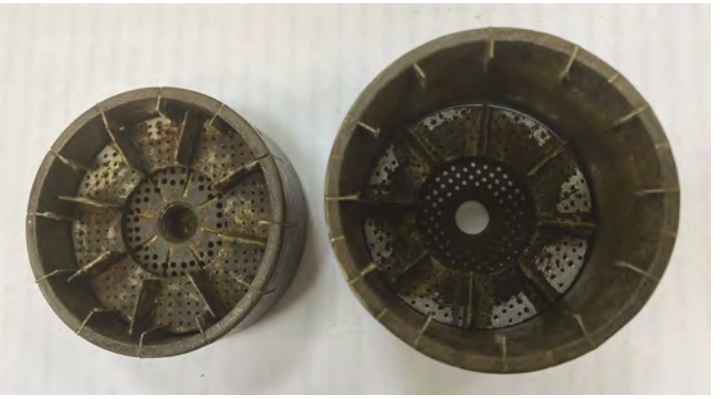

Figure 2. General view of the soil sample box.

Laboratory tests were carried out according to the consolidated-drained scheme in accordance with GOST R 59937-2021 Soils. Method for laboratory determination of strength characteristics by ring shear. Loams were used in this study. They were taken from a depth of 34-36 m. The dimensions of the samples were 71.4 mm in diameter and 35 mm in height which corresponds to the dimensions of the inside of the box. Before the start of each experiment the soil samples were under a vertical load corresponding to the normal pressure during the shear test: 100, 200 and 400 kPa for at least 8 hours. The shear was carried out at a constant speed of 0.1138°/min and a constant vertical load until a rotation angle of 17° was reached. The main physical properties of the tested soil are shown in Table 1.

Table 1. Physical properties of the soil.

Type of soil	Humidity of the lower plastic limit W_P, %	Humidity of liquid limit W_L, %	Plasticity number I_P
Loam	28	44	0.16

4 RESULTS

Using the results of laboratory experiments test reports were obtained containing an array of data on measured stresses and strains. However the shear stress is not constant in the shear plane, it changes according to a linear law: in the center of the section the shear stress is zero and at the points of the outer contour it reaches its maximum values. Therefore, it is necessary to determine the average shear stress in accordance with 9.1 of GOST R 59937-2021 using the formula:

$$\tau = 10\frac{3M_t}{2\pi(R_a^3 - R_i^3)} \tag{9}$$

where M_t moment of rotational force applied to the sample, kN· cm;

R_a – outer radius of the ring sample, cm;

R_i – inner radius of the ring sample, cm.

A similar formula was described by Boldyrev [18]. Based on the test results and using equation (4.1), graphs of shear stresses versus time $\tau = f(t)$ were plotted. These graphs are shown in Figure 3. Nine tests were carried out at three vertical stresses of 100, 200 and 400 kPa. The shear stress was determined only in the resulting shear plane. The friction of the soil along the side surface against the box and blades was not taken into account.

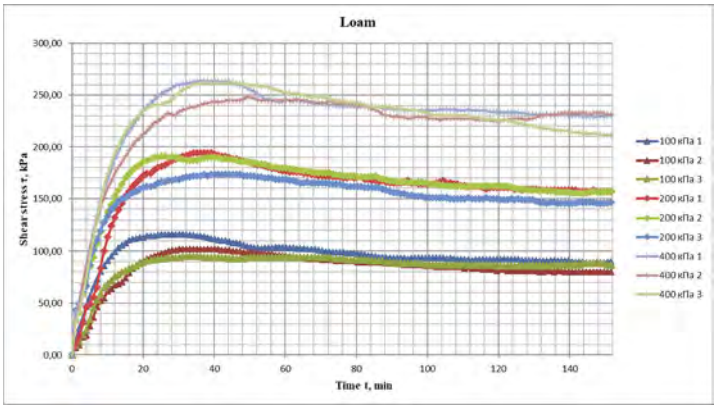

Figure 3. Plots of shear stress versus time $\tau = f(t)$.

As shown in Figure 3 an increase in vertical load leads to an increase in shear resistance: at a vertical pressure of 100 kPa peak shear stresses vary from 90 to 120 kPa, residual stresses from 70 to 90 kPa; at a vertical pressure of 200 kPa peak values of shear stresses vary in the range from 170 to 200 kPa, residual - from 140 to 160 kPa and at a vertical pressure of 400 kPa peak stresses ranged from 240 to 260 kPa, residual vary in the range from 210 to 230 kPa. It should be noted that there is a decrease in strength by 25-30% after the shear stresses reach peak values while most of the graphs plotted have pronounced peaks. Upon reaching shear deformations approximately equal to 6-7 mm shear stresses reach constant values, i.e. for residual strength. The figure shows graphs of the dependence of shear stresses on normal stresses $\tau = f(\sigma)$ which are built as a result of statistical data processing using the least squares method.

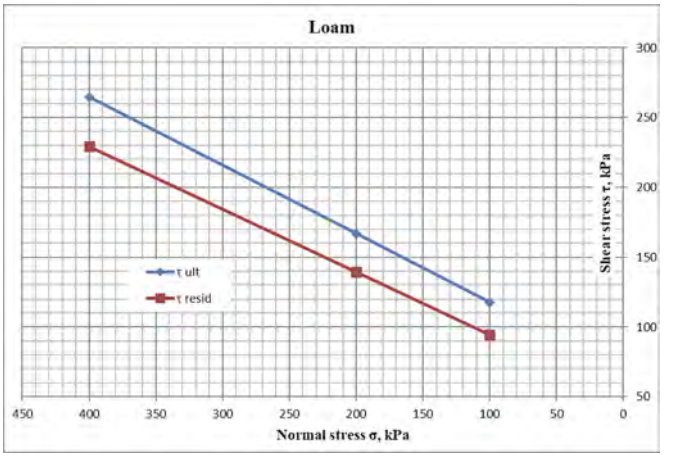

Figure 4. Graphs of dependence of shear stresses on normal stresses $\tau = f(\sigma)$.

Figure 5 shows a tested sample of loamy soil. Furrows formed in the shear plane indicating the nature of the shear - rotation. In addition, it should be noted that the shear is not smooth because there are depressions and elevations which can be one of the reasons for the appearance of peaks in the graphs. This effect was more pronounced for hard clays. The presence of irregularities in the shear plane was in direct proportion to the appearance of one or even two pronounced peaks in the graphs [19].

Figure 5. Tested soil sample (loam).

The calculation of the strength characteristics of soils is carried out by standard well-known methods presented in section 9 of GOST 12248.1-2020. Therefore, they are not of scientific interest and were not determined in this article. The viscous characteristics of soils are an integral part of describing the behavior of soils over time. In some cases, taking into account rheological properties can greatly affect the results. However there are no requirements and recommendations for their determination in the regulatory documentation. For this reason, in this article more attention is paid to determining the rheological properties of soils rather than strength parameters.

Using the shear creep Equation (8) of Ter-Martirosyan A.Z. in the *MathCAD* program graphs of the dependence of shear stress on time $\tau = f(t)$ were analytically plotted which, due to the selection of hardening and softening parameters a, b, α and β allow more accurately describe laboratory shear test curves. Other components of Equation (8) were determined from the results of laboratory tests for torsional shear. In this case, to obtain the values of the initial viscosity η_0 Newton's law (1) was applied. The calculated parameters of the shear creep Equation (8) for describing the laboratory shear test curves are presented in Table 2. The hardening and softening parameters a, b, α and β, selected by enumeration, are presented in Table 3.

Table 2. Parameters of the shear creep equation.

Table 3. Hardening and softening parameters.

Normal stress σ, kPa	№	a	b	α	β
100	1	5,5	2,5	30	1
	2	0,15	0,53	15	0,24
	3	0,4	0,47	12	0,12
200	1	1,8	2,2	19	0,32
	2	26	6,5	50	1,6
	3	10	4,7	35	1,6
400	1	14	7	65	1,2
	2	16	8,5	35	1
	3	1,6	1,7	24	0,4

Analytically obtained plots of shear stress versus time $\tau = f(t)$ were built and compared with the corresponding plots obtained from the results of laboratory tests (Figure 6). Comparison of the experimental and analytical curves shows their high convergence because a new universal rheological model of Ter-Martirosyan A.Z. was used which takes into account the hardening and softening of loamy soil.

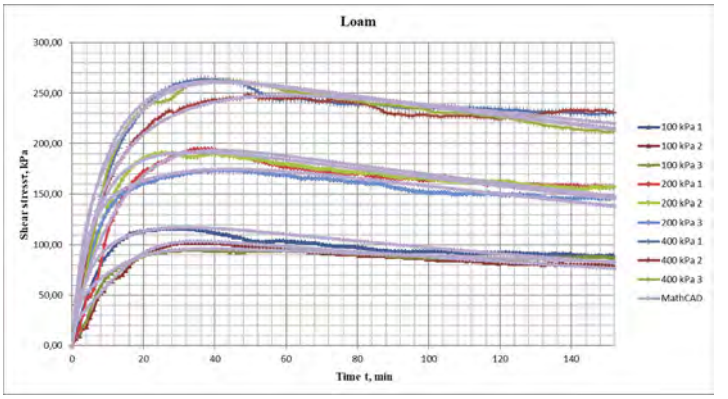

Figure 6. Comparison of experimental and analytical plots of shear stress versus time $\tau = f(t)$.

5 CONCLUSIONS

1. Based on the test results for loam on a torsional shear device plots of the dependence of shear stresses on time $\tau = f(t)$ were plotted at three normal stresses (100, 200 and 400 kPa) at a constant rate of 0.1138 °/min. These plots showed that the increase normal load the shear stress increases too and upon reaching the peak valu, the shear stresses decrease by 25-30% when the shear deformations reach 6-7 mm.
2. Due to the fact that during the transfer of loads to the soil base, deformations develop in time, caused by primary and secondary consolidation, soils are characterized by elastic-viscoplastic behavior. It is most correct to use rheological models to describe the behavior of soils under load over time. Viscosity parameters for such models can be obtained from laboratory shear tests.
3. In this paper for the analytical description of the behavior of soils in a torsional shear a new universal model by Ter-Martirosyan A.Z. is used which due to the parameters a, b, α and β makes it possible to take into account the processes of hardening and softening of the soil. Comparison of plots of shear stress versus time $\tau = f(t)$ obtained analytically and

experimentally showed that the new universal rheological model allows one to describe the behavior of the soil during shear with a sufficient degree of accuracy and obtain dependence curves that almost completely repeat the curves built on the basis of experimental studies of soils using the torsional shear method.

Tunnel and swelling analysis of expansive bedrock considering multiphysics between crystal layers

K. Hoshi, S. Yamada & T. Kyoya
Tohoku University, Sendai, Miyagi, Japan

ABSTRACT: This research proposes a new model targeting expansive bedrock by means of combining an elastoplastic model considering electro-chemo-mechanical phenomena with the Cam-clay model introducing cementation and its degradation due to plastic deformation. Tunnel excavation and swelling analyses are demonstrated by incorporating the proposed model into a finite element analysis code. The simulation results indicate that swelling occurs in narrowed area such as the bottom of the tunnel and swelling phenomena suddenly develops likewise real observation although ion-concentration change is uniformly given in the entire analysis area. This research unraveled the mechanism of the swelling phenomenon with the object of interaction between electro-chemo-mechanical phenomena on the surface of expansive clay mineral crystal and yield of bedrock skeleton accompanied with degradation of cementation.

1 INTRODUCTION

Pore fluid composition affects the mechanical behavior of bedrock containing expansive clay minerals. Moreover, swelling of expansive bedrock often causes problems during tunnel excavation and earth cutting. Thus, it is necessary to elucidate the mechanism behind the emergence of bumps and cracks as well as quantitatively evaluate the deformation caused by swelling. To simulate the issues regarding swelling behavior, a constitutive model that considers the electro-chemo-mechanical phenomena on the surface of expansive clay mineral crystal, stiffness of bedrock, and the degradation of the internal structure is required.

2 MODELING THE MECHANICAL BEHAVIOR OF SWELLING BEDROCK

2.1 *Electro-chemo-mechanical phenomena in crystal layers of clay minerals*

An elastoplastic model considering electro-chemo-mechanical phenomena in the crystal layers of clay minerals (Kyokawa et al. 2019) is used to investigate swelling bedrock. This model assumes swelling soils are composed of expansive clay minerals and non-expansive soil as well as possess a double-porous structure consisting of soil skeleton and interlaminar, as shown in Figure 1.

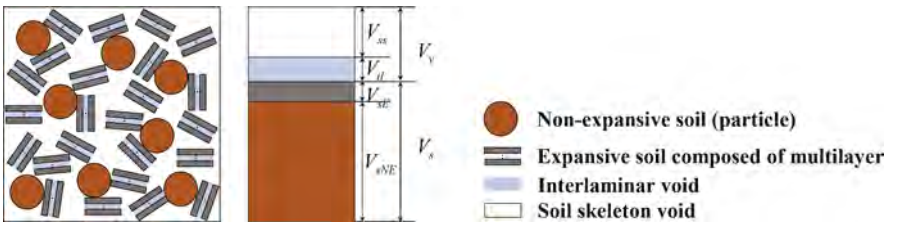

Figure 1. Schematic of expansive soil and its volumetric structure.

DOI: 10.1201/9781003299127-57

In this model, the void ratios (total void ratio e, interlaminar void ratio e^{il}, and soil skeleton void ratio e^{ss}) and the volumetric strain $\varepsilon_v$are defined as

$$\varepsilon_v = -\frac{V - V_0}{V_0} = -\frac{\Delta V_{ss} + \Delta V_{il}}{V_{s0} + V_{ss0} + V_{il0}} = \varepsilon_v^{ss} - \theta^* \frac{d - d_0}{d_0} \tag{1}$$

where θ^*, e^{il}, $e^{ss}$is defined as follows:

$$\theta^* = \frac{V_{il0}}{V_{s0} + V_{ss0} + V_{il0}} = \frac{e_0^{il}}{1 + e_0^{ss} + e_0^{il}}, \ e = \frac{V_v}{V_s}, \ e^{il} = \frac{V_{il}}{V_s}, \ e^{ss} = \frac{V_{ss}}{V_s} \tag{2}$$

where d is the distance of the interlaminar space, d_0 is its initial value.

The swelling behavior is determined by the following equilibrium equation of the electro-chemo-mechanical forces between the crystal layers:

$$F^{il}(c, d, \boldsymbol{\sigma}) = f_a(d) - f_r(c, d) - f_h(d) + f_e(\boldsymbol{\sigma}) = 0 \tag{3}$$

where c is the ion concentration of the pore fluid, f_a is the van del Waals force, f_r is the osmotic pressure from the double diffusion layers, f_h is the hydration force, and f_e is the force from the (mean) effective stress $\boldsymbol{\sigma}$. The osmotic pressure, van del Waals force, and hydration force are monotonically decreasing functions with respect to the interlaminar distance; moreover, the osmotic pressure changes with ion concentration. The osmotic repulsive pressure increases with decreasing ion concentration and vice versa. Therefore, increasing or decreasing interlaminar distance can describe swelling or osmotic compression. In addition to the above equilibrium model, bedrock skeleton behavior is described with Cam-clay model considering cementation and its degradation in Section 2.2.

2.2 *Cementation and internal degradation of swelling bedrock*

A method that considers the cementation effect and its degradation proposed by Yamada et al. (2022) is introduced into the Cam-clay model to describe the degradation of internal structure due to swelling. This model determines the tensile strength due to the cementation effect of the material in soil skeletons, such as cement-treated soil and bedrock, by translating the yield surface to the tensile side, as shown in Figure 2. It can also express high cementation because confining pressure virtually increases by treating translations of the yield surface as modifications of the effective stress. Moreover, it describes the transition from cement-treated soil and bedrock into normal soil by eliminating the deviation of the yield surface from the origin due to progressive plastic deformation. Specifically, the model is expressed with modified effective stress $\bar{\boldsymbol{\sigma}}$, which is the effective stress $\boldsymbol{\sigma}$plus the amount of isotopically parallel shifts of the yield surface Ψ.

$$\bar{\boldsymbol{\sigma}} = \boldsymbol{\sigma} + \Psi \boldsymbol{I} \tag{4}$$

This study applies the Cam-clay model considering cementation and its degradation due to plastic deformation in the soil skeleton aspect of the elastoplastic model that satisfies the interlaminar equilibrium for a double-porous structure.

3 TUNNEL EXCAVATION AND SWELLING ANALYSIS METHODS

Tunnel excavation and swelling analyses are demonstrated by incorporating the proposed model into a finite element analysis code. Excavation analysis is performed by unloading the surface forces acting on circular hole were calculated based on the initial stress state. After that, swelling analysis is conducted by lowering ion concentration uniformly in the entire

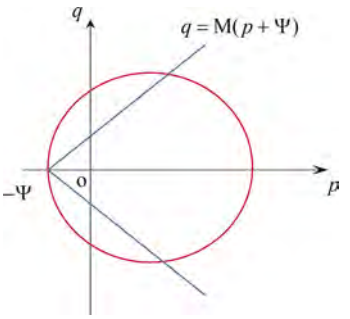

Figure 2. Parallel shift of the yield function.

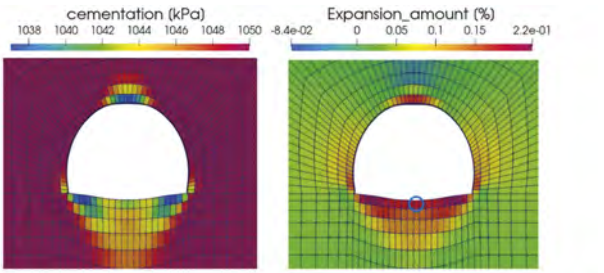
analysis area assuming that groundwater is supplied from the surrounding ground toward the tunnel-cavity under the influence of excavation. Calculations are performed assuming plane strain conditions and the analysis conditions are given assuming tunnel excavation in bedrock with 100 m of earth cover.

4 COMPUTATIONAL RESULTS AND DISCUSSION

Figure 3 shows the distributions of cementation Ψ and volumetric strain in an interlaminar void after excavation and swelling analyses. cementation degradation and swelling progresses in a limited area, such as just below the tunnel bottom, even though the ion concentration is reduced uniformly in the entire analysis area.



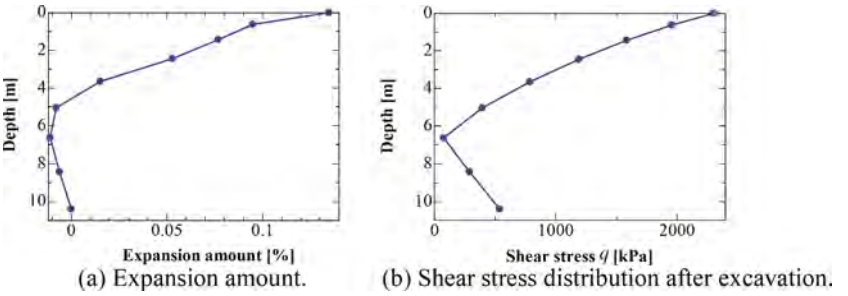
(a) Cementation distribution. (b) Expansion amount distribution.

Figure 3. Cementation distribution and expansion amount distribution.

Figure 4a shows distributions of vertical displacement and expansion amount in bedrock just below the tunnel bottom. Depth from the bottom is plotted on the vertical axis, and the cumulative values are plotted at a fixed point approximately 10 m from the bottom. Note that the expansion and vertical displacement increase remarkably from approximately 5 m just below the bottom. These tendency in the vertical displacement distribution matches the observed results at swelling bedrock.

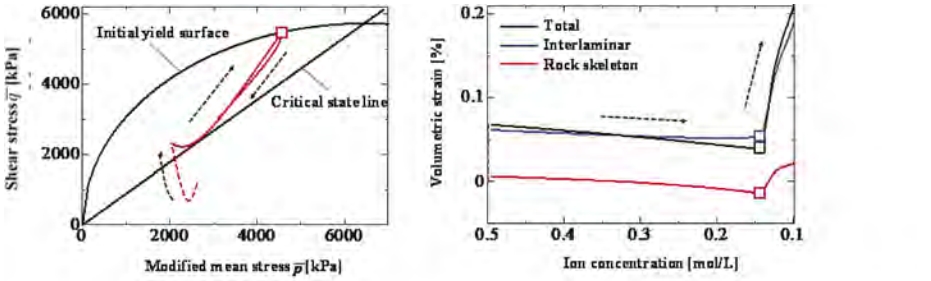
Next, we investigate this remarkable swelling behavior that occurs approximately 5 m below the tunnel bottom. Figure 4b shows the shear stress distribution just below the tunnel bottom after excavation. The shear stress reaches a minimum at 7 m below the bottom and increases rapidly from approximately 5 m below the bottom. This distribution of the shear stress is similar to that of the expansion amount after swelling analysis in Figure 4a.

This correlation suggests that the greater is the shear stress generated during tunnel excavation, the greater is the swelling when ion concentration decreases.



(a) Expansion amount. (b) Shear stress distribution after excavation.

Figure 4. Distributions of expansion amount and shear stress distribution after excavation.



(a) Stress path. (b) Ion concentration versus expansion amount.

Figure 5. Behavior of Element A.

Considering the stress paths of an element shown in Figure 3b, Element A indicated by a blue circle is located at the bottom of the tunnel where swelling is significant. Figures 4 shows the stress path and relationship between ion concentration and volumetric strain in Elements A. Here too, the dashed and solid lines show the excavation and swelling processes, respectively.

In the stress paths, Element A (Figure 5a) achieves a stress state above the critical state line at the initiation of swelling analysis already owing to the influence of the large shear stress caused by excavation. During swelling analysis, the effective stress increases because of interlayer spreading as the ion concentration decreases and the bedrock skeleton yields above the critical state line. In the Cam-clay model, the area above the critical state line is the softening zone with plastic expansion (Asaoka et al. 1994). In the stress path of Element A, the shear and mean effective stresses decrease after yielding, which indicates that softening occurs in the region with pronounced swelling. As the mean effective stress decreases due to softening, the distance between the crystalline layers also increases according to the mechanism described by Equation (3), resulting in significant swelling just below the tunnel base.

Moreover, Figure 5b shows that the expansion amount increases rapidly when the ion concentration falls below a certain value. Considering changing ion concentration as equivalent to evolving time, this figure suggests that deformation due to swelling develops in a short time when the ion concentration falls below a certain value. Here, it becomes clear that the rapid swelling begins when the bedrock skeleton reaches yield after comparing Figure 5a and 5b. This illustrates that the changing ion concentrations induce the bedrock skeleton to yield; moreover, the softening initiated by the yielding of the bedrock skeleton leads to significant swelling of the interlaminar layers. Consequently, the yielding of the bedrock skeleton triggers rapid expansion.

5 CONCLUSION

This paper proposes a novel model targeting expansive bedrock considering multiphysics in crystal layers and degradation of internal structure. The proposed model is incorporated into a finite element analysis code; moreover, tunnel excavation and swelling analyses describe the characteristics of the observed deformations. The results clarify the characteristics of and mechanism behind tunnel deformation in swelling bedrock.

Investigation of the stability of clay slopes under various types of their loading

F.G. Gabibov & A.Z. Zeynalov
Azerbaijan Research Institute of Construction and Architecture, Baku, Azerbaijan

ABSTRACT: It was found that a change in the angle of inclination of the load from 0 to 30° leads to a decrease in the slope stability coefficient K; for clays by 2.8 times; for sandy loams by 2.5 times. The triangular distributed load was applied so that the smaller triangle cathet was at the base of the slope perpendicular to the daytime surface, the hypotenuse of the triangular load coincides with the slope surface. With an increase in the load of 0.40 MPa, the values of the resistance coefficients. To increase for clays in the range of 8.2-21.3%, for sandy loams in the range of 7.7-15.7%. The slope was divided into 10 equal sections. The load is applied simultaneously in Sections 1, 6 and 10. At q = 0.33 MPa, the stability coefficient for clay is 1.066, and for sandy loam 1.79.

1 INTRODUCTION

The study of the stability of clayey slopes is an actual problem of geotechnics. This is due to the fact that most of the landslide slopes are represented by clay soils. Hill (1950), Morgenstern & Tchalenko (1967), Bjerrum & Landva (1966) and others are devoted to the development of methods for studying shear deformations of clay soils. Bishop & Bjerrum (1960), Lo (1970), Skempton & Petley (1967), Kulchitsky & Usyarov (1981), Osipov (1979), Kazarnovsky (1985) and others are devoted to the study of shear deformation patterns and strength parameters of clay soils.

It is of great interest to study the stability of a clay slope under various variants of surface loading.

For analytical studies, a calculation model of a clayey landslide-prone slope with geometric characteristics of the Bailovsky slope in Baku (slope height h = 80 m, slope angle β = 30°) was chosen. When solving the problem, the models and programs for a personal computer (PC) developed at VolgGASU based on the finite element method were used, including the results of studies given in the works of Tsvetkov (1993) and Bogomolov (1996), which allow, based on the solution of plane problems of elasticity theory determine the stresses at various points of the soil mass from the impact of the own weight of the soils and various surface loads, as well as the most probable fracture surfaces (MPFS) and the magnitude of the slope stability coefficients.

In the work of Tsvetkov (1993), based on the exact solution of the problem of elasticity theory for a weighty half-plane with a curvilinear boundary and the use of the technique for constructing the most probable fracture surface, the shape and location of which in the slope zone depend on the stress state and physical and mechanical characteristics of soils, formulas were obtained for determining the stability coefficients K of homogeneous slopes and slopes: at $\lambda \geq 0,1$

$$K = \frac{4}{7}(1+\mu)(a\lambda + b)\ \ tg\phi \tag{1}$$

at $0 < \lambda < 0,1$

DOI: 10.1201/9781003299127-58

$$K = \frac{4}{7}(1+\mu)\sqrt{10\lambda(d^2 + ctg^2\beta) + ctg^2\beta}\ \ tg\,\phi. \tag{2}$$

Here: stability parameter

$$\lambda = \frac{2c}{\gamma\ h\ tg\ \phi}; \tag{3}$$

c – adhesion; γ- density; ϕ- angle of internal friction; μ- soil lateral pressure coefficient; h- height; β- slope angle; *a, b, d* - dimensionless coefficients determined by the graphs.

The dimensions of the computational model are taken on the basis of the well-known position of the theory of elasticity that the boundary conditions practically do not affect the stress distributions if the boundaries of the region are removed from the considered part of the region by at least six of its largest dimensions.

The study area is divided into 17900 triangular elements connected at 9138 nodes. The breakdown was carried out in such a way that the elements had the smallest dimensions in the studied part of the area (Figure 1).

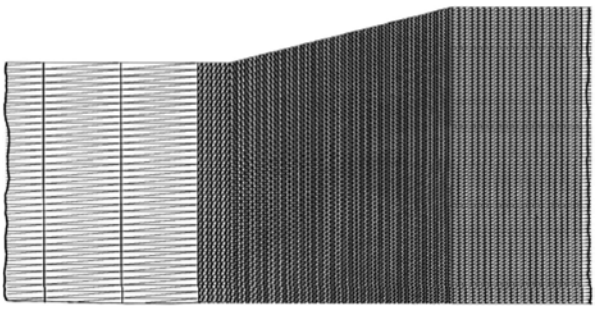

Figure 1. Breakdown of the studied slope into triangular elements.

The boundary conditions are set as follows: 1) there are no movements in the horizontal direction along the vertical boundaries of the design model; 2) there are no vertical movements along the lower horizontal boundary; 3) no restrictions are imposed on the movements of other points.

The initial data for solving the problem under consideration include soil properties (bulk weight γ, deformation modulus E, lateral pressure coefficient μ, cohesion c and internal friction angle φ of the soil), surface loads and boundary conditions.

In calculations, the average values of the physical and mechanical characteristics of soils with a change in their relative humidity from 0.6 to 0.9, based on approved Russian standards, are taken equal to: 1) for clays and loams - $\gamma = 1{,}9 \cdot 10^4$ N/m^3, $E = 48$ MPa, $\mu = 0{,}75$, $c = 0{,}019$ MPa, $\varphi = 20^o$; 2) for sandy loam - $\gamma = 1{,}8 \cdot 10^4$ N/m^3, $E = 49$ MPa, $\mu = 0.65$, $c = 0.011$ MPa, $\varphi = 34.5^o$.

In this case, the values of the loads q applied to individual sections of the slope surface varied from 0.2 to 0.4 MPa.

Figure 2 shows the design scheme, as well as the MPFS of the slope at $q = 0$ (unloaded slope) with the width b of a possible collapse prism.

According to the results calculated on a personal computer in tabular form, the coordinates X and Y (m) at the points of the MPFS are obtained; and at these points: angles α (degrees) between the tangents to the fracture line and the horizontal; horizontal, vertical and tangential stress components; holding and shearing forces; horizontal and vertical movements, as well as work produced by holding and shear forces. At the end of the tables, the areas of the diagrams of the holding and shear forces, as well as the sums of their work and the coefficients of slope stability K are given.

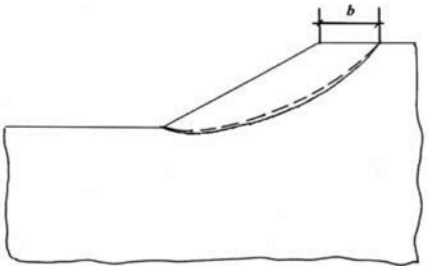

Figure 2. Calculation scheme of a loaded slope with an MPFS - (solid line for clays and loams, dotted line for sandy loam); *b* - width of possible collapse prism.

It should be noted that for the PC program used in this work, the slope stability coefficient *K* is calculated as the ratio of the holding and shear forces acting along the MPFS, and as the ratio of the work performed by these forces during the movement of soil massifs.

2 INVESTIGATION OF THE STABILITY OF CLAY SLOPES UNDER DIFFERENT FORMS OF LOAD DISTRIBUTION ON THEIR SURFACES

The influence of the direction of a uniformly distributed load on the stability of clay slopes was studied. It was revealed that changing the load slope angle from 0 to 30º leads to a decrease in the slope stability coefficient *K*; for clays (loams) 2.8 times; for sandy loam by 2.5 times. Therefore, a vertical uniformly distributed load reduces slope stability minimally.

The stability of clay slopes loaded with a triangular vertical load has been studied. The triangular distributed load was applied in such a way that the smaller triangle was at the base of the slope perpendicular to the day surface, the hypotenuse of the triangular load coincided with the slope surface. With an increase in the load *q* to 0.40 MPa, the values of the stability coefficients increase for clays and loams in the range of 8.2-21.3%, for sandy loams in the range of 7.7-15.7%. Thus, if, during the development of clay slopes, individual objects create a load identical to the triangular load on the slope surface, then the stability of the slope will increase.

3 INVESTIGATION OF THE STABILITY OF CLAY SLOPES UNDER VARIOUS VARIANTS OF APPLICATION OF A DISTRIBUTED LOAD IN LOCAL AREAS

Let us consider the influence of the vertical distributed load applied to local equal sections of the slope surface. We will divide the slope surface 160 m long into 10 sections 16 m long and sequentially apply a load with intensity $q = 0.25$ to each section; 0.33; 0.40 MPa.

In Figures 3–5, as examples, design schemes and MPFS are shown for a slope composed of clays (loams, sandy loams) and loaded in Sections 1, 5, 10 (the sections are numbered from bottom to top). The results of determining the stability coefficient of the considered slope for all 60 options are summarized in Table 1.

If we take into account that the coefficient of stability of an unloaded slope for clays and loams is 1.059, and for sandy loams - 1.792 (Table 1), then the following follows from the analysis. With the movement of the load from the bottom up, the slope stability coefficient decreases for clays (loams) by 7.9-9.9%, for sandy loams by 7.6-11.8%. The slope is most stable at the lower and least stable at the upper load positions, the stability coefficient in the first case is greater for clays (loams) by 3.8-6.0%, and for sandy loams by 4.9-8.1%, in the second case less than the similar coefficient K of an unloaded slope for clays (loams) by 4.4-5.0%, and for sandy loams by 3.1-4.6%. The stability of unloaded and loaded slopes is almost the same if the load is applied approximately in the middle of the slope.

The change in the stability of clay slopes was studied when their surface was loaded with a uniformly distributed load in several areas. The slope was divided into 10 equal sections, the

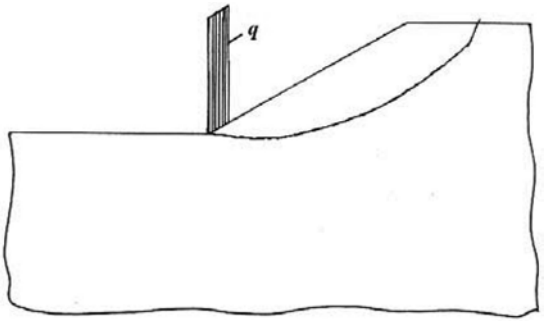

Figure 3. Calculation scheme under the influence of a load applied in section No. 1.

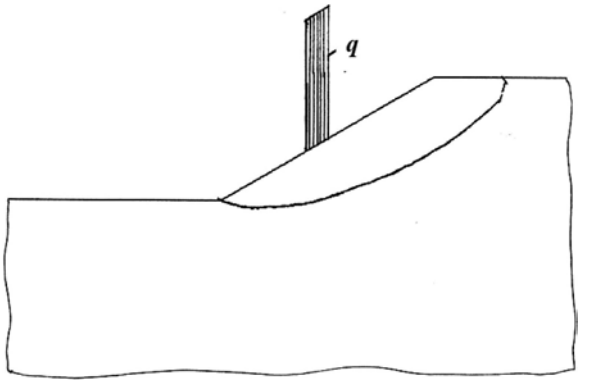

Figure 4. Calculation scheme under the influence of a load applied in section No. 5.

lower section - Section 1, the upper section - section 10. In Figure 6 shows the calculation scheme of the MPFS when the load is applied simultaneously in Sections 1, 6 and 10. At q = 0.33 MPa, the stability coefficient for clay (loam) is 1.066, and for sandy loam 1.79, i.e. compared to the unloaded slope, the stability coefficients remained practically unchanged.

Calculations have shown that at q = 0.25-0.40 MPa, the stability coefficients of the loaded slope are practically the same as compared to the unloaded slope (the difference does not even

Table 1. The dependence of the coefficient of stability of the slope, folded clay soils, on the position and magnitude of the local uniformly distributed load.

	K					
	Clays, loams			Sandy loam		
	q (MPa)			*q* (MPa)		
No. site	0,25	0,33	0,40	0,25	0,33	0,40
1	1,099	1,114	1,123	1,880	1,883	1,937
2	1,080	1,090	1,100	1,849	1,850	1,855
3	1,074	1,080	1,083	1,816	1,844	1,850
4	1,084	1,078	1,077	1,819	1,806	1,803
5	1,069	1,066	1,080	1,809	1,825	1,804
6	1,047	1,040	1,052	1,795	1,802	1,804
7	1,049	1,042	1,046	1,792	1,808	1,806
8	1,042	1,040	1,014	1,789	1,786	1,777
9	1,039	1,028	1,031	1,783	1,739	1,751
10	1,012	1,006	1,012	1,737	1,712	1,709

reach 1%). The results obtained allow us to conclude that the intermittent uniform loading of the slope practically does not change the stability coefficients of clay slopes. With intermittent uniform loading of the slope, each loaded section works according to an independent scheme. The load of the lower 1st section and the potential increase in the coefficient of stability of the slope caused by it compensates for the negative potential of the decrease in the coefficient of stability of the slope caused by the loads of the upper 10th section. The load of the central section 6 is neutral in relation to the stability of the slope.

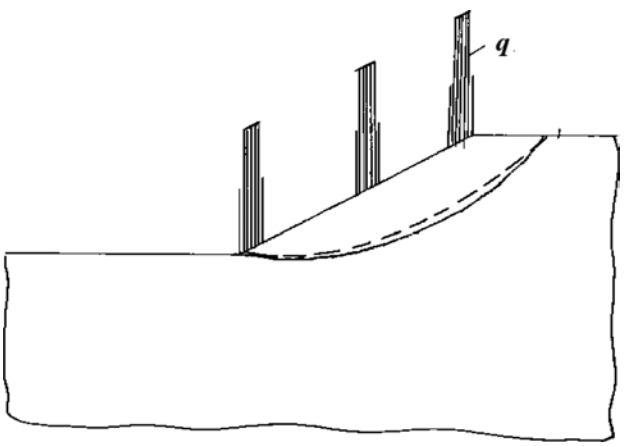

Figure 6. Calculation scheme, as well as the MPFS of a clay slope loaded with a uniformly distributed load in three sections (1, 6 and 10): solid line – clays (loams); dotted line - sandy loam.

Figure 7 shows the scheme and MPFS when the load is applied to Section 1 (q = 0.4 MPa) and to section 6 (q = 0.2 MPa). The calculations showed that the stability coefficient for clays (loams) is K = 1.125, and for sandy loams K = 1.909, i.e. with the last design scheme, the slope stability coefficient is on average 6.3% higher than that of the stability coefficients of an unloaded slope and a slope loaded according to the scheme shown in Figure 6.

These studies have confirmed the expediency of loading clay slopes with a triangular vertical load.

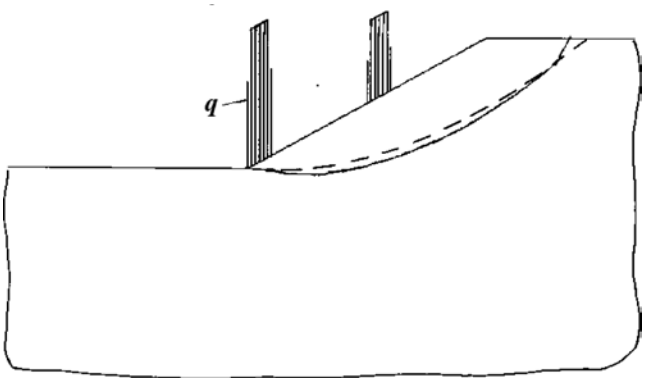

Figure 7. Calculation scheme, as well as the MPFS of a clay slope loaded evenly distributed load in the lower (Section 1) section q = 0.4 MPa and in the middle (section 6) section q = 0.2 MPa, solid line - clay (loam); dotted line - sandy loam.

4 CONCLUSIONS

1. Changing the angle of inclination of the load from 0 to 300 leads to a decrease in the coefficient of slope stability K; for clays (loams) 2.8 times; for sandy loam by 2.5 times.
2. Vertical uniformly distributed load minimally reduces slope stability.
3. A triangular distributed load, in which the hypotenuse of the triangular load coincides with the slope surface, increases the value of the stability coefficients K increase for clays and loams.
4. Intermittent uniform loading of the slope practically does not change the stability coefficients of clay slopes.
5. With the movement of the local load from the bottom up, the stability coefficient of the clay slope decreases.

Acceleration of consolidation of water-saturated loess subsidence massifs during their compaction by deep explosions

V.S. Shokarev
Research Institute Of Building Structures, Zaporozhye, Ukraine

F.G. Gabibov
Azerbaijan Research Institute of Construction and Architecture, Baku, Azerbaijan

ABSTRACT: The authors have developed technologies that significantly reduce the time of filtration consolidation of loess subsidence arrays during their compaction by deep explosions. According to the first new technology, explosive charges are installed in an array of moistened subsidence soil. The moment of sharp attenuation of the precipitation of the soil mass is determined, which makes it possible to determine the time for the initiation of the second series of explosions of charges installed above the charges of the first series. The number of series of exploding charges is accepted from 3 to 5. The duration of the period between explosions, depending on the composition of the soil, is taken from 1 to 15 days. The consolidation time is reduced by 4-5 times. According to the second new technology, the loess subsidence layer is divided into several separate layers.

1 INTRODUCTION

Trofimov (2003), Rendell (1989), Rozycki (1991), Pecsi (1993), Sajgalik (1991), Zarate & Blasi (1991) and others are devoted to research on the properties of loess subsidence soils.

The works of Abelev & Abelev (1979), Klepikov, Tregub & Matveev (1987), Mustafayev (1989), Aliyev (2005), Krutov, Kovalev & Kovalev (2013) and others are devoted to the development of effective construction methods on subsiding loess soils.

One of the cost-effective methods of deep compaction of subsiding massifs with a thickness of more than 10 m, in combination with other methods, is the hydraulic explosive method of deep compaction of subsiding soils. Litvinov (1977), Ryzhov (1995), Gabibov (2011) and others are devoted to the hydraulic explosive method of compaction of subsiding massifs.

2 INFLUENCE OF DEEP EXPLOSIONS ON THE PROCESS OF SOIL CONSLIDATION

Numerous experimental studies carried out on field sites in Zaporozhye (Ukraine) indicate that any violation of the structure of soft soil leads to one degree or another of accelerating the process of filtration consolidation. A particularly effective method of accelerating filtration consolidation is multi-series deep explosions in soaked loess subsidence soil.

The filtration consolidation equation is generally described by the equation

$$\frac{\partial \varepsilon_0}{\partial t} + na\frac{\partial \sigma_\mu}{\partial t} = \frac{k_f}{\rho_w}\nabla^2\sigma_\mu, \tag{1}$$

where is ε_0 - volumetric deformation of the soil; a - coefficient of volumetric compressibility of soil; n - soil porosity; k_f - filtration coefficient; ρ_w - density of water; ∇ - Laplace operator; σ_μ- pore pressure; t- time.

DOI: 10.1201/9781003299127-59

In the case of a plane problem, the consolidation equation is significantly simplified

$$\frac{\partial \sigma_\mu}{\partial t} = \frac{k_f}{\rho_w . a} \cdot \frac{\partial^2 \sigma_\mu}{\partial_{z^2}} . \tag{2}$$

Soil compressibility coefficient is determined from the experimental compression curve

$$e_f = e_s - a\, \ell n \frac{\sigma}{\sigma_s}, \tag{3}$$

where is e_s - initial value of the porosity coefficient; e_f - final value of the porosity coefficient.

Taking the mentioned coefficients constant, it is easy to determine that with two-way water drainage

$$k_f = \frac{0,2 \rho_w\ ah^2}{(1 - e_s)\, t_{50}}, \tag{4}$$

where is h - thickness of the soil sample in the device; t_{50} - time corresponding to 50% filtration consolidation.

The calculation data indicate that the process of filtration consolidation stretches for several years. So, with a subsiding soil thickness of 10-12 m, the estimated time of filtration consolidation is 4.8 years.

It has been experimentally established that the performance of one series of deep explosions reduces the time of filtration consolidation to several months, and two or three series of filtration consolidation to several weeks (Figure 1). Thus, it is achieved that the time of filtration consolidation practically does not hold back the pace of construction.

It remains to estimate the time of secondary consolidation. If the density of the soil in the process of multiple hydraulic explosive compaction changes from initial to critical, then the stabilization of the soil settlement will be more and more complete as the number of series of deep explosions increases (Figure 1).

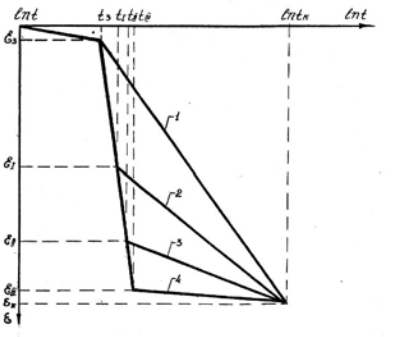

Figure 1. Acceleration of filtration and secondary consolidation of water-saturated loess loams by the energy of deep explosions: 1 – corrected curve of primary and secondary consolidation (before the explosion); 2 - acceleration of consolidation after the first series of deep explosions; 3 - acceleration of consolidation after the second series of deep explosions; 4 - acceleration of consolidation after the third series of deep explosions.

According to Buisman, the process of secondary consolidation of water-saturated structurally unstable soils is quite reasonably described by the equation

$$\varepsilon = \varepsilon_s + tg\, \alpha_1\, \ell n \frac{t}{t_s}, \tag{5}$$

where is ε_s - initial deformation of the soil; ε - current soil deformation; t_s, t - initial and current values of time; $tg\,\alpha$- coefficient of soil compressibility.

The same equation describes with acceptable accuracy the nature of the flow of soil sediment in time after deep explosions. After the first, second and subsequent series of deep explosions, we get

$$\begin{aligned} \varepsilon_1 &= \varepsilon_{s_1} + tg\,\alpha_1\, \ell n \frac{t_1}{t_{s_1}}, \\ \varepsilon_2 &= \varepsilon_{s_{21}} + tg\,\alpha_2\, \ell n \frac{t_2}{t_{s_2}}, \\ &\cdots\cdots\cdots\cdots\cdots\cdots \\ \varepsilon_n &= \varepsilon_{sn} + tg\,\alpha_{n1}\, \ell n \frac{t_n}{t_{sn}}, \end{aligned} \tag{6}$$

If in the initial period (before explosions) the process of filtration consolidation prevailed, then due to a series of deep explosions, the specific effect of filtration consolidation can be almost imperceptible. Then the time of filtration consolidation from soil soaking will be obtained in the form

$$\Delta \ell n\, t_w = \ell n\, t_w - \ell n\, t_s. \tag{7}$$

The time during the transition of the soil from the initial to the final density, spent on plastic deformations of the secondary consolidation, is determined from the formula

$$t_p = t - t_f - t_w, \tag{8}$$

where is t - time of final deformation.

The increment of filtration consolidation time after each new series of explosions rapidly decreases and tends to zero, and the total filtration consolidation time becomes much less than the time spent on plastic deformations of secondary consolidation.

In Figure 1, attention is drawn to the absence of a smooth transition from the filtration area to the secondary consolidation area. This is due to a sharp increase in water loss from the soil in the initial period of time after deep explosions. A sharp inflection of the filtration and secondary consolidation areas indicates that not only the filtration area is reduced, but also part of the non-linear area of the secondary soil consolidation.

3 DEVELOPMENT OF TECHNOLOGY FOR DEEP COMPACTION OF SUBSIBLE LOESS SOILS BY SEVERAL SERIES OF EXPLOSIONS

The authors have developed a new technology for compacting loess subsidence soil by several series of deep explosions. Wells are being drilled in which explosive charges are installed for the first series of explosions.

By leveling the sediment of the soil according to the established marks, the change in the rate of sedimentation of the soil and its individual layers in time is fixed. According to the graph (Figure 2) $S(t)$, the moment of sharp attenuation of the sedimentation of the massif and the time of sedimentation from the explosion of the next series of deep explosions are determined. Then, deep charges of the second series of explosions are installed above the charges of the first series and explosions of the charges of the second series are performed. In the future, all operations are repeated.

By comparing the sinking between series of deep blasts, we determine the sufficient degree of compaction of the soil massif and the time for completion of blasting. For example, if with two explosions the precipitation reached 60%, and with three explosions 80% of the potential, then blasting is stopped after the condition is met

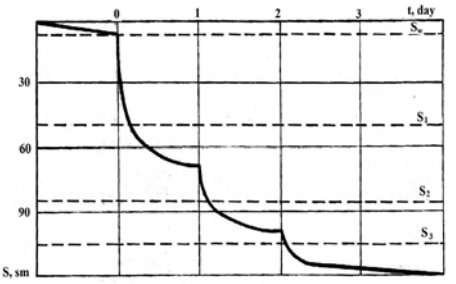

Figure 2. Graph of subsidence of the subsidence soil surface in time during successive blasting of explosive charges in three series: S_W, S_1, S_2, S_3 - precipitation after soaking, the first, second and third series of explosions.

$$S_n = 0,25\, S_{n-1}, \tag{9}$$

where is S_n - *sinking of the final series of deep explosions;* $S_{n\text{-}1}$- sinking of the previous series of deep explosions.

In the example shown in Figure 2, the condition $S_n < 0.25\ S_{n\text{-}1}$ is satisfied by the result of soil sinking after the third series of explosions. The time intervals between series of single deep explosions are taken equal: from 3 to 7 days for light and medium loams; from 7 to 15 days for loess clays.

4 DEVELOPMENT OF A TECHNOLOGY FOR DEEP COMPACTION OF SLOWING LESS SOILS BY EXPLOSIONS IN INDIVIDUAL LAYERS OF THE MASSIF

New technology for deep compaction of a subsiding massif includes the formation of contour trenches, waterproofing the compacted soil massif along the perimeter of the contour trenches, the formation of wells, the placement of explosive charges in these wells, filling the wells with coarse-grained material, soaking the soil to a state of fluid consistency, and explosions of explosive charges with soil sinking under its own weight. The soil mass is divided into several layers by thickness. The soaking of the soil and the initiation of explosions are carried out in separate layers, starting from the bottom layer. After the formation of wells, their walls are fixed with casing pipes, and before explosions, the walls are freed from fastening to the height of the compacted layer. The thickness of each layer of soil in the massif is taken equal to its depth, at which the rock pressure increases to 0.9 - 0.975 kg/cm^2. When compacting the lower layers, water is squeezed out of them and partially moistens the overlying layer. As you can see, the number of series of explosions is equal to the number of installed layers of compacted soil. The time to decrease the consolidation approximately corresponds to the decrease in the time of consolidation according to the first technology.

5 CONCLUSIONS

1. A particularly effective method of accelerating filtration consolidation is multi-series deep explosions in soaked loess subsidence soil.
2. It has been experimentally established that the performance of one series of deep explosions reduces the time of filtration consolidation to several months, and two or three series of filtration consolidation to several weeks.
3. On the basis of analytical studies, it was revealed that the increment of filtration consolidation time after each new series of explosions rapidly decreases and tends to zero, and the total filtration consolidation time becomes much less than the time spent on plastic deformations of secondary consolidation.

4. A new technology has been developed for compacting loess subsidence soil by several series of deep explosions. Graphically determine the moment of sharp attenuation of sedimentation of the array and the time of precipitation from the explosion of the next series of deep explosions. The time intervals between series of single deep explosions are taken equal: from 3 to 7 days for light and medium loams; from 7 to 15 days for loess clays.
5. According to the second new technology, the soil mass is divided into several layers by thickness, and the soaking of the soil and the initiation of explosions are carried out in separate layers, starting from the bottom layer. The thickness of each layer of soil in the massif is taken equal to its depth, at which the rock pressure increases to 0.9 - 0.975 kg/cm^2.

Evaluating the shear strength of agar gum-treated gypseous soil

Ahmed Hammad Hussein
Department of Civil Engineering, College of Engineering, University of Samarra, Samarra, Iraq

Farouk M. Muhauwiss, Naser A. Hassan & Arwa Faaeq Theyab
Department of Civil Engineering, College of Engineering, Tikrit University, Salah Al Deen, Iraq

ABSTRACT: Gypseous soil is strong in its dry state but has real problems when exposed to water, and this requires an effort to improve it and reduce these problems. Soil chemical improvement is a well-known method and leads to environmental problems related to the emission of greenhouse gases and the impossibility of recycling the improved soil in the future. This encouraged the creation of alternatives to stabilizers with a large carbon footprint. Biopolymers are environmentally friendly materials because of their low carbon footprint, resulting in the creation of improved and sustainable geo-structures. Recently introduced as soil improvement materials, they provide significant reinforcement and in lower quantities than conventional binders such as cement. Agar biopolymer was used to analyze the strengthening properties of gypsum soil. Four gypsum contents were used for soil, which are 8, 25, 45 and 59%, agar content by adding (1, 2, 3)%, The curing time for the prepared samples is 14 days before the tests and obtaining the results. The results showed that the resistance of gypsum-agar mixtures was significantly increased even under water saturated conditions compared to pure soil. The value of (Φ) increased by 24.4% and 32.33% for the soil samples improved by 3% agar in the dry and wet conditions, respectively, while the percentage increase in the cohesion (C) of the improved gypsum soil increased by 67.89% and 45.95% for the dry and wet samples respectively.

1 INTRODUCTION

Gypsum soil is regarded as one of the most challenging unsaturated soils to work with while constructing roads and structures. The presence of gypsum (Hydrated Calcium Sulphate (CaSO4.2H2O)) in the soil alters its mechanical and physical qualities, as well as making it more susceptible to water. When water from a strong rain falls on this type of soil, it causes a reconfiguration and a change in volume (reduction). Because the soil loses the bond between the particles and becomes weak to withstand and resist the load applied to it, based on the soil nature and geological structure, the primary soil density, soil structure, the imposed formal stress, and the amount of wetting, this change in volume significantly causes structural failure (Ahmed, Al-Hadidi, & Mohammed, 2020). In civil engineering, soil is classed as Gypsum soil based on the quantity of gypsum content in it, independent of soil color or form. Some scholars suggested that a particular percentage of gypsum should exist, such as 3%, 4%, or 6% as a lower limit (H, 2007). These gypsum rates have a significant impact on the physical and mechanical properties of soil, and this impact varies depending on the quantity of gypsum present.

Problem soils are treated to enhance the engineering properties of the soil. Conventional chemical and mechanical stabilizers to enhance soil properties. Among these stabilizers are lime, cement, chemical plaster, epoxy, phenoplast, polyurethane and acrylamide with the improvement and reinforcement offered by these technologies but these additives have a significant negative impact on the ecosystem (Worrell et al., 2001),(Afolabi, Francis, & Adejompo, 2012),

DOI: 10.1201/9781003299127-60

(Latifi et al., 2017), (Joga & Varaprasad, 2019). The production of the most widely used stabilizers such as lime and cement causes significant emissions of carbon dioxide and nitrogen oxides. In addition to disturbing the ecosystem by changing and increasing the acidity of the soil, it can cause desertification to its low, degrading nature. In addition to chemical germs that have been reported to be toxic and/or dangerous, except for sodium silicate (Smitha & Sachan, 2016). These disadvantages, make stabilization of problem soils with environmentally friendly, harmless alternative stabilizers very necessary and important. Researchers (Mitchell, Santamarina, & engineering, 2005); (Ivanov, Chu, & Bio/Technology, 2008); (Cole, Ringelberg, Reynolds, & engineering, 2012) present attempts to stabilize soils with biotechnical techniques for geotechnical purposes. Presented new stabilizers for soils and gave important results that are biopolymers of a biological nature. Agar, xanthan, chitosan, guar etc. have been used as biopolymers that provide a water-insoluble gel provided by organisms such as algae, bacteria and fungi and prepare hydrogen bonds that form the branched structure of polymeric chains within the soil structure (Smitha & Sachan, 2016); (Joga & Varaprasad, 2019).

A few researchers have used biopolymers to enhance the shear strength and hydraulic conductivity of erosive soils and sandy clays (Orts et al., 2007); (Nugent & Zhang, 2010); (Smitha & Sachan, 2016). (Chang, Cho, & Materials, 2012) and Chang (Chang, Prasidhi, Im, Cho, & Materials, 2015b). Show biopolymers of agar, gellan and beta-glucan have been used successfully to improve the Cheonan sandy soil and the strength of the remaining Korean clay soil. However, the stability of expansive soils has not been examined using the biopolymer mixture. Expansive soil cause serious problems for geotechnical structures due to their excessive collapse and shrinkage behavior due to the dissolution of gypsum salts. In addition, the shear resistance decreases when saturated with water to a higher degree. Hence, in this study an attempt was made to stabilize gypsum soil treated with biopolymer agar. The biopolymer Agar was chosen, because it gives the highest mechanical strength (Khatami & O'Kelly, 2013),(Kantesaria, Chandra, & Sachan, 2021). Agar provides a dense covering and coating that envelops soil particles resulting from the generation of a dense gel network, and this also ensures less biodegradability (Khatami & O'Kelly, 2013). From the above scientific literature, we note the lack of studies on the problems of gypsum soil in the field of biopolymer treatment.

This experimental research was conducted to study the shear strength of gypsum soil treated with agar gum. A solution of 1%, 2% and 3% By soil weight of agar gum which was prepared at optimum water content was added to the soil with different gypsum content. The treated mixture cured for 24 days. Shear properties were evaluated by a series of tests. The microstructure of the treated mixture was explored by scanning electron microscopy (SEM) testing.

2 MATERIALS

2.1 *Soil*

Gypsum soil samples were taken at a depth of one meter in an area of 18 km west of Ramadi city, Anbar, Iraq from places southwest of Lake Tharthar, north of Ramadi city in Iraq, between N43° 15'E32'33°, Anbar, Iraq. Four gypsum contents were used for soil, which are 8, 25, 45 and 59%, which were designed with 1, 2, 3 and 4 soils, respectively. All soils were classified as Poorly graded sand (SP) according to the standard soil system (ASTM D2487-17e1). The chemical composition of gypsum soil was analyzed as shown in Table 1. A modified Proctor test was performed to determine the maximum unit weight (MDD) and the ideal moisture content (OMC) as shown in Table 2.

Table 1. Chemical properties of soil samples.

Properties	Soil 1	Soil 2	Soil 3	Soil 4
Gypsum content %	8	25	45	59
Total soluble salts (T.S.S)%	28	37.13	52.34	64.28
Organic matters (O.M)%	0.45	0.38	0.28	0.13
pH value	8.06	7.8	8.1	8.07

Table 2. Physical properties of soil samples.

	Grain size distributions (ASTM D422, 2007)			Atterberg limits (ASTM D4318)		Compaction test (ASTM D1557)		
Soil type	USCS	uniformity coefficient (Cu)	Curvature coefficient (Cc)	LL%	PL%	γ_{field} (kN/m³)	γ_{dry} max (kN/m³)	OMC(%)
1	SP	6.3	0.64	35	N.P	14.3	17.3	11
2	SP	7.8	0.55	34	N.P	13.5	16.7	12
3	SP	6	0.58	29	N.P	14.8	15.8	11
4	SP	7	0.78	27	N.P	13.2	15.5	12

2.2 *Agar*

Agar is a biopolymer, which form a dissolved suspension at a high temperature (ie 85-90 °C) and coagulated at lower temperature (ie <50 °C) as a gelatinous structure. Agar is a naturally growing polysaccharide, frequently found in the cell walls of some species of red algae such as Gelidium and Gracilleria, which belong to the family Rhodophycae of red marine plants (Smitha and Sachan 2016). Agar gum is a mixture of agaropectin and agarose. Agarose which is responsible for gel formation, when heated and mixed with soil. Agar biopolymer powder used in the study is bacteriological grade bought from local mar-kets.

2.2.1 *Physico-chemical properties*

The physicochemical activities of guar galactomannan and other polysaccharides are determined by how they behave in water. On dispersion, guar gum swells and/or dissolves in polar solvents, forming strong hydrogen bonds. It only forms weak hydrogen bonds in non-polar solvents. The rate of guar gum solubility and viscosity progress generally increases as particle size, pH, and temperature decrease. In the presence of soluble salts and other water-binding agents such as sucrose, hydration rates are reduced. Table 3 General composition of guar gum (Mudgil, Barak, & Khatkar, 2014).

Table 3. General composition of guar gum.

Constituent	Percentage
Galactomannan	75–85
Moisture	8.0–14
Protein (N x 6.25)	5.0–6.0
Fiber	2.0–3.0
Ash	0.5–1.0

3 PREPRATION OF SAMPLES

Agar gum solution was prepared with the optimum moisture content by adding (1, 2, 3)% By soil weight and mixing it properly in the magnetic device. It is added to the soil to make a mixture treated with agar-biopolymer. Then the mixture is transferred to molds 50 * 50 mm (length * width) and 20 mm high with two layers of compaction to obtain the Max dry density Prepared for the direct shear test. Samples were extracted and dried at room temperature for 14 days, while half of the dried samples were soaked in distilled water for 24 hours before being subjected to direct shear tests to represent the “soak condition”. Also, reference samples were remolded without treatment for each of the four types of gypsum soils for the purpose of comparison with the improved samples. All samples were wrapped in plastic bags during the treatment period. All specimens were prepared at optimum moisture content and maximum soil Dry unit weight. To study the interaction in the structure of the soil-agar mixture, Small cubic samples of side length of 10 mm were taken from cylinder molds with 100mm height and 50 mm diameter. After the curing period 14 day was checked by SEM.

4 RESULTS AND DISCUSSION

4.1 *Shear strength*

Figure 1a-d shows the relationship between maximum shear and normal stresses by direct shear test. From these figure, it is noticed that the shear strength of the agar-treated mixture increases in the dry and wet conditions with the increase of the agar content, and the highest increase in strength was when 3% agar was added to all four contents of gypsum. The value of (Φ) increased by 24.4% and 32.33% for the soil samples improved by 3% agar in the dry and wet conditions, respectively, while the percentage increase in the cohesion (C) of the improved gypsum soil increased by 67.89% and 45.95% for the dry and wet samples respectively at the same agar content 3% Table 4. These strengthening mechanisms may be due to particulate interaction and conductance of the pore area. The agar gum modified the bonding features of the treated soil granules because the agar solution encapsulated the soil granules and bridged them by electrical bonding, and/or provided a biofilm. As a result, the shear cycles required to overcome the bridging of soil grains increased (Chang et al., 2020).

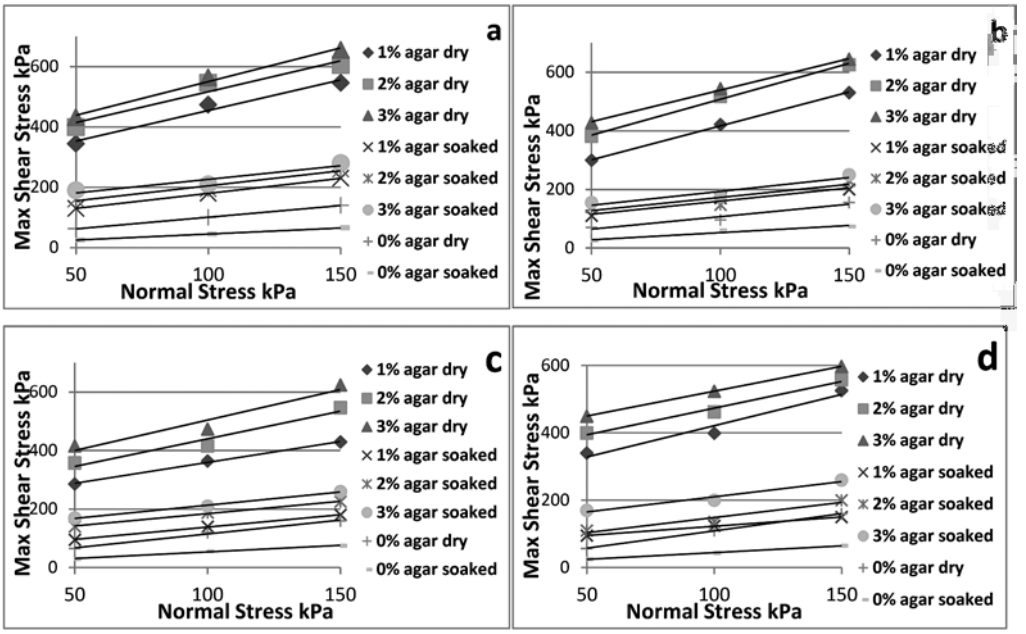

Figure 1. The relationship of shear stress with Normal stress in the dry and soaking condition and with different Agar contents: (a) soil 1, (b) soil 2, (c) soil 3 and (d) soil 4.

In the wet state, the biopolymers absorb moisture and develop hydrogels, and increase the viscosity of a liquid between the pores. This absorption property increases the shear strength of the soil. In addition, the biopolymer hydrogels reduce soil permeability and promote pore blockage, and this reduces seepage and surface erosion. The above mechanisms are involved in enhancing the erosion shear stress in addition to increasing the cohesion and contact between the soil grains (Kantesaria et al., 2021).

When the agar content increases, the internal friction angle in dry conditions Figure 2 a,b and the cohesion Figure 3 and Table 4 increases. This is because drying, which occurs as a result of the drying of the biopolymer hydrogel increases the angle of friction between soil particles that is similar to saturated conditions due to the condensation of agar biofilms, which enhances soil agglomeration by surface coating and antiparticle bridging (Smitha & Sachan, 2016).

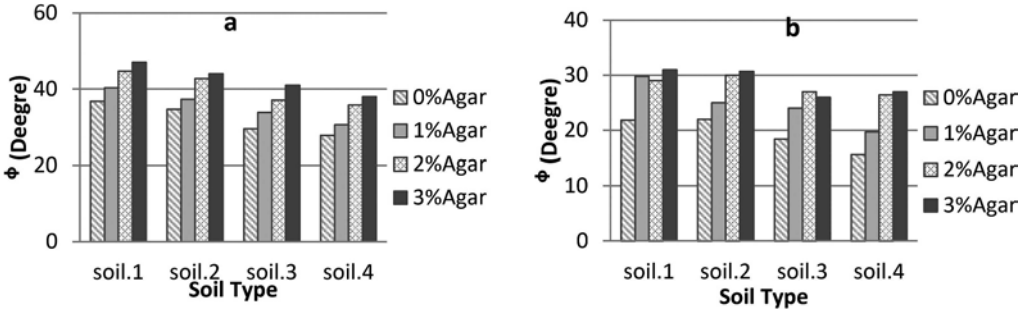

Figure 2. The relationship angle of internal friction and soil type for agar-treated samples after 14 days curing: (a) dry condition and (b) wet condition.

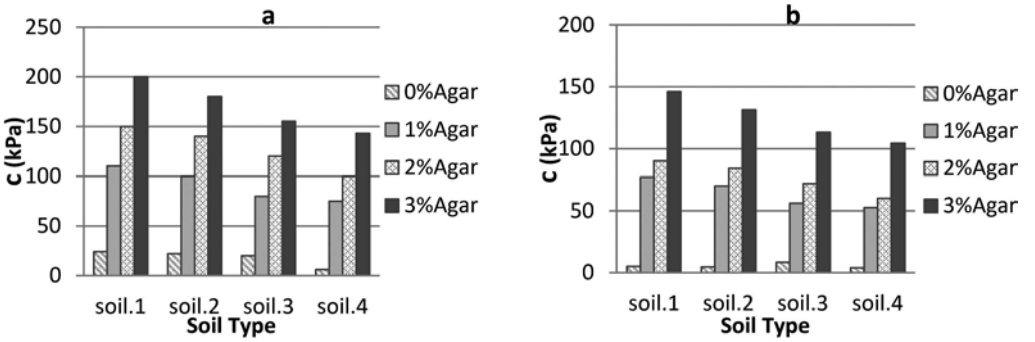

Figure 3. Cohesion and soil type relationship for agar-treated samples after 14 days curing: (a) dry condition and (b) wet condition.

Table 4. Shear parameters for reference and treated samples by Agar.

Parameter	Agar ratio %	soil.1		soil.2		soil.3		soil.4	
		Dry	Wet	Dry	Wet	Dry	Wet	Dry	Wet
Φ (Degree)	0	36.8	21.8	34.65	22	29.53	18.4	27.8	15.6
	1	40.3	29.8	37.3	25	33.8	24	30.6	19.7
	2	44.7	29	42.7	30	37.1	27	35.8	26.4
	3	47	31	44	30.65	41	26	38	27
C (kPa)	0	24	5	22	4.66	20	8.33	6	4
	1	110	77	100	70	80	56	75	52.5
	2	150	90	140	84	120	72	100	60
	3	200	146	180	131.4	155	113.15	143	104.39

4.2 *Scanning electronic microscopy (SEM)*

The microstructure changes of samples treated with agar observed by SEM images. Microscopic analysis was performed on soil 3 only that a gypsum content of 45%. Figure 4a shows the natural state of the soil 3. The compacting of the soil at the optimum moisture content leads to the movement of soil particles inside the pores and their aggregation without any clear physical bonds due to the lack of cohesion between the particles, so the particles move on each other without restrictions.

The pores were more compact in Figure 4a and there is a more dense soil mass, but there is no special bond between the fine particles. In Figure 4b with the addition of 2% agar

biopolymer make an agar hydrogel layer on soil mass. In the case of compacted cohesive soils, the soil particles unite in the form of aggregates. A hydrogel coating on this aggregate binds the soil and provides reinforcement between two sets of aggregates (Kantesaria et al., 2021), which were not initially in contact. Thus, the increase in the total contact area due to the formation of a matrix of sand and biopolymer leads to an increase in the shear strength of the soil.

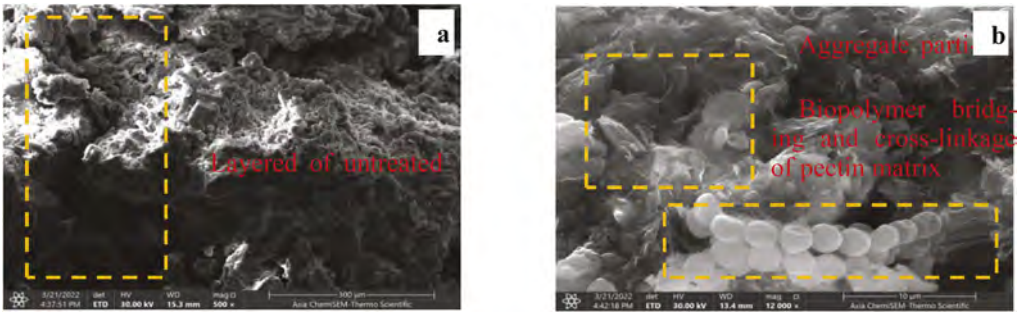

Figure 4. SEM of (a) untreated soil and (b) soil-pectin mixture with 2% pectin after 14 day curing.

5 CONCLUSIONS

The study determined the shear strength, properties and characteristics of the reinforcement after conducting a series of tests to check the direct shear. The structural modification of the treated soil was also studied by assay and SEM. Then it was concluded from the following study:

- Shear coefficients (c, Φ) decrease with increasing gypsum content, and the decrease is greater with water soaking in the soil. Φ decrease 36.8, 34.65, 29.53 and 27.8 for soil 1, 2, 3 and 4 respectively for dry condition and were 21.8, 22, 18.4 and 15.6 for for soil 1,2,3 and 4 respectively at wet condition. C decrease 24, 22, 20 and 6 for soil 1, 2, 3 and 4 respectively at dry condition and 5, 4.66, 8.33 and 4 for soil 1, 2, 3 and 4 respectively at wet condition.
- The shear strength of the treated samples improved and increased with the increase of the agar content, and the improvement efficiency ranged between 3.5 to 5.4 times at a concentration of 3% agar and according to the gypsum content as a result of the interplay of granular cohesion provided by the agar gum biogels. The curing stage of the biopolymer-fixed models is important to obtain the best reinforcement resulting from the addition of biopolymers in different concentrations.
- The value of (Φ) increased by 24.4% and 32.33% for the soil samples improved by 3% agar in the dry and wet conditions, respectively, while the percentage increase in the cohesion (C) of the improved gypsum soil increased by 67.89% and 45.95% for the dry and wet samples respectively at the same agar content 3%.
- Through pictures (SEM) it was concluded that the contact area increased between the gypsum soil particles provided by the sand matrix and the biopolymer as a result of the agar gum hydrogel, which enhanced the physical bonding within the improved soil structure.

ABSTRACT: Pavlodar is one of the main industrial regions of Kazakhstan, with a historically formed territorial and production complex, which is an important part of the national wealth of our country. Increasing volumes of construction of all forms of ownership of this city predetermine further increase of engineering design and survey works. However long-term observations show that technogenic impacts of buildings and structures on the geological environment cause changes in it is elements, which are manifested in the development and activation of such engineering and geological processes as erosion and destruction of the coastal slope, gullying, waterlogging and salinization of soil. Therefore, in order to minimize the damage caused by these processes, it is necessary to develop in a timely development scientifically based urban and architectural planning solutions, where the task of generalizing the results of the current engineering and geological surveys with the purpose of typing geotechnical conditions of the city. The presence of the typing will allow to carry out a more rational study, identification of features and assessment of geotechnical conditions for such issues as, reduction of engineering and geological surveys, increase of economic efficiency. The article considers questions of typification of engineering and geological conditions of the city territory, as the main factor is studied geological structure. An analysis of the physical and mechanical properties of the soils with the study of strength and deformation characteristics of the soils located in the territory of the city of Pavlodar was also performed.

1 INTRODUCTION

As it is well known that any construction begins with the construction of the most important part – the base. The reliability of the building in the processes of construction and operation on foundation which perceives external influences and transfers to the foundation, and the reliability of the foundation and base depends on physical and mechanical properties of foundation soils, which are studied and analyzed in detail engineering and geological surveys.

The territory of the Republic of Kazakhstan is characterized by a wide variety engineering and geological conditions. The issues of designing, construction and operation buildings and structures in difficult engineering and geological conditions are becoming increasingly relevant, taking into account the decrease in the area with favourable soils. However engineering and geological data of surveys in the regions of our country are almost not generalized and are most often in paper form. As a rule, companies engaged in engineering research accumulating impressive archives, most often not very open in the exchange of data.

All this complicates the conduct of survey works, it is more difficult for prospectors to predict development engineering and geological processes, and most importantly, there are cases of duplicate works, sometimes full exploration in the same territories [Zhussupbekov et al. 2021].

DOI: 10.1201/9781003299127-61

Therefore, the timely development of scientifically new urban and architectural planning solutions for the territory of our country on the example of Pavlodar city will be a relevant decision.

2 CHARACTERISTICS OF THE OBJECT OF STUDY

2.1 *Characteristics of the object*

Pavlodar – the largest city of North Kazakhstan located between 41°57′-54°27′ northern latitude and 73°25′-79°20′ eastern longitude from Greenwich and covers an area of 127.5 thousand square kilometers. It is bordered by four regions of the Republic of Kazakhstan (North Kazakhstan, Akmola, Karaganda, East Kazakhstan) and two entities of the Russian Federation (Omsk region, Altai region). The territory of the region, stretching more than 450 km from north to south and over 420 km from west to east, is crossed by the Irtysh River, the main waterway of the region. Currently, there are 10 rural districts, 3 cities of regional subordination, 4 villages, 169 rural districts in the region [Smailov 2015].

Here, in addition to traditional industrial enterprises and the extraction of hydrocarbon raw materials, large-scale industry is developed, with which the Pavlodar city acts as one of the major industrial centers of the Commonwealth of Independent States. The region accounts for 7% of industrial production, 70% of coal production, 3/4 ferroalloys smelting, 40% of electricity generation and oil products processing from the level of the republic [Zhakupov et al. 2014]. Increasing volumes of construction of all forms of ownership of this city predetermine further increase of engineering design and exploration, it is enough to note, renovation and construction of new neighborhoods, such as Saryarka and Dostyk.

2.2 *Characteristics of engineering and geological conditions*

In geological and structural terms, the area of the Pavlodar region is located in the zone of junction of two large geological structures - the Kazakh folded country (Saryarka), which occupies about 25% of the area of the region, and the West Siberian lowland.

Geomorphologically, the location of the territory at the edge of the extensive accumulation of the southern plain of the West Siberian Lowland has led to it is long-term development as a lacustrine, lacustrine-alluvial and alluvial plain since the middle of the Oligocene. The main features of the relief of the territory were created by erosive and accumulative processes of the middle and upper Quaternary time, as well as the modern stage of geological history. The main genetic groups of relief forms are identified: alluvial, lacustrine-alluvial and lacustrine, of various geological ages, from the middle section of the quaternary system to the modern one. The alluvial group includes two terraces above-floodplain and the floodplain of the Irtysh River. Most of the territory is occupied by the second floodplain terrace of the Irtysh river, which is the next oldest relief element. The first terrace above-floodplain of the Irtysh River is covered by a cloak of cover deposits and is characterized by the still quite preserved relief of the former floodplain. It is all indented by numerous lowers, which have the form of a channel bend.

The *geological* structure of the territory of Pavlodar city involves lacustrine-alluvial deposits of the Neogene age (N), which are subdivided into deposits of the Pavlodar suite ($N_{1\text{-}2}$pv), Aral suite (N_1ar) and Kulunda suite (al$N_{1\text{-}2}$kln), overlain from the surface by the upper Quaternary and modern deposits of alluvial-deluvial (ad$Q_{II\text{-}IV}$) and technogenic (tQ_{IV}) genesis.

The *groundwater* of the above-floodplain terraces occurs at a depth of 1 to 17 m (usually 2-5 m). In the last 25-30 years on the territory of Pavlodar city, in particular in the area of the industrial zone of the city, there has been a systematic rise in the level of groundwater. Groundwater depth - 3-5 meters or more.

Physical and geological processes in an urban area are appear processes as erosion and destruction of the coastal slope, gullying, waterlogging and salinization of soil, which in turn cause the changes elements of geological structure. Therefore, in order to minimize the damage, caused by these processes it is necessary to timely development scientifically based urban planning and architectural and planning decisions in order to typify engineering and geological conditions of the city. Engineering and geological typing is one of the practically significant

procedures in the assessment of the conditions building and structures. It allows a more rational study, identification of features and assessment engineering and geological conditions to solve many issues of planning, design and rational use of natural resources [Astvacaturova 2009].

In the course of the study the construction zoning was performed according to the floors and residential buildings and facilities. Three main building areas were identified for residential development in Figure 1:

– building zone of multi-storey residential buildings;
– building zone low-rise residential buildings up to 4 floors;
– building zone with individual residential buildings.

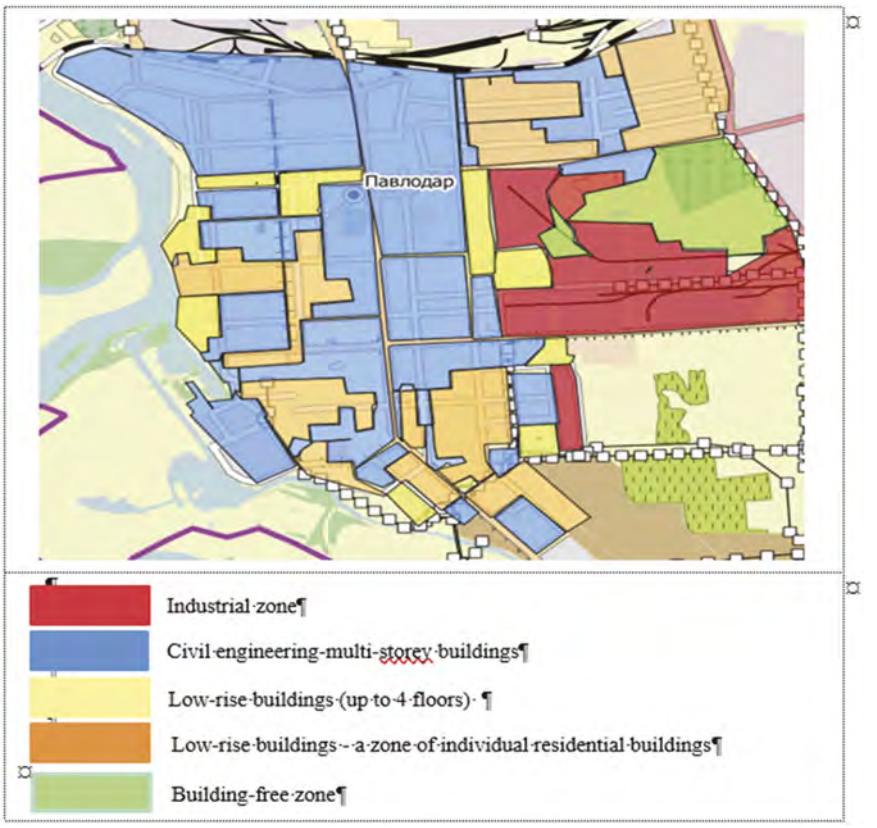

Figure 1. Scheme of construction zoning of the territory of Pavlodar city.

In order to objectively assess of the urban development taking into account various geotechnical conditions geoinformation database program was created, with the help which the regional soil conditions of Pavlodar city were analyzed before a detailed study. In the process of developing Geoinformation Database, the built-up area of multi-storey buildings was investigated.

3 STUDY OF GEOTECHNICAL CONDITIONS OF PAVLODAR CITY USING GEOINFORMATION DATABASE PROGRAM

3.1 *Methodology for the creation geoinformation database*

To create the "Geoinformation Database of Pavlodar city" (Figure 2) published and stock materials of engineering and geological surveys initially were collected and analyzed. Results of boring

of 523 engineering and geological boreholes in 2014-2021 were selected as sources. Composition and physical-mechanical properties studied for 2147 soil samples surface to depth 25 m.

The geoinformation database has a hierarchical structure consisting of two levels and including the following main four functions:

1) General management function (Host DB).
2) Input data management function (Local DB).
3) Data extraction and processing (AP) function.
4) Data augmentation function (Layer DB).

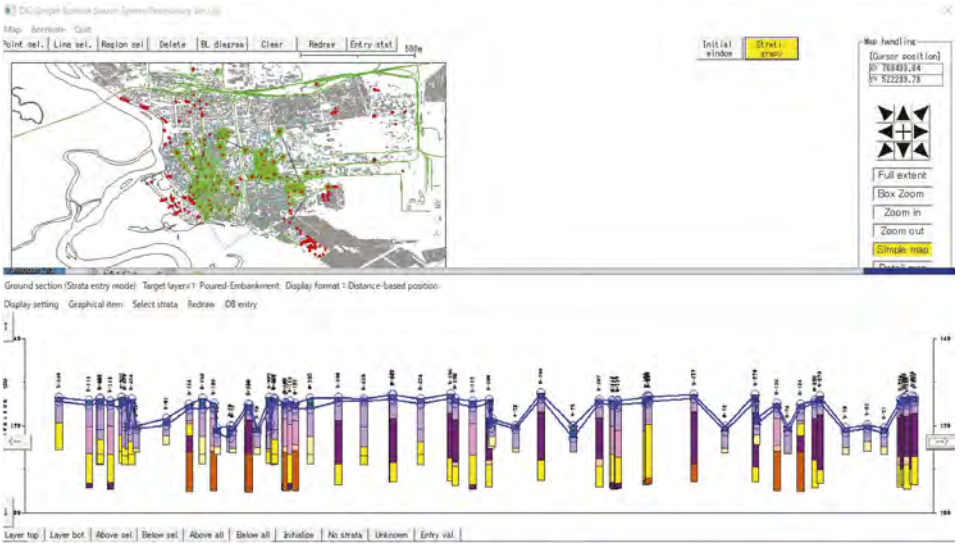

Figure 2. General view of the "Geoinformation Database program of Pavlodar city".

The first level of the hierarchical structure is responsible for the general management function, which provides general management and organization of the graphic process. The second level of the hierarchy includes the remaining three functions that perform preliminary processing of the initial information and ensure the organization of the graphic process [Alibekova 2009].

In the process of executing the initial information of the second level, the following stages of work can be distinguished:

1. The survey area was determined, and a map of the survey area is created in CAD program, i.e., AutoCAD.
2. The location of each borehole was indicated and labeled on the survey area map.
3. The exact X and Y coordinates were determined for each borehole.
4. A set of data was collected in the Excel table to log the information about each borehole.
5. Data on all layers, depth of occurrence, age of rocks are indicated [Zhussupbekov et al. 2019].

3.2 *Research of geotechnical environment of the Pavlodar city*

With the help "Geoinformation Database of Pavlodar city" geotechnical conditions were analyzed, in particular, 5 main engineering-geological elements were identified [Abisheva 2021] and special geotechnical maps of the occurrence of soils of Quaternary deposits and deposits of Neogene age with physical-mechanical characteristics were built in Figure 3:

EGE-1 — *technogenic deposits* (tQ_{IV}) represented by the topsoil (EGE-1a) and backfill (EGE-1b). Topsoil is represented by humus sandy loam with plant roots, the backfill is composed of sandy loam with sand and construction debris of 20%.

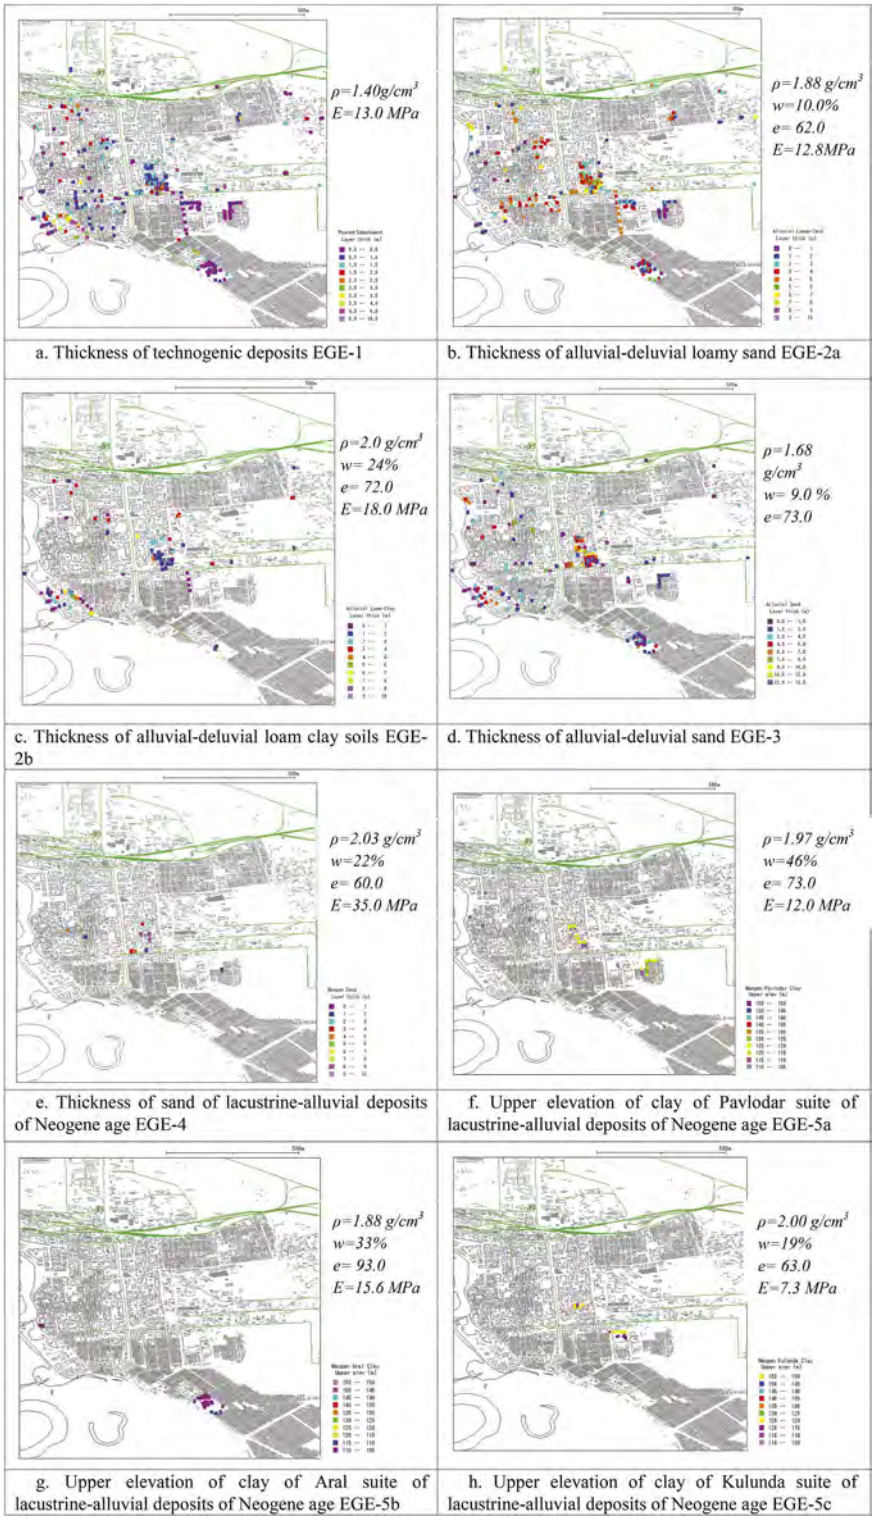

Figure 3. Special geotechnical maps of Pavlodar city.

EGE-2 — *alluvial-deluvial deposits of Upper Quaternary and modern ages* (adQ_{II-IV}), consisting of carbonated, subsident sandy loam (EGE-2a) from solid to fluid consistency and clay loam (EGE-2b). According to [SP RK 1.02–102-2014], the sandy loam in this layer is a specific soil, when soaked with water it has subsidence properties under household and additional loads. Capacity of this soil is measured from 0.9 up to 10.3 m.

EGE-3 — *alluvial-deluvial deposits of Upper Quaternary and modern ages of sand* (adQ_{II-IV}) is located at the depth of 2,5 to 8.0 m. According to the field description, all sands are similar in color, mostly yellow-brown, dense, saturated with water, with single layers of soft-plastic clay, differ only in the amount of the determining fraction according to the granulometric composition.

EGE-4 — *lacustrine-alluvial deposits of neogene age (N)* represented by sand of various size. According to the granulometric composition, the sands of the deposits are medium-sized, coarse. The thickness of the sands increases from south to north and varies from 0.6 to 9.7 m.

EGE-5 — *lacustrine-alluvial deposits of neogene age* includes clays that are represented by lacustrine-alluvial deposits of the Pavlodar suite (EGE-5a), the Aral suite (EGE-5b), the Kulunda suite (EGE-5c). Lacustrine-alluvial deposits of the Pavlodar suite are represented by brown clay and loam, with a thickness of 1.6 to 5.2 m. Lacustrine-alluvial deposits of the Aral suite represented by clay from light gray to gray green, from hard-plastic to semi-hard, ferruginous, manganese, with inclusions of gypsum up to 10% and marl up to 5%. The thickness of clays varies from 2.5 to 16.2 m. Lacustrine-alluvial deposit of the Kulunda suite are represented brownish-gray, greenish-brown, greenish-gray clays, containing calcareous-marl nodules ranging in size from 0.1 to 0.2 cm and interlayers of sand. Clay thickness varies from 0.5 to 7.6 m.

4 CONCLUSIONS

The assessment of the geotechnical conditions of the territory of Pavlodar city served as the basis for the creation of a geoinformation database program. This geoinformation database system allows the development of engineering and geotechnical maps on geotechnical zoning of the city according to the classification of soils and the criteria of homogeneity formed areas. The economic efficiency of a geoinformation system and developing engineering and geotechnical maps will significantly reduce the time and costs during the survey and design work, as well as in the construction of foundations for buildings and structures in difficult ground conditions. Implementation of geoinformation database ensures sustainable development of megacities, models and approaches in urbanistic development of geo infrastructure megapolises and small cities of the new generation.

Typification of engineering and geological conditions of the city territory using GIS

N.T. Alibekova, A.K. Tleubayeva & A. Abisheva
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The relevance of the study is due to the rapid growth of construction of buildings and structures in large cities of the Republic of Kazakhstan over the past thirty years. An engineering-geological assessment of the area is necessary to support the decision-making process on the location of structures, as well as to ensure that the construction of facilities is carried out with less negative environmental impact, accompanied by a reduction in danger and damage to both construction, society, and the economy. As a result, it is necessary to systematize and analyze previously obtained data using modern geoinformation systems (GIS). The relevance of the introduction of GIS in geotechnical research is due to the fact that geoinformation systems and technologies allow creating, storing, analyzing, processing and providing the consumer with spatially distributed information, where the main means of communication for visualizing geotechnical data are special geotechnical maps, so how modern GIS have a wide arsenal of basic methods of spatial analysis that can and should be used to solve the problems of typification of engineering-geological conditions. The results of this work demonstrate the ability of GIS technologies to analyze engineering and geological conditions and zoning development areas according to the types of bases and foundations in such cities of Kazakhstan as Astana and Pavlodar.

1 INTRODUCTION

The formation of an information engineering-geological model of the terrain is the main task of engineering-geological research. This kind of model should contain in an analytical or synthetic form all the data necessary to solve problems related to the placement of building complexes and structures, assess the impact of engineering and geological measures on the natural environment and plan measures for its transformation. At the present stage of development, engineering-geological maps of zoning are used for this purpose, supplemented by engineering-geological sections, an explanatory note, and various tables. The methodology of creation of maps of engineering-geological zoning, developed in the main theoretical positions of N. Nikolaev & F. Savarensky (1939), I. Popov (1951, 1969), is based on consistent zoning of the studied territory on the area, increasingly homogeneous in terms of engineering and geological conditions [Tsotsur 1976].

Zoning is the main tool for flexible regulation in cities when planning urban development, which is a sustainable form of control over the use of land in settlements. Construction zoning of urban space is the division of the residential area of the city into zones with different number of storeys. One of the main goals of construction zoning is the correct placement of the main types of buildings in the city, considering the relief and engineering-geological conditions, the most economical use of the territory both in new construction and in the reconstruction of residential areas. To take into account engineering-geological factors in zoning, it is necessary to know the history of the

DOI: 10.1201/9781003299127-62

development of the territory in the anthropogeny and the current state of the rocks, the main engineering-geological features of the territory that have been created throughout the history of its geological development. Today, the study and use of natural resources, rational economic development, environmental protection, and monitoring, making practical decisions related to the geological environment are impossible without reliable information support [Kozlovskii 2010].

Since the beginning of the twenty first century, there has been a tendency to use digital materials in working with paper primary sources. The problems of the accumulation, processing and storage of geological engineering information should be addressed through the introduction and improvement of automation processes and computer facilities and their subsequent development.

2 BASES OF CONSTRUCTION OF THE GEOINFORMATION DATABASE

GIS in engineering-geological surveys is considered, first, as a means of processing spatial data of the geosystem for obtaining new knowledge and presenting them in the form of special geotechnical maps. According to several authors, the introduction of formal procedures in cartographic work makes it possible to automate the daily and labor-intensive stages of mapping, thereby freeing up time for experimentation and creativity in the field of cartographic modeling and map design [Dyshlyuk et al. 2015].

GIS capabilities applicable in engineering and geological surveys:

- input, accumulation, storage and processing of digital cartographic and geotechnical information;
- construction of thematic maps based on the obtained data, reflecting the current state of the geosystem;
- study of the dynamics of changes in the geotechnical situation in area and time;
- construction of graphs, tables, diagrams;
- modeling the development of the geotechnical situation in various environments and studying the dependence of the state of the geosystem on engineering and geological conditions, characteristics of foundations and construction objects;
- obtaining comprehensive assessments of the condition of construction facilities based on various data [Alibekova 2009].

The development of the "Geoinformation Database program" provides for the collection of geotechnical survey data with its own inherent format that expands the concept of communication of databases [Zhussupbekov & Alibekova 2013].

The main management system of the Geoinformation Database program (DIG-system) has a hierarchical structure consisting of two levels and including the main functions:

1) general management function; 2) input control data function; 3) function of data extraction and processing; 4) data augmentation function.

The first level of the hierarchical structure is responsible for the general management function, which provides general management and organization of the graphic process. The second hierarchical level includes functions that perform preliminary processing of source information and provide organization of the graphic process.

The initial information used in the program is divided into the two main sections:

1. Constant datasets (local data base), included directly in program text (for example, a city map, coordinates and characteristics for obtaining graphic files) (Figure 1).
2. Initial data, prepared directly by the user from the materials of engineering and geological surveys and entered during the execution of the program (Figure 2).

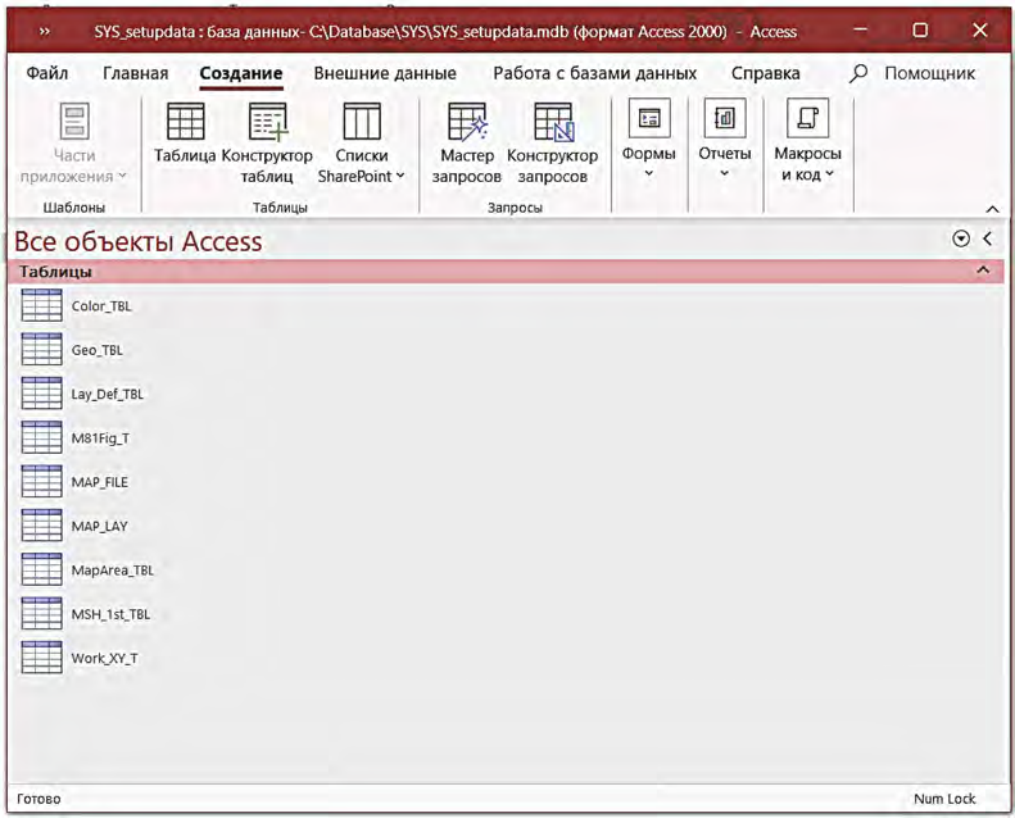

Figure 1. Local data base.

3 TYPIFICATION OF ENGINEERING AND GEOLOGICAL CONDITIONS IN KAZAKHSTAN USING GIS

3.1 *Geoinformation system for Astana*

Astana is a city in the north–east of Kazakhstan, which in 1997 received the status of the capital of the Republic of Kazakhstan and is one of the youngest capitals in the world. For less than 30 years, a modern Euro-Asian-style city has grown up on the site of a provincial town in the middle of the steppe, with skyscrapers, original architectural structures, broad avenues, and spacious areas. The super-accelerated pace of design and construction of the young capital of Kazakhstan requires targeted study, forecasting and management of geological aspects of both existing and planned buildings and structures.

In 2008, the program "Geoinformation Database of Astana" was created for the first time to evaluate engineering and geological studies of Astana (Figure 3), which allowed analyzing regional soil conditions before a detailed study. On the territory of Astana there are six main engineering-geological elements (EGE), diverse in origin and age (Figure 4) [Zhussupbekov et al. 2012].

In addition, with the help of the program "Geoinformation Database of Astana", special geotechnical zoning maps were created by types of foundation and optimization of the lengths of driven piles for buildings of the 2nd (normal) level of responsibility, taking into account the type of foundation (Figure 5) [Zhussupbekov et al. 2012].

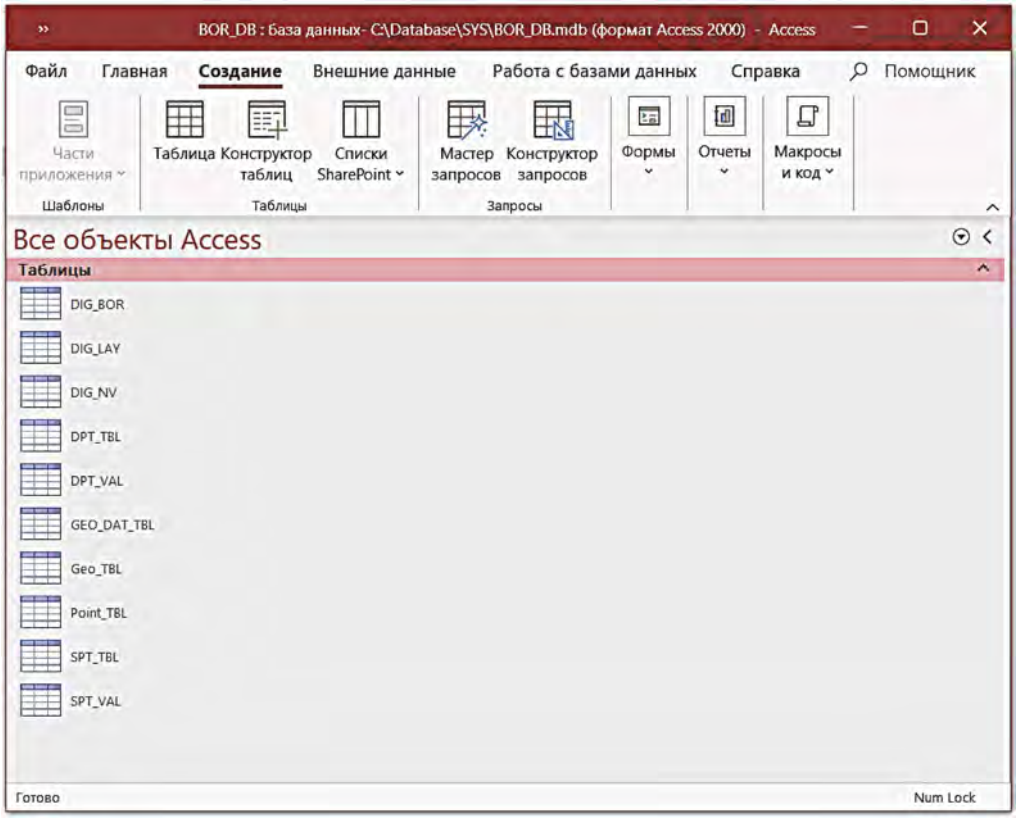

Figure 2. Source data base.

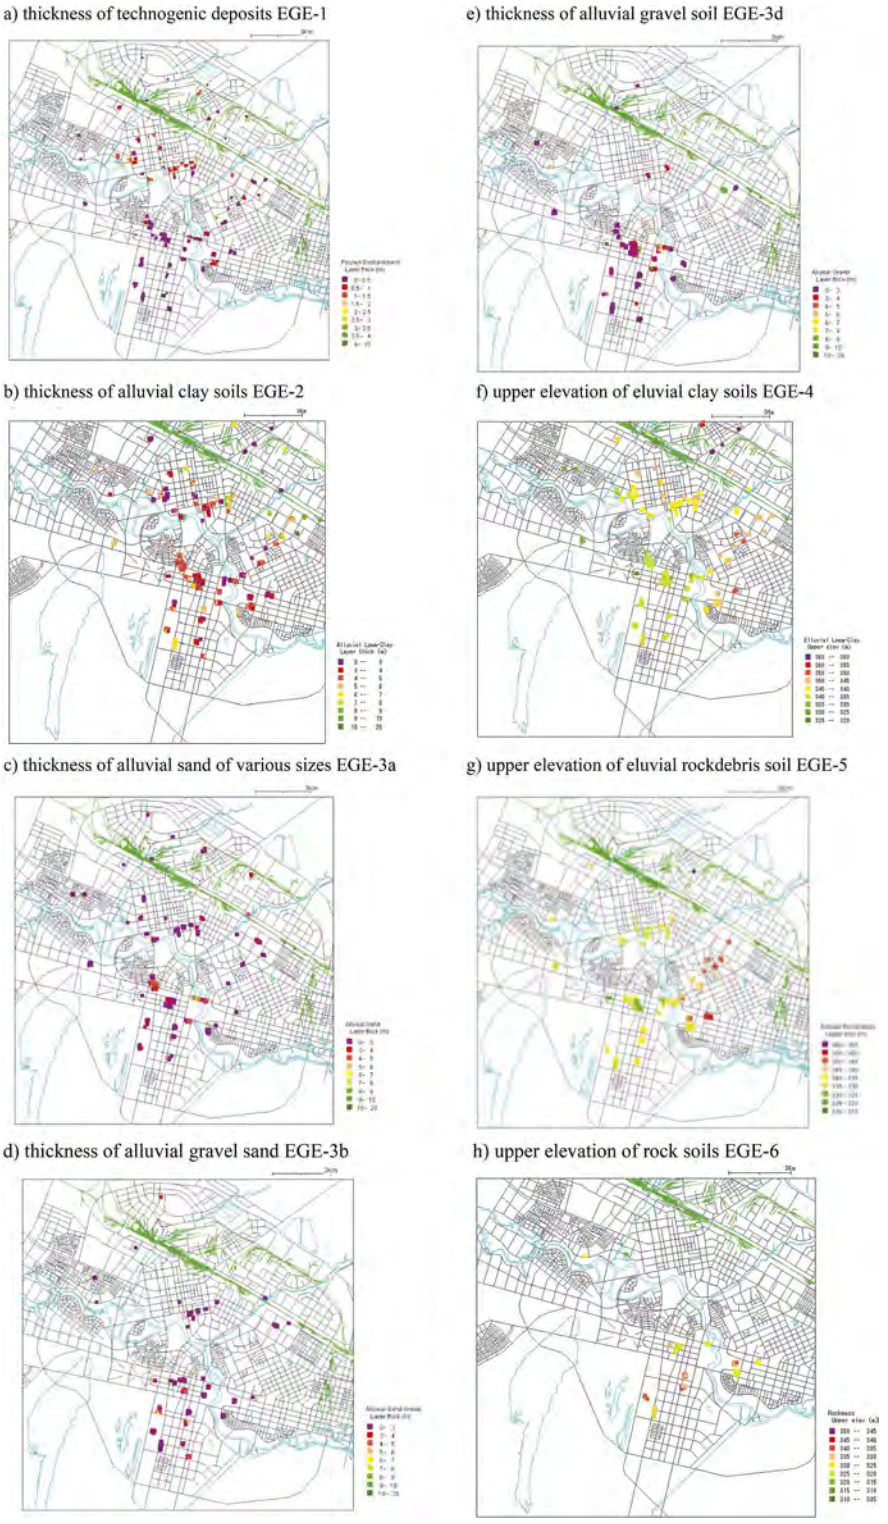

Figure 4. Engineering and geological maps of Astana.

a) geotechnical zoning map by type of foundation

b) geotechnical zoning map for optimizing the lengths of driven piles

Figure 5. Special geotechnical maps of Astana.

3.2 *Geoinformation system for Pavlodar*

Pavlodar is the center of industrial and cultural development in the Republic of Kazakhstan. It is located 450 km northeast of national capital Astana.

In 2022, for the evaluation of engineering and geological research in Pavlodar, the program "Geoinformation Database of Pavlodar" was created for the first time (Figure 6), which also made it possible to analyze regional soil conditions before a detailed study.

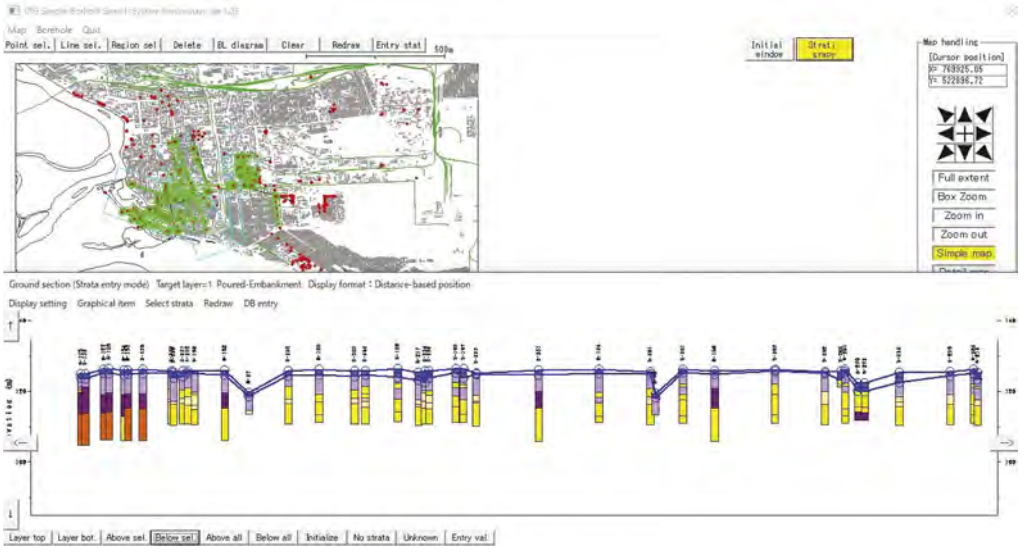

Figure 6. General view of the program "Geoinformation database of Pavlodar".

With the help "Geoinformation Database of Pavlodar" geotechnical conditions of the city territory were analyzed five main engineering-geological elements (EGE) were identified [Abisheva 2021] and special geotechnical maps of the occurrence of soils of alluvial-deluvial deposits and lacustrine-alluvial deposits of Neogene age were built in Figure 7:

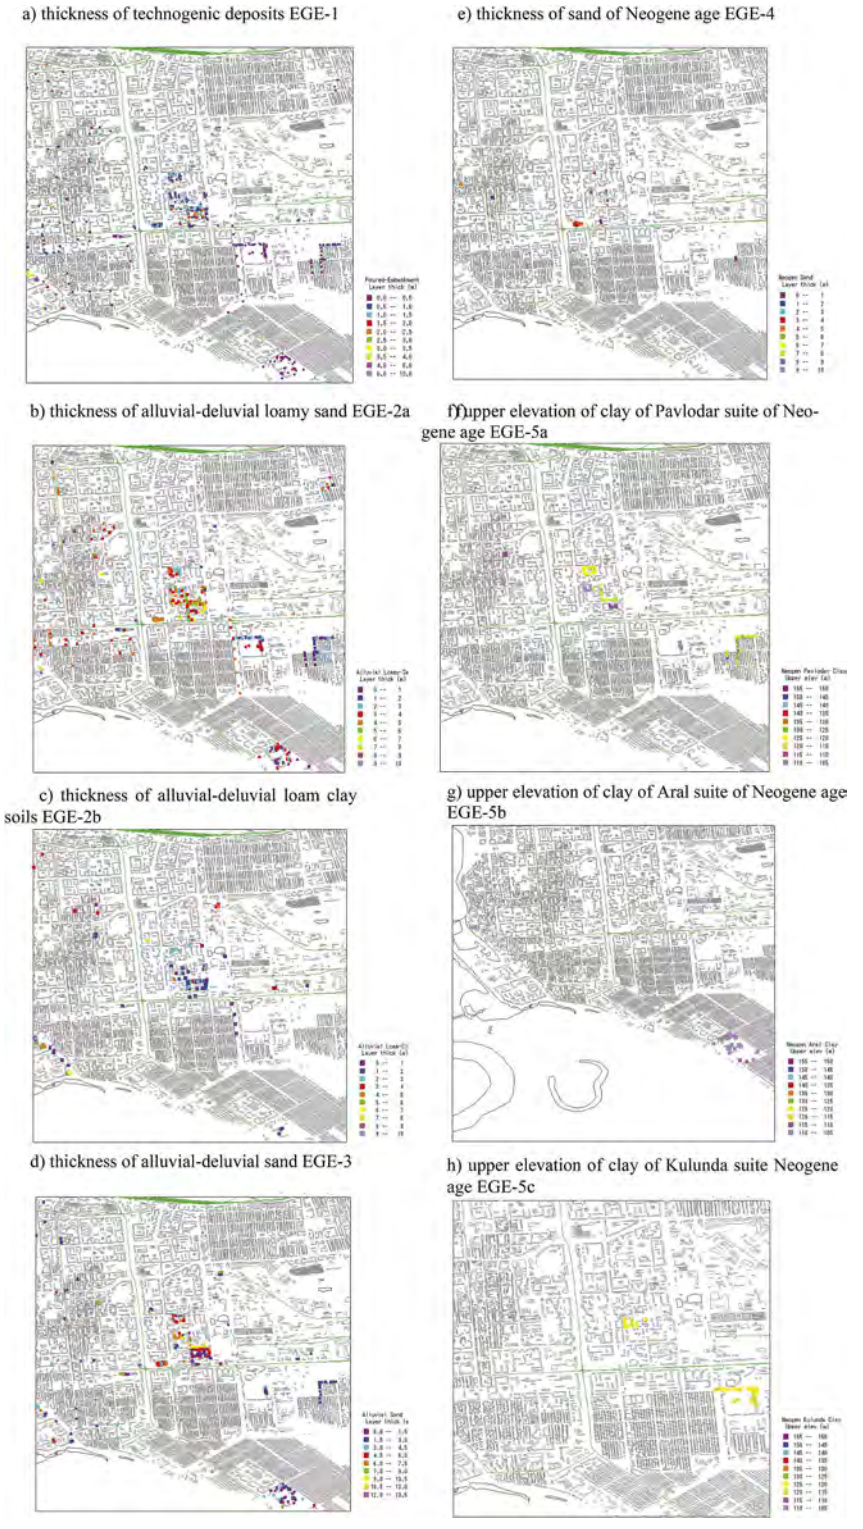

Figure 7. Engineering and geological maps of Pavlodar.

4 CONCLUSIONS

The results of the study suggest that the engineering and geological conditions of the two cities are different. The territory of Astana is represented by a diverse complex of soils, such as loams with interlayer of sandy clay loam and clays, gravel sands, medium-sized sands, silty soils, clays with lenses and layers of sandy loams, gravelly sands and gravel soils, as well sandstones, which are inter bedded with siltstones and mudstones. At the same time, it should be emphasized that groundwater in the undeveloped territories of the capital is at a depth of 5 m, and in most of the built-up areas at a depth of 0 to 2 m. From what has been said, it becomes obvious that most of the city's territory is in a flooded state, which is one of the reasons for the use of pile foundations in the construction. In turn, subsidence soils are most common in the territory of the city of Pavlodar, where the specific soil is a swelling sandy loam, from solid to fluid consistency. The groundwater of the above-floodplain terraces of the city's territory lies at a depth of 1 to 11 m, most often at a depth of 3 to 5 m.

As a result of consideration of this issue, it was found that with the help of special geotechnical maps obtained as a result of the development of geoinformation databases for the city of Astana and Pavlodar, it is possible to quickly obtain the necessary information for the purpose of substantiation when solving problems of industrial and civil construction, namely, typification of engineering-geological conditions and planning of urban development. These data not only systematize already known information, but also significantly accelerate the processing and analysis time for creating new projects, as well as significantly reduce the time and cost of exploration and design work.

Comprehensive study of the mutual influence of closely erected foundations of reconstructed buildings

A.Zh. Zhussupbekov & A.T. Mukhamejanova
Eurasian National University, Nur-Sultan, Kazakhstan

K.A. Abdrakhmanova
NJC "KarTU named after Abylkas Saginov", Karaganda, Kazakhstan

ABSTRACT: A complex of studies of the mechanism of interaction of closely erected foundations with a soil base has been carried out. Based on the generalization of the obtained results of field experiments and field observations, a universal method for calculating the precipitation of foundations of reconstructed buildings has been developed.

The results of complex studies of the mechanism of interaction of closely erected foundations with the ground base are presented. A universal method is proposed for calculating the sediment of foundations that are being built closely, which allows for the design to take into account local changes in compressibility and the stress state of the base due to mutual influence. Comparison of the results of theoretical and experimental studies showed acceptable reliability of the proposed methodology.

1 INTRODUCTION

The existing methods for calculating sediments based on the theory of linearly deformable bodies are designed to calculate idealized soil, do not allow predicting the actual size of the active (compacted) zone of the foundation, and therefore are unacceptable for determining the sediment foundations of reconstructed buildings designed taking into account local hardened and overlapping stress zones in the base caused by compaction and mutual influence of foundations [1].

Let us consider the nature of the development of sediments of the bases of neighboring foundations for three cases of their interaction (Figure 1.), where lpr is the permissible distance between them.

Case 1, when at l = epr (Figure 1a) the isolation of the active zones of the base 1 and 1′ of both foundations is ensured, and their sediment S develops independently of each other.

Case 2 corresponds to the condition l < lpr (Figure 1b) and the simultaneous construction of adjacent foundations, which leads to their roll towards the overlap of active zones 1 and 1′.

Case 3 corresponds to the condition l < lpr (Figure 1c) and the sequential loading of adjacent foundations, which will lead to their roll towards the foundation being erected in the second turn.

One of the main drawbacks of the methods for determining precipitation regulated by building codes is the uncertainty in the choice of compressibility characteristics of the foundation soils, namely the use of an increasing coefficient mk = 2 . . . 6 for the transition from the compression module (Ec) to the die module (S), which significantly reduces the reliability of the results of the calculations performed [2].

Our research has shown that the straightening of the compression curve adopted during the surveys in the area of compacting loads of 0.1. . .0.3 MPa leads to significant errors, in particular, to a decrease in the foundation precipitation by 28%, and the deformation of the base in various zones by 20%, 34% and 51%.

DOI: 10.1201/9781003299127-63

Based on the generalization of the results of complex studies of the mechanism of interaction between the foundation and the foundation, the authors proposed a computational model based on the idea of volumetric compression of soils under the action of the greatest main normal stresses forming a compacted zone in the base. The essence of this approach to the prediction of deformations of the soil base is, as noted above, to use for this purpose solutions of the theory of linearly deformable bodies to determine stresses. At the same time, precipitation is calculated without the use of a deformation modulus, taking into account the real law of compaction of a particular soil by using porosity coefficients along the compression curve corresponding to the actual stress state of the base of the projected object.

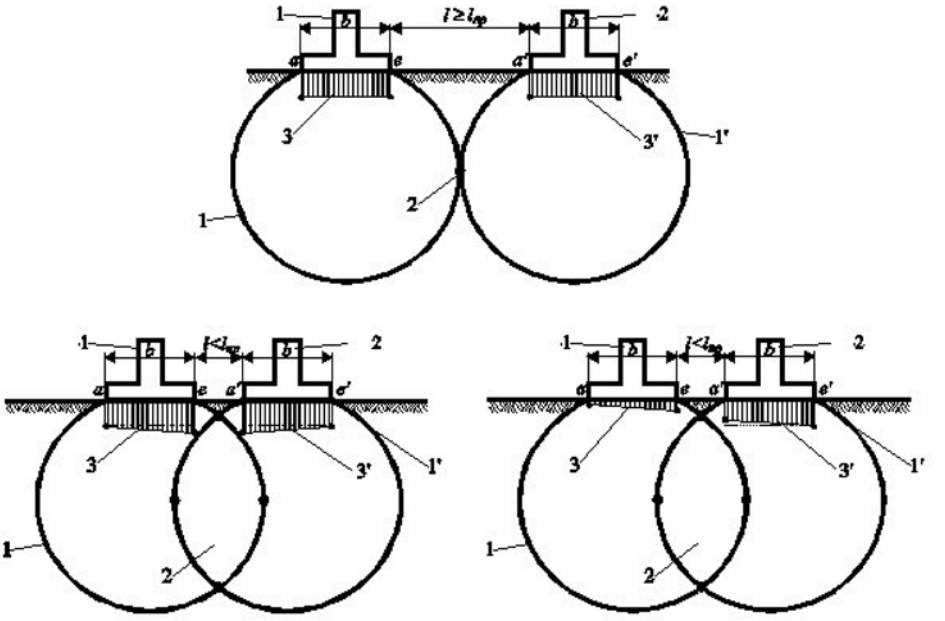

Figure 1. Mutual influence of neighboring foundations on the precipitation of their bases. a - the foundations are not affected by the neighboring; b and c – the foundations are affected by the neighboring, are built simultaneously and sequentially, respectively; 1 and 1′ – the boundaries of the active zones of the bases of neighboring foundations; 2 – the area of overlap of the active zones of the foundations; 3 and 3′ – the assumed plots of the sediment of the bases of neighboring foundations.

2 EXPERIMENTAL STUDIES

Experimental studies of the nature of the mutual influence of neighboring foundations were carried out by simulating their operation in the field by sequentially loading closely spaced two rigid round dies with a diameter of 0.8 m. Stamp experiments were carried out on two sites composed of relatively homogeneous clay soils, significantly differing in compressibility.

The purpose of the experiments is to study the patterns of mutual influence of two adjacent stamps during their sequential loading.

To achieve this goal, the following tasks were set during the experiments: 1) assessment of the size of the soil compaction zone under stamp 1, loaded in the first place; 2) study of the influence of the compaction factor of the stamp base 1 on the nature of the development of precipitation of the adjacent stamp loaded in the second place 2; 3) study of the nature of the development of the roll of the previously loaded stamp 1 in connection with the additional loading of part of its base by the neighboring stamp 2, loaded in the second turn; 4) measurement of the precipitation of the soil surface near the stamps; 5) investigation of the stress-strain state of the bases of adjacent stamps during their sequential loading.

The solution of the tasks of the experiment required conducting experiments on bases composed of homogeneous clay soils. Therefore, when choosing experimental sites, special attention

was paid to the factor of uniformity of the soil composing the assumed compressible thickness under the experimental foundations. The analysis of the data of engineering-geological studies presented in Table 1 showed that the soils of the base of the studied neighboring stamps for experimental sites No. 1 and No. 2 differ significantly in the quality of their physical and mechanical properties. In the experiment at site No. 1, the stamps are based on reliable soils - refractory loams with relatively good construction properties. Site No. 2 is composed of weak soils - ribbon loams in a fluid state, characterized by low strength and high compressibility.

Table 1. Physical and mechanical characteristics of the soils of experimental sites No. 1 and No. 2.

Experimental site	Name of soils	γ gs/cm^3	W	I_L	c, MPa	φ, degree	E_o, MPa
№ 1	The loam is refractory	1,98	0,25	0,36	0,015	17	8,2
№ 2	Fluidplastic loam	1,87	0,36	1,09	0,005	20	4,6

In the course of studies, deformations (stamp deposits and deep movements of the foundation soil) were measured at 37 points (site No. 1) and at 18 points (site No. 2). In addition, in the experiments conducted at site No. 2, vertical normal stresses were measured at 10 points of the base of neighboring stamps by means of the design of B.I. Dalmatov, A.V. Golly and the movement of soils using screw marks with indicators and deflection meters [3].

The stamps were located at a distance of 1.25 D between their centers and were loaded with steps up to pressures along their soles of 0.2 and 0.12 MPa, respectively, at sites No. 1 and No. 2. To assess the size of the soil compaction zone under stamps 1, screw stamps in the base were installed at different depths from the level of the stamp sole and distances from its vertical axis along the grid in increments of 0.125D and 0.25D.

Analysis of the test results of stamp No. 1 according to the "full loading and unloading" scheme at both sites allowed us to establish the actual dimensions of the soil compaction zone at sites No. 1 and No. 2, respectively: depth Ha = 1.25D and 1.60D; width Ba = 1.58D and 1.98D; removal of zone la = 0.29D and 0.49D. It was found that even with a lower load in conditions of weak soils, the size of the studied zone is much larger.

Full loading of stamps 2 at sites No. 1 and No. 2 led to their rolls away from stamps 1, respectively: 0.0030 and 0.0035. At the same time, in turn, stamps 1 received a roll towards stamps 2, respectively: 0.0028 and 0.0030. The measurement of stress under the edge of stamp 1 from the side of stamp 2 at site No. 2 showed an additional increase in stress in the foundation soils up to 30% due to the influence of the neighboring foundation.

Comparative analysis of the results of a test problem for calculating the sediment and depth of the compressible thickness of the base of the ribbon foundation, solved by different methods (Table 2) shows that the proposed sediment calculation scheme models well the patterns of deformation of real soil foundations, the calculated data for the determination of the new method for the ribbon foundation are close to the actual (less than 2.25 b), which is confirmed by the results of experiments [4].

Table 2. Comparative analysis of the results.

Methods for calculating the sediment of the foundation foundations	Initial data				Calculation results				
					precipitation, cm taking into account			compressible thickness, m	
	b, m	p, MPa	E_k, MPa	$E_s=m_k \cdot E_k$, *MПa*	E_k	E_s	$e_i = f(p_i)$	H_d/b	H_a
Layer - by - layer summation	2,0	0,2	6,0	12,0*	8,9	4,5	-	4,2	8,4
Linearly deformable layer	2,0	0,2	6,0	12,0*	10,3	5,0	-	6,0	12,0
Equivalent layer	2,0	0,2	6,0	12,0*	31,0	15,7	-	5,2	10,4
Finite Elements (FEM)	2,0	0,15	6,0	-	4,7	-	-	2,0	4,0
		0,2	6,0	-	6,6	-	-	2,0	4,0
Proposed (model-free)	2,0	0,2	-	-	-	-	5,53	2,25	4,5

The wide potential possibilities of the proposed calculation model (see Figure 2) of the foundation in comparison with the existing ones and its versatility make it possible to determine the precipitation of neighboring foundations of reconstructed buildings, taking into account the distance between them, the sequence of their loading, the size of the sole, the magnitude of loads and the compaction of the foundation soils.

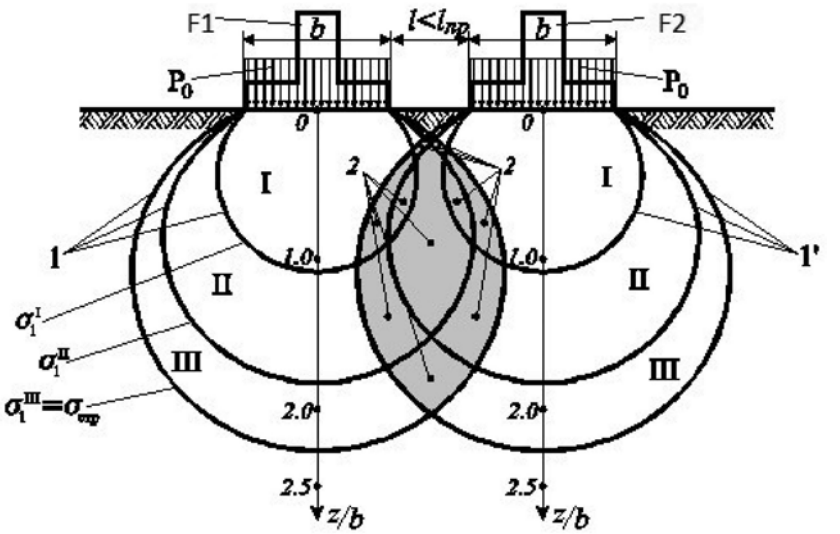

Figure 2. Calculation scheme of the foundation of neighboring foundations: 1 and 1′ – boundaries of various stress zones I, II and III of the foundations of neighboring foundations F1 and F2; 2 – areas of superposition of the stressed zones of the base of both foundations, taken into account when calculating precipitation.

Based on the analysis of the results of the experimental studies carried out, the following can be concluded:

1. A complex of studies of the mechanism of interaction of closely erected foundations with the soil foundation has been carried out by field experiments, field observations, numerical analysis of the FEM. Based on the generalization of the results obtained, a universal method for calculating the sediment of neighboring foundations has been developed.
2. The use of a new technique allowed us to establish the features of the behavior of neighboring foundations erected simultaneously and sequentially. To a greater extent, the mutual influence of neighboring foundations is manifested when they are loaded simultaneously. Sequential loading leads to a significant reduction in additional sediments of both foundations due to the influence of soil compaction at the base of the existing foundation.

Water characteristic curve and permeability function of steel slag

Gulnur Pernebekova, Alfrendo Satyanaga, Rezat Abishev, Sung-Woo Moon & Jong Kim
Department of Civil and Environmental Engineering, Nazarbayev University, Kazakhstan

ABSTRACT: Waste arising from construction and demolition constitutes one of the largest waste streams globally. Construction and maintenance of roads require a large volume of aggregates for use as base and sub-base material. Because of the cost of virgin aggregates, government and local companies are encouraging the use of recycled material in old pavement and construction material. One type of recycled material, steel slag could be used for several construction purposes, such as concrete, road subgrade, and railway ballast materials. In order to utilize steel slag in these constructions, the engineers need to understand the properties of material appropriately including its unsaturated properties. The objective of this project is to study the soil-water characteristic curve, unsaturated permeability and unsaturated shear strength of steel slag. Advanced laboratory testing was conducted to obtain these unsaturated properties. The results of study indicated that the steel slag has the same unsaturated properties as natural aggregate or gravel.

1 INTRODUCTION

One of the main waste streams in the EU and many other countries is waste produced during construction and demolition (C & D). For instance, it is estimated that core C&D waste, defined as items originating from demolished structures or civil engineering infrastructure, amounts to about 180 million tons annually, or 480 kg per person, in Europe (Aggregates Advisory Service-UK, May 1999). Aggregates are needed in huge quantities for base and sub-base material during road construction and maintenance. Because of the cost of virgin aggregates, government and local companies are encouraging the use of recycled material in old pavement and construction materials.

Recycling of material is the process of turning used construction or industrial waste into raw materials that are suitable to be reused again. Natural resource preservation and pollution reduction are its primary goals. Recycling also lowers energy use because it often requires less energy to make a product through recycling than it does to create a new one. Similar to how recycling conserves raw materials and produces less pollution than producing new products. Additionally, less waste is disposed away or burned in incinerators. The term "water content" describes how much water is contained in a material's pores. The amount of water in unsaturated soil depends on the soil's suction. The soil-water characteristic curve (SWCC), which depicts the change of water storage capacity inside the micro and macro pores of the soil with respect to soil suction, can be used to show the relationship between water content and suction.

The properties of recycled materials in saturated conditions have been the subject of numerous studies. However, there haven't been many studies done on the permeability of recycled materials and the water characteristic curve in unsaturated conditions. The shear strength of recycled materials in unsaturated environments has also not been thoroughly studied. Thus, this project aims to investigate the unsaturated permeability and soil-water characteristic curve of steel slag.

DOI: 10.1201/9781003299127-64

2 STEEL SLAG

Researchers found that steel slag might be utilized for a variety of construction purposes, including the production of concrete, road subgrade, and railroad ballast materials (Koh et al., 2018). Li et al. (2022) provided a description of the steel slag's characteristics and talked about how they affected the properties and microstructure of cement concrete. Their research indicates that the volume stability and workability of concrete are adversely affected by steel slag. It improves compressive strength, frost resistance, and wear resistance, although its effects on flexural strength and permeability are questionable. Meanwhile, steel slag can be utilized in road construction since it has qualities that are compatible with unbound and asphalt layers (Motz and Geiseler, 2001). Steel slag may create high-quality aggregates of a level that is comparable to natural aggregates, making its use in road construction plausible due to its great strength and durability. Additionally, characteristics like its high abrasion and rough texture make it appropriate for hydraulic construction (Yi et al., 2012). In their analysis, Yi et al. (2012) note that the Nippon Slag Association in Japan has been investigating the use of steelmaking slag as a material for ground improvement in port and harbour construction since 1993. The study of powdered steel slag was done by Akinwumi (2014). Related experimental results show that it was effectively applied to improve the drainage, plasticity, and uncured strength of lateritic soil without exhibiting any unfavourable swell behaviour.

3 LABORATORY TESTING

Grain size examination of the specimen was performed in accordance with ASTM D422-63. A water pycnometer was used in the test by ASTM D854-06 to estimate the specific gravity. A triaxial permeameter with two back pressure systems was used to obtain the saturated coefficients of permeability from the constant head permeability test (Head, 1986). The best method for figuring out slow flow rates is to do a constant head triaxial permeability test. This test may be executed under real confining stress at pore pressures that are relevant to the site circumstances, and a variety of hydraulic gradients can be applied and precisely quantified.

Three stages—saturation, consolidation, and permeability—of the triaxial test were used to determine the specimen's permeability. The saturated permeability test applied back pressure and water pressure to the specimen while it was inside a specific cell. Water would flow when the drainage intake was opened because of the pressure difference caused by the water pressure that was applied. The water volume change and the passing of time were gauged as the water passed through the specimen. Darcy's Law can then be used to compute the saturated permeability (ks).

An average value of the ks was then determined after several saturated permeability tests under various water pressures.

Using a typical 250 ml sample ring, the HYPROP fully automated laboratory apparatus (Figure 1) can be used to obtain unsaturated hydraulic parameters of soil samples, such as SWCC and unsaturated hydraulic conductivity. When using HYPROP equipment, the phases of the experimental technique include saturating the soil sample, setting up the device with the specimen inside, starting the measurement, and analyzing the results (Satyanaga et al., 2019).

Effective cohesion (c') and effective friction angle (') of soils are measured using the Consolidated-Drained (CD) Triaxial Test. It's a compression test where the sample is allowed to consolidate to its equilibrium moisture content during the application of the cell pressure prior to shearing and the drainage taps are opened during shearing where water is free to flow out of or into the test specimen (Powrie, 2004). Drainage is allowed throughout the test to ensure that consolidation happens fully under the all-around load and that there is no buildup of pore pressure when the deviator stress is applied (Bishop and Henkel, 1962).

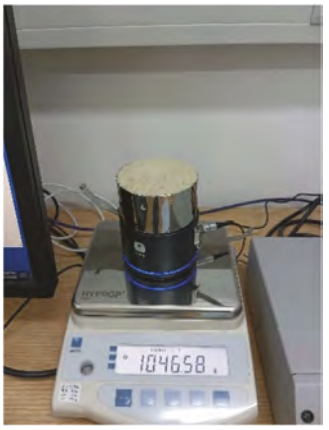

Figure 1. Measurement of SWCC using Hyprop.

4 RESULTS AND DISCUSSION

Based on the grain size analysis, steel slag appeared to have 98.11% of gravel content larger than 4.75 mm. A complete composition can be seen in Table 1, which shows the index properties of the steel slag.

Table 1. Index properties of Steel slag.

	Steel Slag
USCS Classification	GP (Poorly-graded gravel)
Specific gravity, G_s	3.5
Gravel content,% (more than 4.75mm)	98.11
Sand content, %	1.89
Fines content, % (Less than 0.075mm)	0
Saturated permeability, k_s (m/s)	0.98

From the conducted laboratory works, SWCC of steel slag was generated. Accordingly, the relationship between volumetric water content and matric suction can be observed in Figure 2. Equation (1) was used to fit the experimental data of SWCC best. The best fitting parameters of Equation (1) can be seen in Table 2.

Table 2. Best fitting parameters of Satyanaga et al. (2022) equation.

θ_s=	0.27
θ_r=	0
ψ_m=	1.034308
σ=	1.601103
ψ_{aev}=	0.3
ψ_r=	137489.9
r2	0.992052

In order to use Equation (1) for modelling SWCC, each parameter must have a proper initial value (Satyanaga et al. 2017). To best fit the laboratory data of the SWCC, all the parameters can be adjusted via an iterative non-linear regression approach offered in the Microsoft Excel software (Satyanaga et al. 2019b; Dodge and Stinson, 2007). Eventually, SWCC data are applied in subsequent seepage analyses.

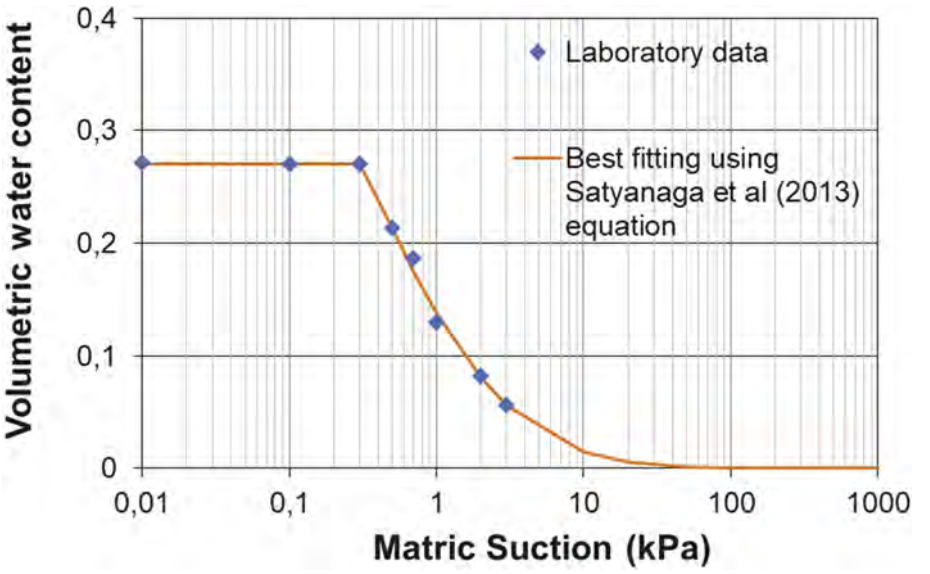

Figure 2. SWCC of Steel Slag.

The permeability function of steel slag was determined from SWCC and saturated permeability using the statistical method following the procedure explained by Satyanaga et al. (2022b) (Figure 3). The permeability function was also incorporated in the numerical analysis together with the best fitted SWCC data.

Figure 3. Unsaturated permeability of Steel Slag.

5 CONCLUSIONS

The results of the study indicated that the properties of steel slag are similar to gravel. The air-entry value of steel is 3 kPa which is corresponding to its saturated permeability (1 m/s).

An assessment of transversely isotropic elastic constitutive models for geomaterials

V.N. Kaliakin
Department of Civil and Environmental Engineering, University of Delaware, USA

ABSTRACT: Due to the manner in which natural soils are deposited, it is logical to expect them to exhibit approximately transversely isotropic response. While this realization is not new, the lack of suitable experimental apparatus to accurately measure the five elastic constants associated with transverse isotropy has, in the past, precluded the use of such idealizations. More recently, substantial progress has been made in experimental techniques that facilitate the measurement of the aforementioned elastic constants. The development of elastic constitutive relations for transversely isotropic geomaterials is complicated by the fact that the elastic material parameters are usually not constant. The elastic strain increments will thus be related to the stress increments through compliance matrices that are functions of the instantaneous stress state, the stress history and so forth. Since the response is thus rendered stress path-dependent, only hypoelastic constitutive models are thought to be relevant. Some of these models are reviewed and assessed in this paper.

1 INTRODUCTION

Gravitationally deposited natural sedimentary soils possess different properties in the direction of deposition as opposed to the planes normal to this direction. Mathematically, such soils are classified as being anisotropic. For a general homogeneous, anisotropic linear elastic (Hookian) material, in the absence of initial strains and stresses, the constitutive relations, in "direct" vector-matrix form, are given by

$$\boldsymbol{\delta\varepsilon}^{e} = \mathbf{A}\,\boldsymbol{\delta\sigma}' \tag{1}$$

where $\mathbf{A}$ is a symmetric (N_{rowb} * N_{rowb}) matrix of compliance coefficients characterizing the material, $\boldsymbol{\delta\varepsilon}^{e}$ and $\boldsymbol{\delta\sigma}'$ are (N_{rowb} * 1) vectors of infinitesimal elastic strain and effective stress increments, respectively, and N_{rowb} is the number of stress and strain components (Kaliakin 2001). For three-dimensional analyses,N_{rowb} = 6, with

$$\boldsymbol{\delta\varepsilon}^{e} = \left\{ \delta\varepsilon^{e}_{11} \quad \delta\varepsilon^{e}_{22} \quad \delta\varepsilon^{e}_{33} \quad \delta\gamma^{e}_{12} \quad \delta\gamma^{e}_{13} \quad \delta\gamma^{e}_{23} \right\}^{T} \tag{2}$$

$$\boldsymbol{\delta\sigma}' = \left\{ \delta\sigma'_{11} \quad \delta\sigma'_{22} \quad \delta\sigma'_{33} \quad \delta\sigma'_{12} \quad \delta\sigma'_{13} \quad \delta\sigma'_{23} \right\}^{T} \tag{3}$$

where γ^{e}_{12}, γ^{e}_{13}, and γ^{e}_{23} are engineering shear strains, and the superscript T denotes the operation of vector transposition. For torsionless axisymmetry, N_{rowb} = 4, while for plane strain analyses, N_{rowb} = 3.

Although some experimental findings (Kirkgard & Lade, 1991) suggest that natural soils are elastically orthotropic, the difficulty associated with determining values for the nine elastic

DOI: 10.1201/9781003299127-65

constants precludes the adoption of such an idealization. Instead, transversely isotropic elasticity is commonly assumed, thus reducing the number of elastic parameters to five.

Although transversely isotropic elastic material characterizations for soils are not new (Barden 1963, Pickering 1970, Atkinson 1975, Graham & Houlsby 1983, Sivakumar et al. 2001), in the past the lack of suitable experimental apparatus to accurately measure the five elastic constants associated with transverse isotropy has precluded the use of such idealizations. More recently (Hoque & Tatsuoka 1998, Lings et al. 2000, Kuwano & Jardine 2002, Arroyo et al. 2003, Nishimura 2014a), substantial progress has been made in experimental techniques that facilitate the measurement of the aforementioned elastic constants.

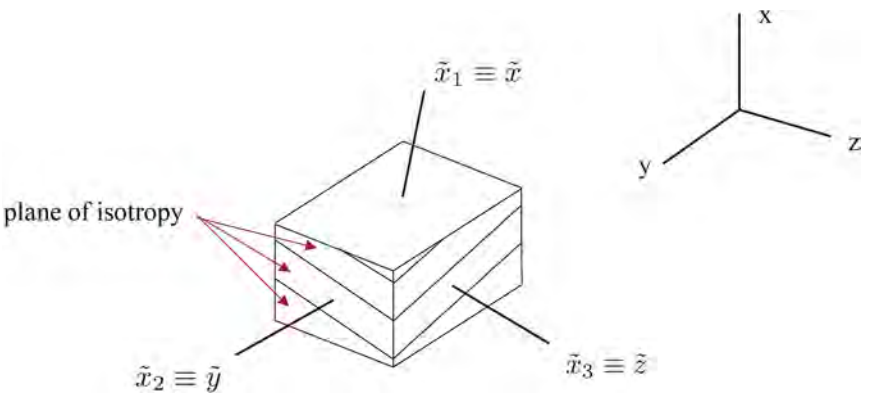

Figure 1. Schematic illustration of an element of transversely isotropic material.

The importance of elastic anisotropy in geotechnical engineering applications has been noted in conjunction with predicting ground deformations associated with tunneling (Lee & Rowe 1989, Simpson et al. 1996, Addenbrooke et al. 1997, Wongsaroj et al. 2007). It is, however, equally relevant to simulating the small-strain response of any two- or three-dimensional geotechnical problem.

2 TRANSVERSELY ISOTROPIC ELASTIC IDEALIZATIONS

Through all points of a transversely isotropic material there pass parallel planes of elastic symmetry in which all directions are elastically equivalent (i.e., planes of isotropy). Thus at each point there exists one principal direction and an infinite number of principal directions in a plane normal to the first direction (Lekhnitskii 1981).

For the present development, assume that the local material axes $(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3) \equiv (\tilde{x}, \tilde{y}, \tilde{z})$ coincide with the global x, y and z coordinate axes (Figure 1). In addition, assume that the global $x_1 \equiv x$-axis is taken normal to the planes of isotropy, with the global y and z axes directed arbitrarily in such planes.

Associated with the definition of a transversely isotropic material are five elastic constants. E_n' is the elastic modulus for compression or tension in a direction normal to the plane of isotropy. E_t' is the elastic modulus for compression or tension in the plane of isotropy. Since the y - z plane is a plane of isotropy, ν_{tn}' is the Poisson's ratio characterizing the lateral contraction normal to the plane of isotropy when tension is applied in the plane. The quantity ν_{tt}' is the Poisson's ratio characterizing transverse contraction in the plane of isotropy when tension is applied in the same plane. Finally, G_{nt} is the modulus associated with shearing involving $\delta\gamma_{12}^e$ and $\delta\gamma_{13}^e$.

The modulus G_{tt}, which characterizes shearing in the plane of isotropy, is obtained from $1/G_{tt} = 2\left(1 + \nu_{tt}'\right)/E_t'$. It is thus evident that G_{tt} is not an independent material constant.

The compliance matrix, given in Equation (1), thus becomes

$$\mathbf{A} = \begin{bmatrix} 1/E_n' & -\nu_{tn}'/E_t' & -\nu_{tn}'/E_t' & 0 & 0 & 0 \\ -\nu_{nt}'/E_n' & 1/E_t' & -\nu_{tt}'/E_t' & 0 & 0 & 0 \\ -\nu_{nt}/E_n' & -\nu_{tt}/E_t' & 1/E_t' & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/G_{nt} & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/G_{nt} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\left(1+\nu_{tt}'\right)/E_t' \end{bmatrix} \tag{4}$$

Since $\mathbf{A}$ is symmetric, $A_{12} = A_{21}$, implying that $\nu_{tn}'/E_t' = \nu_{nt}'/E_n'$ or $\nu_{tn}' = \nu_{nt}'\left(E_t'/E_n'\right)$. Several key issues related to anisotropic elastic material idealizations for soils in general, and transversely isotropic idealizations in particular, are presented elsewhere (Kaliakin 2019).

2.1 *Limiting values for elastic material parameters*

For isotropic elastic material idealizations, the drained Young's modulus (E') is related to the shear modulus (G) and to the drained Poisson's ratio (ν') through the relation $E' = 2G(1+\nu')$. No such relations are possible for anisotropic elastic materials, as the moduli and Poisson's ratios become dependent upon the directions of stretch, lateral strain, and the directions of shear (Love 1927).

Nevertheless, certain limits of the possible values attained by the elastic constants have been derived. For the special case of transverse isotropy, expressions derived by Lempriere (1968) for orthotropic materials reduce to

$$\left|\nu_{tt}'\right| < 1 \;\Rightarrow\; -1 < \nu_{tt}' < 1 \tag{5}$$

In addition,

$$-\left(\frac{E_t'}{E_n'}\right)^{1/2} < \nu_{nt}' < \left(\frac{E_t'}{E_n'}\right)^{1/2} \quad ; \quad -\left(\frac{E_n'}{E_t'}\right)^{1/2} < \nu_{tn}' < \left(\frac{E_n'}{E_t'}\right)^{1/2} \tag{6}$$

For the special case of transverse isotropy, it can also be shown that

$$\frac{1}{2} > \frac{1}{2}\left[1 - \left(\nu_{tt}'\right)^2 - 2\left(\nu_{tn}'\right)^2\left(\frac{E_n'}{E_t'}\right)\right]\nu_{tt}'\nu_{nt}'\nu_{tn}' \tag{7}$$

Considering the left inequality in Equation (7) gives the following relation:

$$\left(\nu_{tt}'\right)^2 < 2\left(\nu_{tn}'\right)^2\left(\frac{E_n'}{E_t'}\right) \tag{8}$$

Adopting a more rigorous form of analysis, Pickering (1970) noted that, similar to Lempriere (1968), the necessary and sufficient condition for the quadratic form $\frac{1}{2}\dot{\sigma}'^T\mathbf{A}\dot{\sigma}'$ to be positive definite is that all of the principal minors of $\mathbf{A}$ should be positive. This leads to the requirements that $E_t' > 0$, $E_n' > 0$, $G_{nt} > 0$, $G_{tt} > 0$. Pickering (1970) also confirmed Equation (5), and from one of the principal minors of $\mathbf{A}$, obtained the following relation:

$$\frac{E_t'}{E_n'}\left(1 - \nu_{tt}'\right) - 2\left(\nu_{tn}'\right)^2 > 0 \tag{9}$$

Finally, Pickering (1970) noted that, similar to G_{nt}, E_t' and E_n' are independent; only the Poisson's ratios are bounded by the ratio E_t'/E_n'.

In commenting on an earlier paper by Barden (1963), Raymond (1970) stated that, from a zero-strain energy function,

$$1 \geq \nu'_{tt} + 2\left(\frac{E'_t}{E'_n}\right)\left(\nu'_{nt}\right)^2 \tag{10}$$

which, except for the case of equality, is identical with Equation (9) given by Pickering (1970).

By requiring the dilation to be the same sign as the applied stress, Raymond (1970) also stated that $\nu'_{nt} \leq 1/2$, and noted that the shear modulus G_{nt} is bounded by the following inequality:

$$G_{nt} \leq \frac{E'_n}{2\nu'_{nt}\left(1+\nu'_{tt}\right) + 2\sqrt{\frac{E'_n}{E'_t}\left[1-\left(\nu'_{tt}\right)^2\right]\left[1-\frac{E'_t\left(\nu'_{nt}\right)^2}{E'_n}\right]}} \tag{11}$$

Additional details pertaining to the limiting values for orthotropic and transversely isotropic elastic material idealizations are discussed elsewhere (Kaliakin 2020).

2.2 *Experimental determination of material parameter values*

The values of the small strain moduli and Poisson's ratios in soils characterized by transversely isotropic elastic material idealizations can be determined from the results of field or laboratory tests. Commonly used field tests include the pressuremeter and in-situ seismic surveys consisting of cross-hole and down-hole techniques. When transversely isotropic shear moduli are determined in the field, the value of G_{nt}, is obtained from a down-hole survey in which the shear wave propagates in the vertical direction and the particles move horizontally; in such tests, the shear wave velocity v_{nt} is measured. By contrast, the vale of G_{tt} is determined from a cross-hole survey, in which the shear wave velocity v_{tt} is measured. Due to the difference in the modes of shear deformation, the results obtained using field tests can, however, be different from laboratory values (Yimsiri & Soga 2002).

Laboratory tests commonly used to determine the small strain moduli and Poisson's ratio values include axisymmetric triaxial, torsional shear, resonant column, and ultrasonic tests. Such tests must be suitably modified in order to determine the values of all five independent parameters associated with a transversely isotropic elastic material idealization. The small-strain probe loadings in such tests are typically applied quasi-statically. The multiaxial body wave measurements in such tests are made using either piezoelectric transducers such as bender elements (e.g., Lings & Greening 2001, Kuwano & Jardine 2002, Nishimura 2014a) or other P- and S-wave transducers (Bellotti et al. 1996). Using such laboratory tests allows for either direct measurement (e.g., Hoque & Tatsuoka 1998) or indirect determination (e.g., Lings et al. 2000) of all five independent parameters associated with a transversely isotropic elastic material idealization.

Additional details pertaining to the experimental determination of material parameter values for transversely isotropic material idealizations are beyond the scope of the present paper. For additional details, the interested reader is directed to the references cited above.

The inclusion of transversely isotropic elastic material idealizations into existing and new elastoplastic and/or elastoviscoplastic constitutive models for soils requires a specific analytical form for the anisotropic idealization, as well as suitable empirical expressions for the associated elastic material constants. These two topics are thus next discussed.

3 DEVELOPMENT OF CONSTITUTIVE RELATIONS

The development of elastic constitutive relations for transversely isotropic geomaterials is complicated by the fact that the elastic material parameters are usually not constant.

Indeed, test results (Hoque & Tatsuoka 1998) indicate that these parameters are a function of the stress state, density, and stress history. The elastic strain increments will thus be related to the stress increments through compliance matrices (**A**) that are functions of the instantaneous stress state, the stress history and so forth. Since the elastic response is thus rendered stress path-dependent, only hypoelastic constitutive models are thought to be relevant (Hoque & Tatsuoka 1998). Some of these models are described in the subsequent sub-sections.

A key assumption underlying the development of hypoelastic models is that the elastic modulus (E_i) associated with a particular coordinate direction is a unique function of the normal stress acting in this direction, and is independent of the other two orthogonal directions (Hardin 1978, Hardin & Bladford 1989). This important assumption has subsequently been supported by data from body wave velocity measurements (Jamiokowski et al. 1991, Lo Presti et al. 1991, Stokoe et al. 1991), as well as by micromechanics-based simulations (Yimsiri & Soga 2000).

3.1 *Hypoelastic model of Yu and Dakoulas*

In their transversely isotropic hypoelastic model, (Yu & Dakoulas 1993) assumed the elastic moduli $E_h \equiv E_t^{'}$ and $E_v \equiv E_n^{'}$ to be functions of the stress state. The two Poisson's ratios were, however, assumed to be constant. Finally, although $E_t^{'}$ and $E_n^{'}$ increase with increasing confining stress, the ratio $E_t^{'}/E_n^{'}$ was assumed to remain constant. The same model was subsequently presented and further discussed by Dakoulas & Yu (1995).

Motivated by the work of Lade & Nelson (1987), Yu & Dakoulas (1993) proposed the following expressions for the elastic moduli $E_t^{'}$ and $E_n^{'}$ associated with a transversely isotropic elastic material idealization:

$$E_t^{'} = MP_a\left[\left(\frac{I_1^*}{P_a}\right)^2 + \frac{6\left(1+\nu_{tt}^{'}\right)}{\left(1-2\nu_{tt}^{'}\right)}\frac{J_2^*}{(P_a)^2} + \frac{3\left(n-m^2\right)}{\left(1-2\nu_{tt}^{'}\right)}\left(\frac{\sigma_{11}{}'}{P_a}\right)^2\right]^{\lambda} \tag{12}$$

$$E_n^{'} = nMP_a\left[\left(\frac{I_1^*}{P_a}\right)^2 + \frac{6\left(1+\nu_{tt}^{'}\right)}{\left(1-2\nu_{tt}^{'}\right)}\frac{J_2^*}{(P_a)^2} + \frac{3\left(n-m^2\right)}{\left(1-2\nu_{tt}^{'}\right)}\left(\frac{\sigma_{11}{}'}{P_a}\right)^2\right]^{\lambda} \tag{13}$$

where M and λ are model parameters, and

$$n = \frac{E_t^{'}}{E_n^{'}} = \frac{\nu_{tn}^{'}}{\nu_{nt}^{'}} \quad ; \quad m = \frac{E_t^{'}\nu_{nt}^{'}}{E_n^{'}\nu_{tt}^{'}} = \frac{\nu_{tn}^{'}}{\nu_{tt}^{'}} \tag{14}$$

$$I_1^* = m\sigma_{11}^{'} + \sigma_{22}^{'} + m\sigma_{33}^{'} \tag{15}$$

$$J_2^* = \frac{1}{2}\left(m\sigma_{11}^{'}\right)^2 + \frac{1}{2}\left(\sigma_{22}^{'}\right)^2 + \frac{1}{2}\left(\sigma_{33}^{'}\right)^2 + \left(\alpha\sigma_{12}\right)^2 + \left(\alpha\sigma_{13}\right)^2 + \left(\sigma_{23}\right)^2 \tag{16}$$

In Equation (16), $\alpha^2 = G_{tt}/G_{nt} = E_t^{'}/\left[2\left(1+\nu_{tt}^{'}\right)G_{nt}\right]$. No explicit expression for G_{nt} is, however, given.

In their paper, Dakoulas & Yu (1995) give the following values for the model parameters associated with a "remolded cross-anisotropic marine clay" from the Gulf of Mexico: M = 3.60, $\lambda = 1.29$, $\nu_{tt}^{'} = 0.18$, n = 1.26, m = 1.39 and $\alpha = 2.39$.

3.2 *Hypoelastic model of Tatsuoka and Co-Workers*

The results of extensive axisymmetric triaxial tests performed on various uncemented sands and gravels (Tatsuoka & Kohata 1995, Jiang et al. 1997, Hoque & Tatsuoka 1998) demonstrated that such soils are inherently transversely isotropic. Based on these results,

a hypoelastic constitutive model was proposed by Tatsuoka & Kohata (1995) and then subsequently refined by Hoque et al. (1996), Jiang et al. (1997), Hoque & Tatsuoka (1998), and Tatsuoka et al. (2001). This model is based on the aforementioned assumptions of Hardin (1978) and Hardin & Bladford (1989) that the Young's modulus (E_i) associated with a particular coordinate direction is a unique function of the normal stress acting in this direction, and is *independent* of the other two orthogonal directions.

For a transversely isotropic elastic material idealization, the following moduli are proposed:

$$E_n^{'} = E_1^{*} F(e) \left(\frac{\sigma_{11}^{'}}{\sigma_{ref}^{'}} \right)^{m_1} \tag{17}$$

$$E_t^{'} = E_1^{*} R_E F(e) \left(\frac{\sigma_{22}^{'}}{\sigma_{ref}^{'}} \right)^{m_2} \tag{18}$$

$$E_t^{'} = E_1^{*} R_E F(e) \left(\frac{\sigma_{33}^{'}}{\sigma_{ref}^{'}} \right)^{m_3} \tag{19}$$

where $E_1^{*} = \left(E_1^{'}\right)_{ref} / F\left(e_{ref}\right)$. The exponents m_1, m_2, and m_3 represent the pressure dependency of the elastic stiffness; this is consistent with the general power law relationship proposed by Hardin & Black (1968). If $m_1 = m_2 = m_3 = 0.0$, the elastic material characterization will be linear. To avoid an overly large number of model parameters being associated with just the definition of the elastic response, the three exponents are commonly assumed to be equal; i.e., $m_1 = m_2 = m_3 = m$. In addition, m is typically assumed to be equal to 0.50 (Hoque & Tatsuoka 1998).

In Equations (17)–(19), the quantity $F(e)$ is the following function of the void ratio (e):

$$F(e) = \frac{(2.17 - e)^2}{1 + e} \tag{20}$$

which was proposed for sands with rounded grains by Hardin & Richart (1963) and Hardin & Black (1966).

The quantity $\left(E_1^{'}\right)_{ref}$ is the value of $E_1^{'}$ for $\sigma_{11'} = \sigma_{ref'}$, and $F(e_{ref})$ is the value of $F(e)$ for $e = e_{ref}$; i.e., the void ratio associated with $\sigma_{11'} = \sigma_{ref'}$. Finally, the quantity $R_E = E_t^{'}/E_n^{'}$ represents the degree of inherent anisotropy ($R_E = 1.0$ implies an inherently isotropic material).

It is timely to note that, since, in general, $\sigma_{22}^{'} \neq \sigma_{33}^{'}$, equations (17) to (19) will not necessarily predict transversely isotropic elastic response. Only under axisymmetric triaxial conditions do these equations predict such response. In particular, under axisymmetric triaxial conditions, $\sigma_{22}^{'} = \sigma_{33}^{'}$. For $m_2 = m_3 = m$, equations (18) and (19) are identical. Thus,

$$E_n^{1} = E_1^{*} F(e) \left(\frac{\sigma_{11}^{'}}{\sigma_{ref}^{'}} \right)^{m} \quad ; \quad E_t^{'} = E_1^{*} R_E F(e) \left(\frac{\sigma_{33}^{'}}{\sigma_{ref}^{'}} \right)^{m} \tag{21}$$

and

$$\frac{E_n^{'}}{E_t^{'}} = \frac{1}{R_E} (R_\sigma)^m \quad \text{or} \quad n = \frac{E_t^{'}}{E_n^{'}} R_E (R_\sigma)^{1/m} \tag{22}$$

where $R_\sigma = \sigma_{11}^{'}/\sigma_{33}^{'} = \sigma_n^{'}/\sigma_t^{'}$. In equation (22), the term $1/R_E$ represents the inherent anisotropy, while the term R_σ represents the stress-induced anisotropy.

Attention is next turned to defining the Poisson's ratios for the material idealization. Assuming symmetry of **A**, $\nu_{tn}^{'} = \nu_{nt}^{'}\left(E_t^{'}/E_n^{'}\right)$. Substituting equations (21) into this expression gives

$$\nu'_{tn} = \nu'_{nt} R_E \left(\frac{1}{R_\sigma}\right)^m \tag{23}$$

Although equation (23) is consistent with equations (21), it does not give explicit expressions for either ν'_{tn} or ν'_{nt}. To overcome this shortcoming, Hoque & Tatsuoka (1998) developed alternate functional forms for ν'_{tn} and ν'_{nt}. They noted that, based on the results of axisymmetric triaxial tests performed on different sands at various stress states in the range $0.5 \leq R_\sigma \leq 2.0$, the Poisson's ratio ν'_{nt} did not vary greatly. Within the range of pressures investigated, the value of ν'_{nt} was not sensitive to the change in σ'_n or σ'_t at a fixed ratio R_σ. This Poisson's ratio did, however, gradually increase with R_σ.

To account for this fact and to include the effect of inherent anisotropy (via R_E) while also satisfying the relation $\nu'_{tn}/E'_t = \nu'_{nt}/E'_n$ that comes form the symmetry of **A**, Hoque & Tatsuoka (1998) proposed the following functional forms:

$$\nu'_{nt} = \nu_0 \sqrt{\frac{1}{R_E}} (R_\sigma)^{m/2} \; ; \; \nu'_{tn} = \nu_0 \sqrt{R_E} \left(\frac{1}{R_\sigma}\right)^{m/2} \tag{24}$$

When

$$\sqrt{\frac{1}{R_E}} (R_\sigma)^{m/2} = 1 \;\Rightarrow\; R_\sigma = (R_E)^{1/m}$$

then $\nu_0 = \nu'_{nt}$ in the first of equations (24). When

$$\sqrt{R_E} \left(\frac{1}{R_\sigma}\right)^{m/2} = 1 \;\Rightarrow R_\sigma = (R_E)^{-m}$$

then $\nu_0 = \nu'_{tn}$ in the second of equations (24).

Regarding the Poisson's ratio ν'_{tt}, Hoque & Tatsuoka (1998) proposed that $\nu'_{tt} = \nu_0$. Then, for isotropic materials (i.e., $R_E = 1.0$) subjected to isotropic stress states, $\nu'_{nt} = \nu'_{tn} = \nu'_{tt} = \nu_0$. Clearly, this choice of ν'_{tt} is somewhat arbitrary.

In light of the assumed expression for ν'_{tt}, the shear modulus associated with the place of isotropy is thus $G_{tt} = E'_t / \left[2\left(1 + \nu'_{tt}\right)\right]$.

Unlike the case of isotropic elastic materials, there is no unique relationship between G_{nt} and the other elastic parameters. Based on equations (21), Tatsuoka et al. (2001) derived the following functional form:

$$G_{nt} = \left(\frac{1 - \nu_0}{1 + \nu_0}\right) \frac{1}{\frac{1-\nu'_{nt}}{E'_n} + \frac{1-\nu'_{tn}}{E'_t}} \tag{25}$$

In summary, as evident from the present development, the hypoelastic model of Tatsuoka and co-workers is useful only under axisymmetric triaxial conditions and is somewhat complex.

3.3 *Hypoelastic model of Lings et al.*

Lings et al. (2000) performed high-quality axisymmetric triaxial tests on samples of natural Gault Clay. The tests involved multiple drained stress excursions and orthogonal determination of horizontal shear wave velocity using bender elements. Small-strain data from both engineering strain and shear wave velocity measurements were combined to derive values for all five material parameters associated with a transversely isotropic elastic material idealization.

Based on the results of their tests, Lings et al. (2000) proposed the following expressions for the elastic moduli:

$$E_n^{'} = 550p' \; ; \; E_t^{'} = 2186p' \tag{26}$$

where p', and thus $E_n^{'}$ and $E_t^{'}$, have units of kPa.

The Poisson's ratios were assumed to be constant; viz., $\nu_{nt}^{'} = 0.00$ and $\nu_{tt}^{'} = -0.04$. No value was reported for $\nu_{tn}^{'}$.

Finally, the independent shear modulus was represented by $G_{nt} = 507p'$. Using the above expression for $E_t^{'}$ and the assumed value of $\nu_{tt}^{'}$ gives $G_{tt} = E_t^{'}/\left[2\left(1+\nu_{tt}^{'}\right)\right] = 1140p'$. The small-strain stiffness anisotropy is thus quantified as follows: $n = E_t^{'}/E_n^{'} = 2186/550 = 3.97$, $G_{tt}/G_{nt} = 2.25$, and $\nu_{nt}^{'}/\nu_{tt}^{'} = 0.0$.

3.4 *Hypoelastic model of Kuwano and Jardine*

Kuwano & Jardine (2002) determined that, although the overconsolidation ratio (OCR) and the recent stress history had no discernible independent effect on the moduli measured in any tests performed on Ham River sand, these factors strongly influenced the extent of the linear strain range. Extending the earlier formulations of Roesler (1979), Yu & Richart (1984), and Bellotti et al. (1996), Kuwano & Jardine (2002) proposed the following expressions for the elastic moduli associated with a transversely isotropic material idealization:

$$E_n^{'} = C_v F(e)\left(\frac{\sigma_v^{'}}{p_{ref}}\right)^{a_v} \; ; \; E_t^{'} = C_h F(e)\left(\frac{\sigma_h^{'}}{p_{ref}}\right)^{b_h} \tag{27}$$

$$G_{nt} = C_{vh} F(e)\left(\frac{\sigma_v^{'}}{p_{ref}}\right)^{a_{vh}}\left(\frac{\sigma_h^{'}}{p_{ref}}\right)^{b_{vh}} \; ; \; G_{tt} = C_{hh} F(e)\left(\frac{\sigma_v^{'}}{p_{ref}}\right)^{a_{hh}}\left(\frac{\sigma_h^{'}}{p_{ref}}\right)^{b_{hh}} \tag{28}$$

where the reference pressure p_{ref} was assumed to be equal to the atmospheric pressure P_a = 101.3 kPa. In *equations (27)* and (*28*), C_v, C_h, C_{vh}, C_{hh} are model parameters that describe the inherent anisotropy of the material. The quantities a_v, b_h, a_{vh}, b_{vh}, a_{hh}, b_{hh} are model parameters that dictate the stress dependency of the cross-anisotropic moduli. For sands, the indexes a_v and b_h, and the sums $a_{vh} + b_{vh}$ and a_{hh}+b_{hh} typically vary from 0.5 to 0.6 (Schadlich & Schweiger 2013). Finally, $F(e)$ accounts for variations of void ratio; Kuwano & Jardine (2002) assumed the void ratio function proposed by Hardin & Richart (1963) and given by equation (20).

Kuwano & Jardine (2002) determined the following model parameter values for Ham River sand: C_v = 204.0 MPa, C_h = 174.0 MPa, C_{vh} = 72.0 MPa, C_{hh} = 81.0 MPa, a_v = 0.52, b_h = 0.53, a_{vh} = 0.32, b_{vh} = 0.20 ($a_{vh} + b_{vh}$ = 0.52), a_{hh} = -0.04, and b_{hh} = 0.53 (a_{hh}+b_{hh} = 0.49). The Poisson's ratios for this material, measured at various stress levels, exhibited substantial scatter.

Nishimura (2014b) used expressions similar to equations (27) to (28) to simulate the small-strain response of six different clays. Schadlich & Schweiger (2013) used such expressions to simulate the stiffness anisotropy of coarse-grained soils.

3.5 *Hypoelastic model of Yimsiri and Soga*

Yimsiri & Soga (2011) used a special triaxial testing apparatus that incorporates local strain measuring system and elastic wave velocity measurement system to determine the five material parameters associated with a transversely isotropic elastic material idealization. The materials tested consisted of two heavily overconsolidated clays, namely London Clay and Gault Clay. Isotropically consolidated drained compression tests and shear wave velocity measurements were undertaken on both vertically and horizontally cut specimens.

Based on the results of their tests on London clay, Yimsiri & Soga (2011) proposed the following expressions for the elastic moduli:

$$E_n^{'} = 5.5F(e)(p')^{0.38} \; ; \; E_t^{'} = 12.0F(e)(p')^{0.38} \tag{29}$$

The values of $\nu_{tt}^{'}$ and $\nu_{tn}^{'}$ measured exhibited some scatter, and but there was no evident relationship with confining pressure. Consequently, Yimsiri & Soga (2011) assumed these Poisson's ratios to be *constant* and *independent* of the confining stress. In particular, ν'_{nt} = 0.07, $\nu_{tn}^{'} = 0.15$ and $\nu_{tt}^{'} = 0.18$.

The independent shear modulus was represented by the following expression:

$$G_{nt} = 4.25F(e)(p')^{0.38} \tag{30}$$

Finally, using equation (29) gives $G_{tt} = E_t^{'}/\left[2\left(1+\nu_{tt}^{'}\right)\right] = 5.10F(e)(p')^{0.38}$. In the above expressions, p', and thus the elastic moduli, are expressed in units of MPa. The void ratio function is assumed to be that proposed by Hardin & Black (1968) for cohesionless soils; viz., $F(e) = (2.973 - e)^2/(1+e)$.

The small-strain stiffness anisotropy is thus quantified as follows: $n = E_t^{'}/E_n^{'} = 12.0/5.5 = 2.18$, G_{tt}/G_{nt} = 1.20, and $\nu_{nt}^{'}/\nu_{tt}^{'} = 0.39$.

Symmetry of the compliance matrix **A** requires that $\nu_{tn}^{'}E_n^{'} = \nu_{nt}^{'}E_t^{'}$. Substituting the values determined by Yimsiri & Soga (2011) gives, in units of MPa,

$$\nu_{tn}^{'}E_n^{'} = 0.825F(e)(p')^{0.38} \;\; ; \;\; \nu_{nt}^{'}E_t^{'} = 0.840F(e)(p')^{0.38}$$

Thus, $\nu_{tn}^{'}E_n^{'} \neq \nu_{nt}^{'}E_t^{'}$, rendering **A** non-symmetric. Yimsiri & Soga (2011) attributed this result partly to the fact that $\nu_{nt}^{'}$ was the most unreliable parameter in this study due to the difficulty in placing the proximity transducer to align exactly to the in-situ vertical direction when horizontally cut specimens were tested.

Based on the results of their tests on Gault clay, Yimsiri & Soga (2011) proposed the following expressions for the elastic moduli:

$$E_n^{'} = 12.5F(e)(p')^{0.34} \; ; \; E_t^{'} = 29.0F(e)(p')^{0.34} \tag{31}$$

The Poisson's ratios were again assumed to be constant; viz., $\nu_{nt}^{'} = 0.13$, $\nu_{tn}^{'} = 0.30$ and $\nu_{tt}^{'} = 0.21$. The independent shear modulus was represented by the following expression:

$$G_{nt} = 7.15F(e)(p')^{0.34} \tag{32}$$

Finally, using equation (31) gives $G_{tt} = E_t^{'}/\left[2\left(1+\nu_{tt}^{'}\right)\right] = 12.0F(e)(p')^{0.34}$. In the above expressions, the void ratio function is as previously defined. The small-strain stiffness anisotropy is thus quantified as follows: $n = E_t^{'}/E_n^{'} = 2.32$, G_{tt}/G_{nt} = 1.68, and $\nu_{nt}^{'}/\nu_{tt}^{'} = 0.62$.

Checking symmetry of the compliance matrix **A** gives

$$\nu_{tn}^{'}E_n^{'} = 3.75F(e)(p')^{0.34} \;\; ; \;\; \nu_{nt}^{'}E_t^{'} = 3.77F(e)(p')^{0.34}$$

As in the case of London clay, $\nu_{tn}^{'}E_n^{'} \neq \nu_{nt}^{'}E_t^{'}$, rendering **A** non-symmetric.

3.6 *Hypoelastic model of Ratananikom et al.*

Ratananikom et al. (2012) performed high-quality axisymmetric triaxial tests on samples of natural Bangkok Clay with OCR≈1.2. The experimental program used an axisymmetric triaxial device that was equipped with local strain measuring systems and bender elements. The latter

were used to measure the small-strain shear modulus (G_{max}). A set of isotropically consolidated CIUC/CIDC tests was performed on vertically and horizontally cut undisturbed specimens.

Ratananikom et al. (2012) used an optimization procedure that assumed that the transversely isotropic elastic parameters for natural Bangkok Clay comply with the simplified model of Graham (1983). Following the approach used by Rampello (1997), they also assumed that all elastic moduli to be power functions of the mean effective confining stress $p_0^{'}$; viz.,$E_n^{'}/P_a = A\left(p_0^{'}P_a\right)^n$, where A and n are dimensionless model parameters, and P_a is the atmospheric pressure (assumed to approximately equal to 100 kPa), which must be expressed in the same units as $p_0^{'}$.

Based on the results of their tests, used in conjunction with an optimization scheme, Ratananikom et al. (2012) proposed the following expressions for the elastic moduli (in units of MPa):

$$E_n^{'} = 23.1\left(\frac{p_0^{'}}{P_a}\right)^{0.62} \; ; \; E_t^{'} = 30.0\left(\frac{p_0^{'}}{P_a}\right)^{0.62} \tag{33}$$

The Poisson's ratios were assumed to be constant; viz., $\nu_{nt}^{'} = 0.068$, $\nu_{tn}^{'} = 0.088$ and $\nu_{tt}^{'} = 0.077$. The independent shear modulus was represented by the following expression:

$$G_{nt} = 12.2\left(\frac{p_0^{'}}{P_a}\right)^{0.62} \tag{34}$$

Thus, $G_{tt} = E_t^{'}/\left[2\left(1+\nu_{tt}^{'}\right)\right] = 13.9\left(p_0^{'}/P_a\right)^{0.62}$. The small-strain stiffness anisotropy is thus quantified as follows: $n = E_t^{'}/E_n^{'} = 300/231 = 1.30$, $G_{tt}/G_{nt} = 1.14$, and $\nu_{nt}^{'}/\nu_{tt}^{'} = 0.88$.

Using equation (33), a check of the symmetry of the compliance matrix **A** gives

$$\nu_{tn}^{'}E_n^{'} = 2.033F(e)(p')^{0.34}\left[P_a\left(\frac{p_0^{'}}{P_a}\right)^{0.62}\right] \; ; \; \nu_{nt}^{'}E_t^{'} = 2.040F(e)(p')^{0.34}\left[P_a\left(\frac{p_0^{'}}{P_a}\right)^{0.62}\right] \tag{35}$$

Thus, $\nu_{tn}^{'}E_n^{'} \neq \nu_{nt}^{'}E_t^{'}$, rendering **A** non-symmetric.

4 CONCLUSIONS

This paper has presented and assessed several transversely isotropic hypoelastic constitutive models that have been proposed for geomaterials. Although the progress in the development of such models is notable, additional work is required before such models can be reliably used in the simulation of geomaterials.

In particular, not all models are complete. That is, they do not necessarily provide explicit functional forms for all five parameters associated with such models. In addition, some models render the compliance matrix **A** is non-symmetric.

Finally, values of the parameters associated with such models are only available for select soils. No attempts have been made to apply a given model to more than one or two specific soils.

ABSTRACT: This study aims to investigate the reuse of resources of the co-firing fly ashes from a bubbling fluidized boiler to produce controlled low-strength material (CLSM). First, we made a pozzolanic-activity test to confirm if the fly ash can be used as a raw material for making cementitious materials. After that we make samples of cementitious materials with the co-firing fly ashes taking different percentages of weights in them (5%, 10%, 15% and 20% for each) and use them to undergo the various tests including initial set time, slump flow, compression, X-ray diffraction experiments and SEM microstructure of mercury.

The result shows that the strength activity index (SAI) of the co-firing fly ashes is greater than 75 percent of the materials that can be used as the raw materials and meet the ASTM C311 standard. The results above show that co-firing fly ashes from a bubbling fluidized bed boiler can be utilized as substitution materials for cementitious materials in the controlled low-strength materials. The best substitution percentage is 15 percent.

1 INTRODUCTION

Taiwan is moving towards the era of circular economy and converting waste into renewable resources [1], which clearly shows that circular economy and waste recycling have become important issues in Taiwan's current development. According to the 2016 statistics from the Environmental Protection Agency's Sustainable Materials Management Database, about 70% of the various types of materials are imported into Taiwan from other countries. Among them, 100% of metals, 99.8% of fossil fuels, 66.3% of biomass and 32.7% of non-metals [2].

Taiwan's per capita consumption of materials is very high, and the amount of various types of waste generated is also staggering. According to the 2016 National Waste Quantity Statistics of the Environmental Protection Agency, the total amount of waste in Taiwan is 26.43 million metric tons [3]. Due to the implementation of the International Basel Convention [4], waste should be disposed in an environmental sound area as much as possible. However, the co-firing fly ash produced by the co-firing of fuels in the commercial waste Bubble Fluidized Bed Boiler (BFBB) in this research cannot be directly for reuse, it can only be disposed of as industrial waste for burial or solidification. The research results are used as supporting materials for other manufacturers who intend to reuse this material to apply for reuse. Let the circular economy continue to move forward.

2 LITERATURE REVIEW

2.1 *Controlled low-strength backfill material*

Controlled Low-Strength Materials (CLSM) is a kind of cementitious composite material with tamping-free self-filling properties. This material currently has many different names, such as fluid backfill, controlled low-strength backfill, fluid mortar, plastic soil cement or soil cement mud. . .etc. [5].

CLSM is defined in accordance with ACI 116R as a material that produces a compressive strength of 8.3 MPa (1200 psi) or less, the lower compressive strength specification being dictated primarily in response to possible future excavation needs. Also as stated in ACI 230.IR CLSM should not be confused with compacted cement. CLSM typically does not require compaction (consolidation) or curing to achieve the required strength and the long-term compressive strength of compacted cement typically exceeds the 8.3 MPa (1200 psi) maximum limit of the CLSM specification [6].

2.2 *The use and specification of controlled low-strength backfill materials in Taiwan*

According to Chapter 03377 of the Construction Outline Specification of the Public Construction Commission, Executive Yuan, CLSM is made by mixing cement (including cement-based treatment agent), pozzolanic admixture, granules and water in a set proportion, and chemical admixtures must be used if necessary. In addition to the special inspection items specified by the engineering department according to the special needs of the project, the basic properties such as pipe fluidity or slump flow, falling strength, 28-day compressive strength and chloride ion content should meet the requirements [7].

It is also specified in the construction specification that the cement (binder) used in CLSM should comply with the specifications of CNS61 "Portland Cement" [8] or CNS15286 "Hydraulic Mixed Cement" [9], and the specifications of pozzolanic admixtures must comply with Specification of CNS3036 "Fly ash and natural or pozzolanic for concrete" [10].

2.3 *Characteristics of co-firing fly ash in a Bubble Fluidized Bed Boiler (BFBB)*

Due to the co-combustion of fuels, the co-combustion fly ash produced by BFBB will have different chemical compositions depending on the type of fuel co-combustion. BFBB usually adds limestone ($CaCO_3$) as a desulfurizing agent. In order to maintain the desulfurization effect continuously, limestone ($CaCO_3$) will be continuously added during the process of fuel addition, so calcium sulfate ($CaSO_4$) and desulfurization will be continuously produced. The intermediate product of the sulfur reaction is calcium oxide (CaO) and the final limestone ($CaCO_3$) that does not react with sulfur. In view of the above and the characteristics of the bubble fluidized bed boiler, the characteristics of BFBB co-firing fly ash are as follows:

(1) High content of calcium oxide (CaO) and limestone ($CaCO_3$) [11]
(2) High calcium sulfate ($CaSO_4$) content [12].
(3) Fewer glassy.

3 RESEARCH RESULTS AND DISCUSSION

3.1 *Pozzolanic activity index test*

Pozzolanic strength activity index (Strength Activity Index, SAI) value to evaluate whether BFBB co-firing fly ash has cementing ability, and BFBB co-firing fly ash replaces 10% and 20% of the cement material in CLSM for cement mortar mixing and preparation of test specimens, and the compression test was carried out when the age of the test body reached 7 days and 28 days.

According to the requirements of ASTM C311 test specification, the SAI value of the test group should be greater than 75% of the strength of the control group. The test results show

that when the age of the test body reaches 7 days, 10% and 20% of the cement material is replaced by co-fired fly ash. SAI is 101.5% and 94.0% respectively; when the test specimens age reaches 28 days, the co-firing fly ash replaces 10% and 20% of the cement material, and the SAI values are 107.6% and 93.4%, respectively, as shown in Table 1. The test results confirmed that the BFBB co-fired fly ash has the activity of Pozzolanic and can be used as a cementitious material.

Table 1. Test results of Pozzolanic strength activity index.

	Compressive strength (kgf/cm^2)		SAI (%)	
Replacement ratio	7 days	28 days	7 days	28 days
0%	31.7	39.3	100.0	100.0
10%	32.5	42.3	101.5	107.6
20%	29.8	36.7	94.0	93.4

3.2 *Slump flow test*

From the slump flow test results (see Table 2), it can be found that the slump flow does not change significantly when the amount of cement replaced by BFBB co-firing fly ash is less than 10%, but the slump flow begins to deteriorate with the increase of the substitution amount. When it reaches 20%, its slump flow is only 85.9% and 87.9% of the original according to Table 2.

Table 2. Summary of slump test results.

Replacement ratio	slump flow (cm)	Average slump flow (cm)	%	Standard (cm)
0%	57 × 58	57.5	100	≧ 40
5%	54 × 57	55.5	96.5	
10%	55 × 59	57.0	99.1	
15%	52 × 54	53.0	92.2	
20%	49 × 51	50.0	87.0	

3.3 *X-ray diffraction test*

This test is mainly based on the spectrum obtained by X-ray diffraction analysis to compare whether the crystalline composition of samples with different substitution ratios and different sample ages after hydration reaction and curing period is different. The results are compared and discussed.

In this experiment, 3 groups of different proportions of specimens (substitution ratios of 0%, 10% and 20%) were selected and made, and the 7th and 28th days of the specimen age were used as the benchmarks, respectively, and were analyzed by X-ray diffractometer as shown in Table 3.

Table 3. XRD analysis results.

Ages	7 days			28 days		
Replacement ratio	0%	10%	20%	0%	10%	20%
Calcite ($CaCO_3$)	3.29	3.04	2.5	4.57	3.51	2.86
Quartz (SiO_2)	63.05	63.54	65.7	53.14	58.84	54.7
Dolomite (Carbonate minerals)	1.67	3.11	4.12	1.31	1.36	0.78
Portlandite ($Ca(OH)_2$)	1.85	2.18	1.57	3.96	3.58	3.49

Comparing the proportions of minerals between the samples with different substitution ratios at 7-day age, it is found that the proportions of carbonates increase proportionally with the increase of the substitution ratios. This is mainly due to the proportion of calcium carbonate ($CaCO_{3)}$ in the BFBB co-firing fly ash reaches 14.39%, the proportion increases with the increase of the substitution ratio.

3.4 *Compressive strength test*

In this test, the compressive strength test of the specimen was carried out according to the CNS1232 specification [14]. According to the data of the test results, it is found that this ratio design meets the requirements of compressive strength (including 1day, 7day and 28day) under different BFBB co-firing fly ash substitution additions. It was found that the compressive strength was the highest when the amount of substitution was 15%, and the compressive strength decreased rapidly if the amount of substitution was increased. The compressive strength values are shown in Table 4.

Table 4. Compressive strength results.

	Compressive strength (kgf/cm^2)
Replacement ratio	28 days
0%	64.9
5%	66.6
10%	74.8
15%	81.8
20%	58.7

4 CONCLUSIONS AND RECOMMENDATIONS

1. Combining the above tests, it can be known that the co-firing fly ash in a bubble fluidized bed can be used to replace the cement material in the controlled low strength material, and the optimal ratio of replacement is 15%. If it exceeds 15%, the performance will drop significantly.
2. In this study, the proportion of BFBB co-firing fly ash to replace cement material in CLSM is only 20%, and the various properties (such as slump flow or compressive strength) are much higher than the CLSM specification. It is recommended to continue to explore the largest replacement in the future.

Comparison of design methods for ground improvement by dry concrete columns

T.V. Tronda
Belarusian National Technical University, Minsk, Belarus

ABSTRACT: Nowadays, admixtures and inclusions are widely used as ground improvement. Variety of inclusions is used for this purpose all over the world. One of the effective types is dry concrete columns which were applied at construction sites in Belarus. For ground improvement design, there are different design methods. However, there is no one for dry concrete columns. Therefore, comparison of existing design methods for ground improvement was carried out in order to determine the most suitable for dry concrete columns design. Moreover, the methods were compared with results of field tests. The comparison and its analysis are described in the paper.

1 INTRODUCTION

Nowadays, there are many ground improvement methods which are used worldwide, also in Belarus. Some methods are described in codes, standards, and recommendations. However, dry concrete columns are quite a novel ground improvement method and there is no special design method for it.

Dry concrete columns (geomassif, vertical reinforcement and drainage elements) are used for upper soft water-saturated clayey soils to reinforce and drain them at the same time. The columns are installed together with a transfer layer under a shallow foundation, e.g. a mat foundation, but they can also be used for ground improvement in other cases. Dry concrete columns have been investigated in the laboratory (Tronda 2017, 2019, Sernov & Tronda 2019) and in-situ (Tronda 2016a, b, Tronda & Sernov 2020), successfully applied at construction sites in Belarus (Tronda 2013, 2016a, b, Sernov & Tronda 2019). The previous studies have proven dry concrete columns to be an efficient ground improvement method.

As dry concrete columns are mainly used for soft clayey soils layered under a foundation, the principal design comes to determination of vertical deformation, which must be less than limit settlement.

Design methods on determination of vertical deformations are described in Belarusian national normative documents for different types of foundation. Ground improvement methods and types of foundation alike dry concrete columns and their design are mentioned in four documents (P6-2000, R 1.02-133-2014, TKP 45-5.01-268-2012, TKP EN 1997-1-2009).

Therefore, the main purpose of the study was to learn design methods mentioned in the normative documents, check these methods for dry concrete columns and compare results with a field test in order to determine the most appropriate method for dry concrete columns design, specifically, for settlements estimation.

2 DESIGN METHODS

In this study, six Belarusian national normative documents were considered.

Initially, the following normative documents which describe similar to dry concrete columns types of foundation and their design were selected for consideration:

DOI: 10.1201/9781003299127-67

– P6-2000 to SNB 5.01.01-99 “Technogenous geomassifs from sand-gravel and crushed stone piles” (P6-2000);
– R 1.02-133-2014 “Recommendations for the design and installation of vertically reinforced foundations (geomassifs) for slab foundations of buildings and structures in the soil conditions of the Republic of Belarus” (R 1.02-133-2014);
– TKP 45-5.01-268-2012 “Bases and structures from the reinforced earth. Rules of designing and device” (TKP 45-5.01-268-2012);
– TKP EN 1997-1-2009 “Eurocode 7. Geotechnical design. Part 1. General rules” (TKP EN 1997-1-2009).

P6-2000, R 1.02-133-2014 and TKP 45-5.01-268-2012 include detailed description of methods for settlements calculation. The methods are based on the layer-by-layer summation method, which is commonly used in Belarus. Moreover, the documents use equivalent modules of deformation for improved ground (technogenic geomassif).

The last one, TKP EN 1997-1-2009 “Eurocode 7. Geotechnical design. Part 1. General rules” (TKP EN 1997-1-2009), is a version of translation of DIN EN 1997-1:2008 “Eurocode 7: Geotechnical design – Part 1: General rules” (DIN EN 1997-1:2008). There are basic geotechnical design approaches similar to national ones (Kravtsov 2019) but the code does not include a detailed design method for technogenic geomassifs or similar structures. Therefore, it will not be considered in this study.

However, two more documents were taken for comparison. These are:

– TKP 45-5.01-67-2007 “Slab foundations. Rules of designing” (TKP 45-5.01-67-2007);
– TKP 45-5.01-254-2012 “Bases and foundations of buildings and structures. The basic rules. Construction standards of designing” (TKP 45-5.01-254-2012).

TKP 45-5.01-67-2007 was considered to determine settlement of a slab on natural ground as if any reinforcement or improvement was not applied. TKP 45-5.01-254-2012 was selected additionally to determine settlement as if it was a pile foundation. For settlement calculation, the mentioned documents are also based on layer-by-layer summation method.

Limit general settlements are given in TKP 45-5.01-254-2012 and must be under 80-150 mm depending on building.

3 FIELD TEST

Ground improvement with dry concrete columns was applied under a foundation slab of a multi-storey building at a construction site in Minsk. In order to determine the accessibility of the improvement method, a set of field tests was fulfilled. One of the tests was static load tests of improved ground massif under each building section. In this study, one of static load tests results was taken for comparison with existing design methods.

Engineering geological conditions of the site included soft sandy clays, peaty soils, chalk, marl and sands. Soil properties are given in Table 1.

Table 1. Sub-surface conditions at the test site.

Unit	γ_{II}, kN/m^3	c_{II}, kPa	φ_{II},°	E, MPa	q_s, MPa	f_s, kPa
Sand transfer layer	17.0	–	–	30	–	–
Technogenic formation						
1 fill-up soil	16.8	–	–	18	5.9	40
Lacustrine, alluvial, swamp deposits						
3 sandy clay	19.7	26	25	8	1.2	45
9 medium-coarse sand	17.9	2	37	21	14.0	102
10 medium-coarse sand	17.9	2	38	33	19.1	113
3 sandy clay	19.7	26	25	8	1.9	41
10 medium-coarse sand	17.9	2	38	33	26.2	115
5 marl, chalk, peaty soil	13.3	28	5	12	2.8	71

The test area included dry concrete columns installed into the ground and a sand transfer layer under a reinforced concrete slab (see Figures 1-2).

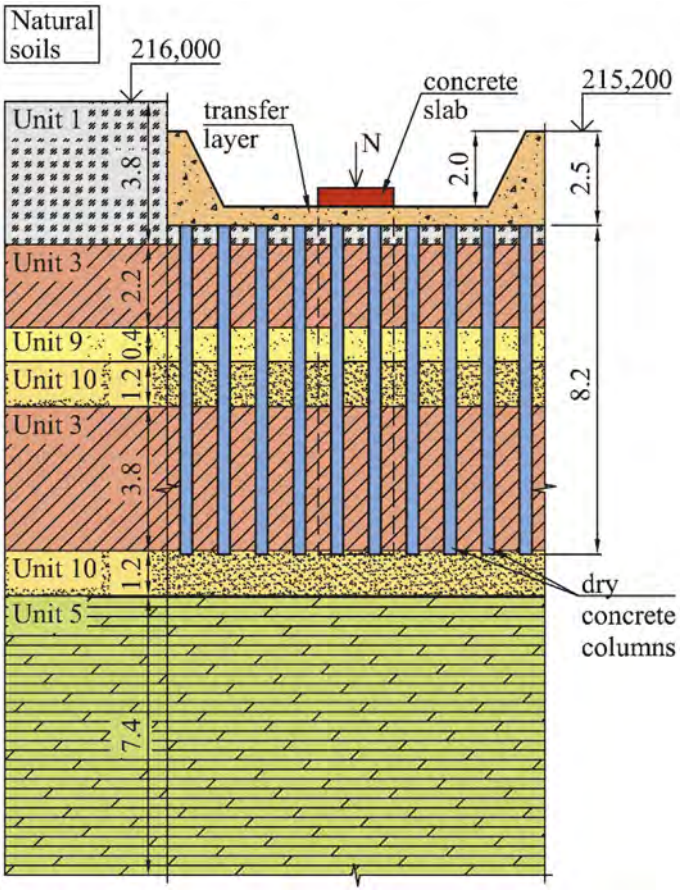

Figure 1. Geotechnical cross section at the test site.

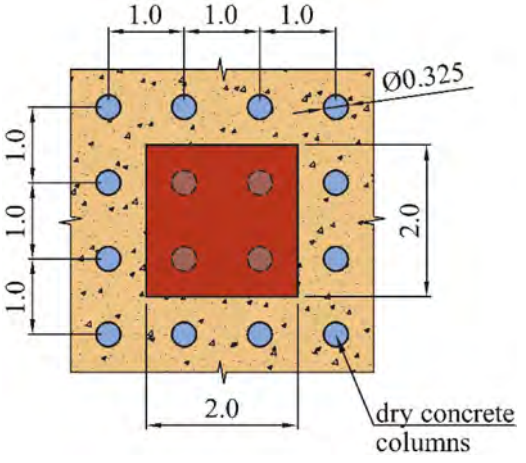

Figure 2. Top view of the test fragment.

The static load test was carried out according to GOST 20276-99 "Soils. Field methods for determining the strength and strain characteristics" (GOST 20276-99) (see Figure 3). Loads were applied to the slab by hydraulic jack step by step beginning from pressure of 50 kPa to 350 kPa. Vertical displacements of the slab were measured with four deflection gauges. Settlements of the slab were stated after each step stabilisation.

Figure 3. Field static load test.

4 STUDY RESULTS

Results of the field test and calculations according to normative documents mentioned above are shown in Table 2 and Figure 4.

Table 2. Settlements *s*, mm received in-situ and calculated according to different methods.

	Pressure *P*, MPa						
Method	50	100	150	200	250	300	350
Field test	1.4	2.8	4.0	5.4	6.8	8.3	9.8
P6-2000	3.8	8.3	13.0	17.8	22.7	27.6	32.6
TKP 45-5.01-268-2012	3.8	8.4	13.3	18.1	23.1	28.1	33.2
R 1.02-133-2014	4.3	9.6	15.1	20.6	26.3	32.0	37.8
TKP 45-5.01-67-2007	5.5	12.0	18.3	24.6	31.1	37.9	44.9
TKP 45-5.01-254-2012	3.8	13.5	23.7	33.9	44.5	55.5	66.5

Thus, field test results show lower settlements at all steps of loading than results of analytical calculations according to reviewed regulations.

The closest method is one described in P6-2000 to SNB 5.01.01-99. The difference between field test results and calculations was from 2.7 to 3.3 times. Similar values were obtained according to TKP 45-5.01-268-2012 but considering calculation of additional stress in the ground according to layer-by-layer summation method. Both methods use equivalent modulus of deformation.

Additionally selected TKP 45-5.01-67-2007 considered only a slab on natural ground without an improvement, and TKP 45-5.01-254-2012 determined settlements as for a pile foundation. The methods did not consider ground improvement, but loads transfer into soft layers. Consequently, high settlements were received.

In general, the difference between field test results and calculations amounted up to 6.8 times. The difference can be explained by the fact that the design methods do not take into account changes on natural soils caused by installation of dry concrete columns. As it was proved in

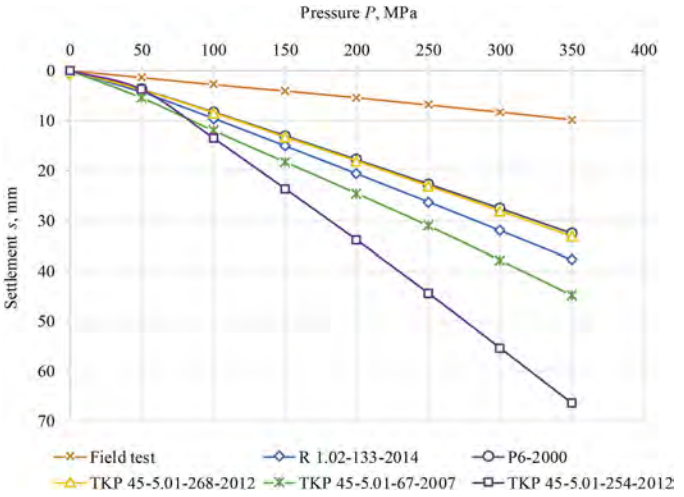

Figure 4. Graphs $s = f(P)$ according to different methods.

earlier study, dry concrete of columns absorbs pore water that leads to decreasing water saturation, the installation method allows natural soils to be compacted that leads to decreasing porosity and strengthening soils. As the result, deformation properties of natural soils improve and settlements decrease.

Moreover, the layer-by-layer summation method for settlement calculation used in all mentioned regulations is not extremely accurate (but quite easy to use) that leads to differences between field test results and analytical calculations.

Therefore, special design methods for dry concrete columns should be developed and implemented into design practice.

5 CONCLUSIONS

Field test of dry concrete columns show lower settlements at all steps of loading than results of analytical calculations according to existing national regulations.

The closest to field test results method is one described in P6-2000 to SNB 5.01.01-99 "Technogenous geomassifs from sand-gravel and crushed stone piles". The difference between field test results and calculations is from 2.7 to 3.3 times.

The difference between field test results and calculations can be explained by the fact that the design methods do not take into account changes on natural soils caused by installation of dry concrete columns.

Not only national normative documents but also unofficial methods should be taken into consideration to find a more suitable one as a base for special design method for dry concrete columns.

Special design method for dry concrete columns should be developed. The method should consider changes on natural soil properties caused by installation of dry concrete columns.

Effect of alkali activated materials in stabilizing sabkha soil

Wagdi M. Hamid, Ahmed M. Alnuaim* & Abdulhafiz O. Alshenawy
Department of Civil Engineering, College of Engineering, King Saud University, Riyadh, Saudi Arabia

ABSTRACT: Sabkha soil is one of the most problematic and hazardous soils in arid areas. Due to the geotechnical concerns connected with sabkha soil an appropriate treatment method must be implemented before using it as a construction material. Ordinary Portland cement (OPC) is one of the major chemical additives utilized to minimize the geotechnical issues of sabkha soil. However, OPC manufacturing is a significant source of carbon dioxide (CO_2) emissions globally. Consequently, environmental issues are gaining prominence around the world, prompting the immediate need for new sustainable solutions. Hence, this paper aims to investigate the potential of alkali-activated material as a promising alternative to OPC. The results show that the geopolymer treatment significantly increase the UCS compared to untreated sabkha soil, and the highest value is obtained when using the molarity of NaOH of 8 M.

Keywords: Sabkha soil, problematic soil, alkali-activated material, chemical stabilization

1 INTRODUCTION

Sabkha sediments have low dry densities and high void ratios. As a result, when wet, sabkha soil is recognized for having a very compressible nature with low bearing resistance and is hence regarded as one of the worst foundation materials. The existing condition of sabkha soil renders it unsuitable as a foundation material and incapable of supporting the vast majority of construction projects. This leads to enhancing the soil's engineering properties prior to applying structural loads (Alnuaim and El Naggar, 2014; Alnuaim, Alsanabani and Alshenawy, 2020; Alshenawy, Hamid and Alnuaim, 2021).

Damage to roads and other infrastructure built on sabkha soil has been documented in many sites around the world, especially in arid and hot areas, resulting in major financial losses. Ordinary Portland cement (OPC) and lime are the most widely used stabilizing binders. However, in the past several decades, the carbon footprint associated with the production of these conventional binders has led to significant environmental risks. The use of alkaline activated aluminosilicate minerals to make binders for soil stabilization is an ecologically friendly and low-energy alternative to the common soil stabilization methods (e.g., OPC and lime) since it permits the efficient recycling of industrial by-products (e.g., fly ash (FA), mine tailing, and granulated ground blast furnace slag). Numerous studies have investigated the potential of geopolymers based on FA in stabilizing various types of soils (Cristelo *et al.*, 2013; Parhi *et al.*, 2017; Teing *et al.*, 2019). There are a number of potential building dangers when working with sabkha soils because of their variability and poor natural strength capacity. The limited bearing capacity of sabkha soils is the main reason for these issues. Also, sabkha soils are extremely water sensitive. Contact with water results in a decrease in bearing capacity and a complete collapse. The objective of this study was to stabilize sabkha soil samples using geopolymerization with sustainable and environmentally friendly raw materials (such as FA). In this study, an FA-based geopolymer that is activated by sodium hydroxide and sodium silicate solutions was utilized. Various laboratory tests, including sieve analysis, standard compaction tests, unconfined compressive strength tests (UCS), and X-ray fluorescence (XRF) tests, were conducted.

DOI: 10.1201/9781003299127-68

2 EXPERIMENTAL METHOD

2.1 *Materials*

Samples of sabkha soil were collected in Ras-Al-Ghar, Eastern Province of Saudi Arabia. Figure 1 displays the particle size distribution curves of the sabkha soil. The percentage of soil that went through the #200 sieve was 6.8%, and the USCS and AASHTO soil classifications are SP-SM and A-3, respectively. In order to synthesize geopolymer, FA class F was utilized as a precursor. Table 2 displays the chemical compositions of the sabkha soil and FA as revealed by X-ray fluorescence (XRF) analysis. sabkha soil was composed primarily of CaO (40.43%) and SiO_2 (16.81%), while FA was composed primarily of SiO_2 (58.196%) and Al_2O_3 (27.78%). The alkaline activator solution was a combination of sodium silicate (SS) (Na_2SiO_3) and sodium hydroxide (SH) in a ratio of 2:1. (NaOH). The chemical composition of the SS solution is 8.7% Na_2O, 28.73% SiO_3, 60 ppm Fe, and 37.43% total solids. At 27°C, the specific gravity of the SS solution was 1.38 and its viscosity was 158 CPS. SH was originally a flake with a molecular weight of 40 g/mole and a purity of 99.9%.

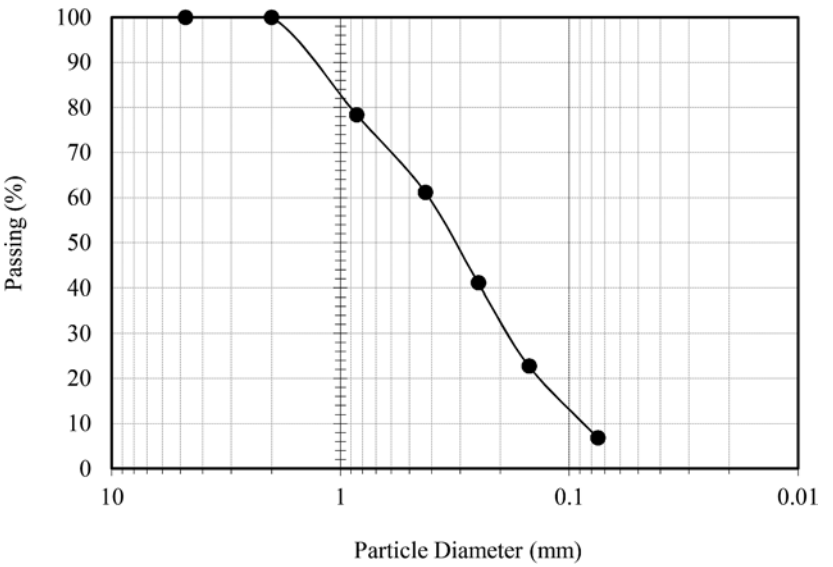

Figure 1. Grain size distribution of sabkha soil.

Table 1. Physical properties of sabkha soil.

Properties	Parameters
Specific gravity, G_s	2.78
Passing through #200 (%)	6.786
D_{10} (mm)	0.09
D_{30} (mm)	0.19
D_{60} (mm)	0.42
C_u	4.67
C_c	0.96

2.2 *Specimens' preparation and testing procedures*

The SH solution was produced by dissolving a certain amount of SH in distilled water, based on its molarity (e.g., 4, 8, 12). SH flakes were dissolved in water, and the resulting

Figure 2. Procedure for preparation of geopolymer-treated samples.

Table 2. XRF analysis of FA, and sabkha soil.

Elemental Oxide	Sabkha	FA
Na_2O	1.408	0.260
MgO	6.519	0.711
Al_2O_3	1.304	27.78
SiO_2	16.814	58.196
P_2O_5	0.03	0.483
SO_3	5.065	0.697
K_2O	0.329	1.505
CaO	40.43	3.948
TiO_2	0.072	1.615
MnO	0.012	0.031
Fe_2O_3	0.503	4.145
Cl	1.659	0.122
CuO	-	0.013
LOI	25.80	0.30

solution was cooled to room temperature before being combined with SS solution. In a cylindrical metal mold with a diameter of 36 mm and a height of 72 mm, the UCS specimens were formed. The needed amounts of dry ingredients (sabkha soil and FA) were weighed and hand-combined to create a dry mixture. An adequate amount of the alkaline activator with a predetermined molar concentration was added to the mixture and thoroughly mixed until it was homogeneous. A predetermined quantity of the mixture was poured in three equal levels into the metal mold. Immediately following compaction, the specimens were extruded and cured at room temperature (23°C). Figure 2 shows the procedure for preparation of geopolymer-treated samples. By conducting UCS tests in accordance with ASTM D2166, the strength performance of untreated and geopolymer-treated sabkha soil samples was determined. The stress–strain curves were created by applying a constant loading rate of 0.5 mm/min to the specimens. The UCS values were derived from these curves as the peak axial stresses.

3 RESULTS AND DISCUSSION

3.1 *Effect of standard compaction test*

The results of the standard proctor compaction test on untreated and geopolymer-treated soil are shown in Figure 3. The results of optimum moisture content (OMC) and maximum dry density (MDD) for 0% of FA represent the untreated soil. The geopolymer-treated soil was found to have a higher MDD and a lower OMC than the untreated soil. Due to the solution's lubricating properties, which reduce repulsive forces and improve soil particle sliding, the OMC was found to have decreased (Abdullah, 2020). However, the increase in MDD was attributed to the fact that FA had finer particles than sabkha soil and that MDD is influenced by grain size distribution. MDD is affected by the grain size distribution because FA has finer particles than sabkha soil (Osinubi, Yohanna and Eberemu, 2015; Ojuri, Adavi and Oluwatuyi, 2017; Murmu, Jain and Patel, 2019).

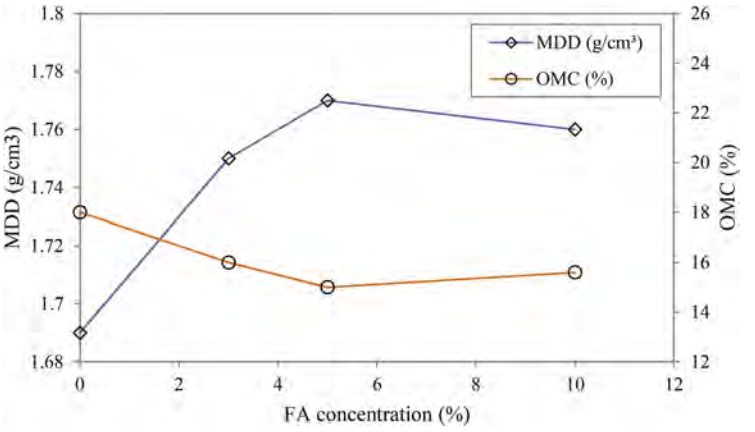

Figure 3. Results of standard proctor compaction tests on untreated and treated sabkha soil.

3.2 *Effect of FA concentration on UCS*

Figure 4 depicts the UCS results at different FA concentration (3%, 5%, and 10%) and different curing periods (1, 7, and 28 days) compared to the untreated UCS values. The UCS was increased by 535%, 536% and 697% compared to untreated soil specimens after 1 day of curing. The strength improvement behavior was also observed clearly for samples cured at 7 and 28 days. The improved binding of soil particles by geopolymer gels is most likely responsible for the higher strength.

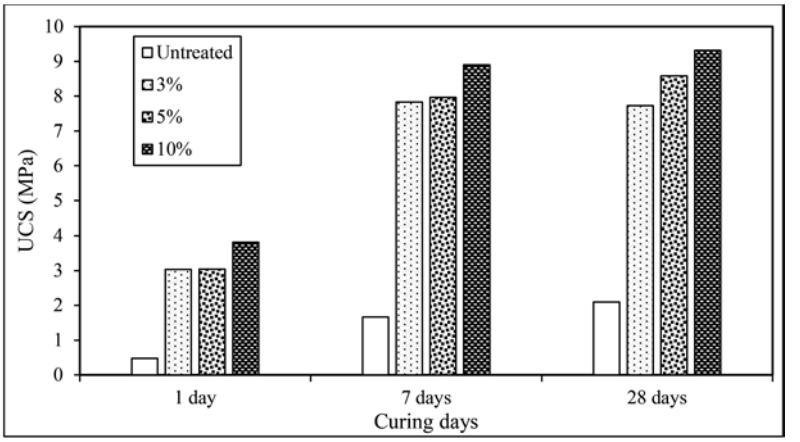

Figure 4. Effect of FA concentration and curing period on the improvement of UCS.

3.3 *Effect of NaOH molarity on UCS*

Figure 5 illustrates the effects of NaOH molarity in the alkaline solution on the UCS of the treated sabkha soil. When the concentration of NaOH was increased, the UCS of the treated soil was considerably enhanced. This performance is due to the effect of SH concentration on the dissolution of silica and alumina, which strengthens the geopolymeric link and increases UCS (Manjarrez and Zhang, 2018; Noolu et al., 2020). Figure 6 displays the effect of FA concentration and NaOH molarity on UCS after 7 days of curing. It is clearly shown that the higher UCS values were obtained when the molarity of NaOH is 8 M. This conclusion was also reported by previous researchers (Ghadir and Ranjbar, 2018; Noolu et al., 2020).

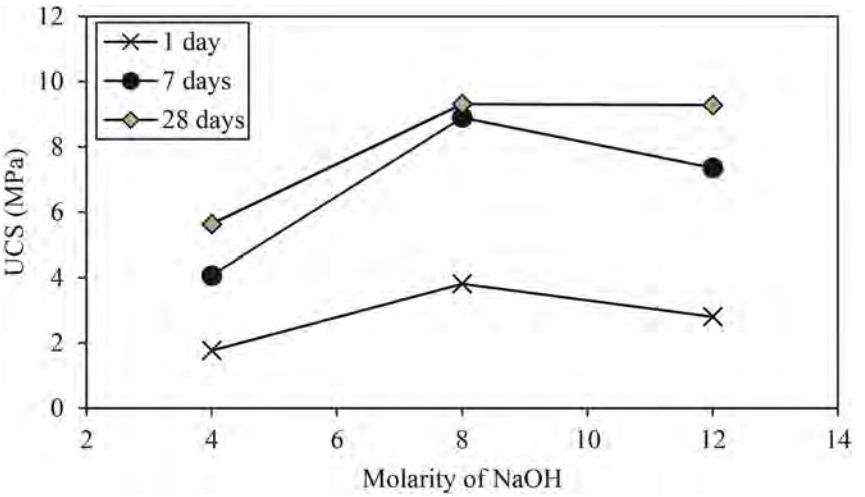

Figure 5. Effect of molarity of NaOH and curing period on UCS.

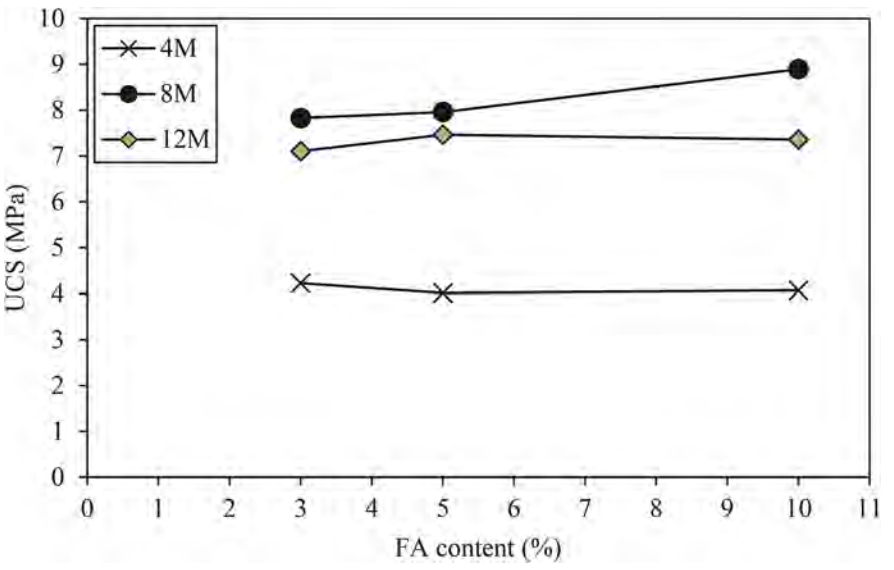

Figure 6. Effect of FA concentration and NaOH molarity on UCS after 7 days of curing.

4 CONCLUSION

This work highlights the ability of alkali-activated materials as an environmentally sustainable solution as a sabkha soil stabilizer. In comparison to untreated sabkha soil, the soil samples treated with geopolymer had higher MDD and lower OMC. In comparison to untreated soil, FA-based geopolymer increases the strength by more than 500%. The maximum value of UCS was measured when using the molarity of NaOH of 8 M and a concentration of FA of 10%. It is expected that the outcomes of the research would motivate geotechnical engineers to employ novel sustainable ways of stabilizing saline sabkha soil, such as stabilization based on geopolymers.

Plastic materials waste for improvement gypseous soil

L.N. Snodi
Department of Civil Engineering, Tikrit University, Tikrit, Iraq

ABSTRACT: Large quantities of plastic waste are released into the environment in an undesirable way, these waste causes many environmental problems. The current research presents an attempt to improve the properties of gypseous soil by using plastic. Different percentages of plastic (2%, 4% and 6%) were mixed with a soil of gypsum content of 57%. The results showed that adding (6%) of plastic leads to a reduction in the maximum dry unit weight by (21.48%), and the optimum moisture content increases by (20.68%). The angle of internal friction decreased by (17.45%) when adding (6%) plastic, and the soil cohesion decreased by (266.125%) when adding (6%) plastic . Overall, the plastic had positive effect on some geotechnical properties of soil and it can be used as admixture in soil.

1 INTRODUCTION

Gypseous soils are considered as collapsible soils, which contain high proportion of hydrated calcium sulfate ($CaSO_4.2H_2O$). Gypsum, dissolves due to water infiltration into soils leading them to be soft and highly compressible causing severe foundation problems due to collapse of soils structure and the formation of cavities (Al-Mohammadi et al. 1987).

Gypsum present in soil structure acts as a binder (cementing material) between soil particles and causes the soil to be very hard when it is dry. The bond between soil particles of fine materials and salts is washed away during saturation process and consequently this results in the general soil collapse. It is well known that many damages are recorded in several projects located in particular regions in Iraq due to presence of gypseous soils underneath the base of foundation. Problems associated with structures constructed on gypseous soils can be summarized as: settlement, collapse due to soaking, collapse due to leaching, delayed compression and shear failure Al-Neami.(2006).

The amount of wastes has increased and the disposal becomes a serious problem. Particularly, recycling ratio of the plastic wastes in life and industry is low and many of them have been reclaimed for the reason of unsuitable ones for incineration. It is necessary to utilize the wastes effectively with technical development in each field**.** For the construction of any kind of structure resting on collapse soil, there are many methods used to improve this soils, such as mixed with other materials lime, bentonite, ashes and chemicals ..etc. Thakur & Yadav (2018).

Rao & Dutta (2004) assessed the overall influence of waste plastic as a reinforced material on the bearing capacity improvement of granular trench. The results of tests concluded that inclusion of waste plastic strips in sand improves the bearing capacity.

This paper studying the ability of plastic waste to improve Gypseous soil.

2 MATERIALS USED

2.1 *Soil*

Soil used in this study is poorly graded (SP) as classified according to USCS. The soil used was brought from Tikrit city, which located in Salah-Aldeen Governorate, in the middle of Iraq at 1m depth Figure 1. The basic properties of soil was listed in Table 1.

DOI: 10.1201/9781003299127-69

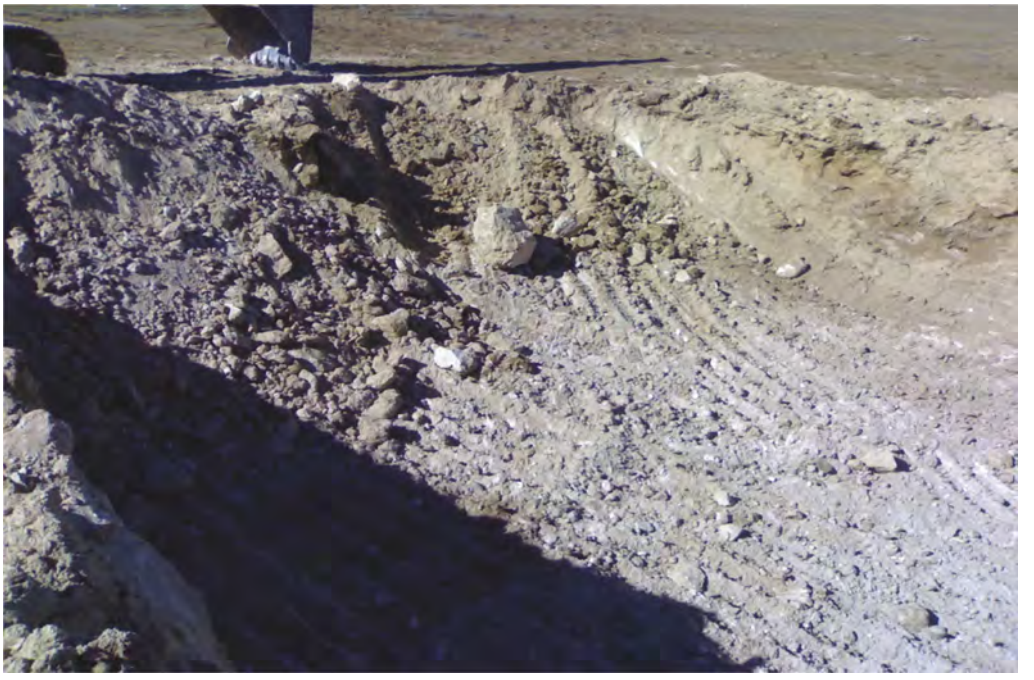

Figure 1. Gypseouse soil depth 1m.

Table 1. Basic Properties of soil used.

Properties	values
Specific gravity, (Gs)	2.46
Liquid limit (L.L)%	N.P.
Plastic limit (P.L)%	N.P.
Maximum dry unit weight (γ_{max}) kN/m^3	16.4
Optimum moisture content %	14.5%
Gypsum content (Gc)%	57%

2.2 *Plastic waste material*

Plastic is an easy-to-form material in various forms that mainly consists of chains called polymers. Since the world knew the Industrial Revolution, societies are still witnessing development from the age of coal to the era of black gold (petroleum), which contributed to the emergence of many new industries that developed over time. The plastic industry appeared and flourished and is today at the forefront of the current industries due to its many uses in daily life, because it is involved in the installation of things and tools surrounding us. Figure (2) shown the plastic used in this study cut from bottle of water each piece was 1cm

3 EXPERIMENTAL WORK

Many tests were done in this study to complete the experimental program, Physical Tests (Particle Size Distribution, Atterberg Limits Test, Specific Gravity, Gypsum Content) and Engineering Properties (direct shear test to obtain the shear parameters (C and φ) and compaction test).

3.1 *The particle size distribution*

The particle size distribution of the tested samples for gypseous soils were determined according to (ASTM D - 422) (dry sieving). The results shows that for gypseous soil the percentages

Figure 2. Pieces of plastic.

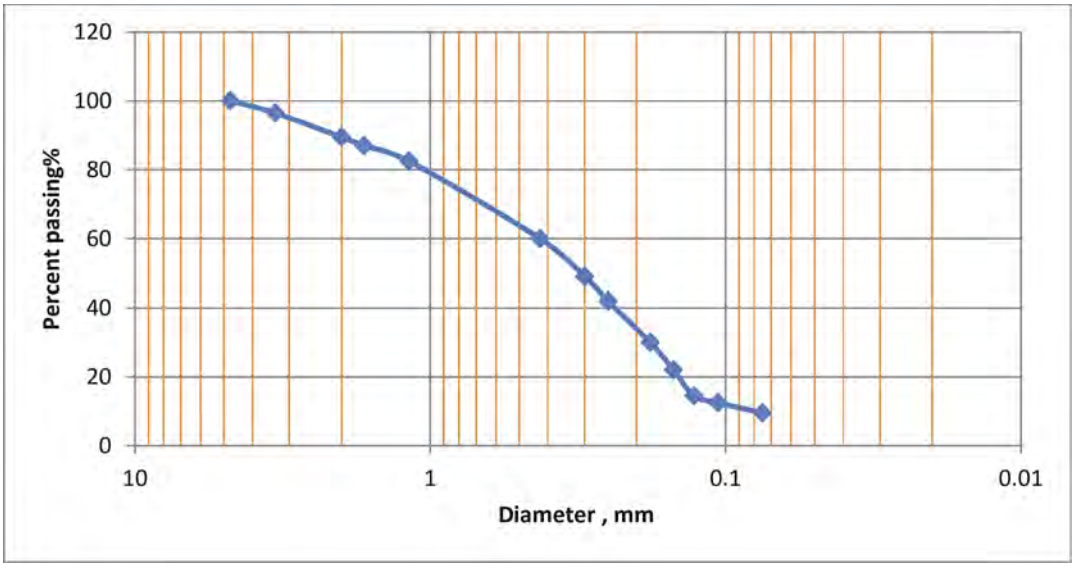

Figure 3. Grain size distribution of gypseous soil.

of gravels, sand and fines were (3.5, 87 and 9.5) respectively. Figure 3 shows the particle size distribution.

3.2 *Gypsum content*

The gypsum content determination Al - Mufty & Nashat method (2000) depending on the heating process. They described that gypsum content could be easily estimated by oven drying of the soil specimen at (45°C) temperature until the specimen weight becomes constant, the weight is recorded. Then the specimen is dried at (105°C) temperature, and the weight is rerecorded. The gypsum content was calculated according to the following equation.

$$Gc\% = \frac{W45^{\circ}C - W105^{\circ}C}{W45^{\circ}C} \times 4.778 \times 100\% \quad (1)$$

Where:
Gc = Gypsum content by weight%
W45°C = Weight of sample at 45°C
W105°C = Weight of sample at 105°C
4.778 = Inverse ration of molecular weight of hydration water to the molecular weight of gypsum. The result are tabulated in Table 1.

3.3 *Direct shear test*

The test is applied on the soil and soil/plastic mixture (2, 4, and 6% plastic/soil mixture) to obtain the shear strength parameters (cohesion c and internal friction angle φ) according to the ASTM specification D3080-72.

3.4 *Compaction tests*

Standard compaction test applied on the original soil and soil/plastic mixture (2, 4, and 6% plastic/soil mixture) to evaluate the effect of plastic percentages on the density of soil. This test applied according to ASTM D 698 – 12 clauses 2.

4 RESULTS AND DISCUSSION

Direct shear test are carried out on dry condition for samples treated with (2%, 4% and 6%) plastic content, Figure 4 shows the relationship between the normal stress and shear stress for treated and untreated samples in dry condition. The maximum shear stress versus normal stress was drawn, and both shear strength parameters, that angle of internal friction (ϕ) and cohesion (c) were calculated. A summary of the test results is given in Table 2. The results show that the cohesion of soil (c) and angle of internal friction (ϕ) decreased as the plastic content increased from (2%) to (6%). The reason behind this behavior is due to the plastic effect which did not create a high bonding force between the soil particles and the plastic which led to a decrease in the strength of the plastic mixture and the gypsum soil.

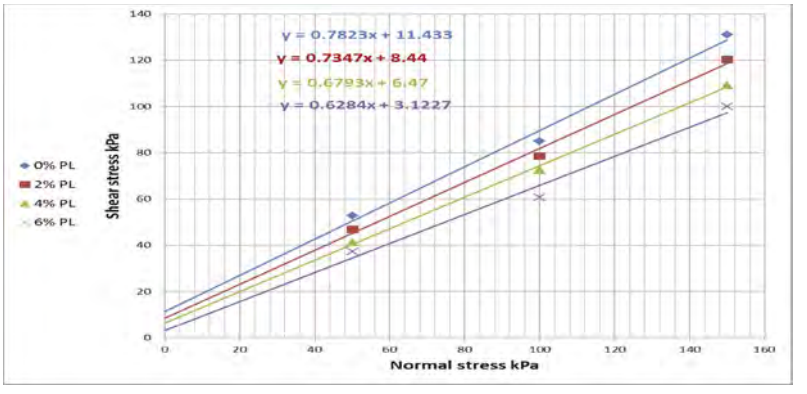

Figure 4. Direct shear results for gypseous soil treated with plastic.

For compaction tests the soil mixtures, with and without additives, were thoroughly mixed. The first series were aimed to determine the compaction properties of the untreated soils. Secondly, tests were carried out to determine the Proctor compaction properties of the treated

Table 2. Summary of the direct shear result of gypseous soil treated with plastic.

Plastic Content%	Cohesion (kN/m^2)	Internal angle of friction(ϕ)
0	11.43	38.6
2	8.44	36.73
4	6.47	34.43
6	3.12	32.87

soils with varying amounts of plastic .It is worth to mention that in this research used the soil which passes on sieve No. 4 for all of the tests.

The addition of plastic affected the compaction parameters of soil-plastic mixtures. It was observed that the maximum dry unit weight decreased and optimum moisture content increase with the addition of plastic and the reason for that the specific gravity of plastic is less than the specific gravity of the soil used. On the other hand, the reason behand the increase in optimum moisture content and decrease in maximum dry unite weight with the increase in plastic proportions because the plastic created large gaps inside the mixture of soil and plastic .

Figure 5 shows the relationship between the maximum dry unit weight and optimum moisture content increase for treated and untreated samples for gypseous content (57%).

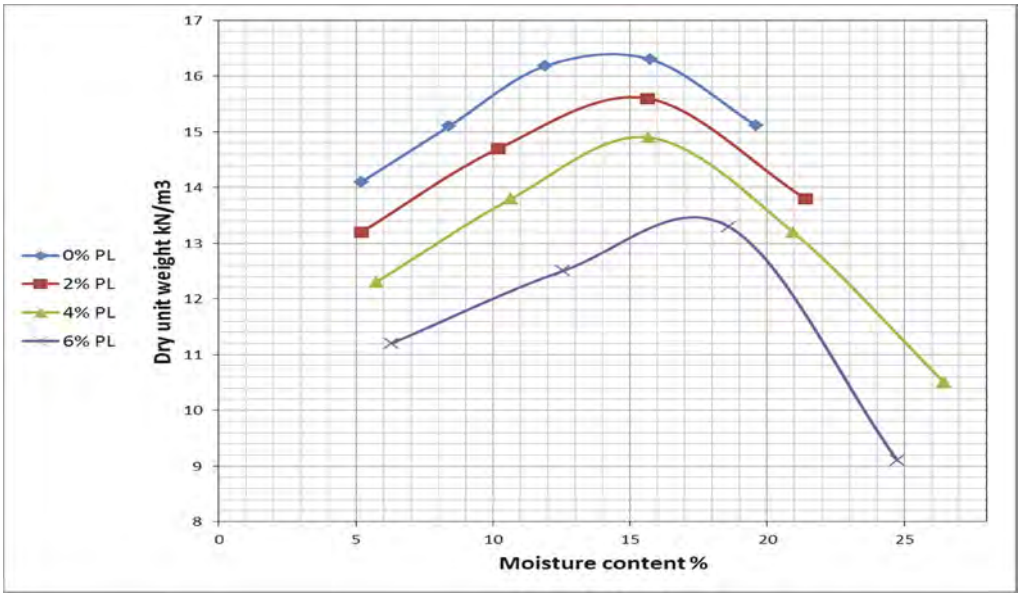

Figure 5. Compaction test results for gypseous soil with plastic.

5 CONCLUSIONS

Based on the results following conclusions can be drawn:

1- Adding plastic decreases the maximum unit weight of the Gypseous soil and also it increases the optimum water content.

2- plastic works as not good filler material to fill the voids between particles of a gypseous soil passes on sieve No. 4.

3- Adding plastic to the Gypseous soil decreases the cohesion value and decreases the internal friction angle when increasing the plastic to (6%).

ABSTRACT: Soil liquefaction is an important issue in geotechnical engineering that would cause damages as a result of bearing loss, lateral spreading, or even flowsliding in a mildly sloping ground. Mitigation of excess pore pressure generation and lateral deformation thus become major concerns for liquefiable deposits. This paper examines three commonly adopted mitigation measures (stone-column/SC, micro-pile/MP, and densification/DS) on their effectiveness in reducing the influences of soil liquefaction. A numerical tool is employed and a real soil deposit of liquefaction concern is assumed for the assessment. In this study, we investigate the improvements for each of the mitigation measures, with their usual ranges of design specifications, on liquefaction phenomena of the original deposit. The study indicates both SC and DS options could effectively reduce the generation of excess pore pressure in soil. However, in reducing the lateral deformation of sloping ground, MP option would be superior than the other two options.

1 INTRODUCTION

Soil liquefaction is a key problem in geotechnical engineering, in particular for lateral spreading or liquefaction-induced flow sliding, which could sometimes be devastating and damaging; such as the case of Petobo flow failure causing significant movements in a mildly sloping ground due to 2018 Palu-Donggala Indonesia earthquake (Kusumawardani et al. 2021). Accordingly, mitigation or prevention of liquefaction disasters would be a primary concern in engineering practice. This paper addresses the numerical assessment of several liquefaction mitigation measures, including stone-column (SC), micro-pile (MP) and densification (DS), with an aim to provide a clearer understanding on the effectiveness of these methods.

2 ANALYSIS METHOD

The assessment adopts a numerical tool, OpenSees, through a graphical user interface for conducting 3D ground-structure finite element analysis (http://opensees.berkeley.edu). A 20-8-node brick element is assumed, where 20 nodes are for solid translational degrees of freedom and 8 corner nodes for fluid pressure. Multi-yield conical surfaces with considering phase transformation are applied for soils. The coupled solid-fluid option of the software enables the performance of liquefaction studies. Details of theoretical background are referenced to the manual (Lu et al. 2011).

DOI: 10.1201/9781003299127-70

Figure 1 indicates a typical soil column of the improved ground with a depth of 30 m, where a periodic boundary condition is assumed for the vertical faces and a fix end at the base of column. Due to symmetry, only one half of the soil column is assumed in the numerical analysis. As indicated, the seismic shaking is assigned at the base of the soil column and acting in X-direction.

A liquefaction-prone area at Chuoshui river alluvial fan-delta of Taiwan (CRAFD; Chang et al. 2012) is selected as the target site, where the log of Borehole W5-3, as shown in Figure 2, is adopted as the soil deposit with improvements by several mitigation measures in current study. It is noticed that nearly top 25m of the deposit comprises of sandy soils which are prone to liquefaction due to seismic shaking. Table 1 indicates the assumed material parameters of soil deposit and mitigation measures in the numerical simulations.

The input motion of this study adopts the recorded motion at CHY002 station during 1999 Chi-Chi earthquake (M_w = 7.6) of Taiwan. The recorded motion, however, should be scaled to the design earthquake of the site (M_w =7.1 & PGA=0.308g) based on local building code (MOI 2011), and then deconvoluted from ground surface to a depth of 30m of the site for OpenSees analysis. Figure 3 shows the deconvoluted input motion for this study (a_{max} = 0.250g).

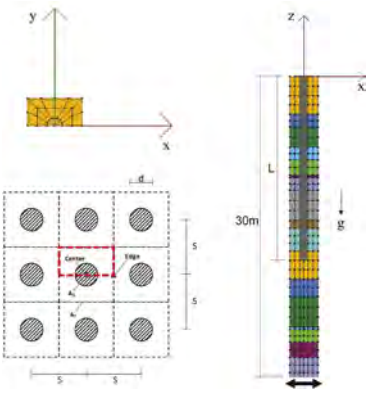

Figure 1. Finite element meshes of representative soil column for numerical simulations.

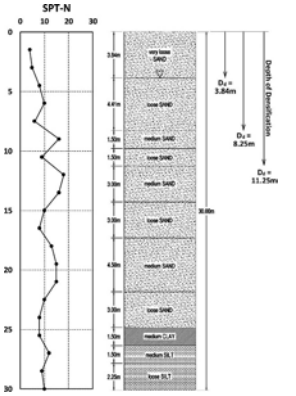

Figure 2. Typical soil/SPT-N profile, based on Borehole W5-3 in CRAFD, for current analysis.

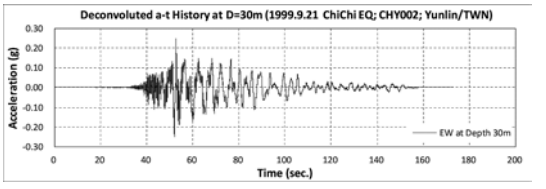

Figure 3. Deconvoluted input motion originally recorded at Station CHY002 (ground surface), in the proximity of Borehole W5-3 with a distance <2 km, during the 1999 Chi-Chi earthquake of Taiwan.

3 ASSESSMENT RESULTS

Three mitigation options are considered, including stone-column (SC), micro-pile (MP) and densification (DS), and the results are compared with the original deposit (i.e., original ground, OG; without improvement). Typical ranges of design specifications for each of the options are selected, as indicated in the relevant figures, with varied spacing (s) for SC option, embedment depths (L) for MP option, and depths of densification (D_d) for DS option.

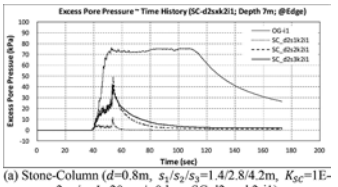
Table 1. Adopted material parameters for original soil deposit (original ground; OG) and for liquefaction mitigation options of stone-column (SC) and micro-pile (MP).

Parameters	Original Ground (OG)						Stone Column (SC)	Micro Pile (MP)
	Very Loose SAND	Loose SAND	Medium SAND	Loose SILT	Medium SILT	Medium CLAY		
γ (kN/m^3)	16.7	16.7	18.6	16.7	18.6	14.7	18.5	24.5
ϕ (deg.)	29	29	33	29	33	0	33	-
c (kPa)	-	-	-	-	-	37	-	-
ϕ_{PT} (deg.)	29	29	27	29	27	-	27	-
G_r (kPa)	5.5E4	5.5E4	7.5E4	5.5E4	7.5E4	6.0E4	7.5E4	1.4E7
B_r (kPa)	1.5E5	1.5E5	2.0E5	1.5E5	2.0E5	3.0E5	2.0E5	-
K_{soil} (m/s)	6.6E-5	6.6E-5	6.6E-5	1.0E-7	1.0E-7	1.0E-9	-	-
K_{SC} (m/s)	-	-	-	-	-	-	1E-4, 1E-2, 1E0	-
E_r (kPa)	-	-	-	-	-	-	-	3.5E7
v	-	-	-	-	-	-	-	0.2
σ_{py} (kPa)	-	-	-	-	-	-	-	5.2E4

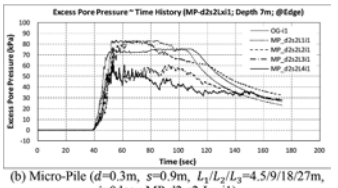
Note: γ = unit weight; ϕ = friction angle; c = cohesion; ϕ_{PT} = phase transformation friction angle; G_r = shear modulus at a reference effective confining pressure of 80kPa; B_r = bulk modulus at a reference effective confining pressure of 80kPa; K_{soil} = hydraulic conductivity of soil; K_{SC} = hydraulic conductivity of stone-column; E_r = Young's modulus at a reference effective confining pressure of 80kPa; v = Poisson's ratio; σ_{py} = yield stress.

3.1 *Excess pore pressure time history*

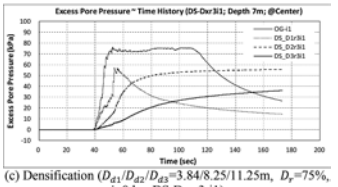
For level ground, the computed excess pore pressures at a depth of 7m of deposit are shown in Figure 4. As seen, the SC option would appear most effective in preventing excess pore pressure generation, hence reducing liquefaction potential. The DS option would also be effective in delaying the pore pressure generation if the depth of densification becomes deeper.



(a) Stone-Column (d=0.8m, $s_1/s_2/s_3$=1.4/2.8/4.2m, K_{SC}=1E-2 m/s, L=20m, i=0deg.; SC-d2-sx-k2-i1)

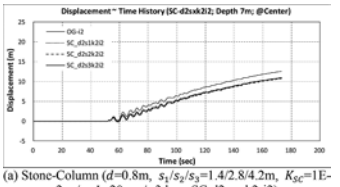


(b) Micro-Pile (d=0.3m, s=0.9m, $L_1/L_2/L_3$=4.5/9/18/27m, i=0deg.; MP-d2-s2-Lx-i1)

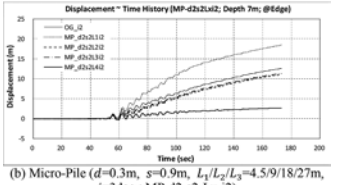


(c) Densification ($D_{d1}/D_{d2}/D_{d3}$=3.84/8.25/11.25m, D_r=75%, i=0dg.; DS-Dx-r3-i1)

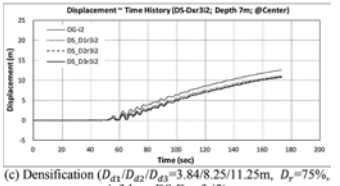
Figure 4. Computed excess pore pressure time histories at a depth of 7m (loose SAND) of the level ground ($i = i_1$ = 0deg.) for various liquefaction mitigation options. (Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification).



(a) Stone-Column (d=0.8m, $s_1/s_2/s_3$=1.4/2.8/4.2m, K_{SC}=1E-2 m/s, L=20m, i=3deg.; SC-d2-sx-k2-i2)



(b) Micro-Pile (d=0.3m, s=0.9m, $L_1/L_2/L_3$=4.5/9/18/27m, i=3deg.; MP-d2-s2-Lx-i2)



(c) Densification ($D_{d1}/D_{d2}/D_{d3}$=3.84/8.25/11.25m, D_r=75%, i=3deg.; DS-Dx-r3-i2)

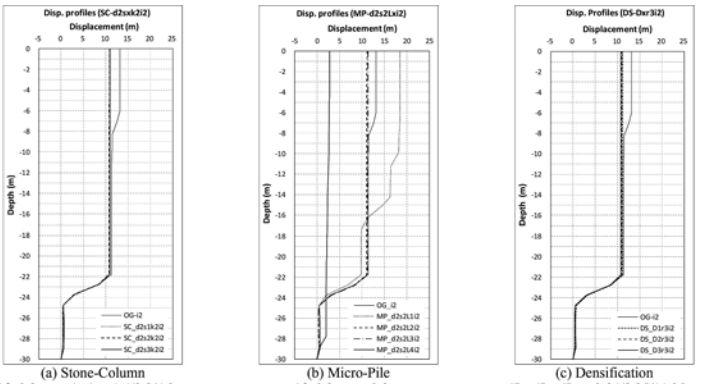
Figure 5. Computed lateral deformation time histories at a depth of 7m (loose SAND) of the inclined ground ($i = i_2$ =3deg.) for various liquefaction mitigation options. (Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification).

3.2 *Lateral deformation time history*

Figure 5 shows lateral deformation time histories computed at a depth of 7m of a mildly sloping ground (i=3deg.). As seen, Both SC and DS options would appear not effective in holding lateral deformation of the ground. For MP option, however, if the embedment depth of micro-pile is long enough, penetrating through the liquefiable zone of deposit, then the lateral deformation of the ground would be significantly reduced.

3.3 *Lateral deformation profile*

Figure 6 illustrates the lateral deformation profiles of soil deposit with a slightly inclined ground (i = 3deg.). Similarly, Both SC and DS options would appear ineffective, while MP option with an embedment depth greater than the liquefiable zone would substantially hold the deformation.



(a) Stone-Column (d=0.8m, $s_1/s_2/s_3$=1.4/2.8/4.2m, K_{SC}=1E-2 m/s, L=20m, i=3deg.; SC-d2-sx-k2-i2)

(b) Micro-Pile (d=0.3m, s=0.9m, $L_1/L_2/L_3$=4.5/9/18/27m, i=3deg.; MP-d2-s2-Lx-i2)

(c) Densification ($D_{d1}/D_{d2}/D_{d3}$=3.84/8.25/11.25m, D_r=75%, i=3deg.; DS-Dx-r3-i2)

Figure 6. Computed lateral deformation profiles of an inclined ground (i = i_2 = 3deg.) for various liquefaction mitigation options. (Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification).

4 CONCLUDING REMARKS

The numerical assessment of various liquefaction mitigation options indicates the stone-column (SC) and densification (DS) options would be effective in reducing or delaying the excess pore pressure generation, hence the risk of soil liquefaction. The micro-pile (MP) option could substantially reduce lateral deformation if the embedment depth is deeper than the liquefiable zone.

ABSTRACT: The number of problems regarding the weak foundation and subgrade profile to support overlaying weight addresses mainly clay soils. Clay soils usually tend to be problematic and exhibit unsustainable infrastructure due to their low stiffness, strength, and high compressibility. In this study, the stabilization of kaolin clay with an iron by-product called Basic Oxygen Furnace (BOF) slag is considered. The aim of this study is to treat the problematic soil and promote the waste disposal of steel waste material. Soil treatment with BOF slag content of 10, 20, and 30% was assessed by an unconfined compressive strength test (UCS) for soil samples cured for 3, 7, 14, and 28 days. This technique would contribute to a sustainable and green environment in road construction.

1 INTRODUCTION

One of the essential aspects of geotechnical engineering is lying on soil stabilization. Soil stabilization means improving soil properties to make it suitable for further application. Soft soils represent weak soil with low stiffness, high compressibility, and inefficient bearing capacity. BOF slag is a steel by-product produced during pig iron transformation in a basic oxygen furnace (Fisher & Barron 2019; O'Connor et al. 2021). There is a tremendous amount of steel production worldwide because it is one of the most demanded materials in the engineering industry.

The chemical binders such as lime, ordinary Portland cement (OPC), and calcium sulfoaluminate cement (CSA) has been generally used as a soil stabilizer due to its high bonding properties when added to the soil (Bazarbekova et al. 2021; Jumassultan et al. 2021; Moon et al. 2020; Ocheme et al. 2023; Sagidullina et al. 2022; Subramanian et al. 2018; Subramanian et al. 2023). However, processing BOF slag to powder-form cementitious material would take only about 10% of the energy needed to produce OPC, releasing a substantial amount of CO_2 (O'Connor et al. 2021; Shi & Qian 2000). Furthermore, because of the similar mineralogical composition of BOF slag and OPC, BOF slag is considered a weak OPC by several researchers (Poh et al. 2006; Shi & Qian 2000). However, BOF slag contains mainly slowly hydrating C_2S, and OPC contains specifically faster hydrating C_3S (Poh et al. 2006). Additionally, it was reported that even a small share of fines (<5%) cannot be ignored in cement-treated sand (Vinoth et al. 2018). Thus, higher BOF content and longer curing time would be recommended for clay soil stabilization with BOF slag (Cikmit et al. 2019; Goodarzi & Salimi 2015; Kang et al. 2019; Poh et al. 2006; Salimi & Ghorbani 2020).

BOF slag has already been used as a primary stabilizing agent for soft clays such as dredged marine clay, English China clay, Mercia Mudstone, dispersive smectite clay, and in combination with Ground granulated blast furnace slag (GGBFS) for kaolin clay. (Cikmit 2019; Cikmit et al. 2019; Goodarzi & Salimi 2015; Kang et al. 2019; Poh et al. 2006). However, the stabilization of kaolin clay with BOF slag as a primary stabilizer has not been researched yet. Therefore, this study examines the stabilization of kaolin clay with BOF slag.

2 EXPERIMENTAL PROGRAM

2.1 *Materials*

The soil used in this study is kaolin clay. It has white color and powder texture. According to the Unified Soil Classification System, this soil has been classified as MH. Basic soil characteristics of kaolin clay are shown in Table 1, specified with corresponding ASTM standards. The soil was dried in the oven before conducting any tests. Particle size distribution (PSD) analysis was performed using the QICPIC (M7) particle size and shape analyzer tool. Fresh BOF slag obtained from a steel company near Karaganda in Kazakhstan is evaluated in grain size, unit weight, chemical composition, and mineralogical composition, which define its basic properties (Table 2).

Table 1. Basic characteristics of kaolin clay.

Property	Value	Standard
Plastic Limit, %	33.1	ASTM D4318
Liquid Limit, %	53.6	ASTM D4318
Plasticity Index, %	20.5	ASTM D4318
Fine, %	> 80	QICPIC
USCS classification	MH	ASTM D1921
Specific gravity	2.4	ASTM D854
Optimum Moisture Content, %	19.3	ASTM D698
Maximum Dry Density, kN/m^3	12.1	ASTM D698

Table 2. Basic characteristics of BOF slag.

Property	Value	Standard
Specific gravity of fine aggregate	3.14	ASTM C188
Absorption rate of fine aggregate, %	3.05	ASTM C128
Free CaO, %	4.51	XRD analysis
Coarse aggregate (>0.075mm), %	99.5%	ASTM C136
Fine aggregate (<0.075mm), %	0.5%	ASTM C136

2.2 *Mixture design and sample preparation*

The standard proctor compaction test (ASTM D698) was used to define the optimum moisture content (OMC) and maximum dry density (MDD) of the future samples. There were three different mixtures according to BOF addition rate. Table 3 demonstrate how OMC and MDD increase with the increase of BOF content. However, the difference in OMC-MDD between BOF content of 10, 20, and 30% is not substantially huge.

Table 3. MDD-OMC of the BOF-stabilized soil.

BOF	Maximum Dry Density, kN/m^3	Optimum Moisture Content, %
BOF D 10%	14.27	27.7
BOF D 20%	14.35	28.9
BOF D 30%	14.48	29.0

Samples were prepared using the ratio of BOF slag mass to the mass of dry soil, and water content was taken as the ratio of water to the total mass of solids (mass of kaolin clay and slag). Initially, dry ingredients were mixed thoroughly, and then water was added. After manually mixing for about 5 minutes, the mixture was mixed with Hobart mixer for another 5 minutes to make a uniformly mixed texture. Cylindrical molds with dimensions 50x100mm, greased with oil inside, were used to prepare specimens. Samples were prepared with manual compaction of 3 layers with 25 blows. Samples were extruded from the mold on the third day of curing to obtain

enough hardening without breaking the specimen. After extrusion, the diameter and height of samples for further testing were recorded. Then, samples were carefully wrapped into polyethylene and rubber bands to avoid moisture loss. The curing period for all samples is 3, 7, 14, and 28 days. Five samples were prepared for each curing day and mix design.

2.3 *Unconfined compressive strength (UCS) and Bender element (BE) tests*

One of the critical parameters of the stabilized soil is increasing the resistance to compressive forces. An unconfined compressive strength test (UCS) was conducted to see the stabilization effect on strength gain. Test was performed according to ASTM D2166 with a standard compressive speed of 1mm/min.

Bender Element (BE) test was conducted according to ASTM D8295, using a peak-to-peak method to determine shear wave velocity at small strains. Two piezoelectric materials are placed on the top and bottom of the tested sample. The height of the sample is measured and input into the GDS Bender Element software. By the signal transmitted from the source (top) and receiver (bottom) of the specimen, the shear wave velocity can be calculated using the wave travel time through the length of the specimen.

It was reported that the maximum stress of the cemented sand has a direct relationship with the shear strength of its particles (Bisserik et al. 2021). This means that with increasing the UCS, the BE also should increase.

3 RESULTS AND DISCUSSION

3.1 *Unconfined Compressive Strength (UCS)*

Figure 1 (a) shows the impact of BOF content on the strength of stabilized soil with 10, 20, and 30% fine BOF particles (i.e., BOF 10%, BOF 20%, and BOF 30%). At an early age, there was no strength development (3 and 7 days), which means that 3-7 days are not enough for strength improvement. The increase in strength occurs only after seven days. Moreover, BOF 30% shows a considerable strength gain compared to BOF 20% and BOF 10%. However, BOF 10% was consistent throughout the whole curing period. BOF 20% has a moderate rate of strength improvement. Furthermore, the difference is also insignificant in regard to 14 and 28 curing days. Consequently, BOF 30% replacement tends to be the most prominent one.

3.2 *Shear wave velocity (Vs)*

According to Figure 1 (b), shear wave velocity starts to gradually increase only after the 7 days. BOF 10% and BOF 20% did not show any substantial difference throughout 28 days. Only BOF 30% started to rise apparently after 7 days. The highest Vs increase is obtained with BOF 30% for approximately 100m/s during the whole curing period. Hence, with an increasing curing period, the shear wave velocity also increases due to the prevalence of fine BOF slag rate. It was reported that with the increasing of curing days the stiffness of the soil is also increasing (Di Sante et al. 2022). It means that Vs increases with the increasing of the soil stiffness.

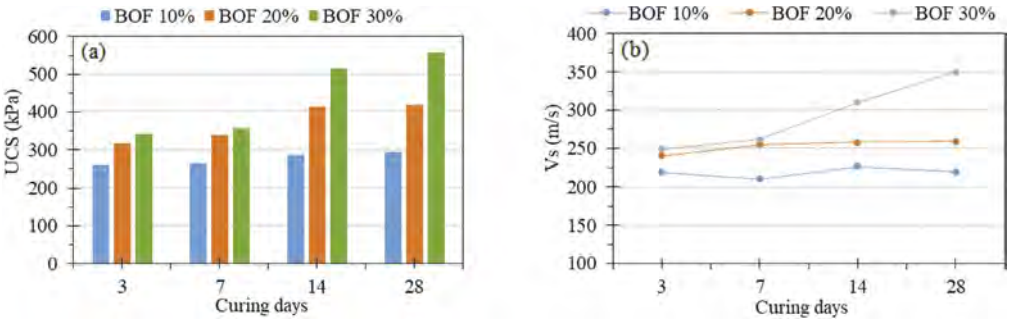

Figure 1. UCS (a) and BE (b) test results of BOF 10%, BOF 20%, and BOF 30%.

4 CONCLUSION

This research's main aim is to stabilize kaolin clay with BOF slag. A considerable strength increase is acquired for BOF 30% after seven days of curing. On the other hand, BOF 10% saved a consistent trend throughout 28 days. Compared to BOF 30% and BOF 10%, BOF 20% showed a moderate strength improvement. However, 3-7 days are insufficient to improve the soil properties in all cases. The highest strength increase is seen in the transition from 7 to 14 days. Bender Element test showed a similar trend with UCS test. BOF 10% and BOF 20% did not increase substantially from 3 to 28 days. Only BOF 30% showed the maximum strength increase after 7 days. It is assumed that shear wave velocity is linked with the soil stiffness, as well as with the strength of the soil sample. To sum up, BOF slag has excellent potential to be used as a stabilizing agent. Although there is a strength development to the maximum value of 557 kPa on the 28th day of curing with 30% of BOF D, it is not enough to stabilize kaolin clay. Therefore, long-term stabilization is needed to see the stabilization behavior of BOF slag. If the results from long-term stabilization (56 and 112 days) will be the same as 28 days, then other calcium-based materials should be added to improve the stabilization effect of BOF slag.

L. Ge
National Taiwan University, Taipei, Taiwan

ABSTRACT: Enzyme Induced Calcite Precipitation (EICP) is an innovative bio-inspired ground improvement technique that promotes calcite ($CaCO_3$) precipitation. This helps in the clogging of pore spaces and increases the strength of the soil. In this paper, a series of consolidated drained triaxial tests were carried out to investigate the effect of EICP treatment on the strength characteristics of soil. Two urease enzymes were adopted for the EICP treatment with different activity rates of 3g/l (5000 Units/g and 3500 Units/g) and mixed with cementation solution (1M Urea and 0.67M $CaCl_2$). The stress-strain curves after a curing of 7 days are presented herein. The volumetric strain response curve demonstrated a more dilative tendency in the EICP-treated specimens than in the untreated. Mohr-Coulomb failure criteria were adopted to determine the shear strength parameters at peak and residual stages. Finally, acid digestion was performed on the specimens to evaluate the calcite precipitation.

1 INTRODUCTIONS

Calcite-induced precipitation methods (CIPMs) are promising techniques for enhancing the strength of the soil. CIPMs include Enzyme induced calcite precipitation (EICP), Microbial-induced calcite precipitation (MICP), and chemical stabilization methods (Pratama et al., 2021). The application of green and eco-friendly techniques has gained attention in recent times. These bio-cementation techniques include using ureolytic bacteria for the ureolysis process in MICP (Wu et al., 2021) and free urease enzymes in EICP(Gao et al., 2018), which are mixed with urea and calcium chloride solution. The calcite precipitation from this technique binds the soil grains together by increasing the particle roughness and promotes the stiffness, dilatancy, and strength of the soil, reducing in hydraulic conductivity of the soil. Enzyme-induced calcite precipitation is adopted in this research. EICP is an innovative, bioinspired ground improvement technique. EICP bio-cementation includes the mixture of free urease, urea, and calcium carbonate. The primary chemical constituents involved in the EICP process are the urease enzyme, urea ($CO(NH_2)_2$), and calcium chloride ($CaCl_2$).

$$CO(NH_2)_2 + 2H_2O \xrightarrow{\text{Urease}} 2NH_4^+ + CO_3^{2-} \quad (1)$$

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3 \quad (2)$$

The urease enzyme catalyzes the hydrolysis of urea ($CO(NH_2)_2$ into carbon dioxide (CO_2) and ammonia (NH3). The process of ureolysis increases the pH and alkalinity of the reagent

DOI: 10.1201/9781003299127-72

solution from the production of carbonate and ammonium ions. The presence of Ca^{2+} cations from the calcium chloride cementation solution combined with the carbonate ions leads to the precipitation of calcium carbonate (Sun et al., 2021). The precipitated calcite gels between void spaces of soil particles and improved the soil's engineering properties. The effectiveness of EICP can be achieved by using additives in the EICP solutions like dried non-fat milk, xanthan gum, magnesium chloride ($MgCl_2$), magnesium sulfate ($MgSO_4$) and zeolite (Ahenkorah et al., 2021). EICP applications in soil improvement include soil strength, liquefaction resistance, remediation of soil contamination, slope stabilization, and surface erosion control (Meng et al., 2021).

2 MATERIAL USED

2.1 *Sand*

Crushed silica sand was purchased from Singapore. Sand properties are derived from preliminary laboratory tests. The coefficient of uniformity Cu is 1.403 and coefficient of curvature Cc is 0.977, and the specific gravity is 2.66. Some of the other geotechnical parameters are D_{60} = 0.205mm, D_{30} =0.171 mm, D_{10} = 0.146 mm, e max = 0.911, e min = 0.574 and γ at 50% Relative Density = 1527 kg/m^3.

2.2 *Characteristics of urease enzyme and reagents*

The cementation solution consisting of Calcium chloride dihydrate ($CaCl_2.2H_2O$) and Urea ($CO(NH_2)_2$) with 99% purity was purchased from Bioman Scientific Co. Ltd. This experimental study uses two urease enzymes (powder form) derived from an agricultural source (jack bean). The urease enzyme was purchased from Sigma-Aldrich Company Ltd. The activity rate of this enzyme in the research is 5000 Units/gram. The urease enzyme was purchased from CDH chemicals Pvt Ltd, India. The enzyme activity rate used in the study is 3500 Units/gram. After the use of the enzyme, it is stored in the refrigerator at 4ºC for future use.

3 METHODLOGY

The paper mold for triaxial specimen with a diameter of 73mm and height of 150mm for the preparation of EICP treated soil specimens. EICP solutions were prepared with 1M Urea, 0.67M $CaCl_2$, and 3g/l urease enzyme with 5000 Units/gram and 3500 Units/gram, respectively. The pure sand is compacted in the paper mold with a relative density of 50%. One cycle of EICP biocementation solution is added from top to bottom in the closed retained columns. After the curing of 7 days, the sample is shifted to the triaxial apparatus for consolidated drained triaxial testing. Consolidated Drained (CD) triaxial tests were conducted to evaluate the influence of biocementation on the sand by the stress-strain behavior. Two types of saturation, manual saturation and backpressure saturation, were performed in the sample to achieve a B value higher than 0.95. The samples were subjected to three different confining pressure – 50 kPa, 100 kPa, and 200 kPa. The samples were monotonically sheared with a shear rate of 0.185mm/min. When the axial strain reached 20%, the test was made to stop, and the data were extracted.

3.1 *Determination of calcium carbonate*

The process of acid digestion of the calcium carbonate precipitation in the following equations

$$CaCO_3 + 2HCl \rightarrow CaCl_{2(aq)} + H_2O_{(l)} + CO_{2(g)} \quad (3)$$

After the completion of each triaxial test, three samples of 10 grams were collected at the top, middle, and bottom. 4M HCl was used to digestion precipitation calcium carbonate over the soil grains. After 24 hours, the sample is washed thoroughly with DI water. The acid

digested specimens were dried. The percentage of calcium carbonate content of 3 illustrations from the top, middle, and bottom is calculated.

$$\% \; CCC = \frac{W_1 - W_2}{W_1} \times 100 \tag{4}$$

W_1= weight of the crushed soil sample before acid washing. W_2 = weight of the oven-dried crushed soil sample after acid washing.

4 RESULTS & DISCUSSION

Table 1. Test scheme.

Tests	Combination	Curing Days	Peak Deviatoric Stress (kPa)	Calcium carbonate content (%)
PS 50 kPa			189.05	0
PS 100 kPa			359.95	0
PS 200 kPa			629.11	0
Sigma 50 kPa	1M Urea	7 days	199.483	1.87
Sigma 100 kPa	0.67M $CaCl_2.2H_2O$		362.862	2.13
Sigma 200 kPa	3g/l urease		686.581	2.13
CDH 50 kPa			173.011	0.37
CDH 100 kPa			275.76	0.34
CDH 200 kPa			575.54	0.4

4.1 *Stress-strain response*

Uncemented and EICP cemented consolidated drained triaxial shear response curves are shown at 50 kPa, 100 kPa, and 200 kPa effective confining pressures at 7 days curing time. The bio-cemented specimens failed in brittle behavior with peak deviatoric stress at 3–5% axial strain, and further shearing led to the reduction of deviatoric stress. After 10-12% of axial straining, the deviatoric pressure falls to a residual state. Treated EICP sand generally has a higher peak deviatoric stress than untreated sand. The higher deviatoric stress is due to the high calcium carbonate content. The urease enzyme with 3g/l urease of 5000 Units per gram showed a higher peak deviatoric stress with 199.483 kPa, 362.862 kPa, and 686.581 kPa at 50kPa, 100kPa, and 200 kPa effective confining pressure. In contrast, the urease enzyme with 3500 Units per gram showed a lesser peak deviatoric stress with 173.011 kPa, 275.76 kPa, and 575.54 kPa at 50kPa, 100kPa, and 200 kPa effective confining pressure. The lesser peak deviatoric stress may be due to the lower amount of CCC in 3500 Units per gram urease enzyme. The weak calcite bonds in the soil particles increase the initial stiffness and are later destroyed by the shear stress, which leads to a decrease in peak deviatoric stress. The peak deviatoric stress is highly influenced by EICP particle-particle contact (Wang et al., 2019). The failure of pure sand and EICP-treated sands showed brittle failure (dilative behavior) at 20% axial shear strain, as shown in the Figure 1.

4.2 *Volumetric strain response*

The volumetric strain in EICP treated specimens with 3500 Units per gram urease enzyme have shown a slightly higher volumetric strain rate compared to untreated pure sand whereas the urease enzyme with 5000 Units per gram have shown higher dilation. The dilation rate decreases with an increase in effective confining pressure (Safdar et al., 2021). The volumetric strain response showed an initial contraction followed by significant dilation. The amount of initial contraction has increased the EICP bio-cemented sand, which can be seen in the repeatability of consolidated triaxial tests at varying confining pressures and curing times. All the EICP-treated specimens transition from contractive behavior to dilative behavior after a certain stage of initial

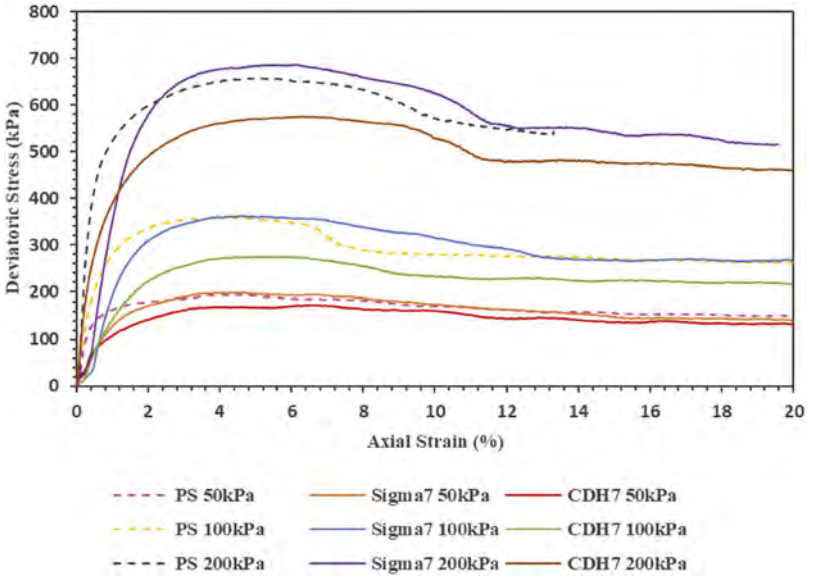

Figure 1. Shear Response curve at 7 days curing in two different urease enzymes at 50 kPa, 100 kPa and 200 kPa confining pressure.

shearing. The increase of CCC in EICP-treated specimens induces dilative behavior compared to the untreated specimens. The EICP bio-cementation enhances the particle interlocking capacity between the soil grains by gelling calcite precipitation between the soil particles. EICP-treated specimens with 5000 Units per gram have shown a higher volumetric strain than untreated pure sand, whereas 3500 Units per gram have shown a slightly higher volumetric strain. One cycle of bio-cementation has shown a lesser amount of calcite precipitation in the EICP treated specimens

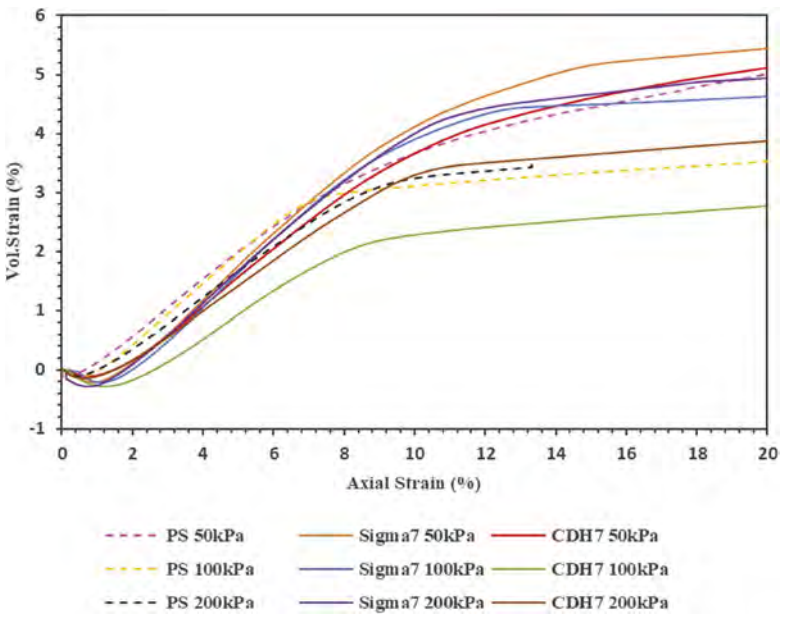

Figure 2. Volumetric strain response curve at 7 days curing in 50 kPa, 100 kPa and 200 kPa effective confining pressure.

with 3500 Units per gram of urease enzyme. Hence, multiple cycles of bio-cementation may increase the calcite precipitation in the treated specimens. High the CCC, higher stiffness and dilations of the bio-cemented specimens. The EICP bio-cementation enhances the particle interlocking capacity between the soil grains by gelling calcite precipitation between the soil particles.

4.3 *Shear strength envelope*

The effective stress strength parameter is derived from the shear strength envelope, which is widely used in the geotechnical field for the quantification of the strength of the soil. The shear strength parameters are measured at peak, and residual strength is determined for each EICP treated specimen at 7 days curing in 5000 Units per gram and 3500 Units per gram urease enzyme. The increase in bio-cementation has increased the cohesion in the EICP-treated specimens (Feng and Montoya, 2016). The EICP treatment increases the soil's residual strength along with the soil's peak strength, which can also be observed from the Table 2.

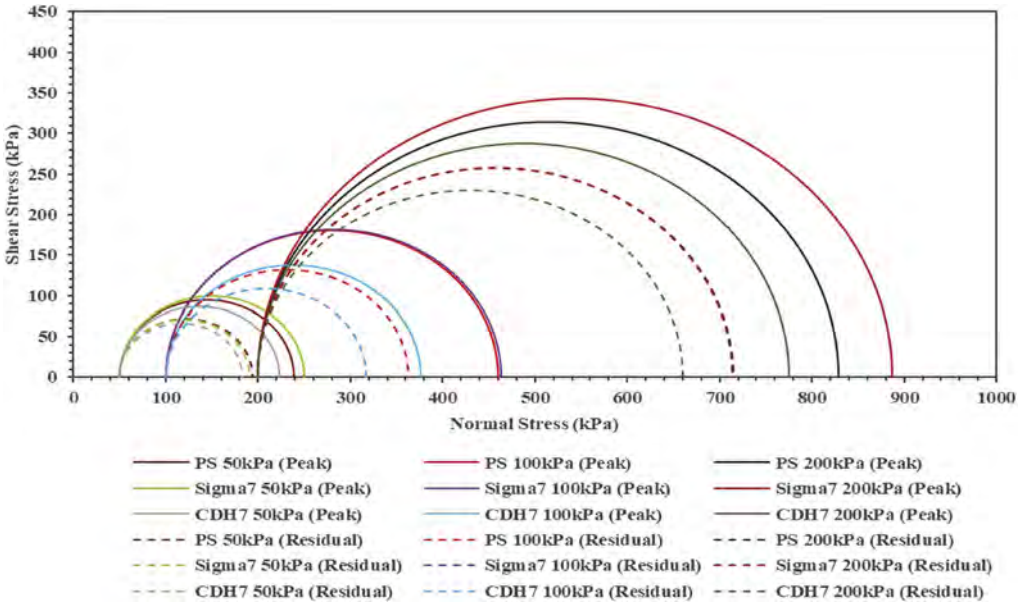

Figure 3. Mohr circles of EICP treated and untreated (Peak and Residual strength) in two different urease enzymes at 50kPa, 100kPa and 200 kPa effective confining pressure.

Table 2. Shear strength parameters (Peak and Residual strength).

	Peak Strength Parameters		Residual Strength Parameters	
Samples	c_p (kPa)	φ_p (deg)	c_r (kPa)	φ_r (deg)
Pure Sand	0	38.35	0	34.43
Sigma	9.13	38.22	2.88	34.32
CDH	5.63	35.32	2.81	31.79

5 CONCLUSIONS

The following conclusions are derived from the research study. The increase of bio-cementation by EICP has increased the higher deviatoric stress and volumetric strain in 5000 Units per gram urease enzyme due to high calcium carbonate content in the specimens. One

cycle of bio-cementation has precipitated lesser calcium carbonate content, leading to lesser deviatoric stress and small amounts of increased volumetric strain in 3500 Units per gram urease enzyme. Higher peak deviatoric stress and higher stiffness of the treated specimen can be achieved by multiple cycles of treatment. The number of treatment cycles directly influences the precipitation rate in the soil particles. The EICP-treated specimens showed an increase in effective cohesion. The influence of % CCC over the friction angle was negligible from the shear strength parameter in peak and residual strength. Increased treatment cycles may significantly improve effective cohesion. The higher CCC from the number of treatment cycles improves the sand's mechanical behavior. The weak cemented bonds can be transformed into stronger calcium carbonated bonds in the treated specimen with treatment cycles. With the inclusion of additives such as powder milk, the conventional EICP solution (urea, calcium chloride, and free urease enzyme) can be changed to produce improved strength in a weakly cemented sand or low calcium carbonate environment ($CaCO_3$).

Stabilization of organic soil with CSA cement

Nazerke Sagidullina, Aiym Muratova, Jong Kim, Alfrendo Satyanaga & Sung-Woo Moon
Nazarbayev University, Nur-Sultan, Kazakhstan

ABSTRACT: Problematic soils, especially organic soils, are not usually suitable for engineering construction purposes due to their high compressibility. The infrastructures built on organic soil can be easily damaged by causing many problems, such as foundation settlement, cracking in the structure, and corrosion. Therefore, this study aims to investigate the effectiveness of CSA cement for the stabilization purposes of organic soil by conducting comprehensive laboratory work for the improvement of organic soil properties. For this purpose, Unconfined Compressive Strength (UCS) and free swell testing were performed on the stabilized soil specimens cured for 3, 7, and 14 days. Samples were prepared at optimum moisture content using different cement content, 0%, 10%, 15%, and 20%. Overall, the use of CSA as a stabilizer for silty would be useful to achieve sufficient strength and meet the requirements subgrade.

1 INTRODUCTION

The problematic soil, especially in severe weather conditions of Kazakhstan, is usually not applicable for geotechnical engineering purposes. Therefore, investigating the characteristics and performance of problematic soil is of great importance. Generally, the soil stabilization method is adopted to improve ground properties. For the treatment of problematic soil properties, chemical soil stabilization has been implemented for several decades due to a potential reduction in the construction and maintenance costs of pavement infrastructure built on problematic grounds. Chemical stabilization generally involves mixing or injecting the soil with a chemical stabilizer (Güllü &Fedakar 2017, Yilmaz &Fidan 2018, Bazarbekova et al. 2021, Subramanian et al. 2023). Cement and lime stabilization are commonly used methods for improving ground properties among the existing soil stabilization techniques.

Ordinary Portland Cement (OPC) is popularly used as a binding admixture, whose behavior has been well investigated by many researchers. On the other hand, using OPC poses environmental problems due to the significant emission of CO_2. Hence, considering global warming and climate change, there has been a strong need for replacing OPC with low CO_2-emitting binders.

Calcium Sulfoaluminate cement (CSA), which releases less carbon than OPC cement, can be used to treat problematic soil since several research works were carried out to assess CSA binder effectiveness. The previous research results showed the rapid strength gain of CSA-treated soil (Ocheme et al. 2022, Bisserik et al. 2021, Subramanian et al. 2018, Vinoth et al. 2018, Moon et al. 2020). Also, the effect of cyclic freezing and thawing was tested, where the addition of CSA cement considerably reduced the effect of cyclic freezing and thawing by improving the performance (Jumassultan et al. 2021, Sagidullina et al. 2022). Therefore, the CSA cement will be tested for the treatment of organic soil by conducting different experimental tests, such as unconfined compressive strength (UCS) and free swell tests.

DOI: 10.1201/9781003299127-73

2 EXPERIMENTAL WORK

2.1 *Materials*

The materials used in this experimental work are natural soil, calcium sulfoaluminate (CSA) cement, gypsum, and water. Table 1 shows the main physical properties of natural soil, which was received from the open-cut excavation in Nur-Sultan. Natural soil is defined as organic soil since it contains 18% of organic matter. The organic content of the soil is determined based on ASTM D2974 standard (2000). Applying the USCS classification, the soil type is classified as poorly graded sand with silt [SP-SM]. The gypsum was used to partially replace CSA cement since previous research by Subramanian et al. (2019) has shown that CSA cement with 30% of gypsum will have a high strength gain in treated soil.

Table 1. Physical properties of the soil.

Property	D_{10} (mm)	D_{30} (mm)	D_{60} (mm)	C_c	C_u	Organic content (%)	LL (%)	PL (%)	PI (%)	USCS
Value	0.08	0.18	0.45	0.90	5.63	18	83.99	74.01	9.99	SP-SM

2.2 *Sample preparation*

The received organic soil is oven dried for 24 hours at 105ºC to be further used in cement-soil mixtures. The mixture should be prepared at the optimum moisture content (OMC) and maximum dry density (MDD) conditions. These conditions are defined by the standard Proctor test, conducted according to ASTM/D698 standard (2007). The results of the testing for 0, 10, 15, and 20% CSA content mixture are given in Table 1. From the results of the Proctor test, it can be seen that with the increase of cement content, the maximum dry density decreases, and optimum moisture content increases. Using the OMC, soil mixtures were prepared, and samples were placed into the mold applying the undercompaction technique in three layers, where each layer was compacted 25 times. Mold with a diameter of 50 mm and a height of 100 mm was used. After the sample preparation step, the samples were cured at room temperature for 3, 7, and 14 days.

Table 2. Standard proctor test results.

Cement Content	0%	10%	15%	20%
OMC	36.0%	41.0%	44.0%	45.5%
MDD	1.148	1.114	1.101	1.062

2.3 *Experimental methods*

After each curing period, samples were tested for expansion and strength by conducting free swell and UCS element tests. A one-dimensional free swell test was performed according to ASTM D4546 standard (2008). The 1-D free swell test was conducted to observe changes in the volume of cement-treated soil. Problematic soils, especially expansive soils, with the change of moisture content, could have considerable changes in volume, which leads to the development of wide cracks with the decrease of moisture and swelling with the increase of moisture. The samples were assembled in an oedometer and inundated until the value of the dial gauge becomes constant. This wetting-induced deformation was measured continuously by setting the dial indicator. As the samples were already in the optimum moisture, content precautions should be applied to avoid test water absorption. The dial gauge reading was taken after 0.5, 1, 2, 4, 8, 15, 60, 120, 240, 480, 960 minutes, and so on until the dial gauge showed constant value over a significant period.

A UCS test was conducted to evaluate the cement-soil mixture's mechanical properties (ASTM/2166 2003). The samples were compressed at 1 mm per minute until the sample breakage. Five samples were tested for each cement content and curing time to get more reliable data.

3 RESULTS AND DISCUSSIONS

Figure 1 illustrates the UCS test results for 3, 7, and 14 days cured samples. It can be observed that the strength of the treated soil sample increases with the increase of cement content, mainly after 7 and 14 curing days. For example, in the case of samples treated with the 10% CSA cement, the compressive strength increased only by 18%, from 3 to 14 curing days, whereas samples with 15% and 20% cement content showed an 82% and 106% increase in strength, respectively.

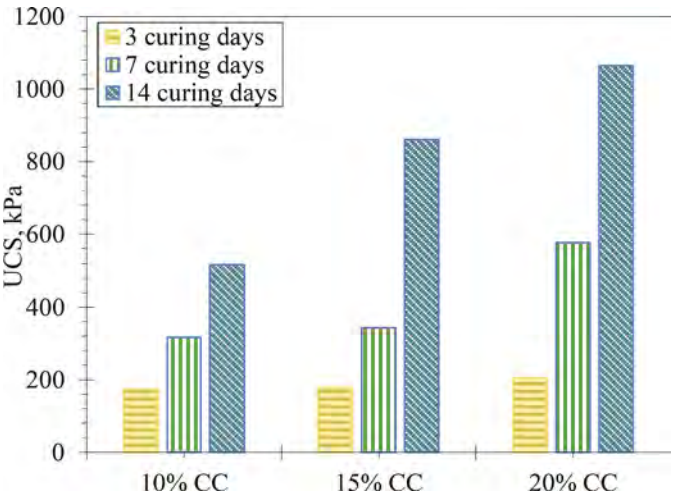

Figure 1. UCS test results.
Note: CC – cement content.

Figure 2 shows the results of 1D free swell testing for the 3, 7, and 14 curing days. Figure 2 shows that with the addition of more cement, the swelling percentage considerably decreased.

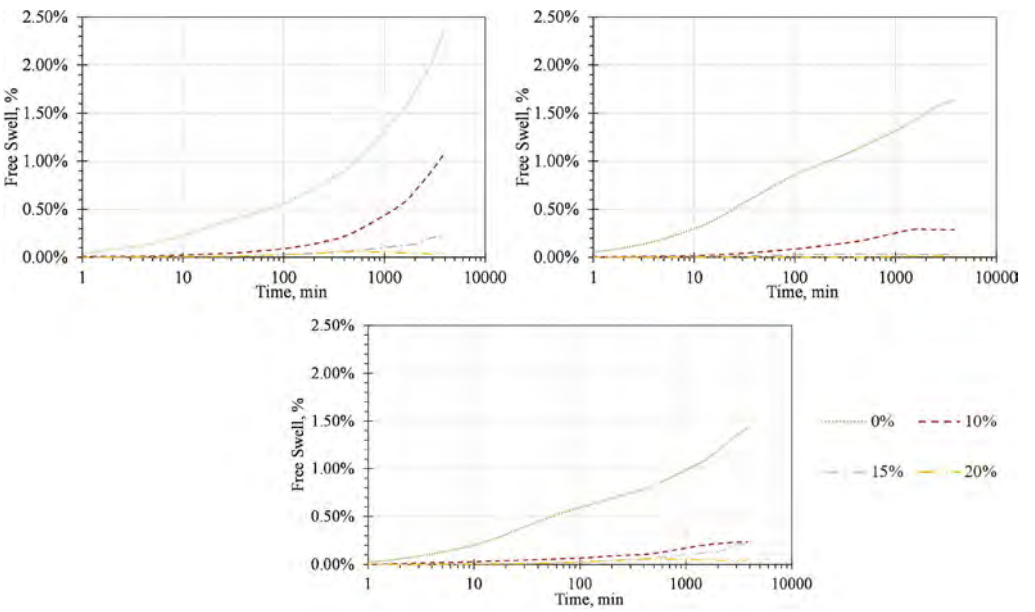

Figure 2. Free Swell test results: (a) 3 curing days, (b) 7 curing days, (c) 14 curing days.

For example, in the free swell test results after 3, 7, and 14 curing days, the swelling percentage decreased from 2.36% to 0.04%, from 1.63% to 0.01%, and from 1.44% to 0.04%, respectively.

Moreover, an increase in the curing period showed a reduced swelling percentage. For the untreated sample, the free swell value decreased by 61% from 2.4% to 1.4% when the curing period increased from 3 to 14 curing period. Overall, the CSA cement effectively reduced the swelling percentage of the soil. The decrease of free swell value depends on the percentage of additive and curing period.

4 CONCLUSIONS

This study is conducted to evaluate the effect of CSA cement used to stabilize problematic soil, categorized as expansive soil with organic content. For the assessment of the CSA cement treatment method, 1-D free swell and UCS tests were performed. The main findings of the research are listed below.

- Adding more cement improved the soil performance and cement-treated soil samples gained more strength with the increase of the curing period.
- The reduced swell percentage of soil can be achieved with an increase in cement content.

Further research will include assessing other parameters of stabilized soil, such as 3-D volume expansion and shear velocity. SEM pictures of soil will also be taken to see the changes in the microstructure of soil. Moreover, the long-term performance of CSA-treated soil will be tested. In addition, the determination of the efficiency of the soil stabilization technique with the CSA cement and other traditional chemical additives will be tested.

Experimental and numerical modeling of load settlement behavior of gypseous soils improved by MICP

Alaa D. Almurshedi
Department of Surveying Engineering, University of Baghdad, Baghdad, Iraq

Mahdi Karkush
Department of Civil Engineering, University of Baghdad, Baghdad, Iraq

ABSTRACT: In this paper the load-settlement of gypseous soils improved by microbial induced calcite precipitation (MICP) have investigated experimentally and numerically. Tests were carried out on two sandy soils collected from two different sites in Iraq, Najaf city and Samawa city. The soil samples were injected with two ratios of bacteria solution (4 and 8%). The load-settlement of gypseous soils were investigated in both cases dry and soaking. A numerical model is developed using PLAXIS software. Finite element analysis is carried out using Mohr coulomb failure criteria to represent 2D soil model. Foundation is modelled as square footing and load increment is applied till the soil model fails. Ultimate bearing capacity is identified as that minimum pressure on footing at which the foundation soil experiences shear failure. The stress distribution in soil and displacement experienced at different locations are obtained. Also, the ultimate bearing capacity of square foundation was computed by Terzaghi's equation to know the preliminary values of bearing capacity of gypseous soil and loading frame which was successfully compared with PLAXIS software. Based on the results of tests, PLAXIS software can be used worthily to understand the load-settlement behavior of gypseous soils in dry and soaking conditions and Mohr-Coulomb model can be considered the best to estimate the ultimate bearing capacity of a foundation constructed on gypseous soils. The difference between the maximum settlement measured from experimental tests and calculated from the numerical analysis was 20% in dry condition and 30-40% in soaked condition. The bearing capacity obtained from experimental tests were identical with results of Terzaghi's equation.

1 INTRODUCTION

The collapsible soil is defined as any soil suffering from volume changes upon wetting which resulted from the radical rearrangement of particles of soil without change in loading (Karkush et al. 2008, Abid Awn 2010, Karkush et al. 2022). The wetting or soaking of gypseous soils causes dissolution the calcite silicate cementing the particles of soil consequently reduces the bonds among soil particles (Al-Mufty 1997, Al-Morshedy 2001). In the past few years, the use of microbial induced calcite precipitation (MICP) has become popular as a ground improvement technique. It is presented as a new and environmentally friendly method (DeJong et al. 2006). This new method has an advantage over conventional chemical treatments, which can be toxic and environmentally harmful and have a limited injection distance ((Karkush et al. 2022). The MICP method is also cost-effective in comparison to chemical treatments. Many studies in the literature have reported that the microbial-induced calcite precipitation technique is very effective in increasing the shear strength and in decreasing the permeability of sandy and gravelly soil (van Paassen et al. 2010, Van Wijngaarden et al. 2011, Martinez et al. 2013). Scaled-up studies were also performed on sandy soil and successful results were obtained (van Paassen et al. 2010).

DOI: 10.1201/9781003299127-74

The main role of bacteria in the calcite precipitation process has been to generate an alkaline environment through different physiological actions (Weaver et al. 2011). Bacillus pasteurii, a highly urease active bacteria, plays an important role in $CaCO_3$ precipitation (DeJong et al. 2014). The main nutrient solution that is commonly used to provide the necessary nutrition for the bacteria, as well as the chemical compounds that are needed for soil cementation, contain $NaHCO_3$, NH_4Cl, $CaCl_2$, urea, and a nutrient broth (mixture of peptone, yeast extract, beef extract, and NaCl). Under favorable environmental conditions, S. pasteurii uses urea as an energy source, producing ammonia (NH_3) and carbon dioxide (CO_2), which tend to increase the pH in the proximal environment. The chemical reaction is given in Equation (1). The calcite bonds tend to form at the particle-to-particle contacts in the soil matrix, which has an overall cementing effect between soil particles (Chou et al. 2011, Qabany & Aziz 2011, Qabany & Soga 2014).

$$Ca^{2+}+HCO_3^- + OH^- \rightarrow CaCO_3+H_2O \quad (1)$$

In the present study the effects of injection bacteria solution (BS) on the load-settlement behavior of two types of gypseous soils collected from two Iraqi cities have been studied experimentally and modeled theoretically using PLAXIS software. Two ratios of bacterial solution injected in the gypseous soils and tested in both cases dry and after soaking.

2 MATERIAL AND METHODS

2.1 *Gypseous soils*

The soil samples used in this study is obtained from Najaf Sea located 10 km from the center of Najaf city and Sawa Lake located 30 km from the center of Samawa city. The soil samples are taken from a depth of (0.5-1.5) m depth below the existing ground level and have gypsum content of 42 and 54% respectively. The results of physical and chemical tests for natural gypseous soils samples are given in Table 1 (Karkush et al. 2020).

Table 1. Physical and chemical properties of the gypseous soils.

Property	Najaf	Samawa	Property	Najaf	Samawa
Specific gravity, Gs	2.54	2.48	Sand, %	80.0	90.5
Maximum dry unit weight, $\gamma_{d,max}$	14 kN/m^3	13.4 kN/m^3	Silt, %	17.0	9.5
Optimum moisture content, ω_{opt}	18%	18%	Clay, %	3.0	-
D_{10}, D_{30}, D_{60}, mm	0.018, 0.175, 0.5	0.075, 0.11, 0.3	Soil type (USCS)	SM	SP-SM
Organic matter content, %	2.15	0.45	pH value	6.8	6.5
Electrical conductivity, μS/cm	2.43	15	SO_3, %	20	24.5
ESP (Exchange sodium), %	13		$CaCO_3$, %	4.6	6.0
TSS (Total soluble salts), %	34.1	63	Cl^-, mg/l	0.04	0.09
CEC (Cation exchange capacity), meq/100g	6.54	5.33	Gypsum content, %	42	54
			$CaCO_3$, %	4.6	6.0

2.2 *Bacterial treatment solution preparation*

To prepare the bacteria treatment solution, urea medium was first created. Nutrient broth (4 g), urea (25 g), NH_4Cl (15 g), $NaHCO_3$ (3 g), and 500 ml of distilled water, were mixed to create the urea medium solution. Each of the solid in gradients was mixed thoroughly in 500 mL of distilled water until it had dissolved, and the pH of the resulting urea medium solution was adjusted to 6.0 with the use of 5 N HCL prior to autoclaving. Distilled water was then added to reach the final required volume (1 L). After autoclaving, the pH of the urea medium was measured to be 7. The pH value of the resulting1Lof solution was adjusted by aerating the solution to increase the initial pH value from 7 to 8. In this way, the solution became suitable for biological activity for bacteria (Ali et al. 2020).

3 MODELING OF PROBLEM

The large-scale model consisting of steel container of dimensions (600×600×500) mm containing gypseous soil, rigid steel foundation is (100×100×20) mm installed in the gypseous soil, Figure 1. illustrates the schematic diagram of the model. The use of PLAXIS 2020 software to solve problems involves the construction of a 3D model consisting of points, lines, surfaces, and volumes by the finite element method. It also requires the properties of materials and the boundary conditions to be defined. The problem geometry is determined using the first two-tab sheets of the program input data. In the last three-tab sheets of the program input data, the mesh generation, description of the boundary conditions, and calculations are done. The physical and mechanical properties of the sandy soil Foundation plate properties used in tests are given in Table 2. The sand's shear strength and stiffness parameters are obtained from a direct shear test conducted according to ASTM (D3080-72) and the triaxial test. The foundation plates are modeled as a plate element and behave as an elastic material, while the steel shaft is modeled with elastic behavior.

Table 2. Inputs parameters of the sandy soils and foundation.

Parameter	Soil	Parameter	Foundation
Material model	Mohr-Coulomb	Material	Rigid steel
Drainage type	Drained	Material model	Liner-elastic
Unit weight, γ (kN/m^3)	✓	Drainage type	Nonporous
Internal friction angle	✓	Young's modulus, E (Pa)	20×10^6
Cohesion	✓	Unit weight, γ (kN/m^3)	78.0

4 RESULTS DISCUSSION

4.1 *Load –settlement test*

Using PLAXIS 2020 finite element analysis is conducted using Mohr-coulomb failure criterion in this study numerical model to represent the three-dimensional soil model. The foundation is designed as a square base (100 mm) and the increase in load is applied before the soil model fails. Ultimate bearing capacity is known as the lowest footing pressure at which shear failure is

experienced by the foundation soil. The validity of PLAXIS 2020 software in the analysis foundation is approved by comparing the load-settlement curve, where good agreement noted with the same curve obtained experimental works as shown in Figures 2 to 5. PLAXIS is a program based on the finite element mechanism (FEM) used to achieve deformation. Geotechnical research programs and flow analysis. A simple strain or axisymmetric model may be modeled for 3D analysis.

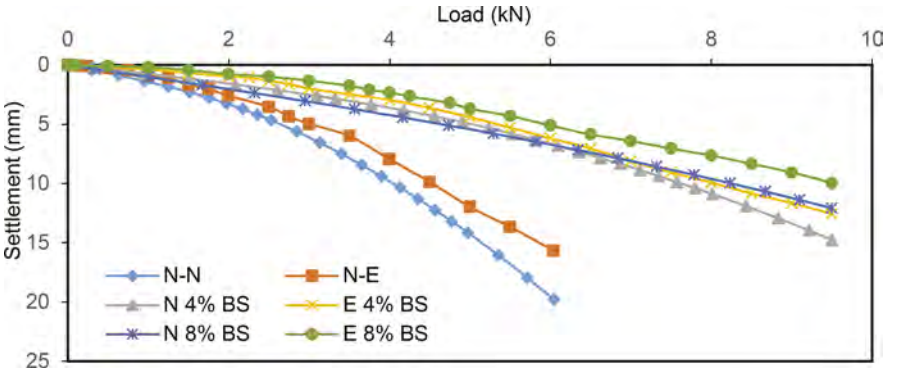

Figure 3. Load versus settlement of Najaf gypseous soil treated with BS in soaking condition.

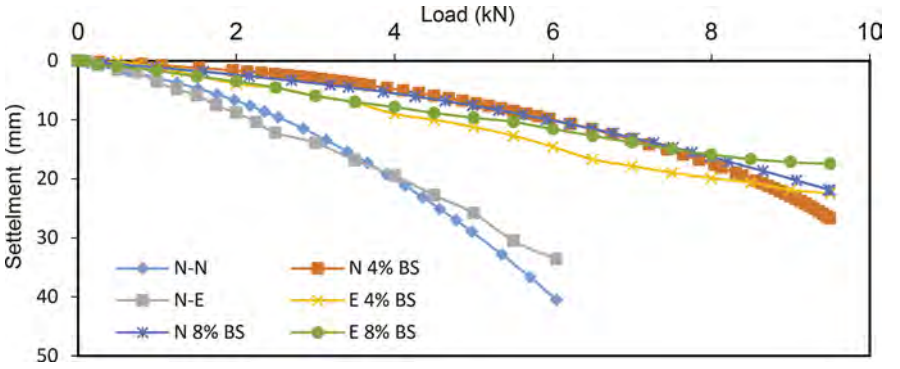

Figure 4. Load versus settlement of Samawa gypseous soil treated with BS.

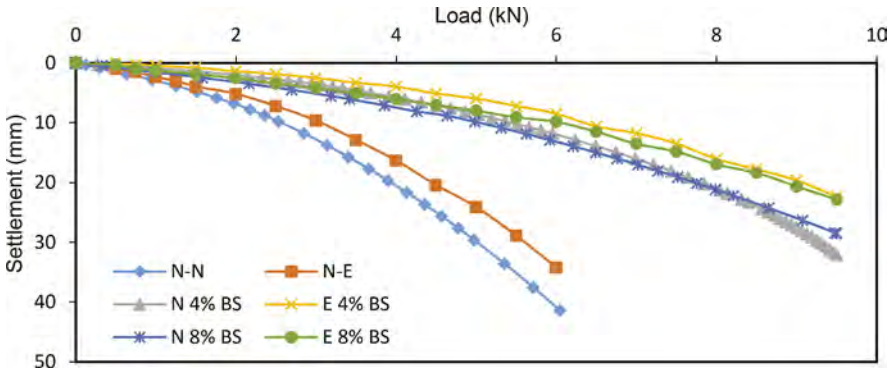

Figure 5. Load versus settlement of Samawa gypseous soil treated with BS in soaking condition.

4.2 *Bearing capacity*

The bearing capacity in this work was calculated according to the failure method. The calculated bearing capacity is higher than the estimated bearing capacity which considered the soil as fully saturated. The results show that the calculated bearing capacity is (5-15) % lower than the estimated by Terzaghi equation (Equation 2) in dry condition and (20-40) % lower than the estimated by Terzaghi equation in soaked condition. Also, the rate of increase in bearing capacity in the soil treated with MICP technique. The bearing capacity of footing is considered as the stress at failure condition. The bearing capacity of square footing increased with the increasing the concentration of the bacteria solution, so the bearing capacity of gypseous soils treated with bacterial solution is higher than untreated gypseous soils. It can be noticed that the soil with a high value of shear strength is affected more by the variation of the moisture content change than the soil with a low value of shear strength.

$$q_{ult} = cN_c + qN_q + \frac{1}{2}B\gamma N_\gamma \tag{2}$$

Where

q_{ult}: ultimate bearing capacity (kPa),

Nc, Nq, Nγ: bearing capacity factors, B: foundation width, c: cohesion, d: depth of foundation = 0, γ: the unit weight of soil, and q =γ×d= 0 (Bowels 1996).

Table 3 shows that the bearing capacity of square footing increased in soil treated by the MICP technique. In both condition of tests (dry and soaked), an increase in soil strength can be attributed to the calcite precipitates produced, which strengthened the bonding between the soil particles. This result is due to the large amount of calcite precipitation that accumulates in the soil. The bearing capacity of the foundation is a primary concern in the field of foundation engineering. The load at which the shear failure of the soil occurs is called the foundation's ultimate bearing capacity. In this study, a numerical model is developed using PLAXIS 2020. Finite element analysis is carried out using Mohr-coulomb failure criteria to represent a 3D soil model. Foundation is modeled as square footing, and load increment is applied till the soil model fails. Ultimate bearing capacity is identified as that minimum pressure on footing at which the foundation soil experiences shear failure. The stress distribution in soil and settlement experienced at the surface location is obtained. In PLAXIS 2020, effective stress is considered as an ultimate bearing capacity. Figures 6 and 7 show the comparison between the results obtained from Terzaghi's equation and PLAXIS software. The results obtained from PLAXIS software are very close to the results of experimental model tests rather than Terzaghi's equation results. Mostly, the same trend of bearing capacity for soil treated with bacterial solution. Also, the soaking causes lowering the bearing capacity of soil.

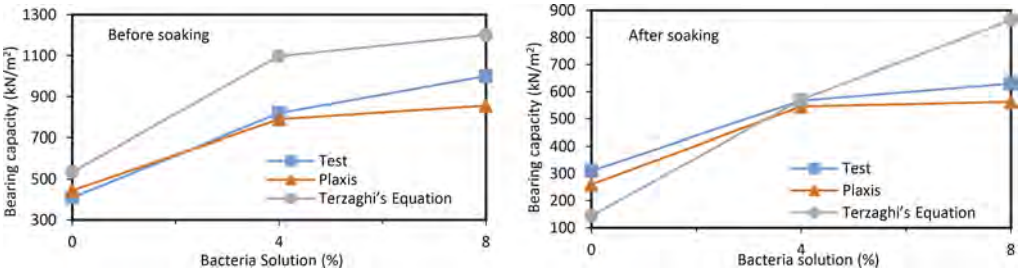

Figure 7. Ultimate bearing capacity for Samawa gypseous soil treated by BS.

5 CONCLUSIONS

Based on the obtained results, the following conclusions can be made:

- PLAXIS 2020 software can be used worthily to understand the load-settlement behavior of gypseous soils in dry and soaking conditions.
- Mohr-Coulomb model can be considered the best to estimate the ultimate bearing capacity of a foundation constructed on/in gypseous soils.
- The difference between the maximum settlement measured from experimental tests and calculated from the numerical analysis was 20% in dry condition and 30-40% in soaked condition.
- The test and Terzaghi's equation values for ultimate bearing capacity are almost identical.

Physical and numerical modeling of strip footing on geotextile reinforced foundation beds

M. Kapor & A. Skejić
Faculty of Civil engineering, University of Sarajevo, Bosnia and Herzegovina

ABSTRACT: The paper presents insights from small-scale physical model tests on statically loaded strip footing resting on dense base sand supported by a single geotextile layer on soft subgrade soil. The benefits of the geotextile were assessed by comparing the results obtained for the improved soil model to the unreinforced beds. Experimental testing was conducted in a steel tank with inside dimensions 120/50/80 cm (width/ length/ height). The images were collected by recording the 120×80 cm transparent front side and analyzed by DIC software. Results confirm the contribution of reinforcement inclusions to the improved behavior of base and subgrade layers. A numerical simulation of the strip footing on reinforced and unreinforced sand was applied to assess the geotextile's influence. Independent laboratory tests were performed to obtain the parameters of numerical models. The FEM results were compared with the experimental observations, and a good agreement with measurements was confirmed.

1 INTRODUCTION

Geosynthetic inclusions can enhance the behavior of loose soft soils when surcharged by foundation loads (Guido et al., 1985, Demir et al., 2014). The different geosynthetic products were used to investigate the reinforcement effect, most being planar geogrids and geotextiles or geocells. Lateral confinement and membrane action of geosynthetics contributes to the reduction of footing settlements and increment of ultimate bearing capacity compared to unreinforced foundation beds. The benefits of planar reinforcement installed in variously compacted sands were investigated by small-scale physical modeling (Latha et al. 2009, Cicek et al. 2015), full-scale tests (Adams and Collin 1997), and numerical modeling (Love et al. 1987, Wang et al. 2019).

Small-scale models with a transparent side of the box were recognized as a powerful tool for observing the displacements at the total foundation soil area. The digital photos collected at the different stages of the footing pressure were implemented in different digital (or velocity) image correlation software, and the displacement of foundation soils with a failure mechanism was declared. The displacement patterns and failure mechanism of reinforced and unreinforced foundations soils were usually compared to understand the soil-reinforcement interaction mechanism in detail (Michalowski, 2003, Gedela et al., 2021). Michalovski (2003) used a very small strip footing (3.2 cm) and reinforced the foundation soil with a single layer of geosynthetic strips. The results arrived at from this study show that the deformation of sand reinforced with one long layer of reinforcement retained many of the features found in the sand without reinforcement. Michalowski (2003) also showed that a single reinforcement layer slightly modifies the failure mechanism compared to the well-known Prandtl mode typically obtained for dense unreinforced beds. This observation is not in agreement with the result reported by Yetimoglu et al. (1994), who obtained typical punching-shear failure for geogrid located at depths below 0.25B the footing, similar to Akinmasuru and Akinbolade (1981), Guido et al. (1987) and Adams and Collin (1997).

DOI: 10.1201/9781003299127-75

Consequently, an additional investigation on the soft subgrade and base layer response is performed in the present study to investigate the displacement pattern and failure mechanism of geotextile reinforced foundation beds on the loose subgrade. Digital image correlation was implemented to assess the loose subgrade and base layer response (displacements and failure mechanism) for different footing surcharge pressures. A complex 3D numerical modeling in Plaxis software was also formed to compare measured and numerically predicted results, and a good agreement was obtained.

2 PHYSICAL AND NUMERICAL MODELS

2.1 *Physical model*

Figure 1 shows the box dimensions and the geometry of a small-scale physical model test performed to investigate the non-woven geotextile reinforcement influence on the behavior of the loose subgrade sand and dense base sand under the strip load surcharge. The same box was used by Skejic et al. (2018) for the small-scale models of the reinforced earth wall. The two different types of sand (loose subgrade sand and dense base sand) were installed in a box with inside dimensions of 120.0 cm (width), 50.0 cm (length), and 80.0 cm (height). A transparent sidewall is made of 5.1 cm thick glass, whereas a thin 0.4 cm thick glass is glued to the opposite stiff wooden wall side to enable the low friction characteristics at the interface. Sidewall surfaces were not lubricated because transparency was requested for a digital image collection during footing pressure application. A 16.0 cm wide, 49.5 cm long, and 2.0 cm thick steel plate was used to simulate the strip footing. The box and steel plate dimensions were adopted to eliminate the influence of box side boundaries on displacements and strains filed.

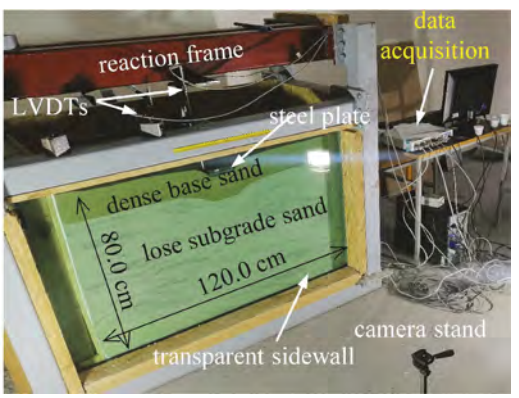

Figure 1. Details of the physical model – deformed sand configuration at the end of the test.

The loose subgrade material was quartz sand of uniform size (SP in the Unified Soil Classification System) with a mean diameter D_{50}=0.22 mm, a coefficient of curvature C_c=0.95, and a coefficient of uniformity C_u=1.9. A small fine particle content and a very low coefficient of uniformity make this material a good choice for the simulation of loose subgrade soils. The dry unit weight of the subgrade sand was 13.4 kN/m3, resulting in D_r = 10%. The base layer was composed of river sand of uniform size (SP in the Unified Soil Classification System), with a mean diameter D_{50}=0.35 mm, a coefficient of curvature C_c=1.0, and a coefficient of uniformity C_u=2.9. The dry unit weight of the base layer was 16.3 kN/m^3, resulting in D_r = 80%.

The non-woven geotextile was used for single-layer reinforcement at the subgrade-base sand interface. This reinforcement (L=2.5B=40.0 cm) was placed 6.0 cm below the surface, which is equal to the thickness of the base sand layer. The subgrade sand layer was 74.0 cm thick, resulting in the total height of the model of 80.0 cm. The manufacturer reported that the in-air tensile characteristics of the 100 g/m^2 non-woven, needle-punched UV-stabilized polypropylene geotextile are: a geotextile strength of 7.0 kN/m and geotextile stiffness of 14.0 kN/m.

The physical model was prepared by installing the dry sand in seven layers with equal thickness, with each layer weighing the equal weight of the installed dry sand. The 74.0 cm tick subgrade sand was installed without compaction to simulate loose soil conditions. After that, the reinforcement was placed and covered by the base sand layer. Compaction of this layer was performed with a 5.0 cm diameter steel rammer weighing 2.0 kg. After the model had been completed, a hydraulic press was placed on a steel plate to simulate a strip footing surcharge. The surcharge was applied in increments of 5.0 kPa/min. After each load increment, the settlement was measured with displacement transducers (LVDT), and images of sand deformation were collected for DIC analysis.

2.2 *Numerical model*

3D numerical model of the test, shown in Figure 2, was formed in Plaxis 3D finite element program (Brinkgreve et al., 2012). Details of the numerical model are described for particular model components, which include: boundary conditions, subgrade and base soil layers, reinforcement, construction phases, and loading program. The model's lateral vertical and bottom boundaries were assumed fixed in all directions. Interface elements are introduced between stiff sidewalls and soil to account for friction. Namely, the direct use of interface strength reduction by applying a reduction factor value ($R_i < 1$) to backfill significantly reduces the normal stiffness, resulting in misleading displacements perpendicular to the sidewall surface. In order to prevent this, an additional material with high stiffness and small strength is introduced for defining a side wall-sand interface. It is found that the glass sidewall-sand friction does not influence the reinforcement behavior significantly if the model width is larger than 0.6H (Skejić et al., 2017). The values of 7° for interface internal friction angle and 0.1 kPa for interface cohesion are adopted for this numerical model since the reported friction angles between glass and sand ranged from 6° to 9° (Tatsuoka and Haibara, 1985).

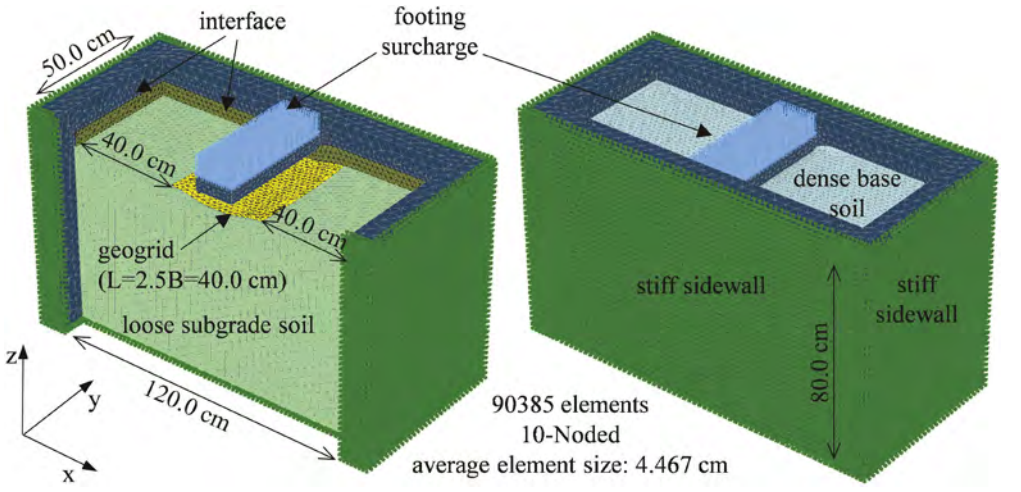

Figure 2. 3D numerical model details.

The base and subgrade sand soil is modeled with the Hardening soil constitutive model. Strength and stiffness parameters are determined following conventional laboratory tests for appropriate relative density. Poisson ratio and empirical m coefficient were adopted according to the suggested values from the literature (Benz, 2007). Reinforcement (non-woven geotextile) was modeled as a linear elastic, ideally plastic material (geogrid). Reinforcement stiffness is defined as the force per unit width ratio at 50% of ultimate strength (F_{ult}) and corresponding axial deformation measured during the in-air tensile test (EA = 14 kN/m and F_{ult} = 7.0 kN/m). The parameters of numerical model components are given in Table 1.

According to the model test setup, a surcharge load is applied as a uniform load applied through a steel plate 49.5/16.0/2.0 cm, with the following properties: unit weight, γ = 78.5 kN/m^3, Young's modulus, $E_{ref}=2\cdot10^8$ kPa and Poisson ratio, ν=0.15. The load is applied following the physical model test procedure, and the load is incrementally increased up to pressure, resulting in a 2.5 cm settlement.

Table 1. Material properties for the numerical model.

Parameter	Base sand HS model	Subgrade sand HS model	Soil-glass interface MC model
Unit weight, γ [kN/m^3]	16.30	13.40	14.0
Internal friction angle, ϕ [°]	40.0	31.0	7.0
Cohesion, c [kN/m^2]	1.0	0.1	0.1
Dilatancy angle, ψ [°]	8.0	0.0	0.0
Reference stress, p_{ref} [kN/m^2]	100.0	100.0	
Tangent oedometer stiffness, E_{oed}^{ref} [MPa]	15.0	7.0	
Secant triaxial stiffness, E_{50}^{ref} [kN/m^2]	15.0	7.0	50.0
Unloading/reloading stiffness, E_{ur}^{ref} [kN/m^2]	45.0	21.0	
At-rest lateral earth coefficient, K_0 [-]	0.35	0.48	
Stress-level dependency factor, m [-]	0.5	0.5	
Poisson ratio, for unloading/reloading, υ_{ur} [-]	0.2	0.2	0.4

3 TEST RESULTS, COMPARATIONS, AND ANALYSIS

Figure 3 shows typical curves for footing pressure (q) vs. footing settlement (s) for the physical and numerical model with and without reinforcement. A notable contribution of reinforcement was confirmed by comparing reinforced to unreinforced foundation bed response, both for the numerical and the physical model.

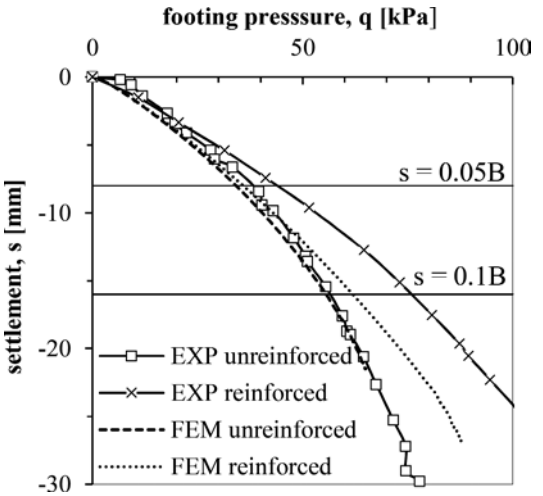

Figure 3. Footing pressure vs. settlement curves for reinforced and unreinforced models.

This improvement is especially noticeable for higher vertical displacements in the physical model. A good agreement on the results was obtained noting that more improvement by geotextile was obtained by experiment (EXP) compared to numerical model results (FEM). Images of the transparent sidewall collected at different stages of the vertical footing pressure were

analyzed using the GOM Correlate digital image correlation software to discuss the influence of reinforcement on displacement field and failure mechanisms. Vertical displacement obtained for the reinforced and unreinforced physical and numerical models at q=60.0 kPa is shown in Figure 4a. The selected load approximately corresponds to the unreinforced model's mobilized load for a 1.6 cm settlement (s=0.1B). Vertical upward movements are considered positive. The numerically obtained settlement bulb corresponds to the measured. The depth of the settlement bulb was generally lower in the case of reinforced soil, compared to the unreinforced bed.

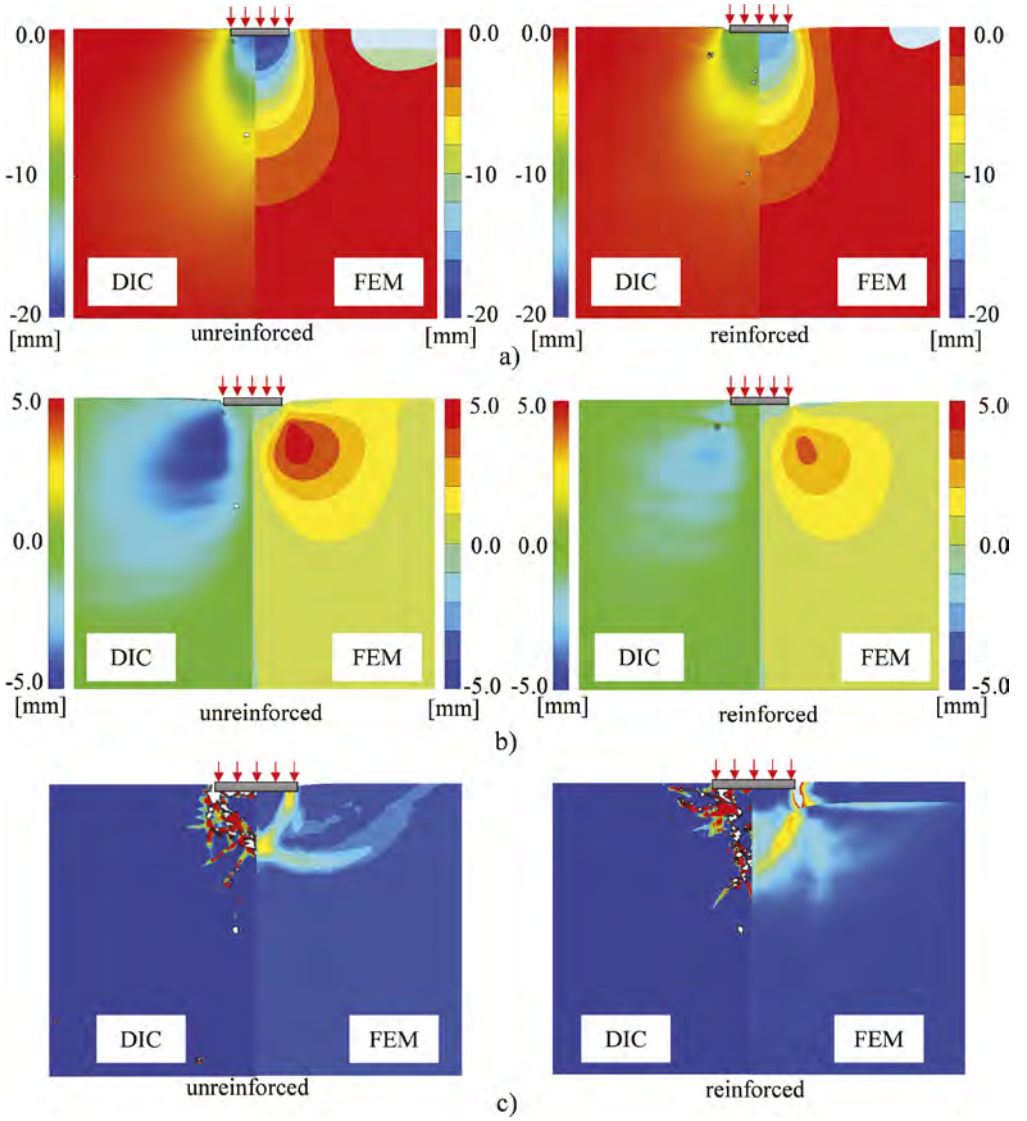

Figure 4. DIC and numerical model results for unreinforced and reinforced foundation bed: a) Vertical settlements at 60.0 kPa footing pressure; b) Horizontal displacements at 60.0 kPa footing pressure; c) Failure mechanism at approx 2.5 cm footing settlement.

An additional set of DIC and numerical model results showing horizontal displacements for reinforced and unreinforced models at 60.0 kPa footing pressure is given in Figure 4b. Rightward movements are considered positive. The geotextile reduces the horizontal displacement

above and below the reinforcement indicating the inclusion confinement effect in both experimental and numerical model results. Figure 4c shows the failure pattern obtained from the major principal shear strains for physical and numerical reinforced and unreinforced models. The obtained results show punching-shear failure without significant heave of the ground surface n both experimental and numerical models. This result was expected due to a very loose, high compressibility subgrade soil located at a relatively shallow depth under the strip footing, illustrating the importance of the sand density influence on the resulting failure mechanism. The failure mechanisms show that shear bands spread deeper under the strip footing in reinforced models compared with unreinforced models in both physical and numerical models.

4 CONCLUSION

This paper uses the physical and numerical models to analyze the benefits of using the one-layer geotextile reinforcement placed at the loose subgrade sand–dense base sand interface. The FEM results were compared with the experimental observations, and a good agreement with measurements was confirmed with some notable deviations in load-settlement response and failure mechanism.

Based on the results of this study, the following conclusions are stated:

a) The reduction of vertical displacement was obtained in reinforced models compared with unreinforced models.
b) The geotextile reduced the horizontal soil displacement in the vicinity of the reinforcement, and this confining effect was recognized by physical and numerical modeling.
c) The punching failure mode is obtained by physical and numerical modeling since very loose subgrade soil was analyzed.
d) The reinforcement affects the failure mechanism in a way that shear bands spread deeper under the strip footing at reinforced models compared with unreinforced models.

Improvement of soil mechanical properties by biomass-derived chitosan and carboxymethyl cellulose

T. Sakai & M. Nakano
Nagoya University, Nagoya, Aichi, Japan

ABSTRACT: In order to investigate the effectiveness of ground improvement methods using chitosan (CS) and carboxymethyl cellulose (CMC), which are biomass-derived polymeric materials, unconfined compression test and triaxial compression test were conducted on specimens compacted after mixing CS and CMC with soil. The results showed that the improved soil had much greater strength than the untreated soil. The dilatancy properties were also found to be different, suggesting that the critical state constant was different. The greater the concentration of CMC solution, the greater the strength; and the most effective mass ratio of CS to CMC was 2 to 3 times CS to CMC.

1 INTRODUCTION

Polymeric materials have been widely used to solve various environmental problems. Solid polymer-ion complexes (polyion complexes, PIC) were used to prevent the dispersion of radioactive materials in soil contaminated by the nuclear power plant accident in Chernobyl (Zezin et al. 2015). In the Fukushima nuclear power plant accident, PIC were used to immobilize the soil surface layer and to detach soil contaminated with radioactive cesium (Kumazawa 2011). The mechanisms of soil immobilization of contaminants are as follows. Strong electrostatic interactions between positively charged polymers (polycations) and negatively charged polymers (polyanions) form PIC (Figure 1, top). In the soil, PIC polymers further bind to soil particles, immobilizing the soil and radioactive materials (Figure 1, bottom). PIC have been actively explored as soil improvement formulations in the agricultural field during several past decades (e.g., Izumrudov et al. 2019).

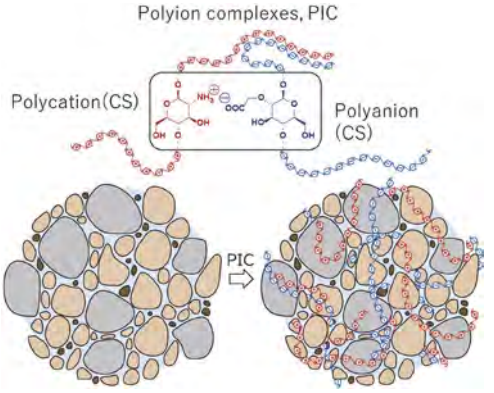

Figure 1. Schematic diagram of polyion complex formation.

DOI: 10.1201/9781003299127-76

In this study, chitosan (CS) was used as a polycation and carboxyl methyl cellulose (CMC) was used as a polyanion to improve soil. CS and CMC are naturally derived polymers and are low cost. Therefore, they are suitable for industrial-scale applications and satisfy the needs of "carbon neutral" and "circular economy". The soil improvement method proposed in this study using biomass-derived CMC and CS is a "green" and sustainable approach and is expected to be a more flexible soil improvement method compared to previous studies.

To investigate the effectiveness of soil improvement methods using CS and CMC, unconfined compression test and triaxial compression test were conducted on specimens compacted after mixing CS and CMC with soil. First, the mixing method of CS, CMC, and soil was investigated, and then the effects of CS and CMC concentrations on the strength were examined. The curing period of the specimens was also investigated.

2 EFFECT OF SAMPLE PREPARATION ON THE STRENGTH OF IMPROVED SOIL

Figure 2 Shows the particle size distribution of the soils used in this study. The soil particle density ρ_s was 2.716 g/cm^3. The maximum dry density ρ_{dmax} was 1.864 g/cm^3 and the optimum water content w_{opt} was 13.5% from compaction test using the A-b method. CS and CMC were mixed with 350 g dry weight of the soil in four methods. Method 1 is to add 0.7 g of CS powder and GDL solution, a pH adjuster, to 70 g of CMC solution and mix them before adding them to the soil. Method 2 is to add 35 g of CS solution to the soil and then mix it with 35 g of CMC solution. Method 3 is to add 35 g of CMC solution to the soil and then mix it with 35 g of CS solution. Method 4 is to first divide the soil into two parts and then mix the two parts with 35 g of CS solution and 35 g of CMC solution, respectively. In all of methods 1 through 4, 0.7 g of CS and 0.7 g of CMC were mixed.

The mixed sample were compacted in the mold in three layers using rammers to prepare the specimens. The density was adjusted to 90% of the maximum dry density, with a water content of approximately 20%. The specimens were cured in the mold for four days.

Figure 3 shows the results of unconfined compression tests conducted in accordance with JIS A 1216:2020. Figure 3 also shows the results for untreated soil adjusted to the same density and water content as the improved soil. Method 1 has the highest strength, with a compressive strength of approximately 140 kPa, about 1.5 times stronger than the other methods and three times stronger than the case with distilled water mixed in. The reason for the small strength in Methods 2-4 was assumed to be that soil particles had a negative charge and wasn't able to form a PIC well when mixed with CS, which had a positive charge in advance.

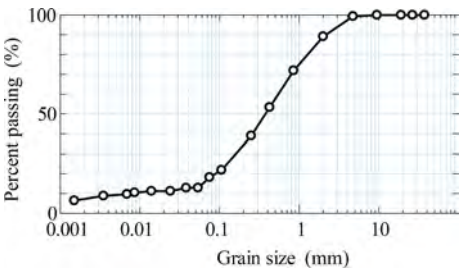

Figure 2. Grain size distribution.

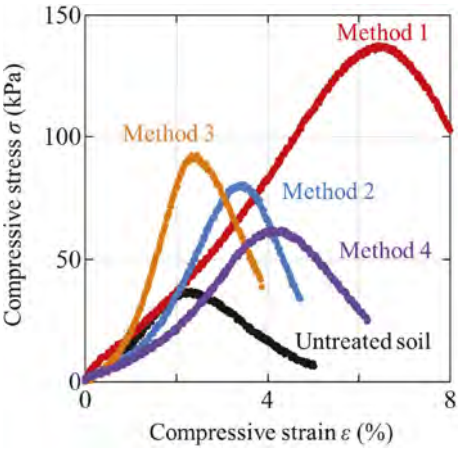

Figure 3. Effect of mixing method on the strength.

3 EFFECT OF CS AND CMC CONCENTRATIONS ON THE STRENGTH OF IMPROVED SOIL

All specimens in this and subsequent section were prepared by Method 1. In this section, specimens were prepared with varying concentrations of CMC and varying mixing ratios of CS and CMC. Figure 4 shows the stress-strain relation for each case. In all cases, peak strength was observed at approximately 5-6% strain. The specimens with higher strength also had higher stiffness. The larger the concentration of CMC solution, the greater the unconfined compressive strength. On the other hand, the optimum ratio of CS to CMC changes depending on the concentration of CMC solution. The unconfined com-pressive strength of the soil was greater when CS is mixed more than CMC. This is be-cause soil particles have a negative charge, and it is important to mix more CS with a positive charge. The case of the highest strength was 560 kPa, which was about 10 times stronger than the untreated soil.

Curing periods were studied for cases with a CMC solution concentration of 1% and a CS:CMC ratio of 2:1. Four cases were tested: 4 days, 1 week, 2 weeks, and 3 weeks of curing after specimen preparation. For the curing method, the specimens were left in the mold, sealed to prevent drying, and left at room temperature. Figure 5 shows the strength increased up to 2 weeks of curing period, with the same strength at 2 and 3 weeks, indicating that 2 weeks of curing was sufficient for improvement. Because the increase in strength after 4 days of curing is not significant, it is possible to design the mix ratio of CS and CMC using specimens with a curing period of 4 days.

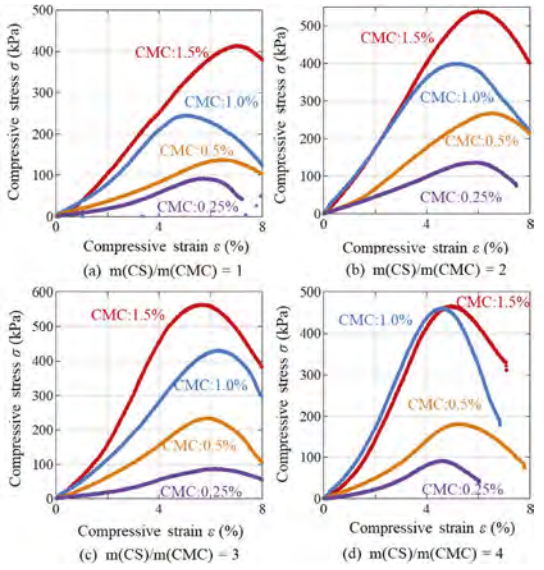

Figure 4. Unconfined compression test results of improved soil with different amounts of CMC and CS.

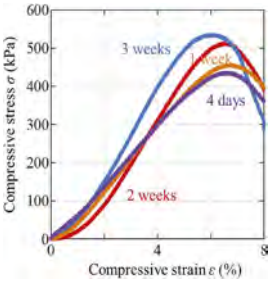

Figure 5. Effect of curing period.

4 TRIAXIAL COMPRESSION TEST FOR IMPROVED SOIL

Triaxial compression tests were conducted in accordance with JGS 0523-2020 with a CMC solution concentration of 1% and a CS:CMC ratio of 2:1. Untreated soil was also tested for comparison. The specimens were saturated using the double-suction and back-pressure method. After confirming that the B-value was larger than 0.95, isotropic consolidation was performed for 24 hours under a confining pressure of 100 kPa. Then, monotonic shear was applied at an axial strain rate of 20%/day under undrained condition.

Figure 6 shows the triaxial compression test results for improved soil and untreated soil. The two specimens were prepared at the same density. The relation between deviator stress q and axial strain ε_a shows that the maximum deviator stress was about 2.5 times higher than that of the untreated soil, even though the densities were the same. The untreated soil exhibited almost constant deviator stress after 5% axial strain ε_a, whereas the improved soil exhibited an increase in q with increasing ε_a. The q-mean effective stress p' relation indicated that the improved soil exhibited a remarkable hardening behavior with plastic expansion. The stress ratio ($\eta = q/p'$) at the transformation point and the η at ε_a of 20% were different, suggesting that the critical state index changes. The relation between excess pore water pressure u_e and ε_a showed that positive excess pore water pressure at the beginning of shear and negative excess pore water pressure at the end of shear for the improved soil were larger than ones for the untreated soil.

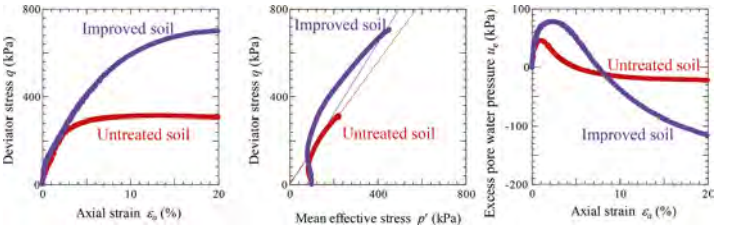

Figure 6. Triaxial compression test results for improved and untreated soil.

5 CONCLUSION

In this study, unconfined compression test and triaxial compression test were conducted on specimens compacted after mixing CS and CMC with soil to investigate the effectiveness of soil improvement methods using CS and CMC. The conclusions are as follows.

1) The most effective improvement was achieved by mixing the CMC solution with CS powder and GDL solution before mixing them with soil. In this method, the strength of the improved soil is clearly increased.
2) The larger the concentration of CMC, the greater the strength. The most effective mass ratio of CS to CMC also depends on the concentration of CMC; mixing two to three times as much CS as CMC was most effective. The greatest unconfined compressive strength of all cases was about 560 kPa, which was approximately 13 times greater than that of untreated soil.
3) The strength increased up to 2 weeks of curing period, with the same strength at 2 and 3 weeks, indicating that 2 weeks of curing was sufficient for improvement. Because the increase in strength after 4 days of curing is not significant, it is possible to design the mix ratio of CS and CMC using specimens with a curing period of 4 days.
4) Triaxial compression test results also indicated that the strength of the improved soil is much greater than that of the untreated soil. The dilatancy properties were also different. The stress ratio at the transformation point and ε_a of 20% were different, suggesting that the critical state index changed.

Impulse compaction - one of the most economical methods in soil improvement

M. Bissmann
Ing., Terra-Mix Bodenstabilisierungs GmbH

ABSTRACT: Impulse Compaction also known as Rapid Impact Compaction (RIC) is a relatively new method of soil improvement and at the same time in principle one of the oldest methods in soil compaction. Already in ancient times, people improved their soil with the help of muscle strength or with small falling weights. In this paper, the origin, the historical roots, the current state of the art practice, and the various possibilities of Impulse Compaction use and application will be discussed. Furthermore, it will be shown how the impulse compaction with some modifications can also be used on weaker soils. Current documentation and quality assurance standards will be shown. Some selected projects will then underline the potential and attractiveness of Impulse Compaction.

1 INTRODUCTION

To improve the subsoil in terms of its load-bearing capacity, soil compaction is still the most economical method because, in general, little to no foreign material is added and instead the inherent load-bearing capacity of the soil material is stimulated and optimized. Stomping is the oldest type of compaction (Figure 1): already in ancient times, people improved their soil with the help of muscle strength or with small falling weights creating dynamic soil compaction. The modern impulse compactor (Figure 1) takes this old principle and adapts it to the demands of modern projects by being much more time efficient and providing better quality results.

Figure 1. Compacting in the past, stomping (left), and now, impulse compactor (right).

DOI: 10.1201/9781003299127-77

Modern Impulse Compaction, also known as Rapid Impact Compaction (RIC), is the action of compacting the ground with a so-called impulse compactor, in which a defined weight falls freely from a height of up to 1.2 m onto a steel plate that is resting on the ground. The dropped weight is hydraulically lifted and this can be done so quickly as to perform up to 60 blows per minute, while the steel plate, the so-called compactor foot, always remains in contact with the ground. Within the family of soil improvement methods, Impulse Compaction can be seen as the "missing link" between near-surface compaction (rolling) and deep compaction (vibro-compaction, dynamic deep compaction) (Figure 2).

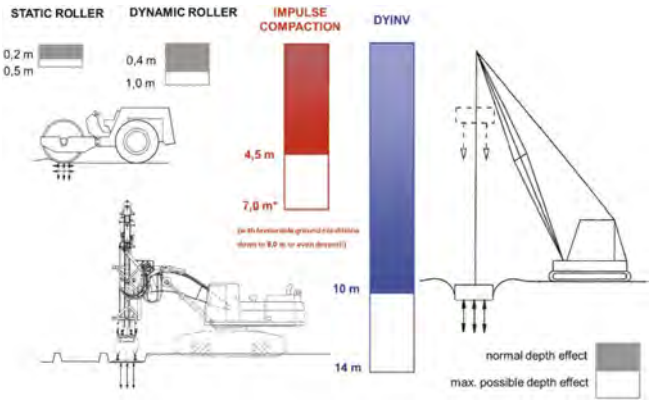

Figure 2. Depth effect of various methods of subsoil improvement: near-surface, impulse and deep compactions.

Impulse Compaction has many advantages when compared to the other compaction methods. Due to the fact that usually no or very little foreign material has to be introduced, Impulse Compaction is not only economically advantageous, it also generates by far the smallest carbon footprint compared to the other processes. Furthermore, compared to dynamic intensive compaction, Impulse Compaction generates far fewer vibrations, which may be of advantage in certain scenarios. However, in some urban settings, the vibrations from Impulse Compaction can still be too high.

To the author's knowledge, modern Impulse Compaction is only commercially done using freely falling weights: companies that use hydraulically accelerated hammers, as opposed to freely falling weights, only use them for driving piles of wood, steel or precast concrete and not for ground improvement as such. There have been attempts and considerations on the part of Terra-Mix to accelerate the falling weight by means of a rocket propulsion system in order to reduce costs by reducing the weight, but these have not yet come to any useful results.

2 TECHNICAL DESCRIPTION OF IMPULSE COMPACTION

The impulse compactor is a dynamic compaction device based on a piling hammer technology and is used to increase the bearing capacity of soils through controlled impacts. A drop weight of 5 to 16 tonnes is dropped onto the compactor foot assembly 40–60 times a minute. The foot, which remains in contact with the ground at all times, has a diameter that can range from 80 cm to 2 m, but 1.5 m is common. The compaction results in a rearrangement of the solid material in the soil, because as the water and air pores are displaced, the solid particles are brought into an even denser positioning. In coarse-grained or mixed-grain soils, water in the soil can be squeezed out of between the grains by pressing the grains together and creating a higher contact pressure. In cohesive soils, instead of reducing the soil volume by displacing pore spaces, the result of the mechanical compaction action is rather to have a constant

displacement of the material, as the (almost) incompressible water pushes the impermeable grain material in front of it. This effect can also be seen occasionally when material bulges out laterally during Impulse Compaction. In such cohesive soil cases, a soil improvement with Impulse compaction can still be achieved by compacting in (time order) primary and secondary grid patterns or by including longer waiting times between the passes. Due to the hammering action and the soil rearrangement below, the compactor foot can penetrate up to 1 m into the soil, and when using a special construction, it can penetrate even deeper (which is desired in that case). During the compaction process, each individual impact is measured and documented by a depth sensor. Data monitoring during the compaction process and the online monitoring display in the operator's cab enable the operator to have detailed compaction control. The total impact depth of the compactor foot, the number of blows, and the "Final Set" of the compactor foot (resulting settlement from each particular blow) all contribute to making the decision to stop a hole. The resulting compaction craters (Figure 4) are usually filled with the site material, and the process is repeated until a previously defined 'stop code' is reached. Alternatively, external stone material can also be used to fill the holes in order to increase the stiffness of the soil. The 'stop code', in particular the 'Final Set' parameter, provides indirect information about the soil improvement. A measurable correlation between the indirect soil improvement information and the direct measurement of the improved soil usually takes place via a soil penetration test, such as the Dynamic Probing Heavy (DPH), which is carried out in the course of the so-called calibration field phase.

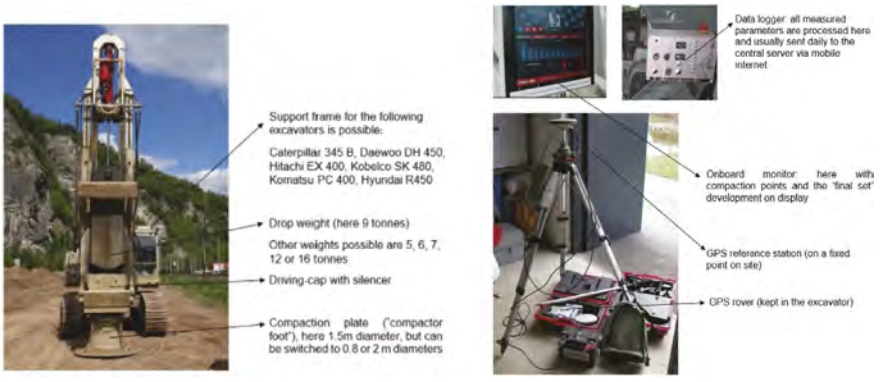

Figure 3. Components of an impulse compactor (standard version in Europe).

The following soil parameters and characteristics can be improved with the Impulse Compaction method:

- compactness of the soil particle packing (bulk density)
- soil stiffness (soil modulus, modulus of subgrade reaction),
- bearing capacity (friction angle, cohesion),
- settlement behaviour
- uniformity of the soil parameters
- weak zones identified
- shear wave modulus (thus mitigating the liquefaction risk)

In Europe, the nine tonne drop weight and the 1.5 m diameter foot, as shown in Figure 3, have proven to be the most economical combination. A heavier drop weight provides relatively little further depth effect, but it does speed up the compaction process because fewer blows are required per pass. Further equipment used in the Impulse Compaction process are shown in Figure 3: the onboard monitor, the data logger and the rover of the GPS system are all installed in the excavator cabin, while the GPS reference station is placed in a secure location on site.

3 LIMITS OF STANDARD IMPULSE COMPACTION

Originally, Impulse Compaction was only intended for sandy and gravelly or mixedgrained soils, in which there can be a deep compaction effect of up to 7 m. In certain sandy soils in Northern Germany or in coastal areas in Southeast Asia, compaction depth effects of up to 9 m have been documented, using the common drop weight of 9 tonnes and the 1.5 m foot. A heavier drop weight and a larger foot diameter allow for a significantly higher compaction speed, but the soil improvement effect at depth is rather small. In certain fine-grained soils, the compaction effect at depth decreases to 4.0–4.5 m. Table 1 can be used as a guideline for the use of Impulse Compaction technology in various soil types. The following values describe general limits of Impulse Compaction application in soft soils:

- coefficient of water permeability (Kf-value): max 10–6 m/s
- silt (grain size < 0,063 mm) content: max 15%

As the soil becomes more fine grained (the yellow cells in Table 1), it generally becomes required to undertake a more thorough soil investigation in order to ascertain the suitability of Impulse Compaction for those soils. In clayey and organic soils, consideration of Impulse Compaction without any additional measures should be rejected from the outset.

Originally, Impulse Compaction was only intended for sandy and gravelly or mixedgrained soils, in which there can be a deep compaction effect of up to 7 m. In certain sandy soils in Northern Germany or in coastal areas in Southeast Asia, compaction depth effects of up to 9 m have been documented, using the common drop weight of 9 tonnes and the 1.5 m foot. - silt (grain size < 0,063 mm) content: max 15%

As the soil becomes more fine grained (the yellow cells in Table 1), it generally becomes required to undertake a more thorough soil investigation in order to ascertain the suitability of Impulse Compaction for those soils. In clayey and organic soils, consideration of Impulse Compaction without any additional measures should be rejected from the outset.

4 DOCUMENTATION AND QUALITY CONTROL

For an Impulse Compaction soil improvement program to be considered successful, an increase in soil stiffness and the homogenization of the soil under individual foundations are required. In Europe, the soil stiffnesses are thus far mostly measured indirectly with Dynamic Probing Heavy (DPH), but Cone Penetration Test (CPT) or Standard Penetration Test (SPT) can also be used. Sometimes, the soil improvement measurements are also carried out by means of geophysics, for example, Continuous Surface Wave (CSW) analysis or similar. DPH soundings, taken before and after Impulse Compaction, show the resulting increase in soil stiffness (Figure 4)

In order to be able to prove a successful soil improvement program, an exact documentation of the effects on the soil is required. During soil compaction, the following data of each point can be recorded continuously and stored daily on the central server:

- local or transferred GPS coordinates (X, Y, Z) (with an assigned point ID)
- date and time
- number of compaction blows

Table 1. Guideline for application of Impulse Compaction in various soil types.

Main group	General group	Abbreviation Group symbol	Replacement base layer System	Impulse Compaction Effective depth	Hybrid Foundation System	RIC Stone Columns Without pre-drilling	RIC Stone Columns Without pre-drilling
Coarse-grained soil	Coarse gravel	cGr		max.6-8m

Fine-grained soil	Silt	MSi, FSi				aprox. 3m	aprox. 3m
Fine-grained soil	Clay	Cl				aprox. 3m	aprox. 3m
			tecnically possible		tecnically eventually possible		tecnically NOT possible

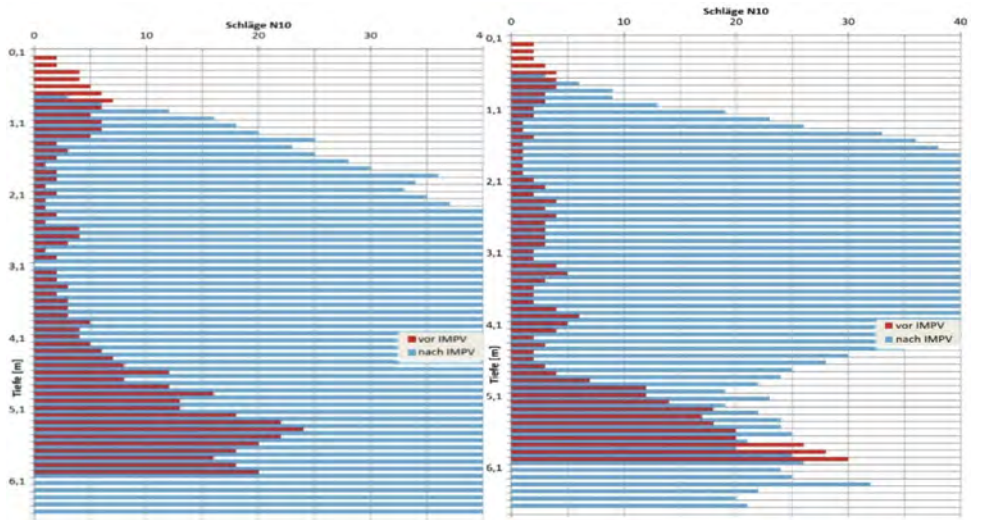

Figure 4. Examples of DPH soundings before (red) and after (blue) Impulse Compaction.

- number of passes (if within certain criteria (depth, time, number of strokes) the desired target is not reached, the hole must be filled again and a new pass from the working plane must be started)
- the penetration depth into the ground per blow
- the total (summed) penetration depth per pass and per point ("Deep Total")
- possibly also vibration and noise measurements

With the recording of these parameters, one of the most important tasks of Impulse Compaction can be verified directly: the homogenization of the subsoil. In practice, this means that every single point is worked on until the same "answer" from the ground can be documented in the form of the 'Final Set'. Furthermore, the choice of the grid of compaction points, or the distance between points under individual or strip foundations, as well as the compaction plate diameter play a big role in the resulting quality of the Impulse Compaction program. These are usually determined beforehand in the geotechnical design according to empirical values and geotechnical calculations and later re-evaluated so that the soil mechanical properties such as stiffness and packing density are improved to the desired levels.

For quality control, the impulse compactor must be "calibrated" to each soil before starting work. This is done in a so-called "calibration field", where a field of at least 3 × 3 points is defined on the construction site, and in which geotechnical investigations are first carried out. After the initial testing, the calibration field is compacted with the impulse compactor according to the preliminary geotechnical plan. Then the same geotechnical soil investigations are carried out again to determine soil improvement and to check that the required improvement has been reached. Depending on the results, the machine parameters are then confirmed or adjusted if necessary. These become the "stop codes", as the on-board computer automatically stops the compaction work at that point once these parameters are reached.

After the calibration process, compaction can be rolled out over the entire construction site.

Compaction quality control continues with regular checks using the investigation methods used in the calibration phase. The continuous recording and documentation of the machine parameters usually means a significant reduction in control testing.

5 DISCUSSION/CONCLUSIONS

Impulse Compaction or RIC is now considered "state of the art" when it comes to economical solutions for soil improvement and homogenisation of non-cohesive soils. In its most basic application, the idea is to improve the ground, primarily the soil stiffness, such that it can support the structural loads with a shallow foundation only. This would help to avoid needing more expensive deep foundation solutions. Therefore, the geotechnical conception and calculation for Impulse Compaction are relatively simple, as improving soil stiffness is the main desired outcome. However, thorough preparatory work (including subsoil investigation) is still essential in order to undertake a successful Impulse Compaction program.

This paper has shown that Impulse Compaction works very well in granular soils to reduce pore spaces and create a stiffer ground. In softer, more cohesive soils, it is also possible to work with this technology, but this requires more detailed preliminary investigations, a greater geotechnical understanding and the selection of an appropriate Impulse Compaction application or combination, such as the variant that combines Impulse Compaction with predrilled stone columns. The calculation and verification of the Impulse Compaction method can be carried out analogously to the recognized method of Priebe [6], which is often used for the dimensioning of vibro compaction. An interesting aspect of Impulse Compaction is that the soil is usually reduced in volume as a result of the compaction. This can lead to additional savings in the cost of excavating a construction pit, especially if the material is contaminated but compactable.

Finally, the noise and vibration of the Impulse Compaction method do not necessarily exclude it from ground improvement choices in sensitive areas. It is important to know the

country-specific regulations and to take the correct precautionary measures. A problemsolving mindset may also find solutions before a problem comes up. For example, in the construction of a building with a planned future expansion, an extra 10–20 m wide strip can be pre-compacted in the direction of the planned expansion so that future compaction work does not have to be undertaken close to the existing building. In conclusion, Impulse Compaction has already established itself as a particularly economical method for improving medium-deep soils. Looking forward, current ongoing research into noise and vibration reductions, into a more direct determination of the improved soil stiffness, and into a reduction of the system's weight will likely find innovations to make Impulse Compaction even more attractive as a soil improvement method.

Imparting soil water repellency with polymeric microcapsules

R. Qi & S.D.N. Lourenço
Department of Civil Engineering, The University of Hong Kong, Hong Kong S.A.R., China

ABSTRACT: Hydrophobized soils, which have a functional hydrophobic coating, can restrict water infiltration and thus have various engineering applications. Microencapsulation approaches, developed for self-healing applications emerge as a potential solution to switch the hydraulic properties of soil. In soils, microcapsules have been successfully implemented in agriculture to improve plant nutrition, based on the release of fertilizers into the soil from the microcapsules. The aim of this study is to impart soil water repellency with polymeric microcapsules by releasing hydrophobic cargo into soil. In this research, the hydrophobic cargo was encapsulated and mixed with soil. The released hydrophobic cargo and the soil hydrophobicity change was measured. The results show that the polymeric microcapsule could impart water repellency in soils.

1 INTRODUCTION

Natural hydrophobic soils originate from fungi and microorganisms, certain types of vegetation, and burning by wildfires, and are known to reduce the rate of wetting and the affinity of soil to water (Olorunfemi et al., 2014). Thus, they have been suggested to be used as an impermeable barrier for landfill cover systems, improving slope stability, and improving drainage in porous pavements (Beckett et al., 2016). Hydrophobic soils could be synthesized artificially by forming a hydrophobic coating on the surface of soil particles, which could adjust the level of soil water repellency and allow their use in infrastructure. Soil hydrophobicity can be quantified by the contact angle (CA) and water drop penetration time (WDPT) (Ng and Lourenço, 2016). The contact angle is a physical expression of the wettability of a surface. Through the Young-Laplace equation, 90° is used as a threshold. CA>90° indicates a hydrophobic surface and CA<90° indicates a hydrophilic surface (GOEBEL et al., 2011). The water drop penetration time (WDPT) measures the persistence of water repellency on the soil surface and classifies the water repellency according to the infiltration time (Olorunfemi et al., 2014). With different infiltration times (<5s, 5-60s, 60-600s, 600-3600s, >3600s), the soil is classified into wettable, slightly water repellent, strongly water repellent, severely water repellent, and extremely water repellent.

There has been an ongoing interest in applying polymeric microcapsules to enhance the performance and duration of various types of infrastructure. Microcapsules typically have a shell and cargo, which can store healing agents inside the microcapsules and release the stored agents to improve the properties of the matrix. They have been successfully implemented in cementitious materials including concrete and asphalt. For microcapsules mixed in concrete, microcapsules were proved to release cargo and fill fissures and thus improve the strength of the concrete (Kanellopoulos et al., 2016, Kanellopoulos et al., 2017). In asphalt pavements, it was found that by mixing with microcapsules, the cracked asphalt mixture recovered 52.9% of its initial strength (Al-Mansoori et al., 2017). For the application of microcapsules in soil, previous studies in agriculture have shown that microcapsules release nutrients into the soil slowly and contribute to plant growth (Cesari et al., 2020). Polymeric microcapsules are a suitable candidate for imparting water repellency in soils. In this study, we test whether polymeric microcapsules with hydrophobic cargo can release hydrophobic substances and impart soil water repellency.

DOI: 10.1201/9781003299127-78

The aim of this study is to induce water repellency in soils by polymeric microcapsules. Specific objectives are (1) to synthesize microcapsules with hydrophobic cargo, (2) to investigate the physical properties of the microcapsules, and (3) to verify the effectiveness of imparting soil water repellency with polymeric microcapsules by measuring the CA and WDPT of the soil.

2 METHOD

2.1 *Materials*

Fujian sand was used in the experiments. The particle size ranged from 150 to 300μm. Polydimethylsiloxane (PDMS) was used as the hydrophobic cargo as past studies show that the PDMS can induce high and stable hydrophobicity in sands (Lin and Lourenço, 2020). Calcium alginate was used as the shell of the microcapsules. Alginate has the advantage of being biodegradable, biocompatible, and non-toxic.

2.2 *Microcapsules encapsulation*

Microencapsulation is a process to produce a protective shell and isolate the cargo material from the surrounding environment (Kanellopoulos et al., 2017). The ionic gelation method was applied to encapsulate the PDMS cargo into a calcium alginate shell. This encapsulation mechanism is the emulsification of PDMS with sodium alginate solution, formation of cross-linking between sodium alginate and calcium ion, and encapsulation of the cargo. The encapsulation process is shown in Figure 1. Firstly, 1.5g of sodium alginate is dissolved in 100g of water. Secondly, PDMS emulsified with a homogenizer (Benchmark, D1000). The PDMS and sodium alginate emulsion was then dripped into calcium chloride solution (1.0 M) and the microcapsules was produced. The mass of PDMS used per 100g sodium alginate solution was defined as PDMS loading. In this study, three different PDMS loadings (5, 10, 20) were used to produce microcapsules with three different PDMS contents.

Figure 1. Encapsulation of hydrophobic cargo with the ionic gelation method.

2.3 *Microcapsules characterization*

The size and shape of microcapsules and sand were measured by a dynamic image analyser (QicPic™, Sympatec GmbH); 0.5 g of microcapsules and sand samples were analyzed to obtain the particle size distribution and the particle shape. Three parameters (aspect ratio, sphericity, convexity) that indicate particle shape were measured. The aspect ratio is defined as the ratio of particles minimum to the maximum Feret diameter indicating the elongation of the particle. sphericity is the ratio between equivalent and real perimeters of the particle profile, and convexity refers to the ratio of the whole area of a particle profile to its convex hull area. The microcapsules surface was characterized by an optical microscope (Leica, CH-9435).

2.4 *Imparting soil water repellency with microcapsules*

The microcapsules with different PDMS loading were mixed with soil. In this study, the number of microcapsules mixed was not studied and 4% mass content of microcapsules were

used. After mixing for 12 days, the microcapsules and the soil were separated, and the released amount of hydrophobic cargo and the soil hydrophobicity were measured.

The released PDMS amount was measured based on the different decomposition temperature points of PDMS and silica sand. Past studies showed that there is 85% mass loss when PDMS was heated to 800°C ((Camino et al., 2001, Sethy et al., 2019) while the silica sand was stable and there was no mass change for silica sand when the heating temperature was below 900°C (Ranjan and Brittain, 2007). In this study, the sand samples with PDMS were heated to 800°C, the mass loss was recorded, and the PDMS amount in soil was calculated.

The contact angle was measured with the sessile drop method, which is an accurate and direct measurement of soil hydrophobicity (Bachmann et al., 2000). The contact angle of the soil samples was tested with the following steps: (1) a layer of sand particles was placed onto a microscopic glass slide. (2) 10 μL of distilled water was dropped and dispensed on the sand surface. (3) the CA was recorded with a drop shape analyzer (DSA100, KRÜSS GmbH).

The WDPT was measured by recording the infiltration time of water into the soil. The soil samples were flattened and then 50 μL of distilled water drops were dispensed onto the surface of the sand with a pipette. The entire water infiltration process was recorded with a digital camera. The time duration of complete water drop infiltration was recorded as WDPT. For each soil sample, six water droplets were tested and the average penetration time was calculated.

3 RESULTS AND DISCUSSION

3.1 *Microcapsules properties*

The physical properties of the microcapsules are shown in Figure 2. Figure 2 (a) shows the particle size distribution curve of calcium alginate-PDMS microcapsules and sand. The majority (approximately 95%) of the capsules were distributed between 1.5mm and 2.0mm. The size of sand is distributed in the range of 0.3mm to 0.6mm. The average particle size of the capsules was 1.6mm. Figure 2 (b) showed the shape and surface features of the capsules. The microcapsules had a spherical shape with a rough surface. The spherical shape of the microcapsules and the sand host were further characterized and shown in Table 1. The aspect ratio, sphericity, and convexity of microcapsules were 0.81, 0.84, and 0.95, respectively. The aspect ratio and convexity of the microcapsules were larger than that of sand, which were 0.73 and 0.91, indicating that the roundness of the capsules is larger than that of the sand.

Table 1. Attributes of calcium alginate-PDMS composite microcapsules.

	Aspect ratio	Sphericity	Convexity
Fujian sand	0.73	0.86	0.91
Microcapsules	0.81	0.84	0.95

*For Microcapsules with 10 PDMS loading.

3.2 *Cargo release*

The released amount of hydrophobic cargo from microcapsules was measured. Figure 3 showed the content of PDMS in soil after mixing with 5, 10, and 20 PDMS loading microcapsules for 12 days. With the increase of PDMS loading in microcapsules, the released cargo amount increased. For soil mixed with 5 PDMS loading microcapsules, the PDMS content in soil was 0.02%. As the PDMS loading of microcapsules increased to 10 and 20, the PDMS content in soil increased to 0.26% and 0.34%, respectively. The increase of PDMS loading in microcapsules leads to a decrease in the proportion of sodium alginate solution, which forms the shell by cross-linking. The decrease of sodium alginate results in a weaker crosslinking structure and increased leakage of the hydrophobic cargo.

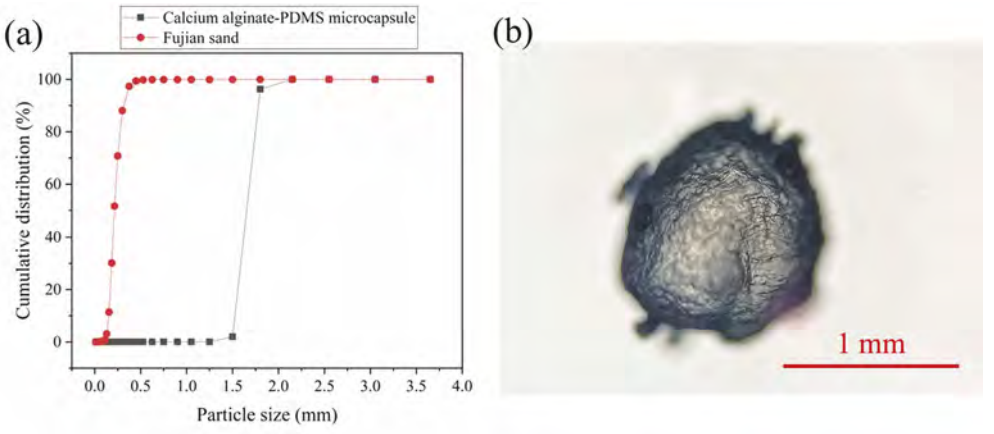

Figure 2. Physical properties of microcapsules: (a) particle size distribution of Fujian sand and calcium alginate-PDMS composite microcapsules; (b) Microphotograph of single calcium alginate-PDMS composite microcapsule.

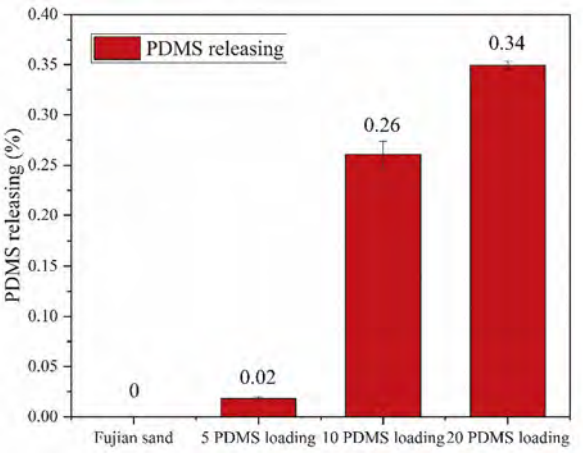

Figure 3. Hydrophobic cargo (PDMS) release amount.

3.3 *Soil water repellency*

The soil hydrophobicity is shown in Figure 4. Figure 4 (a) shows the CA of the soil while Figure 4 (b) shows the WDPT of soil after mixing with 5, 10, and 20 PDMS loading microcapsules for 12 days. After mixing with microcapsules, the CA of the soil increased. Besides, the CA of the soil increased with the increasing PDMS loading of the microcapsules. As shown in Figure 4 (a), the CA of the soil was 29.7° while the soil mixed with the microcapsules increased to 89.5°, 92,8°, and 115.1°, respectively (5, 10, and 20 PDMS loading microcapsules). Past studies have shown that before a critical concentration, the CA of soil increased with the increasing percentage of hydrophobic substances (Ng and Lourenço, 2016). The CA of the soil increased with PDMS loading as more hydrophobic cargo released into soils. With the criteria of CA = 90°, the soil surface was originally hydrophilic. By mixing with calcium-alginate PDMS microcapsules with the loading of 10 and 20, the soil switched to hydrophobic.

The WDPT of soil was smaller than 5s, which also suggested a hydrophilic state. For soil mixed with 5 and 10 PDMS loading microcapsules, the WDPT was also smaller than 5s. When the PDMS loading of the microcapsules increased to 20, the WDPT of sand increased to 3600s, which was an extremely water-repellent state. With the criteria of WDPT, the calcium alginate-PDMS microcapsules with 20 PDMS loading imparted soil water repellency.

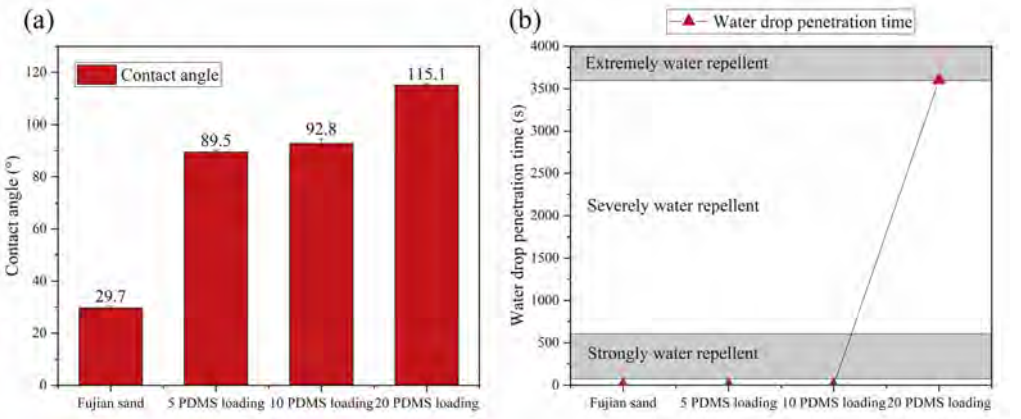

Figure 4. Soil hydrophobicity: (a) contact angle; (b) water drop penetration time.

4 CONCLUSIONS

This study demonstrates that polymeric microcapsules with hydrophobic cargo made of PDMS here, can be used to impart soil water repellency. PDMS was encapsulated with calcium alginate shell and proved capable to release cargo after mixing with soils. The released hydrophobic substances induced soil water repellency which was indicated by increased soil CA and WDPT. The PDMS loading of microcapsules affects the release amount and soil hydrophobicity increase. Higher microcapsule PDMS loading results in a higher amount of released PDMS. Based on the criteria of CA and WDPT, the microcapsules PDMS loading should be large than 20 in order to switch the soil from a hydrophilic state into water repellent state.

ABSTRACT: In offshore reclamation works using dredged soil containing soft soil with high water content ratio, consolidation settlement of the ground is the main problem. In the present study, a large scale model test on a vacuum consolidation method using vacuum well, permeable layer and drains, which was developed to promote early consolidation of such reclaimed ground, was analyzed using a three-dimensional soil-water coupled finite deformation analysis code that can accurately describe the large compression of unconsolidated soil. The analysis accurately reproduced the test results, and showed clearly how the negative pressure propagated efficiently and accelerated settlement due to the effect of the underlying permeable layer and vertical drain.

1 INTRODUCTION

Since dredged soil contains soft clayey soil with high water content ratio, consolidation settlement of the ground is a major problem in offshore reclamation works using the dredged soil. A vacuum consolidation method (Figure 1a) using vacuum well, permeable layer, and vertical drains (Umehara et al. 2020) has been developed to achieve early consolidation of reclaimed ground and control residual settlement. This paper first outlines a large scale model test (Figure 1b, Umehara et al. 2020) on the vacuum consolidation method. Next, since the unconsolidated soil shows large compression in this consolidation problem, a three-dimensional soil-water coupled finite deformation analysis (Noda et al. 2008) employing the elastoplastic constitutive model, SYS Cam-clay model (Asaoka et al. 2002), was conducted to show that the test results were well reproduced (Validation). Through these results, this paper also emphasizes the need for the analytical features shown in the following (1)-(3). (1) Use of the elastoplastic constitutive model which allows to describe the mechanical behavior of unconsolidated (colloidal) soils with high voids ratio and pore pressure greater than the hydrostatic pressure before consolidation begins; (2) use of the soil-water coupled finite deformation analysis that can accurately calculate the amount of large compression from moment to moment while also considering supernatant water; (3) introduction of a permeability change model (Taylor 1948) associated with large compression of the soil.

2 OVERVIEW OF A LARGE-SCALE MODEL TEST OF VACUUM CONSOLIDATION METHOD USING VACUUM WELL

This consolidation method is a ground improvement method that aims to promote consolidation more efficiently by installing vacuum wells in the bottom drainage layer of clayey soil and propagating the negative pressure applied to the vacuum wells through the bottom of the clayey soil

DOI: 10.1201/9781003299127-79

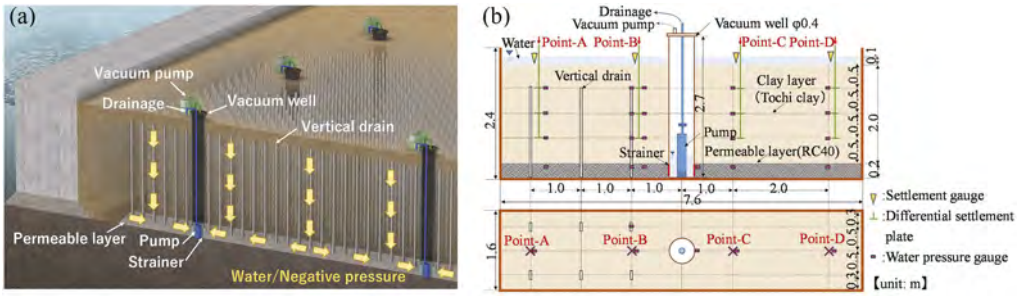

Figure 1. Vacuum consolidation method using vacuum well and a large scale model test.

using vertical drains that do not penetrate the ground surface. This chapter presents an overview of a large scale model test conducted to confirm the effectiveness of this improvement (Umehara et al. 2020). Figure 1b shows a cross-sectional and plan view of a 28 m^3 test soil tank (W7.5 m × D1.6 m × H2.4 m) that reproduces a clay layer 2.0 m thick, as well as the measuring points of settlement gauge, differential settlement plate, and water pressure gauge. The main components of the model are the clay layer to be improved (Tochi clay: plasticity index I_p = 10.0, initial water content w_0 = 38.8% = 1.3w_L, w_L: liquid index), a permeable crushed stone layer (RC40) placed below the clay layer, a vacuum well (φ400mm steel pipe) placed at the center of the soil tank, and vertical drains (plastic board drain, 94 mm wide and 3.6 mm thick) were installed only on the left side of the tank shown in Figure 1b. The vacuum well is a φ400 mm steel pipe with a lid that can be sealed inside, and a vacuum pump installed outside can provide negative pressure inside the well. A strainer installed at a depth equivalent to the crushed stone layer at the bottom of the well and a pump inside the well can pump up water from the clay layer.

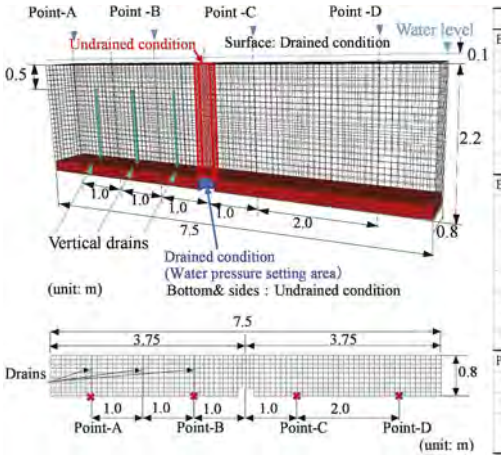
In this test a negative pressure of -70 kPa was applied to the well after the pumping in the well was started. Pumping was controlled in the range of GL-1.7 - -2.0m where the water level in the well did not reach the bottom of the pump. The pressure in the well and the amount of water pumped were controlled by a pressure gauge and a flow meter installed at the top of the well. The vacuum pressure loading time was approximately 80 days.

3 A SOIL-WATER COUPLED FINITE DEFORMATION ANALYSIS CONSIDERING LARGE COMPRESSION OF UNCONSOLIDATED SOIL AND ANALYSIS CONDITIONS

In order to understand the mechanism of this test, a numerical analysis was performed using the analysis code, *GEOASIA* (Noda et al. 2008). The reasons for this are as follows. This analysis code employs the SYS Cam-clay model (Asaoka et al. 2002) as an elastoplastic constitutive model that can describe the mechanical behavior of soil in a colloidal state with a high water content ratio, especially the large compression behavior caused by the vacuum consolidation method, and it is a finite deformation analysis code that can sequentially and exactly calculate the large compression behavior and the geometrical nonlinearities that lead to it. In this analysis, the permeability is also greatly reduced by the large compression, and to evaluate this, the permeability was expressed as $k = k_0 \exp(\Delta e / C_k)$, $\Delta e = e - e_0$ (Taylor 1948). Here, e and e_0 are the voids ratio at the present and reference times, k, k_0 are the coefficients of permeability at the present and reference times, and C_k is the material constant.

Figure 2 shows the analytical conditions of three-dimensional finite element mesh and material constants. The analytical model is a one-half range model, considering the symmetry in the depth direction for the large test. The clay layer of the Tochi clay was determined using the SYS Cam-clay model with reference to the existing material constants (Nakai et al. 2017). The underlying drainage layer (crushed stone layer) and vertical drains were modeled as two-phase elastic materials. For the vertical drain, the compressive stiffness was made smaller than that of the clay layer, and actual permeability values were given.

The pore pressure distribution of unconsolidated clayey soil in the unconsolidated state immediately after soil tank input is almost equal to the total stress distribution. Therefore, as an initial condition for vacuum consolidation, the mean effective stress distribution of the soil skeleton was determined by subtracting the pore water pressure in the vertical direction immediately after clay input from the overburdened soil pressure (total stress distribution) calculated using the unit volume weight of the input clay. The unconsolidated clayey soil in colloidal state was assumed to be a highly structured soil in a normally-consolidated and isotropic stress state. In other words, structure R_0^* in the SYS Cam-clay model was distributed in the vertical direction with normal consolidation, $R_0 = 1$, and anisotropy, $\eta_0 = 0$ (isotropic) while assuming the structure (bulk) is developed equivalent to the pore water pressure.



Tochi clay	
Elasto-plastic parameters	
Compression index $\tilde{\lambda}$	0.07
Swelling index $\tilde{\kappa}$	0.01
Critical state index M	1.2
Void ratio at q=0 and p'=98.1(kN/m^2) on NCL-1 N	1.62
Poisson's ratio ν'	0.3
Evolution rule parameters

Poisson's ratio ν	0.3	0.3
Permiability k(cm/s)	1.0×10^{-2}	1.0

Figure 2. Finite element mesh and material constants used in this analysis.

4 COMPARISON BETWEEN TEST AND ANALYTICAL RESULTS

Figure 3 shows the measured and calculated results of stratified settlement over time in the areas where a vertical drain was placed (left side in Figure 1b or 2) and no drain was placed (right side). In the test the lower layer (GL-1.0 - -1.5 m) of the drain-placed area settled about 6.0 cm at 70 days, while the upper layer (the area not penetrated by the drain) GL0.0 - -0.5 m settled about 3.0 cm, indicating that the effect of the drain was larger in the lower layer. The analysis shows that after 30 days, the progress of consolidation settlement in the lower layer (GL-1.0 - -1.5 m), where the drain was placed, was slightly faster than in the test, but the effect of drain drainage, which promotes consolidation more in the lower layer than in the surface layer, was well reproduced.

Figure 4 shows the measured and calculated isochrones of pore water pressure at measuring Points-B and C. In the test, the initial pore water pressure starts near the total stress because of the unconsolidated condition at the start of consolidation, and then it decreases with time. The test results show that the negative pressure develops over time and approaches each of the assumed values. In the analysis, the SYS Cam-Clay model was used to simulate the unconsolidated state of the clayey soil. As a result, the initial pore water pressure was set close to the total stress, and the subsequent changes toward the final state of vacuum loading were reproduced.

Figure 5 shows the comparison of pore water pressure over time in the clayey soil layer. In the test, the pore water pressure decreased by -40 kPa at GL-1.5m and -15 kPa at GL-1.0 m, indicating that the greater the depth, the larger the negative pressure changes, and the greater the settlement promotion effect appears at deeper depths. This is the drainage effect of the bottom drainage layer in addition to drainage near the bottom drainage layer. The analysis reproduces the test results quantitatively well, and confirms that negative pressure propagates to the upper layer due to the installation of the drain, and that consolidation progresses even in the unpenetrated area.

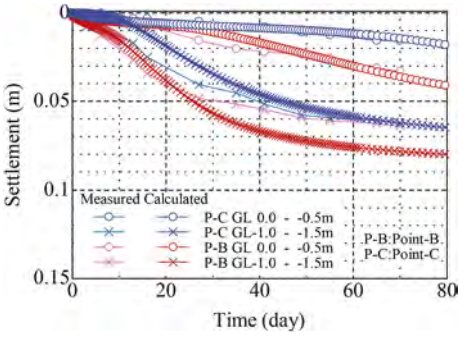

Figure 3. Comparison of stratified settlement.

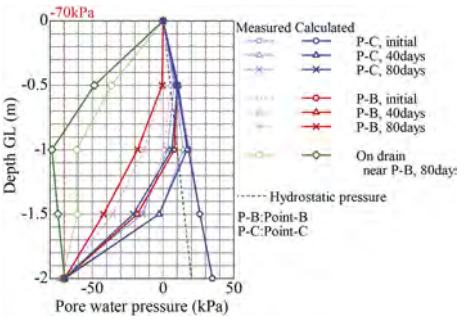

Figure 4. Isochrones of pore water pressure.

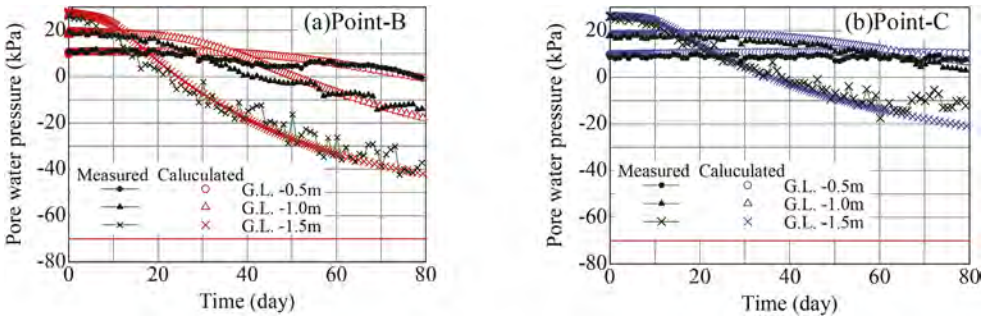

Figure 5. Temporal change of pore water pressure at two measuring points, P-B and P-C.

Figures 6-8 show the contours of pore water pressure (40 days after the vacuum start), deviator stress (40 days) and voids ratio change from the initial state (20 and 80 days), respectively. From these figures, it can be seen that the negative pressure is transmitted to the entire drain section and propagates at each depth as described above, and that the soil around the drains begins to compress subject to significantly high shear stress as a result.

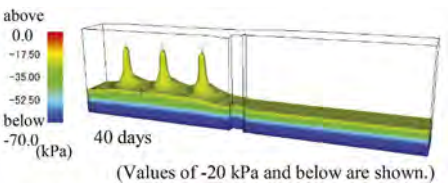

Figure 6. Distribution of pore water pressure.

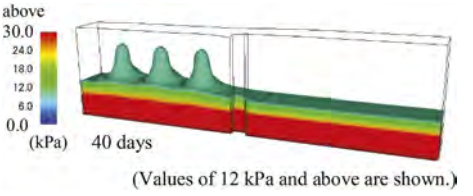

Figure 7. Distribution of deviator stress ratio.

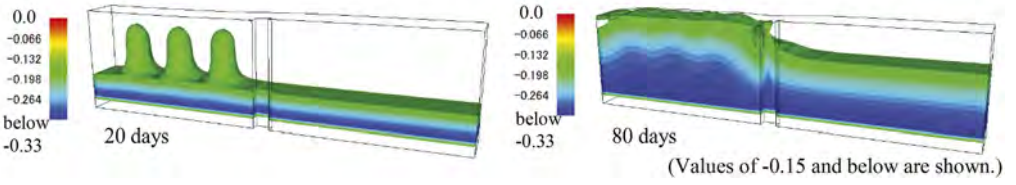

Figure 8. Distribution of voids ratio change from the initial state.

5 CONCLUSION

The soil-water coupled finite deformation analysis, which can accurately track the large compression behavior of soil in an unconsolidated state, was performed for a large model test of vacuum consolidation method using vacuum well. The analysis shows that the test results can be reproduced with high accuracy while clearly showing the mechanism by which the negative pressure is efficiently propagated and settlement is accelerated by the effect of the underlying permeable layer and vertical drain.

The application and benefit of pilot test for ground improvement on reclaimed land

K.S. Sheu & C.R. Chou
Moh and Associates, Inc., New Taipei City, Taiwan

ABSTRACT: Application of ground improvement methods mostly relies on semi-empirical design approaches. Before the construction is commenced, the design is always verified and improved based on the feedback of the pilot test with various on-site monitoring results. This paper presents the pilot test results of dynamic compaction and sand drains and discusses the on-site monitoring results and effectiveness. In the dynamic compaction case, the vibration induced by the falling weights is monitored to determine the impact on the adjacent structures. The observation of piezometer showed that the induced excess pore water pressure dissipated faster than the estimated time based on the permeability of the sand layers. In the sand drains case, the design was assessed by rechecks of the empirical charts and correction of fine grain contents to obtain the optimal spacing that meet engineering economy requirement and improved the construction time and effectiveness of ground improvement.

Keywords: Pilot test, Dynamic compaction, PPV, Sand Compaction Pile

1 INTRODUCTION

This paper takes the dynamic compaction pilot test of the geological improvement of the reclaimed land in Taipei Port as an example, and discusses the influence of different experimental variables such as tamping configuration, tamping energy, and formation conditions on the peak particle velocity (PPV) in the test. To propose construction disposal measures to avoid damage to existing harbor structures caused by construction vibration.

The southern boundary of the reclaimed land in Taipei Port is adjacent to the permanent revetment; sand compaction piles are used for soil improvement. A pilot test is carried out before construction in the formal area, and evaluate the construction distance of the sand compaction piles to meet the requirements of engineering economy, reasonable construction period and improvement effect.

2 SITE CONDITIONS OF THE STUDY AREA

The Taipei Port's South Wharf District A is a large-scale land reclamation project of the north coast of New Taipei County, Taiwan. The reclaimed land in the Taipei Port's District A is created through hydraulic filling. The filling material comes from sediments under the sea, which consists mainly of silty sand to fine sand. The thickness of the hydraulic fill is approximately 9 to 11 m.

This paper collects a total of three groups of pilot test results, including two groups of dynamic compaction (DC) tests and one group of sand compaction pile (SCP) tests as shown in Figure 1. The dynamic compaction pilot test is divided into test zone I and test zone II according to the location of the work area. Because this project is a new land for hydraulic backfilling (the backfilling is completed for half a year), the test zone I is located in the water

DOI: 10.1201/9781003299127-80

end of sand pumping and filling, and fine particles such as silt and clay are easily mixed during the backfilling process, so the strata of test zone I and test zone II are slightly different.

The pilot test site of sand compaction pile (test zone III) is located on the south side of the project site, and the upper half of the stratum is dominated by silty fine sand. The soil conditions of the project site are arranged according to the geological survey results as shown in Table 1. According to the geological survey results, the groundwater within the scope of the project is about 1.18 to 3.45m below the surface.

Figure 1. Layout of the pilot tests.

Table 1. Soil profile of pilot test site.

Pilot test site	Improvement method	Depth (m)	Soil description	SPT-N value	Soil physical property
Test zone I	Dynamic compaction	0~5	Silty clay interbedded with silty fine sand	4	$w_n = 22 \pm 3\%$ FC = 53 ± 8%
		5~10	Silty clay interbedded with silty fine sand	7	$w_n = 22 \pm 4\%$ FC = 54 ± 17%
Test zone II	Dynamic compaction	0~5	Silty fine sand with little sandy silt	10	$w_n = 22 \pm 4\%$ FC = 28 ± 8%
		5~10	Silty fine sand with little sandy silt	15	$w_n = 22 \pm 2\%$ FC=23 ± 2%
Test zone III	Sand compaction pile	0~5	Silty fine sand	8	$w_n = 23 \pm 3\%$ FC = 19 ± 7%
		5~10	Silty fine sand with some clay	7	$w_n = 32 \pm 12\%$ FC = 46 ± 35%

3 TEST AND DESIGN OF DYNAMIC COMPACTION

The dynamic compaction method uses a special construction crane to pull a tamper with a weight of 26.4T and a size of 1.5×1.5×1.6m (length, width and height) according to different energy per drop (396T-M and 600T-M).

3.1 *Test zone I (DC)*

The test area is located in the center of the project scope. The two groups of test areas A and B are arranged up and down about 25 meters apart. The construction plane configuration is shown in Figure 3. The main strike is divided into three stages of tamping. In the first stage, 1-1~1-9 (circle) will be applied first; in the second stage, 2-1~2-4 (hexagon) will be applied; in the third stage, 3-1~3-12 (square) will be applied; as shown in Figure 2.

The test zone I is divided into I-A group and I-B group test. The construction parameters are shown in Table 2. Parameter assumptions in the design stage, and feedback from the test results are applied to the formal construction.

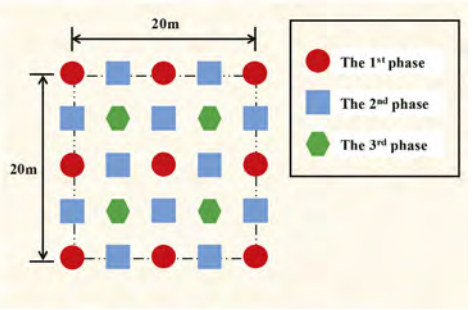

Figure 2. Layout of dynamic compaction procedure (Test zone I).

Table 2. Detail of dynamic compaction (Test zone I).

Test zone I	Group I-A			Group I-B		
Phase	I	II	III	I	II	III
No. of impact point	9	4	12	9	4	12
Energy per drop (T-M)	600	600	600	600	600	600
No. of drops per phase	25	25	19	35	35	25

3.2 *Test zone II (DC)*

The test area is located at the upper edge of the project scope. The two groups of test areas A and B are arranged at a distance of about 25 meters from left to right. The construction plane configuration as shown in Figure 3.

The test zone II includes the tests of group A and group B: group II-A was subjected to three-stage strikes, and group II-B was subjected to two-stage strikes. There was little difference in the total tamping energy between the two groups of test areas.

The idea of this configuration is to compare the relationship between the number of tamping stages and the improvement effect, and obtain the optimal configuration between the improvement effect and the work period. The construction parameters are shown in Table 3.

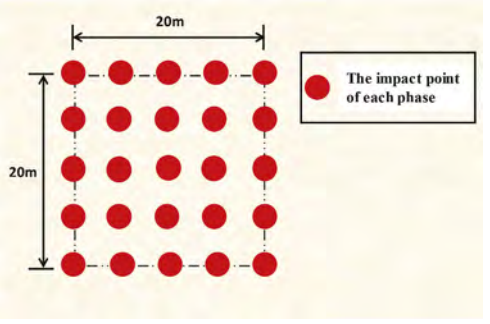

Figure 3. Layout of dynamic compaction procedure (Test zone II).

Table 3. Detail of dynamic compaction (Test zone II).

Test zone II	Group II-A			Group II-B	
Phase	I	II	III	I	II
No. of impact point	25	25	25	25	25
Energy per drop (T-M)	396	396	600	396	396
No. of drops per phase	15	10	6	15	15

3.3 *Dynamic compaction construction monitoring configuration*

The purpose of construction monitoring is to record the effectiveness of the pilot test plan on the improvement area, such as the dissipation time of excess pore water pressure excited by tamping and the measurement of vibration caused. Under the conditions of safety, economy and efficiency, to achieve the expected improvement goals, the related equipment configuration is shown in Figure 4.

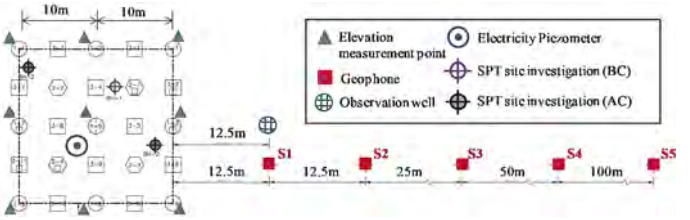

Figure 4. Layout of monitoring instrumentation.

4 TEST AND DESIGN OF SAND COMPACTION PILE

The design method of sand compaction piles was developed in Japan and gradually established by feedback from on-site construction cases. There are three commonly used methods, namely, the Table Lookup method, the N-Dr-e relationship curve method (Gibbs and Holtz, 1957) and the fine particle content correction method (Mizuno et al.,1987). This project is for hydraulic backfilling of new land (backfilling is completed for half a year), and fine-grained materials such as silt and clay are easily mixed in the backfilling process. Considering the chart method and the N-Dr-e relationship curve method, its scope of application is limited to sandy soils with a fine particle content less than 20%, and the influence of fine particle content is not considered. Therefore, in this case, the fine particle content correction method was used to design the pilot test of the SCP (Figure 5).

The test zone III is planned at the south edge of the project scope. It is divided into three areas with 20m×20m. The sand pile spacing of pilot tests are 1.9 meters, 2.1 meters and 2.3 meters as shown in Figure 6. The improvement depth is 10 meters and the pile diameter is 70 cm in equilateral triangle configuration.

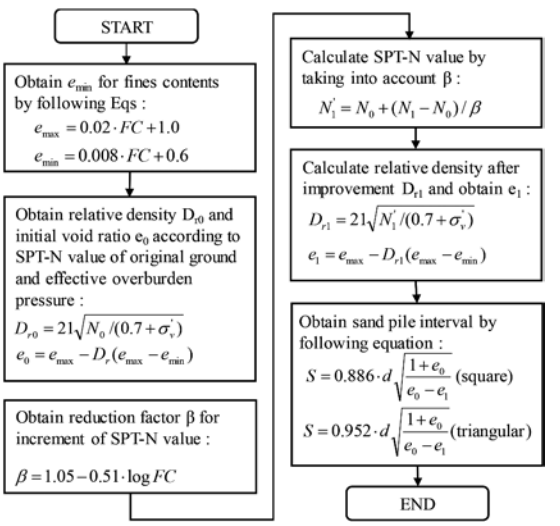

Figure 5. Flowchart of SCP design procedure.

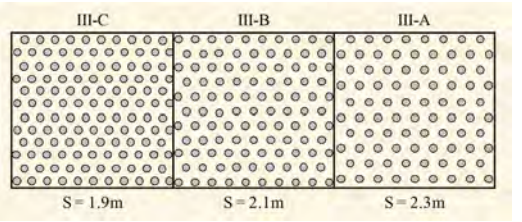

Figure 6. Layout of sand compaction pile (pilot test III).

5 RESULTS OF THE CASE STUDY ON THE EFFECT OF DYNAMIC COMPACTION

In this paper, a case study of ground improvement project to demonstrate the benefits of DC through both the increase in soil strength and the reduction in the variation of the soil strength. In this section, the results of this case study are presented and discussed.

5.1 *Ground water level measurement*

Figure 7 shows the groundwater level measurement data in Zone I-B. During the dynamic tamping operation (1/6 to 1/12), the water level depth is affected by the vibration of the tamping impact, and the water level depth is raised to between 2m and 1.7m underground. After about 12 hours of standing after the daily tamping, the water level returns to the initial level. After the completion of dynamic compaction (after 1/13), the groundwater level returned to stability.

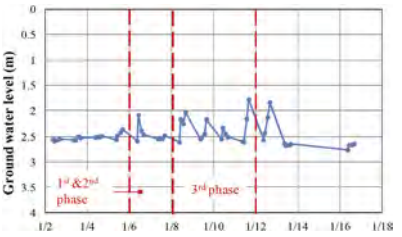

Figure 7. Ground water level during the I-B pilot test.

5.2 *Excess pore water pressure induced by dynamic compaction*

The test results of water pressure measurement with a buried depth of 5m in Zone I-B show that, during the tamping period (1/6~1/12), the excess pore water pressure is excited from 3.5 t/m2 to 7.5 t/m2 maximum, the increase range is about 115%, and within 6 hours after the end of the tamping, the water pressure gradually dissipated to 3.6 t/m2~3.8 t/m2 and returned to the initial state (Figure 8).

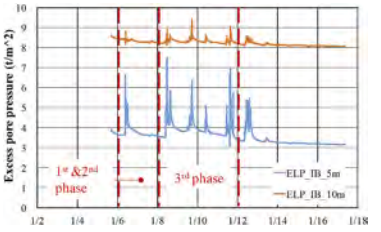

Figure 8. Excess pore pressure during the I-B pilot test.

The water pressure returns to the initial state within 6 hours after the end of tamping. During the test process, the dissipation time of excess pore water pressure is significantly faster than the estimated time of general permeability. A radial drainage path is formed to improve soil permeability and greatly reduce the dissipation time of excess pore water pressure.

5.3 *Ground vibrations induced by dynamic compaction*

Figure 9 shows the attenuation relationship of PPV with distance of two pilot test results. It was found that dynamic compaction has a greater vibration but a slightly faster attenuation rate with distance. The surface vibration decreases most significantly within 25m, and when the distance from the ramming pit is about 20~25m, the PPV value can be less than 20mm/sec, which meets the requirements of relevant regulations.

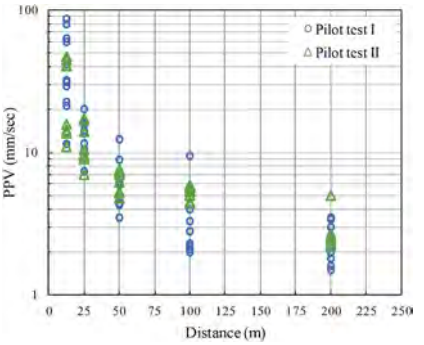

Figure 9. PPV measured at DC pilot tests.

Regarding the measurement results of PPV value and construction distance, considering the drop energy used in each group of cases and the difference in the measurement distance of monitoring instruments, the square root of the measurement distance and click energy is standardized, and the measurement is carried out according to multiple groups of construction cases. Mayne et al (1984) proposed the following formula as a conservative upper limit to the ground vibration levels as shown in formula (1):

$$\mathrm{PPV} = 7\left(\frac{\sqrt{\mathrm{WH}}}{\mathrm{D}}\right)^{1.4} \tag{1}$$

Where PPV is the peak particle velocity (in cm/s), W is the mass of the hammer (in tones), H is the fall height (in meters), D is the distance from the point of impact (in meters).

In this paper, the PPV measurement results o in zone I and zone II are compiled and compared with the upper limit value of the empirical formula and the lower limit value of foreign cases proposed by Mayne et al (1984). The results show that it falls roughly between the upper limit of the empirical formula and foreign cases (Figure 10), and the average PPV of this project can be regressed to an empirical formula as shown in formula (2):

$$\mathrm{PPV} = 2\left(\frac{\sqrt{\mathrm{WH}}}{\mathrm{D}}\right)^{1.4} \tag{2}$$

The engineer can easily estimate the PPV value caused by the tamping energy in the design stage, but the actual PPV value may be different due to the site conditions and construction methods. The adoption of the parameters can achieve a more economical tamping configuration.

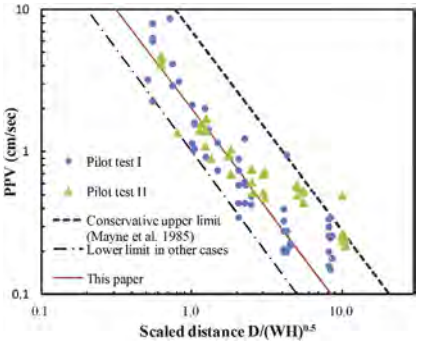

Figure 10. Relationship between measured PPV and scaled distance.

6 RESULTS OF THE CASE STUDY ON THE EFFECT OF SAND COMPACTION PILE

The design of the sand compaction pile is discussed by the method of Table lookup method and the correction method of fine particle content The design details of the pilot test as shown in Table 4. The comparison of SPT-N values with N_0(before SCP) and N_1(after SCP) are shown in Figure 11. The solid line in the figure is the average replacement ratio empirical curve drawn according to the Table lookup method. And the dashed line is drawn according to the fine particle content correction method, which is corrected by considering the average reduction factor ($\beta = 0.28$). The reduction factor β is a correction parameter related to fines content as shown in Figure 8. The increase of the N value between the sand piles after the improvement of the pilot test is positively correlated with the sand pile density, and the improvement effect of the sand pile spacing S = 1.9m is the most significant. In the three groups of tests, the improved SPT-N values of the sand pile spacing S=1.9m and S=2.1m can all meet the design requirements of the fine particle content correction method (dotted line),

Table 4. Detail of sand compaction pile (test zone III).

Group	Pile spacing	Replacement ratio a_s	FC (%)	Reduction factorβ
III-A	2.3m	0.084	29	0.304
III-B	2.1m	0.101	38	0.244
III-C	1.9m	0.123	33	0.276

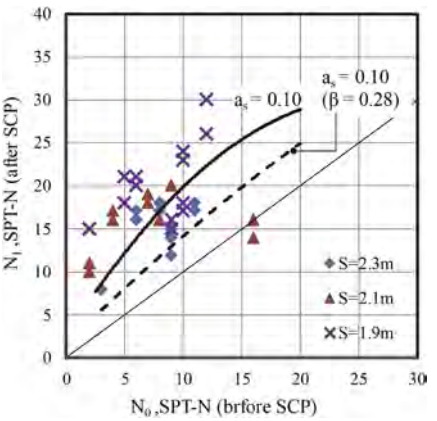

Figure 11. Comparison of SPT-N values with N_0(before SCP) and N_1(after SCP).

only the sand pile spacing S=2.3m at some depths SPT-N value does not meet design requirements.

According to the configuration of this case, the number of sand piles required for geological improvement and the construction period are discussed as shown in Table 5. In summary, comparing the improvement effect, construction quantity and construction period, the sand pile spacing S=2.1m can meet the requirements of construction economy, reasonable construction period and improvement effect.

Table 5. Benefit assessment of SCP in different spacing.

Pile spacing	No. of columns/ha	Working day/ha	Construction cost	Improve performance
S=2.3m	2200	14	High	Δ
S=2.1m	2600	16	Medium	O
S=1.9m	3200	20	Low	O

7 CONCLUSIONS

Through the pilot test results of DC, the water pressure dissipation rate is faster than the estimated time given the permeability of the sand layer. In the future, the dynamic compaction of the whole area can shorten the preset resting time and improve the engineering efficiency. The surface vibration decreases most significantly within 25m, and when the distance from the ramming pit is about 20~25m, the PPV value can be less than 20mm/sec, which meets the requirements of relevant regulations. And the engineer can easily estimate the PPV value caused by the tamping energy with the empirical formula proposed in this paper. The difference between the PPV generated by zone I and zone II configurations is not significant, but in terms of construction efficiency, zone II has the better efficiency

Through the pilot test results of SCP, the improved SPT-N values of sand pile spacing S=1.9m and sand pile spacing S=2.1m can meet the design requirements. A smaller spacing can achieve better improvement results, but the smaller spacing will increase the construction cost and schedule. Economical and effective improvement ratio can be obtained by the pilot test.

Before carrying out large-scale geological improvement, one should select the appropriate construction method according to the local conditions and assist in the review of the pilot test, so as to facilitate the evaluation of the formal area to meet the needs of construction economy, reasonable construction period and improvement effect.

Sanshin Construction (Thailand) Co., Ltd., Bangkok, Thailand

Morris Wang
ISEKI Engineering (Thailand) Co., Ltd., Bangkok, Thailand

ABSTRACT: In Bangkok, Thailand, the soils consist of a layer of soft clay underlain by interlayers of stiff clay and sand. The groundwater level is often observed a few meters below the ground surface. Unexpected incidents, such as water inflow from the sand aquifers and excessive deformation from the soft clay, could occur during TBM breakthroughs in such soil conditions. The jet grouting technique is commonly utilized for ground improvement to avoid these issues. This paper focuses on an evaluation of jet grouting design and construction methods related to water leakage issues for TBM breakthroughs. The design and construction data collected from the MRTA Orange Line East Project in Bangkok, Thailand, were used to evaluate key jet grouting design and construction parameters for TBM launching and arrival. A large-diameter jet grouting technique was used to form jet grouted blocks at the TBM launching and arrival areas. Regarding the design method, it was found that the cohesion of the jet grouting mixture is one of the key parameters that affect the jet grouted block dimension. The permeability and dimension of the jet grouted block are also essential design parameters when the tunnel is subjected to high water pressure at a greater depth. Regarding the construction method, it was concluded that to minimize construction issues a combination of many construction techniques, such as jet grouting, sealing rings, concrete blocks and flood of the chamber, should be applied to provide safer TBM breakthroughs.

1 INTRODUCTION

The high density of a population can be expected in capital cities such as Bangkok, Thailand. The traffic has become a problem as people have been using their personal cars. Hence, the mass rapid transit (MRT) system is a proper solution to solve the traffic problem. An underground transit system is a common MRT system in cities. However, underground space utilization is subjected to many local conditions, such as existing underground facilities, structure foundations, and especially soil conditions.

Groundwater issues and the associated stability of the soil resulting from high groundwater pressure is a common issue for the underground transit system. The groundwater is a significant factor that can lead to water inflow and surface settlement when the underground wall is excavated. The tunnel face can also collapse as it is unsupported. The potential for these problems to occur becomes higher when the tunnels are constructed at a greater depth. Normally, the earth pressure balance (EPB) shield, which is one type of tunnel boring machine (TBM), is chosen for tunneling in soft ground conditions. This EPB shield is capable of minimizing ground loss, and there is a sealing device to prevent groundwater. Besides, jet grouting

DOI: 10.1201/9781003299127-81

is also used to avoid the problems caused by groundwater and ground loss during TBM launching and arrival. However, the water leakage problem sometimes occurs even if jet grouting is constructed according to the design and construction guidelines. Therefore, this paper focuses on an evaluation of jet grouting design and construction methods related to water leakage issues for the TBM breakthroughs.

2 LARGE DIAMETER JET GROUTING TECHNIQUES

A large-diameter jet grouting technique was conducted to improve the soft soils for the MRTA Orange Line East Project. The large diameter jet grouting technique utilizes high-pressured grout slurry to erode and mix the in-situ soil to form soil-cement mixture columns with a diameter up to approximately 4.5 m (Cheng et al. 2021; Chao et al. 2020). This technique is capable to reduces the number of grout holes. Since there are a small number of grout holes, the construction time and cost can be minimized, which is preferable in congested areas. The large-diameter jet grouting techniques are described in Table 1.

Table 1. Large diameter jet grouting techniques.

Technique	Description
Rapid jet grouting (RJG)	This method is a double fluid system with two nozzles placed oppositely on the monitor (Chu et al. 2012).
V-Jet method	This method is a double fluid system. The two nozzles of this method are placed opposite each other and located at different levels (Cheng et al. 2013; Shinsaka et al. 2018).
Rodin jet pile (RJP)	This method is the same as the V-Jet method, whereas this method is a triple fluid system. The cutting nozzle, which is used to inject a water jet shrouded by an air jet, is located above the jet grout nozzle (Wang et al. 2013).
X-Jet method	The X-Jet method is a triple fluid system. The soil is disaggregated under the action of cross-water jets enveloped by an air jet, and the grout jet is injected at low pressure from another nozzle (Njock et al. 2018).

3 METHODS FOR TBM LAUNCHING AND ARRIVAL

Many techniques and methods are used to ensure the safety of TBM breakthroughs. These methods aim to stabilize a tunnel face behind a cutting wheel and prevent groundwater issues. Also, a vertical shaft or diaphragm wall should be delicately removed to provide the safety of launching and receiving processes. Ground improvement techniques and some special techniques for TBM breakthroughs are used to control ground movement and groundwater. The methods for TBM launching and arrival are presented in Table 3. Among the methods described in Table 3, the most common methods that are used for the TBM construction are the ground improvement methods and sealing rings.

4 CONSTRUCTION EVALUATION

The jet grouting soil improvement is commonly applied for TBM construction to prevent water leakage issues. However, water leakage issues could occur due to construction and environmental issues. Examples of the methods that were used to prevent water leakage issues and to ensure the safety of the TBM breakthrough for projects in Thailand are listed in Table 2. A detailed description of the methods shown in Table 2 is provided in Table 4.

Table 2. Examples of the methods applied to prevent water leakage for projects in Thailand.

Project	Permeation grouting	Jet grouting	Sealing rings	Concrete blocks	Flood of the chamber
River crossing water tunnels (Dung 2002)	✓	✓	✓	✓	✓
Blue Line ISP (Homburg, 2001; Suwansawat 2002)	✓	✓	✓	✓	✓
Orange Line East	✓	✓	✓	✓	✓

Table 3. Methods for TBM launching and arrival.

Method	Description
Dewatering	Dewatering can lower the groundwater table to provide dry conditions at the tunnel face and along the tunnel alignment. The drawdown causes an increase in the effective stress of the soil. This increase in the effective stress could result in a consolidation settlement in cohesive soils and elastic compression in granular soils. As a result, dewatering may not be suitable for urban areas where surface settlement is a significant concern. Moreover, in fine-grained layers which are low permeability, dewatering may not be applicable (Kuesel et al. 2012).
Ground freezing	This technique is usually applied in areas with considerable pore water in soils. The pore-water will be converted to ice which strengthens the soil and reduces the soil permeability. However, this technique could result in the ground being stronger than necessary for tunnel excavations. Also, the surface heave can be found due to water freezing, and thawing can lead to subsidence (Kuesel et al. 2012).
Fiberglass nailing	The nails are installed in the excavation face to reinforce and be temporary excavation support. The mesh or series of pins is applied in loose soils to stabilize and control the ground displacements. However, this technique cannot prevent the flow of groundwater (Valle et al. 2017).
Grouting	Grouting has advantages in groundwater control and soil stabilization. Also, grouting can be applied in various soil conditions. Grouting is used to strengthen the loose soil to prevent ground flow. The groundwater inflow can be minimized because of the low permeability of grouted soil. The subsidence due to water drainage and ground loss can be decreased (Kuesel et al. 2012).
Sealing ring	The sealing rings are used to limit the water flow through the annular gap during the entry and exit of TBMs. The gap between a tunnel wall and either the shield or erected segmental rings will be sealed by a rubber device that is pressed against two interfaces. The primary caution is the misplacement between a sealing ring and a cutting wheel during the launching and arrival. The sealing rings are mainly used for launching and are usually combined with other techniques (Valle et al. 2017).
Fake tunnels	This method can be used for TBM launching and arrival, but this technique is commonly used for arrival cases. This technique is used to solve the problems related to site dimension and geotechnical and hydrological conditions. The TBM will be assembled inside a steel sleeve (fake tunnel) for the launching procedure. In arrival cases, the end cap will be installed at the end of a steel sleeve, and the steel sleeve is filled with water to balance forces (Valle et al. 2017).
Concrete blocks	This technique is mainly used for TBM arrival. However, cement concrete blocks may be used for TBM launching. The concrete block is built inside the arrival station to keep the face pressure until the cutting head touches the wall and will be demolished after the TBM crosses (Valle et al. 2017).
Flood of a chamber	This technique is only used for arrival cases of TBMs. The reception station will be filled with water to balance the pressure from the soil and groundwater. This technique is commonly applied when the other common methods cannot be carried out due to limited space or construction difficulties. However, the flooding technique can cause a delay in other construction works (Valle et al. 2017).

5 DESIGN EVALUATION

The jet grouted block design extracted from the MRTA Orange Line East Project for TBM launching and arrival was reviewed and compared with the design manuals (JJGA 2017; Rapidjet Association 2019). Also, the parametric study was carried out to observe the design parameters, which mainly influence the water flow at the opening face. A comparison of jet grouting design for TBM launching and arrival of the MRTA Orange Line East Project was summarized and discussed in the subsequence section. The results of the parametric study are also provided and discussed in the following section.

The typical subsoil along the MRTA Orange Line East Project is the altered layers of clay and sand layer. The uppermost layer is a fill material layer. The following layer is a clay layer, which consists of soft clay, medium stiff clay, and stiff clay, respectively. The layer below these clay layers is the sand layer, and the following subsoil is the altered layers of clay and sand layer till approximately 35 m depth below the surface according to the boreholes.

Table 4. Detailed description of the methods used to prevent water leakage for projects in Thailand.

Method	Description
Permeation grouting	The chemical proportion is a significant parameter and directly controls the setting time of grouting materials. Also, the grain size of soils is a primary concern. As the soil particles are tiny, a grouting mixture may not seep into the ground. In the water transmission tunnel project, the chemical proportion was improperly used, and the opening face was not treated entirely by this grouting. As a result, the water leakage problem might come from these aspects.
Jet grouting	The integrity of jet grouted blocks is a concern. The untreated zone due to a rod inclination can cause the seepage issue. The corrosion should be considered for permanent purposes. In the MRTA Orange Line East Project, the quality control of the jet grouting method is mentioned in the method statement. The core samples are collected at an intersection point for the unconfined compressive and permeability test. Also, the diameter of a jet grouting column is checked by the jet wave monitoring method (JWM). However, the coring and JWM are carried out in the trial test.
Sealing ring	The sealing ring was mounted on the diaphragm wall to limit the water flow during a breakthrough. The sealing ring was installed for the launching of the TBMs. However, in the MRTA Blue Line Initial System project, the sealing ring was also applied for the TBM arrival.
Concrete block	As the length of the jet grouted block was limited by the utilities, the concrete block was built as an additional jet grouted block inside a station to prevent water inflow in both the MRTA Blue Initial System and Orange Line East projects. The TAM grouting was also applied with the concrete block for water prevention at the MRTA Orange Line East Project.
Flood of a chamber	This method is selected when other techniques cannot be carried out. In the water transmission tunnel project, the arrival station was filled with the backfill soil and water to facilitate the TBM arrival because the permeation grouting did not provide suitable treatment. Furthermore, this method was carried out at the IVS shafts to allow the TBM to drive continuously through the shaft in the MRTA Orange Line project.

5.1 *Jet grouted block design*

The procedure to determine the grouted block dimensions for the MRTA Orange Line East Project was evaluated in this study. The design procedure for the MRTA Orange Line East Project, in general, follows the jet grouting design manual by the Japanese guidelines (JJGA 2017). The design is also described in (Duangsano et al. 2021). The calculations use the same equations for the required length (t), the side thickness (B), the top thickness ($H1$), and the bottom thickness ($H2$) of the grouted block. However, there are some minor differences between the design methods. For example, firstly, the minimum dimensions of the jet grouted

block are different. This is because the Japanese guidelines were developed based on a - 25 m depth of tunnels. As the tunnels in the MRTA Orange Line East Project are located approximately 15 – 35 m in depth, the minimum dimensions of the MRTA Orange Line East Project are higher than the minimum dimensions specified in the Japanese guidelines. Secondly, the criteria to determine the required length of the block are different. In the MRTA Orange Line East Project, the required length of the block is determined based on the maximum value out of the values calculated from the following three equations: bending stress equation, arc sliding equation, and punching shear equation. The minimum required length of the block used for the MRTA Orange Line East Project is 1 m. In contrast, the required length of the block in the Japanese guidelines is obtained separately using the following different equations: bending stress equation for sandy soils and arc sliding equation for clayey soils. Lastly, the additional length for the jet grouted blocks in sandy soils is one segmental ring (1.4 m) for the MRTA Orange Line East Project, whereas the Japanese guideline suggests the additional length to be three rings (4.2 m).

Furthermore, the cohesion of a jet grouting material is a significant input parameter that controls the dimension of the jet grouted block. Figure 1 shows the effect of cohesion on the dimensions. According to equations provided in the Japanese guidelines, the dimensions are shorter when the cohesion is higher, and the required length is less sensitive than the rest of the dimensions. Also, the value of bottom thickness is equal to the side thickness if the minimum dimensions by the guidelines and the water pressure condition are ignored.

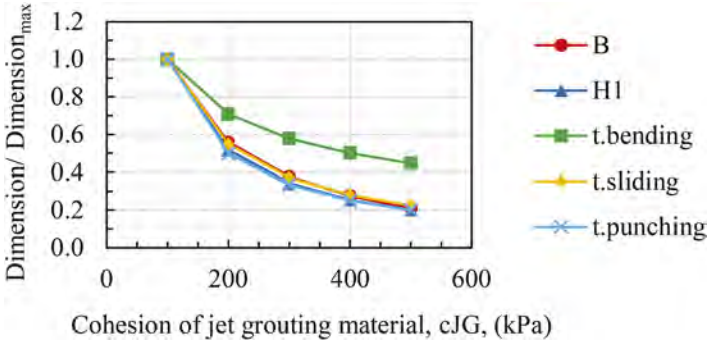

Figure 1. Relationship between dimension and cohesion of jet grouting material.

5.2 *Parametric study*

The parametric analysis was performed by the finite element software for the following two scenarios: (1) the launching cases in the clayey soil (LC) and (2) the launching cases in the sandy soil (LS). The considered design parameters are the length, side thickness, and permeability coefficient of the jet grouted block. The results of the analysis give the same trend of the water discharge in both cases (see Figure 2). The side thickness of the jet grouted blocks has a negligible effect on the water discharge at the opening face, because the changes in water pressure at the opening face are insignificant. The water pressure only dissipates around the opening face even though the side thickness increases. However, at a longer time, the water discharge drops as the side thickness increases. It also shows a little change when the side thickness is equal to the minimum side thickness, which is 2 m according to the Japanese guideline.

The length of the jet grouted blocks has a significant effect on the water discharge at the opening face. The discharge sharply decreases when the length is elongated, and it gives a minor effect when the length reaches the minimum dimension, which is 3.3 m, as suggested by the Japanese guidelines. The permeability coefficient of the jet grouted block also has a significant effect on the water discharge. The water discharge gradually rises as the permeability coefficient is lower.

6 CONCLUSIONS AND RECOMMENDATIONS

6.1 *Conclusions*

1. Among the methods that are used to provide the safety of TBM breakthroughs, jet grouting is commonly used as it can be applied in various ground conditions. The concern of this method is the integrity of a jet grouted block. The untreated zone can cause the seepage issue. Also, the corrosion should be considered for permanent purposes. Based on the subsoil conditions at the MRTA Orange Line East Project, the rapid jet grouting gave the successful treatment for TBM launching and arrival.
2. The results of the construction evaluation in this study indicate that the sealing ring is generally applied to launching cases. However, it can be used for arrival cases. The concern is the position of a sealing ring. The concrete block is built as an additional jet grouted block to ensure that the TBM is covered entirely. Otherwise, water can seep into the station from the TBM rear section when the TBM exposes to the ground. Also, the flood of a chamber method is selected when the other techniques cannot be carried out. This method may cause a construction delay. Also, this method is suitable for a small chamber to allow TBM to drive through continuously.
3. The results of the design evaluation in this study show that the design procedure to determine the grouted block dimensions for the MRTA Orange Line East Project generally follows the Japanese jet grouting design manual. However, there are some minor differences between the design methods, as outlined in Section 5.1 of this paper. The cohesion of a jet grouting material is a significant parameter. The dimensions are directly reduced as the cohesion is high. The side thickness has a negligible impact on the water discharge. However, the side thickness must exist to resist the lateral earth pressure. The water discharge can be reduced by a lower permeability, an extended length, and a large side thickness of the jet grouted block.

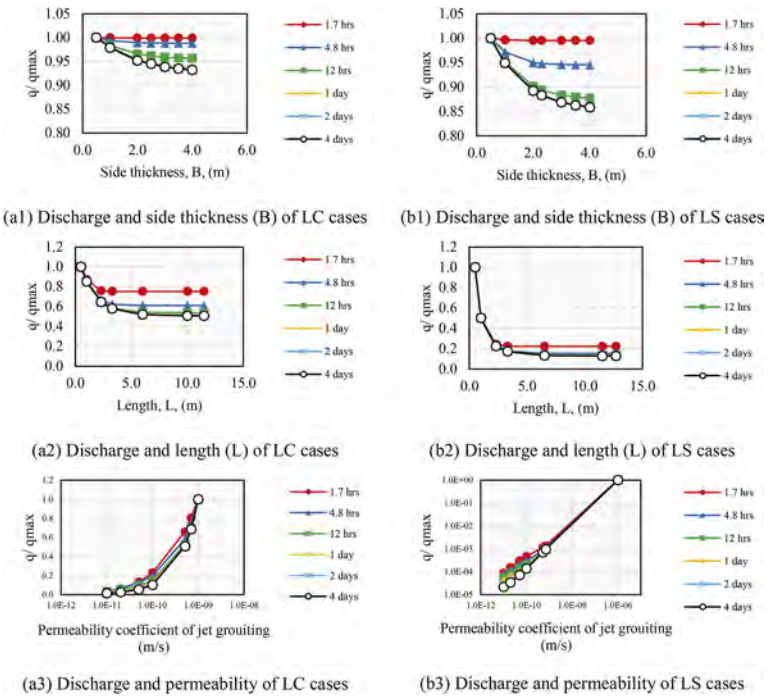

Figure 2. Relationship between discharge and design parameters.

6.2 *Recommendations*

1. The integrity of jet grouted blocks, such as the strength, permeability, and diameter, is only verified in the trial test. Therefore, the combination of many techniques in the construction, as outlined in Section 4 of this paper, should be applied to provide a safer TBM breakthrough.
2. Because of the gap between a tunnel wall and a shield, the additional length for sandy soils should be the three-ring length according to the Japanese guidelines to ensure that the backfill grouting completely seals the gap and prevent the water from the TBM rear section. Also, chemical grouting can be applied to fill the gap along the shield.
3. The cohesion of the jet grouting mixture is a significant parameter. Thus, cohesion should be determined based on local soils to design the dimension of the jet grouted block appropriately.
4. At a greater depth, the tunnel is possibly subjected to high water pressure. Therefore, besides the permeability of a jet grouted block, the dimension should not be overlooked, especially the length. The water discharge at the opening is reduced with an extended dimension of the block, resulting from a longer flow path of water in the structure.

ABSTRACT: Biological soil treatment methods have recently been actively promoted for sustainable and ecofriendly geotechnical engineering. Biopolymer-based soil treatment (BPST) is recognized as a low-carbon footprint ground improvement approach with appropriate pore clogging and strengthening properties. BPST is typically applied as a combination of soil, biopolymer, and water; however, depending on the hydrogel phase and soil type, varied results can be produced. In this study, Decision Tree, a machine learning approach, was used to predict the unconfined compressive strength (UCS) of BPST. The model performed successfully, and the determinant accuracy was more than R^2=0.99. And through permutation feature importance, it was confirmed that biopolymer content and water content act as determinants for the prediction of UCS of BPST.

1 INTRODUCTION

Biopolymers are becoming increasingly popular as a means of improving soil via bioengineering perspectives. Biopolymers are environmentally friendly polymers made from natural resources such as microbial activities or proteins and are widely used in food and pharmaceuticals (Chang et al. 2020, Choi et al. 2020). According to recent studies, due to the hydrogen bonding between soil particles and biopolymer chains, biopolymer-based soil treatment (BPST) increases the soil shear strength as well as the unconfined compressive strength. Moreover, the biopolymer is regarded as a material with low impact on the ground and groundwater environments due to its low CO_2 footprint and natural decomposition (Chang et al. 2019). As a result, BPST is considered a possible method in ground improvement practices, where the commonly used cement is concerned as a high CO_2 emitting material (Worrell et al. 2001).

There are several types of biopolymers that are applicable in geotechnical engineering. In particular, gel-type biopolymers (e.g., xanthan gum, gellan gum) form hydrogel structures that fill intergranular pore spaces which results in interparticle shear strength increase and hydraulic conductivity decrease (Chang et al. 2015, Bueno et al. 2013, Lee et al. 2019, Kwon et al. 2019, Coutinho et al. 2010). Furthermore, the mechanism of BPST varies depending on the type of soil. In general, biopolymers form biopolymer-clay matrices via direct ionic bonding between biopolymers and electrically charged clay surfaces, where it seems to have an optimal biopolymer-to-clay content in mass depending on biopolymer and clay mineral types

*Corresponding author: ilhanchang@ajou.ac.kr

DOI: 10.1201/9781003299127-82

(Chang & Cho 2019). Despite the fact that BPST-related research has been conducted over the past 10 years and is actively ongoing, it is still insufficient to conclude the exact strengthening efficiency of BPST. Thus, a decision tree method was attempted to analyze the unconfined compressive strength (UCS) of BPST from existing literature and to predict the UCS of BPST by integrating existing experimental data achieved over the past 10 years.

2 CHARACTERISTIC OF BIOPOLYMER-BASED SOIL TREATMENT

2.1 *Soil strength improvement*

When gel-type biopolymers dissolve in water, they form viscous hydrogels that transform into condensed biofilms through dehydration (Kulicke & Nottelmann 1989). Poorly graded sand (SP) generally does not have intergranular cohesion, whilst BPST on SP soil provides interparticle adhesion which results in significant strengthening. Furthermore, the strengthening of BPST becomes more effective for clayey soils (e.g. kaolinite, montmorillonite), due to the biopolymer-clay matrix formation via ionic bonding between the biopolymer and clay particles (Chang & Cho 2019).

2.2 *Hydraulic conductivity control*

By altering the soil-water retention characteristics and pore-clogging characteristics, BPST is reported to reduce the soil hydraulic conductivity in orders of 10^{-4} or more (Cabalar et al. 2017, Chang et al. 2020). According to Chang et al. (2016), when BPST is exposed to water, condensed biofilms absorb water and swell to viscous hydrogels due to the hydrophilicity of biopolymers which results in a significant soil hydraulic conductivity reduction.

2.3 *Soil erosion control*

Surface soil erosion is a serious problem in agriculture, climatology, hydrology, natural hazards (e.g. landslides), and human safety. The interparticle bonding enhancement of BPST has the proper function of increasing the erosion resistance of erosion-prone soils and geotechnical engineering structures (e.g., earth dams and levees) (Kwon et al. 2019). In the laboratory, BPST's erosion response was evaluated, and it was observed that BPST was effective in reducing surface erosion. Biopolymers such as xanthan gum, chitosan, and beta-glucan, in particular, exhibit significant erosion resistance, with a cumulative erosion rate of less than 1% (Chang et al. 2015).

3 DATA AND METHOD

3.1 *Target data*

In this study, experimental data was used to perform machine learning-based analysis in order to predict the UCS of BPST, herein eight published articles related to BPST were used. The feature data for the strength of BPST are summarized in Table 1. The target data is unconfined compressive strength (UCS). This is because UCS data was able to account for the majority of the data, and the analysis was concise. Normally, UCS is influenced by biopolymer type, soil type, soil composition, water content, and dry unit weight, etc.

3.2 *Decision tree*

Decision Tree is one of the most commonly used, practical approaches for supervised learning. It can be used to solve both Regression and Classification problems (Pekel 2020). However, Since the UCS data analyzed in this study are continuous data, regression was used.

Table 1. Feature values for machine learning.

Categorization	Feature data
Biopolymer condition	BP type
	BP concentration for total soil mass (m_b/m_s)
Soil condition	Soil type
	Soil source
	clay content ratio to total soil (m_c/m_s)
	50% passing grain-size (D_{50})
	dry density
Water content	initial water content
	test water content
Test condition	BP mixing temperature
	condition (wetted or dried)
	drying time
	specimen size

4 RESULTS

The prediction result of decision tree regression is shown in Figure 2. For analysis, the entire 453 UCS data were split into 407 train data and 46 test data. As a result of finding the condition in which the determinant coefficient (R^2) becomes the maximum while changing the value of Max depth (Figure 1), each train data and test data showed good performance with R^2 values of 0.9997 and 0.9863 (Figure 2).

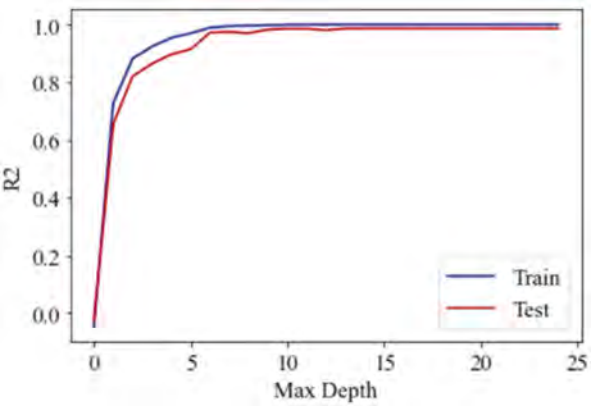

Figure 1. Optimizing hyperparameter (max depth) with the highest R^2.

Additionally, the importance of the feature was determined by comparing the size of the error by substituting a random value for each feature. The most important feature was biopolymer content (m_b/m_s), followed by test water content (Figure 3).

5 CONCLUSIONS

Machine learning analysis is a technique for understanding the behavior of biopolymer-based soil treatment (BPST). It is significant because BPST research period is short (approximately 10 years) and the specific mechanism has not been elucidated. Future BPST experiments or field

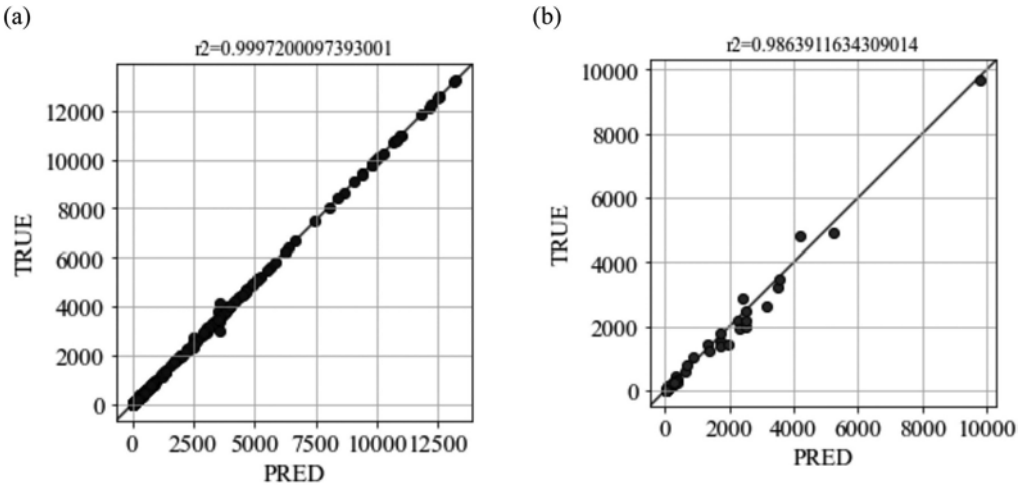

Figure 2. UCS prediction result of decision tree. (a) prediction accuracy of train data; (b) prediction accuracy of test data.

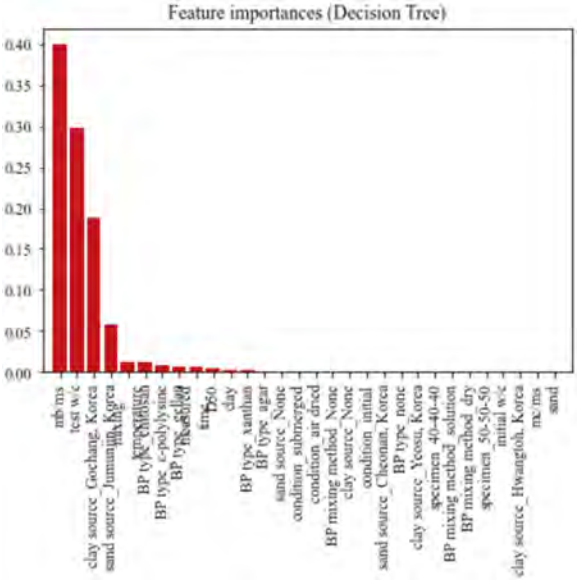

Figure 3. Permutation feature importance.

applications will be less expensive if machine learning can be used to estimate the strength of each material. The prediction accuracy R^2 of the model was 0.99 or better as a result of estimating the strength with decision tree regression. Furthermore, it appears that the biopolymer content and water content are significant. Because the higher the biopolymer concentration, the thicker the hydrogel and matrix are produced. The biopolymer becomes more rigid in the dry state than in the wet state, BPST is thought to have a higher UCS at low water content than at high water content. It can be shown that more exact recording and control of the water content during the test, as well as reducing the water content to enhance strength, will be necessary for future UCS tests.

ABSTRACT: This contribution aims to propose a simple method to quantify the degree of mixture of soil particles stirred by rotation of rods. Discrete element method (DEM) is used to simulate the stirring process and evaluate the degree of mixture at each rotation based on the initial positions of particles. To reduce complexity in the mixing process of actual soil, this study focuses on monodispersed spherical particles where inter-particle cohesion is not considered. The DEM results reveal spatial variation of the degree of mixture (d_m) in the given volume; however, its mean ($\overline{d_m}$) increases with the rotation number of stirring rods. Besides, $\overline{d_m}$ depends on the size of stirring rods whereas the mixing rate is insensitive to $\overline{d_m}$ for the non-cohesive sandy particles.

1 INTRODUCTION

Geotechnical engineering deals with mixing of soil, e.g. deep soil mixing (DSM) and tunnel boring machines, i.e. earth pressure balance (EPB) shields. It is important to evaluate the extent of mixing to confirm the required performance of such phenomenon. The extent of soil mixing in DSM is usually estimated by measuring the permeability or unconfined compression strength of the material at different curing periods (Bruce et al. 2013). Another index to assess the quality of mixing is blade rotation number (Yoshizawa et al. 1996). Moreover, mixing phenomena have been studied in fields other than civil engineering (Khosropour et al. 2000; Bothe 2010). This study aims to define a parameter for calculating the degree of mixture of soils mixed by the rotary action of two stirring rods in a cylindrical soil specimen using discrete element method (DEM).

2 MATERIAL

The DEM simulations were performed using a modified version of LAMMPS (Plimpton 1995) and the model test simulation broadly follows Ali et al. (2020). Spherical particles were used (Young's modulus = 71.6 GPa; Poisson's ratio = 0.23, particle density = 2650 kg/m^3; diameters = 2 to 2.2 mm). The simplified Hertz-Mindlin contact model was used with an inter-particle friction coefficient of 0.05. The wall-particle friction was set to zero.

3 SAMPLE PREPARATION

Table 1 shows the four test cases conducted in this study. Referring to Figure 1, the generated particles were pluviated inside a rigid box from a height exceeding 100 cm. A cylindrical region with rigid walls (diameter = 30 cm, thickness = 2 cm) was created inside the box and extra particles

DOI: 10.1201/9781003299127-83

Table 1. Test cases and specifications.

	Mixing rate	Diameter of stirring rod (φ)	
Case	RPM	cm	Number of particles
1	20	3	165,919
2	100	3	165,919
3	500	3	165,919
4	100	1	169,398

were removed around this region. After this, two rigid stirring rods having their diameters (φ) of 1 or 3 cm (Table 1) and thickness = 2 cm were provided by deleting the particles in the two given regions. The material was mixed by rotating these rods at 20, 100 or 500 RPM (Table 1).

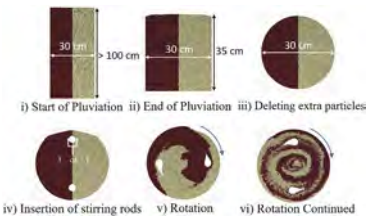

Figure 1. Simulation steps.

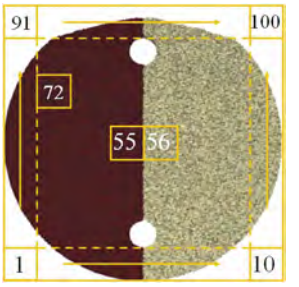

Figure 2. Grid system (not on scale).

4 DEFINITION OF DEGREE OF MIXTURE

4.1 *Local degree of mixture*

For the calculation of local degree of mixture (d_m), the particles in the ground were divided into the two regions (type 1 and type 2) based on their initial coordinate as shown by two different colors in Figure 2. The ground was divided into one hundred equal-sized grids (10×10) over the specimen. For each grid, the d_m value was defined based on the difference in the numbers of type 1 and type 2 particles as follows.

$$d_m = \left(1 - \frac{|n_1 - n_2|}{n_1 + n_2}\right) \times 100\ [\%] \tag{1}$$

where n_1 and n_2 are the numbers of type 1 and type 2 particles, respectively. Equation 1 implies that d_m becomes the highest (i.e. 100%) when $n_1 = n_2$ for each grid. If there are no particles in any grid, that grid was omitted from the calculations.

Figure 3 illustrates a snapshot of the ground after 25 rotations along with the variation of d_m where the color bar corresponds to the magnitude of d_m. Figure 4a provides an example (Case 2) for the variation of d_m for grid number 72 (Figure 2) with the rotation number.

4.2 *Mean degree of mixture ($\overline{d_m}$)*

In this study, the rods are given twenty-five rotations. For each rotation, the mean degree of mixture ($\overline{d_m}$) is defined by calculating the mean of d_m of all the grids, that contain non-zero particles, at the given rotation number using the following equation.

$$\overline{d_m} = \frac{\sum(d_m \text{ for all grids})}{\text{Total number of grids}} \tag{2}$$

The evolution of $\overline{d_m}$ with the rotation number for Case 2 is given in Figure 4b.

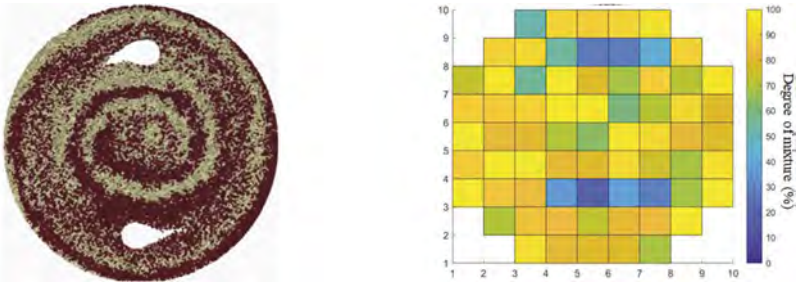

Figure 3. Mixed condition and spatial distribution of d_m at 25 rotations with φ = 3 cm (Case 2).

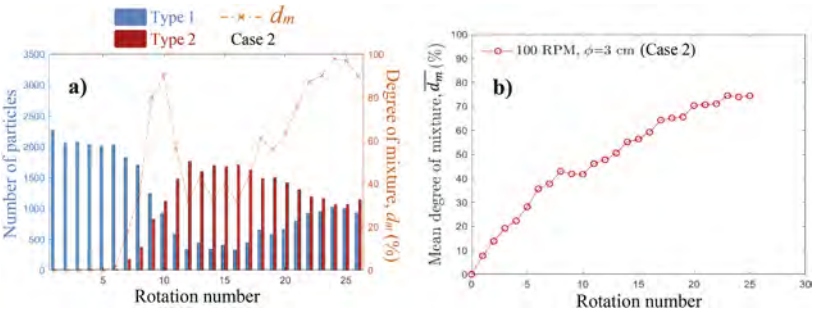

Figure 4. Evolution of degree of mixture with the rotation number (Case 2) (a) Numbers of two types of particles and d_m for grid number 72 (b) Mean degree of mixture ($\overline{d_m}$) of all the grids.

5 DISCUSSIONS

5.1 *Effect of the mixing rate of stirring rods*

Figure 5 compares the mixing conditions after 25 rotations with different mixing rates. It is not easy to differentiate the degree of mixture by eyes. Figure 6 compares the evolution of $\overline{d_m}$ with the rotation number. The mixing rate appears less sensitive to $\overline{d_m}$ where there is no clear dependency of the mixing rate in the given results. It is noteworthy that the current simulation study focuses on coarse particles and does not consider the effect of viscosity or cohesion which can be an influential factor for the mixing phenomenon of finer particles like plastic silt or clay.

5.2 *Effect of the size of stirring rods*

Figure 6 also shows the effect of rod diameter (φ) on $\overline{d_m}$. The larger rods (i.e. φ = 3 cm) are more effective to achieve higher $\overline{d_m}$ for a given rotation number at the same rate of rotation. Figure 5 indicates some locally concentrated zones for the two different colors in Case 4 (φ = 1 cm), probably due to the less influenced zone generated by the motion of smaller rods during rotation.

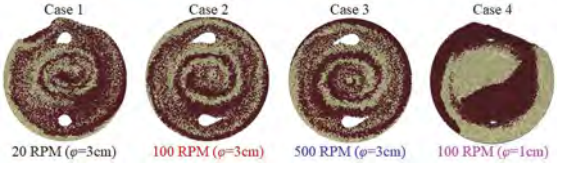

Figure 5. Effects of mixing rate and size of stirring rods on the mixing condition after 25 rotations.

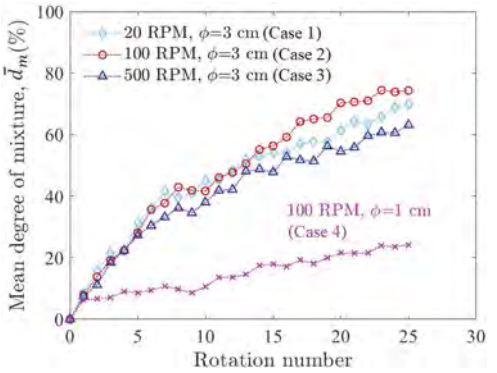

Figure 6. Evolution of the mean degree of mixture ($\overline{d_m}$) with the rotation number for all test cases.

6 CONCLUSIONS

This contribution proposed a simple method to quantify the degree of mixture of soil particles stirred by rotation of rods. Based on a series of DEM simulations using monodispersed coarse spherical particles, the following conclusions can be drawn:

- A new parameter for the calculation of degree of mixture (d_m) has been defined. The results show that the parameter performs well for each grid at given number of rotations.
- The mean degree of mixture ($\overline{d_m}$) increases with the rotation number up to 25.
- Mixing rate is less sensitive to the degree of mixture for non-cohesive sandy particles.
- Larger diameter of stirring rods tends to mix the material well as compared to smaller rods in this study since the smaller rods generate locally concentrated zones.

This study is eventually aimed at enhancing the in-situ mixing and monitoring techniques. Therefore, additional DEM simulations using more realistic material properties are being examined. Besides, some model tests are being performed to validate the results of DEM simulations.

ACKNOWLEDGEMENT

This research was conducted using the Fujitsu PRIMERGY CX400M1/CX2550M5 (Oakbridge-CX) at the Information Technology Center, The University of Tokyo.

Behaviour of randomly distributed fibre reinforced clay

Narendra Kumar Samadhiya
Department of Civil Engineering, Indian Institute of Technology Roorkee, Roorkee, India

ABSTRACT: Various soil improvement techniques have been developed to improve soil properties. One of the soil strengthening technique is mixing of randomly distributed discrete fibres to the soil, termed as a "ply soil". In the present investigation, polypropylene fibres have been chosen as the reinforcement material and were randomly mixed in the soil at 0.1, 0.2 and 0.3% by dry weight of soil. Three different lengths of fibre i.e. 6mm, 10mm and 20mm have been considered as one of the parameters of this study. An intermediate compressible clay (CI) has been used as a soil material in experimental work. The randomly distributed fibre reinforced clay samples were subjected to different types of tests viz. IS: Light compaction tests, unconfined compression tests, consolidation tests, triaxial tests and C.B.R. tests. The results of these tests have clearly shown a significant improvement in the strength properties of the clay.

1 INTRODUCTION

Vidal (1969) demonstrated that the introduction of reinforcing elements in a soil mass increases shear resistance of the medium. The mechanical interlock effect of the fibres provides increased tensile strength and cohesion to the soil matrix. However, as a modification of the same conventional technique, random inclusion of various types of fibres is also considered as a soil reinforcement material. (Prabakar and Sridhar, 2002). The main advantage of randomly distributed fibred soil (RDFS) is the strength isotropy and absence of potential planes of weakness that can develop parallel to the oriented reinforcement. McGown et. al (1978) classified the reinforcements into two major categories viz. a) ideally inextensible inclusions (i.e. metal strips and bars) and b) ideally extensible inclusions (i.e. natural and synthetic fibres, plant roots and polymeric fabrics). The soil reinforced with extensible inclusions is termed as 'plysoil'. Fretaig (1986) investigated the effect of fibre on strength of fine-grained soil which was mixed with 1% by volume of 20-mm-long synthetic fibers. Specimens compacted wet of optimum were found to have somewhat greater strength (up to 25%) and strain to failure with fibers in comparison with specimens without fibers. Reinforcement of micaceous, silt significantly enhanced (65% to 133%) the California Bearing Ratio (C.B.R.). The micaceous silt mixed with fibrillated fibres yielded 16% higher C.B.R. than soil with monofilament fibres (Fletcher and Humphries, 1991). Al-Wahab and Al-Qurna (1995) observed practically no change in the compaction behaviour due to inclusion of fibres in silty clay. The fibre content of approximately 1% of dry unit weight of the soil and a fibre length of 25 mm, maximize the strength, workability and homogeneity of the soil-fibre matrix. Fibre reinforced soil comes under ideally extensible earth reinforcement category. The main advantage of RDFS is the strength isotropy and absence of potential planes of weakness that can develop parallel to the oriented reinforcement. The technique of reinforcing soil increases the stiffness and load carrying capacity of soil through frictional interaction between soil and reinforcement (Chakraborty and Dasgupta, 1996). The other qualities of RDFS are its flexibility, no reduction in permeability, small loss of post peak strength etc. This technique has been effectively used as

DOI: 10.1201/9781003299127-84

ground improvement technique with respect to embankment slopes, slope failure repairs, sports turf, reinforced grass, retaining structures, bridge abutments, foundation slabs and especially in case of subgrade/subbase as well as built and maintained roads.

Nataraj and McManis (1997) achieved optimum values of maximum dry unit weight at a fibre content of 0.2 % for the clay and 0.1 % for the sand. The addition of fibres resulted in an increase in peak shear strength, a reduction in post peak strength loss, substantial increase in peak friction angle and cohesion, signficant increase in compressive strength, and significant increase in CBR values. Ranjan and Charan (1998) reported that the inclusion of fibres to silty sand and clay results in significant increase in cohesion and though the angle of internal friction, φ remains almost unaffected yet there is always an overall gain in strength.

Michalowski and Cermak (2002) concluded that the fibres in the direction of largest extension contribute most to the strength of the composite. Yetimoglu et. al (2005) observed that adding fibre inclusions in sand fill results in an appreciable increase in the peak piston load in C.B.R. test. The effect of treated coir fibres on the shear strength behaviour of clay is presented by Khatri et. al (2016). A series of consolidated undrained test were performed on soil reinforced with untreated, sodium hydroxide treated and carbon tetrachloride treated fibres. The coir fibre content was varied from 0.4% to 1.6%. A significant increase was observed in shear strength parameters of clay reinforced with coir fibres at different percentages.

Suffri et. al (2019) found that increasing the percentage inclusion increases the undrained shear strength of the soil, only up to a certain amount. Wang et. al (2019) have shown that the addition of the fibre leads to a significant increase in CBR strength and stiffness. In addition, samples reinforced with shorter fibres show better behaviour than those reinforced with longer fibres. Valipour et. al (2021) studied the effects of recycled tire polymer fibers (RTPF) and glass fibers (GF) on enhancing the strength/deformation properties of clays. Concerning the shear strength parameters, i.e. cohesion intercept and internal friction angle, the fiber inclusion was particularly influential in increasing cohesion, whereas changes in internal friction angle were minimal. Moreover, the shorter fibers (5 mm) were generally more efficient in reinforcing the clay.

2 EXPERIMENTAL PROGRAMME

The main objective of the study presented herein was to investigate the strength and deformation characteristics of clay reinforced with randomly distributed fibrillated fibres. The properties of the clay used in this study are shown in Table 1. The unconfined compressive strength (UCS) as well as shear strength parameters (c and φ) obtained for clay compacted at maximum dry density (MDD) and optimum moisture content (OMC) are presented in Table 2.

Table 1. Properties of clay used in the experimental investigation.

Liquid limit (%)	Plastic limit (%)	Classification (IS: 1498-1970)	Maximum dry density (g/cc)	OMC (%)
42.5	20.5	CI	1.69	19.0

Table 2. Strength parameters of unreinforced clay.

Strength parameters unconfined compression test		Effective strength parameters (CU) Triaxial Test	
UCS (kPa)	c (kPa)	c' (kPa)	Φ'(°)
118.3	59.1	49.7	29.4

UCS: unconfined compression strength; c': effective cohesion; Φ': effective friction angle of soil

Fibrillated polypropylene fibres with 6 mm, 10 mm, and 20 mm in lengths manufactured by "Zenith Fibre Limited", Baroda, Gujarat, India were used as reinforcement. Fibrillated polypropylene fibres with 6 mm, 10 mm, and 20 mm in length were used as reinforcement. The characteristics of fibres are shown in Table 3. The fibre content in all of the soil test specimens varied from 0.1% to 0.3% of dry unit weight of the soil with fibre length varying from 6mm to 20mm. All test samples were prepared at maximum dry density (MDD) and optimum moisture content (OMC).

Table 3. Fibre characteristics.

Polypropylene	0.91	3	21.6	45.0	5.2	162-170

3 ANALYSIS OF RESULTS

3.1 *Effect of fibre on compaction characteristics*

Figure 1 shows the variation of maximum dry unit weight with fibre length. For all samples, the dry unit weight increases with an increase in water content upto optimum moisture content beyond which it reduces. For a particular percentage of fibre content, the dry unit weight increases with increase in fibre length. However beyond a fibre length of about 10 mm, the maximum dry unit weight has got reduced. The reduction has been found to be more for longer fibres. In the case of 20 mm fibre, maximum dry unit weight has reduced by approximately 3% to that of the unreinforced clay. The maximum dry unit weight has been found to increase with increase in fibre content except for fibres having 20 mm length, as is presented in Figure 2 The optimum moisture content has been found to decrease for all the combinations of length and fibre content (FC) except for 20 mm fibre with 0.3%. F.C. where it is slightly more, as shown in Figure 3. The reduction has been more for 6 mm fibres. Figure 4 shows the variation of OMC with fibre content.

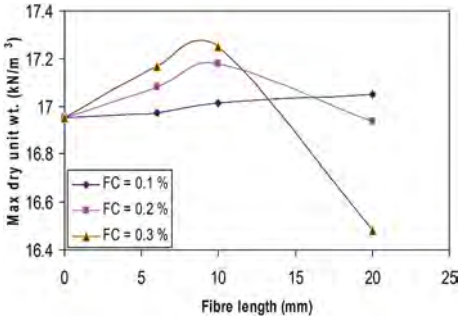

Figure 1. Effect of fibre length on maximum dry unit weight.

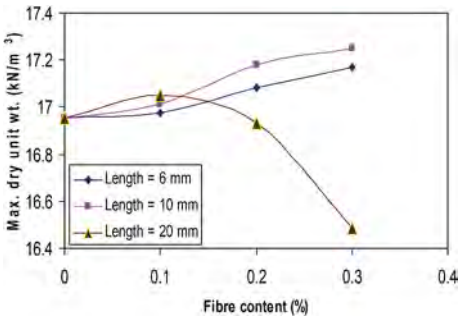

Figure 2. Effect of fibre content on maximum dry unit weight.

3.2 *Effect of fibre on unconfined compressive strength*

The results of the unconfined compression tests are presented in Table 4. The unconfined compression strength increases with increase in fibre length as well as fibre content (FC). It is clear that for all fibre contents, RDFS has got maximum unconfined compressive strength for 20 mm fibre length. It may also be noted that at 0.3% fibre content with 20mm fibre, the

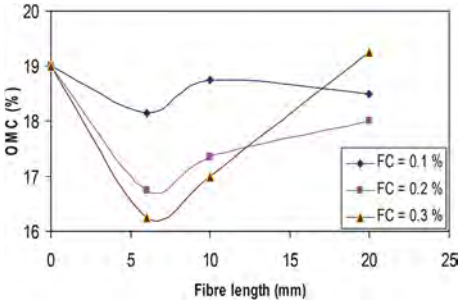

Figure 3. Effect of fibre length on optimum moisture content.

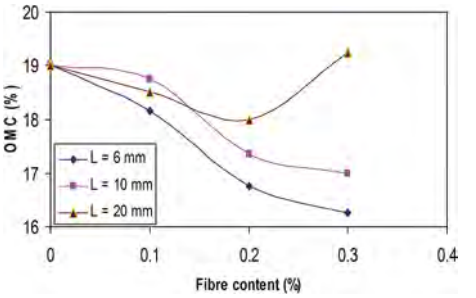

Figure 4. Effect of fibre content on optimum moisture content.

RDFS achieved maximum percentage increase in UCS which is about 95% which is nearly two times as that of unreinforced clay.

Table 4. Effect of fibre length and fibre content on unconfined compressive strength.

Fibre length mm	Fibre content (%)	UCS kPa	Failure strain (%)	Increase in UCS (%)
Unreinforced	0.0	118.3	17.7	-
6	0.1	131.8	17.1	11.4
	0.2	142.0	15.8	20.0
	0.3	184.5	15.1	56.0
10	0.1	168.4	15.8	42.4
	0.2	178.0	15.1	50.5
	0.3	207.1	14.8	75.0
20	0.1	201.9	15.1	70.7
	0.2	217.3	14.5	79.2
	0.3	231.1	13.8	95.4

3.3 *Effect of fibre on compressibility characteristics*

Table 5 shows the effect of fibre length as well as fibre content on compression index and percentage reduction in compression index. It may be observed that there is a significant effect on compressibility of clay due to the fibre content as well as fibre length. The increase in fibre content reduces compressibility of RDFS.

Table 5. Effect of fibre length and fibre content on compression index and % reduction in compression index (Cc).

Fibre length mm	Fibre content (%)	Compression index, Cc	Reduction in Cc (%)
Unreinforced	0.0	0.243	-
6	0.1	0.165	32.1
	0.2	0.144	40.7
	0.3	0.133	45.3
10	0.1	0.148	39.1
	0.2	0.130	46.5
	0.3	0.114	53.1
20	0.1	0.138	43.2
	0.2	0.122	49.8
	0.3	0.106	56.4

3.4 *Effect of fibre on triaxial strength behaviour*

CU triaxial tests with pore water pressure measurement were conducted. The unreinforced clay specimens revealed a shear failure and with the increase in reinforcing fibres, the specimens failed due to bulging at different confining pressures. Increase in deviator stress at failure has been observed for all combination of fibre length and fibre contents. Table 6 shows the effective cohesion (c') and effective angle of internal friction (φ') of the reinforced clay.

3.5 *Effect of fibre on California bearing ratio (C.B.R.)*

A series of C.B.R. tests was conducted in 4 days soaked condition. Table 7 shows C.B.R. values and percentage increase in C.B.R. for different fibre content and fibre length.

It is clear from Table 7 there is a significant percentage increase in C.B.R. as fibre content increases from 0.1% to 0.3%. It can be observed that, at 0.1%, 0.2%, and 0.3% fibre content the percentage increase in C.B.R. are 23%, 35.5% and 51.97% respectively for 20 mm fibre. The percentage increase in the C.B.R. with increase in fibre content is almost linear. So it may be concluded that at 0.3% fibre content (FC) and 20 mm fibre length gives maximum C.B.R. value to RDFS. After each C.B.R. test, the fibres were inspected and showed no signs of breakage.

Table 6. Effect of fibre length and fibre content on strength parameters.

Fibre length mm	Fibre content (%)	Effective cohesion, c',(kPa)	Angle of friction Φ'(°)
Unreinforced	0.0	49.7	29.4
6	0.1	67.7	28.2
	0.2	71.7	28.0
	0.3	94.4	27.4
10	0.1	85.1	27.8
	0.2	88.2	27.5
	0.3	104.6	26.6

It may be observed from Table 6 that there is significant increase in the cohesion value due to increase in fibre content. The influence of fibre length on the cohesion is also significant. However, there is not much variation in the friction angle due to addition of fibres.

Table 7. Effect of fibre length and fibre content on strength parameters.

Fibre length mm	Fibre content (%)	CBR (%)	Reduction in CBR (%)
Unreinforced	0.0	3.04	-
6	0.1	3.39	11.5
	0.2	3.74	23.0
	0.3	4.17	37.1
10	0.1	3.56	17.5
	0.2	3.91	29.0
	0.3	4.43	46.0
20	0.1	3.74	23.0
	0.2	4.12	35.5
	0.3	4.62	51.9

4 CONCLUSIONS

Various parameters namely maximum dry density, unconfined compression strength, compression index, strength and deformation characteristics and C.B.R. were studied with different fibre content and fibre length. Following conclusions may be mde:

i. The compaction characteristics of the fibre reinforced clays were found similar to that of the unreinforced clays. The maximum dry unit weight reached a maximum value at a fibre content of 0.3% with 10 mm fibre length for clay specimens.
ii. The addition of fibres to the clay specimens increased the peak shear strength of the soil and reduced, in some cases, the post peak strength. Also, there is a substantial increase in unconfined compression strength of clay at 0.3% fibre content with 20 mm fibre length.
iii. Due to inclusion of polypropylene fibre, compressibility of clay substantially decreases. At 20 mm fibre with 0.3% fibre content compression index of clay has decreased to the maximum extent.
iv. The inclusion of fibres in clay significantly increases cohesion of soil. However, there is no specific trend in the variation of friction angle with fibre length as well as fibre content. In fact, it is confirmed that reinforcement does not have a significant influence on the improvement of angle of shearing resistance.
v. California Bearing Ratio (C.B.R) increases significantly with the addition of fibres. The maximum C.B.R. value has been found for 20 mm fibre with 0.3% fibre content.
vi. Finally, results indicated that by reinforcing soil with 20 mm long fibrillated fibres, the optimum fibre content is 0.3% of the dry unit weight of soil.

Divya Priya Balasubramani*
Assistant Professor (Senior), College of Engineering Guindy Campus, Anna University, Chennai, India

ABSTRACT: Numerous studies have been carried out to improve the strength characteristics of clay soil using various admixtures and mechanical methods. This study focuses on the influence of Ground Granulated Blast Furnace Slag (GGBS) and banana fibres in improving the strength characteristics of clay soil. GGBS is a known by-product of iron manufacturing industries and banana fibre is a locally available, economic, and eco-friendly agricultural waste produced from the banana plantation. Virgin soils and various combinations of clay soil with GGBS and banana fibres are evaluated by analysing their index properties, compaction, permeability, and strength characteristics. Scanning electron microscopy (SEM) and X-ray diffraction (XRD) analysis have been carried out to understand the physical and mechanical behaviours of soil samples before and after treatment. Based on the results the optimal percentage of GGBS and banana Fibre mixture in clay soil is recommended indicating its suitability as a sustainable stabilizing material.

Keywords: Stabilization, Clay soil, GGBS, Banana fibres, Sustainability

1 INTRODUCTION

Due to the increase in population and urbanization, there is a significant need for the provision of infrastructure facilities and an increase in the construction of superstructures and substructures. With the growing demand due to technological development, the only option is to carry out construction on problematic soils. The Problematic soils are unsuitable without treatment, especially the expansive clays, which swell and shrink with annual moisture changes, affecting the structures built on them. To accommodate loads of the superstructures, these soils must be excavated, replaced, or enhanced (Wei & Huang 1996, Kolias et al 2005, Bhavanna Rao R 2006, Horpibulsuk et al 2012, Saravanan et al 2017,). Hence there is a need to stabilize this type of soil to increase its bearing capacity. On the other hand, industrialization leads to the generation of industrial wastes like, fly ash, phospho-gypsum, blast furnace slags, lime kiln dust, cement kiln dust, red mud, jarosite, steel slags, copper slags, plastic wastes, rubber wastes, rice husk ash, etc. in large quantities. The improper management of these wastes will leads to health and environmental hazards. The use of these industrial wastes as a stabilizing agent to improve problematic soil characteristics is considered the most sustainable solution (Joe & Rajesh 2015). However, carbon dioxide emission from these wastes especially from cement and lime manufacturing unit will lead to environmental degradation and increased global warming (Horpibulsuk et al 2012, Ayeldeen & Kitazume

*Corresponding author: divyapriya.b@vit.ac.in

DOI: 10.1201/9781003299127-85

2017). In recent times, additives with fewer CO_2 emissions and locally available fibres are used as a stabilizing material to improve the mechanical properties of soil (Sharma et al. 2015, Wu et al. 2019). In this study, an attempt has been made to stabilize the clay soil using Ground Granulated Blast Furnace Slag (GGBS) and banana fibres produced from industrial waste and agricultural waste respectively. The use of GGBS and banana fibres will be an economical and sustainable solution and also the addition of fibre in soil act as a reinforcement replacing the cement & lime which in turn reduces carbon dioxide emissions by improving the strength and deformation characteristics of the soil.

2 STUDY AREA

Vellore district is one of the 38 districts of Tamil Nadu state in southern India. It is located between 12°15'23"–13°12'32"N latitude and 78°24'13"–79°54'56"E longitude covering a land area of 5920.18 square kilometers. Geologically the entire area can be classified into hard rock and sedimentary formations. Hard rock covers 90% of the region which is Azoic, Crystalline, and extremely contorted and these are the oldest rocks for the earth's crust. Gneisses and Charnockites are the most common hard rock formations whereas Gneisses are found in nearly all the taluks of the district.

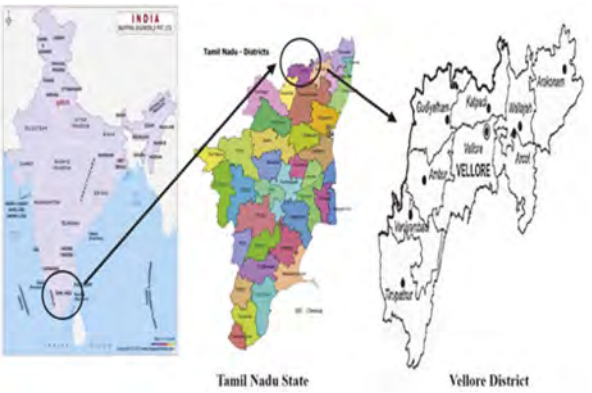

Figure 1. Study area.

3 MATERIAL AND METHODS

3.1 *Material*

3.1.1 *Soil*

The soil in the study (as shown in Figure 1) is collected from the local villages in and around Vellore city at a depth of 2 m from the ground level. Based on the laboratory test the basic properties of the soil are determined and tabulated as shown in Table 1. Based on the index properties, the collected soil is classified as Inorganic clay of low compressibility as per IS 1498:1970. From the free swell index value (see Table 1), the soil can be categorized as highly expansive clay.

3.1.2 *Ground Granulated Blast Furnace Slag (GGBS)*

The Ground Granulated Blast Furnace Slag (GGBS) as shown in Figure 3, is collected from the coal & steel industries located in Ambattur, Chennai city of Tamil Nadu state. In this study, GGBS is used as a basic additive for stabilization with a specific gravity of 2.64. The X-ray diffraction analysis of GGBS indicates the presence of calcite (as shown in Figure 4) which has the potential to improve the engineering properties of soil. GGBS is added to the soil at the percentage of 10%, 20%, and 30% respectively.

Figure 2. Collected soil sample.

Table 1. Properties of soil.

Soil Property		Values
Specific gravity		2.57
Particle size	% Gravel (>4.75 mm)	2.12
	% Sand (4.75-0.075mm)	23.00
	% Silt and clay (<0.075mm)	74.87
Index values	Liquid limit, %	35
	Plastic limit, %	25.17
	Plasticity index, %	9.83
Classification (as per IS 1498:1970)		CL
OMC, %		20.05
Max dry density, g/cc		1.828
Free swell Index (%)		40
Permeability cm/s		$4.46x10^{-5}$

Figure 3. Ground granulated blast furnace slag.

3.1.3 *Banana fibre*

The banana fibre (as shown in Figure 5), is collected from locally available sources. Banana fibre has an average length of 350 mm and an average diameter of 0.11mm. In this study, the banana fibres are uniformly cut into an average length of 2cm and mixed with soil at a percentage of 0.25 0.50, and 0.75 respectively. The properties of banana fibres were

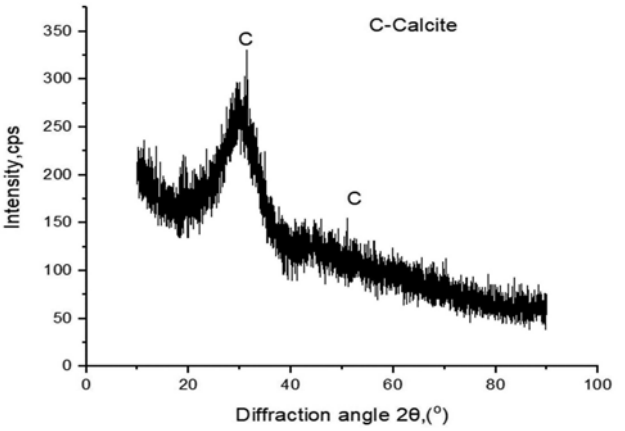

Figure 4. XRD pattern for GGBS.

determined in their natural form as presented in Table 2. The banana fibre when added to soil, will act as a reinforcement material, and interlocks the soil particles.

Figure 5. a. Banana fibre collected from local sources. b. Banana fibre after cut into 2 cm.

Table 2. Properties of banana fibre.

Property (%)	Banana Fibre
Ash content	4.58
Wax content	0.31
Moisture content	11.75
Cellulose Content	71.11
Lignin Content	7.86
Density g/cc	1.23
Hemi cellulose	34.79
Pectin	5.21

3.2 *Methods*

A series of laboratory tests are conducted in the present study in three stages. At stage-I, the virgin soil i.e., without any additives is used. At stage II, GGBS is added in various proportions i.e. 10%, 20%, and 30% of soil. At stage III, the various proportions of banana fibre

(0.25%, 0.50%, and 0.75%) are blended into the soil mixture with different percentages of GGBS. At all the above-mentioned three stages, i.e. the virgin soil and soil mixtures are subjected to basic tests like Specific gravity, Free Swell index, Sieve analysis, and Atterberg limits test. The compaction characteristics are determined using Standard proctor compaction tests at three stages. Then the soil sample is prepared at the respective optimum moisture content and compacted at a maximum dry density to conduct the unconfined compressive strength test. The stepwise procedure from the preparation of soil mixture to failure of soil samples at various compositions is shown in Figure 6. Also, permeability tests for treated and untreated soil at different proportions are conducted using the Falling head permeability test apparatus.

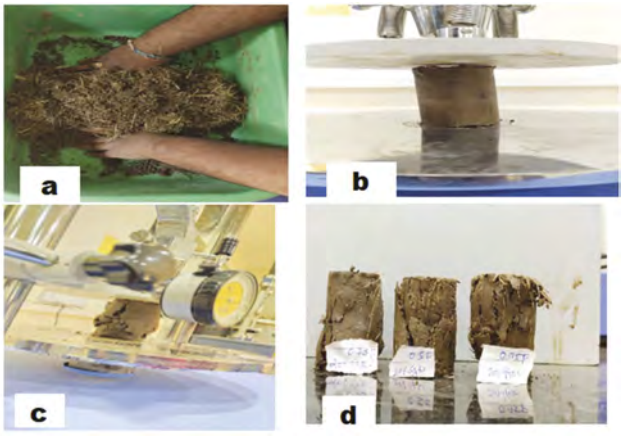

Figure 6. UCS sample preparation a) Mixing of soil+ GGBS+ Banana fibre b) Prepared sample c) Sample under testing d) Samples failed under UCS test.

4 RESULTS AND DISCUSSIONS

As a result of laboratory tests conducted at three stages in this study, the basic properties are obtained for virgin soil and soil mixed with GGBS at various percentages as presented in Table 3. The results indicate that the soil with 30% GGBS shows a decreasing percentage of the free swell index compared to virgin soil. Thus the addition of GGBS reduces the swelling characteristics of the clay soil.

Table 3. Results of the laboratory tests of soil mixed with GGBS.

Sample	LL (%)	PL (%)	PI (%)	Free swell Index (%)
Soil +0 % GGBS	35	25.17	9.83	40
Soil + 10% GGBS	33.15	17.77	15.38	40
Soil + 20% GGBS	26	20.30	5.7	20
Soil + 30% GGBS	24.8	19.50	5.30	15

4.1 *Effect of GGBS and banana fibre on compaction characteristics of soil*

The compaction curves of the virgin soil and soil mixed with variable percentages of GGBS i.e (10%, 20% and 30%) are obtained as shown in Figure 7. The graph indicates that the addition of GGBS into the soil increases the dry density and decrease in optimum moisture decreases. This may be due to the presence of fine particles in GGBS which reduce its affinity with water and replaces the voids in the soil increasing its dry density. From Figure 6, it can be seen that the max dry density with minimum OMC can be obtained when soil is mixed with 30% of GGBS.

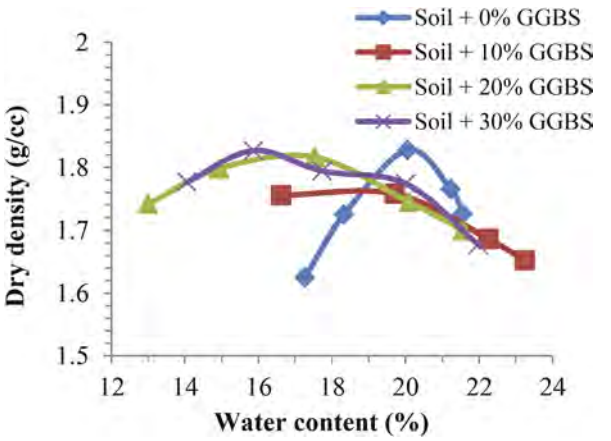

Figure 7. Compaction curves for soil modified with GGBS.

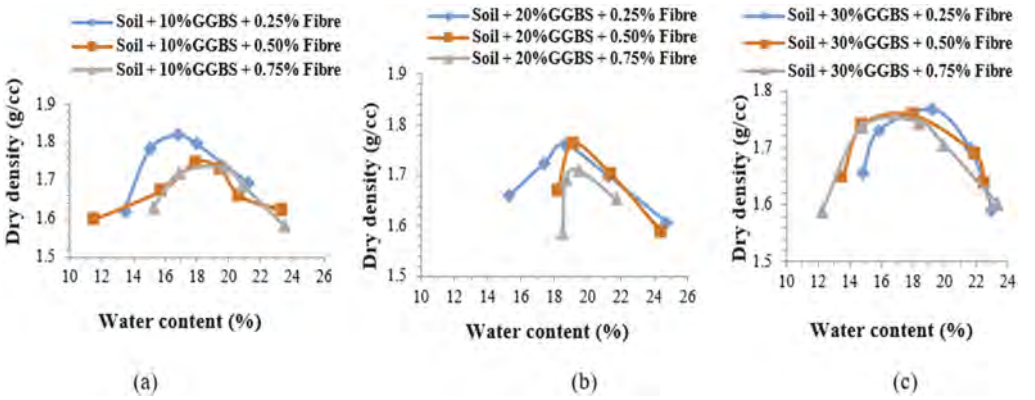

Figure 8. Compaction curves for soil modified with GGBS and Banana fibre (a)10% GGBS with proportions of 0.25%,0.5%,0.75% Banana fibre (b) 20% GGBS with proportions of 0.25%,0.5%,0.75% Banana fibre (c) 30% of GGBS with proportions of 0.25%,0.5%,0.75% Banana fibre.

The compaction characteristics of the soil mixed with GGBS and banana fibre in various proportions are determined as shown in Figure 8. From the Figures 8a, b, c it can be seen that the soil+10%GGBS+0.25% banana fibre is optimum. Similarly, the soil+20% GGBS +0.25% banana fibre is optimum and the soil +30% GGBS+0.75 fibre is taken as an optimum combination as the max dry density with minimum OMC and minimum compactive effort.

4.2 *Effect of GGBS on strength characteristics of soil*

The stress-strain graphs for virgin soil and soil with combinations of GGBS are obtained from UCS tests as shown in Figure 9. It is observed that virgin soil attained a low peak at high strain whereas soil+30%GGBS mix shows a high peak at low strain. The peak stress and the corresponding strain are low for soil with 30% of GGBS. This is due to the higher binding proportion of GGBS which improves the strength of the soil. The strength of the soil is increased to 82.23% by the addition of 30% of GGBS to the virgin soil. In comparison with other proportions of GGBS to the virgin soil, the elevated rise in the strength characteristics is observed at 30% of GGBS hence the combination of soil +30% GGBS is determined as optimum.

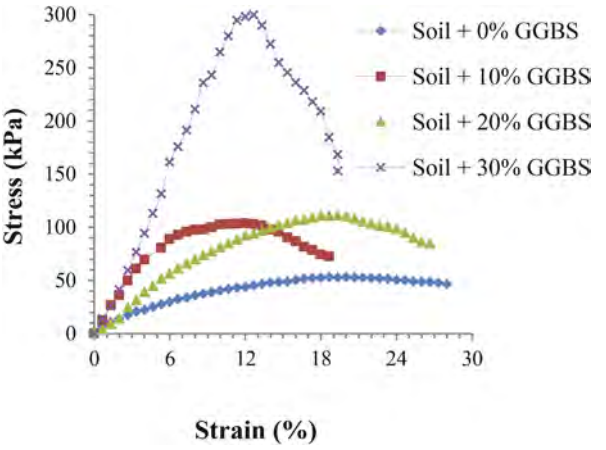

Figure 9. Stress-strain plots for Soil + GGBS mixes.

4.3 *Effect of soil with GGBS and fiber on UCS*

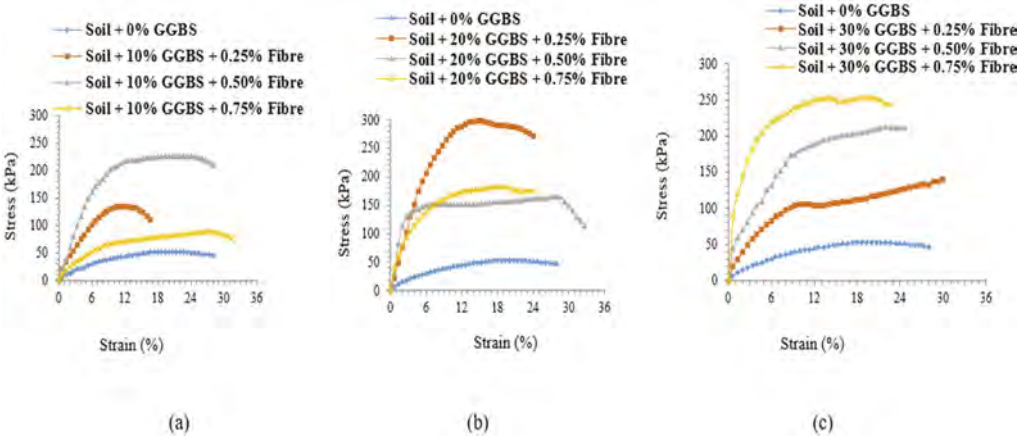

Figure 10. Stress-strain plots for soil modified with GGBS and Banana fibre (a) 10% GGBS with proportions of 0.25%,0.5%,0.75% Banana fibre (b) 20% GGBS with proportions of 0.25%,0.5%,0.75% Banana fibre (c) 30% of GGBS with different proportions of 0.25%,0.5%,0.75% Banana fibre.

The banana fibre is added to the soil and GGBS in various proportions and UCS tests are conducted to determine its strength characteristics. Figure 10 illustrates the stress-strain characteristics of various combinations of soil + GGBS+ banana fibres. Overall, the combination of soil + 30% GGBS + 0.75% fibre is found to be the optimum mixture as it shows an 85% increase in strength characteristics of the soil compared to virgin soil.

4.4 *Effects of permeability*

The soil samples are prepared with respective optimum moisture content and the falling head test is conducted as per IS 2720-17(1986) to determine the permeability of virgin soil and soil treated at an optimum percentage i.e. soil+30%GGBS+0.75 banana fibre. The treated soil increases the permeability by 7.85% compared to virgin soil. This is due to the enlargement of voids by fibres causing an improved permeability which in turn increases the rate of consolidation.

5 MICROSCOPIC STUDIES

Scanning electron microscopy (SEM) and X-ray diffraction (XRD) analysis have been carried out to understand the physical and mechanical behaviors of soil samples before and after treatment. Figure 11–15 illustrates the results of Scanning electron microscopy (SEM) of the virgin soils and combinations of soils with GGBS and banana fibres.

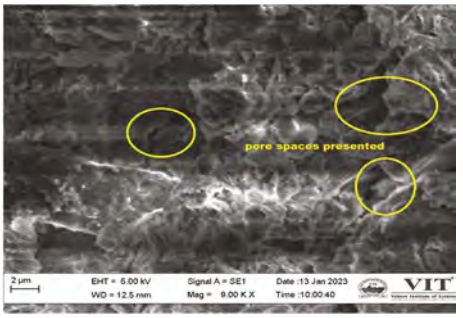

Figure 11. SEM images of soil.

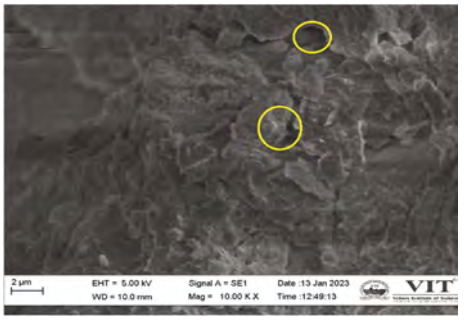

Figure 12. SEM images of soil+ 30%GGBS.

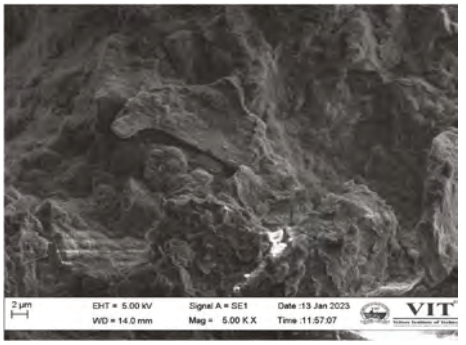

Figure 13. SEM images of soil+30%GGBS +0.25 fibre.

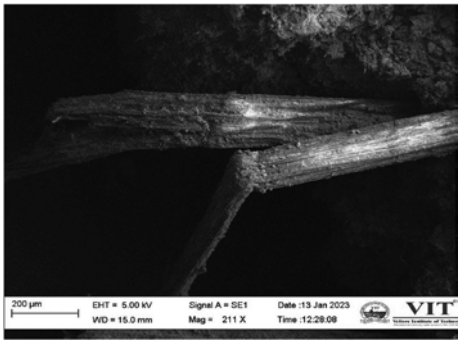

Figure 14. SEM images of soil+30%GGBS+0.5 fibre.

The SEM images of the virgin soil (refer Figure 11) indicates the presence of voids in the soil mass. When GGBS and banana fibres are added to the soil, they act as a binding material interlocking the soil particles as seen in Figures 12–15. Especially addition of fibres at 0.75 % to the soil and 30% GGBS mixture reduces the porous structure of the soil decreasing the soil's compressibility and increasing strength.

5.1 *EDX-analysis*

Energy Dispersive X-ray analysis is carried out for virgin soil and soil+30%GGBS which is an optimum percentage and various combinations of banana fibres like 30%GGBS+0.5F and 30% GGBS+0.75F. The results of the EDX analysis are illustrated in Figures 16–18 respectively.

Figure 16 indicates the presence of the highest peak values of silica and alumina in virgin soil. When the optimum percentage i.e.30% of GGBS is added to the soil, there is an increase in alumina and silica content resulting in the formation of calcium silicate enhancing the soil properties (see Figure 17). The addition of banana fibres to soil + 30% GGBS mixture leads to the formation of cementitious material (Figure 18) and also it acts like a composite material in which fibres withstand tension providing greater resistance to the soil.

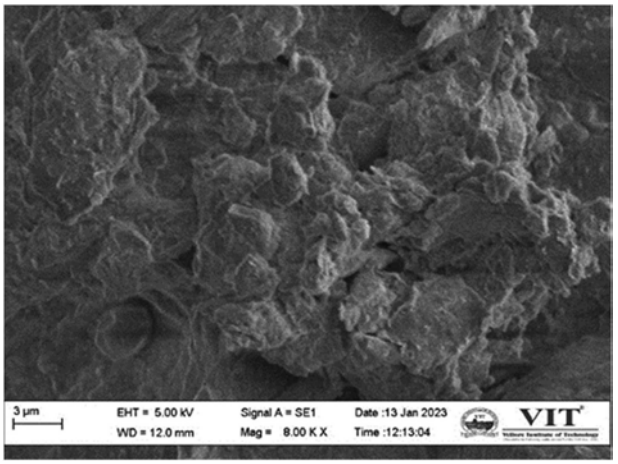

Figure 15. SEM images of soil +30%GGBS+0.75 fibre.

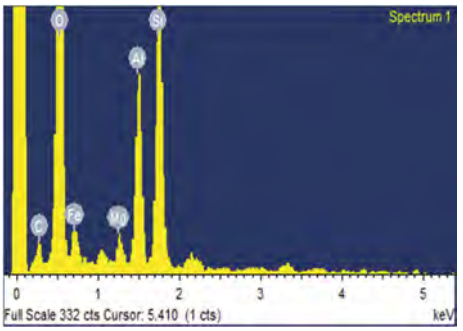

Figure 16. EDX of virgin soil.

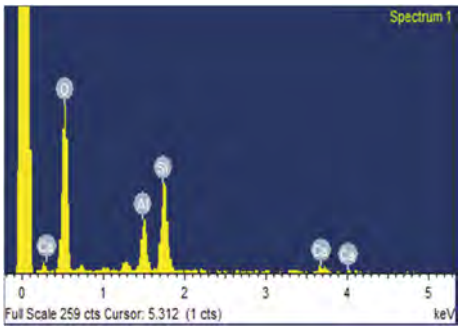

Figure 17. EDX of soil+30%GGBS.

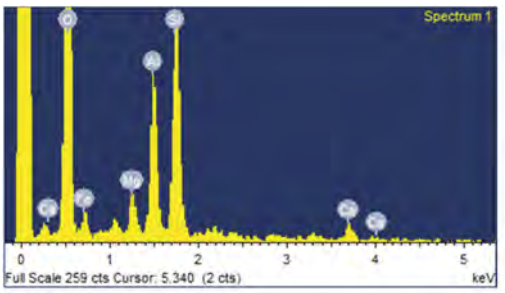

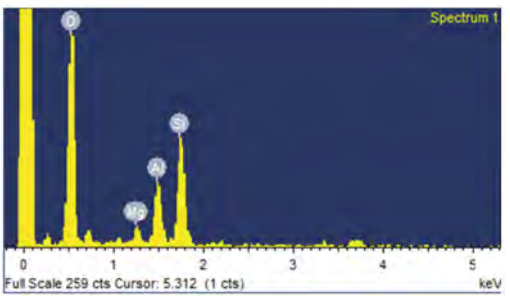

Figure 18. EDX for soil+30%GGBS+ fibre.

6 CONCLUSIONS

In this study, the influence of Ground Granulated Blast Furnace Slag (GGBS) and banana fibres in improving the strength characteristics of highly expansive clayey soil as a stabilizing agent is investigated in detail. From the results, it is concluded that

- The addition of Ground Granulated Blast Furnace Slag to the soil decreases the plasticity of the clayey soil and reduces the swelling characteristics to more than 50% curtailing its expansive nature.

- Based on the results obtained for the various tests to determine compaction and strength characteristics of the various proportions of soil +GGBS+ Banana fibre mixture, it is found that the plasticity (PI) of the untreated soil decreased by 42% and 46% by the addition of 20%GGBS and 30%GGBS respectively.
- Similarly, the strength and drainage characteristics increased by 85% and 10% when the soil is treated with 30% GGBS and 0.75% banana fiber. Thus, proving that the soil + 30% GGBS + 0.75% banana fibre is an optimum combination for stabilizing the expansive clay.
- The formation of Calcium carbonate due to cementitious reactions between GGBS and soil increases the strength properties of soil.
- The addition of GGBS and banana fibres binds the soil particles together along with the reinforcement to bear the tensile stress contributing to the strength improvement of treated soil.

Thus, the Ground Granulated Blast Furnace Slag and banana fibres can be effectively used as a sustainable stabilizing material for clayey soils.

ABSTRACT: This paper presents a case study of the ground improvement works on TBM tunneling for Taipei MRT in the east district of Taipei City. The TBM tunnel is mainly drilled in the composite strata which consist of alluvial deposits, colluvium deposits, and rock formation. The upper half of the improvement zone is a soft soil layer and the lower half of the improvement is a hard rock layer (Sandstone or Shale). The soft soil layers outside of the tunnel-shaft interface require jet grouted body to increase their strength and decrease their permeability. Also, in order to tunnel through the composite stratum, it needs to carry out jet grouting in the soft ground to increase the strength of the soil layer to homogenize the excavation section. Since the hard rock cannot be used by jet grouting, permeability grouting is used to decrease its permeability. In this case, the jet grouting and the permeability grouting were used to overcome the strata with different geological conditions to meet the strength (self-supporting) and to reduce the permeability of the ground. The ground improvement results show that for the jet grout zone, the total core recovery is greater than 90%, the in-situ permeability tests and the laboratory uniaxial compression strength meets the specification requirements. For the TAM grouting zone, the permeability coefficient k carried out by in-situ permeability tests was less than 1×10^{-5} cm/sec. Before breaking the cutter face on the diaphragm wall for the TBM to enter from the shaft, the horizontal leakage tests of the up track and down track at the west side station have been completed. Without supplementary grouting, the permeability coefficient k of all horizontal permeability tests is less than 1×10^{-5} cm/sec.

1 INTRODUCTION

Various ground improvement methods have been adopted in the construction of the Taipei Mass Rapid Transit system (Taipei MRT system). The jet grouting and the chemical grouting technique have been widely used in the tunnel-shaft interface for the TBM launching and arrival works. This study reports the ground improvement works for the Taipei MRT Xinyi East Extension Line in the east district of Taipei City. The TBM tunnels pass through the composite stratum when the TBM arrives at the shaft of the station. The soft soil layers of the tunnel-shaft interface require jet grouted to increase their strength and decrease their permeability. Also, to tunnel through the composite stratum, it needs to carry out jet grouting in the soft ground layer to increase the strength of the soil layer to homogenize the excavation section. Since the hard rock cannot be used by jet grouting, chemical grouting is used to decrease its permeability. In this study, the commercial Rapidjet jet grouting method and the TAM grouting with chemical grouting are used to overcome the strata with different geological conditions to meet the self-supporting and water-proofing required for TBM tunneling. The grouting results show that the total core recovery in the jet grouting zone is greater than

DOI: 10.1201/9781003299127-86

90%, the permeability coefficient k is less than 1×10^{-5} cm/sec and the uniaxial compression strength (UCS) meets the specification requirements (28-days UCS of sand and clay layers is not less than 2.0 MPa and 1.2 MPa). In addition, in-situ permeability tests were carried out in the TAM grouting zone, and the permeability coefficient k was found to be less than 1×10^{-5} cm/sec. The performance and the results of the jet grouting and the TAM grouting works are presented in the following sections.

2 SITE CONDITIONS

The location and layout for the study case of Taipei MRT are shown in Figure 1. It consists of the R03 station, the cross-over, the R03 tail rail ventilation shaft with the cut and cover method, and the shield tunnels with shield machines. The shield tunnel in this study adopts a circular section with an inner diameter of 5.6 m and an outer diameter of 6.1 m. The shield machine adopts the earth pressure balance critical, in which the total length of the shield machine is 8.5 m with an outer diameter of 6.24 m as shown in Figure 2. The lengths of the shield tunnels from the east side of the R03 station to the R03 tail rail ventilation shaft are about 524 m, and the overburden depth is about 20.8 m to 22.0 m. The shield tunnel is mainly drilled in the composite strata which consist of alluvial deposits, colluvial deposits, and rock formations.

The soil condition near the ground surface mainly consists of fill material (SF), alluvial deposit (CL/CH/ML/SM) with a thickness of 10-20 m and a very soft to weak consistency, and underneath is soft to medium-hard, moderately weathered to fresh sandstone (SS), shale (SH). The soil-rock interface is occasionally mixed with colluvial deposits; the main components are gravel and rock blocks. The physical properties of soil near the east side/west side of the R03 station and R03 tail rail ventilation shaft are shown in Table 1. Additionally, the soil and rock properties along the R03 station to the R03 tail rail ventilation shaft are shown in Figure 3. It indicates that the q_u value of the rock formation is > 1000 kgf/cm^2, and the RQD of the rock formation is between 0 and 100. The groundwater level was about 0 ~ 1.8 m below the ground surface.

3 GROUTING WORKS

3.1 *Grouting for tunnel launching and arrival*

For the grouting works of this study case, the soft soil layers outside of the tunnel-shaft interface for tunnel launching and arrival require jet grouting to increase soil strength and decrease ground permeability, but the hard rock layer cannot be performed with jet grouting. Therefore chemical grouting is used to reduce the permeability. In this case, jet grouting (Rapidjet Method) and chemical grouting (TAM method) were used to overcome the strata with different geological conditions and meet the strength and reduce the permeability of the ground. The grouting work and improved zone for the launching and the arrival shield of the presented case as shown in Figure 4 and Table 2.

3.2 *Grouting for soil-rock interface*

When the TBM tunnels pass the interface of the alluvial layer and a colluvial layer or rock formation, it increases the possibility of over-excavation. This is because the stratum on the shield machine's cutting blade disk is soft at the top and hard at the bottom, so the TBM becomes liable

to offset when drilling and digging. The strength of mixed strata varies significantly in some areas of this study case. To minimize the impact of drilling on the surrounding area, ground improvement is carried out for these areas. This study introduces the grouting method of the soil-rock interface located on the east side of the R03 station as shown in Figure 5. The soil layer above the soil-rock interface is performed by jet grouting (Rapidjet method) to ensure that the shield machine does not shift up or cause the ground to collapse due to improper digging. Figure 5 shows the position of the soil-rock interface, grouting zone, and adopted grouting method. However, the TAM grout of the soil-rock interface area is always for building protection.

4 GROUTING METHOD

4.1 *Jet grouting*

4.1.1 *Working procedure*

The jet grouting method used in this study is a double-fluid jet grouting system, commercially named the Rapidjet method. Considering that part of the clay layer has occasionally mixed with a colluvial deposit, and the subsequent construction of double tube double packer grouting requires drilling of sandstone and shale, the jet grouting adopts a rotatable percussion

drilling machine to drill first. The drilling is used directly in the subsequent double tube double packer grouting. The construction process of Rapidjet is shown in Figure 6.

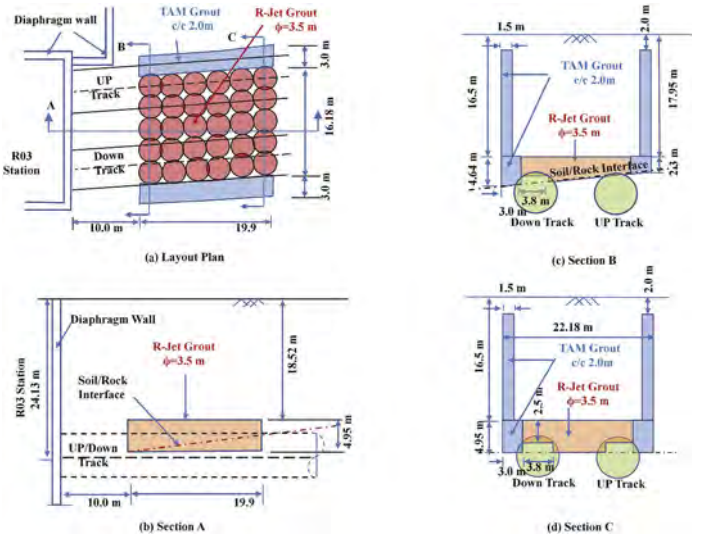

Figure 5. The soil-rock interface, grouting zone, and adopted grouting method the at east side of R03 station.

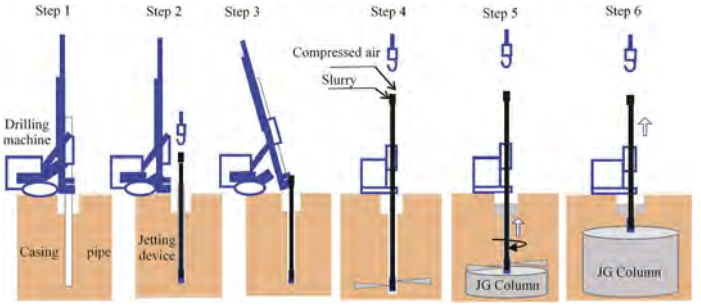

Figure 6. Rapidjet working procedure (Rapidjet association, 2019).

4.1.2 *Material and grouting parameters*

The jet grouting parameters of this method are similar to those proposed by Burke (2004) and Lunardi (1997). The grout jet was shrouded with compressed air (pa = 0.7–1 MPa) and grouting pressure (p_g = 33–37 MPa). The grout flow rate (q_g) was increased to 540 liters/min to enhance its cutting ability and cutting distance while also enhancing the mixing of cement grout with the soil in situ. In the drilling of jet grout holes, rotary drilling and water jet are used to pre-drill the holes. The rotation force provided by the drilling machine is then transferred to the drill bits at the tip of the drill rod. Two nozzles were mounted on the opposite side of the monitor with a 25 mm difference in elevation. The parameters used in this grouting are listed in Table 3. Materials required for Rapidjet are as follows: (1) groundwater is required, and it must not contain oil, acid, alkali, organic matter, or other harmful substances that affect solidification, durability, and strength; (2) cement binder HSC301 material for jet grouting.

Table 3. Jet grouting parameters used in the Rapidjet grouting.

Parameter	Value
Water cement ratio, W/C	1.4
Jetting pressure of air, p_a (MPa)	0.9
Jetting pressure of grout, p_g (MPa)	35±10%
Flow rate of grout, q_g (liters/min)	180 per nozzle
Nozzle diameter, d_0 (mm)	4.24
Number of nozzles on the monitor	2
Rotation speed of the rod, R_s (rad/s)	0.52
Lift up or withdrawal rate of rod, v_s (m/s)	1.19×10^{-3}
Lift up step, ΔS_t(cm/step)	2.5

4.2 *TAM grouting*

4.2.1 *Working procedure*

TAM grouting can be applied to any grouting material in any grouting hole, which is one of its irreplaceable advantages. Generally speaking, when the grouting zone, location of grouting holes, and grouting ratio are decided, pressure control or quantity control can be used for grouting practice. Influenced by non-uniform and anisotropy of soil, pressure control grouting as well as quantity control grouting, can perform better grouting efficiency. It is especially apparent when the value of grouting pressure itself is not so influential and relative change in pressure is essential. Relevant construction procedures are shown in Figure 7:

Step1: Boring

The hole was bored with a 125 mm diameter casing using a high-efficiency rotary percussion boring machine. To prevent disturbance of the surrounding ground, double pipe boring was used and the spoil was withdrawn through the space between the inner and outer pipes. Meanwhile, to ensure the reliability of ground investigation, we also keep track of drilling slag to understand the ground condition more clearly.

Step2~Step 4: Sealing compound injection grouting and external pipe placing

After boring the holes, the inner pipe of the double pipe withdrew, and after injecting the sealing compound the TAM tube was driven into the hole. In order not to cause obstruction when carrying out the drilling work and to withstand the grouting pressures, a TAM tube made of PVC was used. The axial spacing of injection openings in each TAM tube was maintained at 33 cm, and fitted with a packer to seal and prevent the inflow of groundwater/the flow of grout.

Step5~Step 6: The grouting operation

An internal inner pipe, at the end of which is fitted two stages of packing, was inserted into the TAM tube, and step grouting was carried out at predetermined depths.

4.2.2 *Material and grouting parameters*

Two stages of grouting were used in the grouting work: the first-stage grouting used cement and bentonite grout (CB grout) with an injection volume of 5~8 % soil porosity for interlayer. Similarly, a solution-type sodium silicate grout (with MK reagent) with a volume of 30~32 % soil porosity was injected during the second stage. The first-stage CB grouting was aimed to fill and compact the voids in the ground (mix proportions as shown in Table 4). The grouting was not stopped until the mentioned design grouting quantity was reached. Such grout intrusions compress the sandy soil, and make the improved zone homogenization. In comparison, the injection of sodium silicate grout into the sandy layer was for low-permeability purposes and increased its overall strength. TAM Grout injection parameters, grout ratio, and grout volume for the project as shown in Table 5 to Table 7.

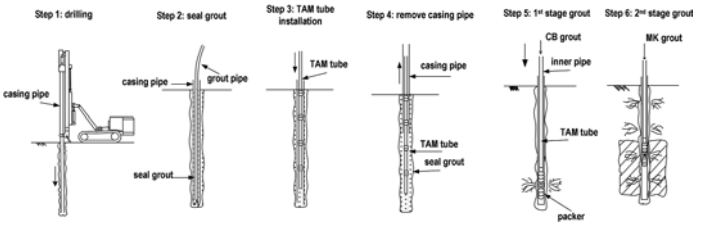

Figure 7. TAM grouting procedure.

Table 4. Summary of mix proportions for CB grout and MK grout.

CB grout	Mix proportion	MK grout	Mix proportion
Cement binder	150~250 kg	Sodium silicate	250 L
bentonite	40 ~ 80 kg	MK reaction	35 ~ 65 L
Water	888~937 L	Water	685~715 L
Total	1000 L	Total	1000 L

Table 5. TAM grouting parameters.

Grouting method		TAM Grout (Double packer method)
Grouting mode		1 shot
Grouting length per step		1 step=0.33 m
Grout flow		q =4 ~15 L/min
Gel Time	CB	-
	MK	≈ 60 min
Quantity control		Flow rate and pressure
Grout type	1st Grout	CB
	2nd Grout	MK

Table 6. TAM grouting ratio.

		Grout ratio %		
Grouting zone	Soil type	1st Grout	2nd Grout	Total
Tunnel-shaft interface	SS/SH	5	10	15
Water-stop section	CL/ML	10	10	20
	SM	15	20	35
	SS/SH	5	10	15
East side of R03 station (Soil-Rock Interface)	CL/ML	10	15	25

Remark: If the filling is completed according to the grouting rate but the pressure is low, the MK material will be used to inject about 3 to 5% of the inspection and supplement grouting.

5 QUANTITY CONTROL AND QUALITY ASSURANCE

5.1 *TAM grout pressure recorded*

Although the value of grouting pressure observed at each step is not so meaningful, the relative change itself is essential. It proves it's helpful to record the 1st and 2nd grouting pressure at the injection hole in each step (33 cm) by comparing them with each other to evaluate the grouting effects and detect the insufficiently-improved areas (Hayashi and Matsubayashi, 1996). TAM

grout pressure was recorded for 1st grout, 2nd grout, and supplement grout as shown in Table 8. The average pressures on the clayey, sandy, and sandstone/shale range from 6.4~8.0, 11.8~13.0 and 7.0~13.3 kg/cm^{2,} respectively.

Table 7. TAM Grouting volume.

Location	Soil volume (m^3)	Grout ration (%)	Nos	Grout volume (m^3) Design	Actual	Soil type
West side of R03 station	853.6	20	53	170.7	186.6	CL/ML
	1569.9	15		235.5	250.4	SS/SH

(Arrival)	SS/SH	13.2	13.3	13.3
	Remark: When the pressure is lower than 9.0 kgf/cm^2, apply about 3.5% MK supplementary grouting, and most of the grouting pressure at this position has increased			
East side of R03 station	CL/ML	6.4	9.1	-
(Soil-Rock Interface)	Remarks: The purpose of the improvement of the low-pressure zone on both sides of the soil-rock interface is to protect the adjacent buildings, and no supplementary grouting is applied.			

5.2 *Permeability test of TAM grout zone*

According to the construction specification, every 100 grout holes should be tested with at least 3 holes. The permeability coefficient k $\leq 1\times10^{-5}$ cm/sec. Table 9 shows the results of the permeability of the TAM grout zone. All test results meet the design requirement.

5.3 *Core sampling and permeability test of the jet grouted zone*

According to the construction specification, every 100 grout holes should be sampled with at least 3 holes. The total core recovery (TCR) of sampling was ≥ 90%, the 28-day uniaxial compressive strength (UCS) of each sample ≥ 20.0 kgf/cm^2 for sandy soil, and ≥ 12.0 kgf/cm^2 for clayey(silty)

soil, and the permeability coefficient k $\leq 1\times10^{-5}$ cm/sec. Table 10 shows the results of coring, UCS, and permeability of the Jet grout zone. All test results meet the design requirement.

Table 9. Permeability test results of TAM grouted zone.

Location	Test No	Depth, E.L. (m)	Permeability k, (cm/sec)
Tail rail ventilation shaft (Arrival)	T-1	87.75~88.75	2.36×10^{-07}

5.4 *Horizontal leakage tests in the grouting zone*

Before breaking the mirror face on the diaphragm wall for the shield machine to enter or from the shaft, it is critical to conduct leakage tests for the grouted zone behind the wall. Typically, horizontal boreholes were drilled at the mirror-face location, through the wall into the grouted zone to the desired length. Then the valve attached to the horizontal borehole is opened to measure the groundwater inflow rate through the grouted zone into the working shaft. The supplement of the grout will achieve the purpose of safely breaking the mirror. According to the construction specification, with five holes within the mirror frame, and nine holes outside the mirror frame, the depth is at least 2 m into the grouted zone. The depth of the hole is at least 1 hole must reach the front edge of the outermost row of the grouted zone or the position 1m before the grouted zone. After drilling the leaking amount of each test, the hole is measured by the measuring cup with a meter after the water leakage is stable. The permeable field test uses a spherical flow method to determine the permeability coefficient. The design permeability coefficient k $\leq 1\times10^{-5}$ cm/sec. The horizontal leakage tests of the up track and down track at the west side of the R03 station for launching as shown in Figure 8. The depth of the center hole was 8.6 m into the grouted zone, and the depth of the other holes was 2 m. There were 5 holes inside the mirror frame that were equally distributed in the center diameter of 4.4 m, and the 9 holes outside the mirror frame distributed the hole positions evenly within the center diameter of 7.2 m. A total of 28 horizontal leakage tests were carried out in the up and down track grout zone, test results of permeability k range 0.0~9.19×10-7 cm/sec, and the maximum quantity of water was 20 cc/min at the center hole. All tests met the design requirement and were without supplementary grouting.

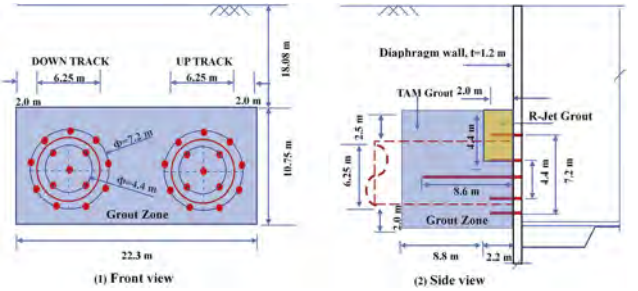

Figure 8. Horizontal leakage tests at the west side of the R03 station for launching.

6 CONCLUSIONS AND RECOMMENDATIONS

This study reports the grouting works for the Taipei MRT Xinyi East Extension Line in the east district of Taipei City. The TBM tunnels through the composite stratum at the east side of the R03 station. The upper half of the improvement zone is a soft soil layer and the lower half of the improvement is a hard rock layer (Sandstone or Shale). The Rapidjet Method and the TAM grouting were used to overcome the strata with different geological conditions to meet the self-supporting and water-proofing required for the TBM break-in and break-out. The following conclusions can be drawn:

1) All the tests carried out in the jet grouted and TAM grouted zone meet the design requirement. For the jet grouted zone: the 28-day uniaxial compressive strength (UCS) of each sample was ≥ 20.0 kgf/cm^2 for sandy soil, and ≥ 12.0 kgf/cm^2 for clayey (silty) soil, and the permeability coefficient k ≤1×10^{-5} cm/sec. For TAM grouted zone: the permeability coefficient k ≤1×10^{-5} cm/sec. For the horizontal leakage test in the grouting zone at the west side of the R03 station, the permeability coefficient k was ≤1×10^{-5} cm/sec.
2) The TBM at the west side of the up-track tunnel of the R03 station was launched smoothly and without supplementary grouting. Therefore, careful planning of grouting methods can significantly shorten construction time and reduce construction costs.
3) In addition, the construction of the diaphragm wall for the TBM launching and arrival works may have an adverse effect on the grouting works (such as the verticality of the grout holes, the impermeability of grouting, etc.), a row of low-pressure inspection grout (TAM grout) can be accessional at the interface between the diaphragm wall and the ground, it can let the grouting works effect more perfect.

Monitoring-based approach for stability prediction of embankments on port-said clay

Mohamed H. Mahmoud
WSP Dubai, U Bora Tower Residence Parking, Dubai, UAE

Mohamed F. Mansour
Department of Structural Engineering, Ain Shams University, Cairo, Egypt

ABSTRACT: This paper presents the results of a numerical study carried out to investigate the stability of preloading embankments on the very soft to firm Port-Said Clay deposit in north-eastern Egypt. Characteristic stability assessment charts were developed to predict the factor of safety against deep-seated failure of preloading embankments based on routine field measurements such as the vertical and horizontal displacements. The results were compared with well-established methods. A new chart is also developed in this study to predict the preloading embankment stability based on horizontal displacement measurements at the embankment toe.

1 INTRODUCTION

Soft clays are often classified as one of the most problematic soil types in terms of their engineering behaviour. Preloading is one of ground improvement methods that induces significant improvement to soft clay. Upon unloading followed by reloading to the operational loads, the compressibility would be governed by the unloading-reloading, rather than the primary compression index. In order to accelerate the consolidation process, particularly for thick clay deposits, sand drains or Prefabricated Vertical Drains (PVD) are installed.

Preloading embankments are monitored for vertical and horizontal displacements in order to control stability and observe any signs of approaching failure. Matsuo and Kawamura (1977) developed a chart to determine the failure load ratio of an embankment resting on soft ground. It based on field measurements during construction of preloading embankments on different types of soft ground and backed by numerical analysis. It should be noted, however, that Matsuo and Kawamura (1977) considered the non-linear elastic analysis to simulate shear deformations in the undrained condition, and an elastic analysis based on Biot's equations to simulate the behaviour during consolidation. These constitutive models were relatively simple in terms of simulation of the soft clay behaviour. Advanced constitutive models based on the critical state theory (Roscoe et al., 1963; Burland, 1965) have been developed over the last decades to better simulate the constitutive behaviour of soft clay materials such as the Modified Cam Clay (MCC) Model (Roscoe and Burland, 1968), the Soft Soil (SS) Model, and the Soft Soil Creep (SSC) Model. The use of advanced constitutive models would have contributed to a more reliable modelling of the soft clay behaviour.

El-Tina plain, located to the east of Port-Said City on the Mediterranean Sea shore in Egypt, consists of a thick deposit of very soft to firm clay known as Port-Said Clay (Hamed et al., 2017a; and Hamed, 2017). The very soft to firm Port-Said Clay represented the delta of an old tributary of the Nile River that dated back to the Holocene Period. The Port-Said Clay was deposited in a marine environment due to the transgression and regression of the Mediterranean Sea shoreline (Ibrahem, 2002; Abdallah, 2006). Geotechnical characterization of Port-Said Clay

DOI: 10.1201/9781003299127-87

and its interaction with quay walls and tunnels were investigated in previous studies (Hamed et al., 2017(a, b); Mansour et al., 2021).

In this paper, the behaviour of a preloading embankment on Port-Said Clay is investigated by numerical analysis. The main objective is to develop characteristic stability assessment charts for preloading embankments resting on Port-Said Clay. The charts would relate the displacement routinely measured in projects involving an embankment on soft clay to the factor of safety against deep-seated failure of the embankment slopes. The numerical study is carried out using the characteristic properties of Port-Said Clay (Hamed et al., 2017a) and the critical state theory-based SSC Model to simulate the constitutive behaviour of Port-Said Clay.

2 PROBLEM CONFIGURATION

The ground conditions in the East of Port-Said region generally consist of an upper crust layer ranging in thickness from 0.5 to 7.4 m followed by the very soft to firm Port-Said Clay deposit to a depth of up to 50 m. The Port-Said Clay layer is underlain by very dense sand with intrusions of very stiff clay. The groundwater table depth ranged from 0.0 to 4.3 m below the ground surface (Hamed et al., 2017b; Rizos et al., 2018). The ground profile considered in this study consisted of an upper 0.5m-thick layer of fill underlain by Port-Said Clay to a depth of 50 m below ground surface where a very dense sand layer was encountered. The groundwater table was taken at 1.3 m below the ground surface (Hamed et al., 2017b).

Preloading embankments are designed such that a minimum overconsolidation ratio (OCR) of 1.1 is achieved after unloading of the preloading embankment and application of the operational loads. This requirement in preloading design ensures that the settlement due to operational loads will be governed by the unloading-reloading/swelling index rather than the primary compression index. The preloading embankment considered in the present study had a height of 6 m, crest width of 65 m and side slopes of 2H: 1V, and consisted of sand fill.

3 METHODOLOGY

The numerical analysis was carried out using the plane strain two-dimensional finite element program PLAXIS (Brinkgreve et al., 2018). Different soil layers were modelled using the 15-node triangular elements. A sensitivity analysis was carried out to determine the appropriate distance to the lateral and bottom boundaries of the model so as to ensure negligible effects of the boundaries on vertical and horizontal displacements. Hence, the model depth and width were taken 60 and 215 m, respectively. The model considered symmetric plane strain configuration. The vertical boundaries of the model were assigned zero lateral movements. A closed flow boundary was defined along the embankment centre. The bottom boundary was restrained against movement in the vertical and horizontal directions and was considered permeable (sand formation).

The embankment fill and lower dense sand, which were modelled using the Hardening Soil Model. While, the upper crust, which was modelled using the elastic perfectly-plastic constitutive model with Mohr-Coulomb failure criterion. Ali et al. (2016) pointed out to the inability of the SSC Model to reasonably predict actual deformations at shallow depths, where the surficial layers are usually overconsolidated. The Port-Said Clay was modelled using the SSC Model, which is an elastic-plastic strain hardening model based on the principles of the critical state soil mechanics (Roscoe et al., 1963; Burland, 1965). The different SSC Model parameters for Port-Said Clay were determined based on the characterization carried out by Hamed et al. (2017a). The primary compression and swelling indices (C_c and C_s) were taken 0.75 and 0.105, respectively. The initial void ratio (e_o) was taken 2.0 (Hamed et al., 2017b). The coefficient of secondary consolidation ($C_{\alpha e}$) was taken 0.011. The drained friction angle (ϕ') was determined from consolidated drained triaxial tests, and was equal to 22 degrees. The Port-Said clay layer was divided into nine (9) sublayers in order to account for the variations with depth of the plasticity index, which affects the at-rest earth pressure coefficient, and hydraulic conductivity (Hamed et al., 2017a; Hamed, 2017).

Six lifts were considered for the embankment construction. Each lift had a thickness of 1.0 m except the first one which had a thickness of 2.0 m, since this height was found to fulfil a factor of safety against embankment slope failure of more than 1.1. The time increments considered in the analysis for each lift are illustrated in Table 1. The time increments corresponding to each lift represent the durations at which the results were extracted.

Table 1. Time increments corresponding to each construction lift.

	Time increments considered in analysis (days)																
Lift	Δ T0	Δ T1	Δ T2	Δ T3	Δ T4	Δ T5	Δ T6	Δ T7	Δ T8	Δ T9	ΔT 10	ΔT 11	ΔT 12	ΔT 13	ΔT 14	ΔT 15	ΔT 16
L2 (2 m)	0.5																
L3 (3 m)		2	10	20	40												
L4 (4 m)					10	15	30	60	120								
L5 (5 m)									0.5	30	60	120	240				
L6 (6 m)													0.5	60	120	240	350

4 NUMERICAL MODEL VERIFICATION

A full-scale earth embankment (TS1) was designed, constructed and monitored at the proposed Second Bangkok International Airport in Nong Ngu Hao, East Bangkok, Thailand (Bergado et al., 2002). A numerical model is developed in this study to verify and validate the use of the SSC Model to predict the vertical and horizontal displacements of embankments constructed on soft clay deposits. The field monitoring program, documented by Bergado et al. (2002), involved measurement of the development with time and embankment construction stages of the vertical displacement at the embankment centre and the horizontal displacement at the crest.

A two-dimensional plane strain model, based on the finite element method, was developed in the present study to simulate the different stages of the TS1 embankment construction over the very soft to stiff Bangkok Clay deposit. The commercial program PLAXIS (Brinkgreve et al., 2018) was employed to carry out the analysis. Different soil layers were modelled using the fifteen node triangular elements. The installed PVD's were modelled using the drain option offered in the utilized program (Brinkgreve et al., 2018). The elastic perfectly plastic model with Mohr-Coulomb failure criterion was adopted to simulate the behaviour of the TS1 embankment fill, sand blanket, clayey sand and the lower dense sand layer. All Bangkok Clay layers were modelled using the SSC Model. The parameters adopted for different soil layers were based on the engineering properties presented in Bergado et al. (1995) and Samieh et al. (2010). Figure 1 presents the measured and predicted vertical displacement (settlement) at the embankment centre. It can be observed that the predicted settlement exceeded the measured settlement during intermediate stages of the embankment construction. However, the final settlement at the end of the monitoring period, i.e. at about 400 days, was in good agreement with the measured settlement. This overestimation by the numerical model during consolidation could be attributed to the presence of low-permeability sublayers within the main Bangkok Clay formation causing some delayed consolidation, which might not have been considered in the primary consolidation parameters reported by Bergado et al. (1995) and, hence, was not captured by the numerical model. Figure 2 presents the measured and predicted horizontal displacement at the embankment crest. The available horizontal displacement measurements were available at a time of about 240 days. Hence, the numerical analysis results were extracted at the same time. The results indicate that the maximum lateral displacement occurred within the very soft Bangkok Clay layer at a depth of about 3.5 m below the ground surface. In general, the horizontal displacement significantly increased within the very soft and soft Bangkok Clay layers. The numerical model underestimated the maximum horizontal displacement by about 14%. The results of the numerical verification indicated that the SSC Model can be utilized to reasonably predict the vertical and horizontal displacement of embankments resting on soft clay deposits.

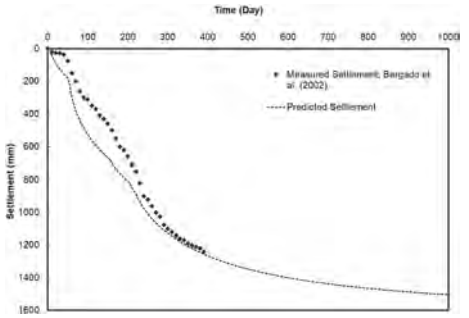

Figure 1. Measured and predicted settlement at the TS1 embankment centre (point A).

5 PRELOADING EMBANKMENT ON PORT-SAID CLAY

This section presents the results of the numerical study carried out on Port-Said Clay in order to assess the stability of the preloading embankment described in the PROBLEM CONFIGURATION Section by developing relationships between the factor of safety against deep-seated failure and routine field measurements including the vertical and horizontal displacements at the embankment centre and toe, respectively.

5.1 *Analysis procedure*

The numerical analysis was carried out in different phases as follows:

- Undrained analysis: This analysis type was adopted in the short-term condition right after placement of the preloading lift in order to calculate the excess pore water pressure.
- Consolidation analysis: This analysis type was adopted to simulate the dissipation with time of the excess pore water pressure during the consolidation process.
- Slope stability analysis: Stability analyses were carried out in each of the above analysis phases. The factor of safety against deep-seated failure was calculated using the c-phi reduction technique in the short-term condition (Brinkgreve et al., 2018).

5.2 *Analysis results and discussion*

The results were interpreted by calculating the factor of safety against deep-seated failure in the preloading embankment and the Port-Said Clay for different preloading lift heights and durations. The analysis results showed that, for lift heights of less than two meters, the critical slip surface was borne by the preloading embankment fill, and did not extend to the Port-Said Clay. Lift heights of two meters or more caused the critical slip surface to be deep-seated. Figure 3 shows a typical geometry of the slip surface, represented by incremental displacement contours, for an embankment height of 5 m. For each embankment height, the factor of safety, vertical displacement at the embankment centre and horizontal displacement at the embankment toe were calculated right after placement of the preloading lift and after different time increments representing different degrees of consolidation. The vertical and horizontal displacements were determined from the respective total displacement contours. Figure 4 shows a typical output of the horizontal displacement contours corresponding to an embankment height of 5 m.

The results are displayed in the same format of Matsuo and Kawamura (1977) and they are presented in Figure 5. The line connecting different data points represents the variation of the factor of safety (FS) since placement of each embankment lift until the end of the time period corresponding to each lift. This figure also shows the variation of the FS due to application of

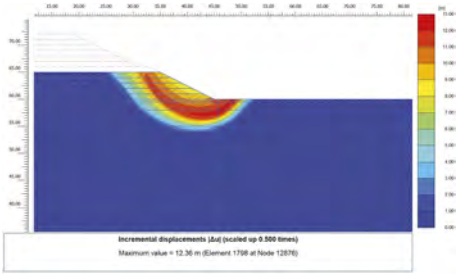

Figure 3. Contours of incremental displacement for one of the intermediate stages (embankment height = 5 m).

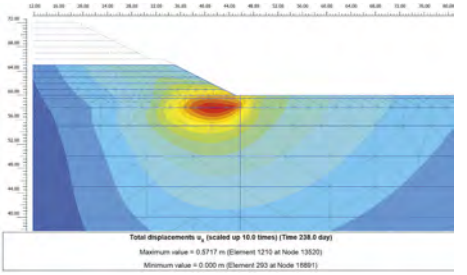

Figure 4. Horizontal displacement contours showing the location of maximum horizontal displacement (embankment height = 5 m).

a new preloading lift. As expected, the minimum FS for each preloading lift occurs in the initial stage right after placement of the additional lift (undrained stage). The FS increases with time due to dissipation of excess pore pressure with the ongoing consolidation process. The commercial software DPlot® was utilized to develop FS contours for different combinations of the horizontal to vertical displacement ratio and vertical displacement, as shown in Figure 6. The developed contour lines represent FS ranging from 1.05 to 1.35. Preloading embankments are typically designed to achieve short-term stability during construction where the target FS is in the order of 1.1 or 1.2. Hence, the developed FS contours will enable the design engineer to predict the preloading embankment stability based on field measurements of vertical displacement at the embankment centre and horizontal displacement at the embankment toe. The developed contours are considered characteristic to Port-Said Clay. A comparison is carried out between the Port-Said Clay-characteristic FS contours, shown in Figure 6, and the contours developed by Matsuo and Kawamura (1977), referred to herein as the MK FS contours. The comparison is shown in Figure 7. It can be observed that the FS contours characteristic to Port-Said Clay spanned over a bigger range of horizontal to vertical displacement ratio compared to the MK contours. Therefore, the use of the well-established MK contours for Port-Said Clay would require some judgement for δ/d values outside the range of FS contours. It is believed that Port-Said Clay exhibits high lateral displacements in the toe area due to the very soft to soft consistency in the upper twenty meters (Hamed et al., 2017a). It can be also observed that the Port-Said Clay FS contours are narrower than the MK FS contours. In other words, the variation of the FS for preloading embankments on Port-Said Clay is more sensitive to changes in the vertical and horizontal displacements than the predicted values based on Matsuo and Kawamura (1977) diagram. Furthermore, the Port-Said Clay contours are more optimistic in terms of the corresponding FS against deep-seated failure.

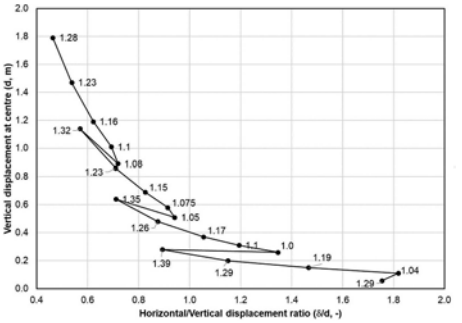

Figure 5. Variation of the FS against deep-seated failure for an embankment on Port-Said Clay.

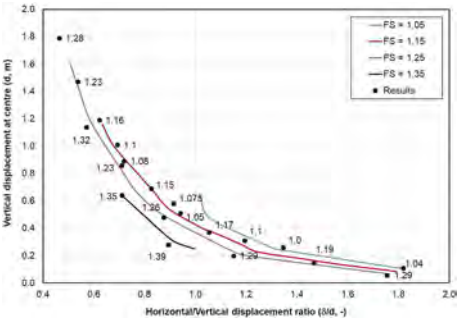

Figure 6. Characteristic factor of safety (FS) contours for Port-Said Clay.

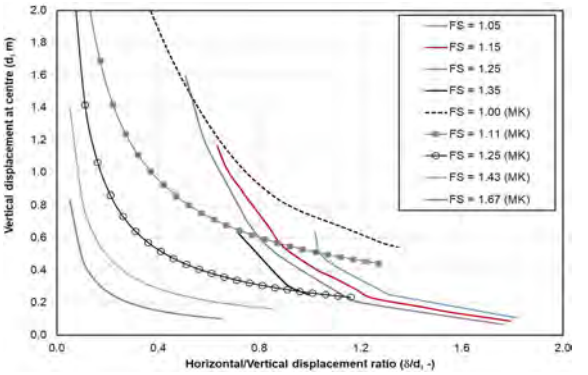

Figure 7. Comparison between the Port-Said Clay FS contours and the Matsuo-Kawamura (MK) FS contours.

The observed discrepancy between the contours developed in this study and the Matsuo and Kawamura (1977) contours could be attributed to the difference in modelling the constitutive behaviour of soft clay. Matsuo and Kawamura (1977) adopted the elastic nonlinear (hyperbolic) model to simulate the behaviour in undrained conditions. The consolidation behaviour was modelled by formulating Biot's multi-dimensional consolidation theory using the finite element method. These constitutive models could have represented the latest development at that time in terms of modelling the constitutive behaviour of soft soils. The comparisons provided in Matsuo and Kawamura (1977) indicated differences between the measured and predicted displacements of up to 250 and 70 mm in the vertical and horizontal displacement, respectively. On the other hand, the more robust SSC Model was utilized in this study, which enabled better agreement between the measured and predicted displacements of a soft soil deposit, i.e. Bangkok Clay, with similar geotechnical properties, as explained in detail in section 4.

The analysis results showed that the horizontal displacement reached a maximum value at a depth of about two (2) m below the toe level, which corresponded to a depth of about 1.5 m inside the Port-Said Clay layer. The pore water pressure should be measured at the same level of maximum horizontal displacement. Hence, the excess pore water pressure can be calculated, and the FS can be estimated.

6 CONCLUSIONS

This paper presents the results of a numerical study to develop a monitoring-based approach to predict the stability of preloading embankments on the very soft to firm Port-Said Clay deposit in north-eastern Egypt. The conclusions of the study can be summarised in the following points:

- Characteristic stability prediction charts have been developed to predict the factor of safety against deep-seated failure for preloading embankments resting on Port-Said Clay.
- The developed chart has a similar form to the chart developed by Matsuo and Kawamura (1977). However, the factor of safety prediction is different, which is attributed to the lack of advanced constitutive models at the time the Matsuo and Kawamura (1977) chart was developed. The Port-Said Clay characteristic chart is more optimistic in terms of the factor of safety against deep-seated failure.
- Characteristic charts should be developed for each soft clay deposit due to the uniqueness of deposition environment and engineering characteristics of each deposit.
- The critical-state-theory-based SSC Model can reasonably predict the deformation behaviour of Port-Said Clay.

Study on reinforcement of existing retaining walls with small diameter steel pipes

M. Ogawa
Hokoku Engineering Co. Ltd., Chiba, Japan

M. Hyodo
Yamaguchi University, Ube, Yamaguchi, Japan

ABSTRACT: In this paper, the authors investigated the effectiveness of three types of small diameter steel pipe reinforcement on the reduction of horizontal displacement of soil and stability of a retaining wall, using a soil tank and simulated house on land with a sloped retaining wall. Horizontal and vertical loads were applied to the base of the house and images taken with a digital camera were used in 2D image correlation analysis in order to measure the amount of horizontal displacement of the soil and retaining wall. It was found that the pattern of slip failure was different for unreinforced and reinforced soil. Also, out of the three types of reinforcement, the Λ-type reinforcement was most effective in restraining the horizontal displacement of the soil and increasing stability of the retaining wall.

1 INTRODUCTION

During recent major earthquakes, there has been an increase in the collapse of retaining walls on sloped land and consequent damage to houses located behind the retaining walls (Okimura, et al。 1999) (Hashimoto 2017). As the retaining wall itself is not strong enough to remain standing, it collapses, leading to damage of residential properties due to ground deformation. Therefore, there is an urgent need to reinforce such existing retaining walls, to ensure the stability of residential foundation soils.

In this study, the behaviour of simulated residential land with a retaining wall under vertical and horizontal loads was investigated. In addition, the effectiveness of three different types of reinforcement placed behind the retaining wall was also investigated.

2 LOADING TESTS

2.1 *Outline of the tests*

An overview of the apparatus used in the tests is shown in Figure 1. The soil tank is 1,500 mm (length) x 1,000 mm (depth) x 200 mm (width) with five sides made of 30 mm thick acrylic boards. Air-dried Toyoura sand (ρ_{dmax}=1.652 g/cm^3, ρ_{dmin}=1.369 g/cm^3) was used as the soil material. In order to observe the behaviour of the ground behind the retaining wall up to failure and the effect of loading on the retaining wall, as well as the effect of reinforcement, the upper layer of sand was loosely packed with a relative density of D_r = 30% (ρ_d = 1.443 g/cm^3), whilst the lower layer was medium-dense packed with D_r = 50% (ρ_d = 1.497 g/cm^3). The two layers were prepared using the air-pluviation method (Toki, et al。 1979).

Eight 40 mm x 40 mm x 195 mm aluminium bars, stacked at an angle of 70°, were used to represent the retaining wall and the house was simulated by placing a 140 mm x 195 mm x 12 mm steel plate (hereafter referred to as the load plate) on the ground behind the retaining

DOI: 10.1201/9781003299127-88

wall. This set-up simulated a house constructed behind a block retaining wall. Vertical loading was carried out by stacking one 22 N steel plate on top of another, on top of the load plate, and horizontal loading was carried out by pulling the load plate horizontally with a load of roughly 0.2 times the vertical load.

In this study, images taken by a digital camera were analysed using 2D image correlation, and the displacement was measured over the entire target area (Demizu, 2012). The digital camera was installed 1.5 m away from the front of the tank and images were taken at each step of vertical loading, until the retaining wall collapsed or until the loading capacity of the apparatus was reached.

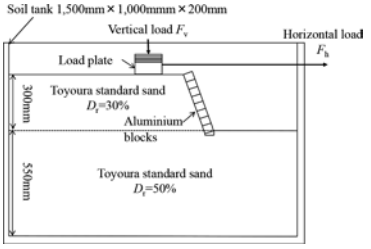

Figure 1. Outline of the test.

2.2 *Test results*

The results for horizontal displacement obtained through image analysis at the final load before failure, for vertical loading only and for simultaneous vertical-horizontal loading, are shown in Figure 2. As can be seen, compared with only vertical loading, failure occurs under a smaller total load during simultaneous vertical-horizontal loading, indicating the more severe influence of horizontal loading on ground stability compared with vertical loading.

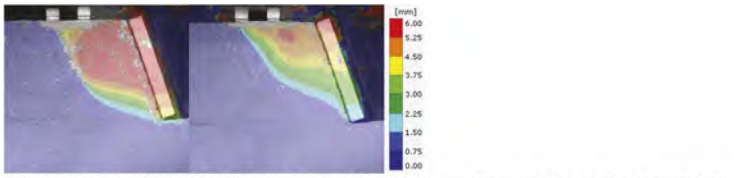

Figure 2. Horizontal displacement at final load before failure.

3 COMPARISON OF REINFORCEMENT TYPE

3.1 *Reinforcement types*

Aluminium pipes with a diameter of 5 mm, a wall thickness of 0.5 mm, a specific gravity of 2.7 and a tensile strength of 185 N/mm^2 were used as the reinforcing material. The following three types of reinforcement were tested in this study, as shown in Figure 3.(i) a single row of pipes parallel to the retaining wall, placed at the midpoint between the wall and the load plate with 40 mm spacing (hereafter referred to as Type I); (ii) two staggered rows of pipes with 20 mm spacing (hereafter referred to as Type II); and (iii) a row of pairs of pipes in a Λ-shape with an internal angle of 20°, spaced 40 mm apart (hereafter referred to as Λ-type). Note that for (iii), the heads of each pair of two pipes were joined using a nut and bolt. The reinforcement passes through the upper layer (D_r=30%) and is set into the lower layer (D_r=50%). For each type of reinforcement, as well as with no reinforcement, vertical and horizontal loads were applied to the foundation soil through the same load plate, and the displacement of the soil was measured at each loading stage.

3.2 *Effect of reinforcement on horizontal displacement*

Figure 4 shows the amount of horizontal displacement for each type of reinforcement, at the same load step as that of the final load before failure during the unreinforced test (vertical load 231.9 N, horizontal load 48.8 N). The dotted red lines represent the position of the reinforcements.

It can be seen that the amount of displacement decreases with increasing depth from the load plate. In the case of unreinforced soil, displacement appears in the form of an arc, whilst in the case of reinforced soil, the shape of the arc changes to become almost horizontal in the area of the reinforcement. Comparing the areas of horizontal displacement above 3.75 mm, the difference between Type I and Type II is not significant.

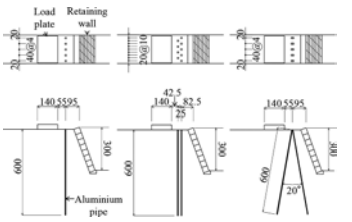

Figure 3. Types of reinforcement.

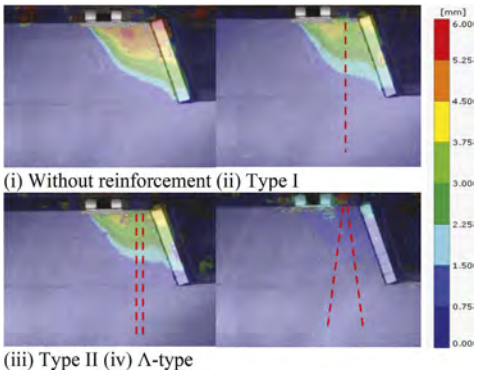

Figure 4. Horizontal displacement at vertical load of 231.9N and horizontal load of 48.8N.

On the other hand, in the case of the Λ-type, the maximum horizontal displacement is 2.25 mm at the same vertical load, indicating that the Λ-type is most effective at restraining the soil movement behind the retaining wall. The amount of horizontal displacement of the retaining wall based on image analysis was in the following order: no reinforcement > Type I ≈ Type II > Λ-type, when compared at the top of the retaining wall. Figure 5 shows the amount of horizontal displacement at final load before collapse of the retaining wall for the cases of no reinforcement, Type I and Type II, and at maximum load capacity of the apparatus for Λ-type. The grey areas immediately below the load plate show where large displacement occurred and the arrangement of the soil particles changed significantly, such that the amount of displacement could no longer be measured through image analysis. The red dotted lines represent the reinforcements and how much they have tilted due to ground deformation, assuming that the base of the reinforcement remains in the same position as in the initial loading stage.

In the case of no reinforcement, the grey area extends to the bottom of the retaining wall, showing the aspect of slip failure. On the other hand, in reinforced soil, a triangular soil "mass" appears between the reinforcement and the retaining wall, indicating the mitigating effect of the reinforcement on soil deformation. A comparison of the these "masses" clearly shows a size relationship of Type I < Type II < Λ-type, which is consistent with the results shown previously. From this, it can be seen that although for Type II, the increase in number of pipes does not give

a significant change in results compared to Type I, in setting the pipes in a Λ-shape, the resistance to horizontal displacement increases greatly.

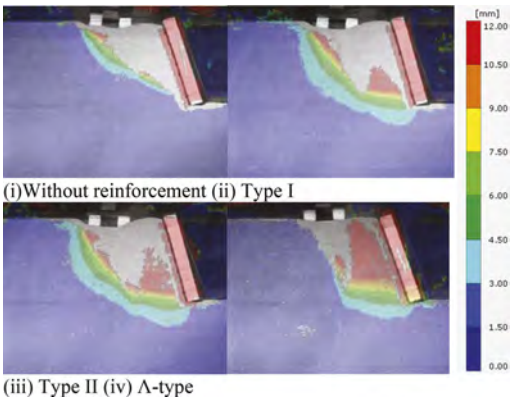

Figure 5. Horizontal displacement before collapse of retaining wall (at maximum load for Λ-type).

4 CONCLUSIONS

The displacement of the retaining wall and the deformation of the soil due to the application of vertical and horizontal loads on a simulated house on land behind a retaining were investigated using image analysis and the effectiveness of three types of reinforcement were compared. The findings are summarised as follows:

1) Simultaneous vertical and horizontal loading caused the retaining wall to collapse under a smaller total load than vertical loading alone. This is due to the predominant horizontal movement of the soil from under the load plate towards the retaining wall and the horizontal force due to soil displacement on the retaining wall.
2) In the case of unreinforced soil, displacement appeared in the form of an arc, whilst in the case of reinforced soil, the shape of the arc changed to become almost horizontal in the area of the reinforcement.
3) In the case of no reinforcement, an area of large deformation extended to the bottom of the retaining wall, showing the aspect of slip failure. On the other hand, in reinforced soil, a triangular soil "mass" appeared between the reinforcement and the retaining wall, indicating the mitigating effect of the reinforcement on soil deformation.

ACKNOWLEDGEMENTS

The authors would like to thank Professor Nakata of Yamaguchi University for his guidance, Mr. Kawasaki of Misawa Homes and Dr. Kuroyanagi of Hokoku Engineering for their assistance in this research. We hereby express our gratitude.

Effect of incorporating kaolinite geopolymer on some mechanical properties of subgrade soil

A.H. Abdulkareem & T.M. Ahmed
Department of Civil Engineering, University of Anbar, Anbar, Iraq

N.F. Kwad
College of Engineering, University of Anbar, Anbar, Iraq

ABSTRACT: Subgrade soil is a critical element in the pavement system and can be considered as one of the major challenges for civil engineering applications. This paper investigates the efficiency of geopolymer material in sandy silt soil stabilization in terms of the strength and durability. Various proportions of the kaolinite (5, 10, 15, 20, 25, and 30%) by weight were used as a raw material to produce the geopolymer. The alkaline liquid consists of the NaOH at 8M and Na2SiO3 liquid, at 1.5 ratio of the NaOH:$Na2SiO_3$. Laboratory investigation involves the compaction and mechanical properties of the natural and stabilized soil mixtures. The results showed a great improvement in the strength of the soil in terms of the unconfined compressive strength (UCS) and the indirect tensile strength (ITS). The optimum content of the kaolinite was 15%, which achieved the maximum UCS and ITS values. The CBR index of the soil significantly increased with the kaolinite-based geopolymer. Specimens stabilized using the optimum content of the kaolinite-based geopolymer did not pass the durability test in terms of the weight loss and volume change. The microstructural analysis of the stabilized specimens showed a poor distribution of the geopolymer binder. Moreover, pores were clear in the structure and this may indicates the poor behavior during the durability test.

1 INTRODUCTION

The subgrade layer is a foundation for the pavement structure, which represents the in situ or the modified soil that provides the support to upper layers of pavement system and distributes traffic loads within the soil. The subgrade impact is a critical for the pavement design and long-term performance, where the strength and stiffness of the subgrade soil are the most important factors to define the quality of the subgrade material. High-quality subgrade reduces the thickness of the upper layers, especially the pavement layer. This leads to a significant cost reduction in road construction. The strength and stiffness of the subgrade can be determined by conducting common tests such as the California Bearing Ratio (CBR), Resilient Modulus, Unconfined Compressive Strength, Indirect Tensile Strength and Modulus of Subgrade Reaction [1].

Kaolinite is a clay mineral and produced naturally through weathering or by hydrothermal process of aluminosilicates-rich rocks such as granite. Kaolinite as a clay mineral is generally composed of $Al_2Si_2O_5(OH)_4$. Kaolin terminology comprises both of the raw clay and the net commercial kaolin [2]. The white color and the fine particles distinguish the kaolin from the other types of clay. Kaolinite clay is a suitable raw material for geopolymer production. The kaolinite is aluminosilicate material can be activated by the alkali solutions to produce the geopolymer binder. Many researchers utilized the kaolinite in geopolymer production. The compressive strength of kaolinite-based geopolymer was studied by [3]. Various concentrations of NaOH (6-14 mol/L) was used and cured at 80°C. Three periods of curing, i.e. 1, 2, and 3 days were tested in the study. It was reported that NaOH concentration of 12 mol\L is sufficient for strength development. The compressive strength also showed a proportional trend with the increasing curing period, where the samples cured for three days in oven achieved the highest compressive strength.

DOI: 10.1201/9781003299127-89

Synthesis of kaolinite-based geopolymer at various conditions was studied by [4] through the calcined kaolinite to produce the reactive metakaolin by heating the kaolinite at several temperatures, i.e. 550, 700, 900, and 1100°C. The produced material was used to form the geopolymer binder. The Potassium hydroxide (KOH) and NaOH were used at a molarity ranges between 5 to 18 mol\L. It can be noticed that 700°C is the temperature required to produce metakaolin with the highest level of reactivity. At this temperature and at a base concentration of 13 M, the various physical characteristics reached their ideal levels. Moreover, the physical and mechanical properties of the geopolymer were evaluated. The results showed that the compressive strength of geopolymer samples were extensively low for samples activated by NaOH and KOH solution below 10M concentrations. Further increase in the molarity, i.e. 13M of NaOH and 15M of KOH maximized the strength and the density. While the porosity showed an adverse behavior to the compressive strength. The relatively low porosity was observed for the specimens at the maximum compressive strength and optimum density. However, water absorption was low. The influence of the alkali solution concentration in the kaolin-based geopolymer was studied by [5] . The outcomes revealed that 8M is the optimum molarity for NaOH solution, which provided the highest compressive strength. Also, the scanning electron microscope (SEM) images confirmed the presence of geopolymer binder as a dense structure. The results obtained showed that the temperature required to obtain a metakaolin with the highest degree of reactivity is approximately 700°C. The various physical properties reached optimum values at this temperature and for base concentration equal to 13 M. These values decreased at higher temperature and concentration.

The results indicate that 700°C is the temperature required to produce metakaolin with the highest level of reactivity. At this temperature and at a base concentration of 13 M, the various physical characteristics reached their ideal levels. At higher temperatures and concentrations, these values decreased.

The study aims to investigate the strength and durability of soils in the subgrade layer after the incorporation of kaolinite - geopolymer mixture. The main interest of the study is the incorporation of a chemical stabilizing agent and kaolinite with the soil. This may produce high-quality material that can be used as a roadbed or stiff foundation for the road. The kaolinite and the chemical agent used in the study are available and can be utilized in Iraq.

2 MATERIALS AND METHODS

2.1 *Soil*

One type of soil was used in this study and collected from Msheheeda quarry in Ramadi city. The soil consists of 60% of silt, 9 % of clay and 31% of fine sand. Due to the high content of silt, the soil is classified as sandy silt according to the USCS system. The physical and chemical properties of the soil are presented in Tables 1 and 2 respectively. The chemical composition shows that the soil is composed mainly of the silicon, aluminum, and calcium oxide. The result of the X-Ray Diffraction (XRD) test is presented in Figure 1, which describes the crystalline structure and the mineral compounds of the soil. The soil has a lamellar composition and exhibited loosely structure as shown in the SEM image in Figure 2.

2.2 *Kaolinite (kao)*

Kaolinite is the alumina-silicate material used to produce the geopolymer. It was dried at ambient temperature as shown in Figure 2. More than 71% of the kaolinite particles passed No.200 sieve. The chemical composition through the X-Ray Fluorescence test is listed in Table 2. The specific gravity of the kaolinite is 2.35. The chemical analysis showed that the amount of silica and alumina are high, while it has a low content of CaO.

2.3 *Alkaline activator solution*

The alkaline activator solution consists of 99% pure sodium hydroxide (NaOH) pellets and sodium silicate (Na_2SiO_3) liquid. The concentration of NaOH was 8 molar, as 40 g/mole is the NaOH molecular weight. The liquid form of the sodium silicate (Na_2SiO_3) contains 32.5% of SiO_2, 13.4%

of Na_2O, and 54% of water. The NaOH:Na_2SiO_3 ratio was 60:40. The UCS test was performed to assess the variation in the strength with different molarity of NaOH and NaOH:Na_2SiO_3 ratios.

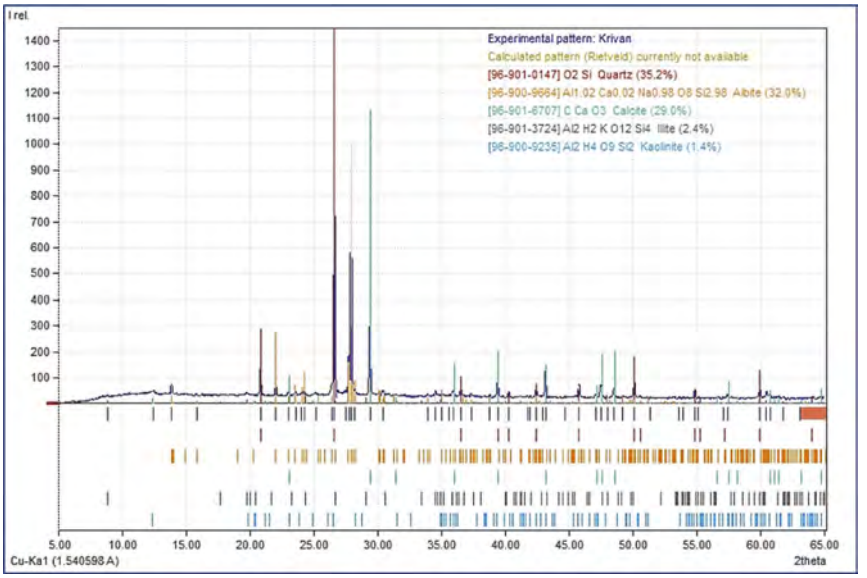

Figure 1. X-ray Diffraction (XRD) pattern of soil.

Figure 2. (a) Dried soil (b) SEM image of soil (c) Kaolinite.

2.4 *Sample preparation*

The oven-dried soil was mixed with the kaolinite and the alkali solution to produce the geopolymer material. The mechanical mixing was used to ensure a homogeneous mixture. Specific

weights of soil and kaolinite were mixed prior to the alkaline solution addition. As estimated by the compaction test, the alkali content corresponds to the optimum moisture content of the mixture. The extra weight of the alkali liquid was added to the blend to compensate the dissolved NaOH weight in the solution. The extra weight is approximately 30 % at 8 M of the NaOH concentration [6]. The UCS test specimens were compacted into steel molds with a diameter of 100 mm and a height of 200 mm according to the requirements of the ASTM D4219-08. The alkaline solution has been used as a replacement for the OMC of the soil-kaolinite mixtures. For each mixture, three samples were prepared. UCS test was carried out at a constant loading rate of 0.1 kN/sec. The ITS test involves preparing soil specimens compacted under the modified effort method. The ITS value can be calculated by:

$$\sigma_t = (2P/\pi dt) \tag{1}$$

Where:
σ_t = Tensile strength (MPa)
P = Maximum load at failure (N)
d = Diameter of specimen (mm)
t = Thickness of specimen (mm)

The percentages of kaolinite in the UCS and ITS tests were (5, 10, 15, 20, 25, and 30 %) by weight of the soil. CBR test involves applying gradual loads using cylindrical piston (Plunger) having 50 mm diameter at constant penetration rate of 1.3 mm/minute according to ASTM D1883-14. CBR index is given by Equation 2 [10]:

$$CBR\% = (X/Y)100 \tag{2}$$

Where:
X: The load (pressure) required to have a penetration of 2.54 mm or 5.08 mm
Y: Standard load (pressure) of the well-graded crushed stone, which are:
6.9 MPa for 2.54 mm penetration
10.3 MPa for 5.08 mm penetration

The CBR specimens were soaked in water for 96 hours before the test. Mixing time was 10 minutes, dry mixing by hand for 3 minutes and mechanical mixing for 7 minutes to ensure the uniform distribution of the alkaline solution and the mixture components. The stabilized samples were molded and cured in the oven for 48 hours at 65°C for the UCS, ITS and CBR tests. After the heat-curing which depending on previous study, the specimens were removed from the oven and covered by cling film and kept at room temperature to be tested after 7 and 28 days. The modified proctor test was performed according to ASTM D 1557-12 in order to obtain the moisture-density relationships.

3 RESULT AND DISCUSSION

3.1 *Compaction test*

Figure 3 presents the moisture-density curves of the soil-kaolinite blends. It can be seen that the maximum dry density increased from 1.73 g/cm^3 for the natural soil to 1.94 g/cm^3 for soil +30% kao. While the optimum water content decreased from 15.5% for the natural soil to 13% for the soil+30% kao mixture. Also, Figure 3 shows a noticeable increase in the maximum dry density of the soil at the various kaolinite percentages and obvious decrease in the optimum moisture content at the same percentages. The clear trend of compaction curves reveals that adding more of kaolinite to the soil leads to higher MDD and less OMC. The higher MDD may be attributed to the role of the fine particles of kaolinite, which are likely to fill the pores in the soil as a filler material resulting in a denser state in the soil. In addition, there is no evidence of kaolinite reaction with the water; this justifies the OMC decrease at the high content of kaolinite. It is also known that the compaction results are highly affected by the compaction energy, where the modified proctor method is likely to result in higher densities due to the higher energy applied to the soil.

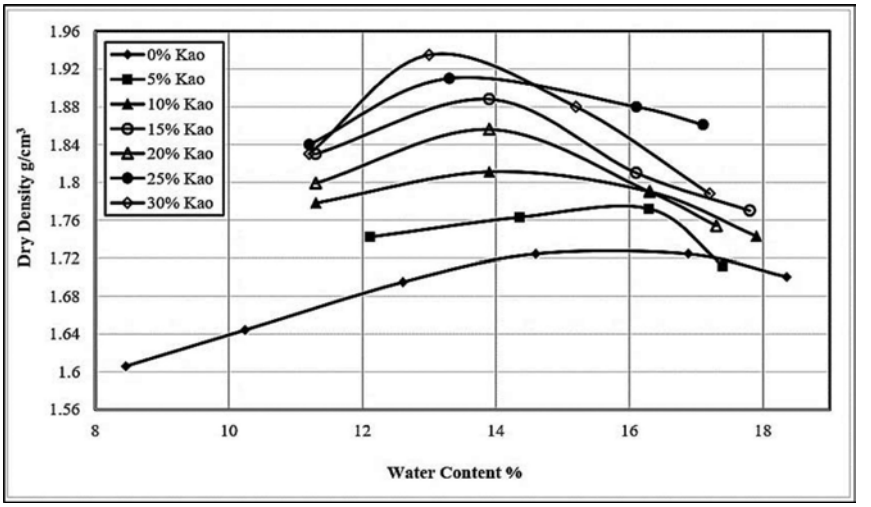

Figure 3. Moisture-density relationship of soil-kaolinite mixtures.

3.2 *Unconfined Compressive Strength (UCS) test*

The UCS is one of the major mechanical properties to be considered in the soil. UCS test was conducted to evaluate the effectiveness of the kaolinite-based geopolymer as a soil stabilization agent. The results of the UCS test at 7 and 28 days of curing time are shown in Figure 4. It can be noticed that the kaolinite-based geopolymer significantly improved the UCS of the soil and the maximum strength observed at 15% of the kaolinite percentage by weight of the soil irrespective of curing period. By inspecting Figure 5, it can be observed that low percentages of kaolinite (10% and 15%) provided the highest strength at the early ages in comparison with the other percentages. In addition, there was no big variation between 7 and 28 days cured specimens except the specimens that contain 20% of the kaolinite content which exhibited a noticeable gap in the strength. This behavior is related to the fact that 48 hours of curing at 65°C corresponds to 28 days of curing at the room temperature as found by [7].

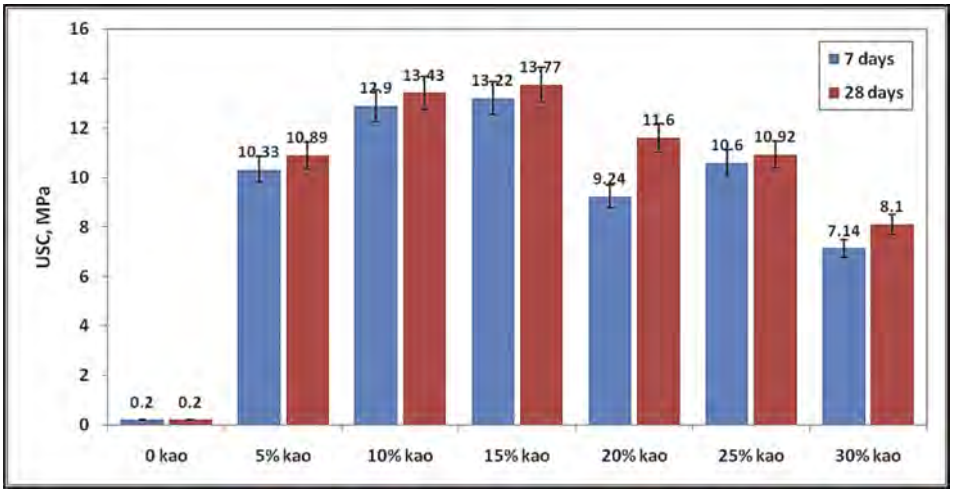

Figure 4. UCS test results of the soil–kaolinite geopolymer at 7 and 28 days.

This behavior may be attributed to the curing time, as 48 hours of curing at 65°C corresponds to 28 days of curing at the ambient temperature as found by [7]. Brittle failure was observed in the stabilized specimens as shown in Figure 6. This pattern of cracks points out the stiff structure within the soil. The kaolinite has a chemical composition of silica and alumina particles which make it proper material in geopolymer synthesis. However, there is no clear study investigated the results of kaolinite-based geopolymer in the silty soil stabilization.

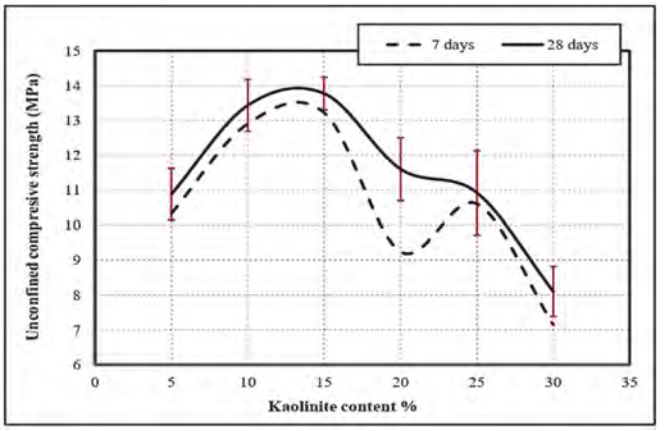

Figure 5. Variation of UCS with Kaolinite content for soil- kaolinite geopolymer mix.

Figure 6. Failure of soil-kaolinite geopolymer UCS test specimen.

3.3 *Indirect Tensile Strength (ITS) test*

The interest in tensile property of the stabilized soil due to concerns related to cracking behavior in the fully bonded materials. The soil is very weak in tension and may easily collapse under the light tension stresses.

Figure 7 shows ITS test results of soil with kaolinite geopolymer at 7 and 28 days of curing period . It can be seen that there was no significant variation in the tensile strength between 7 and 28 days cured specimens at the low content of kaolinite. The noticeable variation occurs at the higher content of the kaolinite. This behavior may be attributed to the continuous geopolymerzation reactions of the kaolinite particles with the alkali liquid. These reactions take place in the soil structure at ambient temperature. However, this increase insignificant for the long-term performance, where the geopolymer material gains most of the compressive strength by heat-curing at 70-80°C [8]. Figure 8 shows the clear splitting of the stabilized specimens in the longitudinal plane after conducting the ITS test.

3.4 *California Bearing Ratio (CBR) test*

CBR index provides significant information about the bearing capacity of the soil and compare it with the strength of the well graded crushed stone which possess a high strength and CBR index by 100% [9].

All CBR tests were performed according to (ASTM D1883-14). Kaolinite percentage used in the CBR test was the optimum proportion estimated from the UCS and ITS tests which is 15% by weight. The CBR index of the natural soil is 3.8% at the soaked condition. The load-penetration curve of the soaked soil-Kaolinite geopolymer mixture is shown in Figure 9. It can be seen that 2.54 mm of penetration into the soil surface requires corresponding load of 19.24 kN, while a penetration of 5.08 mm requires 31.54 kN. The CBR index was 143% at 2.54 mm and 162% at the 5.08 mm penetration. The CBR value for the stabilized soil is 162% according to the ASTM D1883-14. This means that the CBR index has improved to 40 times

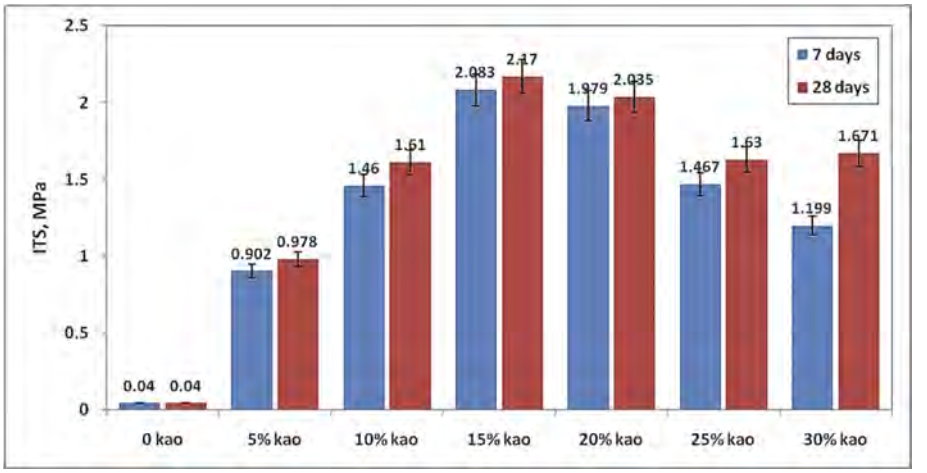

Figure 7. Effect of soil–kaolinite geopolymer on ITS test with curing period at 7 and 28 days.

Figure 8. Failure of ITS test specimens of soil-kaolinite-based geopolymer mixture.

after adding the kaolinite-based geopolymer to the soil, which is significant improvement in the soil strength. The increase in the CBR index indicates that the bearing capacity and the shear strength of the stabilized soil were highly improved [11]. The chemical composition of the kaolinite is the key factor in the geopolymer synthesis. The high amount of the silica and alumina in the kaolinite material determines the nature of the new products in the soil. In addition, the heat curing at 65°C accelerates the geopolymer reactions and synthesis, consequently, rapid strength gain in the stabilized soil.

3.5 *Durability test*

Long-term performance of the stabilized soil is one of the important concerns in the chemical stabilization methods. The new chemical components in the soil may be affected by water, especially the effect of chemical leaching of the new chemical products. The test was conducted according to the method outlined in ASTM D559-15. This method can be applied by subjecting accelerated moisture fluctuations to simulate the actual conditions in the field during the seasonal variation. The optimum mixture of the kaolinite (15%) was also adopted in the test. Wetting and drying conditions were subjected on the same specimens size that used in the UCS and ITS tests. One cycle of the test involves immersing the specimens in the water for 5 hours followed by 42 hours of drying in the oven at 70°C and one hour for stroking and taking weight and volume records. The test results are listed in Table 3. The specimens could not sustain its stability after two cycles of wet/dry conditions, and it collapsed after taking it out from the water in the second cycle as shown in Figure 10. This rapid collapse of specimens may be attributed to the weak bonds of the alkali activated material inside the soil. Also, the leaching of the

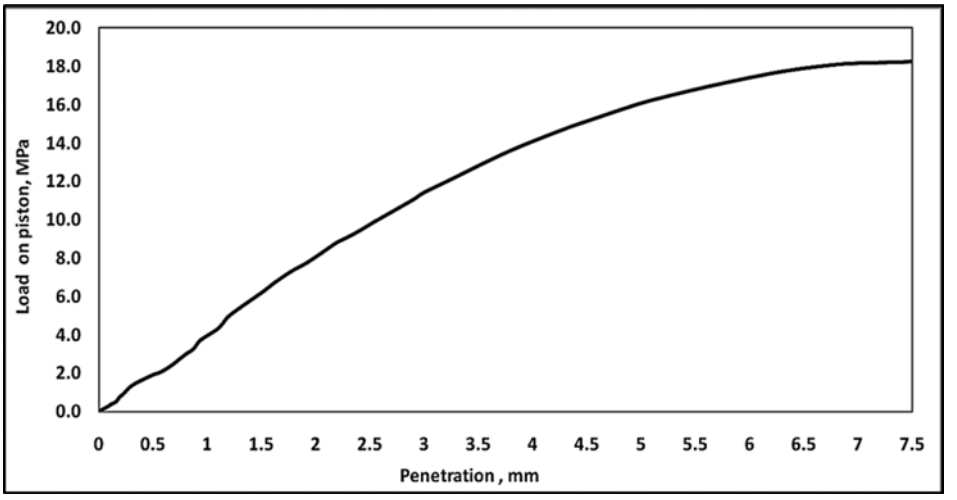

Figure 9. Load – Penetration curve of CBR test for the soil +15 Kao mixture.

alkali material due to water infiltration inside the voids may be one of the factors that affected the stabilization efficiency. The rapid loss of consistency in kaolinite geopolymer stabilized specimens may be due to the small cracks in the mixture. These cracks caused by the reaction between the reactive-silica in the soil and kaolinite with the hydroxide from the alkali liquid. This reaction increases the volume of the specimen and cracks formation due to the new products [12]. The collapse of the specimens may be considered as an indicator of the calcium role in the geopolymer reactions, as the calcium may prevent the formation of the geopolymer binder at the early ages of the alkaline activation resulting in weaker structure in the soil.

Table 3. Wet-dry test results after 28 days of curing period.

Mixture	Weight loss %	Volume change %	Durability against W-D conditions
Soil+15Kao geopolymer	Collapsed	Collapsed	Failed

Figure 10. Soil stabilized using kaolinite geopolymer after two cycles of W-D conditions test.

3.6 *Microstructure*

The microstructural analysis presents valuable evidence on the new transformations after the geopolymer addition to the soil. Figure 11 shows the SEM image for the natural soil. It is

obvious that the soil has a laminar composition and loosely structure. Also, the soil composition was inhomogeneous and contains scattered voids as shown in Figure 11.

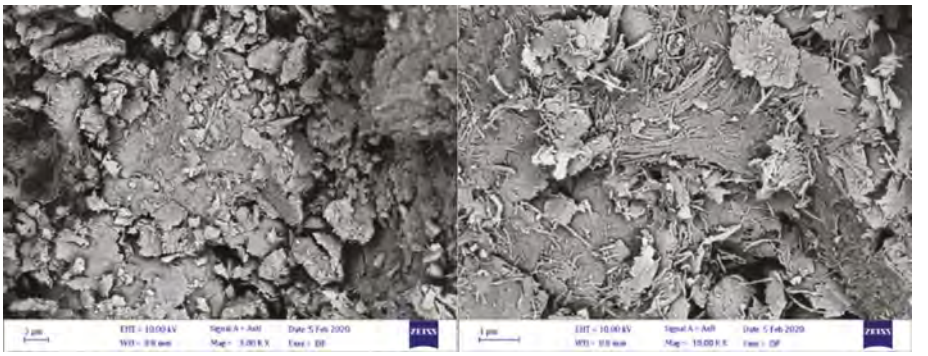

Figure 11. SEM images of the natural soil.

The SEM image of the soil and kaolinite geopolymer mixture is shown in Figure 12 and the size analysis is shown in Figure 13. The analysis of these images indicates the formation of the geopolymer binder in nanometers size. However, it can be observed that the microstructure of this blend has a lot of connected pores distributed randomly in the structure. These pores explain the poor performance of the stabilized soil in the durability test as the geopolymer binder did not fill the soil voids and bind it strongly. The structure of kaolinite geopolymer was likely to be a plate-like structure as shown in Figure 12. The particles act as combined plates to form layered texture with small surface area [13]. The SEM images confirm the loose state of the kaolinite geopolymer in the soil and the presence of unreacted kaolinite particles accumulated around the soil particles. In addition, the lamellar texture was observed in the microstructure, which results in weak composition and performance. In addition, accumulated C-S-H gel was observed with high intensity in the microstructure of the soil-kaolinite geopolymer mixture as shown in Figure 13.

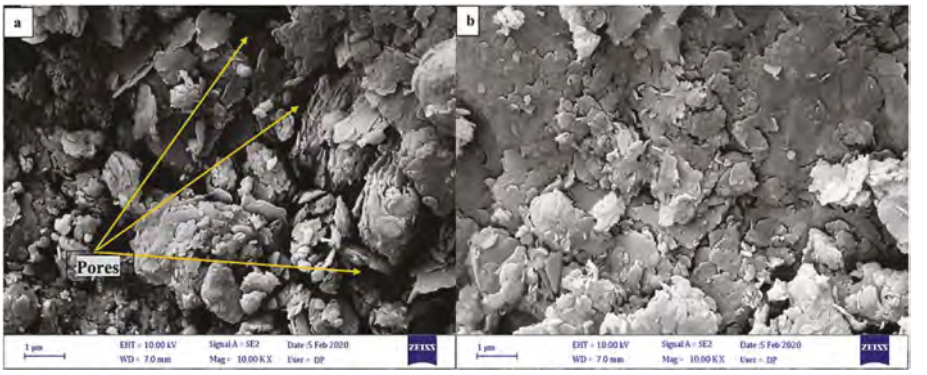

Figure 12. SEM image of soil+15Koalinite geopolymer mixture at 1μm magnification, a) micro pores b) Plate-like structure.

4 CONCLUSIONS

The study proves the efficiency of using kaolinite based geopolymer in weak subgrade soil stabilization. The following conclusions are drawn:

- As kaolinite content in the soil increased, the MDD increased while the OMC reduced in the same proportions. When kaolinite was 15% of the soil's weight, the MDD increased from 1.73 g/cm^3 of natural soil to 1.93 g/cm^3.

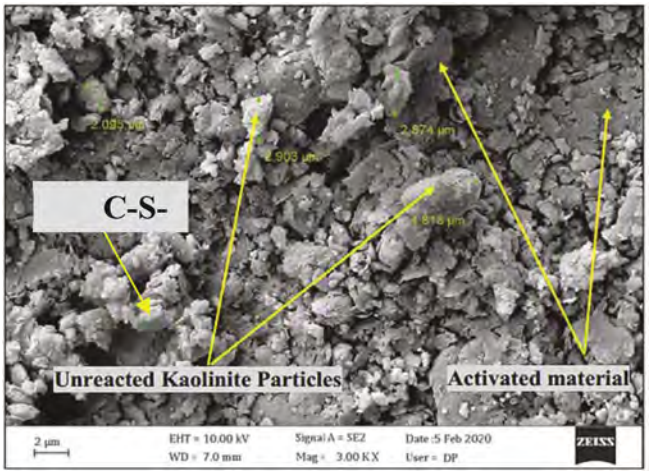

Figure 13. Size analysis using SEM image for the soil with kaolinite geopolymer mixture.

- The UCS strength of the stabilized soil was improved significantly at the optimum content of the kaolinite compared to the natural soil at both 7 and 28 days of curing time.
- The tensile strength of the stabilized soil increased significantly after the addition of the kaolinite based geopolymer.
- CBR index was highly improved due to the kaolinite geopolymer addition. The stabilized soil exhibited high CBR index by 162%.
- The stabilized specimens by the kaolinite-based geopolymer did not pass the durability test and exhibited bad performance in the initial cycles.
- When the soil's microstructure was analyzed using SEM images, weak and random geopolymer binder was found in the kaolinite-based geopolymer stabilized soil.
- It is recommended to study the influence of the low temperatures below 25°C on the strength development of the stabilized soil by the geopolymer. This is important to reduce the curing temperature and period of the geopolymer as it one of the most critical challenges in the site applications when it used with the soil or as a geopolymer concrete.

ABSTRACT: Taken the environment into consideration, in geotechnical engineering waste materials are tested to prove their compatibility for soil improvement. One such product is fly ash, being waste of the coal burning process. Fine-grained soils enhanced with fly ash have shown to have better strength and deformation properties, as well as benefits as fill material. However, the properties of sandy soil mixtures have not been extensively investigated. Therefore, research has been started by determining the chemical properties of the fly ash samples, followed by specialized tests in the field of soil mechanics, on samples of fly ash and Skopje sand, in order to identify the benefits of such mixtures. This paper has the purpose to present the obtained results from monotonic triaxial tests on Skopje Sand – fly ash mixtures with different percentage of fly ash, namely 5, 10 and 20%, tested under effective stress of 100 kPa.

1 INTRODUCTION

As the term "Environmental Geotechnics" is becoming more popular, globally there is an intensive tendency for use of waste materials instead of their deposition in landfills. One such product is the fly ash, being waste or secondary industrial product of the coal burning process. Fly ash has been greatly examined for use in civil engineering, especially for soil improvement in road construction. Additives as fly ash can improve the mechanical and chemical properties of the soils such as strength, swelling, plasticity index and compressibility (Amiralian et al., 2012). Its compaction properties have been widely studied for road construction (Beeghly, 2003; Senol et al, 2006; McCarthy et al., 2009; Santos et al, 2011; Vukićević et al, 2019), as use of fly ash in practice has been frequently reported (Beeghly, 2003; Parsons and Kneebone, 2005; Edil and Benson, 2007; Jackson et al, 2007; Lin et al, 2009; Trast et al, 2011). However, there are less studies for mixtures of sand and fly ash, such as those by Keramatikerman et al. (2017) and Kolay et al. (2019). This paper presents the results from monotonic triaxial tests done on mixtures of the natural Skopje Sand and fly ash.

The chemical properties of fly ash depend on the composition of coal, as well as the technology of burning. Therefore, the chemical composition of fly ash must be examined first for its suitability. The chemical characterization of the used fly ash is also presented in this paper accompanied by classification of the used sand and mixtures.

2 PROPERTIES OF THE USED MATERIALS

2.1 *Fly ash (FA)*

The used fly ash in this study is from location of freshly deposited fly ash. Therefore, the properties of fly ash are in relation to the composition of the coal burnt at the time of sampling as well as the

DOI: 10.1201/9781003299127-90

current burning technology in the power plant. Table 1 presents the chemical composition of the fly ash, which classifies the fly ash in Class F, according to the standard for definition of the fly ash class ASTM C618 (2019). It should be noted that the used fly ash does not contain organic toxic elements and compounds, or any excessive trace elements, so it can be further used.

Table 1. Chemical composition of the used fly ash.

Oxide	(%)
Al_2O_3	23.85
BaO	0.073
CaO	3.49
Fe_2O_3	8.14
K_2O	3.00
MgO	1.95
MnO_2	0.31
Na_2O	0.89
P_2O_5	0.20
SO_3	0.60
SiO_2	54.61
SrO	0.035
TiO_2	0.84
LOI	2.875

Additionally, microscope imaging was done for the fly ash using Scanning Electronic Microscopy (SEM). This test is useful to discover the shape of the particles as well as the range of their size. As it can be observed in Figure 1, the fly ash does is not consisted only of spherical particles called cenospheres. Despite irregular particles being present, also there are groups of particles attached to each other forming groups of particles called flocculations, which could not be dispersed by the method of ultrasound. Also, the particle size distribution was determined for the fly ash, being classified as sandy silt with a little clay (Figure 2).

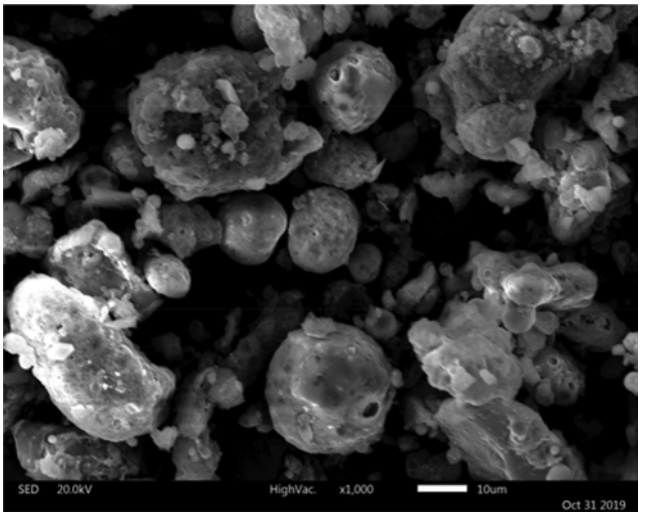

Figure 1. SEM image of fly ash with magnification 1000x.

2.2 *Skopje Sand (SS)*

The sand used in this study is called Skopje Sand. It is a natural sand from the alluvial deposit from river Vardar in the region of the city Skopje. It has been used in previous studies

(Bojadjieva, 2014 et al; Bojadjieva, 2015; Kitanovski et al, 2018; Bojadjieva, 2019) as clean sand, however this is the first extensive study for mixtures of Skopje Sand and fly ash. This sand is classified as poorly graded sand with silt (Figure 2).

2.3 *Skopje Sand – fly ash mixtures*

The main tests in this study are done on samples of Skopje Sand mixed with fly ash. The percentage of fly ash was chosen to be 5, 10 and 20% in order to be able to observe the influence of low but also high percentage of fly ash in the sand. According to the results from the particle size distribution test, the mixture with 5% fly ash is poorly graded sand with silt, the mixture with 10% fly ash is well-graded sand with silt, whereas the mixture with 20% fly ash is silty sand (Figure 2).

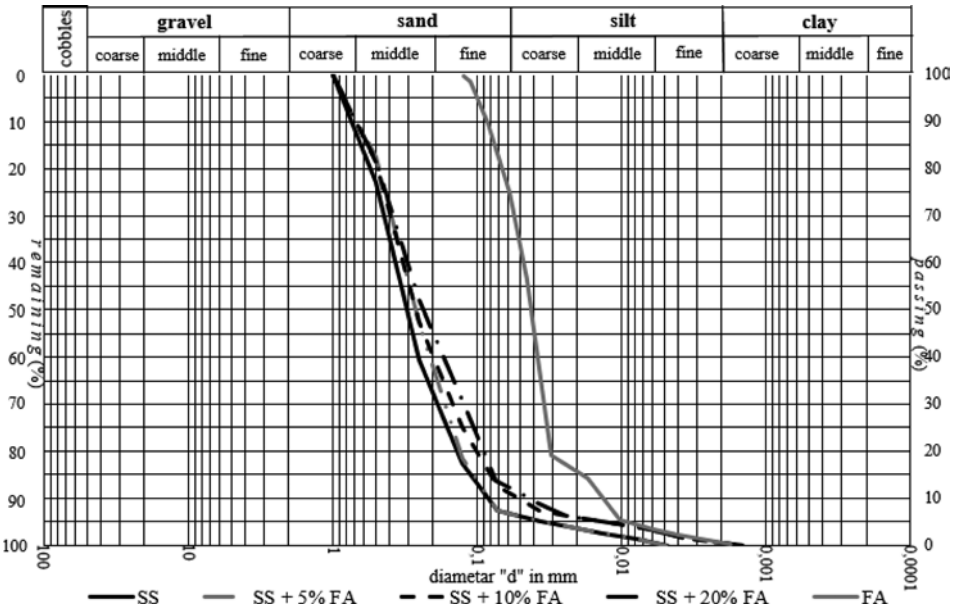

Figure 2. Particle size distribution of Skopje Sand, fly ash and their mixtures.

3 MONOTONIC TRIAXIAL TESTS

The possibility to use fly ash for soil improvement or soil replacement is studied through element tests such as triaxial tests. It was decided to perform triaxial tests on samples with relative density around 50%, with effective stress of 100kPa, using the same sample preparation procedure with wet tamping as in the work by other authors (Edip, 2013; Bojadjieva, 2015; Edip et al, 2018; Bojadjieva et al, 2018). The monotonic compression drained tests are performed with loading rate 0.2mm/min and axial strain limit of 15%. Considering that Bojadjieva (2015) performed an extensive testing program on Skopje Sand, this study is continuation of her work. It is used as referent for comparison of her results for clean Skopje Sand and the results of this study for mixtures of Skopje Sand with different amount of fly ash. The results from monotonic triaxial tests performed on clean Skopje Sand by Bojadjieva (2015) and on mixtures of Skopje Sand and fly ash done in this study are presented in Figure 3.

It can be noticed that the mixture with 5% fly ash shows the highest peak deviatoric stress which supersedes the peak strength of clean Skopje Sand, referring to soil improvement. It can be noticed that this mixture follows the referent Skopje Sand after the peak value with almost parallel trend towards the residual strength. As the amount fly ash increases the peak strength drops, so the Skopje Sand with 10% fly ash mixture has slightly lower peak strength than clean Skopje Sand. The effect is more drastic for the Skopje Sand - 20% fly ash mixture in which case the deviatoric stress requires higher axial strains to reach peak value.

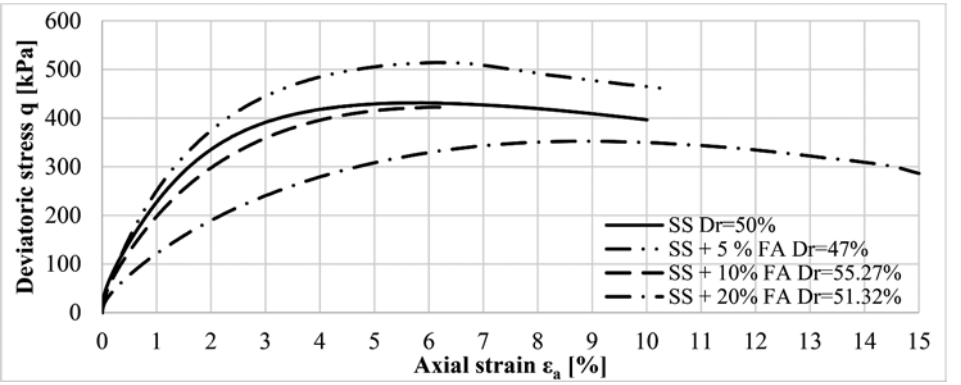

Figure 3. Deviatoric stress versus axial strain for clean Skopje Sand and mixtures with fly ash.

4 CONCLUSIONS

From environmental aspect the use of fly ash is of high importance. This paper presents the results from monotonic triaxial test on mixtures of natural Skopje Sand and fly ash with different percentage.

The strength properties of Skopje Sand can be improved with low quantities of fly ash, around 5%. If fly ash is mixed with Skopje Sand for soil replacement purposes, at higher percentage of fly ash the mixtures have to be with higher relative density in order to retain the referent strength properties of Skopje Sand at certain relative density.

Based on these initial results, it is recommended that the further work should be in direction of testing mixtures with different percentage of fly ash in order to establish correct mathematical correlation between the percentage of fly ash and the peak strength. Also, field tests or large scale laboratory tests can be performed and compared to the laboratory results from the element tests in order to validate the proposed assumptions.

Ricky K.N. Wong
Sanshin Construction (Thailand) Co., Ltd., Bangkok, Thailand

ABSTRACT: The undrained shear strength is a critical design parameter in the design of soil-cement columns for ground improvement projects. This paper presents an evaluation of undrained shear strength in soil-cement columns constructed with the dry mixing method for Bangkok soft clay. The relationships between undrained shear strength and design parameters including cement content, total water-cement ratio, curing time, and natural moisture content were established using machine learning (ML) techniques in this study. Soil samples of soil-cement column (SCC) were obtained from two sites including the AIT site and Highway No. 35 site. Different varieties of cement contents were mixed using the dry method to prepare laboratory SCC samples with curing times of 7, 14, and 28 days. The SCC samples were utilized to develop models including the multivariate regression (MLR) model, random forest (RF) model, and artificial neural network (ANN) regression model for prediction of the undrained shear strength. The coefficient of determination (R^2), mean absolute error (MAE), and root mean square error (RMSE) were used as performance detectors for different models. It was found that R^2 values for all models ranged from 0.70 to 0.99 for the training data and from 0.5 to 0.94 for the testing data. A linear equation using the MLR model to predict undrained shear strength was proposed using cement content, natural moisture content, and curing time as the primary parameters. Various graphs to predict undrained shear strength were also proposed using the RF and ANN models.

1 INTRODUCTION

Soil cement column is the application of deep mixing for ground improvement projects. It is a technique in which the grout is injected using the tip of a mechanical icer consisting of a basic drilling head and separated horizontal blades. It is generally used with lime or cement in soft soil. The main purpose of this method is to improve the soil, physical and mechanical characteristics. The wide range of applications that address a variety of geotechnical issues includes road and railway subgrade reinforcement, supporting deep excavations and protecting surrounding structures, slope stabilization retaining walls, cut-off walls, seepage control, improving the ground under existing construction, applying shallow foundations for future construction, and remediation of pollutant soil (P. G. Nicholson, 2014) and (Porbaha, 1988). There are two type of soil cement mixing methods; dry mixing method (DMM) and wet mixing method (WMM). In this study the DMM was used to improve the soft clay in Bangkok, Thailand.

There are fewer control elements in the DMM, such as cement content (C), curing time (CT), machine execution, and so on, making the task more difficult than in other types of mixing

DOI: 10.1201/9781003299127-91

methods. Because the natural moisture content (NMC) and the cement mixture are not regulated during the process, it is more complicated in the DMM to estimate the strength. Most construction firms encounter these challenges. So, to improve the projects using this technique, the most appropriate way of prediction is required. Permeability, compressibility, and shear strength are the key mechanical characteristics of the soil to be determined before use. In soft soils, like Bangkok clay, these characteristics fail to perform, so improvement is needed to increase its workability. In soil cement columns the shear strength plays a vital role, and the prediction for that is a difficult task in a laboratory and in a field. In this study, certain parameters which influence the shear strength of the soil cement columns were considered to predict the undrained shear strength. Empirical equations developed by utilizing statistical methods and data from extensive laboratory or filed testing are commonly used in geotechnical engineering practice to estimate undrained shear strength. Prediction of the undrained strength with multivariate parameters is a complex work. Therefore, machine learning (ML) was used in this study to conduct the prediction of the undrained shear strength efficiently and accurately.

The use of ML in geotechnical engineering has developed significantly in recent years (Shahin M. A., 2004); (Zhang, 2021); (Jin Y. F., 2019), (Jin Y. F., 2019), (Jin Y. F., 2019) to assist in estimating geotechnical engineering parameters. There are three major categories of ML algorithms, Supervised learning; Unsupervised learning, and Reinforcement learning. In this study, supervised learning algorithms is more highlighted than the others.

In this study, the supervised learning technique was used as Random Forest (RF), a model to predict the undrained shear strength. Random Forest, a well-known supervised ML algorithm, is a nonparametric methodology evolved from classification and regression trees (CART) that solves problems using the ensemble learning method (Breiman, 2001). The term "RF" refers to the building of multiple trees, each of which is created by bootstrap samples (H-B., 2020). Then, a specific number of samples are maintained for validation, which is referred to as out-of-bag predictions (OOB).

A random procedure was used to produce a subset of the predictors at each node of the tree. The ultimate output of RF is the average of all the trees' findings (Breiman, 2001). The data set was separated into two parts: training and testing. Model learning was implemented using a training set, and the correctness of the model is determined using a test set (Kulkarni, 2013). The training test was used to produce a tree, and a random vector that is independent of previous random vectors with the same distribution (Breiman, 2001) has presented a randomization method that is more effective than bagging or the random space method.

2 METHODOLOGY

2.1 *Sampling and testing*

The soil test samples were collected GTE's testing field at AIT and the Highway No. 35 Bang-Khun-Thain-Ekachai intersection (part-1) in Bangkok, Thailand. The obtained samples were used to evaluate physical properties and prepare specimens using the dry method of deep mixing. The base clay in this study is Bangkok soft clay. A rotary driller was used to extract undisturbed samples up to 8.5 m below the ground surface. Atterberg limit, uniaxial compression (UC) test, total unit weight, and dry unit weight were determined. The dry method was used for the preparation of the SCC specimen. After mixing was completed, the treated soil was immediately used to prepare for testing.

Cement amounts of 150, 175, 200, and 250 kg/m^3 were tested. The mold of the specimen was wrapped in plastic foil and stored in a humid condition box for 7, 14, and 28 days of curing. The water content and unit weight of the sample were determined before testing in accordance with the guidelines from (ASTM-D2216, 1998) and (ASTM-D7263, 2021), respectively. The UC test was performed following (ASTM-D2166-00., 2000) recommendations. The same method was used to prepare samples obtained from the Highway No. 35 site, with slight variation in curing times of 1, 3, 7, 14, and 28 days and cement amounts of 150, 175, 200, and 250 kg/m^3. Compressive strength data were compiled from both sites.

A total nine parameters including natural moisture content, plasticity index, unit weight, maximum dry unit weight, cement content by amount, curing time, total water-cement ratio, undrained shear strength and cement content by weight were determined for samples obtained from the two study locations The laboratory and field shear strengths were separated from both sites and compiled together. The total number of data points is 92. The compilation was completed with the goal in mind. Separate data compilation was performed for prediction models and correlation analysis. The laboratory data obtained from both sites were used to create prediction models.

Using the deep machine learning method, the relationship between strength and other parameters was chosen. For this process, the 'seaborn' library was chosen, and a heat map was generated using 'SciPy' Stats library. The function "Pearson r" was used to evaluate the R^2 value between two variables. The heatmap shows each R^2 value for the correction. The input parameters were then chosen by observing the highest value.

Three models were proposed for the prediction of the strength of the SCC constructed by DMM. A trial-and-error method was conducted for each method to improve the accuracy of the model, considering the most effective input parameter. The following section describes the detailed execution of each model.

2.2 *Multiple linear regression model*

The general model of MLR used in this study is presented in the equation below.

$$Y = a + b_1 V_1 + b_2 V_2 + \ldots . + b_n V_n$$

where Y =the dependent variable (strength); a =constant; b_1 to b_n = partial regression coefficients for V_1 to V_n; V_1 to V_n = independent variables.

The trial-and-error were done with changing input parameters for the best R^2 value. The best input parameters are then trained and tested in the model for the prediction of strength.

2.3 *Random forest machine learning algorithm model*

Random Forest Machine Learning Algorithm was developed for a quick estimation of the undrained shear strength of SCCs. In this algorithm, parameters were fed to predict the strength of the column. Various libraries like pandas, NumPy, 'Sklearn' were imported for this model. Random forest regressor was used for the regression process. The dataset was split into training and testing data. A total of 80% of data were used as the training and 20% of data were used as the testing dataset. These data sets were kept in the model for the prediction.

2.4 *Artificial Neuron Network (ANN)*

ANN is mainly utilized for the resolution of difficult issues. The issues are regarded in engineering as tough if the link between independent variables and dependent variables is extremely non-linear. Therefore, it will be a difficult task to develop a closed-form solution. Nevertheless, a feedforward neural network is the most often utilized family of neural networks (A. R. Bunawan, 2018). Some investigators, such as (Shahin & Jaksa, 2004) and (Macmillan, 1999) revealed that the multilayer perceptron network is one of the most common feedback ANNs. Multilayer perceptron ANNs typically consist of at least three layers, which are joined by connection weights known as the input, hidden, and output layers.

3 RESULTS AND DISCUSSION

The results of the UC test from the two sites with curing times of 7, 14, and 28 days are presented in Table 1. The influencing factors to affect strength in gaining strength are shown in detail. The deep machine learning models were generated to predict the strength in the laboratory for DMM.

Table 1. Unconfined compressive test from the sites.

Cement content (kg/m^3)	UCS 7 days (kPa)	UCS 14 days (kPa)	UCS 28 days (kPa)
0	28.08(undisturbed)	-	-
150	893.718	1441.251	1479.49
200	1403.197	1636.65	1764.86
250	1859.579	1899.63	2018.021
300	2928.54	3235.5	3600.94

3.1 *Influencing parameter for undrained shear strength*

NMC of the soil directly influences the strength development in SCC. Further analysis was carried out for to find the factors influencing the strength development using the Pearson correlation coefficient by deep machine learning. A total of 9 parameters were used in this study. Among them trial-and-error approach was carried out to find the most affecting factors for strength. Using the Pearson correlation coefficient analysis (PCA), it was found that cement content (C), total water-cement ratio, and curing time (CT) are mostly correlated. Cement content and curing time are positively correlated with R^2 values of 0.77 and 0.5, respectively, whereas the total water- cement ratio is inversely correlated with an R^2 value of 0.79.

3.2 *Prediction using multiple linear regression*

After the compilation of data from the two sites, MLR was set up. A total number of 92 data points were taken from the laboratory work. The undrained shear strength (S_u) is the dependent variable and the independent variables selected from previous sections were cement content (C), water-cement ratio, curing time (CT), and NMC. Although, trial-and-error approach was conducted to check the reliability of parameters in the multiple regression model. Different models with a selection of different parameters along with the selected parameters were run. The training and testing predicted data were evaluated with an R^2 correlation value. A total of six models were created & ran, and R^2 values less than 0.7 were neglected. Previously analyzed parameters which were C, CT and NMC gave the best R^2 values, 0.90 (train) and 0.92 (test). The outcome of this model was a linear equation which is:

$$Su = 5.12 + 0.05x_1 - 0.12x_2 + 0.13x_3$$

Where:-, Su = Undrained shear strength in ksc; x_1 = Cement Content in kg/m^3; x_2 = NMC in %; and x3 = CT in days

3.3 *Prediction model using Random Forest algorithm (RF)*

The models were trained and tested, using 80 % of training data and 20 % of testing data from the total data. Cement content, curing time, and NMC gave the best results with 0.99 (training R^2), 0.94 (testing R^2), 0.47 MAE, and 0.59 as RMSE. Figure 1 shows the results of the prediction using the Random Forest model. Obtaining lower values of RMSE and MAE indicates better prediction capability of the model, and the higher the value of R^2 the better the performance.

Due to the space limitation of the paper only four graphs representing the NMC are presented in this study, as shown in Figure 1. NMC of Bangkok soft clay ranges from 76 – 84%, but can differ from plain. In this study, a maximum of 95.5 % water content and a minimum of 75% water content have been used. For the prediction of undrained shear strength, we can have a prediction relying on these NMC. In practice, usually average NMC is used as NMC before mixing cement. So, the range in this model fits the average NMC of the Bangkok clay.

Figure 1 provides information about the relationship between the required amount of cement and the resulting undrained shear strength. The graphs mentioned in Figure 1 can be directly used to predict the undrained shear strength of SCC in the laboratory. With the NMC

which is the easiest property that can be obtained in any project, the undrained shear strength can be predicted. The right amount of cement required for the design strength can be predicted and, thus, reduce the laboratory works. This approach can make the project more economical from the initial phase.

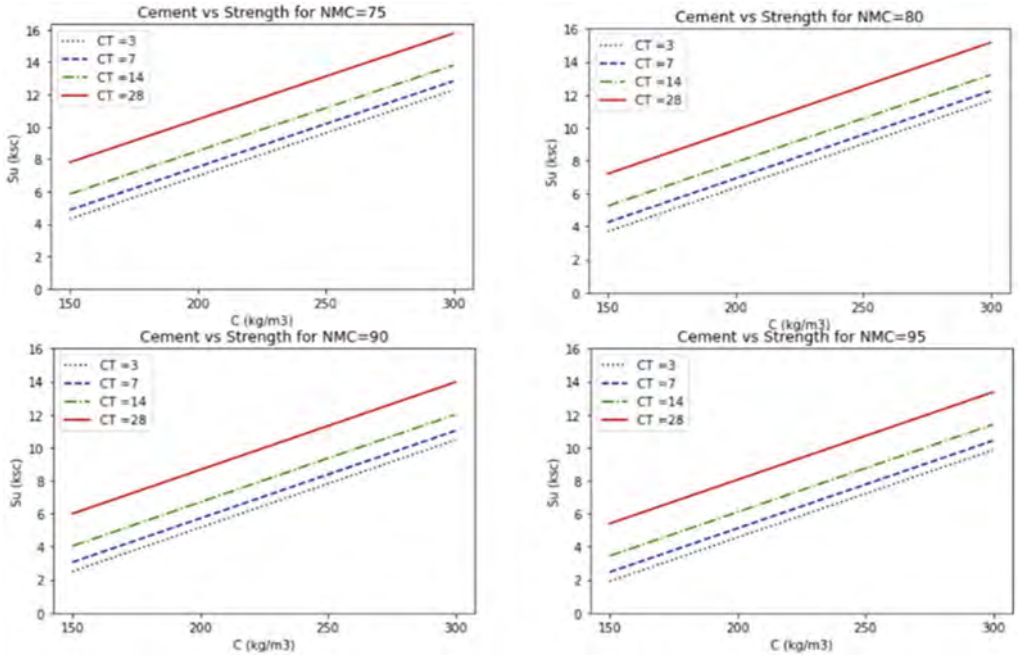

Figure 1. Graphical representation of prediction model using Random Forest model.

3.4 *Prediction model using Artificial Neuron Network (ANN)*

This model is different from other previous models as it can perform non-linear regression. The model was set up with various parameters such as optimizer, normalizer, learning rate, features splitting ratio, hidden layers, nodes, and epochs. The number of input parameters in this model makes it more complicated than other previously mentioned models. The input features were selected as before and run in the model for the trial-and-error process. The best results with various input parameters were noted for further investigations and analysis.

Several models were discarded due to low performance in prediction by, observing R^2 values of the trained and tested datasets. These models used different parameters and different settings in neuron networks. In this study, ANN performance was not satisfactory compared with other models. A multilayer perceptron was used in this analysis with one input layer, one hidden layer, and one output layer. This network architecture gave the best result, compared to others.

Three independent input variables were used, and one output dependent variable was used, like in the previous models. The R^2 values of 0.96 and 0.87 for the training and testing datasets, respectively, were achieved using the ANN model. The difference in R^2 values between the training and testing datasets is signidicant, which is not a good scenario in a neuron network.

4 CONCLUSIONS

In this study, a total of nine parameters including moisture content, plasticity index, unit weight, maximum dry unit weight, cement content by amount, curing time, total water-cement ratio,

undrained shear strength and cement content by weight were selected to predict the undrained shear strength of the treated samples. It was found that the undrained shear strength can be predicted with a reasonable accuracy when at least three parameters were used in all the models. Among those nine parameters, it was concluded that the natural moisture content, cement content, and curing time has the most significant impact on the strength of Bangkok soft clay using the deep mixing method.

Conventional prediction methods were replaced by deep machine learning for predicting the strength using the most influencing factors in this study. This methodology of a prediction model using ML makes the work more effective and is recommended to be widely used in the geotechnical engineering field. The R^2 values of 0.91 and 0.87 for the MLR model and 0.99 and 0.94 for the RF model were obtained from the models which indicate strong correlation results for prediction purposes. The linear equation has the advantage of predicting the wide range of data outside the fed dataset in this study, whereas the random forest is the best within the fed dataset. So, if both prediction methods are used, a good prediction of the undrained strength of Bangkok soft clay can be obtained in a cost and time- efficient way. The results of the analysis indicate that using multiple linear equations and random forest model graphs can predict laboratory strength with higher accuracy.

Pavement design improvement through implementation of processed admixture in subgrade

F. Hakimzadeh Zargar, M.A. Zarco & A.P. Acacio
Institute of Civil Engineering, University of the Philippines, Diliman, Quezon City, Philippines

ABSTRACT: This study presents a new approach for further improving the strength and compressibility characteristic of soils using Type I Portland Cement (PC) and Class F Fly Ash (FA) by processing the individual components of the admixture through ball milling. Unconfined Compression Strength (UCS) and California Bearing Ratio (CBR) Tests were performed on improved soils using 5% PC+5% FA and 10% PC+10% FA. Using 5% PC+5% FA resulted in a 46% and 31% increase in UCS and CBR values, respectively, for improved soils using processed admixtures versus improved soils using unprocessed (commercial) admixtures. Using 10% PC+10% FA resulted in a 55% and 80% increase in UCS and CBR values, respectively, for improved soils using processed admixtures versus improved soils using unprocessed admixtures. The flexible pavement design of a typical 4-lane expressway with 110,000,000 ESALs was used to illustrate the potential cost savings from processing PC and FA components before deep mixing.

1 INTRODUCTION

In every pavement construction, to avoid bearing capacity failure and excessive settlement while ensuring a stable, long-lasting, and maintenance-free roadway, a subgrade that carries the imposed load of the whole pavement section must be constructed using specific established procedures that provide satisfactory results. Moreover, an enhanced subgrade with a higher resilient modulus (M_r) reduces the Structural Number (SN) and thickness (D) of the required pavement resulting in economic savings in terms of construction materials, power, and labor costs.

Among the many approaches for improving subgrades in roadway projects, the most commonly used technique is chemical stabilization through admixtures. In this study, the efficacy of a stabilizing admixture consisting of Portland Cement (PC) and Class F Fly Ash (FA) was enhanced by grinding each component individually through ball-milling. The approach of stabilization in this study involved blending soils and additives thoroughly with a Rotary Mixer Drum (RMD) *in situ* before compaction to achieve a more homogenous layer and attain the desired gradation, maximum dry density (MDD), and optimum moisture content (OMC) of the admixture closest to laboratory conditions.

The flexible pavement design for a 4-lane expressway, 30.7 km in length and 60 m in width having a 110,000,000 Equivalent Standard Axle Load (ESALs), was considered. Tests included specific gravity, compaction, UCS, and CBR tests for both unimproved and improved subgrades with unprocessed (commercial) and processed soil additives were examined; and then resilient modulus correlation (M_r) was obtained before determining the Structural Number (SN) of the pavement. Following the American Association of State Highway and Transportation Officials (AASHTO) Guide for Design of Pavement Structures, the most economical approach was considered for each unimproved and improved structure in the pavement design.

DOI: 10.1201/9781003299127-92

2 MATERIALS

2.1 *The subgrade soil*

Before mixing the admixture, sieve analysis (ASTM D6913M-17), sedimentation (ASTM D7928-17), Atterberg limits (ASTM D4318-17), and specific gravity (ASTM D854-14) were conducted on excavated soil of the subgrade. The laboratory tests' results are shown in Tables 1 and 2.

Table 1. Sieve analysis and sedimentation (hydrometer) tests' results.

Sieve size mm	4.75	2	0.85	0.425	0.25	0.105	0.075	0.0537	0.039	0.0284	0.0184	0.011	0.008	0.0057	0.0041	0.0029	0.0021
Pass finer %	100	92	81	70	62	55	51	45	42	39	35	31	27	26	24	23	21

Table 2. Atterberg limits and specific gravity tests' results.

LL	PL	PI	USCS	specific gravity
44	29	15	CL (lean clay)	2.63

2.2 *Commercial (unprocessed) and processed cement*

The usual Type I Portland Cement was used as the commercial soil additive, while the processed cement was produced after 4 hours of grinding by ceramic ball-milling. Through laser diffraction technique (USP 429 standard), within three trials, the mean values of the particle size distribution from D0.02 (min.) to D100 (max.) for both commercial and processed cement were obtained, as reflected in Table 3.

Table 3. Particle size distribution of commercial and processed cement.

Material	D0.02	D10	D20	D30	D40	D50*	D60	D70	D80	D90	D100
Commercial (μm)	0.04	1.54	3.5	5.63	7.4	9.18*	11.23	14.17	23.93	40.21	74.98
Processed (μm)	0.04	0.6	1.11	1.67	2.43	3.42*	4.53	5.83	7.5	10.56	65.615

* 50% of the commercial sample had a size of 9.18 μm or finer, while it was decreased to 3.42 μm or finer for the processed sample.

2.3 *Commercial (unprocessed) and processed fly ash*

Class F Fly Ash taken from the coal power plants in Batangas, provided by Pozzolanic Philippines, Inc., was used as another commercial soil additive. Processed fly ash, the same as processed cement, was produced after 4 hours of grinding by ceramic ball-milling. Via the same mentioned technique and standard (laser diffraction, USP 429) also undergoing three trials, the mean values of the particle size distribution from D0.41 (min.) to D100 (max.) were obtained for both commercial and processed fly ash as shown in Table 4.

Table 4. Particle size distribution of commercial and processed fly ash.

Material	D0.41	D10	D20	D30	D40	D50	D60	D70	D80	D90*	D100
Commercial (μm)	0.04	0.75	1.44	2.38	3.36	4.33	5.36	6.62	8.5	27.97*	66.98
Processed (μm)	0.04	0.73	1.27	1.97	3	4.09	5.27	6.53	8.23	11.61*	61.47

* 90% of the commercial sample had a size of 27.97 μm or finer while it was decreased to 11.61 μm or finer for the processed sample.

3 GEOTECHNICAL TESTS AND RESULTS

3.1 *Laboratory tests*

Using the above materials, a series of compaction (ASTM D1557-12e1), UCS (ASTM D2166), and CBR tests (ASTM D1883–16) was conducted on subgrade for both unimproved and improved designs of subgrade. A modified proctor (AASHTO proctor) test indicated the maximum dry density (MDD) and optimum moisture content (OMC) of the unimproved and improved subgrade soil before conducting any UCS (after 7-day curing) and CBR test (after 96-hour soaked condition) at 95% MDD.

3.2 *Results*

Table 5 shows the results for unimproved (compacted subgrade soil) and improved designs (compacted subgrade in a certain percentage of commercial and process ed soil additives).

Table 5. MDD, OMC, UCS, CBR, and M_r* values of all subgrade designs.

Material	Design	MDD g/cc	OMC %	UCS psi	CBR %	MR psi*
0% PC+0% FA	unimproved	1.697	17.86	43.08	6.01	6800
5% PC+5% FA	commercial	1.404	23.41	60.33	32.29	21000
5% PC+5% FA	processed	1.564	21.36	88.08	63.24	33000
10%PC+10%FA	commercial	1.333	22.41	104.84	116.17	53500
10%PC+10%FA	processed	1.633	19.61	162.02	196.31	75000

* Established from AASHTO correlation chart relationship between CBR and M_r values of the subgrade. (AASHTO interim guides, 1972).

4 PAVEMENT STRUCTURE COMPUTATION

The basic Equation 1 was applied for flexible pavement design (AASHTO,1993):

$$\log_{10}W18 = Z_R \times S_0 + 9.36 \times \log_{10}(SN+1) - 0.20 + \frac{\log 10\left(\frac{\Delta PSI}{(4.2-1.5)}\right)}{0.4 + \left(\frac{1094}{(SN+1)^{5.19}}\right)} + 2.32 \times \log_{10}M_r - 8.07 \quad (1)$$

where *W18* = designed ESALs; Z_R = standard normal deviation for a given reliability (R = 85%); S_0 = overall standard deviation; and ΔPSI = Present Serviceability Index.

Given *W18* = 109, 620, 118; Z_R = -1.037; S_0 = 0.45; ΔPSI = 1.7; and = values in Table 5; the structural number (*SN*) for each pavement could be computed and shown in Table 6, where the sum of designed structural numbers in every layer above the subgrade shown in Figure 1 should not be any value less than the computed *SN* for the entire pavement.

5 FLEXIBLE PAVEMENT DESIGN

Targeting the most economical pavement consideration: applying the material's minimum allowed thickness (D), coefficient ($a_{sandy\ gravel\ subbase}$ = 0.11, $a_{crushed\ stone\ base}$ = 0.14, $a_{cement\ treated\ base}$ = 0.2, $a_{HMA\ binder}$ = 0.4, $a_{HMA\ surface}$ = 0.44) (SUDAS, 2019) and drainage factor of each layer (m_{base} = 1and $m_{subbase}$ = 0.7) the entire pavement structure for each design is summarized in Table 6. (Richardson, et al. 1996).

To evaluate the significance of this study, processed designs versus commercial and unimproved designs were compared geotechnically and economically, as shown in Table 7.

Table 6. Minimum pavement SN and layer thickness in each design.

Material	Design	SN min.	subgrade cm	treated-subgrade* cm	subbase cm	base cm	CTB cm	binder cm	surface cm	cost** USD
0%PC +0%FA	unimproved	9.45	30.48	N/A	49.7	49.3	49.3	5	3.8	125.51M
5%PC +5%FA	commercial	5.3	30.48	52.6	49.2	22.9	15.2	5	3.8	99.54M
5%PC +5%FA	processed	4.1	30.48	25.9	23.5	15.2	15.2	5	3.8	83.93M
10%PC +10%FA	commercial	3.17	30.48	22.5	0	15.2	15.2	5	3.8	79.95M
10%PC +10%FA	processed	2.76	30.48	7.7	0	0	17.9	5	3.8	70.88M

* Treated subgrade is where the proposed materials/admixture is used.
** Includes materials, equipment, processing, hauling, power, and labor costs for the entire pavement. (1USD = PHP56.00)

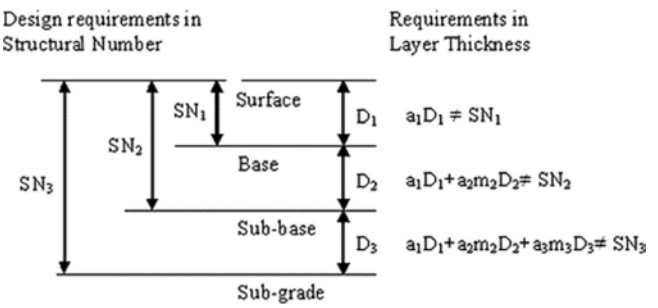

Figure 1. AASHTO structural number equation (AASHTO,1993).

Table 7. Processed designs *vs*. commercial and unimproved designs.

Comparison	MDD	OMC	UCS	CBR	M_r	SN	savings
5% PC+5% FA (processed *vs*. commercial)	+11%	-9%	+46%	+31%	+57%	-23%	+16%
10%PC+10%FA (processed *vs*. commercial)	+23%	-12%	+55%	+80%	+40%	-13%	+11%

6 CONCLUSION

Based on the evaluation summarized in this study, it can be seen that the processed designs for the described improved subgrade could significantly increase MDD, UCS, CBR, M_r and correspondingly decrease OMC and SN. The study showed that a processed admixture of 10% PC+10% FA could save $9.07M compared with the cost of 10% PC+10% FA commercial admixture. Moreover, the processed admixture of 10% PC+10% FA could save $54.63M compared to the unimproved design.

Similarly, for a 4-lane expressway, 30.7 km long and 60 m wide with 110,000,000 ESALs, 5% PC+5% FA processed material indicated an economic achievement of $15.61M and $41.58M compared to the cost of 5% PC+5% FA commercial and unimproved designs, respectively.

Investigation of combined support structures under complex geological conditions

R.K. Zhanakova & A.O. Sagybekova
Kazakh Automobile and Road Institute named after L.B. Goncharov, Almaty, Republic of Kazakhstan

ABSTRACT: At present, the construction of mine and underground structures is intensively growing in our country. In the mining industry and transport systems, the role of horizontal and inclined mine workings is very large. In their length they cross a rock mass with different stability characteristics. In general, for the support of the workings, they account for 30-40% of the funds spent on driving the workings, therefore, the provided new, inexpensive, innovative design of the lining is relevant. It is especially necessary to carry out scientific work to create a rational innovative technology for the passage of underground workings in an array with complex mining and geological conditions. This paper considers a new approach that will allow to fix the workings, to divide the workings into separate sections along the working route, suitable for specific geomechanical conditions, with fasteners of various designs. As a result, it is possible to achieve an improvement in the technical and economic indicators of tunneling and an increase in labor productivity. The presented reasoned method and fastening methods can be widely applied in the mining industry.

Keywords: Support structure, Combined structures, Mine workings, Massif

1 INTRODUCTION

At present, for fixing complex development workings (drift, crosscut), only one type of fixing is used without taking into account the frequent change in the mining and geological conditions of the massif along its length.

For the object of study, monolithic concrete lining is used as the main permanent support at the Beskempirsky and Akbakaysky mines. At the same time, unreasonable safety margins of the lining are often created in areas with favorable mining and geological conditions. All this leads to a deterioration in the indicators of tunneling, an increase in the labor intensity of underground work and the estimated cost of driving underground workings [1,2,11,13,20].

Existing and used in the complex mining and geological conditions of the Beskempir mine, when the designed drifts cross the zones of geological faults, traditional types and methods of fixing and maintaining mining developments become expensive and laborious.

To do this, it is necessary to simulate the stress-strain state of the massif of the Beskempir mine (+230 m) and determine the stability of the rocks using several alternative methods. Based on the results of the study, it is very important to determine the boundaries of sections along the drift route, consisting of unstable sections with high cracks, the stability and stress properties of which have changed due to the influence of tectonic disturbances [3-15].

This innovative approach makes it possible to fix sections of workings, dividing them along longitudinal sections, with fixation by various structures suitable for specific tectonic conditions. As a result, it is possible to improve the technical and economic indicators of underground mining and increase labor productivity. The fixing methods proposed by the research results of the dissertation work can be used in other mines.

2 LITERATURE REVIEW AND PROBLEM STATEMENT

Research specialists like: M.M. Protodyakonova, P.M. Tsimbarevich, V.D. Slesarev, V. Fenner, A. Labas, K.V. Ruppeneita, J.S. Erzhanova, Yu.L. Lieberman et al. gave hypotheses about rock pressure. Which at present, all known theories of rock pressure, depending on the methods underlying them, can be divided into three groups:

- methods for calculating the load;
- calculation methods for given deformations;
- calculation methods for given deformations and loads.

The third method of rock pressure calculation combines the advantages of the first two calculation approaches. Which is taken to calculate the magnitude of the load on the support of the object under study [12-22].

3 THE AIM AND OBJECTIVES OF THE STUDY

At present, for fixing complex development workings (drift, crosscut), only one type of fixing is used without taking into account the frequent change in the mining and geological conditions of the massif along its length (Table 1).

Table 1. Initial data of the object under study.

Excavation size, m		Fault zone size, m	Distribution size Voltage, m	Max stress MPa
Working area	S=10,9м^2	a=138	от 0-183	от 30 до -60
Entry length	L=1300	b=138	от 0 до 52	от 30 до 90
Fault zone size, m	B=3,2	c=138	От 0 до 152	от 30 до 120

For the object of study, monolithic concrete lining is used as the main permanent support at the Beskempirsky and Akbakaysky mines. At the same time, unreasonable safety margins of the lining are often created in areas with favorable mining and geological conditions. All this leads to a deterioration in the indicators of tunneling, an increase in the labor intensity of underground work and the estimated cost of sinking underground workings (Figure 1).

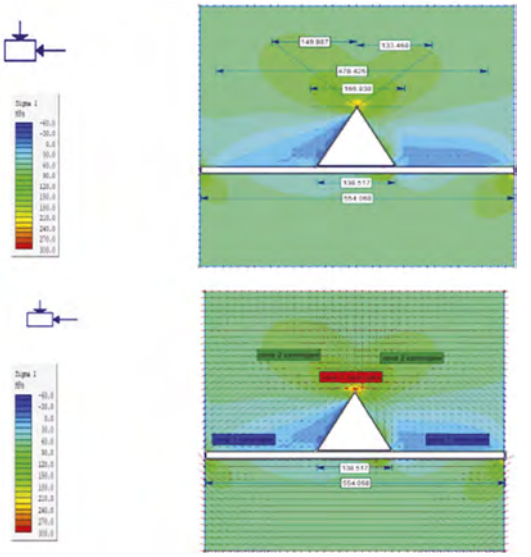

Figure 1. The results of modeling the stress-strain state of the massif, taking into account the tectonic fault.

Existing and used in the complex mining and geological conditions of the Beskempir mine, when the designed drifts cross the zones of geological faults, traditional types and methods of fixing and maintaining mining developments become expensive and laborious.

To do this, it is necessary to simulate the stress-strain state of the massif of the Beskempir mine (+230 m) and determine the stability of the rocks using several alternative methods. Based on the results of the study, it is very important to determine the boundaries of the sections along the drift route, which consist of unstable sections with high cracks, the stability and stress properties of which have changed due to the influence of tectonic disturbances (Figure 2).

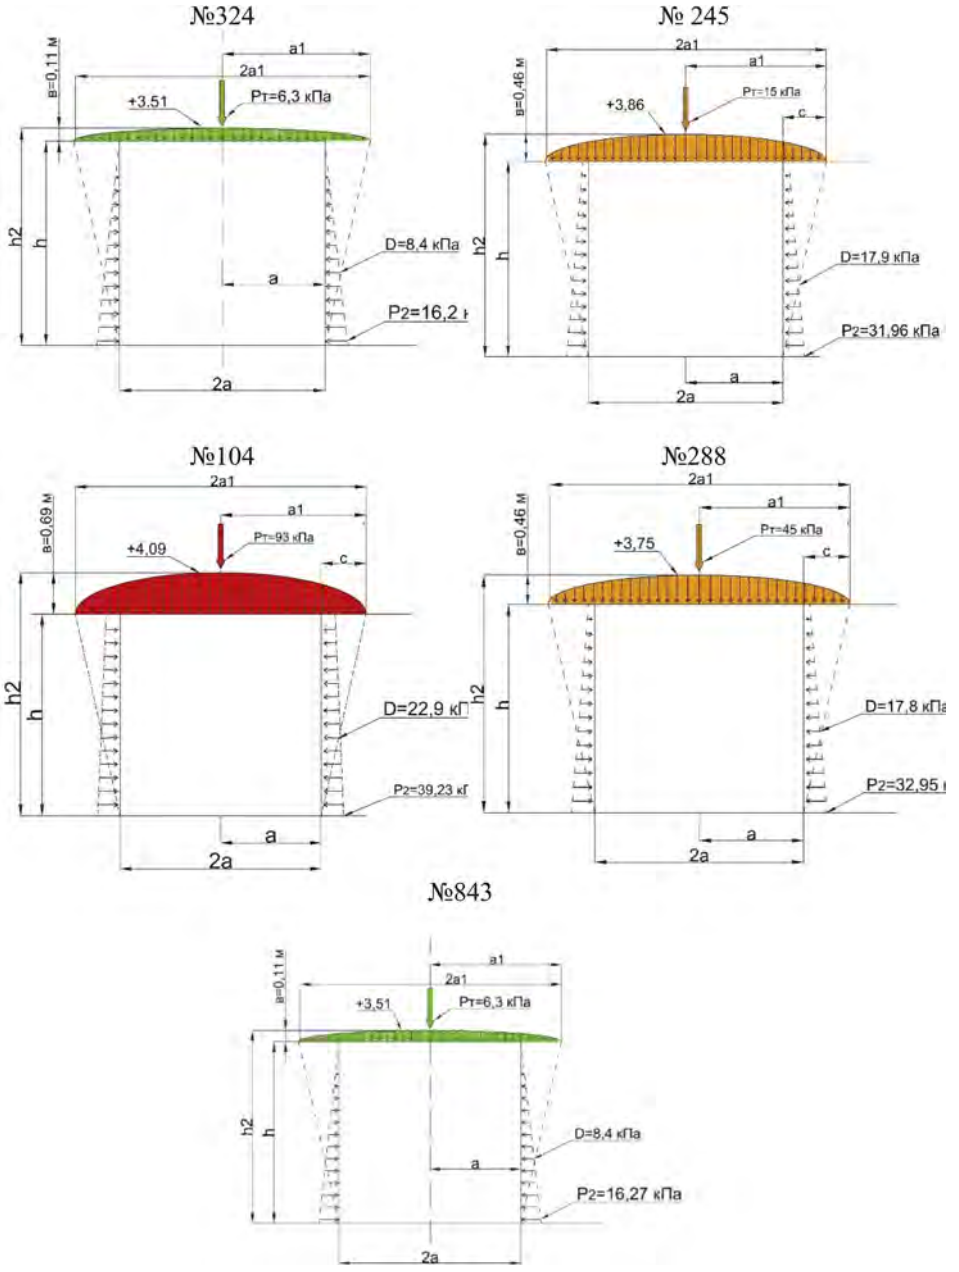

Figure 2. Results of rock pressure calculation for wells No. 324, No. 245, No. 104, No. 288 and No. 843.

4 MATERIALS AND METHODS

Studied the stability of rocks at rest in three alternative ways in accordance with the specific mining and geological conditions of development:

- official traditional method
- according to the rating (RMR) of Z. Benyavsky and according to the drawing up of the diagram by E. Hook (E. Noak);
- Empirical method of N. Barton (Q-rating)

The types of rational fastenings and their designs are determined, suitable for fastening each section of the roadway, their parameters, in accordance with the stability of rocks.

5 RESULTS OF RESEARCH

This innovative approach makes it possible to fix sections of workings, dividing them along longitudinal sections, with fixation by various structures suitable for specific tectonic conditions. As a result, it is possible to improve the technical and economic indicators of underground mining and increase labor productivity. The fixing methods proposed by the research results of the dissertation work can be used in other mines [21-27].

To solve these problems, research and analysis of actual geological data and test materials and performed laboratory work experiments. To determine the digital estimates of the stress-strain state, a numerical simulation of the studied mass was created.

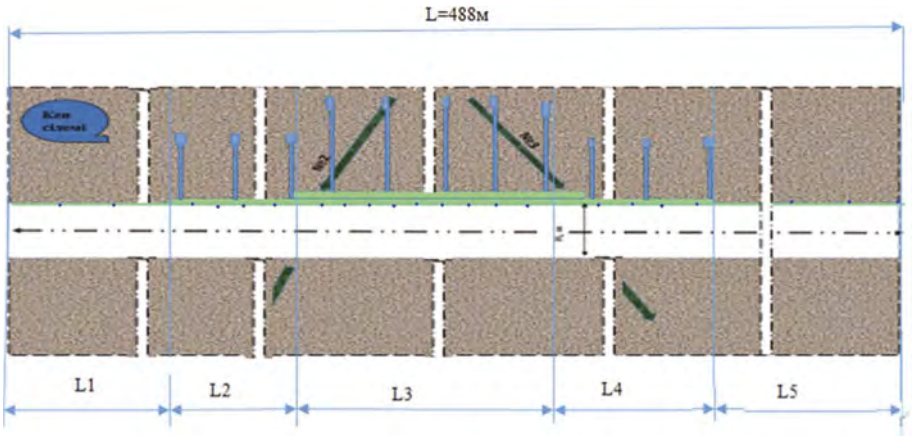

Figure 3. Recommended support design.

Based on the modeling of specific values of stress-strain loads that occur in the working area in the "Rocks-massif-working" system, it is determined with a breakdown by sections in accordance with the distribution zones of the state of the massif (Figure 3).

Based on the obtained data, it was determined that the drift can be fixed with fastening structures having different bearing capacity and design, which can withstand geomechanical processes in the massif. A new method of fastening horizontal workings is proposed, in which the methods of fastening (sprayed concrete) are justified in areas with high stability of the workings, as well as in unstable areas with high load-bearing fasteners, i.e. load-controlled fastening system.

As a result of a special study of stress-strain states in the rock mass intersected by the working route, taking into account the influence of tectonic faults, it was found that the stability of rocks in the vicinity of the working was determined using several new methods and, as a result, a system of combined supports with various designs was reasonably presented, managed and regulated by the values of the bearing capacity of the mine

ABSTRACT: Microbially Induced Calcite Precipitation (MICP) has emerged as an innovative and sustainable soil improvement technique, which can improve liquefaction resistance. This paper presents a numerical study on the mechanical behavior of MICP cemented sands in cyclic triaxial shear tests by CFD-DEM simulations. Firstly, a novel three-dimensional cyclic contact model for cemented sand was proposed, associated with the time-dependent relationship describing the microbial denitrification reaction, and employed into a commercial DEM software, PFC3D 5.0. Secondly, undrained cyclic triaxial tests were simulated respectively on clean and cemented sands using the CFD-DEM coupling method. Finally, liquefaction resistance of specimens microbially-treated with different times were analyzed macroscopically and microscopically. The results show that the liquefaction resistance of MICP cemented sand is larger than that of clean sand. The increases of pore pressure ratio are suppressed significantly with decreases of mechanical coordination number and bond coordination number, due to different amounts of MICP cementation.

1 INTRODUCTION

Liquefaction of sand manifests itself as the reduction of the effective stress of soil, and the increase of the pore water pressure, which eventually results in the insufficiency of the shear strength of soil. It causes uneven settlement of building foundations and structural damage, even leads to serious disasters and casualties. Since the traditional methods enhancing liquefaction resistance have lots of disadvantages, microbial geotechnical approaches have become a better choice. Among traditional chemical soil modification technology, the microbially induced calcite precipitation (MICP) technology is simpler and has less impact on the environment (Tang et al., 2020), which is extensively studied for soil improvement in geotechnical engineering (Wang et al., 2019, Liu et al., 2020).

In recent years, most studies on liquefaction resistance of MICP cemented sand has been analyzed through laboratory tests, paying more attention to the influence of biological bond. Inagaki et al. (2011) conducted consolidated-drained triaxial compression tests and centrifuge tests on MICP cemented sand. Gao et al. (2019) used triaxial consolidated drained tests and K0 consolidation tests to understand the mechanical behavior of bio-cemented sand at various cementation levels and relative densities. Liu et al. (2018) investigated the evolutions of the

DOI: 10.1201/9781003299127-94

dynamic characteristics under different degrees of bio-cement as well as the micromechanism of the MICP-treated calcareous sands by dynamic triaxial tests and SEM tests.

However, laboratory tests suffer from the shortcomings of long time-consuming, high cost, and poor repeatability, so it is necessary to use numerical simulation methods for analysis. The distinct element method (DEM), which was firstly developed by Cundall and Strack (1979), provides an effective approach describing the micromechanical behaviors of particle assemblies. Previous studies simulated the triaxial test of MICP cemented sand by DEM, and analyzed the characteristics of strength and stiffness of cemented and uncemented samples (Evans et al., 2015, Khoubani et al., 2016). Feng et al. (2017) used three-dimensional discrete element software PFC3D (Particle Flow Code) to simulate the mechanical properties of MICP cemented sand, analyzing the macro and micro mechanical responses, and the shear band phenomenon was observed.

The existing simulation results fail to consider the influence of water and cannot reflect the interaction between particles and fluid in the whole liquefaction process, while the influence of water flow cannot be ignored. So, coupling methods is a good choice to research on macroscopic and microscopic mechanism of the effect.

The computational fluid dynamics (CFD) is the method of replacing the governing partial differential equations of fluid flow with numbers, and advancing these numbers in space and/or time to obtain a final numerical description of the complete flow field of interest (Anderson and Wendt, 1995).DEM can be coupled with CFD to describe fluid-particle interaction systems, and using this type of coupled simulation can get an effective description of the interaction between particles and pore water during liquefaction (Zeghal and El Shamy, 2008). Jiang and Zhang (2014) established CFD-DEM codes to simulate the porous media with weakly compressive fluid introduced the fluid state equation considering the weak compressibility of the fluid, and used FISH language to couple CFD and PFC2D discrete element calculation to simulate the undrained consolidated shear test of saturated sand.

Based on the theoretical framework of geomechanics from micro to macro (Jiang, 2019), employing the CFD-DEM coupled model, this paper aims to simulate MICP cemented sands of different reaction time under undrained consolidated cyclic triaxial tests, tracing and analyzing the changes of some mechanical parameters during the simulation procedure to study mechanical properties from macroscopic and microscopic scales. And finally, get some conclusions about the effect and possible mechanism of the presence of cementation on anti-liquefaction capacity.

2 CONTACT MODEL AND MICROBIAL TREATMENT PROCESS

The contact model of this paper is on the basis of the three-dimensional (3D) contact model incorporating rolling and twisting resistances at inter-particle contact (Jiang et al., 2015b) and 3D bonded aluminum ball tests (Jin, 2016) of our team's previous work, and takes the cyclic load effect on microbial cementation and mechanical properties of MICP cemented sands into further consideration.

2.1 *Contact model*

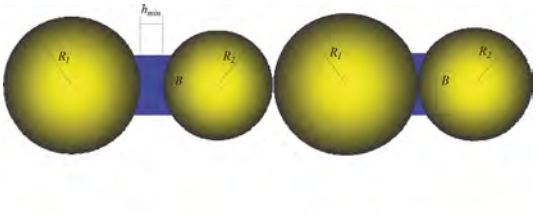
Like the regular discrete element bond contact model, the bond contact between MICP cemented sand particles can be simplified as thick cementation and non-thick cementation. Soil particles with radius R_1 and R_2 are connected by calcareous cementation. The minimum thickness of cement is h_{min} and the width is B, as shown in Figure 1. The thickness cementation refers to the formation of cementation between two separated particles, which means the minimum thickness $h_{min}>0$; while the non-thick cementation means cementation between two contact particles with the minimum thickness $h_{min}\leq 0$. The cement is simplified to two cylinders with spherical ends. The mechanical model of non-thick cementation can be simplified as a parallel connection between particle spring and cementation spring, while that of thickness

cementation can be regarded as a series connection of particle spring and cementation spring. Since the particle stiffness of MICP cemented sand is much larger than that of bond stiffness, the contact stiffness is approximately equal to the bond stiffness. It is considered that the thickness bond only has bond forced.

The particle part of DEM contact model is based on the 3D contact model for granulates incorporating rolling and twisting resistances (Jiang et al., 2015b). In order to consider the small plastic deformation under cyclic loading (Thornton et al., 2013), this paper adopts the linear hysteretic contact model in the normal contact component, that is, different loading and unloading stiffness, so that the plastic deformation dissipation energy caused by the collision of particles under cyclic loading can be considered. The ideal elastic-plastic model is still used in tangential, rolling and torsional directions. The mechanical response of the particle part can refer to previous study (Tan, 2018).

The law of force and displacement of the bond part of 3D contact model is derived by formula (Shen et al., 2016). It is considered that the two ends of the cement are spherical, and the bond cylinder between spheres is dissected into hollow cylinder elements for integration operation. The stiffness of cementation is obtained by integral calculation. Similar to the particle part, the mechanical response of the bond part can be divided into normal, tangential, rolling and torsional directions.

The strength criterion used in the bond part of the model is extracted by previous experiments (Jiang et al., 2015a). The bond strength criterion is obtained by combining the simplified elliptic formula with the indoor 3D microscopic contact mechanics test, and the tensile strength R_{nt}, compressive strength R_{nc}, shear strength R_s, bending strength R_r, and torsional strength R_t of bond are gotten. Based on the test results under complex loading conditions of indoor tests, the spherical failure envelope controlled by peak shear load, bending moment and torque is established, and the size of failure envelope is controlled by normal force, as shown in Figure 2, where F_s is the bond shear force, M_r is the bond rolling moment, and M_t is the bond twisting moment.



(a) thickness cementation. (b) non-thick cementation.

Figure 1. DEM diagram of MICP cemented contact.

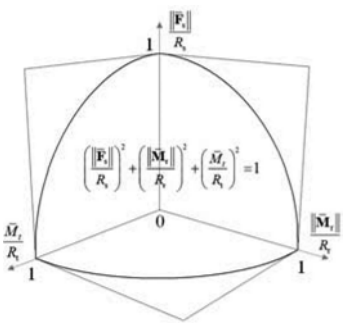


Figure 2. Cemented failure criterion.

In addition, since the mechanical behavior of granular materials has obvious rate correlation (Peng et al., 2007, Yamamuro et al., 2011, Svoboda, 2013, Sheahan et al., 1996), to consider the rate correlation of MICP cemented sand under cyclic loading, viscous damping is added to the contact model. The viscous damping at contact is determined by the dash pot element and can also be divided into normal, tangential, rolling and twisting direction (Thornton et al., 2013).

This improved microstructural bond model is implemented into the commercial DEM code PFC3D via C++ coding. Then a set of micro parameters are calibrated by the laboratory data and experience, the micro parameters of MICP cemented sand are shown in Table 1 (Tan, 2018).

Table 1. Micro parameters of MICP cemented sand.

	Model micro parameters	Value
Particle part	Particle modulus E_p (MPa)	3×10^8
	Normal tangential stiffness ratio ξ	1.5
	Friction coefficient μ	0.5
	Anti-rotation coefficient β	0.2
	Local crushing coefficient ζ_c	2.1
	Normal contact loading and unloading stiffness ratio e_n	0.95
Bond part	Slenderness ratio δ	0.05
	Radius proportional coefficient η	(0.5)*
	Elastic modulus E_b (Pa)	2×10^8
	Poisson's ratio v_b	0.2
	Tensile strength σ_t (Pa)	1.6×10^6
	Compressive strength σ_c (Pa)	8×10^7
Viscous damping	Normal critical damping ratio β_n	0.6
	Tangential critical damping ratio β_s	0.6

* Radius proportional coefficient takes 0.5 during parameter calibration, and it takes the calculated parameter that controls the cementation content in the subsequent simulation.

2.2 *The time-dependency characteristic of microbial treatment process*

The microbial treatment process is a new type of foundation treatment technology, it has many advantages over traditional methods, but it is necessary to require considerable time and economic costs in the early cultivation and reinforcement process. So, the time-dependency characteristic was established by summarizing the data of precipitation rate and gas generation rate in the laboratory biological denitrification tests. The microbial denitrification was chosen in this paper to consider MICP reaction, for the reason that denitrification was chemically inert, non-toxic, and potential (Hamdan et al., 2017).

According to previous studies (Van Paassen et al., 2010, He, 2013), the formation rate of denitrifying cementation is 91mmol/day in laboratory tests. Using this formation rate, this paper recorded the number of the sample cementation with 2-, 3- and 5-day reaction separately. Then the corresponding parameters were chosen and calculated in the numerical simulation, applying to the following undrained cyclic shear simulation. The calculated volume growth rate of calcium carbonate cementation of denitrification reaction is 0.359mm^3/day. So, after 2-, 3-, 5-day reaction, the cementation volume is respectively 0.718mm^3, 1.077mm^3, 1.795mm^3, and the proportional coefficient of cementation radius (η) is separately 0.273, 0.3, 0.34. The final calculation results are shown in Table 2.

Table 2. Cementation formation of microbial treatment.

Reaction time (day)	Cementation volume (mm^3)	Proportional coefficient of cementation radius η
0	0	0
2	0.718	0.273
3	1.077	0.3
5	1.795	0.34

3 CFD-DEM SIMULATION

3.1 *Specimen*

Figure 3 provides the grain size distribution of Ottawa 50-70 sand used in this study (Feng and Montoya, 2016). The DEM sample was prepared using the Multi-layer with the Undercompaction Method (UCM) (Jiang et al., 2003). 10-layer preparation was used

with the initial void ratio of 0.73. Then the sample was pre-compressed to a vertical load of 12.5 kPa by servo system.

After precompression was stable, the servo system was used in the isotropic consolidation stage, the average effective principal stress of the consolidated sample is 100 kPa. The figure of sample consolidation is illustrated in Figure 4. Then apply model cementation parameters provided in Table 1, and the parameters for clean sand refer to the particle part in Table 1.

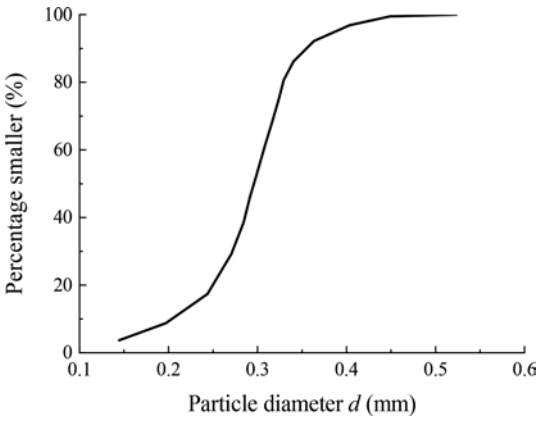

Figure 3. Grain size distribution.

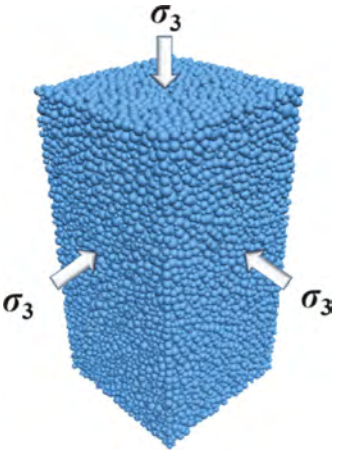

Figure 4. Schematic diagram of sample consolidation.

3.2 *Shear test*

The CFD-DEM coupling method is developed by Zhang et al. (2020). The DEM calculation adopts PFC3D, and the CFD calculation is carried out by OpenFOAM to simulate the fluid including the pore water and possible microbial bubble. The data exchange of CFD-DEM is realized by Python using TCP socket programming.In this cyclic shearing stage, the CFD module was added for coupling simulation of cyclic shear. The DEM time step is 1×10^{-6}s/cycle, the exchange frequency between DEM and CFD is 25, and the CFD time step is 2.5×10^{-5}s/cycle. The initial density of the fluid is 1000 kg/m^3 and the compression coefficient is 4.5×10^{-7}. The number of fluid grids is 6×6×12, and the CFD grid boundaries are consistent with the coordinates of the six walls in the DEM. Before cyclic loading, the backpressure of 100kPa was applied. The upper and lower walls were loaded at a uniform speed. When the deviator stress reached the stress amplitude q_{cyc}, the upper and lower walls continued to move in the opposite direction. Then, until the stress amplitude q_{cyc} in the opposite direction was reached, the moving direction reversed again. The sidewall was still controlled by servo system, and the servo stress is the effective stress of confining pressure minus pore pressure. The fluid boundary uses a velocity boundary, which is consistent with the velocity of the wall.

3.3 *Simulation scheme*

To investigate the liquefaction resistance of MICP cemented sand specimens with different degrees of cementation, specimens were selected for comparative analysis at 2, 3, and 5 days after microbial treatment. MP2/3/5 represents MICP cemented sand specimens after microbial treatment for 2/3/5 days, and MP2-1/2/3 represents the cyclic triaxial tests of specimens with different cyclic stress ratios after microbial treatment for 2 days, respectively. The cyclic results showed that the failure modes of specimens are initial liquefaction failure (I. L.), except for specimen MP5-1, which did not fail. And L0 represents the pure sand specimens. Detailed parameters and basic results are shown in Table 3.

Table 3. Working condition list of MICP cemented sand cyclic triaxial tests.

	Simulated conditions			Cyclic results	
Test number	Days	η	Cyclic stress ratio CSR	Failure vibration frequency N_L	Failure mode
L0	0	0	0.15	0	I.L
MP2-1	2	0.273	0.5	37	I.L
MP2-2	2	0.273	0.6	5	I.L
MP2-3	2	0.273	0.75	3	I.L
MP3-1	3	0.3	0.6	55	I.L
MP3-2	3	0.3	0.75	5	I.L
MP3-3	3	0.3	0.9	3	I.L
MP5-1	5	0.34	0.75	(132+)*	/

4 SIMULATION RESULTS

4.1 *Liquefaction resistance*

The liquefaction vibrations N_L and CSR of MICP specimens with different days of microbial treatment were plotted in semi-logarithmic coordinates, to obtain the anti-liquefaction strength curve of MICP cemented sands shown in Figure 5. At the same time, a comparison is made with the clean sand specimen without microbial treatment.

The liquefaction resistance of MICP cemented sands after microbial treatment gets a significant rise than pure sand. And with the increase of treatment time, the development of cementation content leads to a gradual increment of the liquefaction resistance. When CSR is the same value 0.75, the specimen with 2 days treatment reaches liquefaction after 3 vibrations, the specimen with 3 days treatment needs 5 vibrations, and the specimen with 5 days treatment does not fail after 132 vibrations.

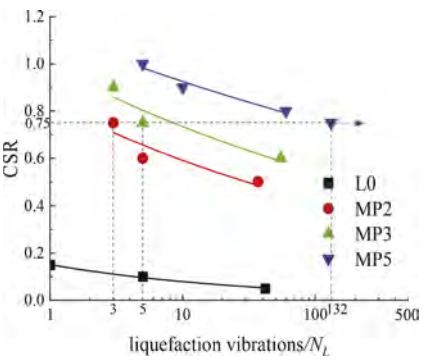

Figure 5. Cyclic stress ratio - liquefaction vibration times curves ratio.

(The arrow represents that the specimen of this vibration has not been destroyed.)

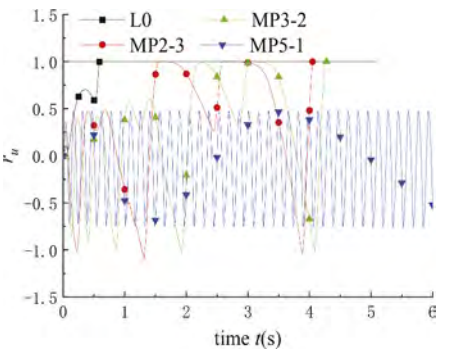

Figure 6. Development curve of pore water pressure of different specimens.

4.2 *Excess pore water pressure ratio*

The water pressure ratio is the ratio of pore water pressure increment to lateral effective consolidation stress under cyclic stress. Figure 6 shows the evolution of pore water pressure ratio of specimens with different cementation contents under same CSR=0.75 and the pure sand

specimen with CSR=0.15. For the pure sand specimen, the specimens with 2 days, and 3 days microbial treatment, the pore pressure ratio increases to 1 after several loadings, with soil reaching the initial liquefaction state. The cementation of microbial treatment has an obvious inhibitory effect on the development of pore pressure ratio, even when CSR is 5 times higher than that of the pure sand, it still takes more time to reach liquefaction. Moreover, the longer the microbial treatment time is, the longer the liquefaction time required. When CSR is 0.75, the pore pressure ratio of the specimens with 5 days treatment changes periodically with no upward trend, and soil does not reach the initial liquefaction.

4.3 *Mechanical coordinate number*

The mechanical coordination number is the average coordination number of particles without the particles with 0 or 1 contact, which can characterize the contact state of particles. (Thornton, 2000).

Figure 7(a) gives the evolutions of mechanical coordination number of specimens with different cementation contents under the same CSR=0.75, which are compared with that of the clean sand specimen L0. The mechanical coordination numbers of the specimens with 2 days and 3 days treatment decrease rapidly, and the decreasing tendency of 2 days' is much faster. At the end of loading, the mechanical coordination numbers of these two specimens are about 3.4, which is close to the pure sand. Whereas the value of the specimen with 5 days treatment decreases from 5 to 4.6, then fluctuates around 4.6.

Figure 7(b) demonstrates the evolutions of bond mechanical coordination number of different cemented specimens when CSR is 0.75. The decline is sharper and more obvious than that of mechanical coordination number. The bond mechanical coordination number before loading is 4.8, which is slightly smaller than the value of the mechanical coordination number. The fall decreases with the increase of processing time. Contrast 2 days' and 3 days' specimens, the descending speed of bond mechanical coordination number is much quicker than that of mechanical coordination number. The value of the specimen with 5 days treatment decreases to 3.7, then remains unchanged.

Figure 7. Development curve of (bond) mechanical coordination number of different specimens.

5 CONCLUSIONS

This paper introduced a coupled CFD-DEM simulation of MICP cemented sands under undrained cyclic triaxial shear tests to consider the liquefaction resistance. The main conclusions can be drawn as follows:

1) The presence of cementation has a great improvement on the liquefaction resistance. The anti-liquefaction capacity of MICP cemented sands is higher than that of clean sand. The failure mode of MICP cemented sands is initial liquefaction.

2) With the increase of treatment time, the cementation content grows gradually, leading to stronger liquefaction resistance. And the development of excess pore water pressure ratio is suppressed more significantly, the downward trend of (bond) mechanical coordinate number becomes weaker.

Geotechnical properties and embankment construction of crushed solidified soil

A. Sato & H. Hayashi
Civil Engineering Research Institute for Cold Region, Sapporo, Japan

ABSTRACT: One method of improving soft soil materials generated at construction sites is to use a solidifier. The authors focused on solidified crushed soil, which is a compactable material produced by strengthening crushed soil with a solidifier using this method, and studied its geotechnical properties as an embankment material. This paper presents the results of the study and an example of embankment construction using solidified crushed soil.

1 INTRODUCTION

For the effective use of resources, soft soil materials generated during road and river works can be improved for use as an embankment material (CERI 2013). One of the improvement methods involves mixing the materials with cement, lime or other solidifiers. The aim of improvement is to ensure both sufficient strength for construction work and stability of the embankment, while the elution amount of hexavalent chromium is within the standard value range. All of these conditions must be satisfied. Improvement using a solidifier can ensure increased strength. However, the strength of the embankment may exceed the required level if an amount of solidifier that provides adequate strength for trafficability of construction machinery is mixed. It may also complicate re-excavation of the embankment for the installation of median strips or guardrails, since the strength of material improved with a solidifier increases over the course of time. In case of construction on soft ground, there is also a risk of slip failure because the embankment cannot follow ground deformation. The authors have therefore focused on crushed solidified soil as a material of which strength development can be minimized or reduced when mixed with a solidifier. This paper presents the geotechnical properties of crushed solidified soil as an embankment material (Sato, A. & Hatakeyama, O. 2021), and the results of the construction of a river embankment using this material.

2 CRUSHED SOLIDIFIED SOIL

Crushed solidified soil is produced by mixing a solidifier with the soil subject to improvement (original soil) and crushing the solidified soil after some time to allow compaction. Figure 1 shows the definitions of terms used in the paper. Crushed solidified soil means a material produced by crushing a mixture of original soil and a solidifier (solidified soil) after some time (standby time). The time until the implementation of testing and research on crushed solidified soil samples and the embankment is defined as the curing time. The strength of crushed solidified soil at the time of compaction is low if the standby time is short, as it is crushed when solidification has not progressed much. However, the strength further increases with a longer

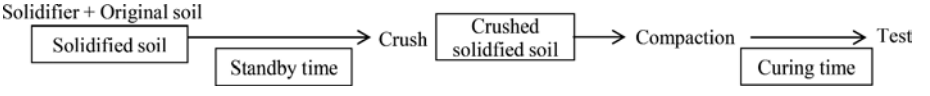

Figure 1. Definition of the terms.

DOI: 10.1201/9781003299127-95

curing time, because of its remaining solidification capacity. If the standby time is long, the material is crushed when the solidifying capacity is expressed, resulting in higher strength at the time of compaction, but less increase in strength, even if the curing time is long.

3 TEST METHOD

In this study, a laboratory test was conducted to investigate the geotechnical properties of crushed solidified soil as an embankment material (Sato, A., Hatakeyama, O. & Chujo, G. 2021). An embankment was also constructed using the material. The original soil used for the laboratory test and the construction of the embankment is different. The basic physical properties are shown in Table 1. Since the original soil materials were soft and the cone index (Japanese Industrial Standard 2020) with a natural water content was too low to ensure trafficability of swamp bulldozers, they could not be used for earthworks without improvement.

Table 1. Physical properties of original soil.

No.	Laboratory test	Construction of embankment	Standard number
Soil particle density ρ_s (g/cm^3)	2.675	2.662	JGS 0111-2009
Natural water content w_n (%)	34.5	54.2	JGS 0121-2009
Grain size characteristics 2mm-(%)	0.0	0.0	JGS 0131-2009
75μm-2mm(%)	34.0	7.7	
-75m(%)	66.0	92.3	
Liquid limit w_L (%)	N.P.	60.9	JGS 0141-2009
Plastic limit w_P (%)	N.P.	28.9	
Ground material classification	ML	MH	JGS 0051-2009
Cone index q_c (kN/m^2)	64	34	JGS 0716-2009
Maximum dry density ρ_{dmax} (g/cm^3)	1.665	1.359	JGS 0711-2009
Optimum moisture content w_{opt} (%)	19.1	29.4	(A-c)

3.1 *Laboratory test*

In the laboratory test, crushed solidified soil samples were prepared on site by setting a standby time of 0, 7, 28 and 91 days. The sample with a standby time of 0 days was solidified soil. The solidified soil and the crushed solidified soil were brought to the laboratory immediately from the site to conduct a compaction test and cone index measurement. The unconfined compression test was conducted by setting a curing time of 0, 7, 28, 91 and 183 days. For a curing time of 0 days, samples were collected immediately after preparation. For 1 m^3 of the original soil, 70, 110 and 150 kg of solidifier, respectively, was used to prepare solidified soil and crushed solidified soil.

3.2 *Embankment construction*

Figure 2 shows embankment construction procedures using crushed solidified soil. The most economical combination of the type and the amount of solidifier to satisfy the requirements for embankment construction was found based on the laboratory test. The requirements for crushed solidified soil are a cone index of 400 kN/m^2 or higher to allow trafficability of a 3.5-ton combined roller, a 90% or higher degree of compaction (Japan Road Association 2001), which is the standard value for embankments in Japan, and an elution amount of hexavalent chromium of 0.05 mg/liter (Ministry of the Environment 1991), which is the standard

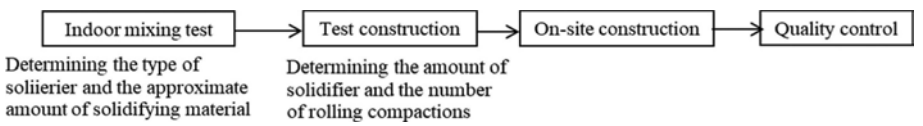

Figure 2. Embankment construction procedures using crushed solidified soil.

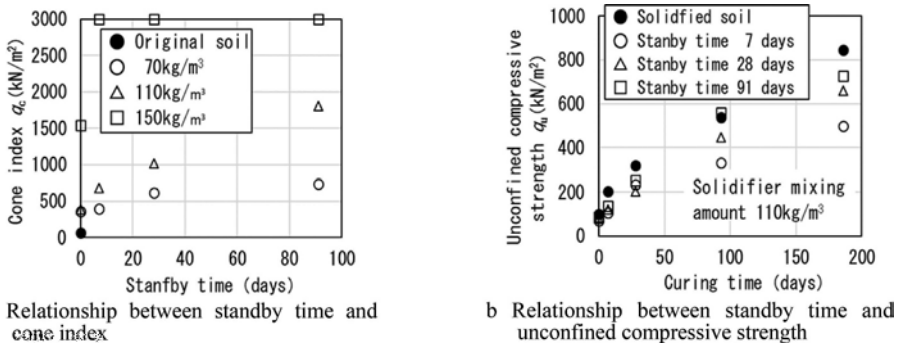
value for soil improved with a cement-based solidifier in Japan. Since the compaction, curing and other procedures differ between the laboratory test and the on-site construction, test construction was conducted to determine the mixing proportions for actual construction. In test construction, the soil and solidifier were mixed and compacted using the actual construction machines. Based on the test results, an actual embankment was constructed and managed.

4 RESULTS

4.1 *Laboratory test*

Figure 3a shows the relationship between the standby time and the cone index of crushed solidified soil. The cone index, which was 64 kN/m^2 for the original soil, increased when it was made into crushed solidified soil. The index increased as the amount of solidifier increased and the standby time increased. The solidified soil had to be mixed with 150 kg/m^3 of solidifier to achieve the target value of 400 kN/m^2. However, the target value could be achieved with crushed solidified soil using only 70 kg/m^3 of solidifier by setting a standby time of seven days. By preparing crushed solidified soil, the amount of solidifier can be reduced to less than half the amount needed for solidified soil.

Figure 3b shows a case of 110 kg/m^3 of solidifier as an example of the relationship between the curing time of crushed solidified soil and unconfined compressive strength. The unconfined compressive strength increased with a longer curing time. When the curing time was the same, the unconfined compressive strength of crushed solidified soil was lower than that of solidified soil, indicating that it is possible to suppress the development of strength.



a Relationship between standby time and cone index

b Relationship between standby time and unconfined compressive strength

Figure 3. Strength properties of crushed solidified soil.

Figure 4a shows the compaction curves of crushed solidified soil with a standby time of seven days. The maximum dry density of crushed solidified soil was lower than that of the original soil, and its compaction curve was different from that of the original soil. Figure 4b shows the relationship between the standby time and the maximum dry density. When the amount was 70 kg/m^3, the maximum dry density of the crushed solidified soil was higher than that of the solidified soil. When the amount was 110 kg/m^3, the maximum dry density was almost the same for both materials, regardless of the curing time. When the amount was 150 kg/m^3, the maximum dry density of crushed solidified soil was lower than that of solidified soil, and tended to decrease with a longer standby time. The maximum dry density of crushed solidified soil seems to be affected more by the amount of solidifier than by the standby time.

4.2 *Embankment construction*

At the embankment construction site, the standby time of crushed solidified soil was set as seven days, based on accumulated past knowledge about the material, the preparation amount and the size of the construction yard. Based on the results of the indoor mixing test for embankment construction, it was found that mixing 95 kg/m^3 of blast furnace cement Type B was the most
