of the pile are computed as 10196 kN and 2500 MN/m based on which the corresponding values of the parameters k_r, k_b, τ_{max} and q_u contributing to the pile response are 11.9 MN/m^3; 1402.3 MN/m^3; 28.8 kPa, and 7.07 MPa respectively. Based on empirical formulae from Section 2 of IS 2911 Part 1 for piles constructed in non-cohesive soils, the shaft and end bearing resistance for the pile are predicted to be 51.9 kPa and 6.5 MPa, respectively. According to IS 2911-Part 4, the base resistance is 1.76 MPa, while the shaft resistance is 85.14 kPa.

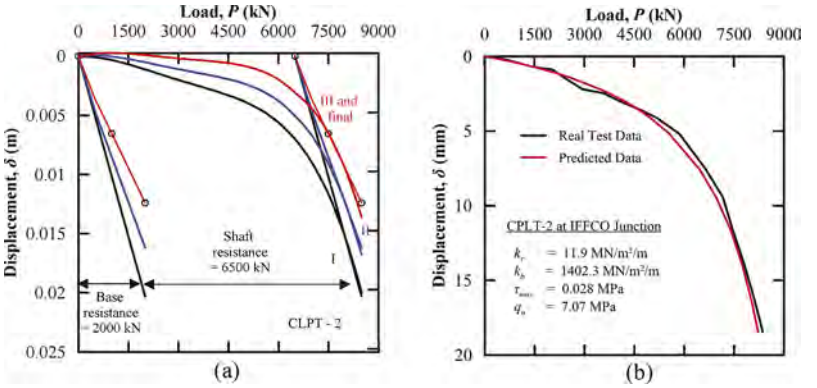

Figure. 4. (a) Shaft and base resistances based on IS-2911 for CLPT-2 (b) Comparison of measured and predicted load-displacement curves for CPLT-2.

4.3 *Test Location – 3*

Similar results as the above two case studies are presented in Figure 5 comparing measured and predicted load-settlement curves for cyclic pile load test (CPLT-3). The length and diameter of the pile installed are 20.25m and 1.2m respectively. The ultimate load and initial stiffness modulus, k_p are computed as 9859 kN and 2782 MN/m. The parameters k_r, k_b, τ_{max} and q_u contributing to the pile response in resisting loads are 11.25 MN/m^3; 1700.6 MN/m^3; 42.25 kPa, and 5.86 MPa respectively. The load-displacement plot from PLT is compared with estimated data, and matches well with the actual. The shaft and end bearing resistance of the pile are anticipated to be 52 kPa and 10.96 MPa, respectively, based on empirical formulas from Section 2 of IS 2911 Part 1 for piles built in non-cohesive soils. The base resistance is 1.76 MPa and the shaft resistance is 85.14 kPa, respectively, according to IS 2911-Part 4 graphical approach.

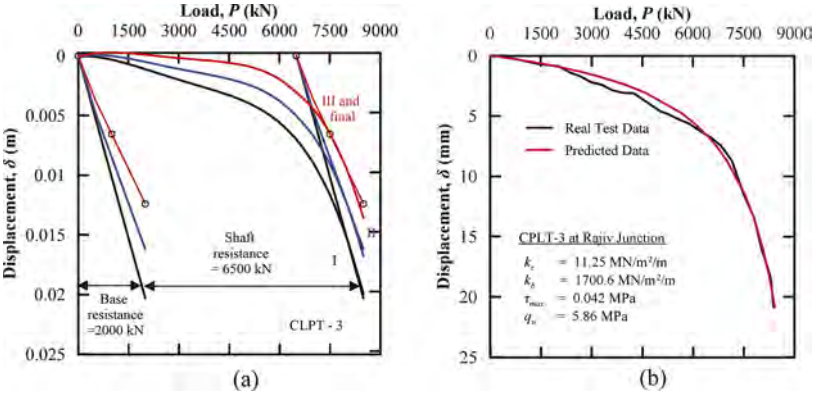

Figure. 5. (a) Shaft and base resistances based on IS-2911 for CLPT-3 (b) Comparison of measured and predicted load-displacement curves for CPLT-3.

4.4 *Test Location - 4*

Figure 6 Compares measured and estimated load-settlement curves for pile load tests (CPLT-4). The length and diameter of the pile installed are 18m and 1.2m respectively. The ultimate load and initial stiffness modulus, k_p are computed as 9322 kN and 3180 MN/m. The parameters k_r, k_b, τ_{max} and q_u contributing to the pile response in resisting loads are 46.2 MN/m^3; 40.39 MN/m^3; 91.59 kPa, and 2.74 MPa respectively. The load-displacement plot from CPLT is compared with estimated data, and matches well with the actual. Based on empirical calculations from Section 2 of IS 2911 Part 1 for piles installed in non-cohesive soils, the shaft and end bearing resistance of the pile are estimated to be 74.4 kPa and 9.3 MPa, respectively. According to the IS 2911-Part 4 graphical method, the base resistance is 2.21 MPa, while the shaft resistance is 88.41 kPa.

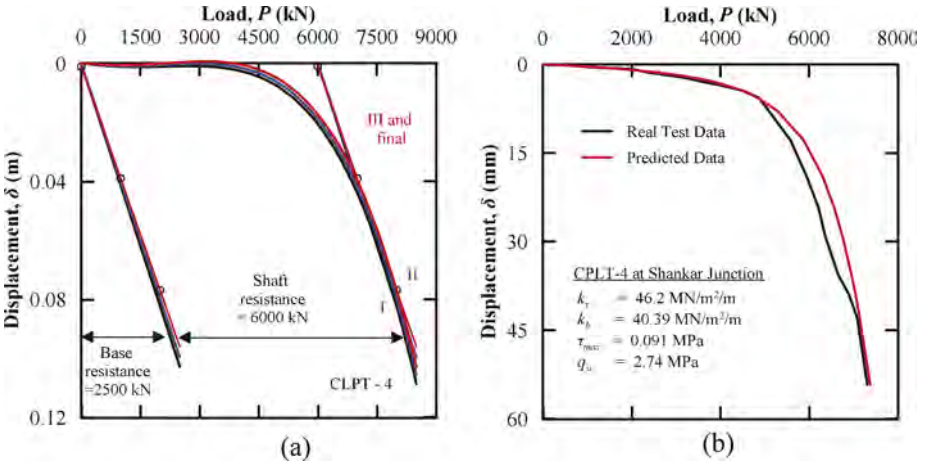

Figure. 6. (a) Shaft and base resistances based on IS-2911 for CLPT-4 (b) Comparison of measured and predicted load-displacement curves for CPLT-4.

5 RESULTS AND DISCUSSION

The predicted and actual load-displacement curves are compared in Figures 3 through 6. A close match in all four of them is obtained in the present study. These comparisons show that the non-linear load transfer functions used in the proposed method are appropriate and effective in characterizing the in situ load-displacement behaviour. Table 2 compiles the information for the four test sites and compares the predicted values with the estimated shaft and base resistances derived using various empirical correlations. The results are very consistent with the correlations in IS 2911 (Part 1 Section 2) that were based on SPT-N. However it should be noted that the empirical equations often underestimate the shaft and base resistances (ratio < 1). The results also match fairly the graphical approach provided in IS 2911 Part-4 in terms of results. Notably, this approach (IS 2911 Part 4) often overestimates (ratio > 1) base and underestimates (ratio < 1) shaft resistances.

6 CONCLUSION

A simple method to estimate the initial shaft-soil and base stiffnesses and the ultimate shaft and base resistances of a pile from the results of initial pile load test data is proposed. The predicted load – displacement plots based on the computed results compare well with the measured load - settlement curves. It is now possible to estimate the average shaft and base stiffnesses and resistances of the pile as installed from initial load test and compare the predictions with assumed values. A large data base can be built for all such cases which may help in revising the Code.

Efficient reduction of piles frost jacking with special coating

A.G. Alekseev, E.S. Grechishcheva, O.V. Kozlova & R.V. Makhota
N.M. Gersevanov Research Institute of Bases and Underground Structures, Russia

ABSTRACT: Air temperature in the Northern Hemisphere has been progressively warming in the recent decades, and the ground temperatures have increased correspondingly. The air temperature increasing due to the climate change induces degradation of permafrost and frost heaving activation. The frost heaving forces cause unevenly distributed damaging displacement of foundations and thus poses problems to the development of Arctic regions. Frost jacking can be reduced by protecting piles with an OSPT Reline (or Reline) polymer heat-shrinkable jacket. The interaction of heaving soil with a pile covered with the Reline jacket is modeled in laboratory to estimate the uplift force and the related shear strength of frozen soil along the soil-pile adfreeze surface at temperatures from −6 to −1 °C. The data are obtained for silty sand and silty clay soils and mortar (1:5 cement-sand mixture). The experiments show that frost-heave uplift forces on Reline-protected piles are 52% to 85% lower than on uncovered steel piles (steel grade 09G2S—analog to European steel grade S355JR), depending on soil type and temperature.

1 INTRODUCTION

The degrading permafrost loses its bearing capacity, which leads to damaging displacements of buildings and engineering structures [1,2]. Field observations from 1995 to 2007 revealed progressive active layer thickening [3], which continues to increase at 5 cm per year [4]. The mean annual temperature of the active layer was predicted to keep increasing in the future [5]. As the thaw depth increases, the surface area of the contact between the freezing ground and the foundations becomes larger, and the related processes in susceptible soils become ever more hazardous for the infrastructure. The frost heaving of freezing soils is one of such dangerous processes, which can lead to significant deformations of buildings and constructions. Currently, this process is widely studied by various specialists, and one of its directions is focused on the pile foundation stability to the effects of frost heaving forces.

Formation of ice lenses in the ground, or frost heaving, produces uplift forces that can act in tangential (shear) or normal planes, i.e., along the lateral surface or orthogonally to the foundation, respectively [6]. Pile foundations are commonly subject to shear forces that can reach considerable magnitudes and cause major damage to the infrastructure. These forces are caused by soil-pile adfreeze. In 2013–2014, frost heaving caused accidents to two new tanks of liquid natural gas, 20,000 m3 each, in the Zapolariye–Port Pur Pe pipeline system, as 10–15 cm cracks appeared in the cap of piles along the whole perimeter. The ground was stabilized by thermosyphons to −15 °C, till depths of 13–16 m, but the design took no account of the frost-heave uplift forces [7]. Another accident was reported in the same year [8] from the Urengoi area, where a pipeline segment rose 1.5 m above the ground for one year. In general, up to 1 billion USD is spent yearly for maintenance of pipeline structures and mitigation of damage associated with permafrost degradation [9]. One more example of deformation, other than in pipelines, comes from the Norilsk area where about 250 buildings and structures have been deformed for the recent decade out of which 40 houses had to be demolished [8,10].

DOI: 10.1201/9781003299127-215

The frost heave hazard has been currently prevented by placing piles to greater or by layer-by-layer ground freezing [11]. The other method for frost jacking prevention is based on using specially designed piles: screw piles [12] and belled piles [13] of different configurations. An alternative approach is to coat the pile surface with various protective compounds (epoxy or polyurethane resin, zinc, etc.), which can reduce frost-heave uplift forces. An advantageous solution that differs from the existing coating methods is to protect piles with a heat-shrinkable ready-made jacket OSPT Reline designed at the Ural Plant for Polymer Technologies "MAYAK" (Ozyorsk, Chelyabinsk region, Russia).

2 MATERIALS AND METHODS

2.1 *Materials*

Piles were modeled by plates made of 09G2S steel (analog to European steel grade S355JR), which is used for piles in industry. The samples were cut in the form of square parallelepipeds 80 × 50 × 20 (length, height, and width, respectively, in mm) and trimmed to surface roughness similar to that of hot-rolled pipe material. A half of samples was covered by Reline jacket (heat-shrinkable jacket made of a complexly-modified polyolefin polymer composite) 90 mm in diameter, in accordance with the size of the steel piles, and 2.1 mm thick on average.

The soil samples were selected among soil types which are widespread in the Russian Arctic regions. They were silty sand, known to be frost-susceptible [6], and soft high-plasticity silty clay collected, respectively, from the Zapolyariye–Pur-Pe pipeline area and the East Messoyakha oil-gas-condensate field. The investigated samples had a moisture content corresponding to 80% of the water saturation. Unlike the overdriven piles, bored precast piles are embedded into drilled holes of a larger diameter, and the space between the pile and the natural ground is backfilled with mortar (cement−sand mixture in a ratio 1:5). Thus, the precast piles contact the mortar rather than soil. Mortar was prepared by mixing carefully pre-dried silty sand with cement 500. The required amounts of sand–cement mixture were wetted successively. The mixture was compacted by rodding using a steel rod.

2.2 *Samples preparation*

The shearing tests were performed on a system designed by V. Ermakov, which allows estimating adfreeze strength [15], and is especially convenient for coated piles. The design permits coating the tested model and increasing its size correspondingly without changing other units of the system. Furthermore, the larger surface area of the sample (70 cm^2 instead of the 40 cm^2 standard size) ensures better accuracy of adfreeze estimates in the region of low values. The system consists of a steel casing and a covered or uncovered pile model.

Air-dried natural soil samples were saturated with water till specified moisture contents, and the obtained paste was compacted layer-by-layer in a sleeve. Density and moisture content were monitored while compacting and after the tests, respectively. The prepared samples were frozen to −15 °C, and then exposed to the specified run temperatures. We prepared 6 samples for each soil an each temperature (72 samples at all).

2.3 *Shearing tests*

In Russia, methods for estimating uplift forces associated with frost heaving in soils were developed long ago [6,15,16]. The forces of this kind are equivalent to shear strength and arise when the pile walls adfreeze to the ambient soil or mortar. The frost-heave uplift forces mainly consist of adfreeze force (70−80%) and friction (20−30%) [6]. Thus, the tests focused on estimating adfreezing by a well-known method. The testing was performed by incremental stepwise loading to determine shear strength along the adfreezing surface (Raf). The magnitude of load at the first and subsequent steps was chosen to provide at least four loading steps before fracture. Each step lasted till displacement stabilization, which was assumed to

correspond to displacement increment of 0.01 mm for 12 h. The shear strength along the adfreeze surface was determined as the highest shear stress at which displacement stabilized.

3 RESULTS AND DISCUSSION

The efficiency of coating was tested at negative temperatures of −1, −2, and −6 °C corresponding to the temperature range of natural soils (current values to temperatures). The tests provided estimates of shear strength along the adfreeze surface for covered (with Reline) and uncovered steel piles. The results (are applicable to estimate the bearing capacity of soil for permafrost foundation designs, as well as the reduction of frost-heave uplift forces due to Reline jacket. For comparison, a series of tests was performed on uncovered plates. The obtained shear strength values were considered as reference for further testing. Another series of tests was with samples in the Reline jacket. We provide results after statistical processing (Figures 1-3). Every point on a graph is designed value calculated on 6 values by statistical methods.

The testing results (Figures 1–3) show that the soil-pile adfreeze strength becomes lower at higher temperatures, for all materials (soils and mortar), in both covered and uncovered samples. However, the difference is much smaller for the piles in the Reline jacket. The effect of Reline was estimated (in %) by comparing the results for covered and uncovered samples. The result for uncoated steel was taken as 100%. Then the relation of coated (in the Reline) and uncoated steel in % was calculated. The difference between them is the reduction of adfreeze strength. The obtained estimates were applicable to calculate the reduction of frost-heave uplift forces due to Reline, since they are mostly associated with adfreezing. This approach can provide relative estimates despite large ranges of shear strength values for natural soils varying as a function of moisture content, density, mineralogy, and particle size of soils.

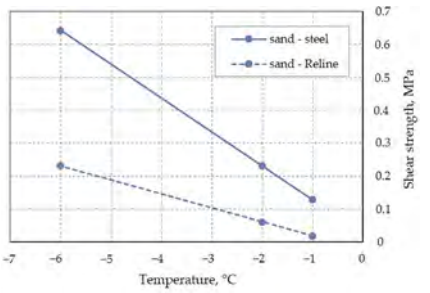

Figure 1. Temperature dependence of shear strength: sand-steel and sand-Reline.

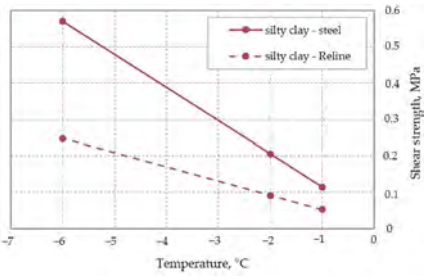

Figure 2. Temperature dependence of shear strength: silty clay-steel and silty clay-Reline.

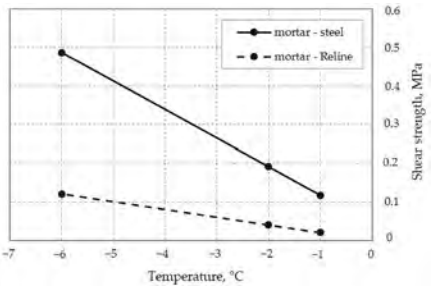

Figure 3. Temperature dependence of shear strength: mortar-steel and mortar-Reline.

Adfreeze strength (uplift forces) for soil and foundation material are usually determined during geotechnical surveys. However, in practice, the decision about frost jacking prevention measures are usually made at the stage of construction designing, when engineering surveys are completed. The calculated reduction of frost heave uplift forces at various temperatures can be used for forecasting of pile foundation stability of real building or engineering construction based on adfreeze strength values (or frost-heave uplift forces) obtained earlier (for example, during geotechnical surveys).

Thus, the use of Reline provides significant reduction of adfreeze strength and related uplift forces (and frost jacking as a result): 62–85% for silty sand, 52–55% for silty clay, and 80–85% for mortar (1:5 cement-sand mixture). The poorer effect of Reline in the case of silty clay at the same roughness reduction (~93%) may be due to smaller particle sizes: on a rough surface, it is easier to displace fine-grained clayey soil than coarser sand. Since the size of sand particles is commensurate with the roughness height of uncovered piles, the roughness reduction causes a greater adfreezing effect on sand than on clay. Furthermore, the effect of coating in the case of sand soil varies with temperature: it increases from 62% to 85% upon warming from −6 to −1 °C, possibly, due to greater amounts of unfrozen pore water and related moisture increase (from 0.2 to 2%, or ten times). The water content increase in silty clay at the same warming conditions is much smaller: 3 to 6%, i.e., two times [17]. The reduction of uplift forces is the greatest in mortar (80–85%), irrespective of temperature. The reason is that mortar develops additional strong structural bonds (compared with fine-grained soil) and lacks unfrozen pore water, due to mineralogy (99% is quartz) and particle sizes of the sand (predominate fraction is 0.2–0.3 mm), since all unfrozen pore water is spent for cement hydration.

4 CONCLUSION

The use of Reline jacket reduces significantly (52 to 85%) the adfreeze strength and related frost-heave uplift forces on piles (and frost jacking too). The jacket is the most efficient for mortar (80–85%) and least efficient for silty clay (52–63%). In general, the reduction of uplift forces and its temperature dependence have several causes: changes in the roughness of protected pile surfaces; soil particle sizes; presence or absence of unfrozen pore water; temperature dependence of total moisture content at the account of unfrozen pore water.

Reline can successfully combat frost jacking of foundations, for both overdriven and bored precast piles. This effect is especially important in the context of ongoing permafrost degradation. Design solutions with due regard for the global change are indispensable for new construction projects in permafrost, in order to minimize deformation of foundations and structures associated with frost jacking and the ensuing accidents. The use of the Reline jacket can be an ideal solution for bored precast piles with grouting.

Determination of the helical pile bearing capacity by its installation torque

A.G. Alekseev, S.G. Bezvolev & S.A. Vinogradova
N.M. Gersevanov Research Institute of Bases and Underground Structures, Russia

ABSTRACT: The paper characterizes the state of the issue of designing effective structures of helical piles, testifying to the relevance of this scientific and technical problem in conditions of insufficient development of the existing norms. The technique of determining load-carrying capacity of a pile by the moment of screwing fixed during its immersion is considered. The correlation coefficient formula and the technique of determining the ultimate soil contact friction on the side surface of several types of helical piles developed as part of the advancement in solving the research problem are presented.

1 INTRODUCTION

At the present time, large construction companies (A.B.Chance Co., etc.) which use helical piles (HP) have the practice of controlling the bearing capacity of HP F_u by the value of the screwing resistance torque T_k fixed during their immersion at the construction site due to the generalization of data on the objects. Even in the absence of normative expressions for the transient dependence $Fu = f(T_k)$, the method of measuring T_k and the determination of this dependence on a particular site allows to reduce the number of control piles at expensive field static tests. For this purpose, in the Russian practice, according to [Town Planning Code of 29.12.2004], individual special technical specifications (STS) are developed for design of foundations made of HP at individual construction sites. In order to develop normative dependences for $f(T_k)$ allowed for use in designing or to develop a corporate standard of the organization (STO), it is necessary to develop a justification for specific types of HPs and soil conditions.

The analysis of the state of the issue is performed on the basis of the research data [Alekseev, Beszvolev et al 2018a. 2018b. 2020], thematic review articles [Halturin 2012] and capital monographs [Zhelezkov 2004, Perko 2019]. According to the current Russian regulatory document [SP 24.13330.2021] for helical piles is allowed to determine the bearing capacity of soils based on the results of static testing of natural piles and using the recommended in [SP 24.13330.2021] for certain types of HP algorithms for calculating the strength characteristics of soil found during the survey.

The most reliable method for determining the bearing capacity of piles is the method of field static tests, at the same time it is the most costly both financially and in terms of time. When applying the calculation methods, there is a question of applicability of the existing calculation algorithms to helical piles of different types (Figure 1), because its size (configuration, number of propeller blades, distance between them, etc.) largely determines the mechanism of the propeller pile. However, analytical methods of calculation [SP 24.13330.2021] are actually developed on the basis of researches only of single helical wide-bladed HP (Figure 1.1a). In addition, in these methods there are inevitable errors associated with the definition of soil characteristics, as well as their averaging over a large volume of heterogeneous soil mass.

The general disadvantage of the recommended methods [SP 24.13330.2021] is the lack of control over the bearing capacity of each pile being installed, which is especially relevant for the building area with heterogeneous engineering and geological conditions. One of the

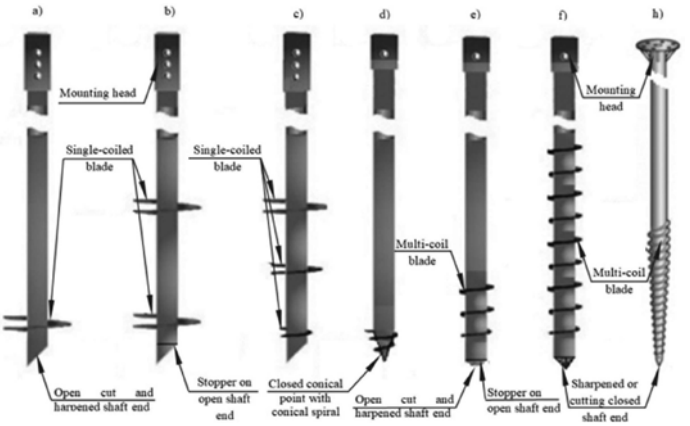

Figure 1. Main types of helical piles produced in Russia and features of their design.

a) single-blade with one working blade, formed by a coil spiral, wide-blade (d/D<0,6); b) multi-blade (two-blade example) cylindrical (with the same blade diameter) wide-blade; c) multi-blade (three-blade example) cone (with different blade diameters); d) single-blade with a solid conical tip with a cone spiral; e) multi-coiled narrow-bladed (d/D>0,6) with open sharpened or cutting shaft end; f) also with closed end; h) also with elongated conic point with conic spiral.

peculiarities of HP foundations arrangement is the possibility to measure the T_k required for pile driving. The presence of correlation between helical pile`s F_u at static compressive and pulling loads and the T_k applied during its immersion has been identified since the 1960s by developers in various countries on a significant number of sites.

The formula [Hoyt et al. 1989] is usually used for the experimental estimation of the calculated helical pile`s F_u by T_k, necessary for its immersion:

$$F_u = K_t T_k \tag{1}$$

where K_t = coefficient of proportionality.

In works [Hoyt et al. 1989, Ghaly 1995, Zhelezkov 2004, Livneh et al. 2008, Tsuha et al. 2010, Perko 2019] the values of K_t, as well as the factors determining it, were studied for different types of HP in different soil conditions. In work [Hoyt et al. 1989] the results of full-scale tests on static pulling loads of 91 piles with the number of turns from 2 to 14 and blade diameters from 152 to 508 mm, performed at 24 different sites were considered. Based on the data obtained in work [Hoyt et al. 1989], it was assumed that the K_t coefficient depends mainly on the diameter of the pile shaft.

In work [Perko 2019] an analysis of the results of more than 300 tests of the HP in different engineering-geological conditions was carried out. Within the framework of testing the hypothesis [Hoyt et al. 1989] that the K_t coefficient depends mainly on the diameter of the pile shaft, a correlation formula was obtained:

$$K_t = \lambda_k / d_{ef}^m \tag{2}$$

where d_{ef} = effective diameter of the pile shaft (for a circular cross-section equals the diameter, for a square cross-section equals the length of the diagonal); m = power factor equal to 0.92; λ_k = coefficient equal to 1433 mm^m/m.

It turned out that dependence (2) has a very low coefficient of determination (R^2) equal to 0.64, therefore, the coefficient K_t depends significantly on other parameters besides the diameter of the pile shaft.

To analyze the parameters influencing the K_t coefficient, in work [Perko 2019] the dependence:

$$K_t = H / d_{ef} \tag{3}$$

in which the parameter H turned out to depend mainly on the diameter of the HP barrel, the diameter, pitch and thickness of its propeller blade, the type of ground and, insignificantly, on the number of coils of the propeller blade, as well as the values of the axial load and torque.

In work [Livneh et al. 2008] the results of full-scale tests of 19 HP on one site with sandy soil and on two sites with dusty-clayey soils are presented. Were tested HP with a square cross-section shaft with a diagonal of 45 mm and three welded blades with diameters of 200, 250 and 300 mm, spaced along the length of the trunk. In work [Livneh et al. 2008] it was concluded that the value of K_t coefficient largely depends on the direction of the force on the pile and on the type of soil.

The article [Tsuha et al. 2010] presents laboratory tests of model HP on pulling out in a centrifuge in sands of different density. The results showed that the value of K_t coefficient depends on relative density of sand, size of barrel and blades of HP and does not depend on their number. The authors developed a formula:

$$K_t = 2/(d_c \tan(\delta_r + \theta)) \tag{4}$$

where δ_r = angle of metal-sand friction; d_c and θ = parameters depending on the diameter of the pile barrel, diameter and pitch of the propeller blade.

A comparison of formulas (2) - (4) shows their common empirical basis. In particular, (2) and (4) can be reduced to the more general form (3).

In Russian practice, the connection between the load-carrying capacity of the HP and the torque was considered by Zhelezkov V.N. in his monograph [Zhelezkov 2004]. The dependence of the K_t coefficient on the load direction and on the physical and mechanical characteristics of the soil was revealed. Dependence on HP configuration was not obtained due to insignificant difference in geometric dimensions of blades and barrels of tested HP.

The above analysis of the articles testifies about the sufficient validity of the determining method of helical piles carrying capacity by the amount of installation torque required for pile`s screwing. The corresponding dependence (1) with the proportionality coefficient K_t has been qualitatively confirmed by numerous experimental and theoretical researches. Quantitative match between the calculated and experimental results is determined by the reliability of the coefficients used for calculations, linking the bearing capacity of the pile and the amount of the installation torque. In order to develop normative dependences allowed for use in designing for calculating the K_t coefficients, it is necessary to conduct experimental studies for each type of helical piles used in various soil conditions.

An essential weak point of published data [Hoyt et al. 1989, Ghaly 1995, Zhelezkov 2004, Livneh et al. 2008, Tsuha et al. 2010, Perko 2019] is a different and sometimes indefinite approach to the evaluation of an amount (criteria) of helical pile`s carrying capacity according to the F_u test results and the differences in their methods (continuous immersion, staggered, accelerated, long-term). At the moment, dozens of different criteria for the experimental value F_u are used during the practice of the geotechnical science. Significant uncertainty is also created by the effect of differences in the designs of the tested helical piles and the immersion techniques (rotation speed, axial load size, etc.), that also includes impact on the value of the torque of screw resistance T_k.

For these reasons, the use of published [Hoyt et al. 1989, Ghaly 1995, Zhelezkov 2004, Livneh et al. 2008, Tsuha et al. 2010, Perko 2019] data on the values of T_k and the correlation between T_k and F_u in order to check the theoretical dependence of T_k and to calibrate the correlation dependence T_k - F_u seems to be difficult due to the practical impossibility of selecting results that meet the requirements of criteria and methods listed in the regulatory documents of the Russian Federation. It also seems problematic because of the inaccessibility of materials related to the characteristics of the tested soils.

2 THEORETICAL BASE OF THE IMPLEMENTED RESEARCH

This article is limited by constructions which are close to cylinder-shaped ones (Figure1d–h). We are going to call it “ground-screw pile” (GSP).

GSP is made of a metal pipe with a spiral-ply and a closed cutting tip with a sharpening angle of 60°. This kind of pile is immersed in the soil by rotation in combination with indentation, it has found application in domestic practice as a bearing element of foundation or hoarding [Moscow Government 1997]. Simple national equipment makes it possible to successfully immerse such constructions with a pipe diameter of 600 mm and length up to 12 m even in very dense and durable soils [Moscow Government 1997].

Recently, foreign cone-spiral screw piles (CSSP) «BAU» [Altai region national expertise 2011], which are close to GSP have appeared in Russia. Spiral winding of these piles is performed on an elongated conical part. With a length up to 3-3.5 m and a tubular shaft diameter up to 108-133 mm CSSPs are immersed with a small torque using a low-power rotator. In addition to transport construction, the driving of such micropiles is very popular in the sphere of small entrepreneurship for the rapid construction of small buildings and constructions, for example, agricultural facilities or residential cottages.

The theoretical analysis of screw pile immersion mechanism which was provided by Gersevanov Research Institute of Bases and Underground Structures shows that T_k (installation torque) is determined mostly by contact friction of the soil and the surface of cylindrical-shaped shaft τ_s, round blade τ_{fi} and soil core τ_{fl} that is located near shaft edge. We should ignore less significant factors such as soil resistance in order to achieve in particular, friction on the surfaces of the edges τ_{ti} and soil resistance to cutting by the edge of the frontal (lower) blade σ_{t1}, the inclination of the helix of the blades and the cone of the tip, as well as the value τ_{fi} that is typical for narrowed (d/D> 0.8) blades (helix) of the GSP. Very complex, actually unsuitable for practical application and, in our opinion, controversial expressions for taking into account these factors are given in [Zhelezkov 2004]. We also note that at the end of the immersion, the friction at the tip of the shaft τ_{fl} along the frontal surface is obviously less than the lateral friction τ_{sl} on the shaft inner surface against the soil "plug" formed during screwing inside the shaft near the edge.

According to the mechanism of immersing GSP, we`ve got a formula for T_k as follows:

$$T_t = 2\pi r^2 \int_0^l \tau_s(z)dz + 2/3\pi r^3 \tau_f(l) \tag{5}$$

where r = radius of tubular shaft (pipe) considering a GSP spiral; l = work length (immersed in the soil) of GSP.

The degeneracy of the second component(5) while pulling out the GSP means a direct proportionality between the corresponding ultimate soil resistance F_u and the installation torque $F_u=T_k/r$. Thus, in this case, the coefficient K_t of dependence (1) is theoretically determined by the formula $K_t = 1/r$, and for dependencies (2) and (3) we obtain $\lambda_k = H=2$, $d_{ef}=2r$ and $m=1$.

According to the presented analysis, it is expedient to process the data of static tests of the GSP to determine the correlation dependence of the helical piles carrying capacity on the installation torque based on the formula:

$$F_{u,n} = K_f T_{k,n}/r \tag{6}$$

where

$F_{u,n}$ = partial value of immersed GSP bearing capacity on the ground for the vertical load; $T_{k,n}$ = installation torque fixed when a helical piles is immersed to the designed mark; K_f = dimensionless correlation parameter.

The absence of dimension demonstrates the obvious advantage of the parameter K_f in comparison with the dimensional proportionality coefficient K_t discussed in detail above (formulas (3) and (4) over (1) and (2)). Thus, the developed equation allowed us to theoretically confirm the feasibility of using the empirical formula (3), which coincides with (4) for $d_{ef} = 2r$ and $H = 2K_f$. By highlighting the main influence of the shaft cross-section (3) and (4), the dimensionless correlation parameter makes it possible to better reflect the influence of other factors.

For FM24 model of CSSP with a shaft diameter d=76.2 mm, there is a set of studies presented in work [Noskov et al. 2019], including experimental immersion and static tests of the CSSP on an experimental site composed of loess-like solid sandy loam. Tested on 2 piles with a length l of 1.5; 2, 2.5, 3 and 3.5 m with a lower conical part 55 cm high. In the last 50 cm of the pile insertion, the average value of the torque T_k was recorded.

The tests were carried out according to the method of the standard [GOST 5686-2012], taking into account the instructions of the standards [SP 24.13330.2021]. The static load was brought to a value at which the draft was at least 40 mm. With this settlement, in all experiments, the pile bursting was achieved, and the particular value of the ultimate pile resistance F_d was taken equal to the previous load value, at which the stabilized pile settlement ranged from 4 to 13 mm. A summary of measured T_k and set F_d is given in the Table 1.

Table 1. Cone-spiral helical piles test results [Noskov et al. 2019].

№	1	2	3	4	5	6	7	8	9	10
l, mm	1500	1500	2000	2000	2500	2500	3000	3000	3500	3500
F_d, kN	20,0	22,5	28,0	28,0	40,0	35,0	42,0	36,0	52,5	52,5
T_k, kN m	0,8	0,91	1,21	1,08	1,65	1,42	1,61	1,5	2,25	2,15

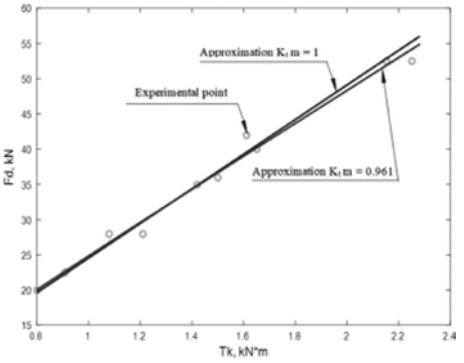

Figure 2. Matching of approximations listed in [TKP 45-5.01-254-2012] experimental data.

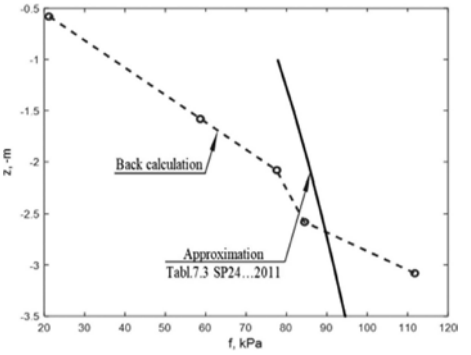

Figure 3. Using the results back calculation method τ_s with f tabl.7.3 [SP 24.13330.2021].

Statistical processing [Noskov et al. 2019] of the obtained data series $F_d - T_k$ using a power model of paired (one-factor) regression led to a two-parameter dependence $F_d = 24{,}845\ T_k^{0{,}961}$ with coefficients of determination $R^2 = 0.986$ and variation $v = 0.040$. The proximity to 1 of the power exponent $m = 0.961$ of this dependence confirms the assumption made above about the direct linear correlation of $F_u - M_u$ for GSP. Thus, our alternative statistical processing with the choice of $m = 1$ led to a one-parameter dependence $F_d = 24{,}552 T_k$ with determination coefficients $R^2 = 0.983$ and variation $v = 0.042$. Thus, both dependencies have excellent and practically equivalent indicators (Figure 2). A certain deviation in the direct one-parameter dependence of the coefficient $K_t = 24.552\ m^{-1}$ from the theoretical value $K_t = 2/d = 26.247\ m^{-1}$ is apparently caused by the frontal work of the cone part of the CSSP when it is pressed in.

For example, the one-parameter dependence $F_d = 24{,}552 T_k$ obtained above for GSP in loess-like sandy loam is converted to $F_d = 0{,}935 T_k/r$, which shows that the influence of other factors is 6.5%.

Tracking the measured values of the screwing torque $M_{u,n}$ as the GSP is immersed and comparing them with the M_u values calculated by (5) is an effective way to assess the strength properties of soils in their natural occurrence [2].

In the simplest case of GSP (see Figure 1d–h), by inverse calculation from formula (5) it is possible to determine the distribution along the length of the pile (the depth of the soil base) of the specific contact friction of the soil on the side surface of the steel shaft of the pile τ_s. In particular, neglecting a slight change with depth τ_f, sequentially determining $\tau_{s,i}$ for each segment of the depth dz_i by $dM_{u,i}$

$$\tau_{s,i} = dM_{u,i}/A/dz_i \tag{7}$$

where $A = 2\pi r^2$; $dM_{u,i} = M_{u,i} - A\sum_{k=1}^{i-1} \tau_{s,k} dz_k$,

Such a definition of τ_s is of great practical importance, since the use of the tabular values τ_s for helical piles established for the side surface of reinforced concrete driven piles (*f* Table 7.3) allowed [SP 24.13330.2021] is theoretically incorrect. In this regard, we note that in the modern standards of the Republic of Belarus [TKP 45-5.01-254-2012], when calculating the helical piles, the values of f are established according to the processing of the results of testing soils with steel piles.

Using the data of [Noskov et al. 2019] (table) and formula (5), the graph of the change in $\tau_s(f)$ along the length of the CSSP immersed in the loess-like solid sandy loam presented in Figure 3 was obtained.

Comparison of the obtained τ_s with the values of *f*, obtained according to the data of Table 7.3 [SP 24.13330.2021], confirms the adequacy of the developed back calculation method. Thus, the average values of τ_s and f in the general depth interval are close to each other. In this case, the growth of τ_s with depth is much more intense than that of *f*, which is consistent with the generalized experimental data [Glotov et al. 1975].

3 CONCLUSION

The theoretical analysis carried out showed the feasibility of using the obtained dependence (6) to determine the bearing capacity of a screw pile $F_{u,n}$ by the value of the torque $M_{u,n}$ required for its twisting. By highlighting the main influence of the shaft radius, the dimensionless correlation parameter K_f makes it possible to better reflect the influence of other factors. The difference between the value of K_f and 1 shows the degree of influence of other factors, in particular, the role of the operation of the blades and the tip in the bearing capacity of the helical pile.

In the simplest case of a helical pile recursive calculation using formula (7) can determine the distribution along the length of the pile (depth of the soil base) of the specific contact friction of the soil on the side surface of the steel shaft of the pile τ_s. Such a definition of s is of great practical importance, since the values of τ_s used by the norms [SP 24.13330.2021] for helical piles established for the side surface of reinforced concrete driven piles (*f* Table 7.3 [SP 24.13330.2021]) are theoretically incorrect. Based on the results of processing the results of soil tests by means of the GSP, reliable and rational standard values of *f* for the lateral surface of steel helical piles can be established.

On the use of seismic energy in deep compaction of loess subsidence soils by hydraulic explosions

ABSTRACT: The authors have developed a method of deep compaction of loess subsidence loams, which uses the energy of an earthquake (or earthquakes). The energy of earthquakes is commensurate with the energy of explosions, therefore, pre-humidification of the compacted subsidence layer during the seismically active period will improve the quality of soil compaction. Initially, the seismic activity of the territory is recorded. When the locking through drainage wells to a state of fluid consistency stops, deep explosions are produced in the wells. Under the conditions of seismic activity of the territory, physico-chemical processes in the soils are intensified due to the activation of geoelectromagnetic and geoacoustic fields. Under these conditions, capillary and mass transfer processes in soils are intensified. Therefore, during this period, it is most effective to carry out locks and explosions in the ground mass. Post-explosive consolidation of the main part of the deformation of the compacted subsidence array lasts at least 5-8 months. Such a long period is sufficient for the realization of a natural earthquake. Seismic activity during the consolidation of the subsidence array contributes to the consolidation of the subsidence array and accelerates the process. Any tangible earthquake is effective for the process of doubling the subsidence array. The efficiency of the use of earthquake energy in compaction of subsidence soils by hydraulic explosions is theoretically justified.

Keywords: subsidence, earthquakes, energy, territory, explosion, well, compaction, consolidation, seismic activity

The works of V.T. Trofimov [1], N.I. Krieger [2], H.M. Rendell [3], S.Z. Rozycki [4], M. Pecsi [5], J. Sajgalik [6], Wei Lanying, Gui Jiuxi, Lu Yanchon [7] are devoted to the study of the properties of loess subsidence soils, M.Zarate, A. Blasi [8] and others.

The works of Yu.M. Abelov and M.Yu. Abelov [9], I.M. Litvinov [10], S.N. Klepikov, A.S.Tregub and I.V. Matveev [11], A.A. Mustafayev [12], S.K. Aliyev [13], V.I. are devoted to the development of effective methods of construction on subsident loess soils. Krutova, A.S. Kovaleva and V.A. Kovaleva [14] and others.

As is known, a significant part of the areas of subsidence of loam falls on areas with high seismic activity. In this regard, the issue of using earthquake energy during deep compaction of subsident loamy massifs with a capacity of more than 10 m, in combination with other methods of deep compaction of subsident soils, in particular with hydraulic explosions, becomes very relevant.

Studies of I.M.Litvinov [10], A.M.Ryzhov [15], F.G.Gabibov [16] and others are devoted to the hydro-explosive method of compaction of subsidence arrays.

2 THEORETICAL FOUNDATIONS OF THE POSSIBILITY OF USING EARTHQUAKE ENERGY IN DEEP COMPACTION OF SUBSIDENCE SOILS

For the first time, the idea of using earthquake energy for deep compaction of subsident loams was put forward by F.G.Gabibov [17] in the early 90s of the last century. The energy of earthquakes is commensurate with the energy of high-power explosions, therefore, pre-humidification of the compacted subsidence layer during the seismically active period will significantly improve the quality of soil compaction.

If, according to the project, the work on deep compaction of subsident loess soils coincides with the seismic activity of the territory, then this factor can practically be used from an engineering point of view.

Modern scientific and engineering achievements allow us to use proven methods of recording seismic activity of the territory. Among them, we can mention seismogeodynamic, electromagnetic and biological methods, described in detail in the monographs of M.Ikea [18], K.Mogi [19], T.Rikitake [20] and others.

Among the seismogeodynamic methods of earthquake prediction, it is interesting to use a seismic harbinger discovered by Soviet scientists. Many months before an earthquake, rock cracking reduces the velocity of longitudinal waves. Based on the algorithms of long-term forecasting developed under the guidance of V.I. Keylis-Borok, the accuracy of the forecast increases several times. The most informative geochemical harbingers are the appearance of components of deep origin in the composition of groundwater and gases: inert gases (primarily helium and radon), hydrogen, nitrogen, as well as mercury vapor. Their variations provide material for various stages of medium- and short-term forecasting (days, months).

Electromagnetic phenomena are short-term harbingers. During compression and destruction of rocks, various mechanoelectric and electrokinetic effects occur, which generate alternating electric fields underground and in the atmosphere. The most effective, although not frequent, electromagnetic harbinger is light phenomena.

Biological methods of earthquake prediction are associated with the abnormal behavior of animals (mammals, birds, reptiles, fish) manifested before an earthquake.

3 DEVELOPMENT OF AN ENGINEERING METHOD FOR DEEP COMPACTION OF SUBSIDENCE SOILS USING EARTHQUAKE ENERGY

The authors have developed a method of deep compaction of loess subsidence loams by hydraulic explosions, which uses the energy of an earthquake (or earthquakes).

Using one of the methods of earthquake prediction, or a set of these methods, the seismic activity of the territory is first recorded.

The compacted section 1 (see Figure 1) is separated from the non-compacted section 2 by digging contour trenches 3. Drainage and blast wells 4 are drilled, into which blast pipes 5 are installed. Explosive charges (explosives) are installed at the bottom of the pipes 6. After that, drainage wells 4 are filled with drainage material 7. The sealed area is locked in a limited zone with boundaries 8, which on the sides coincide with the bottom of contour trenches, and from below reaching the boundary between the subsidence array 9 and the underlying non-subsidence soil 10.

After the seismic activity of the territory is recorded along the boundaries of the compacted area 1, contour trenches 3 are dug using, for example, a deep trencher, to a depth of 5-7 m. Then, within the compacted sections 1, drainage and explosive wells 4 are drilled to a depth of 2/3 of the subsidence array 9. Explosive pipes 5 made of metal or plastic are installed in these wells, at the bottom of which explosive charges 6 are installed. After that, the space between the walls of the well 4 and the blast pipes 5 is filled with drainage material 7,

for example coarse sand or gravel. The compacted section 1 is soaked through drainage wells 4 with water to a state of fluid consistency (see Figure 1). The boundaries of moisture 8 should coincide with the bottom of contour trenches 3, and from below reach the upper boundary of the underlying non-sedimentary soil 10.

When the lock stops, explosives 6 explode in wells 4. Under the influence of these deep explosions, artificial seismic vibrations are created in the compacted subsidence area 1, which contribute to accelerated deep compaction of the subsidence array (see Figure 2).

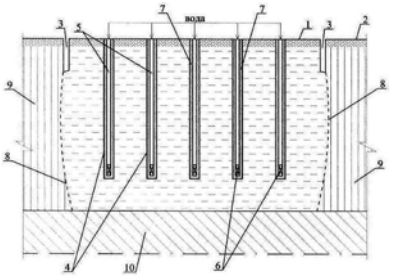

Figure 1. Scheme of deep compaction of loess subsidence loamy massif during soil moistening in the seismically active period before an earthquake.

Under the conditions of seismic activity of the territory, physico-chemical processes in the soils are intensified due to the activation of geoelectromagnetic and geoacoustic fields. Under these conditions, capillary and mass transfer processes in porous media are intensified. Therefore, it is during this period that it is most effective to carry out locks and explosions in the ground mass. After explosions of explosive charges 6, explosive pipes 5 are removed from the well by vibration pulling, which also contributes to additional compaction of the subsidence array. It should be noted that soaking of the compacted area and deep explosions are carried out in the seismically active period before an earthquake.

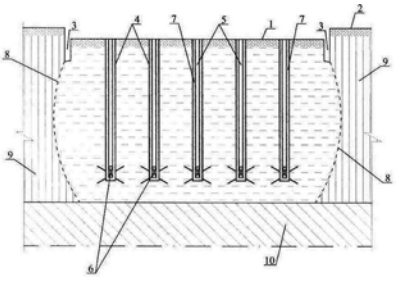

Figure 2. Scheme of deep compaction of loess subsidence loamy massif during the impact of deep explosions on the soil massif in the seismically active period before the earthquake.

The post-explosive consolidation of the main part of the deformation of the compacted subsidence massif lasts at least 5-8 months (see Figure 3). Such a long period is sufficient for the realization of a natural earthquake predicted by the seismic activity of the territory. Thus, an earthquake (or earthquakes) occurred during the consolidation of the subsidence array (see Figure 4) contributes to the consolidation of the drawdown array and accelerates the consolidation process. It should be noted that any tangible earthquake (intensity of at least 3 points) is effective for the process before compaction of the subsidence array. Even if an earthquake does not occur during the period after explosive consolidation in the seismically active period, the activity of geomagnetic and geoacoustic fields, which are an integral part of seismic energy, leads to activation of the consolidation deformation process.

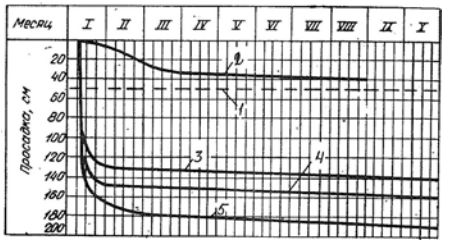

Figure 3. Graphs of consolidation of surface subsidence arrays: 1-calculated drawdown according to the SNiP; 2 - actual drawdown during normal soaking; 3, 4, 5 - actual drawdowns and precipitation during hydro-explosive compaction (according to those characteristic sites).

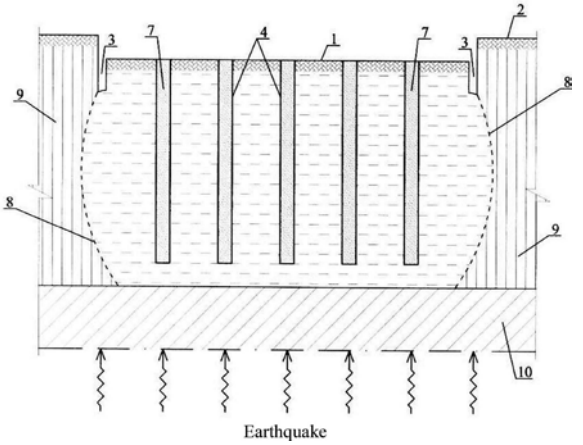

Figure 4. Scheme of deep compaction of loess subsidence loamy massif in the process of compaction of the soil mass by the energy of a natural earthquake.

Seismic waves passing through the ground during the period after explosive consolidation are practically elastic waves, of which transverse waves are of the greatest importance from an engineering point of view. With transverse waves, elastic soil particles oscillate in a direction perpendicular to the motion of the wave front. Let's denote the direction of motion of the wave x, and the direction of vibration of the particles y (see Figure 5). Under the action of a passing wave, the ABCD element moves and takes the form of an element. If the movement of the AB side is assumed to be equal to and, and the sides, then

$$du = \frac{\partial u}{\partial x} dx, \tag{1}$$

where $\partial u/\partial x$ characterizes the shear deformation.

Similarly, if the direction along AB is τ, and along CD $\tau + d\tau$, then

$$d\tau = \frac{\partial \tau}{\partial x} dx. \tag{2}$$

Since the element $ABCD$ experiences acceleration determined by the difference of forces on the sides AB and CD, the equation of motion takes the form

$$d\tau = \frac{\partial^2 u}{\partial t^2} \rho dx, \tag{3}$$

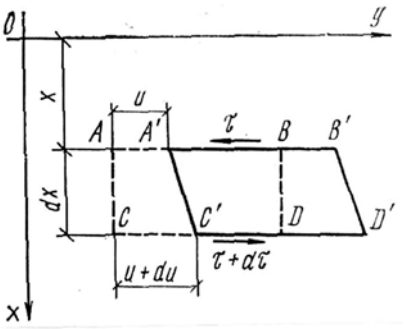

Figure 5. Diagram of the movement of the soil element when the wave is found.

where $\rho-$ the density of the element of the compacted subsidence soil. From here

$$\rho = \frac{\partial^2 u}{\partial t^2} = \frac{\partial \tau}{\partial x}. \tag{4}$$

In an elastic soil environment, stresses are proportional to deformations

$$\tau = G\frac{\partial u}{\partial x} \tag{5}$$

and therefore:

$$\rho = \frac{\partial^2 u}{\partial t^2} - G\frac{\partial^2 u}{\partial x^2} = 0. \tag{6}$$

Taking now

$$c = \sqrt{\frac{G}{\rho}}, \tag{7}$$

we get

$$\frac{\partial^2 u}{\partial t^2} - c^2\frac{\partial^2 u}{\partial x^2} = 0. \tag{8}$$

The resulting equation is a differential equation of shear oscillations. If the appropriate function $F_1(z)$ argument $z = t - \frac{x}{c}$ substitute in (8) instead of and and consider it to be twice differentiable, then any function of the accepted class will satisfy this condition. Therefore:

$$u = F_1\left(1 - \frac{x}{c}\right). \tag{9}$$

With such a fluctuation in the case of constancy $t - \frac{x}{c}$ the displacement in the compacted soil will be the same. Thus, moving in a place with the x coordinate at time t will be the same as moving through time Δt at a point $x + c\Delta t$. This means that a certain set point in the process of oscillation moves in a positive direction with a constant velocity of C. This phenomenon is called wave motion, and c is the propagation velocity. By analogy with the expression (9), another suitable function $F_2(z)$ argument $z = t + \frac{x}{c}$:

$$u = F_2\left(t + \frac{x}{c}\right) \tag{10}$$

it will also satisfy equation (8) and characterizes the wave motion in the negative x direction. The sum of expressions (9) and (10) is also a solution of equation (8).

In an elastic ground environment with propagating waves, deformation occurs at a certain moment t at a distance of x

$$\gamma = \frac{\partial u}{\partial x} = \frac{1}{c} F_1^{'}(z), \tag{11}$$

where the stroke means differentiation F_1 by z. Hence the energy of deformations in a single volume

$$W_s = \frac{G}{2}\gamma^2 = \frac{G}{2c^2}\left\{F_1^{'}(z)\right\}^2 = \frac{\rho}{2}\left\{F_1^{'}(z)\right\}^2. \tag{12}$$

The velocity of the soil particle in this place is equal to:

$$\upsilon = \frac{\partial u}{\partial t} = F_1^{'}(z) \tag{13}$$

and kinetic energy in a single volume

$$W_k = \frac{\rho}{2}\upsilon^2 = \frac{\rho}{2}\left\{F_1^{'}(z)\right\}^2. \tag{14}$$

If we now denote the total energy in a unit volume by W, then as the sum of the deformation energy and kinetic energy, it is equal to

$$W = W_s + W_k = \rho\left\{F_1^{'}(z)\right\}^2. \tag{15}$$

Since this energy is associated with the movement of waves at a speed of c, the energy per unit area per unit of time (the intensity of the energy flow) is equal to:

$$Q = c\rho\left\{F_1^{'}(z)\right\}^2. \tag{16}$$

Usually, waves moving forward and waves moving backward exist simultaneously, and the energy in a single volume is equal to the sum of the corresponding energies of incident and reflected waves in the same volume.

The rising wave, reaching the surface of the earth, is reflected and goes back. In Figure 6, the abscissa axis along the ground surface shows an incident (suitable from below) wave:

$$u_1 = U\left(t + \frac{x}{c}\right) \tag{17}$$

and the wave reflected from the surface (going down)

$$u_2 = D\left(t - \frac{x}{c}\right). \tag{18}$$

In this case, the displacement of the soil is equal to:

$$u = D\left(t - \frac{x}{c}\right) + U\left(t - \frac{x}{c}\right), \tag{19}$$

and the resulting deformations

$$\gamma = \frac{\partial u}{\partial x} = -\frac{1}{c} D'\left(t - \frac{x}{c}\right) + \frac{1}{c} U'\left(t + \frac{x}{c}\right), \tag{20}$$

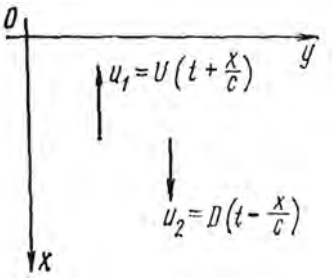

Figure 6. Scheme of incident and reflected waves.

where D' – derivative from D by $t - \frac{x}{c}$, but U' – derivative from U by $t + \frac{x}{c}$.

Shear stress on the ground surface $(x = 0)$ equal to zero. Consequently, the shear strain is equal to zero, i.e.

$$D'(t) - U'(t) = 0. \tag{21}$$

Therefore

$$D(t) = U(t) \tag{22}$$

and

$$D\left(t - \frac{x}{c}\right) = U\left(t - \frac{x}{c}\right). \tag{23}$$

This equation determines the shape of the reflected wave, i.e. the shape and amplitude characteristics of the reflected wave are the same as the parameters of the incident wave. Hence the equation of wave motion in elastic soil.

$$u = U\left(t - \frac{x}{c}\right) + U\left(t + \frac{x}{c}\right). \tag{24}$$

On the surface when $x = 0$ we get

$$u = 2U(t), \tag{25}$$

that is, the amplitude of the surface vibrations is equal to twice the amplitude of the incident wave.

The above relations are valid for the case of reflected waves S moving perpendicular to the surface. When the waves S of the input action approach the ground surface at an angle, the reflected waves, in addition to the waves S, will contain waves P. Similarly, when the waves P approach perpendicular to the surface, the reflected waves will be only P waves, and when falling obliquely, in addition to the waves P, there will be transverse waves in the reflected waves.

When a wave approaches a flat boundary between two layers with different characteristics (in our case, we mean the boundary between the compacted subsidence layer and the lower stable substrate), part of the waves is reflected, and the other passes through the boundary. In

the case of the wave approach perpendicular to the boundary of the layers, the reflected and passing parts of the waves are determined as follows. The fluctuations of the two layers are determined by the expressions:

$$u_1(t,x) = U_1\left(t + \frac{x}{c_1}\right) + D_1\left(t - \frac{x}{c_1}\right), \tag{26}$$

$$u_2(t,x) = U_2\left(t + \frac{x}{c_2}\right) + D_2\left(t - \frac{x}{c_2}\right). \tag{27}$$

Because on the border $(x = 0)$ at any given time, the conditions of continuity of displacements and stresses must be observed, we obtain:

$$u_1(t,o) = u_2(t,o) \tag{28}$$

and

$$\left(G_1 \frac{\partial u_1}{\partial x}\right)_{x=0} = \left(G_2 \frac{\partial u_2}{\partial x}\right)_{x=0}, \tag{29}$$

where from

$$U_1(t) + D_1(t) = U_2(t) + D_2(t) \tag{30}$$

and

$$\frac{G_1}{c_1}\left\{U_1^{'}(t) - D_1^{'}(t)\right\} = \frac{G_2}{c_2}\left\{U_2^{'}(t) - D_2^{'}(t)\right\}. \tag{31}$$

Integrating this equation, we get:

$$U_1(t) - D_1(t) = \frac{G_2 c_1}{G_2 c_2}\{U_2(t) - D_2(t)\} \tag{32}$$

and assuming that

$$\frac{G_1 c_2}{G_2 c_1} = \frac{\rho_1 c_1}{\rho_2 c_2} = k, \tag{33}$$

then

$$U_1(t) - D_1(t) = \frac{1}{k}\{U_2(t) - D_2(t)\}. \tag{34}$$

From the joint solution (30) and (34)

$$U_1(t) = \beta_o U_2(t) + \alpha^{'} D_1(t); \tag{35}$$

$$D_2(t) = \alpha_o U_2(t) + \beta^{'} D_1(t), \tag{36}$$

Where

$$\alpha_o = \frac{1-k}{1+k},\ \beta_o = 1+\alpha_o,\ \alpha^{'} = -\alpha_o,\ \beta^{'} = 1-\alpha_o. \tag{37}$$

Then

$$U_1\left(t+\frac{x}{c_1}\right) = \beta_o U_2\left(t+\frac{x}{c_1}\right) + \alpha' D_1\left(t+\frac{x}{c_1}\right), \tag{38}$$

$$D_2\left(t-\frac{x}{c_2}\right) = \alpha_o U_2\left(t-\frac{x}{c_2}\right) + \beta' D_1\left(t-\frac{x}{c_2}\right). \tag{39}$$

To clarify the physical meaning of dependencies (38) and (39), it is convenient to give the following definitions: α_o– reflection coefficient from the lower boundary of the interface plane; β_o– transmission coefficient from the lower layer to the upper layer along the interface plane; α'– reflection coefficient from the upper boundary of the interface plane; β'– the transmission coefficient from the upper layer to the lower layer along the interface plane.

In the case of the transition of waves from hard substrate soil to soft subsidence soil: 1) the amplitude of the passing wave is greater than the amplitude of the incident wave, and the maximum gain is two; 2) the reflected wave has the same phase as the incident one, and the amplitude of the reflected wave is less than the amplitude of the incident wave.

In the case of the transition of waves from soft subsidence soil and hard underlying soil: 1) the amplitude of the passing wave is less than the amplitude of the incident wave; 2) the reflected wave is opposite in phase to the incident wave, and the amplitude of the reflected wave is less than the amplitude of the incident wave.

Although the reflected waves have reduced amplitudes compared to the incident waves, the shape of the waves and their propagation velocities do not change. Therefore, the ratio of energy fluxes of reflected and incident waves is equal to α_o^2. If the ratio of energy flows of passing and incident waves (energy transfer coefficient), denote λ_o, then

$$\lambda_o = 1-\alpha_o^2. \tag{40}$$

Because $|\alpha_o| = |\alpha^{'}|$, the energy transfer coefficient is the same for the cases of waves approaching the interface plane from below and from above.

As can be seen, even in the theoretical interpretation, made in the first approximation (i.e. idealized), the efficiency of using the energy of an earthquake or earthquakes (taking into account aftershocks) with the hydro-explosive method of compaction of the subsidence of the ground layer is beyond doubt.

The technical and economic effect of the proposed engineering development is that an increase in the period of dynamic impact on the compacted mass of subsidence soil and an increase in the quality of soil compaction due to the energy of natural seismics of the territory is achieved.

4 CONCLUSIONS

1. A significant part of the territories of the distribution of subsidence soils falls on areas with high seismic activity, therefore, the issue of using earthquake energy during deep compaction of subsidence massifs becomes very relevant;
2. Modern scientific and engineering achievements allow us to use proven methods of recording seismic activity of the territory. Among them are seismogeodynamic, electromagnetic and biological methods;
3. A method of deep compaction of loess subsidence loams by hydraulic explosions has been developed, in which the energy of an earthquake (or earthquakes) is used. Under the

conditions of seismic activity of the territory, physico-chemical processes in the soils are intensified due to the activation of geoelectromagnetic and geoacoustic fields. Under these conditions, capillary and mass transfer processes in porous media are intensified. Therefore, it is during this period that it is most effective to carry out locks and explosions in the ground mass;

4. Even if an earthquake does not occur during the post-explosive consolidation in the seismically active period, the activity of geomagnetic and geoacoustic fields, which are an integral part of seismic energy, leads to activation of the consolidation deformation process.
5. Theoretical studies have shown the effective effect of seismic waves on the intensification of deep compaction of soaked subsidence arrays.

Study on evaluation of vertical bearing capacity for soil-cement composite pile

K. Watanabe
Department of Civil Engineering, Aichi Institute of Technology, Japan

S. Koga
Construction Robotics Division, Obayashi Corporation, Japan

ABSTRACT: In recent years, works to improve existing structures and strengthen their seismic resistance have increased. Pile construction in narrow spaces is constrained by the site and process. Therefore, a construction method of H-section steel pile construction with soil-cement ground improvement using a mechanical agitator was developed. This construction method which is called as soil-cement composite pile is characterized by having no need to drill up to a fixed depth as in the pre-boring pile construction method. Instead, soil is agitated along with the cement milk at the original position. In this study, static compression load tests on the soil-cement composite pile that were constructed with the actual construction method were carried out to evaluate the vertical bearing capacity. Furthermore, it was evaluated the performance of vertical bearing capacity on the soil-cement composite piles based on the evaluation method as described in the design specifications in Japan.

1 INTRODUCTION

There are several pile construction methods with relatively small construction machinery that are suitable for construction in narrow urban spaces and areas with low overhead clearance. The Top drive Boring Hole (TBH) method, which has a machine height of 4.5m, is often used. However, there are many cases where even these construction machines are interfered with by architectural limitations and existing structures. The Boring Hole (BH) pile method can handle narrow spaces and low overhead clearances better than the TBH method. However, because the BH pile method is a direct circulation method, mud cakes easily form on the hole walls, and slime tends to accumulate at the pile tip.

Pile construction in narrow urban spaces and for existing structures to strengthen the seismic resistance is subjected to constraints on the construction site and process. Especially, this pile is subjected to the lack of bearing capacity due to the increase of superstructure weight by strengthening the superstructure. Therefore, a method for H-section steel pile construction with soil-cement ground improvement (called as the soil-cement composite pile) was developed that uses a compact mechanical agitator. The construction machine is a mechanical agitator with an attached vibrating mechanism and improved drilling capacity. However, there are some problems to be solved on the vertical bearing capacity of the developed soil-cement composite pile.

The purpose of this study is to evaluate the performance of vertical bearing capacity on the soil-cement composite pile that were constructed by the developed construction method. Static compression load tests for the soil-cement composite pile were carried out. Furthermore, it was evaluated the vertical bearing capacity on the soil-cement composite pile based on the evaluation method as described in the design specification in Japan.

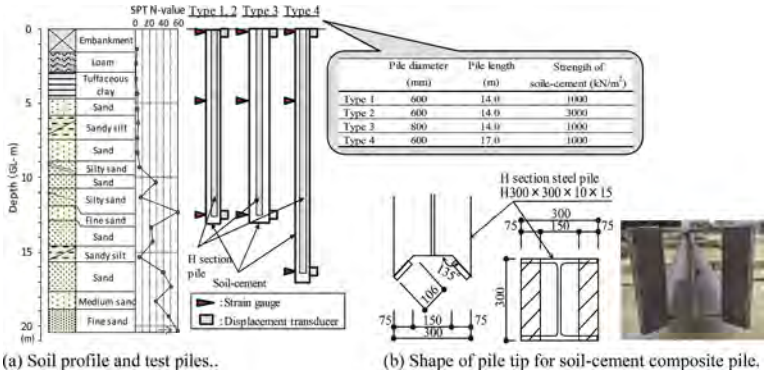

Figure 1. Summary of compression load tests.

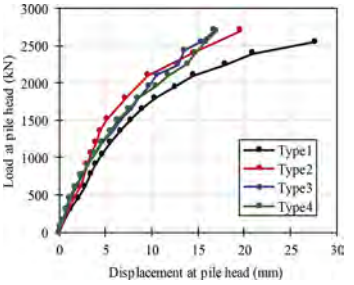

Figure 2. Relationships between load and displacement at pile head.

2 FULL SCALE LOAD TESTS

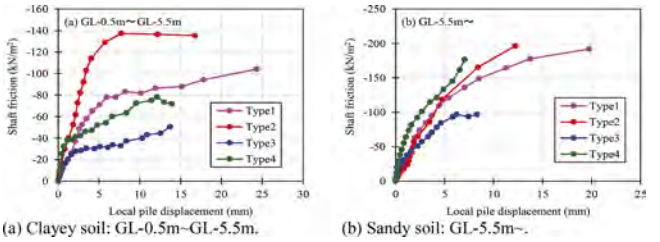
2.1 *Summary of compression load tests*

The summary of compression load tests indicates in Figure 1. Four piles were constructed for the static load test with varying the soil-cement diameter, pile length, and soil-cement strength as parameters. The specifications of the test piles is also presented in Figure 1. The bearing stratum was adopted to be N=20 and 40 from the results of ground investigation; the test piles were embedded in the bearing stratum. The test piles were pre-drilling soil-cement column diameter of 600mm and 800mm, H-section steel shape of H-300×300×10×15. It was examined that the average strength of soil-cement for all of the test piles was larger than the target strength when the unconfined compression tests for the core specimen of four test piles were carried out after the compression load test.

The static load tests were carried out based on the standards of the Japanese Geotechnical Society (Japanese Geotechnical Society, (2001)). A stepwise multi cycle loading system was employed with a new load holding period of 30min and hysteretic load holding duration of 2min. The measured parameters were the pile head load, pile head and pile tip displacements, and strain of the H-section steel. In order to evaluate the shaft friction of each stratums and the end bearing capacity, the strain was measured at the tip of pile and the boundary of each stratums and pile top.

2.2 *Results of compression load tests*

Figure 2 shows the relationships between the load and displacement at the pile head. The maximum loads were 2500kN for Type 1 and 2700kN for Type 2~Type 4. For all of the piles, the curve was steep from the initial of loading, and all of the piles possessed a large initial stiffness. The gradient of the curve then changed with the loading and reached the maximum load.



(a) Clayey soil: GL-0.5m~GL-5.5m. (b) Sandy soil: GL-5.5m~.

Figure 3. Relationships between shaft friction and local pile displacement.

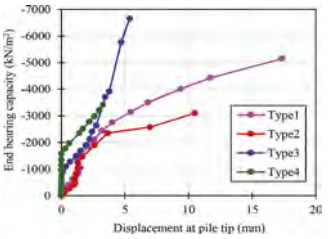


Figure 4. Relationships between end bearing capacity and displacement at pile tip.

The axial force was calculated by considering only the H-section steel such as the measured strain of the H-section steel, the Young's modulus and the cross-sectional area of the H-section steel. The relationships between the shaft friction and local pile displacement which was obtained by dividing this axial force difference by the circumferential area are shown in Figure 3. Figure 3(a) shows that the maximum shaft friction of 50~140kN/m^2 was mobilized in the clayey soil stratum. The average value of the unconfined compressive strength at the corresponding section of the ground was 57kN/m^2. Thus, it can be concluded that the shaft friction was more than the undrained shear strength of the ground (=28kN/m^2). In the sandy ground stratum, it is observed that the maximum shaft friction is 100~200kN/m^2.

The end bearing capacity was calculated by dividing the axial force reaching the pile tip by the envelope area of the H-section steel (BxH). The relationships between the end bearing capacity and displacement at pile tip indicates in Figure 4. The maximum displacement at pile tip is not mobilized the reference displacement which is equal to 10% displacement of the pile diameter when the end bearing capacity is evaluated in these load tests. Thus, the end bearing capacity is evaluated by the value at the maximum displacement at pile tip. The end capacity of 3000~6600kN/m^2 is examined in these load tests. The trend indicates that the end bearing capacity is gradually increasing because the displacement at pile tip is small and does not mobilize the reference displacement to evaluate the end bearing capacity. In addition, the end bearing capacity of the test pile Type 3 indicates the largest value of four test piles.

3 COMPARISON OF DESIGN SPECIFICATION

The vertical bearing capacity which was obtained from the load tests for the developed soil-cement composite pile is compared to the calculated bearing capacity as shown in the design specification in Japan. In this study, the calculated value is estimated by the Design Standards for Railway Structures and Commentary (Railway Technical Research Institute, 2012) because the developed soil-cement composite pile is applied to the railway structure.

The relationships between shaft friction and SPT N value for a clayey soil and a sandy soil indicate in Figure 5. The estimated values are also plotted in Figure 5. According to Figure 5, the shaft friction which was obtained from the load tests is larger than the estimated value from the design specification. Therefore, it is said that the shaft friction of the developed soil-cement composite pile has the enough performance.

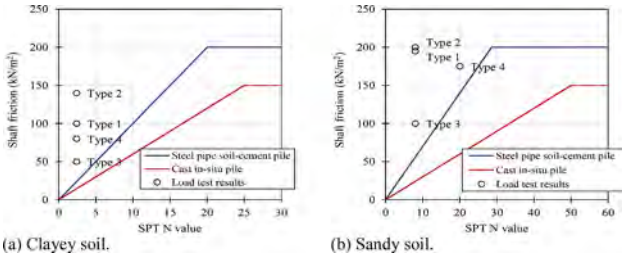

Figure 5. Relationships between shaft friction and SPT N value.

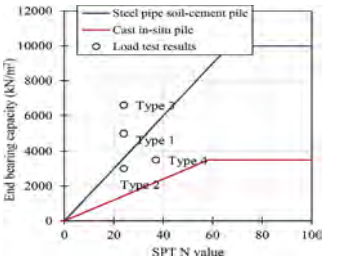

Figure 6. Relationships between end bearing capacity and SPT N value.

The relationships between end bearing capacity and SPT N value for sandy soil are presented in Figure 6. The estimated values are also plotted in Figure 6. It is seen that the end bearing capacity of Type 1 and Type 3 is larger than that of the estimated value. However, the end bearing capacity of Type 2 and Type 4 is lower than the estimated value for a steel pipe soil-cement pile although the end bearing capacity of load test shows the large value for the cast in-situ pile. This means that the end bearing capacity does not mobilize because the displacement at the pile tip is too small and does not mobilize the reference displacement.

4 CONCLUSIONS

The static compression load tests on the soil-cement composite pile were carried out to evaluate the vertical bearing capacity in this study. The following findings were obtained from this study.

1) According to the compression load tests, both the shaft friction and the end bearing capacity has the enough performance on the vertical bearing capacity.
2) It is concluded that the shaft friction of the load test is larger than the estimated shaft friction which is calculated by the design specification in Japan.
3) Compared to the end bearing capacity of the load test and that of estimated value from the design specification, the end bearing capacity of the load test shows the large value. However, the partial results is lower than the estimated value. This means that the end bearing capacity is gradually increasing because the displacement at the pile tip is too small.

ABSTRACT: The article presents the results of analytical analysis of the bearing capacity of a single baretta in hard geological conditions in the city of Hanoi and compares it with the field test results. The methods provided in the regulatory documents SP 24.13330.2011 "Pile Foundations" [1] have been adopted when determining the bearing capacity of piles and barrettes. As well as the results of field tests with piles (static load method) were used. A new method has been proposed which accounts the mutual arrangement of piles in the ground, their length, pitch, etc. Appendix E of the specified regulatory document provides this method. The investigation shown that the test bearing capacity of a single barrette with a limiting settlement of up to 40 mm is in a good agreement with the results of analytical analysis by proposed method, which accounts unloading on soft soils in deep pits.

1 INTRODUCTION

Since the 21st century, there has been an increase in the loads transferred to the base, and the settlement of structures due to the rapid grow in the construction of high-rise buildings. These circumstance determines the wider use of pile foundations (even if there are sufficiently strong

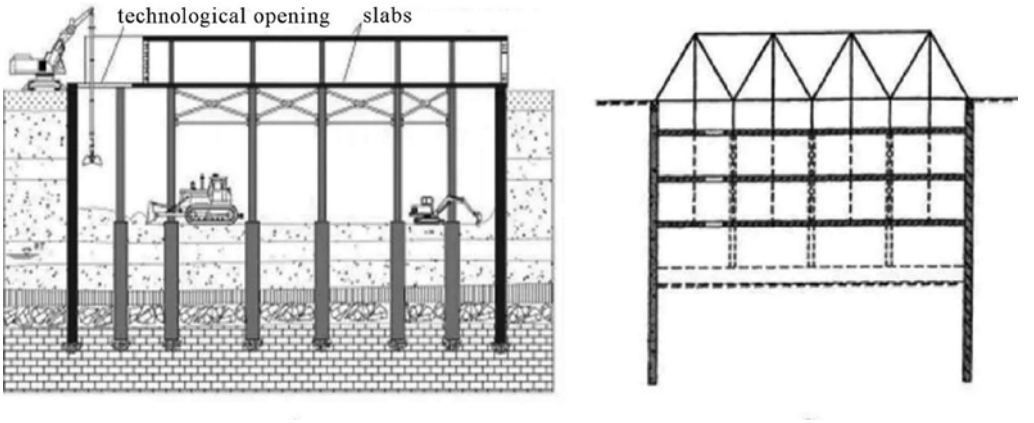

Figure 1. Technological scheme by the "top-down" method.

DOI: 10.1201/9781003299127-219

soils near the surface). The technology of developing deep pits by the "top-down" method is most common approach in the construction of underground structures in such densely populated urban areas (Figure 1) [4].

Barrettes are effective foundation designs for the construction of underground structures by this method and for the work using underground space in soft soils, with a high level of groundwater and in cramped urban conditions. The technological sequence of the installation of a single barrette is the same as in the case of the installation of a "wall in the ground" (Figure 2).

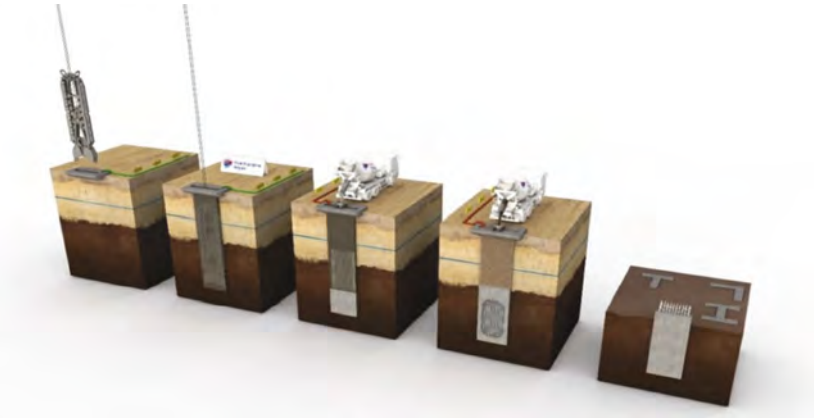

Figure 2. Technological sequence of the barrette installation.

A number of Russian and foreign scientists [6–9] studied the applicability of piles and barrettes in practice, considering the peculiarities of the interaction of piles and barrettes with each other and with the soil. The use of barrettes in these conditions leads to the search for new ways to improve the efficiency of pile foundations. In particular, a possible important condition is the refinement of calculation methods. A new method has been proposed that accounts the mutual arrangement of piles in the soil base, their length, pitch, etc. (Appendix D to SP 24.13330.2011) [1]. The article discusses the existing methods for assessment the bearing capacity of barrettes and compares the results obtained with full-scale field static tests.

2 MATERIALS AND METHODS

In world practice, field tests for assessing the bearing capacity of barrettes allows verification and confirmation the accuracy of the analysis and the quality of the entire construction process [10]. In the problem under consideration, vertical static load testing of a single barrette was carried out using hydraulic jacks up to a maximum load of 30 MN that simulates the 'Top-Down' method. The test procedure met to GOST 20276-2012 [2]. During the field static tests, vertical displacement of the pile under test load had been determined by sensors located on the pile head according to the requirements of 8.2.2 [3].

Since the bearing capacity of a pile depends on the physical and mechanical properties of soil base, the most common analytical method for its determining is the calculation according to tables of standard soil resistances [11]. Let us calculate the bearing capacity of the barrettes, immersed with excavation and filling with concrete. In accordance with 2.7.6. [1], it can be determined from the formula.

$$F_{d,1} = \gamma_c \left(\gamma_{cR} \cdot R \cdot A + u \sum \gamma_{cf} \cdot f_i \cdot h_i \right), \quad (1)$$

where γ_{cR}, γ_{cf} – are the partial factors for condition of soil base resistance under the pile tip and side surface respectively; γ_c – is the partial factor for pile behavior in the soil base, which is adopted as 1; A – is the pile area for supporting on the soil base, m^2, which adopted as cross-sectional area brutto or cross-section of the camouflage widening by its largest diameter, or by the area of the shell pile and the net hollow pile; u – is the external perimeter of the pile cross-section, m; R – is the design strength of the soil under the pile tip, kPa; f_i – is the design strength of the soil layer through the pile surface, kPa; h_i – the depth of the *i-th* soil layer, contacting with the pile surface, m.

We adopted table values of f, R and liquidity index I_L in formula (1) to evaluate the bearing capacity of a structural member (pile, barrett) through the side surface. In this problem, the design strength R of the soil under the lower end of the piles is determined in the case of coarse and sandy soils by the formula.

$$R = 0,75\alpha_4(\alpha_1\gamma_1^{'}d + \alpha_2\alpha_3\gamma_1 h), \quad (2)$$

where $\alpha_1,\alpha_2,\alpha_3,\alpha_4$ – are dimensionless coefficients determined from the table depending on design value of the internal friction angle for the soil; $\gamma_1^{'}$ – is the design value of the specific soil weight, kN/m^3 under the pile lower end (taking into account the weighing effect of water for water-saturarted soils); γ_1 – is the average through the layers design value of specific weight of the soils, kN/m^3, above the pile tip (taking into account the weighing effect of water for water-saturarted soils); d – is the diameter of the pile, m; h – is the depth from the natural relief or from the level of planning in case of cutting to the pile tip, m.

It is necessary to take into account the unloading process, when constructing deep pits. In the soil next to the pit, horizontal stresses decrease during excavation, vertical stresses do not change. At the same time, in the soil at the bottom of the pit, the horizontal stress does not change, the vertical stress decreases when the soil is excavated. At depths of more than 5 m, the effect of "unloading - reloading" becomes most pronounced for a certain thickness of the base as a result of excavation. The phenomenon of "unloading - reloading" is especially manifested in the foundations, composed of weak soils with a small modulus of deformation. Taking into account the significant thickness of soft soils with such a modulus of deformation, deformations under load will play a significant role within the barrett shaft. Applicability limits have also been introduced - the settlements of a small group ($n \leq 25$) and a large pile field are determined considering mutual influence. Therefore, the method for determining the settlement of a single pile depending on the average value of the soil shear modulus G within the pile and under its lower end is also described by the following formula according to 7.4.2–7.4.3 [1]:

$$s = \beta \frac{N}{G_1 l}, \quad (3)$$

where N – is the vertical load on the pile, MN; β – is the dimension factor; G – is the shear modulus, MPa; l – is the pile length, m.

In theoretical soil mechanics, as in continuum mechanics, several deformation moduli are also used. What they have in common is that they are parameters of Hooke's law [5]:

$$\varepsilon = \frac{1}{E}\sigma, \quad (4)$$

where ε – is the strain; σ –is the stress, kPa; E – is the deformation modulus, kPa.

The modulus of deformation is the same coefficient of proportionality in dependence (4) and at a higher level of deformation, when residual deformation occurs during unloading.

It is necessary to determine two moduli of deformation – on the branches of primary (E) and secondary (E_e) loading (Figure 3) in order to calculate the settlement of foundations. Deformation moduli are determined by testing soil samples under uniaxial compression and axisymmetric (triaxial) compression.

In order to find the deformation modulus E_e, it is necessary to know the values of the unloading stresses, upon reaching which the soil sample should be unloaded, and then loaded again (carry out secondary loading). In accordance with the paper [1] soil unloading should be taken into account if the depth of the pit is more than 5 m.

A new method has been developed for the analysis of piles in deep pits. This method based on approach described in Appendix E [1]. The proposed modification of the analytical method for calculation the settlement of a single pile in order to take into account the unloading of the foundation during the development of a deep pit allows describing the behavior of the barrette under load with sufficient accuracy. Therefore, to calculate the settlement of barrettes in deep pits, we proposed to determine the shear modulus accounting the unloading of the soil base and the average value of the soil shear modulus. Within the unloading thickness H_{ur} for soils, the shear modulus G_{ur} of elastic deformations is defined as

$$G_{ur} = \frac{1}{2(1+\nu_{ur})} E_{ur}, \tag{5}$$

where E_{ur} – the soil deformation modulus during unloading/reloading; the lateral to longitudinal deformation ratio of the soil under unloading/reloading.

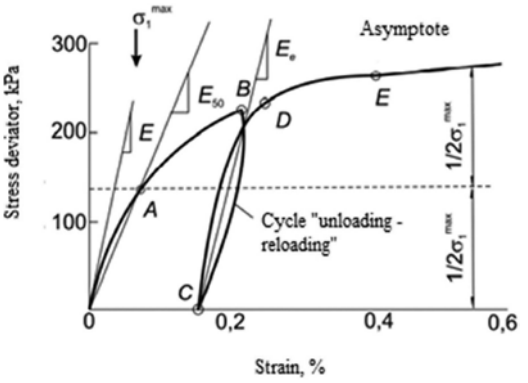

Figure 3. Stress – strain curve to determine deformation modulus in triaxial compression.

As Figure 3 shows, the modulus of soil deformation during unloading and reloading E_{ur} shall be determined from triaxial tests at a compression value equal to the modulus of soil deformation during initial loading. In fact, the soil deformation modulus E_{ur} takes values 2 ... 7 times greater than the secant deformation modulus at 50% of the ultimate stress deviator under conditions of unloading and reloading. Then you can apply the following formula to calculate the approximate values

$$E_{ur} = 5E_{50}. \tag{6}$$

3 RESULTS

According to GOST 5686-2012 "Soils. Field test methods by piles" [3], testing of the barrette should be provide a vertical settlement of 40 mm, which is achieved under the action of a vertical load $F_{d,\text{исп}..}$ = 27500 kN (Figure 4).

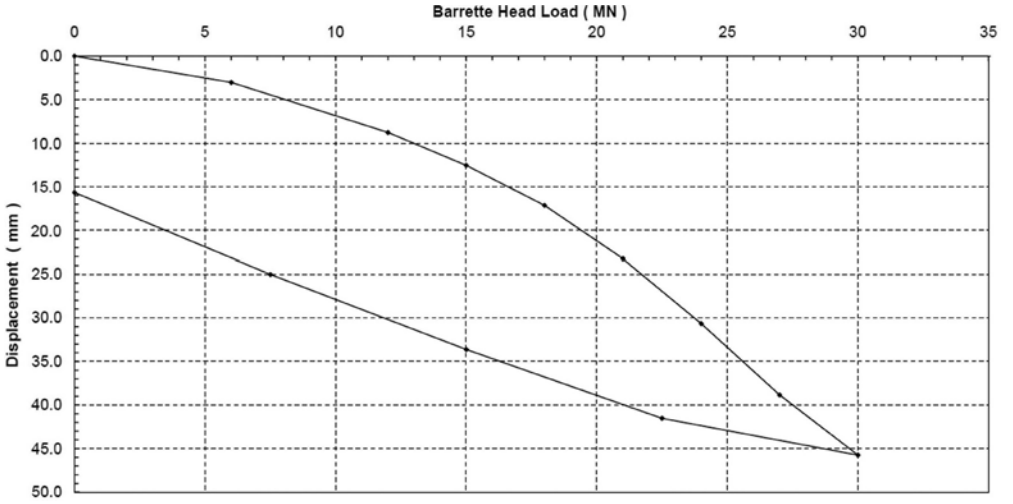

Figure 4. Settlement vs. load relation from field tests of barrettes.

To compare the bearing capacity of single barrettes according to the indicated formulas, let's consider an example for hard geological conditions at the construction site in Hanoi. Experimental single barrettes with a cross section of 800 × 2800 mm and a length of 37 m had been tested in the framework of this study. The dimensions of the baretta are typical for Hanoi. The barrettes located on a site with layers of soft soils near the surface and at a high level of groundwater at a mark from a relative mark of -0.60 m.

According to the results of engineering and geological surveys, it was established that the geological zone under the well has a depth of 61 m and consists of 9 soil layers: compacted embankment (EGE 1), fluid clay, brownish-gray, mixed with organic inclusions (EGE 2), loose sand, ash gray, medium brown, medium density, low moisture (EGE 3), fluid-plastic clay, brownish gray,

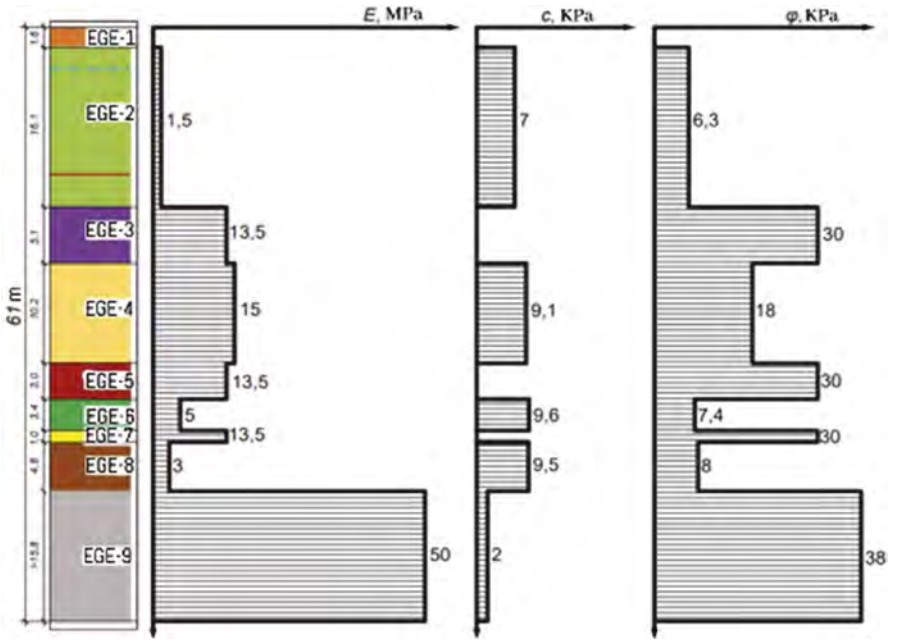

Figure 5. Geotechnical cross-section of the test site with soil characteristics under triaxial compression.

mixed with organic inclusions (EGE 4), sand fine, gray, yellowish gray, medium density, low moisture (IGE 5), soft-plastic loam, brownish-gray (IGE 6), fine, medium-sized, low-moisture sand (IGE 7), fluid-plastic loam, brown-gray, dark gray, mixed organic (IGE 8), gravel-pebble soil (IGE 9). Figure 5 shows an engineering-geological section with the characteristics of the site soils.

Thus, classic analytical calculation allows obtaining the value of the total bearing capacity of this barrette F_d = 27285 kN. According to the results of the calculation, it was found that 77% falls on the tip and only 23% on the lateral surface.

In this problem, the depth of the projected excavation is almost 15 m. After excavation of the pit, we determined the depth of the soil massif of the unloading zone within the unloading thickness for soils in the problem under consideration: H_{ur} = 10 m and the width of the pit b = 61 m. the condition for limiting the draft to 40 mm was $F_{d,2}$ = 24600 kN.

Table 1 presents the calculation and test results for bearing capacity of the barrette in the soil.

Table 1. Calculation and test results for bearing capacity of the barette in the soil.

Methods for calculating the bearing capacity of a pile	bearing capacity F_d, kN
Field test results	27500
Analytical classical method [1]	27285
Analytical method according to the criterion of settlement [1] (consider unloading)	24600
Analytical method according to the criterion of settlement [1] (do not consider unloading)	18450

Thus, it is clearly seen that the bearing capacity of the pile according to the results of field tests:

- 1.0% higher than the bearing capacity of the barette, calculated from the results of analytical solutions using tabular values of soil resistance;
- 10% higher than the bearing capacity of the barette, calculated from the results of analytical solutions for the criterion of settlement (modified) taking into account unloading;
- 33% higher than the bearing capacity of the barette, calculated from the results of analytical solutions based on the criterion of settlement without unloading.

Figure 6 shows the combined load vs. settlement graph for various considered analytical methods and full-scale tests.

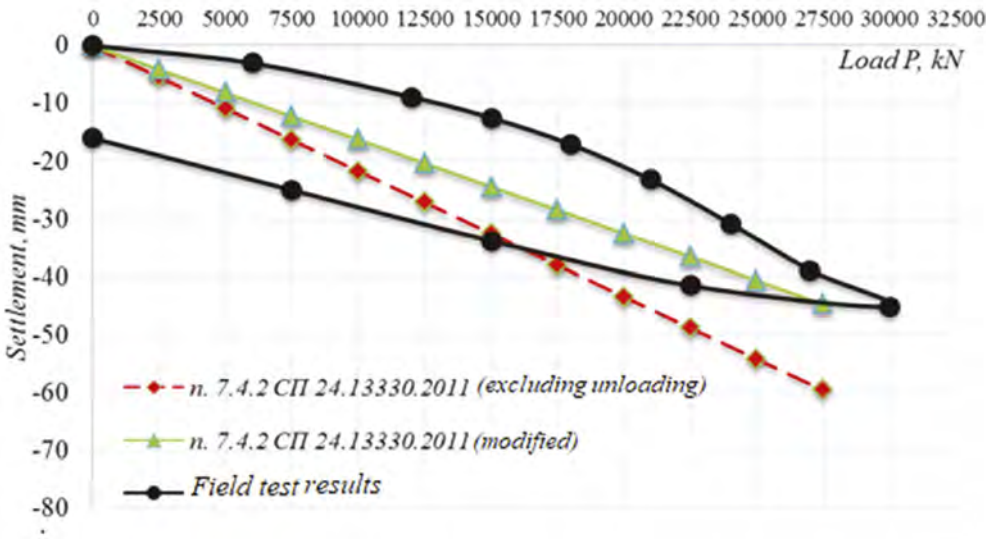

Figure 6. Combined load vs. settlement graph for analytical calculations and field tests.

As we can see from Figure 5, field tests showed a slightly higher indicator than the analytical method without taking into account unloading or modified. The soil around deep pits are always in a complex stress state and considering of the process of unloading is very important in this case. Thus, the results of conventional tests of simple models without unloading describe approximate characteristics of the stress-strain state of soils.

Methods for determining the settlement of a single pile according to the Russian standard, where the soil is considered as a linearly deformed half-space, characterized by a shear modulus and Poisson's ratio, are in good agreement with each other. The bearing capacity values differ by about 10% as Table 1 shows. However, the solutions according to these methods do not meet well with the results of field tests and cannot be applied for practical purposes in conditions of soft soils in deep pits.

4 CONCLUSION AND DISCUSSION

The analysis of the obtained results shows the convergence of the value of the calculated and test bearing capacity of the barette in the soil. In the analytical solution, the reduced shear modulus G is determined taking into account the unloading thickness of the base, for which the soil deformation modulus E_{ur} under unloading/reloading is applied.

The authors recommend further research and use of this method for preliminary calculations of settlement and bearing capacity of piles.

Preliminary study of ultimate load prediction using the DINGO database

J.J. Crispin
University of Oxford, Oxford, UK

ABSTRACT: Chin's analysis method can be employed to interpret the ultimate capacity of pile load tests. Using maintained pile load test data from the DINGO database, consisting of axial compressive loading, the performance of Chin's method was investigated for piles in various UK soil deposits. It is shown that Chin's method tends to be unconservative when predicting ultimate pile capacity regardless of how 'failure' is defined (e.g. head settlement over 10% of pile diameter). The results are compared with test data from Ireland where similar trends were observed.

1 INTRODUCTION

Chin's method is a procedure for predicting the ultimate load a pile can carry without reaching 'failure' during testing (Chin 1970, 1972). In this method, the recorded settlements from load/settlement data are divided by the corresponding load for the same set of data and then plotted against only the settlements from the same load/settlement dataset, and a linear regression in the form of Equation (1) fitted. The ultimate load of the pile is then calculated as the inverse of the slope of the fitted line (Equation 1):

$$\Delta/P = M\Delta + B \tag{1}$$

where Δ = pile head settlement; P = applied load at the pile head; $1/M$ = ultimate pile head load; and B = constant. Chin's method is essentially an extrapolation method (cf. Galbraith et al. 2014).

Other methods have been developed based on forms of Equation (1) (e.g. Fleming 1992, Fellenius 1980, Comodromos *et al*. 2003, Topacio *et al*. 2022) with various modifications proposed. Fleming (1992) suggested that Chin's method may overestimate the ultimate load. In this study, Equation (1) is employed to analyse data extracted from the DINGO database (see Vardanega *et al*. 2021a, 2021b, Voyagaki *et al.* 2022). The DINGO database contains pile load-settlement data (alongside ground investigation data) for 551 piles of various types constructed in different soil deposits in the United Kingdom. The DINGO database data were obtained from various resources in which some of the data were hand digitised from figures and tables.

This study assesses the reliability of Equation (1) for predicting the ultimate load of a pile when a load-test does not reach 'failure' compared to measured ultimate loads in testing based on pile head settlement exceeding 10% of the pile diameter (BSI 2004, Frank *et al*. 2004). Although Equation (1) can be used for different pile loading methods (Chin 1972), this study focusses on compression Maintained Load (ML) tests.

DOI: 10.1201/9781003299127-220

2 DATA SELECTION & FILTERING

It was determined that for 378 piles from the DINGO database a compression ML test had been carried out. Load-settlement tables for each pile were constructed and datapoints from any unloading phases (if present) were excluded. All piles reported with less than 3 load-settlement datapoints were not considered in this analysis (40 piles). The remaining 338 piles were analysed using Equation (1) as shown in the example illustrated in Figure 1. Figure 2 presents the load-settlement datapoints distribution in DINGO database. Confidence interval (CI) analyses were performed on the resulting R^2 values of the Equation (1) fittings to the test data combined with the number of load-settlement datapoints (e.g. Paradine & Rivett 1953, Johnson 1978). The pile tests were then divided into three categories based on the aforementioned analyses. The first category (CI 98%) contains all the piles that have R^2 values equal or higher than for 98% confidence interval for the same number of load-settlement datapoints (degrees of freedom). The number of piles in this category was 296 piles. The second category (CI 90%) presents all the piles with R^2 values equal or higher than that found for the 90% confidence interval but less than for the 98% confidence interval for the same degrees of freedom (17 piles). The third category presents piles with R^2 less than for 90% confidence interval for the same degrees of freedom (25 piles). This analysis indicates that Equation (1) generally provides a robust statistical fit to the pile load test data.

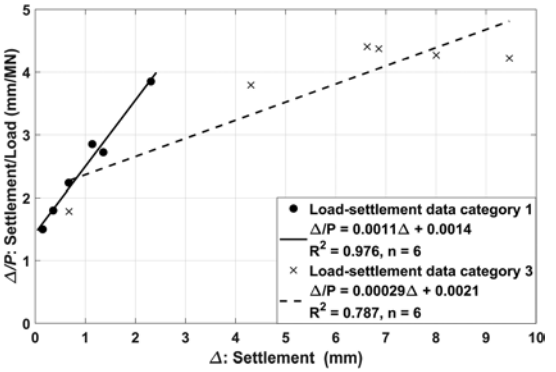

Figure 1. Example of fitting data using Equation (1); for a pile with R^2 higher than that for 98% confidence interval and for a pile from the group with R^2 less than that for 90% confidence interval.

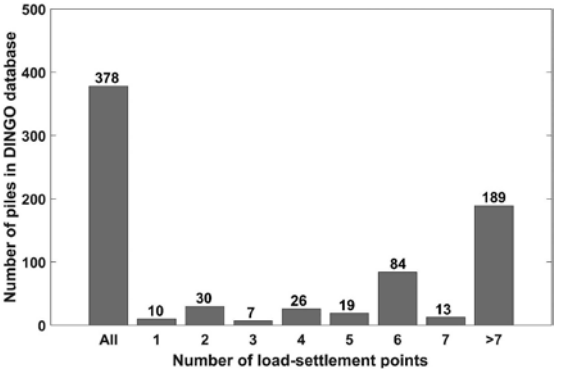

Figure 2. Load-settlement data point distribution for ML piles in the DINGO database.

3 DATA ANALYSIS

Piles from the first category (CI 98%) were used, as the low number of piles in the other categories did not (in the view of the authors) justify lowering the confidence level. The mean (μ) and standard deviation (σ) for the M and B parameters in Equation (1) were calculated and categorised based on the load-settlement datapoints available (Table 1). The values of μ and the σ of the fitting parameters for all the piles are mainly affected by that of piles with more than 7 datapoints (highest number of piles), with no obvious trend observed for μ of M and B with the increasing number of points. In Figure 3, a box plot is shown for coefficient of determination (R^2) values obtained from fitting the piles within CI 98%. Figure 4 shows the pile diameter distribution used in this study with the percent of piles in each diameter range reaching a settlement equal or greater than 10% of the diameter.

Table 1. Descriptive statistics for M and B from Equation (1) applied to pile tests from the CI 98% category.

		All	3	4	5	6	7	>7
Slope (M)	μ	0.86	0.70	1.30	0.78	0.91	1.30	0.75
[MN^{-1}]	σ	0.93	0.64	1.20	0.59	0.86	1.40	0.90
Intercept (B)	μ	3.50	1.50	3.50	1.70	1.50	2.40	4.80
[mm/MN]	σ	6.40	1.50	4.90	1.50	1.90	1.40	8.10

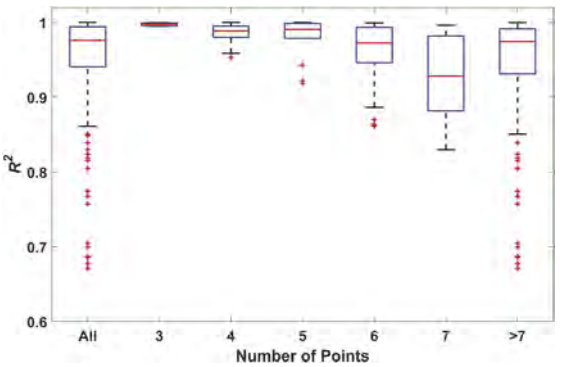

Figure 3. Boxplot of R^2 categorized based on the number of load-settlement data points for piles in CI 98%.

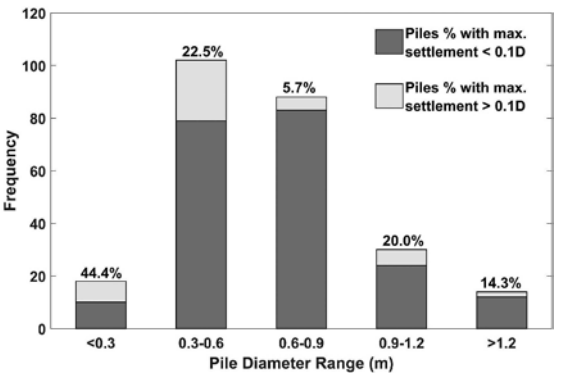

Figure 4. Pile diameter distribution of CI 98% presenting the percentage of piles in each range group with a maximum settlement equal or higher than 10% of the pile diameter.

Initially, piles with maximum test settlement reaching or exceeding 10% of the base diameter were selected (44 piles) and the load corresponding to 10% diameter settlement ($P_{ult,10\%}$) was recorded as the measured ultimate load for each test. This criterion was also used in Galbraith (2011) and Galbraith *et al.* (2014). Figure 5(a, b) shows that most of the predictions fall within the ± 50% bounds shown. However, Equation (1) tends to systematically overestimate the ultimate load. These trends were also observed for 10 pile load tests with recorded settlements greater than 10% of pile diameter hand digitised from Galbraith (2011). Then using the maximum recorded load from the pile testing ($P_{ult,max}$), the number of piles available for analysis increased from 44 to 252 tests. However, the maximum test settlement to diameter ratio, Δ_{max}/D, for this approach ranges from 0.1% to 108%.

To analyse the data using this approach, the piles were divided into three classes based on settlement diameter ratio: (i) Class 1: $\Delta_{max}/D \geq 10\%$ (44 tests); (ii) Class 2: $2\% \geq \Delta_{max}/D > 10\%$ (98 tests) and (iii) Class 3: $\Delta_{max}/D < 2\%$ (110 tests). Figure 6(a, b) shows the measured vs. calculated ultimate load plot with these three sub-groups highlighted. Similar results to those shown in Figures 5(a, b) are shown however, increasing Δ_{max}/D appears to improve the accuracy of Equation (1) to some extent.

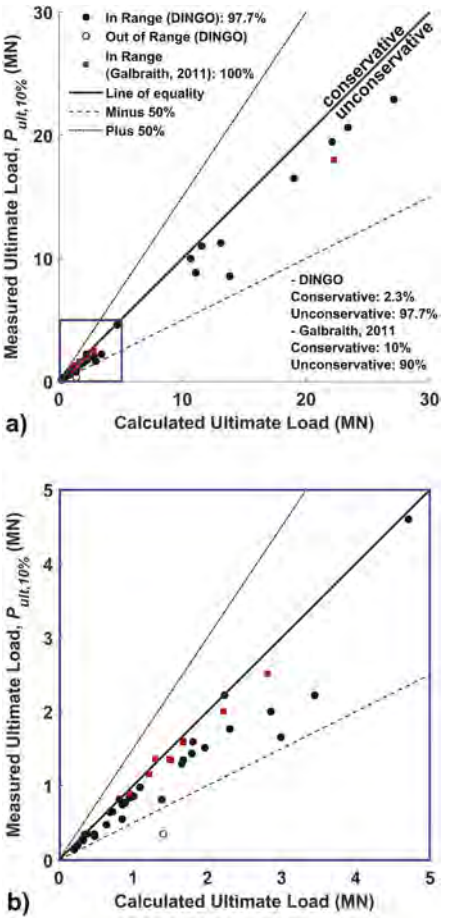

Figure 5. Measured $P_{ult,10\%}$ vs. calculated ultimate load using Equation (1): (a) all data (average over-prediction is about 19.2%), (b) plot for load range 0 to 5MN.

For those tests with recorded settlements equal or greater than 10% of the pile diameter, $P_{ult,10\%}$ and $P_{ult,max}$ have similar values (not shown here for the sake of brevity), which is likely as reaching this settlement threshold was the objective of the original testing. This may

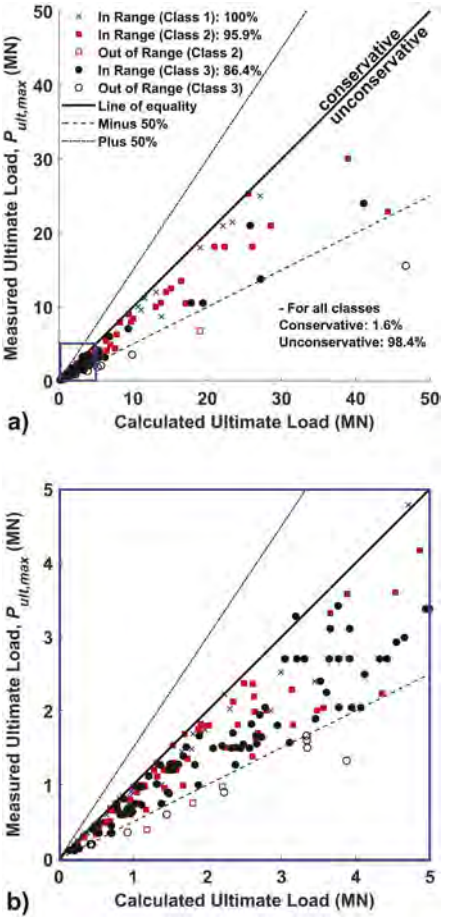

Figure 6. Measured $P_{ult,max}$ vs. calculated ultimate load using Equation (1): (a) all data plot (average overprediction is about 24.8%), (b) plot for load range 0 to 5MN.

explain why the trends observed comparing Figure 5(a, b) with Figure 6(a, b) are similar. In addition, it results in a slightly larger overprediction of $P_{ult,max}$ (24.8%) compared to $P_{ult,10\%}$ (19.2%) as, on average, the former is lower. These trends may not be the case for other data-sets of pile-load tests.

4 SUMMARY & CONCLUSIONS

ML compression pile load tests from the DINGO database (along with data from Galbraith 2011) were analysed using Chin's method (Equation 1). The applicability of Equation (1) for prediction of ultimate pile capacity was assessed by comparing predicted ultimate load values against $P_{ult,10\%}$ and $P_{ult,max}$. For the unconservative predictions across the DINGO database (which equate to around 98% of the analysed pile tests) the Chin method tends to overpredict $P_{ult,10\%}$ by around 19.2% and $P_{ult,max}$ by around 24.8% on average.

ABSTRACT: Quasi-static problems with respect to the stress-strain state and a class of problems with respect to forced vibrations acting in plain and spatial nodes of a high-class mechanism with elastic links are considered, taking into account the model of friction forces in kinematic pairs under the action of vertical and horizontal concentrated forces in kinematic pairs. The developed algorithms of solving quasi-static problems by the finite element method for the entire system of the elastic mechanism with the friction force in kinematic pairs are presented; the basic resolving equilibrium equations for the entire system are drawn up without and taking into account friction forces. The basic relations of the finite element method for plain and spatial nodes of high-class elastic mechanisms with the friction force in kinematic pairs under dynamic loading are presented.

1 INTRODUCTION

The finite element method is better than other methods provided with numerical procedures for studying the mathematical model of an object. Its most important advantage is the presence of implicit unconditionally stable methods of the numerical integration of systems of differential equations of motion that describe the motion of mechanisms and are compiled taking into account the links elasticity.

2 RESEARCH METHOD

For the finite element method in the variant of the displacement method when solving problems of structural mechanics and the theory of elasticity, internal small displacements, velocities, and accelerations are used as unknown values. From the point of view of convergence, when solving this class of problems, there are imposed certain requirements (Zenkevich O. 1975) on the functions of the finite element shape, the most important of which in the case under consideration is the following: it has realized and has not accumulated the energy of elastic deformations.

Modeling the kinematic pairs of a plain and spatial elastic high-class mechanism (HCM) with allowance for Coulomb friction is shown in Figure 1 (Volmir A.S. et al. 1989).

$$\bar{F}_{mp} = -\bar{R}_{jX}, F_{mp} = fN_{Д}\ signR_{jX}, N_{Д} = R_{jY} \tag{1}$$

If a translational pair in a flat mechanism (Figure 1) moves along a fixed guide, then the sliding friction $\bar{F}_{mp}$ force will be directed oppositely to the horizontal component $\bar{R}_{jx}$ of the complete reaction.

DOI: 10.1201/9781003299127-221

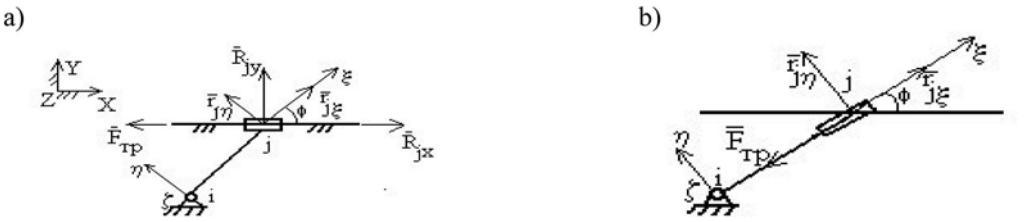

Figure 1. The friction forces in the translational kinematic pair of the plain mechanism.

The R_{jx}, R_{jy} nodes of the complete reaction are determined through the reactions in the $r_{j\xi}, r_{j\eta}$ local coordinate system (LCS):

$$\begin{bmatrix} R_{jX} \\ R_{jY} \\ M_{jZ} \end{bmatrix} = \begin{bmatrix} \cos\phi & \sin\phi & 0 \\ -\sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} r_{j\xi} \\ r_{j\eta} \\ m_{j\zeta} \end{bmatrix} \tag{2}$$

In turn, reactions in the LCS are expressed through the unknown internal forces N, Q_η, M_ζ at the nodes in such a way:

$$\begin{bmatrix} r_{i\xi} \\ r_{i\eta} \\ r_{i\zeta} \\ r_{j\xi} \\ r_{j\eta} \\ r_{j\zeta} \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & l & -1 \\ 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} N \\ Q_\eta \\ M_\zeta \end{bmatrix} \tag{3}$$

When studying the dynamics of hinge mechanisms taking into account the friction forces, the reaction $\bar{r}_{j\eta}$ is considered passing through the center of the pivot; in kinematic pairs, the frictional moment is also taken $m_{j\zeta}^{mp}$ into account. In the presence of a rotational $m_{j\zeta}$ pair in a plain mechanism (Figure 2), the frictional moment is directed opposite to the internal moment. It is $\bar{F}_{mp}$ assumed that the normal pressure forces are concentrated at point A and the friction force is applied at the same point. Then:

$$m_{j\zeta}^{mp} = -m_{j\zeta} = -F_{mp} \cdot r = -frN_{Д} = -fr\sqrt{r_{j\zeta}^2 + r_{j\eta}^2} \;\; N_{Д} = \sqrt{r_{j\zeta}^2 + r_{j\eta}^2} \tag{4}$$

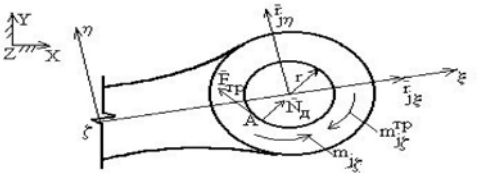

Figure 2. The rotational kinematic pair with the friction force in the plain mechanism.

Figure 3 conventionally shows the slider of the spatial translational pair of the fifth class, which can move along the axis. In such a kinematic pair, it is assumed that the contacts of the links occur in two planes.

Sliding friction forces arise in these planes. The friction force F_{mp1} is proportional to the second component of the reaction in the LCS, and the friction force F_{mp2} in the side face is proportional to the third component of the reaction in the LCS:

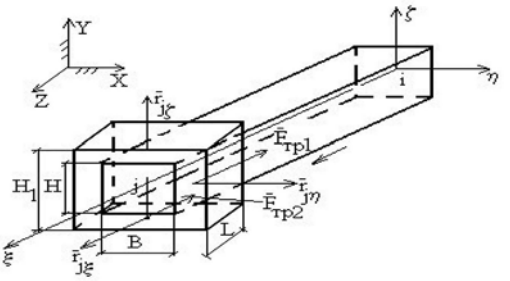

Figure 3. Translational kinematic pair with a frictional force in the spatial mechanism.
B – the slider contact width, L – its length, H1 – its height, H – is the slider contact height

$$F_{mp1} = fr_{j\eta} \cdot signr_{j\eta}, \overline{F}_{mp2} = -\bar{r}_{j\xi}, F_{mp2} = fr_{j\zeta} \cdot signr_{j\zeta}, F_{mp} = F_{mp1} + F_{mp2}. \quad (5)$$

In turn, reactions in the LCS are expressed through the unknown internal forces $N_j, Q_{j\eta}, Q_{j\zeta}, M_j, M_{j\eta}, M_{j\zeta}$ are the nodes and are presented in the form:

$$\{\bar{r}\} = \left[d_{r,s}\right] \cdot \{N\} \quad (6)$$

Where $\{\bar{r}\}^T = \left(r_{i\xi}, r_{i\eta}, r_{i\zeta}, \ldots, m_{j\zeta}\right)$, $\{\bar{N}\}^T = \left\{N_j, Q_{yj}, Q_{zj}, \ldots, M_{z\zeta}\right\}$ $a_{kk} = -a_{k+6,k} = -1$; $a_{5,3} = a_{6,2} = l$; the rest elements are equal to zero.

In the spatial model of a rotational kinematic pair, it is assumed (Figure 4) that contacts occur in the end planes of the hinge at two different points A and B.

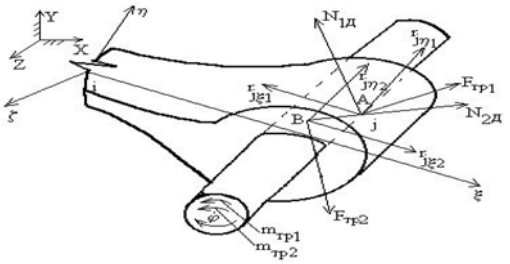

Figure 4. Rotational kinematic pair with a frictional force in a spatial mechanism.

Reactions in the LCS are $r_{j\xi 1}, r_{j\xi 2}, r_{j\eta 1}, r_{j\eta 2}$ determined through the internal forces by formula (6). The friction forces moments are determined by the following formulas:

$$m_{mp1} = -F_{mp1} \cdot r = -fr|N_{1Д}| = -fr\sqrt{r_{j\xi_1}^2 + r_{j\eta_1}^2}, \quad (7)$$

$$m_{mp2} = -F_{mp2} \cdot r = -fr|N_{2Д}| = -fr\sqrt{r_{j\xi 2}^2 + r_{j\eta 2}^2}, \quad (8)$$

$N_{1Д}, N_{2Д}$ where are the normal pressure forces; r is the pivot radius. Reactions *are* determined $r_{j\xi 1}, r_{j\xi 2}, r_{j\eta 1}, r_{j\eta 2}$ by formula (6).

Based on the finite element method and analysis of the stress-strain state of plain and spatial structures based on the HCM with elastic links and friction forces in kinematic pairs, elastic displacements, internal forces in the elements of the rods are determined with and without regard to friction forces.

The relationship equations between the vectors of nodal forces $\{f_\Lambda^e\}$ and displacements are $\{\delta_\Lambda^e\}$ represented in the form:

$$\{f_\Lambda^e\} = [K_\Lambda^e] \cdot \{\delta_\Lambda^e\} \tag{9}$$

where $[K_\Lambda^e]$ is the symmetrical square matrix of rigidity of the 12x12 FRE (finite rod element) order. It is called the matrix of rigidity of a spatial rod element:

$$[K_\Lambda^e] = [K_{ij}],\ (i,j = 1,2,\ \ldots,12) \tag{10}$$

The elements of the matrix of rigidity of the FRE (finite rod element) connecting the force and kinematic parameters at the nodes of a given FRE are determined through its geometric parameters of the cross section, elastic characteristics and length (Postnov et al., 1979, Archer 1965).

If there is a hinge at nodes *i* and *j* of the design element "e", bending moments M_i or M_j in them are equal to zero. In this case, the equations for linking the forces at the nodes with the displacements of the nodes are transformed accordingly. If the node *i* has a hinge, then the corresponding row of the element matrix of rigidity is excluded in the usual way.

If the spatial structure consists of *m* rod elements, then the basic system of equilibrium equations is written as follows:

$$\{F_k\}^T = (F_1, \ldots, F_m), \tag{11}$$

where $\{F_k\}^T = (F_k, F_{yk}, F_{zk}, M_{xk}, M_{yk}, M_{zk})$, $k = 1,2,\ldots,m$ is the vector of external forces applied to the k-th node in the global coordinate system (GCS) OXYZ, m is the total number of nodes.

To determine displacements, angles of rotation and forces in the system of *m* rod elements that make up the structure, it is necessary to satisfy the deformation compatibility conditions and equilibrium equations.

The kinematic characteristics at the nodes of each element automatically satisfy the first condition. Therefore, it is enough to satisfy the equilibrium conditions at the nodes of the structures. Essentially, satisfying these conditions at all nodal *m* points, we construct the main resolving system of linear algebraic equations for the components of the nodes displacements and angles of rotation in the form:

$$\{F\} = [K]\{U\}, \tag{12}$$

where $[K] = [K_{rs}]$, $(r,s = 1,2,\ldots,6m)$ is the square matrix of the 6m*6m order; it is called the system matrix of rigidity (SMR);

$$\{U\}^T = \left(u_1, \vartheta_1, w_1, \phi_{x1}, \phi_{y1}, \phi_{z1}, \ldots, u_m, \vartheta_m, \ldots, \phi_{zm}\right),\ \{F\}^T = \left(N, Q_y, Q_z, M_x, M_y, M_z\right)$$

Thus, the SMR (the system matrix rigidity) is formed from the rigidity matrices of all m rod elements of the mechanism defined in the GCS. Taking into account the boundary conditions, the components of displacements and deformations of the nodes of the mechanism are found by solving system of equations (17) by the iterative Gauss-Seidel method. This method is easy to program, each equation is iterated, and the determined value is refined. The process is repeated as many times as needed to obtain the acceptable solution accuracy.

Accounting for the boundary conditions in the GCS in the presence of friction forces in kinematic pairs is carried out by excluding the corresponding degrees of freedom. This is done using the procedure of calculating the number of zeros in the given matrix ID, the degree of freedom of nodes IID, the boundary condition of internal force factors, and replacing them with the ordinal numbers of the corresponding degrees of freedom, and replacing units with

zeros. When frictional forces act on a structure, corresponding bending moments are generated in rotational kinematic pairs. To study the impact of forces and moments of friction forces of translational and rotational pairs at a certain quasi-static position of the structure, the values of forces and moments of friction are calculated using the determined internal forces at the nodes according to the corresponding formulas [4].

Solutions by the finite element method for plain and spatial dynamic problems on the stress-strain state of structures based on the HCM with elastic links and friction forces in kinematic pairs at their different positions and subject to external dynamic loads.

Methods of accounting for friction forces in various kinematic pairs of plain and spatial elastic HCMs are considered when obtaining the basic systems of differential equations of motion relative to the kinematic parameters of all the structural units for the development of computational algorithms and quantitative analysis of their state at different fixed positions, taking into account the corresponding boundary, initial conditions and specified external variable forces.

The system of equations for the dynamic equilibrium of a set of finite rod elements, with the help of which the considered structure is discretized at the t moment with the mechanism position under study has the form:

$$[M]\{\ddot{U}\} + [C] \cdot \{\dot{U}\} + [K] \cdot \{U\} = \{F(t)\} \tag{13}$$

where $[M], [C], [K]$ are respectively the matrices of the system mass, damping, and rigidity that are obtained by summing up the corresponding matrices of all the computed rod elements; $\{\ddot{U}\}, \{\dot{U}\}, \{U\}$ are vectors of accelerations, velocities and displacements of the nodes with the use of which the computed rood structures are divided into finite two-node rod elements; $\{F(t)\}$ is the given vector of the external variable forces acting at the nodes.

In the calculations of the dynamic stress state of plain and spatial elastic HCMs taking into account the friction forces in kinematic pairs, the matrix of the system damping $[C]$ according to Rayleigh is taken in the form of the combination of the mass matrix $[M]$ and system rigidity $[K]$, i.e. $[C] = \alpha[M] + \beta[K]$; the α and β constants are determined from the values of the damping coefficients related to the two lowest frequencies.

When studying and analyzing the stress state of plain and spatial elastic HCMs taking into account the friction forces in kinematic pairs from the action of external variable forces, system of differential equations (18) was solved by the convenient absolutely stable stepwise method of direct integration according to the Newmark scheme with the step $\Delta t = 0,01$ (Hack & Becker 1999, Harlecki Andrzej. 1999).

3 CONCLUSION

In accordance with the theoretical solution of the quantitative and qualitative analysis of the dynamic stress state of plain elastic HCMs of II, IV classes and the spatial mechanism of VShD-8, taking into account the friction forces in kinematic pairs, algorithms have been developed and object-oriented software packages have been compiled in the Fortran high-level algorithmic language.

In the numerical calculations of the forced vibrations and the dynamic stress state, when the concentrated variable force $F = F_0 \sin \omega t$ acts on them, the dynamic analysis of the stress state of plane elastic HCMs of II, IV class was first carried out taking into account the friction forces in kinematic pairs at different static positions (Chernousko 2000, Massanov, et al. 1994). The elastic physical and geometric characteristics of the link materials are the same as when considering the static problems.

Logistic regression models to predict the probability of high pile rebound using SPT or CPT data

Fauzi Jarushi
Associate Professor, University of Tripoli, Libya

Paul J. Cosentino1
Professor of Civil Engineering, College of Engineering, Florida Institute of Technology, Melbourne, FL

Omran Kenshel
Assistant Professor, University of Tripoli, Libya

ABSTRACT: At certain depths during driving of large diameter displacement piles, rebound greater than 0.25 inches (6.35 mm) occurs followed by a small permanent-set after each hammer blow. High pile rebound (HPR) soils may stop the pile driving and result in a limited pile capacity. The overburden depth at which HPR occurred is typically greater than 50 ft (15.3m). In some cases, rebound leads to pile damage, delaying of the construction project, and the requiring foundations redesign. A simple models for evaluating probability of HPR using Cone Penetration Test (CPT) and Standard Penetration Test (SPT) data are developed based on logistic regression analyses of 18 case histories. The proposed model uses the pore water pressure and sleeve friction and/or SPT blow count with fines content (pass #200 sieve) as input parameters. Comparisons of the proposed probability model with actual pile-driving analyzer (PDA) rebound data are performed to demonstrate the improvements. As a result, the models showed that the probabilities of HPR (percentage) increased as either the pore water pressure or sleeve friction or SPT N-values with fines content. The statistical logistic regression modeling and developed equations showed promise in predicting rebound. This methodology may lead to a simpler evaluation process which allows for the prediction of HPR during the design phase.

1 INTRODUCTION

Contractors and engineers have experienced pile installation problems while driving high displacement piles with single-acting diesel hammers at Florida Department of Transportation (FDOT) construction sites located in the Central and Panhandle regions of Florida. Problems occur during pile driving, when a large initial penetration per hammer blow is followed by a large elastic rebound (termed High Pile Rebound or HPR) resulting in a small or negligible permanent-set per blow. Figure 1 illustrates a typical HPR pile-top displacement versus time record for a single hammer blow obtained from Pile Driving Analyzer (PDA) strain gages and accelerometers. The maximum initial downward motion "DMX," is the sum of elastic and plastic deformations of the pile and soil system. The final displacement is the pile penetration per blow, or "set." Rebound is the difference between the pile maximum displacement and final set.

HPR may prevent the required driving resistance from being achieved and or stop the pile driving process, placing the foundation performance at risk or requiring redesign. HPR problems generally occurred in soils that did not display any unusual geotechnical properties during routine soil investigations 0.

FDOT road and bridge construction specification 455-5.10.3 defines refusal as 20 blows per inch (25 mm) with the hammer operating at its highest fuel setting or at a setting determined

DOI: 10.1201/9781003299127-222

by the engineer with a limit of 0.25 inch (6.35 mm) rebound per blow (Cosentino et al. 2010). For this research, HPR was defined as any rebound exceeding the specified 0.25-inch (6.35 mm) limit.

The objective of this research was to develop a geotechnical engineering protocol that would help engineers anticipate HPR.

2 HISTORY OF HPR

Murrell et al. 2008 presented a case history of HPR which occurred during the construction of a new ferry terminal in coastal North Carolina. Prestressed concrete piles (PCP), 20-inch (508 mm) square and 70 ft (21 m) long, were designed to support an over water structure. The authors describe the high rebound using the term "Bounce". Pile bounce was observed at an overburden depth of 53 ft (16 m) (elevation -43ft, -13m) when the piles penetrated into saturated, firm to stiff, fine-grained marine soils along the southeastern coast of the United States.

During the geotechnical investigation at this site, excess pore water pressures u_2 greater than 20 tsf (1915 kPa) were measured during CPTu testing at the depth where bouncing occurred .When the blow counts during pile driving were at 303 blows per foot (bpf,) (blows per 0.3m), the pile displacement became zero. The driving process was then stopped for two hours and restrike was carried out. However, an additional 2.5 ft (0.76 m) (of pile length was driven with blow counts of 73 bpf, 112 bpf, and 87 blows/6 in (blows/152mm). Again the driving was halted when a large rebound resulted in near zero set. In order to achieve the pile capacity and overcome pile rebound, the pile was driven after four days using a hammer with a larger ram and a shorter stroke.

Hussein et al. 2006 presented a case study related to HPR during driving of PCP for the State Road 528 Bridge over the Indian River in Florida. A group of 30-inch (762 mm) square, hollow core PCP with a length of 115 ft (35m) were used to support the bridge. The piles rebounded when they penetrated into hard soils consisting of saturated medium dense sand with silt (SP-SM) to fine silty sand (SM) to clayey sands and sandy clays (SC). The authors believe that the incompressible water in the soil near and below the pile tip produced excess pore pressure during the driving process which created an upward force on the pile, thereby causing rebound. However, no analytical proof of this conclusion is available.

Likins 1983 analyzed three sites with high pile rebound between 0.4 and 1 inch (10 mm and 25 mm). He determined that the only common geotechnical parameter observed at each site was the fully saturated soils. Preliminary analysis using the basic wave equation was conducted for each site. The author then modified the results to match field data acquired by CAPWAP (Case Pile Wave Analysis Program). He proposed that the only reasonable cause of the HPR was the buildup of excess pore pressure beneath the pile tip. It was also clear through testing, that pile capacities decreased when high quake/rebound occurred. Findings from the work indicated that high quake lowers the pile capacity by a factor of 3. Field observations often led to a false interpretation that the hammer is not large enough for the pile. In these cases where the hammer size is increased, the pile could be damaged. Likins (1983) concludes that alternative pile designs, such as hollow piles, should be considered as an effective way to avoid high soil quake.

Studied by Jarushi et al. 2013 on the effect of fines content (material that pass # 200 sieve) and uncorrected standard blow count (N_{SPT}) on HPR at the presented sites. The study showed that permanent-set and rebound were a direct function of N_{SPT} and fines content of the soil at the pile tip. The authors reported that when the NSPT was less than 15 blows/ft (blows/0.3m) and a fines content of less than 25 percent, the rebound was less than 0.25 inches (6.35mm), yielding an acceptable permanent-set of up to 3 inches (76mm). For N_{SPT} values between 15 and 40 blows/ft (blows/0.3m) and a fines content of 25 to 40 percent, the pile rebound varied between 0.25 and 0.6 inches (6.25 mm and 15mm), yielding acceptable permanent-set values. For cases where the N_{SPT} exceeded 40 blows/ft with a fines content greater than 40 percent, pile rebound was greater than 0.6 inches (15mm) and was accompanied by an unacceptable permanent-set.

3 METHODOLOGY AND TESTING PROGRAM

3.1 *Dynamic PDA testing*

During FDOT construction at seven sites, pile driving was monitored with PDA equipment. Figure 1.Typical PDA pile top displacement versus time diagram from one hammer blow for FDOT HPR site shows typical HPR PDA data from one pile blow at a FDOT site. The plot, with displacement in inches on the vertical axis and time in milliseconds on the horizontal axis, shows a maximum displacement (DMX) of 1 inch (25mm), an inspector permanent-set (iSet) of 0.11 inches (2.8mm) and a digital set (DFN or dSet) of 0.27 inches (6.85mm). The dSet is not used for this study because it is recorded in a short time of 200 milliseconds. The number of hammer blows per foot is used to produce an average inspector set per blow. The maximum displacement and iSet were subtracted to determine the rebound per hammer blow (i.e., DMX-iSet =Rebound), yielding a rebound of 0.89 inches (23 mm). Plots for each of the case studies were developed relating elevations to iSet and rebound. The elevation associated with the start of the PDA data corresponded to the depth at which pile driving commenced. This elevation was below the ground surface because piles at these sites were set into predrilled holes.

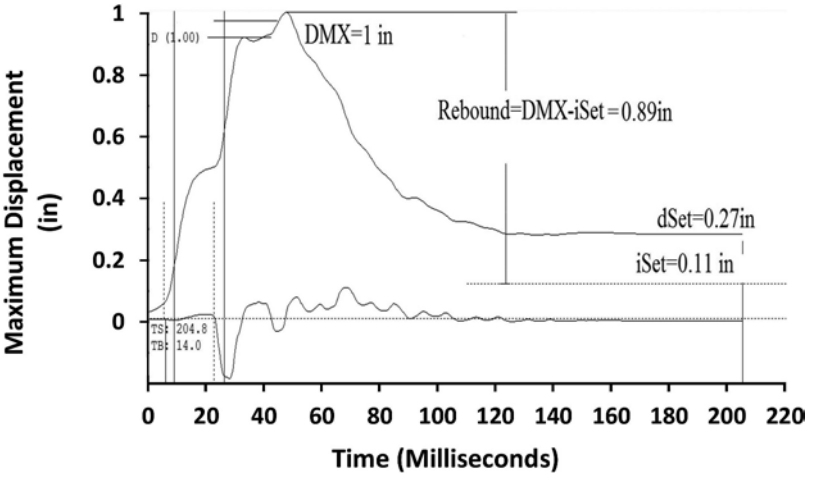

Figure 1. Typical PDA pile top displacement versus time diagram from one hammer blow for FDOT HPR site.

3.2 *CPTu and SPT testing*

An extensive field included SPT, CPTu and laboratory-testing program was carried out the FDOT sites where rebound was encounter. The SPT test procedure followed ASTM D1586 "Standard Test Method for Penetration Test and Split-Barrel Sampling of Soils".

CPTu testing with pore water measurement was performed in soundings and signals were digitally recorded using the Hogentogler standard recording system. The CPTu test procedure followed ASTM D3441-05 "Electronic Friction Cone and Piezocone Penetration Testing." During testing, data was collected digitally to record the cone resistance q_c, sleeve friction f_s, inclination, and designated pore water pressure u_2 at every 2 inches of penetration.

3.3 *Logistic regression models to predict HPR*

The objective of the statistical investigations was to establish relationships that make it possible to predict one variable, rebound or non-rebound in terms of the other variables. SPSS (Statistical Package for the Social Sciences) software was used for this investigation.

In this study, the regression method was used to determine whether these variables are significantly related, and also, the direction and strength of their relationship. The rebound or

non-rebound was represented as a dependent variable (P variable) in the statistical analyses and the remaining variables (N_{SPT} , fine content f_s, q_c, PWP u_2) were represented as the independent variables or the explanatory variables (the X's in the equation). The probability that an event will occur can be predicted using the following equation described by Cox (2010).

$$P = \frac{e^{B_0+B_1X_1+B_2X_2+\ldots\ldots\ldots B_n}}{1+e^{B_0+B_1X_1+B_2X_2+\ldots\ldots\ldots B_n}} \quad (1)$$

Where P= Probability; e= the base of the natural logarithm;
$\beta_0 \ldots \beta_n$ = regression coefficients

Once the model has been fitted to the data, it is a good practice to investigate the adequacy of the fit. This analysis helps to determine how well the model actually correlates with the observed data and which parameters do have significant relationships.

4 RESULTS AND DISCUSSION

Findings from the testing program indicated that the most critical parameters associated with HPR werepercent fines and uncorrected SPT blow counts N_{SPT} or corrected blow counts N_{60}. The fines content defined as the percent passing the No. 200 sieve. CPT Pore water pressure was also an indicator of HPR.

Probabilities between HPR and N_{SPT} and fines content, and between HPR and CPTu data (i.e., f_s, q_c and pore pressure) were developed and resulting trends were examined. After several computational iterations, the N_{SPT}, fines content, pore pressure, and f_s were used, while q_c was eliminated because of its low statistical coefficients (i.e., Significant or p-value >0.05).

4.1 *Model 1: Probability of HPR using N_{SPT} and fines content (%)*

The relationship between the rebound or non-rebound and the other variables, N_{SPT} and fines content was determined. A total of 79 cases or data points were used. The probability of HPR from model 1 predicted by shows a summary of the model 1 classification results (see Table 1). This model allows for correctly classifying the data for 20/29 or 69% of the subjects where the predicted event (Rebound) occurs, and correctly classifies 45/50 or 90% of the subjects where no rebound occurs. Overall 65 predictions were correct out of 79 cases and results in the overall success rate of 83%. The probability of HPR from Model 1 can be predicted using the following equation:

$$P = \frac{e^{(-5.714+0.071NSPT+0.127FC)}}{1+e^{(-5.714+0.071NSPT+0.127FC)}} \quad (2)$$

Table 1. Model 1 prediction accuracy classification.

Field Observed data		Model Prediction		Model Accuracy (%)
Non-rebound	Rebound	Non-rebound	Rebound	
50	NA	45	5	90
NA[a]	29	9	20	69
Overall Prediction				83

[a]not applicable

Where P= Probability of rebound (percent); N_{SPT}= SPT blows count (blows/ft); FC= percent fines content

Table 2 shows the significance test for each of the coefficients in the logistic regression model. Both N_{SPT} and fines content are significant as "sig" is less than 0.05.

Table 2. Variables in the equation.

V Variables	B[d]	S.E.[e]	df[f]	Sig.[c]
FC[a]	0.127	0.031	1	0.000
N[b]	0.071	0.024	1	0.003
Constant	-5.714	1.269	1	0.000

[a]fines content; [b]SPT blows count; [c]significance of model; [d]regression coefficient; [e]standard error around the coefficient; [f]degrees of freedom.

Figure 2 shows the probabilities of HPR using equation (2) increased as either the fines content or N_{SPT} increased and the regression coefficient R^2 approached 1.0. The probability of the HPR was greater than 50 percent when the N_{SPT} exceeded 30 blows/ft (blows/0.3m) and the fines content exceeded 35 percent.

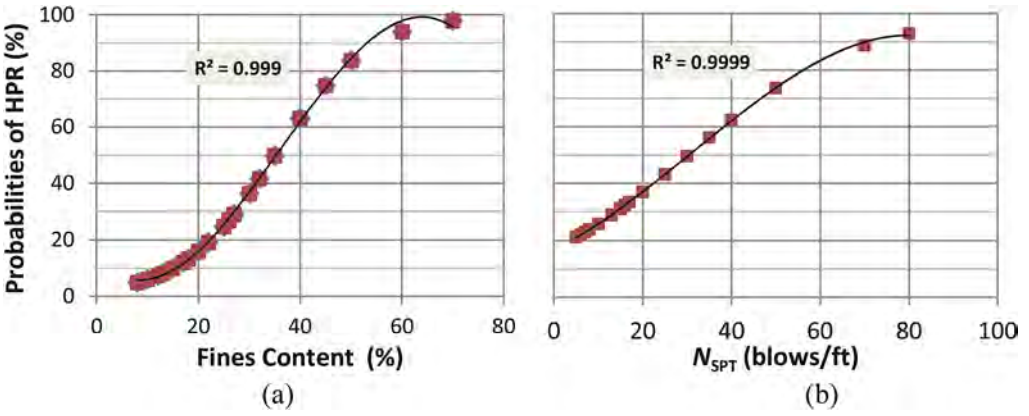

Figure 2. Probability of HPR versus (a) Percent fines content and (b) N_{SPT} based on equation (2).

The probability of rebound (percentage) using equation (2) was also examined using actual PDA rebound data from four of the HPR sites. As shown in Figure 3, probabilities of HPR reached 100 percent at same elevation where rebound increased to over 1 inch. Test piles at these sites, as presented in Figure 3 experienced excessive rebound followed by minimal set.

Similarly using equation (2), the probabilities of HPR was very low and less than 50 percent for the data at three sites which did not experience any driving problem (i.e., rebound < 0.50 with acceptable set) as shown in Figure 4.

It can be concluded that model 1 using N_{SPT} and fines content showed promise in predicting rebound, this methodology may lead to a simpler evaluation process allows for the prediction of HPR during the design phase.

4.2 *Model 2: Probability of HPR using CPTu pore water pressure*

The probability of predicting HPR using CPT pore pressure was also developed and examined using 32 data points. The probability equation is presented in equation (3) shows this model's accuracy in that it correctly classifies 7/8 or 88 % of the subjects for the "rebound" predicted event while 23/24 or 94% of the subjects where the predicted non-rebound was not observed. Overall, model predictions were correct 30 out of 32 cases, for an overall success rate of 94%.

$$P = \frac{e^{B_0 + B_1 X_1 + B_{2X_2 +} \ldots\ldots\ldots\ldots B_n}}{1 + e^{B_0 + B_1 X_1 + B_{2X_2 +} \ldots\ldots\ldots\ldots B_n}} \quad (3)$$

Where P= Probability of rebound (percent); PWP = CPTu pore water pressure (tsf)

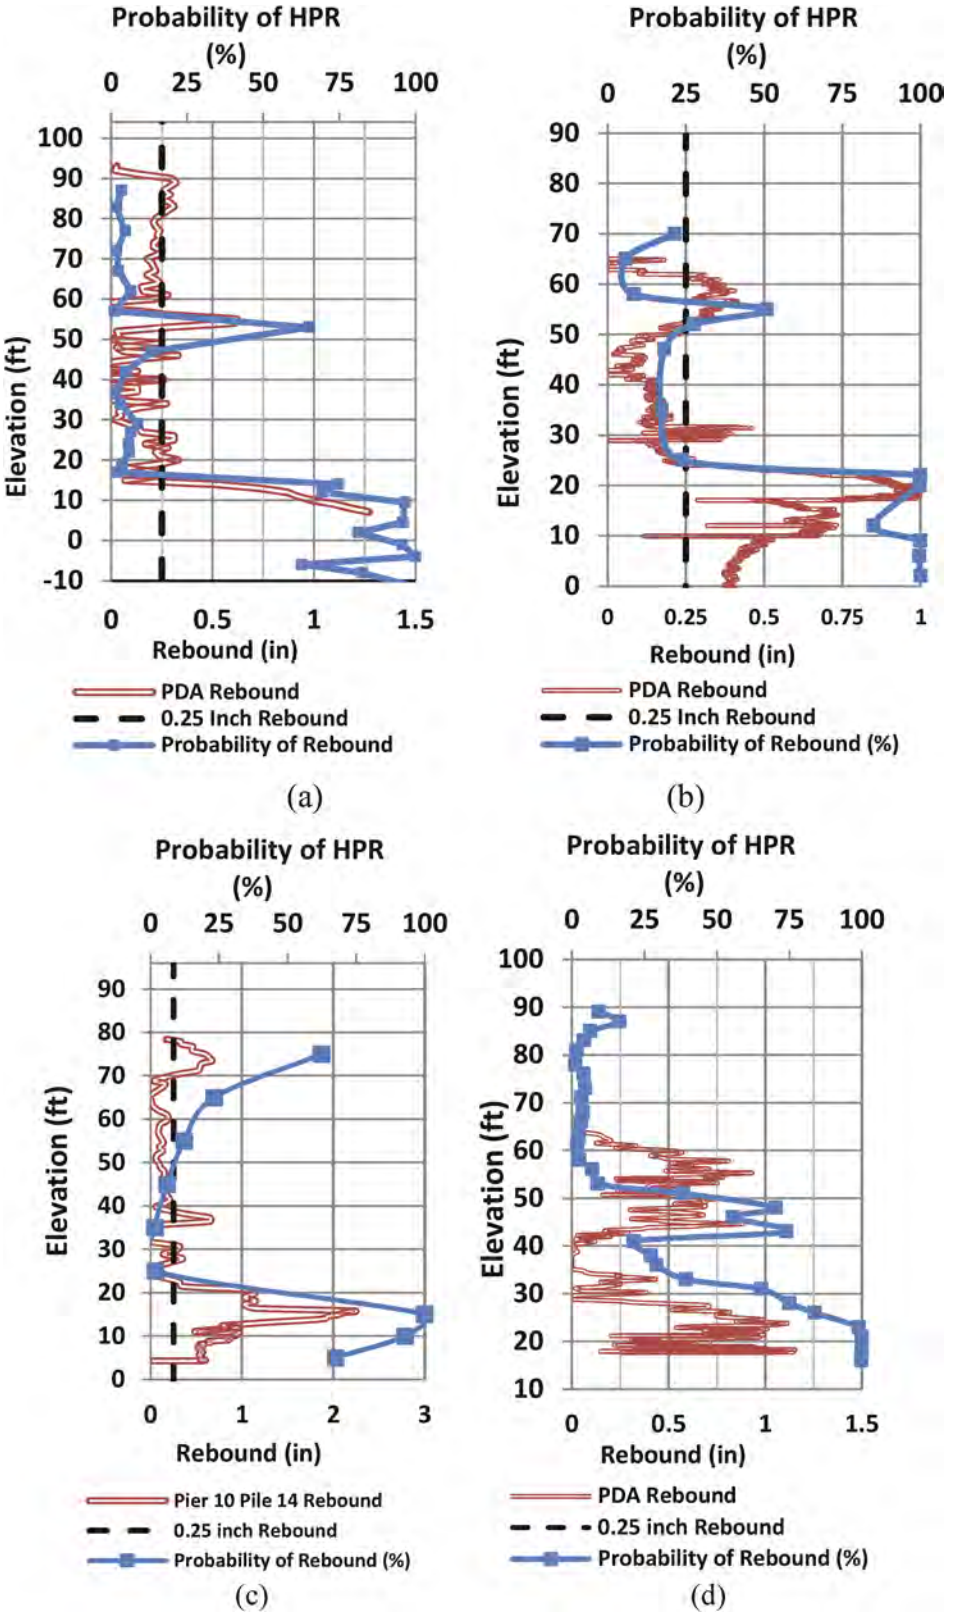

Figure 3. Probabilities of HPR using equation (2) for HPR sites with a minimal set (a) Anderson Street Overpass, (b) I-4/US192 Ramp D and (c) I-4/John Young Parkway and (d) SR50/SR436.

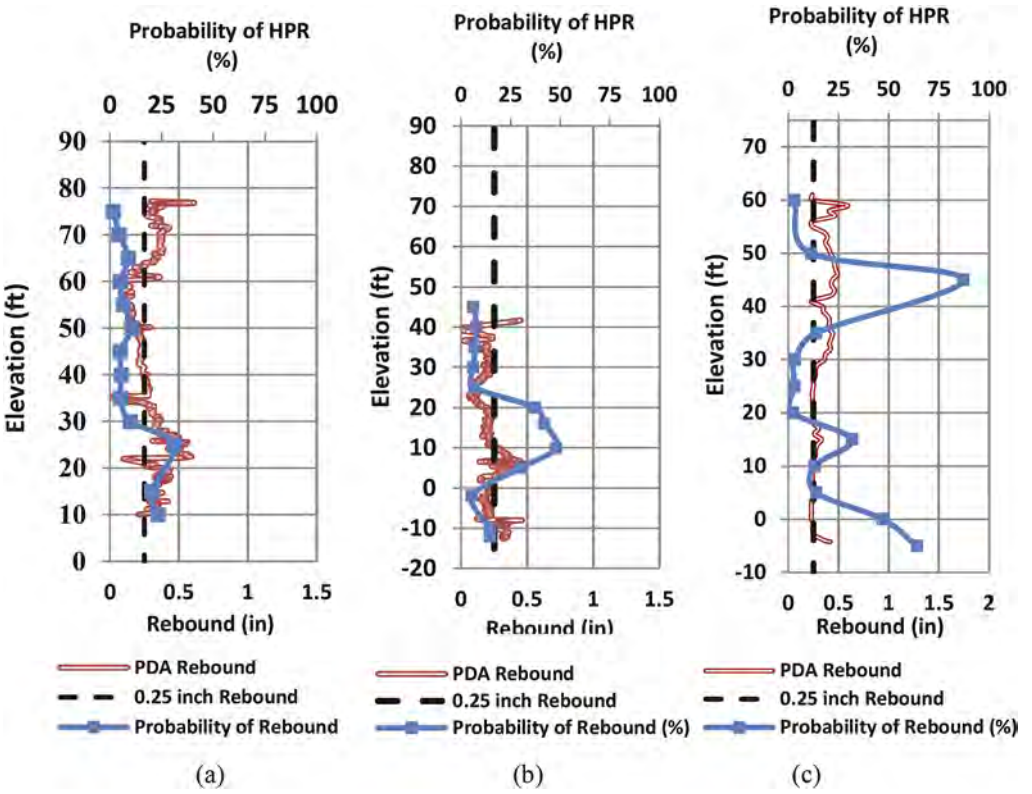

Figure 4. Probabilities of HPR using equation (2) for HPR sites with Acceptable Set (a) I-4/ US192 West Bound, (b) I-4/US192 East Bound and (c) SR417/International Parkway.

The applicability of equation (3) and PDA actual rebound were plotted versus elevation for more than 5000 data points (i.e., CPT record measurements from each 2 inches). It can be seen in Figure 5, that the probability of HPR reached 100 percent at two sites, which experienced excessive HPR with minimal set (i.e. Anderson Street Overpass and I-4/US192). It is also reached 75 percent at the third site but CPT data is not to end of PDA elevation. The probability of HPR was very low (i.e., 2 percent or less) at sites, which experienced low CPTu pore pressure where rebound was less than the FDOT limit of 0.25 inches (6.35mm) as shown in Figure 6. It can be summarize CPT PWP is statistically related to rebound. The overall accuracy of model 2 is higher than model 1.

4.3 *Model 3: Probabilities of HPR using sleeve friction and pore water pressure*

Probability of predicting HPR using CPT pore pressure and sleeve friction was also developed using 51 data points. The probability equation is presented in equation (4).

$$P = \frac{e^{B_0+B_1X_1+B_{2X_2+\ldots\ldots\ldots\ldots}\ B_n}}{1+e^{B_0+B_1X_1+B_{2X_2+\ldots\ldots\ldots\ldots}\ B_n}} \tag{4}$$

Where

P= Probability of rebound (percent); PWP= CPTu pore water pressure in (tsf); f_s =CPT sleeve Friction in (tsf)

The the probability accuracy of HPR using model 3 equation (4) and PDA actual rebound were plotted versus elevation. It can be noted in Figure 7 that the probability of HPR increased to 100 percent at the same elevation where rebound occurred with a minimal set.

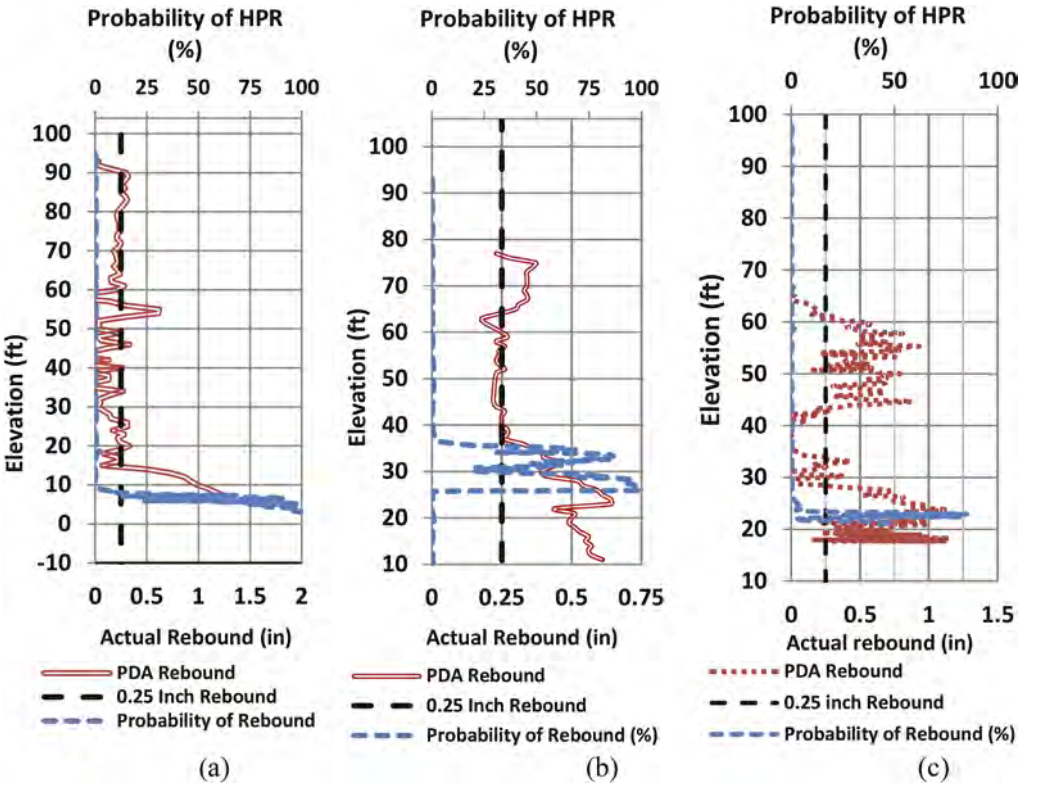

Figure 5. Probabilities of HPR using equation (3) for HPR sites with minimal Set (a) Anderson Street Overpass, (b) I-4/US192 Ramp CA and (c) SR50/SR436.

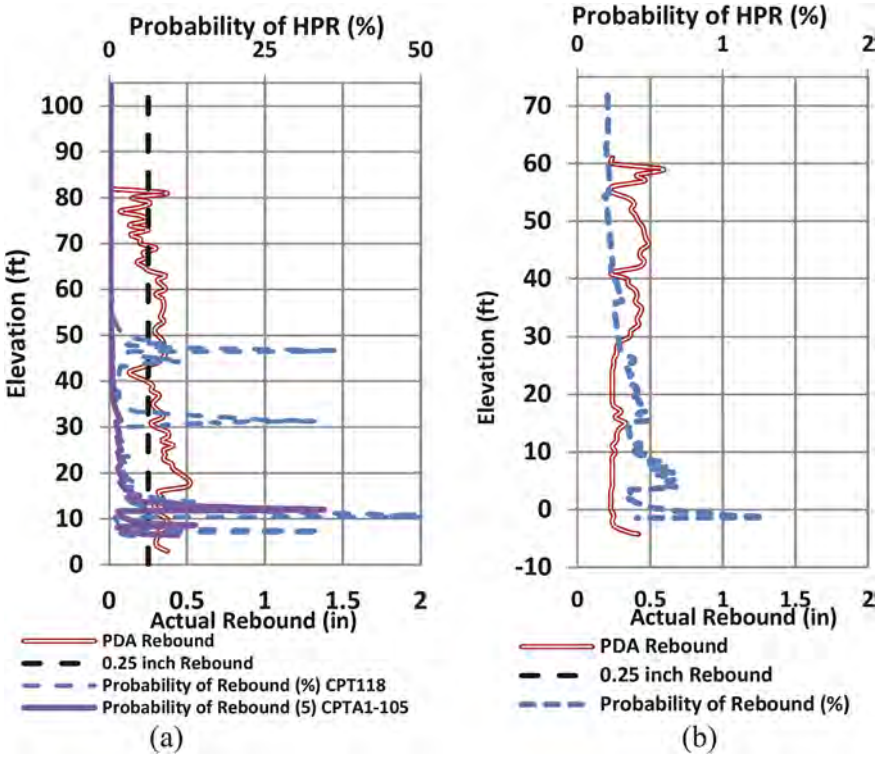

Figure 6. Probabilities of HPR using equation (3) for HPR sites with acceptable set (a) Ramp B and (b) SR 417/International Parkway (minimal Rebound).

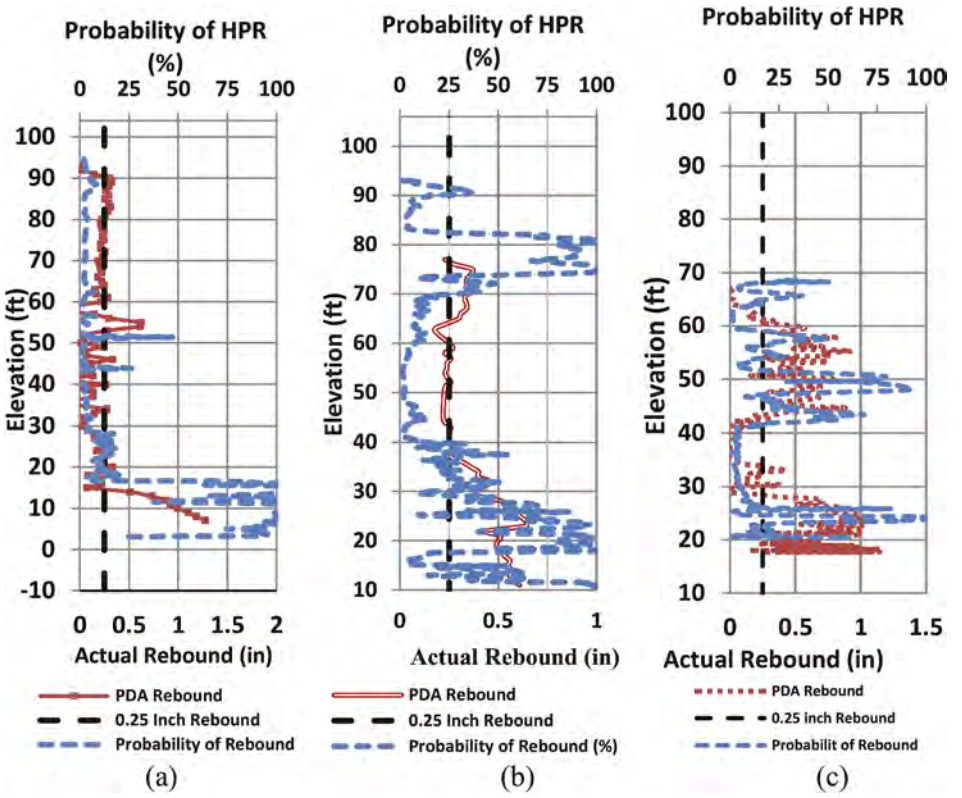

Figure 7. Probabilities of HPR using equation (4) for HPR sites with minmal Set (a) Anderson Street Overpass, (b) I-4/US192 Ramp CA and (c) SR50/SR436.

These sites experienced excessive HPR with minimal set (i.e. Anderson Street Overpass and I-4/US192). The probability of HPR was very low (i.e., < 20 percent) at SR417/International Parkway (see Figure 8). This site experienced rebound of less than 0.25 inches (6.25mm). The probability of HPR was 75 percent at the site where a maximum rebound of 0.50 inches (12mm) followed by an acceptable set (i.e., Ramp B).

5 CONCLUSION AND RECOMMENDATIONS

In summary, probability equations, which relate pile rebound to geotechnical parameters including N_{SPT} and fines content and CPTu pore pressure and sleeve friction were developed. These equations indicated that probability of rebound occurring was a direct function of these parameters. Therefore, this methodology can be used to predict HPR problem during design phase.

Probabilities equations to predict HPR based on fine content, N_{SPT}, CPTu PWP, and f_s, showed that probabilities of rebound were a direct function of these parameters. They showed promise in predicting rebound as the models developed fitted the data and the adequacy of the fit was excellent with R^2 approaching 1.0. This methodology may lead to a simpler evaluation process, which allows for the prediction of HPR during the design phase.

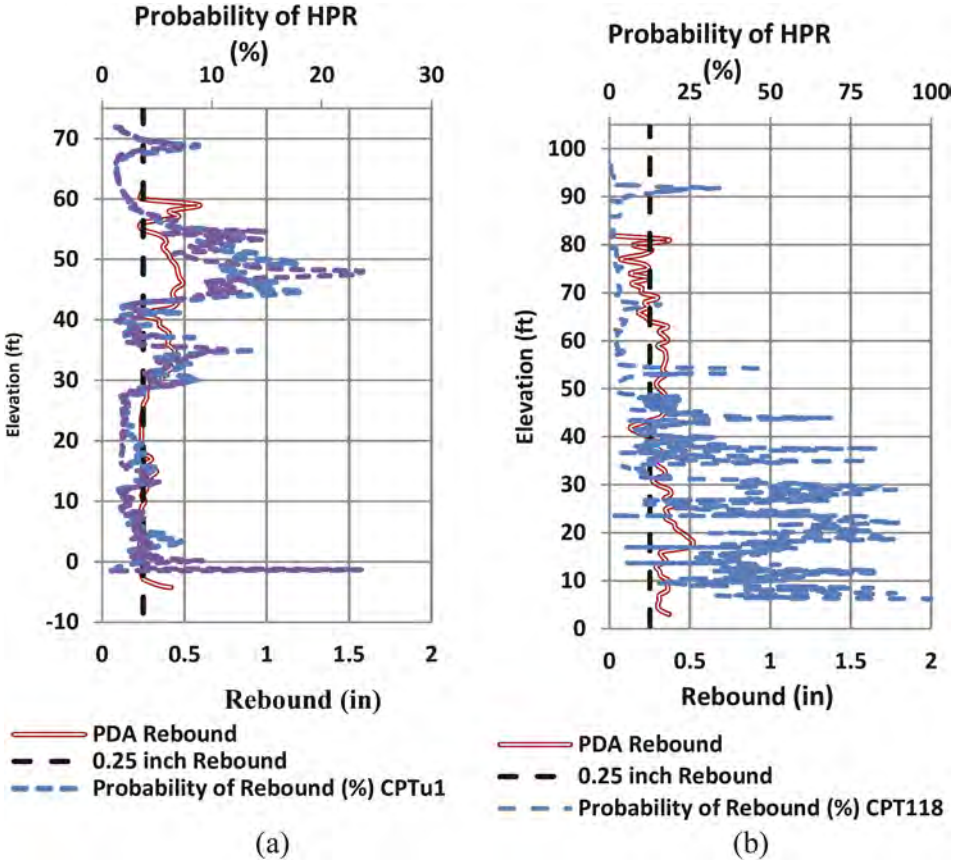

Figure 8. Probabilities of HPR using equation (3) for HPR sites (a) SR 417/International Parkway (minimal Rebound) and (b) I-4/SR408 Ramp B (Rebound with acceptable set).

ABSTRACT: This article discusses some issues on the development of a calculation scheme, a method for calculating a pile in subsiding soil conditions and determining the numerical values of the coefficient of influence of a vertical load on the horizontal bearing capacity of a pile. Developing the methodology for determining the coefficient of influence of the vertical load on the horizontal bearing capacity of the pile, developed by Professor V.V. Znamensky for calculating the cluster pile foundation, a calculation scheme and a calculation method have been proposed for determining the value of the influence coefficient with an increase in the vertical load and wetting of the subsiding soil of a single pile. According to the proposed method of calculation, the numerical values of the coefficients of the influence of vertical loads on the horizontal bearing capacity of bored piles were determined (Table 1). As a result of the latest compared results without taking into account the coefficients, the horizontal bearing capacity is increased at a natural humidity of 181.5. . . . .217 kN and in a water-saturated state of 193.5. . . . .238.5 kN.

1 INTRODUCTION

The basic concept of the operation of a pile in saturated soil under the action of a special combination of loads, including the seismic ones, is that the pile rotates around a certain point 0 located at a depth Z_0 from the ground surface, i.e. a short pile(a length of up to 12.0 m) works according to a rigid scheme. At the same time, an important, somewhat understudied problem arises that the action of a vertical load affects the horizontal bearing capacity of piles. This article discusses some issues on the development of a calculation scheme, a calculation method in accordance with the abovementioned operating conditions of a pile and determining the numerical values of the coefficient of influence of the vertical load on the horizontal bearing capacity of the pile (Mangushev, R.A. et al. 2018; Ishihara, K. 2006; Ilyichev, V.A. et al. 2010; Finn, W.D.L. et al. 2002; Ter-Martirosyan, A.Z. et al. 2020).

2 METHODS AND MATERIALS

Developing the methodology for determining the coefficient (U_{Γ}^{b}) of influence of the vertical load on the horizontal bearing capacity of the pile, developed by professor Znamensky V.V.

DOI: 10.1201/9781003299127-223

(Znamensky, V.V. 2002) for the calculation of a cluster pile foundation, a calculation scheme and a method for calculating the value of the coefficient (U_{Γ}^{b}) with an increase and wetting of the subsiding soil of a single pile have been proposed (Nyamdorj, S. 2023).

For the purpose of a comparative analysis of the patterns of pile operation using the proposed calculation scheme and method, the authors carried out analytical calculations and numerical simulation using the numerical values of the horizontal bearing capacity (150kN) established by the results of field experiments.

3 DESIGN SITUATION

Calculated situation: the territory of the city of Darkhan, soil conditions: subsiding silty sandy loam with preliminary soaking, the calculated indicators of the soil are given in accordance with the natural humidity and water saturation. Piles: single bored reinforced concrete, with the diameter of 0.6 m and the length of 8.0 m, design vertical bearing capacity: 630 kH according to the standard (BNbD 50.01-16), conditional design vertical loads: 300kH, 450kH and 600kH, seismic condition: 7 points (for micro-zoning of the territory the city of Darkhan).

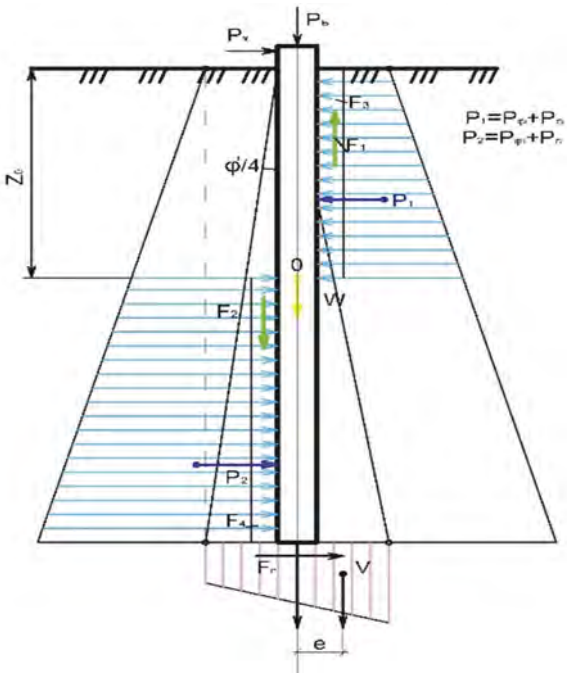

Figure 1. Calculation diagram of a pile to determine the coefficient of influence of the vertical load on the horizontal bearing capacity. Pg-horizontal load; Pv-vertical load; W-weight of the conditional foundation; P1 and P2- soil resistance force on the front and back sides of the pile; F1 and F2 - horizontal force of soil resistance on the front and back sides of the pile; F3 and F4 - resistance force of the lateral surface; Fn - friction force on the plane of the tip of pile; V - total pressure of the tip of pile.

In this calculation scheme it is not possible to fully reflect the mechanisms of various phenomena and processes occurring in the soil near the pile, but it is also possible to reflect the relationship between the main factors influencing the vertical load on the bearing capacity of the pile with a horizontal load, such as a value of the vertical load, which can be determined experimentally, soil conditions of the foundation and the depth of piling.

4 RESULTS OF ANALITICAL CALCULATIONS

The calculation of U_{Γ}^{b} coefficient value for evaluation of influence of the vertical load on the change of the limit horizontal load of the drilled cast-iron pile in the silty sandy loam soil of the given settlement is analytical and numerical in order to evaluate the effect of the vertical load on the value of the limit horizontal load determined by the results tested in the conditions of the silty sandy loam soil of Darkhan city. The tests were carried out under natural and water-saturated wet conditions as well as earthquake intensity of 7 points.

The parameters of the silty sandy loam soil of the test site are taken from Table 3.4 (Nyamdorj, 2023). The purpose of the calculations was to determine the effect of vertical loads Pv = 300kH, 450kH and 600kH on the experimentally determined maximum horizontal load of a single pile and to establish the dependence of the value of a coefficient U_{Γ}^{b} calculated by formula (1) for subsiding clayey sandy soil, taking into account soaking and seismics.

$$U = 1 + \frac{N_1 P_B}{\{n\, D^2[\gamma \cdot n \cdot D(N_3 + N_4)] + C\, N_5\}'} \tag{1}$$

where n = L/D = 8.0/0.6 = 13.338; c - cohesion of the soil, D - diameter of the pile, γ - dead weight of the soil Annex V Table E-1; m' = H/L; n' = L/D; $\alpha = Z_0'/H$, where H, L, D-3 - see the calculation scheme. Z_0' - reduced location depth O of the turning point of the pile, is determined depending on the reduced depth $(\bar{l})$:

$$\bar{l} = \alpha_{\varepsilon}' \cdot \ell; \tag{2}$$

where α_{ε}' – a deformation coefficient, determined by formula (3), l - pile length, m;

$$\alpha_{\varepsilon}' = \sqrt[5]{\frac{K \cdot Bp}{\gamma \cdot EJ}}; \tag{3}$$

where K is a coefficient of the proportional, $\ell_k = 3.5D + 1.5 = 3.5 \cdot 0.6 + 1.5 = 3.6\,m$ within the depth (SP 24.13330.2011. Pile foudndations) is determined according to tables B1, ℓ_k is the depth of the subsiding soil with natural moisture and it is equal to $\ell_k = 0.62$; $\varphi' = 25°$, $c = 10.8$kPa, J_2<0 (solid consistency). K'is determined according to table B1 at J2<0 K'=12000 kN/M4. Bp - a conditional pile width determined according to the following dependence: at D ≥ 0.8 m Bp = (D+1); at D < 0.8m Bp = (1.5D + 0.5);

According to our calculation conditions, D = 0.6 m, therefore, Vr = (1.5 · 0.6 + 0.5) = 1.4 m; γ- γ = 3.0 per 1 pile, EJ- stiffness of pile, concrete B15, E=24·106 kN/m2; J is the moment of inertia of the cross section. $J = \pi r^4/4 = 0.003066$ м^4; EJ=2410^{6}0.003066=73584kH.m^2; $\alpha_{\epsilon}' = \sqrt[5]{\frac{12000 \cdot 1.4}{3.73584}} = 0.612\text{м}^{-1}$, n = 0.8/0.6 = 13.33, m= 7.7/8.0 = 0.963

where $\bar{l}$ = 0.583 ·8.0=4.664, Z-value at $\bar{l} \le 2.5$ $Z_0 = \bar{l}/3$ and $Z_0 = \bar{l}$ along these deep 2 sections, at $\bar{l} > 2.5$ $Z_0 = 0.85/\alpha_{\epsilon}$ are calculated according to the depth section. For our condition z'=0.85/0.583=1.46.

A. The value of the angle of internal friction of soil with natural moisture (W) is assumed to be φ=23°- 2°=21° due to a 7-point earthquake in Darkhan under the condition φ = 25°, V = 0.25; α=0.612. At m=0.963 it is determined according to Table. 5 and provided that α=0.612, m=0.963, according to Table 7, the values of coefficients N_1', N_2', N_3', N_5'.

   a) α=0,6; m=0.5=> 20°=0,347; 25°=0,360; according to φ =21°

$$N_1^{0.5} = \frac{0.360 - 0.347}{5} 1 + 0.347 = 0.350$$

α=0.6; m=1.0=> 20°=0.395; 25°=0.419, according to φ =21°

$$N_1^{1.0} = \frac{(0.419 - 0.395)}{5} 1 + 0.395 = 0.400$$

m=0.963; φ =21˚ value $N_1^{'}$ of silty sandy loamy soil with natural humidity:

$$N_1^{'} = \frac{0.400 - 0.350}{0,5} 0.463 + 0.350 = 0,426$$

b) α=0,6; m=0.5=> 20˚=0,065; 25˚=0,093 according to φ =21˚

$$N_2^{0.5} = \frac{0.093 - 0.065}{5} 1 + 0.065 = 0.071$$

α=0.6; m=1.0=> 20˚=0.353; 25˚=0.494 according to φ =21˚

$$N_2^{1.0} = \frac{(0.494 - 0.353)}{5} 1 + 0.353 = 0.381$$

m=0.963; φ =21˚ value $N_2^{'}$ of silty sandy loamy soil with natural humidity:

$$N_2^{'} = \frac{0.381 - 0.071}{0,5} 0.463 + 0.071 = 0,358$$

c) α=0,6; m=0.5=> 20˚=0,068; 25˚=0,095 according to φ =21˚

$$N_3^{0.5} = \frac{0.095 - 0.068}{5} 1 + 0.068 = 0.073$$

α=0.6; m=1.0=> 20˚=0.392; 25˚=0.529 according to φ =21˚

$$N_3^{1.0} = \frac{(0.529 - 0.392)}{5} 1 + 0.392 = 0.419$$

m=0.963 φ =21˚ value $N_3^{'}$ of silty sandy loamy soil with natural humidity:

$$N_3^{'} = \frac{0.419 - 0.073}{0,5} * 0.463 + 0.073 = 0,393$$

d) α=0,6; m=0.5=> 20˚=0,298; 25˚=0,306 according to φ =21˚

$$N_4^{0.5} = \frac{0.306 - 0.298}{5} * 1 + 0.298 = 0.300$$

α=0.6; m=1.0=> 20˚=0.653; 25˚=0.683 according to φ =21˚

$$N_4^{1.0} = \frac{(0.683 - 0.653)}{5} * 1 + 0.653 = 0.659$$

m=0.963 φ =21˚ value $N_4^{'}$ of silty sandy loamy soil with natural humidity:

$$N_4^{'} = \frac{0.659 - 0.300}{0,5} * 0.463 + 0.300 = 0,63$$

e) α=0,6; m=0.5=> 20˚=0,317; 25˚=0,385 according to φ =21˚

$$N_5^{0.5} = \frac{0.385 - 0.317}{5} * 1 + 0.317 = 0331$$

α=0.6; m=1.0=> 20˚=0.994; 25˚=1.156 according to φ =21˚

$$N_5^{1.0} = \frac{(1.156 - 0.994)}{5} * 1 + 0.994 = 1.026$$

m=0.963 φ =21˚ value $N_5^{'}$ of silty sandy loamy soil with natural humidity:

$$N_5^{'} = \frac{1.026 - 0.331}{0,5} * 0.463 + 0.331 = 0,794$$

There have been defined coefficients $U_{300}^{'}$, $U_{450}^{'}$ and $U_{600}^{'}$ of influence of the vertical load of 300kH, 450 kH and 600 kH on the bearing capacity of the pile with the maximum horizontal load of 150kH at natural (W) humidity in silty sandy loamy soil and the dynamics of the effect is analyzed (Nyamdorj, S. 2023):

1. At the ultimate horizontal load Q=150 kH and vertical load P^b=300 kH, then the value of $U_{300}^{'}$:

$$U'_{300} = 1 + N'_1 P_B / \{n.B^2[\gamma \cdot n\, D(N'_3 + N'_4)] + c\, N'_5 = 1 + 0.426 \cdot 300\kappa H / \{13.33 \cdot 0.6^2[15.5 \cdot 13.33 \cdot 0.6(0.393 + 0.632)] + 10.8 \cdot 0,794\} = 1 + 0,355 * \frac{300}{618,51} = 1.21 \quad (4)$$

2. At the ultimate horizontal load Q=15.0 tons and vertical load P^b=450kH the value of $U_{450}^{'}$:

$$U_{450}^{'} = 1 + 0,426 * \frac{450}{618,51} = 1.31$$

3. At the ultimate horizontal load Q=15.0 tons and vertical load P^b=600kH the value of $U_{600}^{'}$:

$$U_{600}^{'} = 1 + 0,462 * \frac{600}{618,51} = 1.45$$

B. The value of the coefficient U of influence of the vertical load on the horizontal bearing capacity of a pile operating in silty-sandy soil with water-saturated moisture (Wsat) is determined by formula (1). The calculated values of $N_1^{"}$, $N_2^{"}$, $N_3^{"}$, $N_4^{"}$, $N_5^{"}$ are determined by the same method as for soil with moisture content W with parameters φ"=17° and C"=0.68 kPa corresponding to humidity W_{sat}. The earthquake of the region is 7 points, then φ "=17 ° - 2°=15° is taken into account.

a) α=0.6, m=0.5 => at $\varphi^{"}$=15° then $N_1^{0.5} = 0.335$
α=0.6, m=1.0 => at $\varphi^{"}$=15° then $N_1^{1.0} = 0.370$
m=0.963; $\varphi^{"}$=15° => with soil humidity W_{sat} from the value of N_1^{II}:
$N_1^{''} = \frac{0.370-0.335}{0,5} \cdot 0.463 + 0.335 = 0.367$

b) α=0.6, m=0.5 => at $\varphi^{"}$=15° then $N_2^{0.5} = 0.044$
α=0.6, m=1.0 => at $\varphi^{"}$=15° then $N_2^{1.0} = 0.244$
m=0.963; $\varphi^{"}$=15° => with soil humidity W_{sat} from the value of N_2^{II}:
$N^{"}{}_2 = \frac{0.241-0.044}{5}$ 0.463+0.44 = 0.469

c) α=0.6, m=0.5 => at $\varphi^{"}$=15° then $N_3^{0.5} = 0.048$
α=0.6, m=1.0 => at $\varphi^{"}$=15° то $N_3^{1.0} = 0.290$
m=0.963; $\varphi^{"}$=15° => with soil humidity W_{sat} from the value of N_3^{II}:
$N_3^{"} = \frac{0.290-0.048}{0,5}$ 0.463+0.048=0.272

d) α=0.6, m=0.5 => at then $N_4^{0.5} = 0.291$
α=0.6, m=1.0 => at $\varphi^{"}$=15° then $N_4^{1.0} = 0.624$
m=0.963; $\varphi^{"}$=15° => with soil humidity W_{sat} from the value of N_4^{II}:
$N_4^{"} = \frac{0.624-0.291}{0,5}$ 0.463+0.291=0.356

e) α=0.6, m=0.5 => at $\varphi^{"}$=15° then $N_5^{0.5} = 0.259$
α=0.6, m=1.0 => at $\varphi^{"}$=15° then $N_5^{1.0} = 0.821$

m=0.963; $\varphi^{"}$=15° => with soil humidity W_{sat} from the value of N_5^{II}:
$N_5^{"} = \frac{0.821-0.259}{0,5}$ 0463 + 0.259 = 0.779

When determining the value of the coefficient $U^{"}_{300}$; $U^{"}_{450}$; $U^{"}_{600}$ according to formula of (Znamensky, V.V. 2002) for piles embedded in saturated (W_{sat}) silty sandy loamy soil with the same design parameters as in part A, the adhesion force of saturated subsiding soil $C^{"}$ = 0.68 kPa is very small, i.e. it can be considered as non-cohesive soil, therefore, the results of a comparative assessment of the coefficients of influence of the vertical load according to formula (5) for non-cohesive soil and according to formula (6) for cohesive soil show the following:

I. According to formula (5) for non-cohesive soils: the value of $U^{"}_{300}$ at the maximum horizontal load on the pile determined by full-scale tests Q=150 kN and the vertical load P_B = 300 kN:

$$U''_{300} = 1 + N''_1 P^B/\gamma \cdot n^2 \cdot D^3(N''_2 + N''_4) = 1 + 0.338 \cdot \frac{300}{15.5} \cdot 13.33^2 \cdot 0.6^3(0.062 + 0.033) = \\ = 1.57. \quad (5)$$

II. According to formula (6) for cohesive clay soil: $U^{"}_{300}$ value at horizontal load Q=150 kN and vertical load P_B = 300 kN:

$$U''_{300} = 1 + N''_1 P^{30}_B/\left\{n.D^2\left[\gamma \cdot n\left(N''_3 + N''_4\right)\right] + c\,N''_5\right\} = 1 + 0.367 \cdot 300/\{13.33 \cdot \\ 0.6^2[15.5 \cdot 13.33 \cdot 0.6(0.272 + 0.356)] + 0.68 \cdot 0.794\} = 1 + 110,1/376,24 = 1.39 \quad (6)$$

6 DISCUSSION OF THE RESULTS

According to the calculations, the values of the coefficient $U^{"}_{300}$ of the water-saturated silty sandy loamy soil (W_{sat}) calculated by the formula (4) and the values of $U^{"}_{300}$ = 1.57 and by the formula (5) the value of $U^{"}_{300}$ = 1.39, the compatibility of the values of these coefficients is 91%. As a result of the latter, we can conclude that these formulas work with high accuracy and show a high degree of reliability of analytical calculations and field experiments. For further calculation, formula (5) has been chosen for saturated silty sand ($C^{"}$=0.68 kPa).

The value of $U^{"}_{450}$ with horizontal ultimate load Q=150 kN and vertical load P^b = 450 kN:

$$U''_{450} = 1 + 0.367 \cdot 450/376,24 = 1,43$$

The value of $U^{"}_{600}$ with horizontal ultimate load Q = 150 kN and vertical load P^b = 600 kN:

$$U''_{600} = 1 + 0.367 \cdot 600/376,24 = 1.59$$

The pattern of increasing the limit value of the horizontal load on the pile, depending on the effect of the vertical load, is calculated using formula (7) and given in Table 1.

$$P^B_h = U \cdot P_h \quad (7)$$

where U is a coefficient of influence, P_h is the ultimate horizontal load, kN

The growth pattern of the influence coefficient and horizontal bearing capacity is shown in the diagram.

Graphs of the dependence of the coefficient of influence of the vertical load on the horizontal bearing capacity of piles immersed in subsiding soils of the city of Darkhan with natural and water-saturated humidity $U^I = f(P^\sigma)$; $U^{II} = f(P^\sigma)$; $P^I_n = f(U^I)$; $P^{II}_n = f(U^{II})$; $U^I = f(Q/Q^I_n)$; $U^{II} = f(Q/Q^{II}_n)$ are shown in the following figures.

Table 1. The coefficient of influence of the vertical load on the horizontal bearing capacity of piles and its increase.

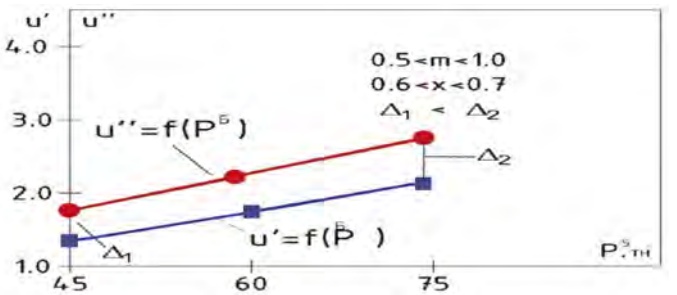

Figure 3. Graph of influence of the vertical load on the horizontal bearing capacity of the pile $U^I f = (P^\sigma)$ and $U^{II} = f\ (P^\sigma)$.

7 CONCLUSIONS

Based on the analysis of the results of calculations to determine the values of the coefficients of influence, the following regularities have been established:

- depending on a moisture content of the subsiding soil and the values of the vertical load, the horizontal bearing capacity of the pile increases;
- compared with the result without taking into account the coefficients of 150.0 kN, the horizontal bearing capacity is increased depending on the intensity of the vertical load at natural humidity 181.5. . .217 kN, and in the water-saturated state 193.5. . .238.5 kN.
- indicators of inequality $\Delta_1 < \Delta_2$ grow with increasing value of the vertical load, and the effect of vertical load decreases with increasing pile length or driving depth. In this case,

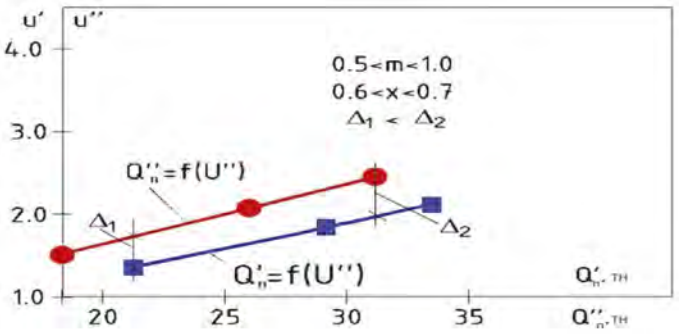

Figure 4. Graph of influence of the vertical load on the horizontal bearing capacity of the pile. $Q_n^I = f(U^I)$ and $Q_n^I = f(U^{II})$.

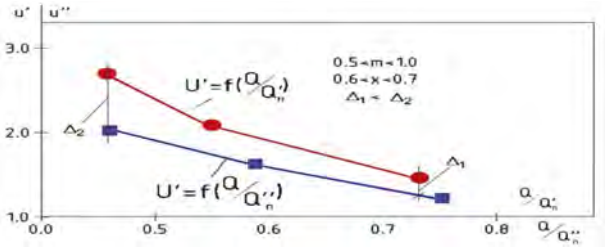

Figure 5. Graph of the influence of the vertical load on the horizontal bearing capacity of the pile $Q^I = f(Q/Q_n^I)$ and $Q^{II} = f(Q/Q_n^{II})$.

a length of pile or a depth of immersion is the main factor of influence, and it can be adjusted by increasing a diameter of pile and an immersion depth;

- with an increase in the intensity of earthquakes, the angle of internal friction decreases (by 2 . . . 7°);
- for subsiding soil with natural and water-saturated moisture, the area of subsoil of the conditional pile foundation decreases inversely and the value of the coefficients U' and U'' increases;
- these processes of increase and decrease are linearly proprotional and their intensity depends on the depth of pile, the coefficients n and m, the angle of internal friction φ and the cohesive force C of soil, the nature of change in physical and mechanical properties of the subsiding soil of pile subsoil when moistened, as well as the I and II type of soil conditions as per subsidence.

A. Marinucci
V2C Strategists LLC, New York, USA

ABSTRACT: A Smart Cell is a closed-type grout distribution system that is attached to the bottom of a reinforcement cage for drilled shaft foundations and acts in a similar manner to a hydraulic jack in bi-directional static load testing. Control of the grout is maintained within the device during grouting and a uniform stress is imparted across entire base area simultaneously. The goals of tip post-grouting are to improve the stiffness of the in-situ soil, improve the shaft's nominal axial resistance, and better align the load transfer curves to the project requirements. This paper will present an overview, basic principles, and the design methodology of tip post-grouting using this technique. The construction, tip post-grouting, select results, and general observations from the grouting performed on more than 40 total drilled shafts for the Urubó vehicular bridge structure crossing the Piraí River in Bolivia will also be presented and discussed below. The general subsurface conditions for the sedimentary deposits at the two bridge sites consist of highly variable soil deposits, bedding, composition, and engineering characteristics. The diameter of the temporarily cased drilled shafts was either 1200 mm and the length ranged from nearly 22 m to nearly 28 m Most of the drilled shaft foundations for these bridge structures were installed with a Smart Cell at the bottom of its reinforcement cage to enhance performance and to reduce uncertainty. Using the measurements of the grouting operation, the premobilization of axial resistance and induced load imparted into the drilled shaft and to the soil beneath the base will be discussed.

1 INTRODUCTION

The generalized load transfer behaviors of a conventional (i.e., ungrouted) drilled shaft in cohesionless and cohesive soils loaded in axial compression are presented in Figure 1. The side resistance of a drilled shaft will mobilize its peak strength after a normalized vertical displacement, ΔD_{vn}, (i.e., vertical displacement, δ_v, divided by the diameter of the drilled shaft, D_p) of about 0.2% to 0.4%, regardless of soil type. Chen and Kulhawy (2002) presented that, at a normalized displacement of about 0.4%, approximately 50% of the failure threshold axial resistance is mobilized, about 90% of which is from side resistance and 10% is from end resistance.

The end or tip resistance does not fully mobilize until much larger normalized displacements have been realized: about 4% to 5% in cohesive soils and about 10% (practical limit) in cohesionless soils. At a normalized displacement of about 4%, Chen and Kulhawy (2002) reported that 100% of the failure threshold axial resistance is mobilized (i.e., ultimate state for cohesive soils and serviceability state for cohesionless soils), where about 76% of which is from side resistance and 24% is from end resistance. For cohesive soils, this is the maximum axial resistance that can be achieved. For cohesionless soils, however, the maximum axial resistance is achieved at much larger normalized displacements (governed by bearing capacity), thereby mobilizing 159% of the failure threshold axial resistance, where 76% of the axial resistance is from side resistance and 83% is from end resistance. For practical design purposes, however, the end resistance is typically capped at a normalized displacement of about 10%. Due to this strain incompatibility in

DOI: 10.1201/9781003299127-224

achieving the peak strength, utilizing the full side and end resistance in design is not realistic and designers have typically neglected one component or reduced the relative contributions of side and/or end resistance. Design is clearly and fundamentally essential; however, long-term performance of a drilled shaft is mainly governed by the construction technique(s) utilized and the quality of the craftsmanship applied to install the foundation element.

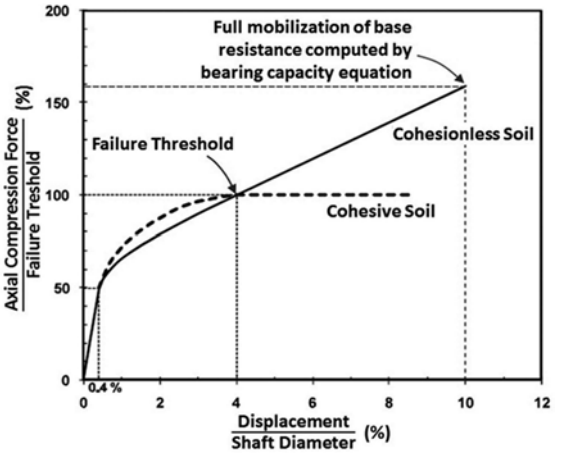

Figure 1. Normalized load-displacement curves of drilled shafts in axial compression in cohesive and cohesionless soils (mod. after Brown et al., 2018).

Holding the concerns of strain incompatibility aside, other issues may manifest as a result of the construction process, even with high quality craftsmanship, which include the accumulation of sediment (i.e., soft bottom condition) and the change in the state of stress (i.e., stress relief) at the bottom of the shaft. As described above, vertical settlement of the shaft is required to mobilize resistance; with an excess of accumulation of sediment and/or stress relief of the in-situ conditions, a greater amount of vertical settlement would be required to mobilize the axial resistance required for the design and proper long-term performance of the constructed shaft.

Tip post-grouting is a technique used to pre-mobilize the axial end resistance of the shaft as well as to mitigate against a soft bottom condition and stress relief due to installation. This technique is used to inject a neat cement grout, under pressure, beneath the base of a drilled shaft to improve its performance when subjected to compressive axial loads. (Note: tip post-grouting should not be used in lieu of proper execution and good quality workmanship in the construction of a drilled shaft.) It is accomplished using an open- or closed-type grout distribution device that is incorporated into the bottom of the steel reinforcement cage. For open-type systems (i.e., sleeve-port or tube-á-manchette systems), the grout is injected out of the supply tubes and into the surrounding ground around the tip of the shaft; conversely, for closed-type systems (e.g., Smart-Cells), the grout is contained within the expanding device and does not contact the ground directly. The key objectives of this technique are to improve the stiffness of the soil, improve the nominal resistance (i.e., load-displacement performance) of the shaft to axial compressive loading, and better align the load transfer curves via mobilization (preloading) of end resistance (Figure 2).

2 OVERVIEW AND BASIC PRINCIPLES

A Smart Cell (SC) is a closed-type tip post-grouting device that is attached to the bottom of the steel reinforcement cage of drilled shafts (Figure 3a) and acts as a hydraulic jack to mobilize the end resistance of the drilled shaft irrespective of the type of ground condition. The device itself comprises top and bottom steel plates, cell walls, and internal connections and appurtenances. As grout is injected under pressure into the device, the cell expands thereby pushing upward against the drilled shaft and downward against the in-situ soil below the base of the shaft and device.

During this process, a bi-directional force is induced into the drilled shaft above and to the soil below, resulting in a pre-mobilization (i.e., preloading) of the side and end resistances. The injection pressure is typically measured at the grout pump as it is being pumped and at a short distance above the top of the drilled shaft. Vertical movements of the top and bottom steel plate during the grouting operation are typically measured using tell tales, and the uplift displacements at the top of the shaft are typically measured using optical survey methods and using displacement transducers.

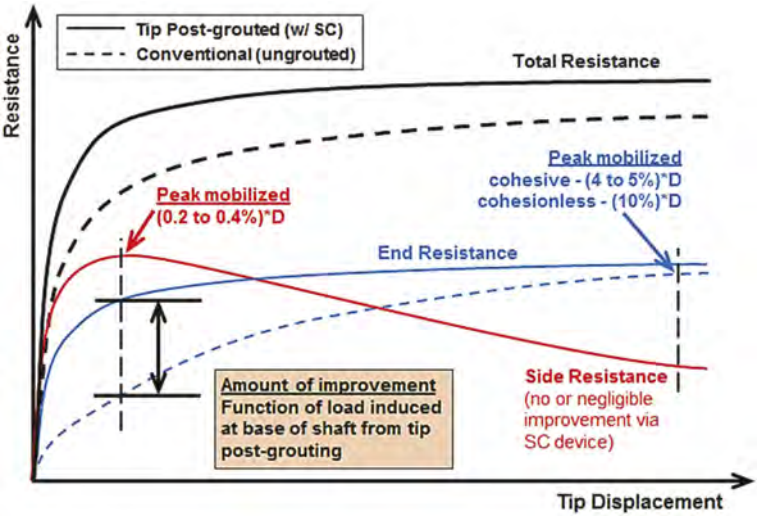

Figure 2. Generalized load transfer behavior of conventional (ungrouted) and tip post-grouted drilled shafts (mod. after Brown et al., 2010).

Since the grout is contained (Figure 3b), the bi-directional load that is induced (P_{SC}) during the grouting process can be computed by multiplying the injection pressure (p) by the cross-sectional area of the device (A_{SC}). The induced load is a function of the in-situ stress state of the soil, self-weight of shaft, and available side resistance between the shaft and the surrounding soil. With this technique, the pressure acts across the entire base of the device simultaneously. In general, the greater amount of load that can be induced from the grout injection process, the greater the pre-mobilization (pre-loading), the greater the increase in soil stiffness, and the greater the improvement in performance that can be achieved (Loehr et al, 2017). Successful and reliable implementation of tip post-grouting will allow designers to optimize the design of a tip post-grouted pile by stiffening its end-bearing response and by allowing the maximum tip resistance at a downward displacement that is consistent with the maximum side resistance (i.e., optimizing of load transfer curves). Other benefits of tip post-grouting with a Smart Cell include stiffening the load-deformation response under working loads, reducing settlement of the pile under applied loading, shortened constructed length of the shaft, ability to be performed in a range of ground conditions, utilizing usable tip resistance in design computations, verifying a lower bound of axial resistance, and improving the ground beneath the base of the shaft.

3 TIP POST-GROUTING – IMPLEMENTATION AND RESPONSE

The general sequence of operations when tip post-grouting is performed along with the ensuing response is described hereinafter. After the borehole is drilled (i.e., dry method, wet method, and/or casing method), the steel reinforcement cage along with the required embedded appurtenances (e.g., NDT access tubes, instrumentation, SC device, and components) is installed in the borehole, which is then filled with concrete and allowed to cure (Figure 4a). A neat cement grout with a water-to-cement ratio (w/c) between 0.45 and 0.55 is typically used with this tip post-grouting technique. The injection of pressurized grout induces a bi-directional load (P_{SC})

Figure 3a. Photograph of a smart cell attached to the bottom of a steel reinforcement cage.

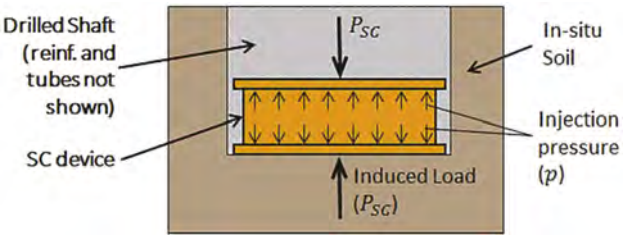

Figure 3b. Graphical depiction of grouting and induced loading.

within the device, which simultaneously mobilizes negative side resistance to resist the upward loading and positive tip resistance to resist the downward loading (Figure 4b–4d). During the grouting process, the side resistance is mobilized first, which along with the self-weight of the shaft, reacts against the upward force and facilitates the pre-mobilization or pre-loading of the in-situ soil below the device. Pre-mobilization or pre-loading of the in-situ soil does not result in an increase in the ultimate axial resistance of the shaft but should reduce the magnitude of displacement that will occur up to the induced load (P_{SC}).

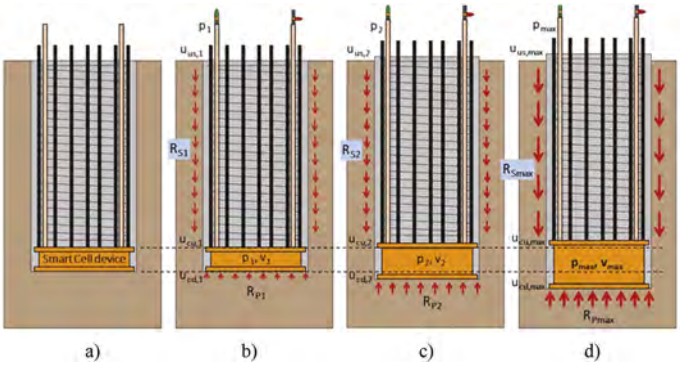

Figure 4. Generalized sequence: (a) installation into borehole and concrete placement, (b) early during grouting process, (c) intermediate grouting stages, and (d) grouting completed.

Since the elastic axial behavior of the drilled shaft is dissimilar to that of the in-situ soil surrounding the shaft, the resulting differential strains induced during tip post-grouting and then later during axial top-down loading cause debonding at the weakest interface, which tends to be along the soil-shaft interface. As a unit length of the shaft (within soil layer i) approaches the geotechnical strength limit state (i.e., ultimate soil- shaft resistance), a highly non-linear profile of bond stress results, whereby this progressive debonding generally results in an inefficient use of the in-situ soil-shaft bond strength. As the shaft is displaced during grouting or axial loading, the available side resistance increases to a peak state; however, once the peak soil-shaft bond strength has been exceeded, the available resistance reduces to a softened strength state and then to a residual strength state with continued deformation. For this reason, quality control measures are employed to mitigate against the negative effects to and reduction in side resistance. Hence, uplift displacement measured at the top of the drilled shaft is typically limited to less than about 0.013 m. Ideally, at the completion of grouting, the end resistance will have been fully mobilized while the side resistance would not have been degraded to a strain-softened state.

The grouting is performed using a controlled process to ensure proper performance of the system as well as to ensure minimal-to-no excess pore water pressures are generated. To ensure control of the grout and its effect on the load response behavior of the drilled shaft, multiple parameters are measured as a function of time, recorded, and analyzed throughout the grouting

operation as part of termination criteria and the overall QA program. The injection pressure, volume and flow of grout, and movements at the top of the shaft and at the SC device are measured and recorded throughout the grouting operation. The grouting operation is continued until the prescribed grouting termination criteria is achieved. The termination criteria for tip post-grouting includes target grout pressure, net grout volume in excess of the amount to fill the delivery system and supply tubes, and maximum uplift displacement of the pile during grouting, and expansion limit of the SC device. During grouting, real-time or near real-time plots of grout pressure vs. injected volume, grout pressure vs. shaft uplift, grout volume vs. expansion of the SC, and grout volume vs. shaft uplift are monitored for conformance with the termination criteria.

The relationship between the induced load (P_{SC}) and the measured vertical displacement provides valuable insight into the behavior during grouting and for estimating the stiffness (or modulus) and unit end resistance of the soil at the completion of grouting. After the net volume has been injected, the injection pressure (or induced load) required to initiate the expansion of the cell is equal to the lesser of the reaction from the self-weight of the shaft along with the side resistance above the cell or the bearing end resistance below the cell. Measurements of vertical displacement and computed induced load from a completed project (Figure 5) will be used to highlight the behaviors and characteristics observed during the grouting operation:

- At about 45 tons of induced load – the load required to initiate the expansion of the cell (downward into the soil below the device) was reached.
- From about 45 to 65 tons of induced load - the disturbed or loose soil was recompressed about 0.018 m, resulting in an average stiffness (k_1) of about 1.1 tons/mm.
- From 65 to 170 tons of induced load - as additional grout was injected, the device continued to expand and compressed the in-situ soil, which resulted in an additional 0.022 m of vertical displacement along with a corresponding increase in the average stiffness ($k_2 \approx 4\ k_1$) from about 1.1 to 4.4 tons/mm.
- Uplift movement of the shaft was first noticed at induced load of about 150 tons, which was close to the second inflection point of the induced load-displacement response. That is, no uplift movement was realized until after the soft bottom was fully restored and the soil compressed. It is fair to say that the induced loads corresponding to the initiation of uplift movement and to the second inflection point would have been in closer agreement had displacement transducers been used to continuously measure/record the displacements instead of discrete optical survey methods.
- From 170 to 380 tons of induced load - higher levels of injection pressure were required to inject the grout, whereby only an additional 0.009 m of vertical displacement occurred resulting in a considerable increase in the average stiffness ($k_3 \approx 7.9\ k_2 \approx 31.8\ k_1$) from about 4.4 to 35.0 tons/mm and a corresponding premobilization of the load into the soil and shaft. For this project, the unfactored design load for each drilled shaft was about 540 tons. The resulting induced load of about 380 tons was about 70% of the design axial load.

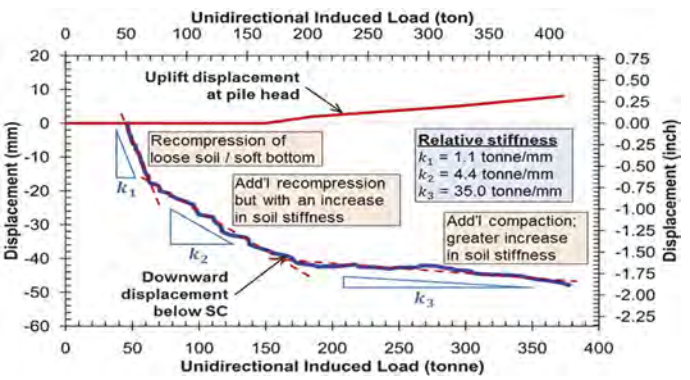

Figure 5. Representative example of induced load vs. vertical displacement during grouting.

4 TIP POST-GROUTING DESIGN – TARGET PRESSURE

An engineer designs a drilled shaft (i.e., diameter, depth, and reinforcement) to resist the anticipated imposed loading while satisfying the applicable limit state conditions. Once the diameter and depth of the drilled shaft have been established using the appropriate axial end and side resistances afforded by the in-situ ground conditions (for strength limit state conditions), the target injection pressure (p_t) can be estimated (for service limit state conditions). Even with the best modeling and the highest quality of construction utilized, the estimated value of p_t is not guaranteed. p_t is dependent upon various factors, including soil type, in-situ stress state, shear strength of the soils, and available reaction force (i.e., self-weight of the drilled shaft plus side resistance).

As discussed by Loehr et al (2017), for tip post-grouting applications, contractors and service firms have reported maximum achieved p_t as high as about 15 MPa in sands and about 8 MPa in clays/silts. Based on experience, the general trend of an injection pressure-vs.-grout volume curve resembles in nature one of the normalized load-displacement curves shown in Figure 1 (Marinucci et al, 2020). That is, if the trend indicated a relatively low maximum grouting pressure that had flattened, this would be indicative of tip post-grouting in cohesive soils, whereby the end resistance fully mobilized. Conversely, if the trend indicated a continued increase in injection pressure with continued grouting, this would be indicative of tip post-grouting in cohesionless soils, whereby the end resistance may not have fully mobilized.

For tip post-grouting with a SC device in Bolivia, the load-displacement curves presented by Chen and Kulhawy (2002) and described by Brown et al (2018) are used to compute the target injection pressure based on the prescribed tolerable displacement of the drilled shaft. The target volume of grout to be injected is dependent upon the dimensions of the drilled shaft and the expanded limits of the SC. The induced load (P_{SC}) is computed by multiplying the measured injection pressure (field) by the internal bearing area of the cell (A_{SC}). As defined in AASHTO §10.8.3.5 (2012), the nominal axial compression resistance of a single drilled shaft (R_n) is computed using Equation (1). The amount of allowable vertical displacement due to axial compression loading indirectly establishes the amount of axial resistance that can be mobilized for that given displacement (i.e., service conditions). If the allowable displacement is less than that required to fully mobilize the axial resistance, tip post-grouting can be used to achieve and induce a bi-directional force to pre-mobilize the required axial resistance.

$$R_n = R_S + R_p = \sum_{i=1}^{n} (q_{si} A_{si}) + q_p A_p \quad (1)$$

where: R_n = nominal axial compression resistance of a single drilled shaft; R_S = nominal side resistance of a single drilled shaft; R_P = nominal end resistance of a single drilled shaft; q_{si} = nominal unit side resistance for soil layer i; A_{si} = nominal surface area of the soil-shaft interface for soil layer i; n = number of soil layer; q_p = nominal unit end resistance; A_p = nominal cross-sectional area of the tip of the drilled shaft.

Recalling, the side resistance is fully mobilized at a normalized displacement (ΔD_{vn}) of about 0.2% to 0.4%, whereas the end resistance is mobilized at ΔD_{vn} of about 4% to 5% for cohesive soils and about 10% for cohesionless soils (Figure 1). The vertical axis on the figure represents the ratio of the axial compression load to the failure threshold (i.e., nominal axial compression resistance, R_n). As shown on Figure 1, 100% of the failure threshold typically occurs at ΔD_{vn} of about 4% for both cohesionless and cohesive soils.

5 CASE HISTORY -URUBÓ BRIDGE PROJECT

The new Urubó Bridge is being constructed adjacent to the existing bridge, which connects the municipalities of Porongo (west) and Santa Cruz de la Sierra (east) in Bolivia. The new bridge will be about 12 m wide and about 420 m in length. The 5-span bridge (Figure 6) will be supported by four pier structures, located about 100 m apart and each with seven drilled shafts (arranged in two rows), located in the Piraí River and two abutments supported by 3 drilled shafts each (arranged in one row), which are located beyond the extents of the river's

edges. Based on the project drawings, each of the bored piles is 1.2 m in diameter with an embedment depth of about 25 m at the abutments and about 30 m for each of the piers.

5.1 *Subsurface conditions*

As shown in Figure 6, one soil boring was performed at each of the four pier locations to a depth of about 40 m along with Standard Penetration Testing (SPT). At the time the soil borings were performed, the elevation of the ground surface at the borings was approximately El. +399.4 m, and the ground water was located just below the ground surface. The soil deposit is classified as quaternary sedimentary silty-clayey sands of alluvial and flood plain origin. In general, the subsurface consists of highly variable soil deposits, bedding, composition, and characteristics, which are the results of a dynamic river environment. The general subsurface profile (Figure 7) contains an upper layer of granular fill underlain by highly heterogeneous and interbedded layers consisting of clay, silt, and sand. For the west and east abutments, the bored piles were tipped into silty sands and lean clay with silt, respectively. The bored piles for the piers were tipped into lean clay soils: lean clay with sand for piers 1 and 2 and lean clay with silt for piers 3 and 4.

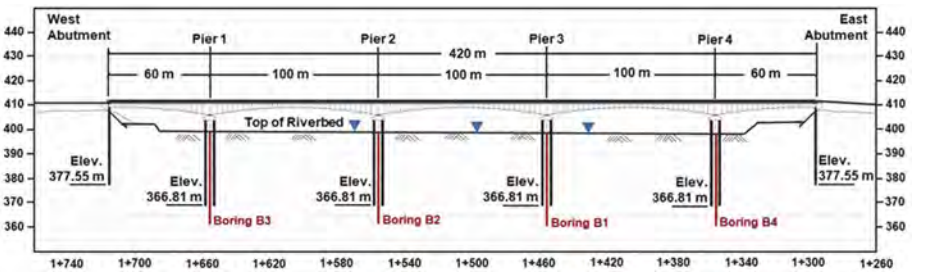

Figure 6. Elevation profile of the bridge super- and substructure and approximate boring locations.

5.2 *Pile installation and Tip Post-grouting*

The bored piles were constructed using temporary segmental casing with the use of a drilling support fluid (water) to prevent instability at the bottom of the borehole. A SC device and attachments were incorporated into the bottom of the steel reinforcement cages and lowered into the borehole, after which the concrete was placed the using tremie method. After the concrete achieved the required minimum unconfined compressive strength and when the water level within the river permitted work to proceed, the tip post-grouting was performed individually for each bored pile.

The target pressure for the tip post-grouting was computed for its worst-case condition. The upper 1.5 m of side resistance was neglected for the computations. For the pier structures, the unfactored axial compression design load per pile ($P_{d,serv}$) was 400 tons with a maximum allowable post-construction vertical settlement ($\delta_{v,allow}$) of 30 mm, resulting in a normalized post-construction displacement (ΔD_{vn}) of 2.5. For the worst-case scenario, the minimum required target pressure was estimated to be about 1025 kPa. Monitoring and recording of the injection pressure, grout volume injected, and grout flow rate were performed in real time using transducers connected to a data acquisition system and observed on a laptop computer. The uplift and downward movements of the bored pile and the SC were measured using manual readings obtained via visual survey and telltale extensometers, respectively.

The target pressure for the tip post-grouting was computed for its worst-case condition. The upper 1.5 m of side resistance was neglected for the computations. For the pier structures, the unfactored axial compression design load per pile ($P_{d,serv}$) was 400 tons with a maximum allowable post-construction vertical settlement ($\delta_{v,allow}$) of 0.03 m, resulting in a normalized post-construction displacement (ΔD_{vn}) of 2.5. For the worst-case scenario, the minimum required target pressure was estimated to be about 1025 kPa. Monitoring and recording of the injection pressure, grout volume injected, and grout flow rate were performed in real time using transducers connected to a data acquisition system and observed on a laptop computer.

5.3 *Results from injection of production piles*

A summary of the results of the tip post-grouting performed at the abutments and the pier structures is provided in Table 1. As listed, there was considerable variability in the injection pressures achieved and with the observed behavior, even within short distances from each other. The achieved pressures, on average, were notably higher for the piles at the pier structures than for those at the abutments, possibly due to the additional side resistance available for the deeper shafts and due to the increased relative strength at the greater depths. In addition, some of the differences can be attributed to the different soil type present at the base of piles – ranging from silty sand to lean clay.

At the abutments, the unidirectional induced loads ranged from 1538 to 4534 kN, which were about 39% to 116% of the unfactored design load ($P_{d,serv}$). The induced load resulted in a normalized downward displacement ranging from about 1.4% to 4.0%, which corresponds to an average mobilized total axial resistance of about 75% to 100%. For the piles at the pier structures, the unidirectional induced loads ranged from 2239 to 4526 kN, which were about 57% to 115% of the unfactored design load ($P_{d,serv}$). The induced load resulted in a normalized downward displacement ranging from about 0.3% to 4.9%, which corresponds to an average mobilized total axial resistance of about 40% to 109%. As a result of the tip post-grouting and resulting displacement via preloading, increased stiffness of the soil beneath the base of each pile and smaller post-construction vertical displacements would be anticipated.

The maximum achieved injection pressures reported in literature and by firms performing tip post-grouting (not limited to a particular country or region) has been about 15 MPa in sands and about 8 MPa in clays/silts (Loehr et al, 2017). The injection pressures achieved at the west abutment (in silty sand) were on the low range of what has been reported in the literature and is even on the low expected range based on experience in the Santa Cruz region. The injection pressures achieved at the pier structures and east abutment (lean clay with sand or silt) were in the middle to higher end of what has been reported and is in line with what has been achieved on past projects in this soil type in the Santa Cruz region.

The (computed) induced load-displacement relationships from the tip post-grouting performed at piles 2, 3, 5, and 6 at Pier 3 (tipped in lean clay with silt) and Pier 4 (tipped in lean clay with silt) are shown in Figure 8. As shown in Equation (1), the induced load is correlated to the injection pressure: $P_{SC}=p \cdot Asc$, and the downward displacement is measured using telltale extensometers (and can be deduced using the grout volume and the internal dimensions of the cell). The differences in the grouting pressures that were achieved varied appreciably over short distances across each pier (Table 1). In addition, the measured downward displacements varied considerably when compared with the neighboring pier as well as at each pier though the displacements were more similar at Pier 4 than at Pier 3, as did the trend or the development of the load-displacement relationships. Static loading tests were performed in those piers. See results in Figure 9.

Tabla 1. Results of tip post-grouting performed at the Urubó Bridge.

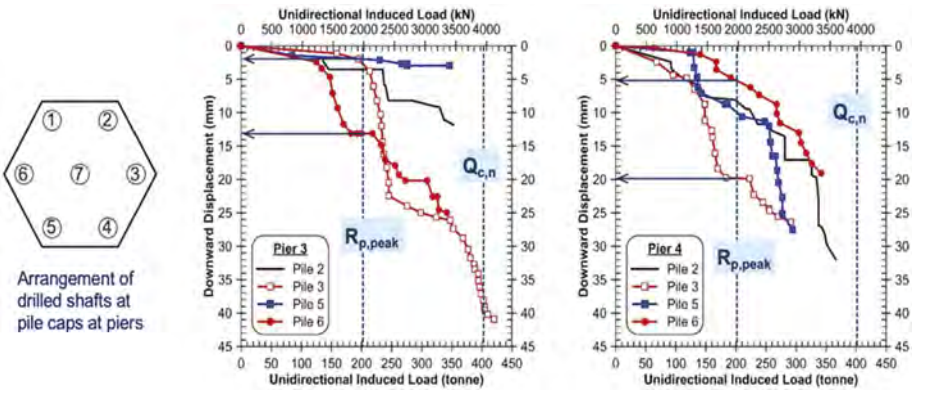

Figure 8. Select results of induced load vs. displacement from tip post-grouting (a) at Pier 3 and (b) at Pier 4.

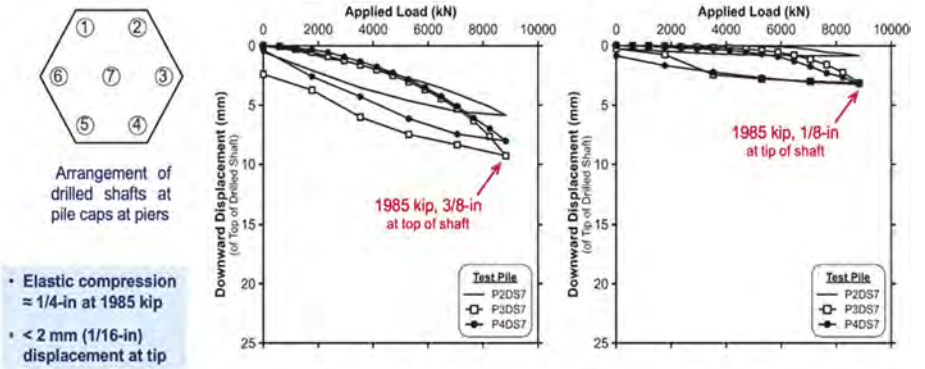

Figure 9. Loading test results from tip post-grouted piles (a) at Pier 3 and (b) at Pier 4.

The differences in the load-displacement behavior reflect the local differences present at the base of the pile and within the soil below. A stiffer soil response would be reflected by a gradual slope in the curve, whereas the curve for a softer soil would be represented by a steep slope. As each of the responses does not reflect a constant slope (i.e., instances of gradual and steep slopes at each pile), the tip post-grouting is influenced not only by the soil conditions immediately below the base of the pile but also by the soil within the influence zone of the loading. In addition, the influence zone may be changing during the grouting process as a compacted soil plug is being formed, which is then facilitating the distribution of the injection pressure into the soil.

6 CONCLUSIONS

During grouting, loose soil or debris (i.e., soft bottom condition) is first compacted, and then, as the injection pressure increases, the in-situ soil is compressed, resulting in a pre-mobilization of the end resistance. Although there was considerable variability in the injection pressures achieved and trends observed in the measured pressure-volume and inferred induced load-displacement responses, even within short distances at the same support structure. Overall, the unidirectional induced load ranged from 1642 to 3931 kN in Las Marotas bridge and from 1538 to 4534 kN in Urubó bridge, which equated to about 91% to 252% (Las Marotas) and from 39% to 116% (Urubó) of the design service load. Although the difference in the responses of a pile under load is typically attributed to the effects of the construction technique and process employed, many of the differences can be explained by the depositional environment and highly variable soil characteristics. The key benefit of using this tip post-grouting technique at each bored pile was the reduction of risk and uncertainty of performance due to the highly variable soil conditions. As a result of the tip post-grouting and resulting displacement via preloading, increased stiffness of the soil beneath the base of each pile and smaller post-construction vertical displacements would be anticipated.

Studies on applications of precast pile planting method

Yan Zhang, Zhigao Li, Youtian Mao & Weihua Zhao
Jianhua Construction Materials Group, Zhenjiang, The People's Republic of China

ABSTRACT: In this paper, engineering applications of precast pile planting under different geological conditions have been carried out, which solved the engineering application problem of precast pile under complex geological conditions such as dense sand layers, aged clays, and shallow buried bedrocks, and greatly expanded engineering application ranges of precast pile. At the same time, through the test analysis of bearing capacity performance, the design method of controlling the bearing capacity of single pile by strength of precast pile body with precast pile planting method is proposed.

1 INTRODUCTION

Many methods have been successfully used to install precast piles, and new techniques and methods are constantly being developed. These methods differ according to the type of precast pile being installed, the purpose to be served by the pile, the forces to be resisted, the soils into which the piles are installed, the structure to be supported, and the pile orientation (vertical or battered)[1]. The most common method of installing precast piles is pile driving hammers. But driven pile is not suitable for some geological conditions such as dense sand layer, aged clays, and shallow buried bedrocks, etc. The construction unit should limit or exclude the use of that installation method that would be harmful. In order to expand engineering application range of precast pile, the precast pile planting has been developed.

The precast pile planting technology is to use a drilling rig or other hole-forming equipment to form a hole in the pile position in advance and fill the filling material or use the stirring and rotary spraying process to form an outer pile, and then use the pile driving equipment to drive, press or insert the precast pile as a core pile. The construction process is shown in Figure 1. The construction ways of drilling mainly include bored pile method, continuous flight auger pile method, cement-soil mixing pile method, high pressure rotary jet pile method, etc. According to the hole-forming way, precast pile planting technology can be divided into soil-taking pile planting and non-soil-taking pile planting. Soil-taking pile planting generally includes rotary drilling hole-forming pile planting, rotary digging pile planting, mid-digging bottom expansion pile planting, continuous flight auger pile planting, etc. Non-soil-taking pile planting includes cement-soil mixing pile planting and high pressure rotary jet pile planting, etc.

The composite piles formed by precast pile planting technology include core piles and outer piles (as shown in Figure 2.). The core piles could be precast piles such as ordinary precast prestressed spun-cast concrete cylinder piles (known as PHC pile) and super high-strength precast prestressed spun-cast concrete cylinder piles (known as UHC pile). And the outer piles could be cast by concrete, cement mortar or soil cement. Composite piles could give full advantages of two types of piles: for example, rotary digging pile planting, which combine the characteristics of two different pile-forming techniques of cast-in-situ piles and precast piles, solve the problem of precast piles that are difficult to pass through thick sand layers and shallow buried bedrocks. This kind of technology has been gradually used in Guangxi, Sichuan, Jiangxi, Hunan, Anhui and other regions of China in recent years. Another example is cement-soil mixing pile planting,

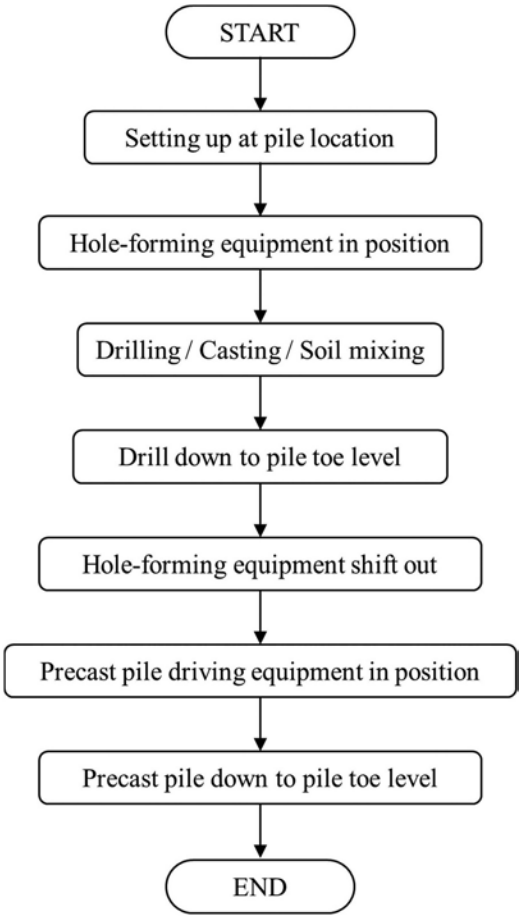

Figure 1. Construction process of precast pile planting.

which not only solves the problem of limited load transmission depth of soil-cement piles, but also solves the problem of the limited application in special geology such as deep and saturated soft soils, they have been widely used in Eastern China in recent years[2].

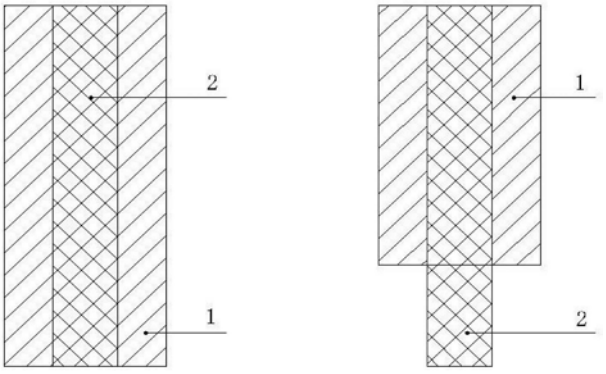

Figure 2. Layout of Precast Pile Planting. 1 – Outer pile (Concrete, cement mortar or soil cement); 2 – Core pile (Precast concrete pile).

2 EXPERIMENTAL RESEARCH ON PRECAST PILE PLANTING

In order to find out the bearing characteristics of precast pile planting technology and expand the application ranges of precast piles, engineering application research on pile planting technology under different geological conditions have been carried out.

2.1 *Soil-taking pile planting technology*

2.1.1 *Railway bridge's pile foundation project (rotary digging pile planting)*

Project overview: Rotary digging pile planting's test were carried out between the S191# and S192# pier of an intercity railway bridge's project. The soil boring's site belongs to the first-order terrace landform of the Huai River. The upper layer of the subsurface is silty clay and silty sand, the lower layer is silt, and the bearing layer is clay.

3-1 layers of the project's site soil are 10 meters thick silty sand. The research on the rotary digging pile planting technology of this project is mainly to solve the problem of the difficulty of sinking precast piles in thick sand layer.

According to the soil conditions of the test site, precast piles are driven by the pile planting method of the rotary drilling pile planting. First, the holes are formed by the rotary drilling equipment with a diameter of 1 meter. The depth of the holes is same as the designed pile length with 34 meters. After the fine stone concrete is poured underwater, the precast piles are sunk by a vibratory hammer.

Design parameters of rotary digging pile planting design parameters: outer pile is fine stone concrete pile which diameter is 1 meter, and pile length is 34 meters. Core pile is UHC800AB130 (UHC pile in diameter of 800 millimeters, wall thicknesses of 130 millimeters), and pile length is 34 meters too. The soil profile is shown in Figure 3.

Figure 3. Soil profile on site.

Results of static load testing: Results of the static load testing are shown in Figure 4, and the vertical ultimate bearing capacities of the rotary digging pile planting piles are higher than 15000 kN. For the core pile of UHC800 pile, the ultimate bearing capacity of the pile concrete strength is 12855 kN, and the bearing capacity estimated by the soil resistance is 12133 kN.

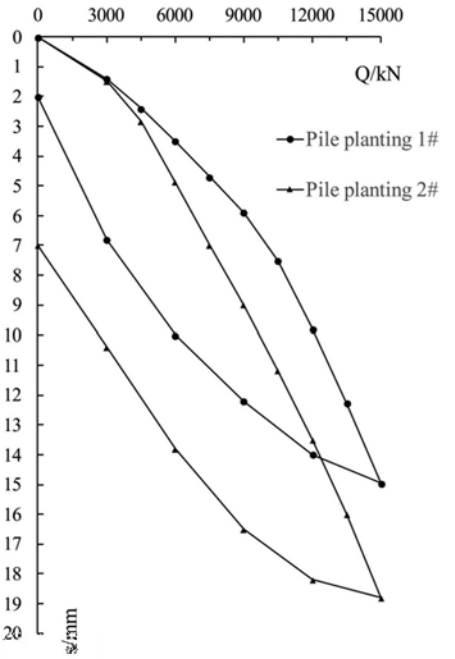

Figure 4. Results of static load testing.

2.1.2 *Residential's pile foundation project (rotary digging pile planting)*
Project overview: A residential project in Xuancheng, Anhui Province, which main buildings include 19 residential buildings with 4, 11 and 17 floors. The subsurface soil layers on the site are embankment fills and clay. The middle layer is coarse sand, and the lower part is bedrock. The research on pile planting technology is mainly to solve the problem that the bedrock of the bearing layer is buried shallowly, and the pile length is difficult to control.

Design parameters of rotary digging pile planting design parameters: outer pile is fine stone concrete pile which diameter is 1 meter, and pile length is 11 meters. Core pile is PHC600A110 pile (PHC pile in diameter of 600 millimeters, wall thicknesses of 110 millimeters), and pile length is 11 meters too. The soil profile is shown in Figure 5.

Results of static load testing: The static load testing results are shown in Figure 6, the vertical ultimate bearing capacity of the rotary digging pile planting piles are higher than 5000 kN. For the core pile of PHC600AB110 pile, the ultimate bearing capacity of the pile concrete strength is 7654 kN, and the bearing capacity estimated by the soil resistance is 4700 kN.

2.1.3 *Commercial complex's pile foundation project (continuous flight auger pile planting)*
Project overview: Continuous flight auger pile planting was carried out at a large-scale commercial complex project in Zhengzhou, Henan Province. The test site is an alluvial plain, the subsurface soil layers on the site is mainly silt and silty sand, the middle soil layer is mainly silt sand and fine sand, the bottom soil layer is mainly dense fine sand or silty clay. The sand layer is buried deeper than 12m.

According to the site conditions, the piles is sunk by continuous flight auger pile planting. The pile site holes are pre-formed by a continuous flight auger which diameter is 900 millimeters. After reaching the design depth of 14 meters, the cement-mixed mortar or fine stone concrete is sent to the bottom of the hole by pressure through the core pipe of the drilled pipe, and the drill lifted to the top of the pile hole. In the end, precast piles are impacted by hammer to reach the bottom of pile hole in concentrically.

Design parameters of continuous flight auger pile planting: outer pile is cement mortar mixture pile which diameter is 900 millimeters, and pile length is 14 meters. Core pile is PHC600AB110

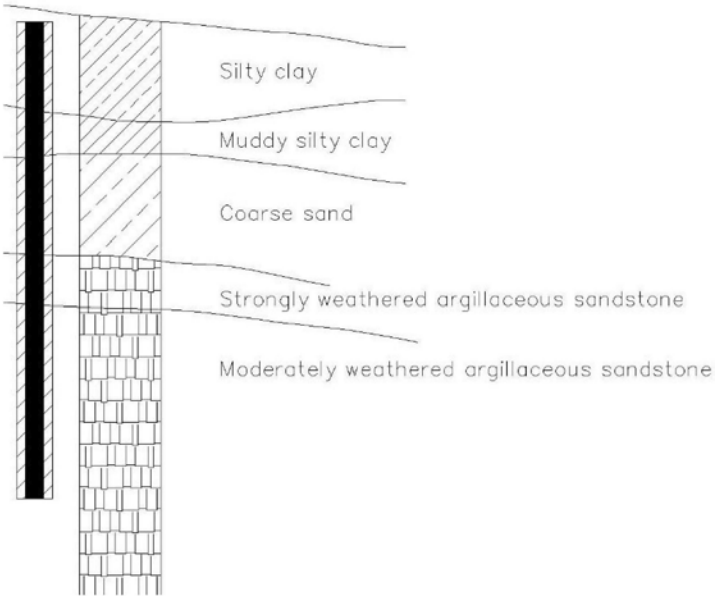

Figure 5. Soil profile on site.

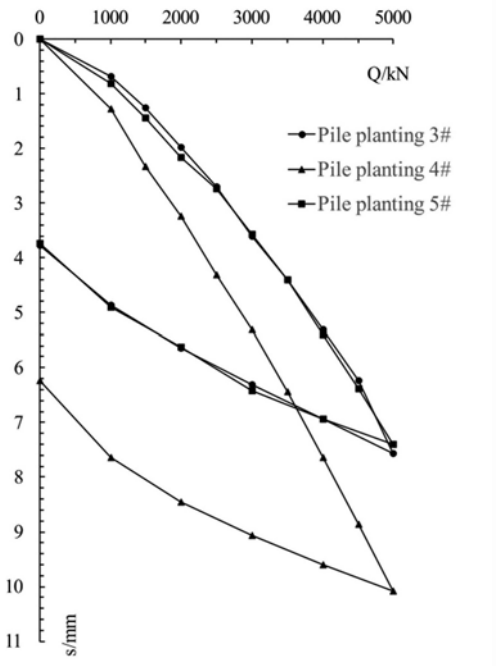

Figure 6. Results of static load testing.

pile (PHC pile in diameter of 600 millimeters, wall thicknesses of 110 millimeters) which pile length is 14 meters too. The soil profile is shown in Figure 7.

Results of static load testing: The static load testing results are shown in Figure 8, the ultimate bearing capacity of the continuous flight auger pile planting piles are higher than 6480 kN.

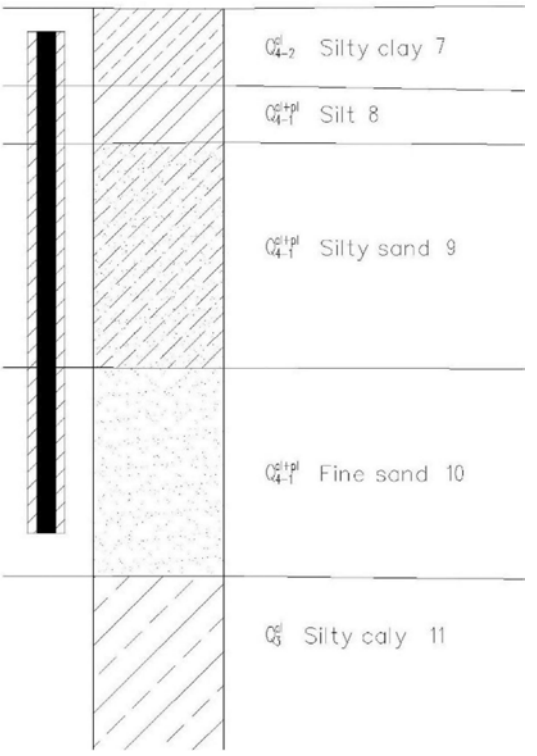

Figure 7. Soil profile on site.

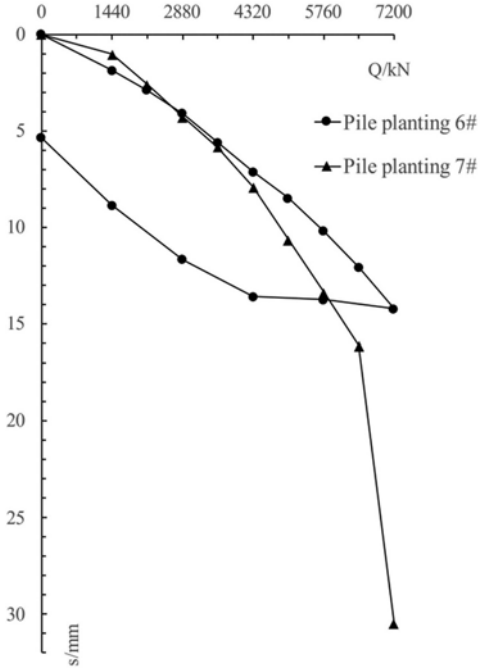

Figure 8. Results of static load testing.

For the core PHC pile, the ultimate bearing capacity of the pile concrete strength is 7654 kN, and the bearing capacity estimated by the soil resistance is 6380 kN.

2.2 *Non-Soil-taking pile planting technology*

2.2.1 *Residential's pile foundation project (cement-soil mixing pile planting)*

Project overview: A residential project in Fuyang, Anhui province, including 14 high-rise residential buildings with 25-34 floors and several commercial and public centers with 3-7 floors. The project site belongs to Quaternary Alluvium which composed by clay, silty clay, medium sand, and coarse sand. This research on the cement-soil mixing pile planting technology of this project is mainly to solve the application problem of precast piles in aged clay area.

Design parameters of cement-soil mixing pile planting: outer pile is cement-soil mixing pile which diameter is 800 millimeters, pile length is 22 meters. Core pile is PHC500AB125 pile (PHC pile in diameter of 500 millimeters, wall thicknesses of 120 millimeters), pile length is 22 meters too. The soil profile is shown in Figure 9.

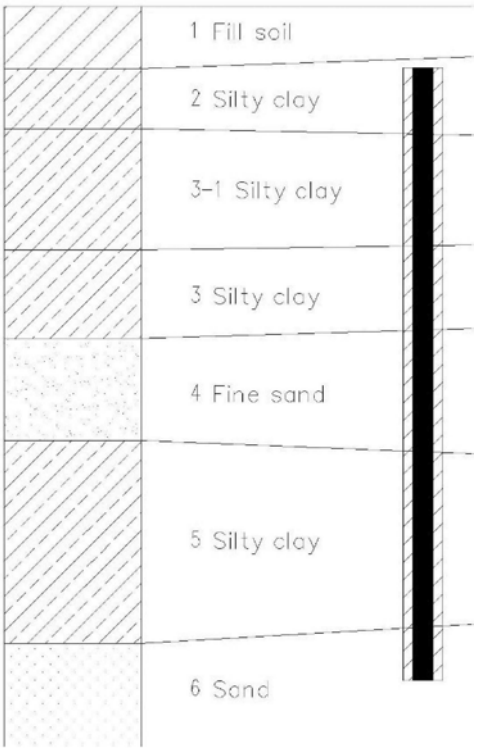

Figure 9. Soil profile on site.

Results of static load testing: The static load testing results are shown in Figure 10. The concrete at the pile head was destroyed at the maximum load of the test, and the vertical ultimate bearing capacity of the cement-soil mixing pile planting piles are 5400 kN. The ultimate bearing capacity of the core PHC pile concrete strength is 5480 kN, and the bearing capacity estimated by the soil resistance is 5300 kN.

2.2.2 *Industrial plant's Pile Foundation Project (high pressure rotary jet pile planting)*

Project overview: A food industrial plant in Yuci, Shanxi province, which's in mountain front alluvial sloping plain. The main soil layers are embankment, silt and sand. Except for the surface silt, which is slightly dense, the other layers are medium dense. And sand layers are

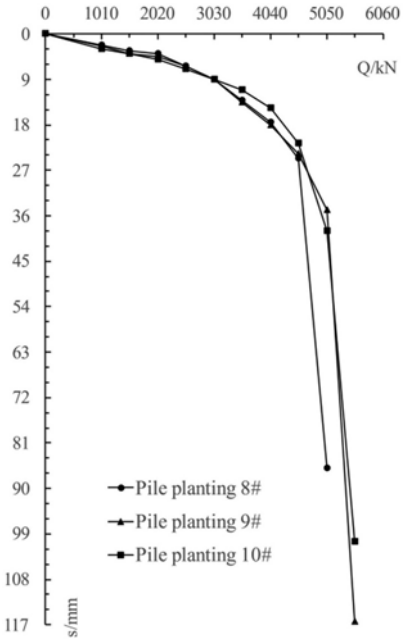

Figure 10. Results of static load testing.

slightly dense. The research on the high pressure rotary jet pile planting technology of this project is mainly to solve the application problem of precast piles in thick sand geology.

Design parameters of high pressure rotary jet pile planting: outer pile is high pressure rotary jet pile which diameter is 850 millimeters, and pile length is 26 meters. Core pile is UHC400AB95 pile (UHC pile in diameter of 850 millimeters, wall thicknesses of 95 millimeters), and pile length is 26 meters too. The soil profile is shown in Figure 11.

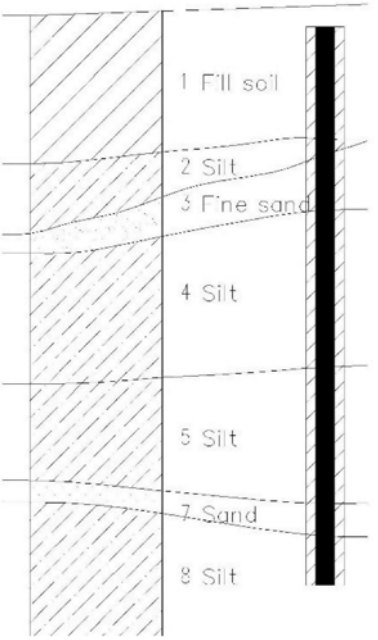

Figure 11. Soil profile on site.

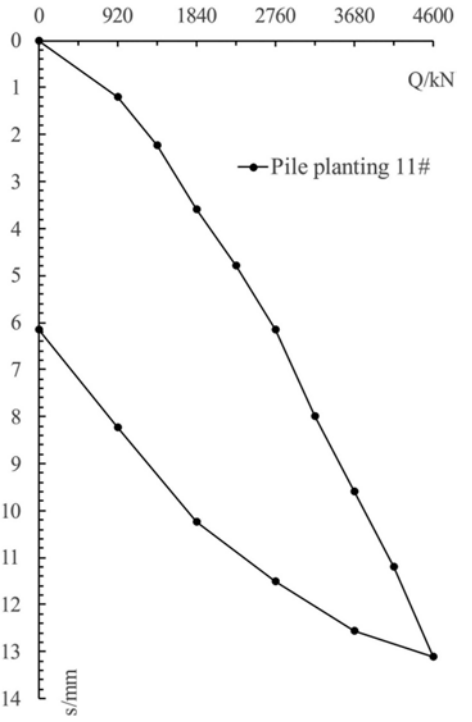

Figure 12. Results of static load testing.

Results of static load testing: Results of the static load testing are shown in Figure 12, and the vertical ultimate bearing capacity of the high pressure rotary jet pile planting pile is 4600 kN. For the core UHC400 pile, the ultimate bearing capacity of pile concrete strength is 4275 kN, and the bearing capacity estimated by the soil resistance is 4500 kN.

3 DESIGN METHOD OF PRECAST PILE PLANTING TECHNOLOGY

The bearing capacity of piles in above engineering applications are estimated based on the design method of precast pile concrete strength. Pile planting's shaft resistance is obtained by outer pile's shaft resistance, and the toe resistance is obtained by core pile's toe resistance. Both are the nominal resistance of the pile planning pile. The comparison of theoretical estimation results and experimental results shows that two are basically consistent, and this design method has greater reliability. The specific calculation method is as follows:

The vertical ultimate bearing capacity of single pile by pile planting method can be estimated by the following formula:

$$Q = u_D \Sigma q_{sik} l_i + q_{pk} A$$

where Q = Vertical ultimate bearing capacity of single pile by pile planting method (kN); u_D = Perimeter of the outer pile (m); l_i = Thickness of soil layer i (m); A = Total cross-sectional area of the core pile toe (m^2); q_{sik} = Unit shaft resistance over the pile surface area (kPa); q_{pk} = Unit toe resistance over the pile toe area (kPa).

The vertical ultimate bearing capacity of single pile can be estimated by the following formula:

$$N = \psi_c f_c A_p$$

where N = Vertical ultimate bearing capacity of single pile (kN); Ψ_c = Working factor, =0.85; f_c = Concrete strength (kN/m^2); A_p = Cross-sectional area of the pile (m^2).

The results of a large number of engineering cases show that in preliminary design, it is feasible to use the above formula to estimate the vertical ultimate bearing capacity of single pile planting pile, and the results have a high degree of agreement with the measured values (Figure 13).

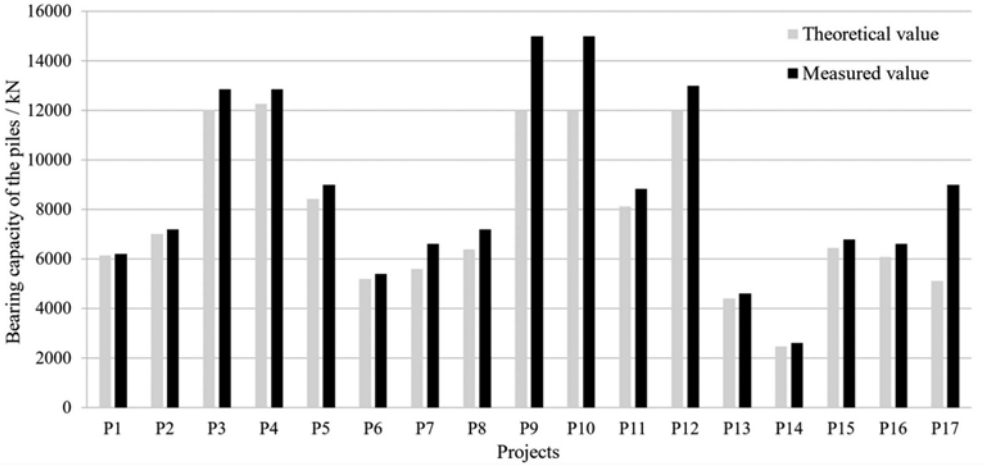

Figure 13. Comparison between theoretical values and measured values of bearing capacity in 11 projects.

4 EPILOGUE

Relevant data show that in Japan, South Korea and other countries, the application of precast pile planting technology has accounted for more than 80% of the total pile foundation projects [3]. The application of precast pile planting technology in Japan is relatively mature. In order to control noise and environmental pollution in cities, Japan introduced the *Noise Regulation Law and Vibration Regulation Law* in 1968 and 1976 respectively, which limited the driven piles. The application in urban areas, on the other hand, also promotes the continuous development of pile planting technology, so that precast pile planting technology has become the mainstream in pile foundation engineering.

Compared with traditional concrete cast-in-site piles, pile planting technology can take advantage of the cast-in-place piles and precast piles, give full play to the bearing capacity of precast piles, and have good economic benefits. At present, in the domestic pile foundation market, the application range of precast pile planting technology is constantly expanding.

Following conclusions are drawn by using precast pile planting technology to test engineering piles under different complex geological conditions:

(1) The precast pile planting technology can give full play to the characteristics of cast-in-situ piles and precast piles, solve engineering application problems such as precast pile construction under complex geological conditions, also obtain better economics, greatly broadening the application of prefabricated piles scope.
(2) Through the comparative analysis of the theoretical value and the measured value, it is verified that the design method of controlling the bearing capacity of a single pile based on the strength of the precast pile body has greater reliability.

Features of the application of pile technologies in restrained urban conditions in the historical downtown of Saint-Petersburg on the soft soils

A.I. Osokin
Saint-Petersburg State Architectural and Civil Engineering University, Saint-Petersburg, Russia

ABSTRACT: The geotechnical practice of the construction and restoration in historical downtown of Saint-Petersburg in among old residential and revenue houses, mansion-houses, architectural monuments show, that the main issue is safety of technological processes in relation to the soil massive and foundation of neighboring buildings. The proposed evaluation approach is based on the analysis of the technological features of pile technologies and the determination of the safest. Examples of technical solutions that illustrate the effectiveness of this approach are given. The use of a geotechnical barrier, compensation grouting, reinforcement of the foundations of neighboring buildings with micropiles is considered as preventive measures of protection against the construction impact.

1 INTRODUCTION

The importance of pile foundations on soft soils cannot be overestimated. Today, this is practically the most common method of foundation in conditions of dense urban development in terms of minimizing the impact on the neighboring buildings. Due to the technological nature and definitely ensuring a high degree of reliability, they have become widely used both in domestic and foreign practice of foundation construction. Pile foundations are the only way to erect the foundation of a structure for many construction situations in difficult construction and engineering-geological conditions. The main advantages of pile foundations are optimization of construction time, high manufacturability, reduction of labor intensity of work and volume reduction of excavation work.

The experience of construction and reconstruction in recent years in conditions of dense urban development in the cities of Moscow and St. Petersburg shows that during zero-cycle work, the neighboring buildings often receive greater deformations that impact of deformation from the static loaded foundations of new buildings or overloaded the reconstructed buildings.

2 MODERN PRACTICE OF PILE FOUNDATION CONSTRUCTION IN DENSE URBAN DEVELOPMENT

All applied pile technologies used in dense urban development can be divided into three groups: pile excavation with soil extraction, without soil extraction and with partial soil extraction.

Drilling and piling technologies are widely used in the construction of buildings in dense urban areas. In case with small loads on the piles of a building under construction and to strengthening the foundations of old buildings and monuments during reconstruction and renovation we use micropiles.

In modern conditions of inner-city construction, the following technologies are used for the manufacture and installation of piles (data obtained from the analysis of the experience of geotechnical construction at 64 sites in the central part of St. Petersburg):

DOI: 10.1201/9781003299127-226

– jacked piles - 35%;
– displacement piles – 50%;
– micropiles – 10%;
– drilling piles with excavation - 5% (under the protection of bentonite mortar, under the protection of the casing pipe, continuous through auger (short through auger).

The need to carry out work in cramped conditions of dense development, including in the historical part of the city, led to the fact that since the mid-1980s in St. Petersburg they began to use a self-propelled machine USV-80 (USV-120, USV-160) for jacking prismatic precast piles. Since 2008, pile jacking machines has been carried out on construction sites using hydraulic system which manufactured by the Chinese companies "Strarke" and "Sunward", designed for jacking of precast piles, metal profiles, steel pipes and sheet piling. This modifications of machines presented on the St. Petersburg market have a maximum pressing force of 3600 kN using a additional loads.

For this technology, the following possible geotechnical quality risks can be specified:

– piles don't reach to the design mark;
– possible deviation or displacement from the design location both in terms of already depressed piles and in height due to the removal of piles due to subsequent impact during mass jacking of piles or excavation of the pit;
– non-compliance with verticality;
– in soils with a ribbon texture, the sinking of piles can lead to additional deformations of the foundations and foundations of buildings located at a distance of up to 3 m and the removal of soil with the lifting of previously made piles.

When assigning a method for reducing soil resistance to pile jacking (drilling of lead wells, preliminary loosening with a screw, washing), a possible reduction in the bearing capacity of piles is taken into account due to the use of reducing coefficients in calculations.

Among the replacement piles we distinguish the several types that are actively used today in the construction of foundations in dense urban buildings in weak soils.

Drilling piles arranged under the protection of bentonite mud have been known in Russian construction practice since the mid-50s of the last century.

Rotary drilling machines are used for the manufacture of piles under the protection of bentonite mud. The process of soil destruction during drilling occurs due to mechanical or physico-mechanical impact on it with the help of a drilling tool. At the same time, a field of mechanical stresses is formed that is sufficient to break the continuity in a certain volume of the soil mass, transform it into a solution by feeding the washing liquid into the well, and then removing the loosened soil to the surface.

In unstable and water-saturated soils, an internal overpressure exceeding the external pressure is created in wells to keep the walls from collapsing. To do this, the well is filled with a flushing drilling fluid in the form of process water, water with additives of surfactants (surfactants), polymer or bentonite solution. It should be noted that in order to create excessive pressure on the walls of the well, the drilling bentonite mud level had to be several meters above the groundwater level.

The advantage of the technology of manufacturing drilling piles under the protection of bentonite mud is its safety in relation to neighboring buildings, which allows it to be actively used in reconstruction and engineering restoration, including in operating conditions in buildings when installing reinforcement piles.

Structurally and technologically, the following risks should be noted that affect the quality and reliability of the pile structure manufactured in the ground under the protection of bentonite mud: deviation of the pile from the vertical during drilling; ensuring the stability of the walls of the well when drilling in weak water-saturated soils; formation of "necks", caverns, areas with mixed bentonite mud and concrete is possible; sticking of pieces bentonite mud on the reinforcement frame.

This technology, in compliance with the basic regulatory and technological parameters, allows for the installation of piles in close proximity to existing buildings, without significantly

affecting the condition of the soil mass at the base of the foundations. When installing geotechnical barriers and pit fences when using drilling technology under the protection of clay mortar, the sequence of pile production and their step by grappling, as well as the period of standing during the subsequent manufacture of piles, are additionally regulated.

In the manufacture of piles in water-saturated weak soils, the most reliable protection of soil massive from technological impacts of drilling of the well is the use of casing method. In geotechnical practice bored piles have been used in wells drilled by the Kelly system under the protection of a casing pipes. The Kelly system involves the process of drilling of soil with a drilling tool (a short auger, bucket or core drill) fixed at the end of a telescopic bar (Kelly system).

The technology of arranging piles under the protection of the casing pipe using the Kelly system has a number of advantages, main of them are: direct control is carried out over the compliance of the actual characteristics of the soil laid down in the project during the drilling process, the absence of dynamic and vibration effects on the ground allows you to perform piles near existing buildings and structures.

The disadvantage of the technology is low productivity, so design solutions should ensure full use of the bearing capacity of piles on the ground. In addition, when passing water-saturated soils, in order to avoid their discharge into the well, it is necessary to create a high-altitude ground plug (by calculation) or excessive pressure in the well with water or bentonite solution.

In geotechnical construction, the technology is known like "Double Rotary" in which the production of piles according to this technology is carried out by drilling a well under the protection of an inventory casing pipe with simultaneous right rotation of a continuous through screw located inside the casing pipe and left rotation of the pipe.

The advantages of this technology are: the technology is applicable for all types of dispersed soils (loose dense soils, silts, hard clays); absence of noise and significant vibration effects (this allows you to arrange piles near existing buildings); high productivity due to the extraction of soil by a continuous auger; high quality of filling the well with concrete, due to the supply of concrete mixture under pressure.

Drilling control, regulation of the rotation speed of the drilling body, the supply of concrete and its pressure at the bottom is carried out using a computer installed in the operator's cabin.

The history of the appearance of piles arranged by the method of continuous flight auger piles CFA using modern equipment in St. Petersburg was dramatic. For the first time this technology was applied to the device of bored piles in 1995.

In 1998, during the construction of the transport and commercial complex, the using technology CFA for the installation of drilling piles with a diameter of 600 mm and a depth of 25 m had got catastrophic deformations of the existing houses had occurred with the formation of cracks with an opening of up to 50 mm. The buildings have fallen into disrepair. This required their dismantling. When performing piles using continuous fly auger technology on a construction site stacked with weak soils, it was noted that with the sequential manufacture of these piles, the volume of concrete absorption per well increases several times.

The underestimation of thixotropic decompression of water-saturated clay soils in a near-pile soil array when using this technology with continuous production of a pile field leads to a significant overspending of the concrete mixture (twice or more). The increased consumption of the concrete mixture, as a rule, occurs when there are significant layers of fluid, fluid plastic loams and sandy loams with low strength and deformation characteristics at the base of the site [Dalmatov, 1999].

Let us identify the main geotechnical risks of manufacturing piles arranged according to the technology CFA:

- active mechanical impact on soils;
- in the presence of dense layers of soil, due to a change in the rate of penetration of the well, the removal of excessive soil volume is possible;
- there is a negative impact on the foundations of neighboring buildings;
- overspending of concrete relative to the physical volume of the well (up to 40%).

A significant part of the total volume of pile foundations in urban conditions is made up of displacement piles. Displacement piles are concreted in wells formed as a result of forced

displacement of soil. Wells can be made by punching, rolling, static or vibrational punching of the soil. During construction in dense urban development in conditions of weak soils, methods of static and rotational impact on soils with the exception of vibration and dynamic loads are considered acceptable for use in terms of safety conditions for buildings of neighboring buildings.

The screw-pushing of the well is performed by screwing a spiral projectile or pipe into the ground, the lower end of which is closed by a screw tip left in the ground.

The possibility of using one or another method of well formation for packed piles should be established at the stage of engineering and geological surveys. Table 1 shows the scope of application of various methods of well formation for packed piles, depending on ground conditions (Table 1).

Table 1. Methods of borehole-making for displacement piles depending on soil conditions.

	Soil conditions	
Borehole-making method	Clay soils with index of liquidity I_L	Sand
Static displacement	$I_L > 0,3$	–
Reaming	$I_L > 0,2$	Silty soft water-saturated
Vibration displacement	$I_L > 0,6$	Soft water-saturated
Percussion	$I_L > 0,3$	Fine- and medium-grade

If there are thixotropic soils in the engineering-geological section of the site in depth, their sensitivity to the violation of structural bonds should be determined, i.e. the degree of reduction in the mechanical (strength and deformation) characteristics of soils and the bearing capacity of piles as a result of well penetration. The time of restoration of structural bonds and the degree of increase in soil strength should also be determined.

The technology of the device of displacement piles with a lost tip "Fundex" it was first used in St. Petersburg in 2001. Wells for piles are performed without soil extraction by displacing the soil with a screw-in inventory steel pipe with a tip mounted at the lower end. The spiral tip is a drilling working tool that ensures the process of creating a well and, at the same time, the tightness of the coupling of the casing pipe and the tip through the sealing gasket. When the design mark is reached, the screw tip is separated from the casing (lost tip). A reinforcing frame is lowered into the dry inventory pipe through the open upper end. The drill pipe is removed from the ground by return rotation with simultaneous pulling.

Displacement piles DDS (FDP), manufactured using spiral tool. Wells for such piles are performed without extraction of soil, due to its displacement to the sides-up by a rollout-tool, which is a cone or cylinder of variable cross-section with a screw blade.

When the helical tool is submerged, the soil is displaced to the sides and upwards, a compacted zone is formed around the well, the size of which depends on the properties of the soil, the rate of immersion and the design of the projectile.

A feature of the use of DDS technology is in the implementation of the formation of a well with the stratification of dense interlayers or layers of soil, as well as a condition that ensures the achievement of design marks in the bedrock soils is the possibility of combining a sealing drilling body with a mechanical ripper installed in its lower part, which provides the possibility of preliminary loosening of the stiff soil lays and minimizes the impact on the soils of the base.

3 ANALYSIS OF FACTORS OF TECHNOLOGICAL IMPACTS ON EXISTING BUILDINGS WHEN USING PILE TECHNOLOGIES IN CONDITIONS OF SOFT SOILS

It is recommended to evaluate the technological impact on buildings and structures falling into the zone of influence when installing piles in conditions of dense urban development on weak soils when dividing them into two main groups: arranged with soil extraction and performed without soil extraction.

The degree of technological influence on buildings and structures of the surrounding development from the manufacture of piles arranged using various technologies is assessed in building conditions by observing the deformations of buildings of the surrounding development and measuring deformations on the ground surface.

Conducted field studies of the zone of influence in the manufacture of stuffed piles of displacement of DDS at the construction site in the central part of St. Petersburg [Mangushev R. A., Oshurkov N.V., Osokin A.I., Sbitnev A.V., 2005] using a mobile RIG204 static sensing installation showed that the zone of influence ranged from 2.0 to 2.5 m from the faces of the manufactured pile with a diameter of 520mm. Graphs of the soil resistance to the probe immersion were plotted along the tip and along the lateral surface at depth from the day surface, compared with the sounding data before the pile device, as well as among themselves. This made it possible to estimate the zone of influence from the device of the packed pile of DDS displacement 2 hours after its manufacture.

If we consider the manufacture of a group of piles, there is a mutual influence of the compacted array during the manufacture of earlier piles (as a rule, a technological gap is assumed between the piles in the bush for 3 days) and the soil, which is compacted during the subsequent manufacture of the pile foundation. In the mass production of piles with compaction and displacement of soil, the effect of active impact on the surrounding buildings is observed. This is determined by the principle of superposition of fields that occurs during the sequential manufacture of printed piles. At the same time, it should be noted that observations of deformations of buildings of the surrounding development show the rise of buildings with the concentration of manufactured piles near the existing building. In this regard, the direction of production of piles without excavation (made with displacement of soil) should be determined from the existing development to the center of the site. In this case, the piles made earlier are a screen when the wave of discharge from the devices propagates.

Let's consider the results of observing the deformations of buildings of the surrounding buildings during the manufacture of piles using various technologies (Table 2):

Table 2. Deformations of structures of surrounding buildings in the manufacture of piles using various technologies.

Type of pile technology	Characteristics of the effect on the soil near-pile array	The degree of influence on the soil mass in weak soils	The degree of influence on the neighboring buildings	Manufacturability	Risk of poor quality of pile
Drilling with casing	Mechanical destruction of the soil during drilling	Low or medium. (4,0)	Low (4)	Medium (3)	Low (4)
Drilling under protection the bentonite mud	Mechanical destruction of the soil during drilling, moistening of the soil in the drilling zone	Low (5)	Low (5)	Low (2)	High (2)
CFA -piles	Mechanical destruction of the soil and its continuous transportation along the edges of the auger to the surface	High (1)	High (1)	High (5)	Medium (3,0)
FUNDEX – piles	Compaction and displacement of soil from the volume of the well down-side-up	Medium and high (3,0)	Medium (3,0)	High (5)	Medium (3,5)
Displacement piles DDS	Crushing and compaction with displacement of soil from the volume of the well down-side–up, crushing during compression with a concrete mixture	Medium and high (3,5)	Medium (3,5)	High (5)	Low (4,5)

4 CONCLUSIONS

The result of the presented study allows us to form an understanding of the technological factors for the additional draft of the S_{tech} (1) building located in the zone of influence of geotechnical construction (pile foundation device):

$$S_{tech} = f\ (G,\ M_{dp},\ T_{cb}), \tag{1}$$

$$G = f\ (\gamma,\ \varphi,\ c,\ E,\ W,\ I_L,\ WL), \tag{2}$$

$$M_{dp} = f\left(M_{rot}, N_p, C_{dst}, P_{con}\right) \tag{3}$$

где, *G –a parameter that evaluates the impact of engineering and geological conditions of the construction site (2):* γ – specific gravity of the soil, кN/m^3; φ – the angle of internal friction of the soil, deg.; c – specific cohesion, KPa; E – modulus of general soil deformation MPa; W – natural soil moisture; I_L – consistency indicator; WL – groundwater level; M_{dp} – a parameter that evaluates the impact of drilling technology and the formation of a drilling or packed pile *(3):* M_{rot} – the amount of torque kN*m, N_p – feed force of the working tool, kN, C_{dst} – construction of the working tool, P_{con} – the method of feeding the concrete into the well

Dynamic soil structure interaction of beams on multilayered continua

H. Elhuni & D. Basu
University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT: A new method for dynamic analysis of Euler-Bernoulli beams resting on multi-layered viscoelastic continua (soil) is presented. The governing differential equations of beam and soil displacements are obtained using the extended Hamilton's principle, and these equations are solved analytically and numerically. An iterative solution algorithm is used in conjunction with an implicit time integration scheme to obtain the beam and foundation (soil) responses as functions of time. The developed model resembles the traditional two-parameter spring foundation model, but the analysis shows that the traditional foundation spring parameters cannot be prescribed a priori, but determined as part of the solution. The model produces accurate beam responses as illustrated by comparisons with equivalent two-dimensional finite element analysis results. A few problems are analyzed that illustrate the novel features of the dynamic foundation model.

1 INTRODUCTION

In geotechnical engineering, the concept of beams on elastic or viscoelastic foundations is widely used to analyze the behavior of flexible footings and structural elements such as strip footings, grade beams, and concrete pavements. These structural elements are idealized as beams resting on the underlying soil, which is often termed as the foundation (Morfidis and Avramidis 2005). Different models with different degrees of idealization have been proposed to simulate the behavior of the foundation (soil). The simplest and oldest idealization is to represent the soil as a bed of closely spaced linear springs (Winkler 1867). The Winkler model (also often termed as the one-parameter model) is characterized by the spring constant k_s, which represents the compressive resistance of soil against applied vertical loads and can be related to the modulus of subgrade reaction of soil. The main drawback of the Winkler model is that the vertical springs are assumed to work in isolation with respect to each other because of which the resistance of soil obtained through shear stresses are neglected. An improvement over the Winkler model was proposed by several researchers like Hetenyi (1946), Filonenko-Borodich (1945), Pasternak (1954), and Terzaghi (1955) by introducing a second parameter t_s, which essentially captures the shear interaction between adjacent Winkler springs (this model is often referred to as the two-parameter model). The two-parameter model has been widely adapted by researchers to analyze beam on elastic foundations problems under static and dynamic loads (Basu and Rao 2013).

The difficulty in using the Winkler or two-parameter models is that the two foundation parameters k_s and t_s cannot be reliably obtained from measurable soil properties and are often inaccurately determined from ad hoc, empirical equations (Bowles 1996). Further, for dynamic analysis, geometric damping cannot be explicitly considered using the one- or two-parameter models (Elhuni and Basu 2019).

Improvements to the one- or two-parameter models have been proposed by some researchers in which the soil is idealized as an elastic continuum with simplified assumptions regarding its stress or displacement fields, and applied the simplified continuum approach to beam on foundation problems (Biot 1937, Reissner 1936, 1958, Kerr 1964, Protsenko and Rvachev 1976, Vlasov and Leont'ev 1966). However, these simplified continuum approaches mostly depend on specifically assumed contact pressure distributions that may not be true for

DOI: 10.1201/9781003299127-227

all possible cases of contact, are often mathematically complex, are applicable to linear elastic materials only, and do not take into account material damping in the system (Haldar and Basu 2016, Tvrdá 2017, Sitharam 2018).

Out of the simplified continuum approaches, the one by Vlasov and Leont'ev (1966) is distinct because it leads to the same simple differential equation as that of the two-parameter model (mentioned earlier) but has the additional advantage that the parameters k_s and t_s in this model are rigorously related to the elastic constants of the soil without any empiricism involved. Vallabhan and Das (1989) improved the model of Vlasov and Leont'ev (1966) for static beam problems, and Liang and Zhu (1995) analyzed using the model the steady-state (time-independent) response of beams. All these studies considered a single-layer soil (foundation) beneath the beam. There is no systematic time-dependent, dynamic study performed on beams resting on multi-layered elastic foundations following the modified simplified continuum approach by Vallabhan and Das (1989).

In this paper, a dynamic soil-structure interaction model is developed for the steady-state and transient vibrations of beams resting on multi-layered viscoelastic soil and subjected to oscillatory and moving loads. A layered soil continuum under the beam is considered. The differential equations describing the beam motion and soil displacement are obtained using Hamilton's principle and calculus of variations, and are solved following an iterative algorithm. The resulting differential equation for beam motion resembles that of a beam interacting dynamically with a two-parameter foundation with parameters k_s and t_s. These two parameters are mechanistically related to the soil Young's modulus and Poisson's ratio, and, interestingly, change with time even though the soil elastic constants remain constant – this is a novel development of the new model. The accuracy of the analysis is verified by comparing the results of the analysis with those of equivalent two-dimensional (2-D) finite element (FE) analysis performed using Plaxis. Examples illustrate the application of the method for different oscillatory and moving loads.

2 ANALYSIS

2.1 *Problem definition*

A uniform Euler-Bernoulli beam of length L, width b, depth (thickness) d, mass density ρ_b, and Young's modulus E_b is assumed to be resting on a layered elastic soil (continuum), as shown in Figure 1. A dynamic vertical load $P(x, t)$ is assumed to act on the beam which either moves from left to right in the positive x direction with a velocity v or oscillates in magnitude (with time t) but remains stationary in space. In fact, the load P can both oscillate in magnitude and move with time. The continuum (soil) beneath the beam is split into n layers with the bottom nth layer resting on a rigid base. The total thickness of the continuum is H_{Total}, and the i^{th} layer spans over $H_{i-1} \leq z \leq H_i$ with a thickness $T_i = H_i - H_{i-1}$. The soil is assumed to be isotropic, linear elastic, and homogeneous within any layer i with Young's modulus E_{si}, Poisson's ratio υ_{si}, and mass density ρ_{si}. The details of the soil geometry and Cartesian (x-z) coordinate system are illustrated in Figure 1.

2.2 *Soil displacement, strain, and stress fields*

For the plane-strain problem described above, it is assumed that the horizontal soil displacement u_x caused by the vertical forces are negligible (i.e., $u_x = 0$) and that the vertical soil displacement u_z (Figure 1) can be expressed as a product of separable functions:

$$u_z = w(x, t)\phi(z) \tag{1}$$

where $w(x, t)$ is the beam deflection (considered positive in the positive z direction), which is the same as the displacement of the top surface of the continuum, and $\phi(z)$ is a dimensionless soil displacement function varying with depth z. It is assumed in the analysis that $\phi(0) = 1$, which ensures perfect contact (with no separation) between the beam and the underlying continuum, and that $\phi(H_{\text{total}}) = 0$, which ensures that the vertical displacement in the continuum decreases with depth. Thus, the function ϕ takes into account the geometric damping of the beam-foundation system in the vertical direction.

For the assumed displacements in equation (1), the soil stresses and strains at any point in the continuum is given by

$$\begin{Bmatrix}\sigma_{xx}\\ \sigma_{zz}\\ \sigma_{xz}\end{Bmatrix}=\frac{E_s}{(1+\upsilon_s)(1-2\upsilon_s)}\begin{bmatrix}1-\upsilon_s & \upsilon_s & 0\\ \upsilon_s & 1-\upsilon_s & 0\\ 0 & 0 & 0.5-\upsilon_s\end{bmatrix}\begin{Bmatrix}\varepsilon_{xx}\\ \varepsilon_{zz}\\ \varepsilon_{xz}\end{Bmatrix}=\frac{E_s}{(1+\upsilon_s)(1-2\upsilon_s)}\begin{bmatrix}1-\upsilon_s & \upsilon_s & 0\\ \upsilon_s & 1-\upsilon_s & 0\\ 0 & 0 & 0.5-\upsilon_s\end{bmatrix}\begin{Bmatrix}0\\ -w(x,t)\frac{d\phi(z)}{dz}\\ -0.5\frac{\partial w(x,t)}{\partial x}\phi(z)\end{Bmatrix} \tag{2}$$

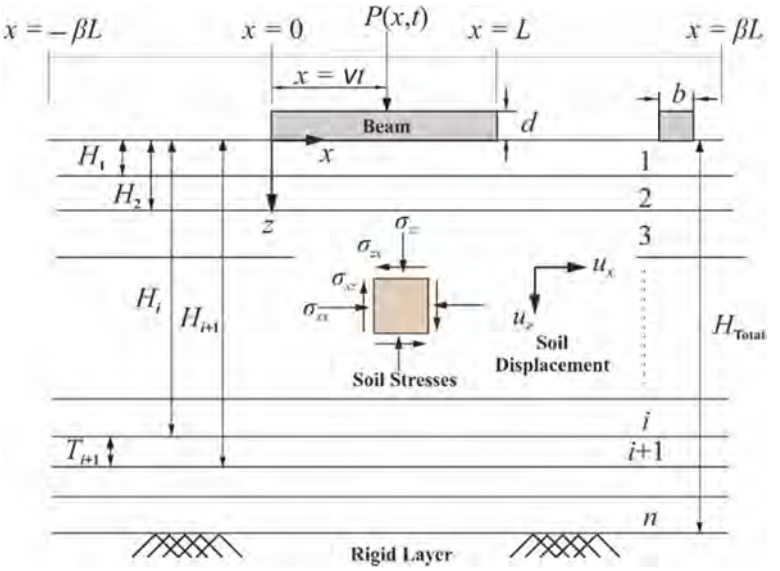

Figure 1. Soil profiles considered in this study.

where $\{\sigma_{xx}, \sigma_{zz}, \sigma_{xz}\}^{\mathrm{T}}$ and $\{\varepsilon_{xx}, \varepsilon_{zz}, \varepsilon_{xz}\}^{\mathrm{T}}$ represent the soil stress and strain tensors, respectively (compressive stresses and contractive strains are considered positive).

2.3 *System energy and extended Hamilton principle*

The extended Hamilton principle of least actions is used to obtain the differential equations of motion of the beam and continuum under dynamic equilibrium:

$$\delta\int_{t_1}^{t_2}(T-U+W_{nc})dt=0 \tag{3}$$

where T and U are the kinetic and potential energies of the beam-soil system participating in the vibration, W_{nc} is the work done by the non-conservative forces acting on the system, t_1 and t_2 are any arbitrary times at which the equilibrium configuration of the beam-soil system is known, and δ is the variational operator. Using equation (2), equation (3) can be rewritten for the present beam-continuum system as

$$\delta\int_{t_1}^{t_2}\left[\int_0^L\frac{\rho_b A_b}{2}\left(\frac{\partial w}{\partial t}\right)^2dx+\sum_{i=1}^{n}\int_{-\beta L}^{\beta L}\int_{H_{i-1}}^{H_i}\frac{\rho_{si}b}{2}\left(\frac{\partial w}{\partial t}\right)^2\phi_i{}^2dzdx\right]dt-\delta\int_{t_1}^{t_2}\left[\int_0^L\frac{E_bI_b}{2}\left(\frac{\partial^2 w}{\partial x^2}\right)^2dx\right.$$
$$\left.+\sum_{i=1}^{n}\frac{1}{2}\int_{-\beta L}^{\beta L}\int_{H_{i-1}}^{H_i}\left(\bar{E}_{si}w^2\left(\frac{d\phi_i}{dz}\right)^2+2G_{si}\phi_i{}^2\left(\frac{\partial w}{\partial x}\right)^2\right)dzdx-\int_0^L P\delta_d(x_0-vt)wdxdt\right]+\delta\int_{t_1}^{t_2}\left[-\frac{1}{2}c\left(\frac{\partial w}{\partial t}\right)^2\right]dt=0 \tag{4}$$

where δ_d is the Dirac delta function, x_0 is the initial position of the applied load P, c is the coefficient of viscous damping of the system, and $\bar{E}_{si}$ (constrained modulus) and G_{si} (shear modulus) are given by:

$$\bar{E}_{si} = [E_{si}(1 - \upsilon_{si})]/[(1 + \upsilon_{si})(1 - 2\upsilon_{si})] \tag{5a}$$

$$G_{si} = E_{si}/[2(1 + \upsilon_{si})] \tag{5b}$$

2.4 *Differential equations for beam and soil displacements*

Considering the variations of functions w and ϕ in equation (4), the differential equations for the beam and soil surface displacements, and for the soil displacement function can be respectively obtained as:

$$E_b I_b \frac{\partial^4 w}{\partial x^4} - 2t_s \frac{\partial^2 w}{\partial x^2} + k_s w + c\frac{\partial w}{\partial t} + (\eta_s + \rho_b A_b)\frac{\partial^2 w}{\partial t^2} = P(x,t) \text{ for } (0 \le x \le L) \tag{6a}$$

$$-2t_s \frac{\partial^2 w}{\partial x^2} + k_s w + c\frac{\partial w}{\partial t} + \eta_s \frac{\partial^2 w}{\partial t^2} = 0 \quad \text{for } (-\beta L \le x \le 0)\ \&\ (L \le x \le \beta L) \tag{6b}$$

$$\frac{d^2\phi_i}{dz^2} - \left(\frac{\zeta_{si} - n_{si}}{m_{si}}\right)\phi_i = 0 \qquad (\text{for } H_{i-1} \le H_i) \tag{7}$$

The parameters in the above equations are given by:

$$\eta_s = \sum_{i=1}^{n} \rho_{si} b \int_{H_{i-1}}^{H_i} {\phi_i}^2 dz \tag{8a}$$

$$k_s = \sum_{i=1}^{n} b \int_{H_{i-1}}^{H_i} \bar{E}_{si}\left(\frac{d\phi_i}{dz}\right)^2 dz \tag{8b}$$

$$t_s = \sum_{i=1}^{n} \frac{b}{2} \int_{H_{i-1}}^{H_i} G_{si}{\phi_i}^2 dz \tag{8c}$$

$$m_{si} = b \int_{-\beta L}^{\beta L} \bar{E}_{si} w^2 dx \tag{9a}$$

$$n_{si} = b \int_{-\beta L}^{\beta L} G_{si}\left(\frac{\partial w}{\partial x}\right)^2 dx \tag{9b}$$

$$\zeta_{si} = b \int_{-\beta L}^{\beta L} \rho_{si}\left(\frac{\partial w}{\partial t}\right)^2 dx \tag{9c}$$

The domains $-\beta L \le x \le 0$ and $L \le x \le \beta L$ for equation (6b) are chosen by trial and error after eliminating the boundary effects (β is a fraction or multiple of L).

The initial conditions required to solve the set of differential equations (6a) and (6b) are that $w = 0$ and $\partial w/\partial t = 0$ at $t = 0$. However, the boundary conditions depend on the end conditions of the beam. For free end beams, the soil domains on both sides of the beam are required in the analysis, and equation (6b) is required to be solved in conjunction with equation (6a) in order to ensure continuity of displacement on both sides of the beam. For such free end beams, the displacements w at $x = \pm\beta L$ are assumed to be zero and continuity of displacement

w at $x = 0$ and $x = L$ is maintained. Further, the beam bending moment $E_bI_b\partial^2 w/\partial x^2$ and shear force $E_bI_b\partial^3 w/\partial x^3$ are assumed to be zero at $x = 0$ and $x = L$. For simply supported or fixed beams, only equation (6a) is solved with the domain spanning $0 \le x \le L$, and the beam deflection w and bending moment $E_bI_b\partial^2 w/\partial x^2$ are assumed to be zero at $x = 0$ and $x = L$ for simply supported beams, while beam deflection w and slope $\partial w/\partial x$ are assumed to be zero at $x = 0$ and $x = L$ for fixed beams. For solving equation (7), the boundary conditions required are $\phi = 1$ at $z = 0$, $\phi_i = \phi_{i+1}$ at $z = H_i$, and $\phi = 0$ at $z = H_{\text{total}}$.

It is important to note that the parameter η_s represents the mass of soil per unit beam length participating in the vibration, the parameter k_s is analogous to the Winkler spring constant of soil and represents the compressive resistance of soil, and the parameter t_s represents the shear resistance of soil and can be interpreted as the shear force acting between adjacent soil springs that are compressed differently because of the applied load.

2.5 *Solution of differential equations*

Solution of the differential equations (6a)-(6b) of w is obtained by using the FE method. Two-noded rod (bar) elements with linear Lagrangian shape functions are used to discretize the domains $-\beta L \le x \le 0$ and $L \le x \le \beta L$ (i.e., the domains in x direction with no beam) and two-noded beam elements with cubic Hermitian shape functions are used to discretize the domain $0 \le x \le L$ (i.e., the domain in x direction in which the beam is present) to obtain a set of algebraic equations of the form:

$$\sum_e [m]^e\{\ddot{w}\} + \sum_e [c]^e\{\dot{w}\} + \sum_e [k]^e\{w\} = \sum_e \{f\}^e \tag{10}$$

where $[m]^e$, $[c]^e$ and $[k]^e$ are the elemental mass, damping, and stiffness matrices, respectively, $\{f\}^e$ is the elemental force vector, $\{w\}$ is the global degrees of freedom vector (consisting of the unknown nodal displacements w for the entire domain and nodal slope $\partial w/\partial x$ for the portion of the domain within the beam), $\{\ddot{w}\}$ is the global acceleration vector, $\{\dot{w}\}$ is the global velocity vector, and $\sum$ represents assembly. The time integration to obtain solutions is performed following the Wilson-θ method (Bathe 1996).

Solution of the differential equation (7) for ϕ is obtained analytically, which for a single soil layer (of thickness T_1) can be expressed as

$$\phi_1(z) = \left\{\sinh\left[\left(\frac{T_1^2(\zeta_{s1} - n_{s1})}{m_{s1}}\right)^{0.5}\left(1 - \frac{z}{T_1}\right)\right]\right\} \Big/ \left\{\sinh\left(\frac{T_1^2(\zeta_{s1} - n_{s1})}{m_{s1}}\right)^{0.5}\right\} \tag{11}$$

2.6 *Solution algorithm*

The parameters k_s, t_s, and η_s must be known in order to solve the differential equations for w (equations (6a) and (6b)) and these parameters depend on ϕ. At the same time, the parameters m_{si}, n_{si} and ζ_{si} must be known in order to obtain ϕ (from Eqs. (7) or (11)) and these parameters depend on w. Therefore, the equations of w and ϕ are coupled, and are solved simultaneously following an iterative scheme.

A guess for the spatial distribution of ϕ is made by assuming a linear distribution of ϕ. With this assumed distribution, k_s and t_s are calculated (note that η_s is not considered in the initial calculation) using equations (8b) and (8c), and these parameters are then used to calculate the displacement w and its spatial derivative $\partial w/\partial x$. Using the calculated w and $\partial w/\partial x$, parameters m_{si} and n_{si} are calculated from equations (9a) and (9b) (note that ζ_{si} is ignored). The parameters m_{si} and n_{si} are then used to obtain a new $\phi(z)$. The newly calculated $\phi(z)$ is compared with the assumed $\phi(z)$ and, if the difference is greater than a prescribed tolerance, the calculations are repeated with the calculated ϕ as the new guess. The iterative calculations are continued until the assumed and calculated ϕ values fall within a tolerance limit. The tolerance limit set on ϕ for the iterations is 10^{-5}.

The distribution of ϕ obtained from the above calculations is given as input to the dynamic analysis (following the Wilson-θ method), and iterations similar to those described in the previous paragraph are performed within each time increment Δt. For the first time step, the initial position

x_0 of the applied load, geometry, material properties, and $\phi(z)$ are given as inputs, and the parameters k_s, t_s, and η_s are calculated. These calculated parameters are used to obtain the beam and soil displacement w, spatial derivative $\partial w/\partial x$ (which is the slope for the beam), velocity $\partial w/\partial t$, and acceleration $\partial^2 w/\partial t^2$. These quantities are used to calculate m_{si}, n_{si} and ζ_{si}, which are used to calculate the distribution $\phi(z)$. The newly obtained ϕ (dynamic) is checked against the previous ϕ (which is the ϕ for the first iteration of the first time increment), and iterations are continued until the difference between two consecutive distributions of $\phi(z)$ fall within the tolerable limit of 10^{-5}. At this point, the calculated w, $\partial w/\partial x$, $\partial w/\partial t$, and $\partial^2 w/\partial t^2$ are the final values for the given time step, and the next increment of time is then applied and the whole iterative process is repeated for each subsequent time steps until the final time increment is completed to reach the final time.

3 RESULTS

3.1 *Verification*

In order to verify the accuracy of the present analysis, comparisons of beam responses obtained from the present analysis are made with those obtained from equivalent two-dimensional (2-D) FE analysis (using Plaxis) in which the linear viscoelastic constitutive relationship is used. The nature and type of load, geometry of the problem, end conditions of the beam, and the material constants are selected differently in the multiple verification problems to ensure that the present analysis works for all possible cases. The boundaries of the FE domain were chosen sufficiently far from the beam (by trial and error) to avoid any boundary effects. Additional boundary conditions are prescribed at the end points of the beams to simulate different types of beam-end conditions (i.e., fixed, free, and hinged supports).

Figure 2 shows the free-end displacement time-history response $w(L, t)$ of a cantilever beam subjected to a concentrated ramp load at the free end with a maximum value of 20 kN and acting over a duration of 1 sec. The figure also shows the corresponding beam response obtained from 2-D FE analysis. The beam is considered to be free to displace and rotate at the right end and completely restrained against translation and rotation at the left end. The details of the beam and soil inputs are given in the figure. From the comparisons it is apparent that the results from both the analyses are in good agreement, with the maximum difference between the results of the present analysis and 2-D FE analysis being 6.2%.

A comparison of beam displacement profiles obtained from the present analysis and 2-D FE analysis for a free-free beam subjected to a point step load of magnitude 60 kN and duration 1 sec acting at the mid-span of the beam is shown in Figure 3 (other inputs for the problem are shown in the figure). The beam rests on a three-layer soil deposit and is free to displace and rotate at both the ends. The maximum difference between the beam displacements obtained from the present analysis and 2-D FE analysis is 3.8%, which further proves that the present analysis framework produces accurate beam response.

3.2 *Dynamic characteristics of the foundation*

The characteristics of the dynamic two-parameter foundation model and its advantage over the conventional beam-foundation models are illustrated by studying the time histories of the soil resistance parameters k_s and t_s obtained using the present analysis for a 10 m-long free beam vibrating on a 10 m thick single soil layer and subjected to different dynamic loads. The time history responses of k_s and t_s for are shown in Figures 4(a)-(c). The details of the beam-soil inputs are given in the figures. In Figure 4(a), the beam is subjected to a 30 kN point load moving with a constant velocity v = 10 m/sec, while a sinusoidal load with 20 kN amplitude, 15 HZ frequency, and 5 sec duration acts at the mid-span of the beam in Figure 4(b). A step load of 25 kN magnitude and 4 sec duration acts at the mid-span of the beam in Figure 4(c).

Interestingly, the two soil parameters change with time even though the soil elastic constants remain constants. The effect of different types of load on k_s and t_s is clear in Figures 4 (a)-(c). Thus, k_s and t_s cannot be given as input a priori, as is conventionally done. These parameters depend on the elastic constants of the soil, on the relative stiffnesses of the beam and soil, and on the loading characteristics.

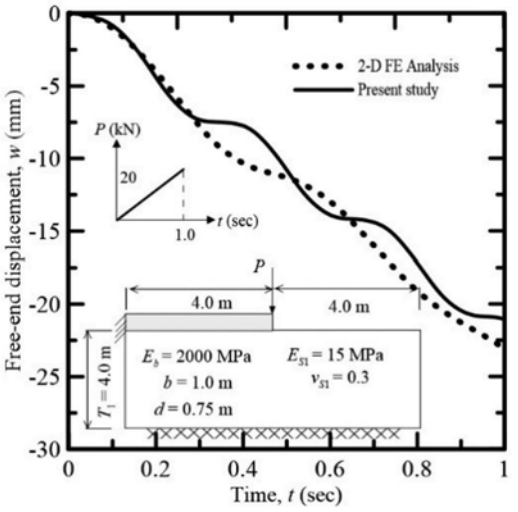

Figure 2. Time history response of free-end displacement of a 4 m long cantilever beam resting on a 4 m thick homogeneous soil deposit and subjected to a ramp load with a maximum value of 20 kN.

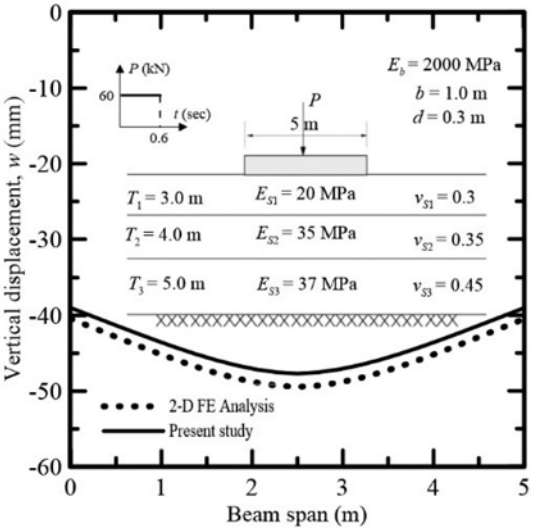

Figure 3. Beam displacement profiles corresponding to time t = 0.6 sec of a 5 m long free-free beam resting on a three-layer soil deposit and subjected to a point step load of magnitude 60 kN acting for 0.6 sec.

The characteristics of the foundation system is further investigated for a free beam resting on a three-layer soil deposit, as shown in Figures 5(a)-(b). The details of the beam-soil inputs are given in the figure. The beam is considered to be free to displace and rotate at both ends (free ends). A concentrated ramp load with a maximum amplitude of 25 KN and duration of 1 sec is assumed to act at the mid-span of the beam. The time histories of the parameters k_s and t_s, and of the vibrating soil mass η_s are plotted in Figures 5(a)-(b). The parameters k_s and t_s tend to be constant at the beginning of the dynamic analysis when the contribution of the vibrating soil mass η_s is small. As η_s starts contributing to the vibrating system over time, the parameters k_s and t_s start to vary as functions of time. In fact, η_s also varies with time initially and becomes constant over time. This is in stark contrast to the discrete two parameter model in which k_s and t_s are kept constants and η_s is usually neglected.

3.3 *Effect of variable speed on the dynamic beam response*

A 20 m long simply-supported beam is considered for investigating the effect of variable velocity of moving load. The beam is assumed to rest on a 4 m thick single-soil layer. The details of the beam-soil system are given in Figure 6. To investigate the effect of variable velocity, four cases are considered. In Case 1, a 5 kN point load starts moving from the left end at x = 0 m with a constant speed of 5 m/sec and exits the beam at x = 20 m with the same speed. In Case 2, the same 5 kN load starts moving from x = 0 m with an initial speed of 5 m/sec and with uniform deceleration of –0.625 m/sec^2 such that the load stops at the right end of the beam corresponding to x = 20 m. In Case 3, the same 5 kN load starts to move from x = 0 with zero initial velocity and uniform acceleration of 0.625 m/sec^2 such that the load attains a speed of 5 m/sec at the right end corresponding to x = 20. In Case 4, a 5 kN point load enters the left end of the beam at point x = 0 with an initial velocity of 5 m/sec and uniformly decelerates at –1.25 m/sec^2 so that the load stops at the mid-span of the beam (corresponding to x = 10 m).

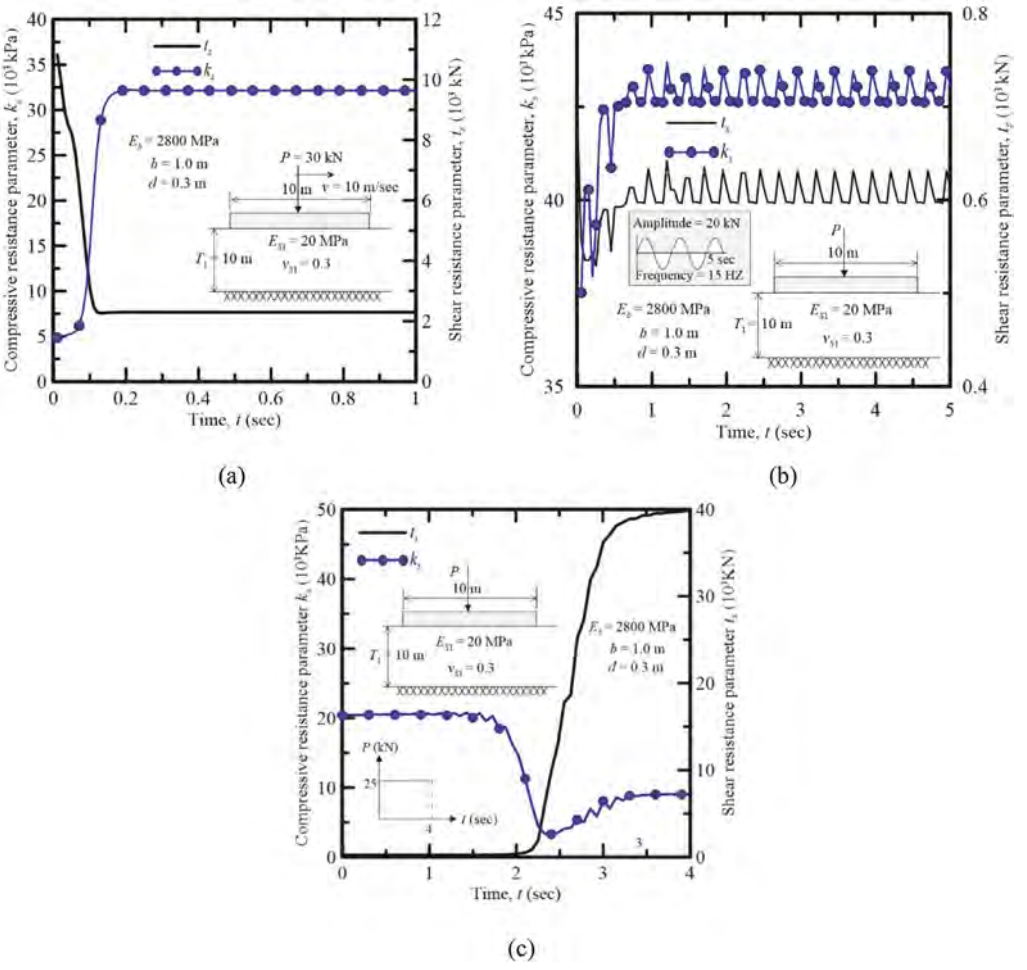

Figure 4. Time history responses of the soil resistance parameters k_s and t_s for a 10 m long free beam resting on a single-layer soil deposit and subjected to (a) a 30 kN point load moving with a constant velocity of 10 m/sec, (b) a sinusoidal point load with a maximum amplitude of 20 kN acting at the mid-span of the beam, and (c) a step point load of 25 kN magnitude acting at the mid-span of the beam.

Figure 6 shows the dynamic amplification factor ψ_D versus the normalized load position vt/L for Cases 1-4. The dynamic amplification factor ψ_D is calculated as the ratio of the mid-span dynamic

displacement $w(0.5L, t)$ to the maximum mid-span static displacement $w(0.5L)$. The beam response is different for loads moving with constant and variable velocities. Accelerating and decelerating loads tend to produce greater dynamic displacements compared with those corresponding to loads moving with a constant velocity.

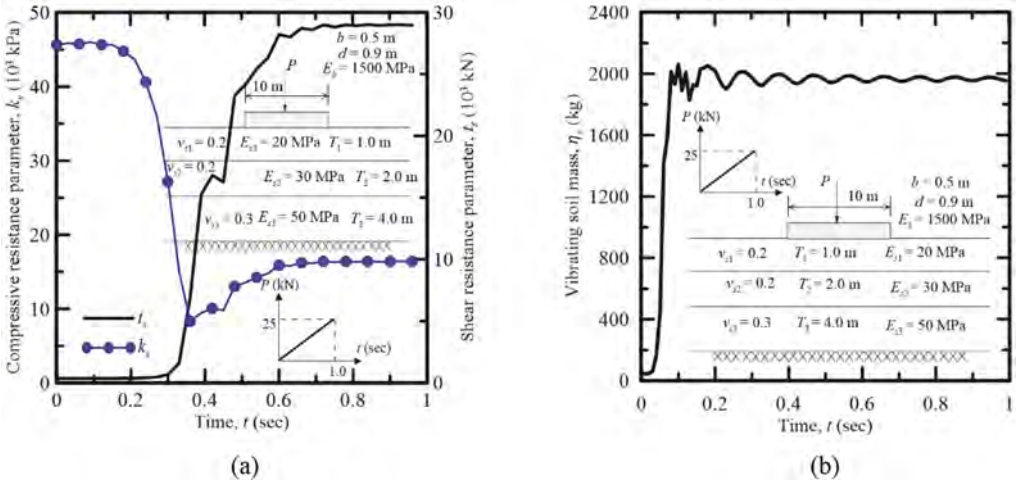

Figure 5. Time dependent response of a 10 m long beam resting on a three-layer soil deposit and subjected to a ramp point load with maximum amplitude of 25 KN: time histories of (a) k_s and t_s, and (b) η_s.

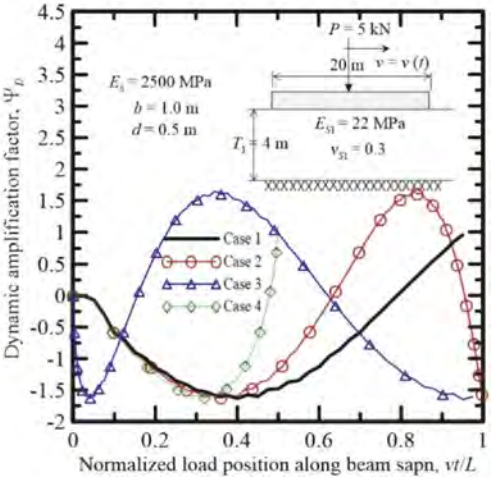

Figure 6. Beam response under loads moving with variable speeds.

4 CONCLUSIONS

A new model for dynamic soil structure interaction is developed using the variational principles of mechanics. The model is applied to the analysis of beams resting on multi-layered viscoelastic soil subjected to oscillatory and moving loads. A continuum approach is adopted in which assumptions regarding the displacement field in the multi-layered soil are made. The extended Hamilton's principle is applied to obtain the Euler-Lagrange equations of motion describing the dynamic equilibrium of the beam-soil system. Solutions are obtained analytically and numerically using an iterative algorithm along with a numerical time integration

scheme. Accuracy of the model in producing reliable beam response is verified through comparisons with equivalent 2-D finite element analysis. Appropriate equivalent elastic constants of soil have to be used to obtain accurate beam response in practice.

The developed model leads to equations similar to beams resting on bed of springs (i.e., the soil is represented by springs, which is commonly termed as the foundation on which the beam rests) characterized by two parameters k_s and t_s representing the compressive and shear resistances of the foundation. However, unlike the traditional approach, k_s and t_s are not foundation constants but depend on the beam-foundation interaction and, therefore, are functions of time – this is a novel finding and a significantly different approach for problems related to dynamic interaction of beams with underlying foundations. These parameters are determined as part of the solution and no empirical estimations are necessary. The inertial resistance of soil (i.e., the foundation) is explicitly taken into account by a parameter η_s, which is also a function of time (inertia of foundations are not taken into account for traditional spring-based foundation models). Thus, the parameters k_s, t_s and η_s are interaction parameters and change with load frequency and velocity. Geometric damping is explicitly taken into account in this model through a function ϕ, which is typically not available in traditional spring-based soil-structure interaction models.

Shaking analysis of masonry wall in large deformation range using coupled MPM-DDA

S. Kawano & R. Hashimoto
Hiroshima University, Higashi-Hiroshima, Hiroshima, Japan

ABSTRACT: For the investigations on the effective seismic reinforcement method of the masonry walls, a stability evaluation method to reveal the collapse mechanisms of the masonry walls is strongly demanded. This study focused on a coupled Material Point Method and Discontinuous Deformation Analysis (MPM- DDA) that can treat the mechanical interaction among the materials such as the stones and the backfill soil within a large deformation range. A shaking table experiment of a masonry wall model was simulated using the MPM-DDA to check the validation of the method for seismic response analysis of masonry walls. The simulated results agreed quantitatively well with the experiment using the material properties obtained in the experiment, and the validity of the MPM-DDA was successfully confirmed.

1 INTRODUCTION

There exists a lot of castle masonry walls all over Japan, and the conservation of them becomes an important task from the viewpoint of their historical and cultural values. However, in recent years, the masonry walls frequently suffered collapse due to strong earthquakes such as the 2016 Kumamoto Earthquake (Figure 1), and investigations on the mechanical characteristics and the effective reinforcement method of the masonry walls have become an urgent task. The masonry has various structural variables such as the stone size, slope, and height. Therefore, it is required to investigate their dynamic behaviors by parametric analysis of the structural variables using a numerical method. In addition, the analytical method used must be able to consider the nonlinear deformation characteristics of the ground behind the stone wall and discontinuities such as displacement and separation between stones and between stones and ground.

Figure 1. Collapsed masonry wall of Kumamoto Castle during the 2016 Kumamoto Earthquake (Kamiya et al., 2018).

At present, the seismic response of masonry walls is often simulated by Discrete Element Method (DEM) using granular elements. Fukumoto et al. (2014) investigated the stone shape effect on the seismic behavior of masonry walls using particle DEM. A series of centrifugal shaking table experiment was reproduced the deformation even after the large deformation. However,

DOI: 10.1201/9781003299127-228

calibration of the mixing ratio of the particles with different shapes was needed to reproduce the experimental results. Meanwhile, Hashimoto et al. (2017) developed a coupled Numerical Manifold Method and Discontinuous Deformation Analysis (NMM-DDA), a combined continuum-discontinuum method, to achieve a strong coupling analysis of a soil-masonry structure system. In the NMM-DDA, the deformation of continuum is modeled with the NMM (Shi, 1991) is a mesh-based similar to the Finite Element Method, and the discrete behaviors of the masonry stones are modeled with the DDA (Shi and Goodman, 1989)considering the contact between the materials defining. Therefore, the NMM-DDA can simulate the interactive behaviors between the masonry stones and backfill soil. Sueoka et al. (2020) applied the NMM-DDA to a simulation of a shaking table experiment of a masonry wall model, and the failure initiation time and failure mode such as the location of the slip line in the backfill were reproduced. However, since the NMM is a mesh-based method, a complete collapse of the soil could not be reproduced. Hence, to reveal a total failure process of the masonry wall, a method that can simulate soil behavior in a large deformation range is required.

To overcome the above problem, this study focus on a coupled Material Point Method and Discontinuous Deformation Analysis (MPM-DDA) proposed by Hashimoto et al. (2022), a new combined continuum-discontinuum method. Combining the DDA and the MPM which is a numerical method for large deformation of continua, the collapse of stones, large deformation of soil, and interaction between them can be analyzed simultaneously. In this study, the MPM-DDA is applied to the simulation of the shaking table experiment of a masonry wall model by Sueoka et al. (2020), and the validation of the method for seismic response analysis of masonry walls is discussed.

2 A COUPLED MPM-DDA

This section provides an outline of the MPM-DDA (Hashimoto et al., 2022). As mentioned above, the MPM-DDA is a combined continuum-discontinuum method based on the MPM and DDA (Figure 2). The MPM (Suslky et al., 1994) is a hybrid particle-grid based numerical method fo large deformation of continua. A continuum is divided into subdomains and represented as particles, called material points, that have mass, volume, stress, strain, and other state variables. The mass, momentum, and internal force of the material points are projected to nodes of a background finite element mesh prepared over the physical domain, and then, the equation of motion is solved on the mesh. Since the material points can move across the elements, large deformation of the objects can be analyzed without mesh tangling problems in the finite element method.

In the MPM-DDA, a target system that consists of multiple objects is divided into the continuum (e.g., soil) and the discrete objects (e.g., masonry stone), and the former part is modeled with the MPM and the latter ones are modeled with the DDA. Then, the contact between the material points and the polygonal blocks of the DDA is formulated by the penalty method (see Figure 2). An implicit time discretization scheme using the Newmark's β method is employed for the MPM (Iaconeta et al., 2017) as same as for the DDA that originally employs the Newmark's β method. Based on the above formulation, the deformation and motion of the material points and the DDA blocks are solved monolithically including their interactions.

3 SHAKING TABLE EXPERIMENT OF A MASONRY WALL MODEL

To investigate the applicability of MPM-DDA to the seismic response analysis of stone walls, a simulation of a shaking table experiment of a masonry wall model by the second author (Sueoka et al., 2020) is conducted in this study. The outlines of the experiment are explained in this section.

Figure 3 is the schematic figure of the masonry wall model used in the experiment. The model consists of the backfill soil, and the masonry wall that retains the backfill. The masonry wall consists of five stones, named stone 1~5 from bottom to top, stacked with uniform overlapped width. The bottom stone is fixed in contact with the soil container wall. Sydney sand with a moisture content of w_s = 4.31 %, specific gravity G_s = 2.65, and mean grain size D_{50} = 0.31mm was used for making the backfill soil, and hollow concrete blocks (average density: 0.876 g/cm^3, mass: 12.33 kg) were used as the wall material. The strength parameters of the Sydney sand

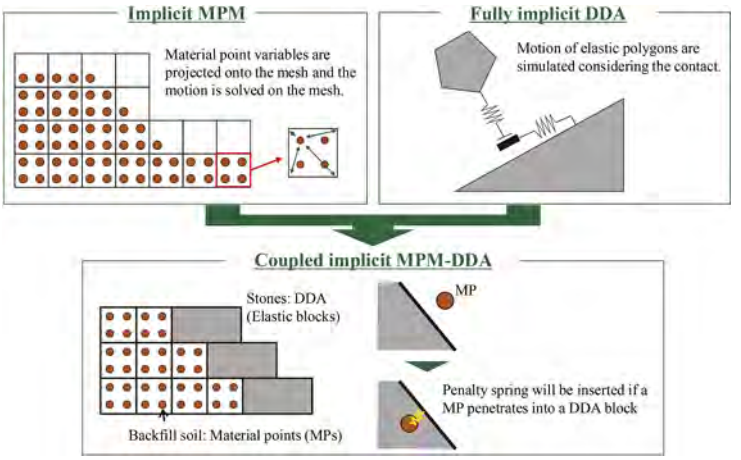

Figure 2. Outlines of the implicit MPM-DDA.

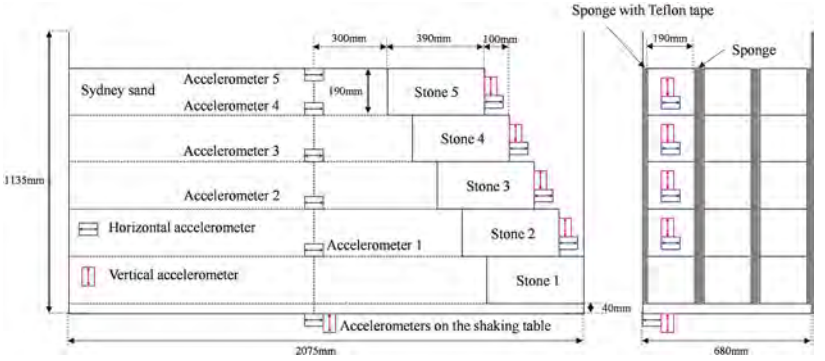

Figure 3. Masonry wall model.

were determined by the direct shear test. The cohesion was 4.09 kPa, and the internal friction angle was ϕ = 33.7 °. The static friction angle ϕ_s and dynamic friction angles ϕ_d between the stones were measured by a shaking table experiment conducted on a pair of stacked concrete blocks. As a result, ϕ_s = 37.0 ° and ϕ_d = 27.5 ° were obtained. The friction properties between the stones and the backfill soil were obtained by a friction test, and both ϕ_s and ϕ_d were 31.0 °.

Figure 4 shows the input acceleration used in the experiment (waveforms measured by an accelerometer installed on the shaking table). The frequency was 4 Hz in the horizontal direction only, and the amplitude was tapered to 706.3 gals from 0 to 20 seconds, followed by 20 seconds of maximum acceleration. Though only the horizontal wave was input, large vertical acceleration was observed due to the collision between the stone and the soil container. To observe the behavior of the stones and the ground behind them, five horizontal accelerometers were attached to the ground behind them, and horizontal and vertical accelerometers were attached to the stones 2~5 and to the shaking table. The displacement of each stone was calculated by analyzing the video taken during the experiment.

4 ANALYSIS USING THE MPM-DDA

4.1 *Analytical conditions*

Simulation of the shaking table experiment explained in the last section is conducted here using the implicit MPM-DDA. Figure 5 is the analytical domain of the masonry wall modeled

with the MPM-DDA. The stones and the soil container are modeled with the DDA and the backfill soil is discretized to the material points. Here, the inner width of the container is slightly different from Figure 3 due to the particle representation of the soil, but the size and shape of the wall are the same as those of the experimental model.

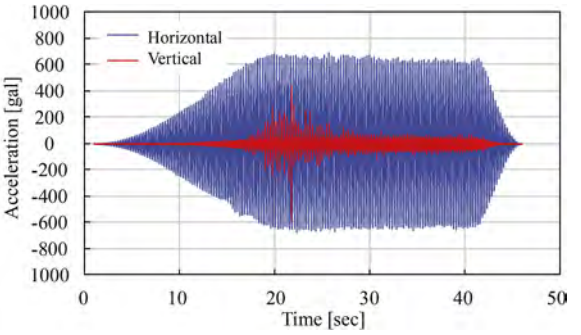

Figure 4. Input acceleration of the shaking table experiment.

The material properties are summarized in Table 1. The stone was modeled as elastic, and the Drucker-Prager model with strain-softening was applied to the backfill soil. The internal friction angle and initial cohesion were set based on the direct shear test, and the initial dilatancy angle was matched to the internal friction angle. Cohesion and dilatancy angle were reduced linearly to zero as the accumulated plastic deviator strain approached 0.1. Table 2 shows the parameters for the material interfaces, and the friction angles were set based on the experiment. The penalty values were determined so that a large penetration between the objects does not occur. It is noted that the B-bar method was used to avoid volumetric locking. Time increment was 0.00005 sec.

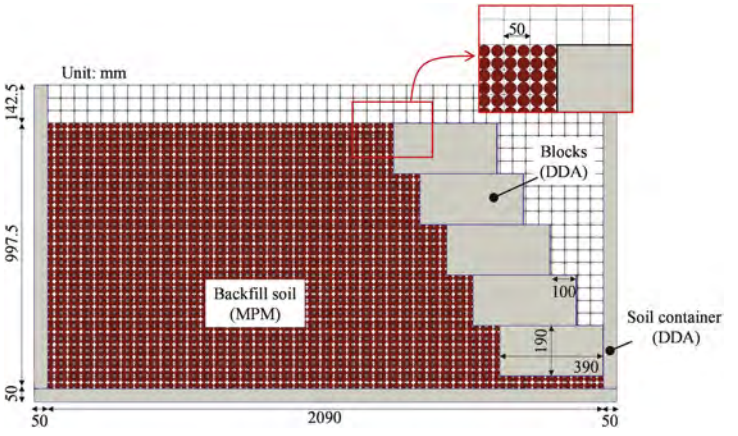

Figure 5. Analytical domain of the masonry wall model.

After giving the initial stress under gravity, the input acceleration in Figure 4 was applied to the soil container. Since the deformation of the wall converged after around 17 seconds from the start of the shaking in the experiment, the simulation was performed for the first 20 seconds.

4.2 *Results*

Figure 6 is the time history of the horizontal displacement of the stone 2 relatives to the soil container. Here, rightward in Figure 3 is the positive direction. In the experiment (black line), the stone started to move rightward around 14 seconds, and then, the velocity increased as the deformation progressed. Finally, the stone stopped at the displacement of 45 mm because

Table 1. Material properties.

		Stone (Elastic)	Backfill soil (Drucker Prager)
Unit weight	[kN/m^3]	8.6	14.8
Young's modulus	[MPa]	1.0×10^4	10.0
Poisson's ratio		0.2	0.3
Internal friction angle	[deg.]	-	33.7
Initial cohesion	[kPa]	-	4.09
Residual cohesion	[kPa]	-	0.0
Initial dilatancy angle	[deg.]	-	33.7
Residual dilatancy angle	[deg.]	-	0.0
Accumulated plastic deviator strain at the residual state		-	0.1

Table 2. Parameters of the contact interfaces.

		Stone-Stone	Stone-Soil
Normal penalty coefficient	[kN/m]	1.0×10^6	1.0×10^6
Shear penalty coefficient	[kN/m]	1.0×10^5	1.0×10^5
Static friction angle	[deg.]	37.0	31.0
Residual friction angle	[deg.]	27.5	31.0

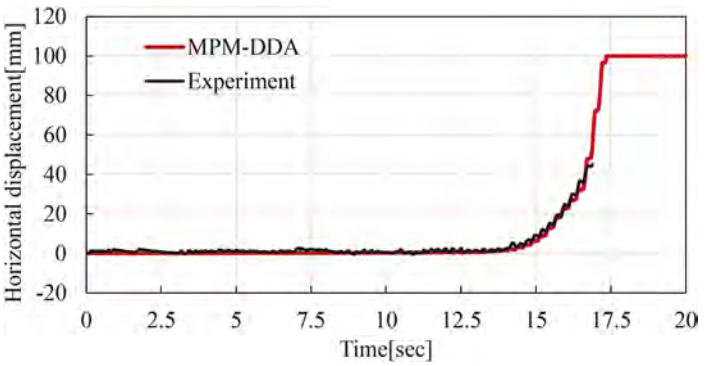

Figure 6. Time history of the relative horizontal displacement of the stone 2.

the accelerometer attached to the stone contacted with the container wall. On the other hand, the simulated result with the MPM-DDA (red line) showed almost identical curve to the experimental result. Since the shape of the accelerometer was not considered in the simulation, the displacement increased up to 100 mm which is the initial clearance between the stone 2 and the container wall.

Figure 7(a) is the snapshot of the model configuration at the moment that the stone 2 reached the soil container wall (17 seconds from the start of shaking) in the experiment, and Figure 7(b) is the simulated deviator strain contour at the same moment with Figure 7(a). According to Figure 7(a), the masonry wall slid rightward and the backfill soil collapsed. Since there was a stepped surface due to a tensile crack on the top of the backfill soil, the location of the slip line in the backfill was presumed to be the white line in the figure that connects the crack and the initial toe of the backfill.

In Figure 7(b), the backfill soil deformed largely showing a clear shear band mainly owing to the strain softening of the soil, and a stepped surface was generated on the top of the backfill as observed in the experiment. In addition, the location of the shear band was almost identical to the presumed slip line in the experiment. Considering these results, therefore, the MPM-DDA could reproduce the experimental results quantitatively even in the large deformation range.

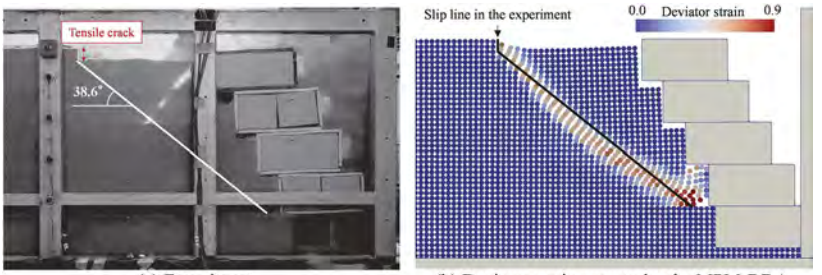

Figure 7. Deformation of the masonry wall when the stone 2 reached the container wall.

5 CONCLUSION

In this study, to establish a numerical method for castle masonry walls in a large deformation range, the applicability of the MPM-DDA, a novel combined continuum-discontinuum method, was examined through the simulation of the shaking table experiment of a masonry wall model. By using the material properties obtained in the experiments, the simulated results agreed quantitatively well with the experimental results from the viewpoint of the stone displacement and failure mode in the backfill soil. As a result, the validation of the MPM-DDA for the seismic response analysis of the masonry walls was confirmed successfully. For further study, the MPM-DDA will be applied to a parametric study on the structural characteristics of the masonry walls.

Methods of setting stiffness of horizontal joints of large-panel buildings at soil-structure interaction calculation

V.V. Bakrysheva & K.G. Shahskin
Institute "Georeconstruction", Saint-Petersburg, Russian Federation

ABSTRACT: The literature does not pay any attention to stiffness of a horizontal connection of floor slabs between each other in a platform joint. The objective of this paper is to analyze the level of development of calculation methods for stiffness of joints of panel buildings, compare the analytical calculation and numerical solution. There have been analyzed formulae for calculation of compliance of platform joints of panels given in the regulations. There are given results of calculations using numerical methods for defining compliance of a platform joint and comparison with the analytical solution. As the result it is concluded that for the vertical direction the numerical solution is almost equal to the analytical one (the difference is less than 5%), at shear along the wall the discrepancy is a bit bigger, the largest discrepancy with the analytical solution occurs at shear across the wall.

1 INTRODUCTION

Calculation methods for defining forces and deformations in elements of panel buildings and joints of elements at design began to develop at construction of the first large-panel buildings. However, before development of computers the most relevant problems included definition of a total stiffness of a building and evaluation of summarized forces in large-panel buildings; generally, analytical methods were used. Due to decreasing interest to large-panel construction in the post-Soviet period, contrary to the general principles of numerical methods for calculating structures of a building, methods of calculation of large-panel structures were almost not updated.

There are several variants that can be used to calculate stiffness of horizontal joints of large-panel buildings. But it is not clear which of them is more adequate for practical use.

"The textbook for calculation of large-panel buildings. Issue 1. Characteristics of stiffness of walls. Elements and joints of large-panel buildings" issued by V.A.Kucherenko Central Research Institute of Building Structures and Moscow Research and Design Institute of Typology and Experimental Design (1974), Industry specific construction standards 32-77 "Guidelines for design of structures of panel residential buildings" of Gosgrazhdanstroy (1978), "Textbook for design of residential buildings. Issue 3. Structures of residential buildings (to Construction Code 2.08.01-85)" issued by Central Research and Design Institute of Residential and Public Construction, Goskomarchitecture (1989) were the main documents, which regulate design and calculations of large-panel structures in the Soviet period throughout Russia.

In 2017 the new set of construction rules "Set of Rules 335.1325800.2017. Large-panel structural systems. Rules of design" replaced the existing Soviet regulations. At the same time some enterprises involved in panel construction developed standards of organizations which contain guidelines on methods of calculations and design of panel buildings. The main types of calculations and formulae stated in these documents repeat the content of the Soviet regulatory documents.

When calculating structures of panel buildings it is important to consider forces in elements and nodes of structures generated by soil strains. According to Set of Rules 335.1325800.2017

DOI: 10.1201/9781003299127-229

calculations of the structural system of large-panel buildings should be made "in spatial domain with account of joint behavior of underground and above-ground parts of a building as well as the foundation and subsoil".

Joints of panels and floor slabs are the most understudied but the most interesting in terms of strains and strength of structures of a large-panel building in general.

In each joint there are possible displacements and turns of each panel/slab relative to each other in three directions. That means that in a general case each joint of slabs and panels has 12 translational and 12 rotational degrees of freedom. As a rule, at ignoring small values of rotational stiffness due to a possibility of turning of slabs and wall panels and at equal stiffness of both slabs of floors and both wall panels (in case of the same floor slabs and wall panels of the upper and lower floors) each joint still has 6 independent stiffness and strength properties.

In Central Research and Design Institute of Residential and Public Construction, Goskomarchitecture (1989) and Set of Rules 335.1325800.2017 there are given formulae to define strength and stiffness of panels and slabs only at application of a vertical load, at action of horizontal forces the calculation of a joint of wall panels for a shear of the upper wall panel is made. However, for example, at differential strains of subsoil of a building or application of horizontal loads horizontal forces also occur in discs of floors, they "pull out" slabs of floors or compress a joint, their value is compatible with a strength of joints for action of horizontal forces, moreover, a rotation of wall panels and floor slabs etc. occurs.

Strength and stiffness of joints at action of horizontal forces in discs of floors and shear of panels are not defined according to the existing methods of calculations. We consider in detail obtaining values of stiffness of platform joints required for calculation of a large-panel building.

The following types of horizontal joints are used in bearing structures of large-panel buildings: platform, contact and combined ones. Platform joints are the most wide-spread.

According to formula (A.9) of Set of Rules 335.1325800.2017, which was earlier given in Central Research and Design Institute of Residential and Public Construction, Goskomarchitecture (1989), a coefficient of compliance at compression for a platform horizontal joint, where a load is transferred via support sections of floor slabs and two mortar joints between connected elements, is computed as per the formula:

$$\lambda_{c,pl} = (\lambda_m^{'} + \lambda_m^{''} + \frac{h_{pl}}{E_{pl}})\frac{A}{A_{pl}} \tag{1}$$

where $\lambda_m^{'}$, $\lambda_m^{''}$ - coefficients of compliance at compression of the upper and lower mortar joints, respectively; h_{pl} – a thickness of a support part of a floor slab; E_{pl} – an initial elastic modulus of concrete of a support part of a floor slab; A_{pl} – an area of platform sections of a joint through which a compressive load is transferred.

According to formulae (A.4)-(A.5) of Construction Codes 335.1325800.2017 a coefficient of compliance of a mortar joint λ_m (mm^3/N) at a short-term compression of the mortar joint, with the compressive strength of mortar 1 MPa and more and the joint thickness 10-20 mm is recommended to be defined according to formulae:

$$\text{at } \sigma_m \le 1,15R_m^{2/3} \quad \lambda_m = 1,5 \cdot 10^{-3} R_m^{-2/3} t_m \tag{2}$$

$$\text{at } \sigma_m > 1,15R_m^{2/3}, \text{ but more than } 2R_m^{2/3} \quad \lambda_m = 5 \cdot 10^{-3} R_m^{-2/3} t_m \tag{3}$$

where σ_m – an average value of compressive stresses in a mortar joint, MPa; R_m – a cubic strength of mortar, MPa; t_m – a thickness of a mortar joint, mm.

If a long-term compressive load is applied to a joint a coefficient of compliance of a horizontal mortar joint is defined according to formula (A.6), Set of Rules 335.1325800.2017 as per formula:

$$\lambda_{m,t} = \lambda_m(1 + \varphi_t), \tag{4}$$

where φ_t – the characteristics of joint creeping taken as equal 1. That means that a long-term compliance of a mortar joint is accepted twice as high as the short-term.

These dependencies of deformability of mortar joints have been evidently obtained empirically. It is also witnessed by dimensionality of multipliers used in formulae and a desired coefficient to compliance (meanwhile formulae are not in a form which depends on dimensionality of values). There is no information on the origin of the given formulae.

Formulae (2), (3) show the dependency of a joint compliance on a strength and stiffness of a joint mortar if reflected through a parameter of cubic strength of joint mortar R_m. In order to compute a value of a joint stiffness not only in the vertical direction there is a need to know an elastic modulus and a shear modulus of cement mortar used in panel joints. However, there is no single method for defining these moduli – different values and options of calculation of these properties are stated in different sources.

The analysis of formulae (2), (3) and evaluation of a value of deformability of a mortar joint are given in Danel (Danel 2010). It is noted the adequacy of definition of a value of a mortar elastic modulus from expressions (2), (3) according to the formula $E_r = \frac{h_r}{\lambda_r}$ and getting a value of a mortar shear modulus from the well-known ratio $E_r = 2G_r(1 + \mu)$, where μ - Poisson ratio of mortar.

Contrary to vertical joints, which are highly influenced by non-linear behavior of embedded parts, as for horizontal joints, Set of Rules 335.1325800.2017 considers linear behavior of mortar joints and concrete of floor slabs. In this connection behavior of horizontal joints can be quite accurately simulated using the finite element method in linear domain.

2 DEFINITION OF STIFFNESS OF HORIZONTAL JOINTS OF WALL PANELS

In order to evaluate stiffness of a platform joint in the software FEMmodels (IEEcloud) there has been created a parametric finite element model using finite elements of the second order. Properties and parameters used in the calculation are presented in the Table 1. Displacement of the upper wall in a joint in three directions was set as an action. Consequently, joint stiffness is computed according to results of solving the problem by division of the obtained force by the set displacement. The calculation results for 200-mm-thick walls of concrete B30 and 160-mm-thick floor panels of concrete B22.5 are given below in Figures 1-4.

Calculation of stiffness of a platform joint

Table 1. Properties and parameters used in the calculation.

Geometrical parameters (m)	
Wall thickness	b=0.2
Floor slab thickness	h=0.16
Supporting width	b_1=0.09
Mortar thickness	t=0.02
Material parameters	
Strain modulus of concrete of slabs (kPa)	$E_{b,p}$=28750000
Strain modulus of concrete of walls (kPa)	$E_{b,w}$=32500000
Calculated resistance of mortar (MPa)	R=20
Value of stresses in a joint (κPa)	$\sigma_m = 5000$
Poisson's ratio of mortar	$\mu = 0.2$

Strain modulus in different stress ranges, kPa:

$$E_{m,1} = \frac{1}{1.5 \cdot 10^{-3} \cdot R^{\frac{-2}{3}}} \cdot 1000 = 4912042.0 \text{ while } \sigma_{m,1} = 1.15 \cdot R^{\frac{2}{3}} \cdot 1000 = 8473.3$$

$$E_{m,2} = \frac{1}{5 \cdot 10^{-3} \cdot R^{\frac{-2}{3}}} \cdot 1000 = 1473612.6 \text{ while } \sigma_{m,1} = 2 \cdot R^{\frac{2}{3}} \cdot 1000 = 14736.1$$

Account of duration of load application:

$$\phi = 1 \qquad E_{m,t} = \frac{E_m}{1+\phi} = 2456021 \qquad E_{b,p,t} = \frac{E_{b,p}}{1+\phi} = 14375000 \qquad E_{b,w,t} = \frac{E_{b,w}}{1+\phi} = 16250000$$

Mortar shear modulus, kPa $\qquad G_{m,t} = \frac{E_{m,t}}{2\cdot(1+\mu)} = 1023342.1$

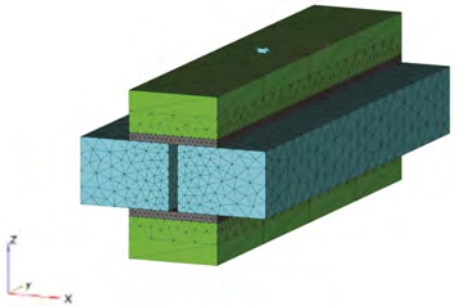

Figure 1. Calculation model.

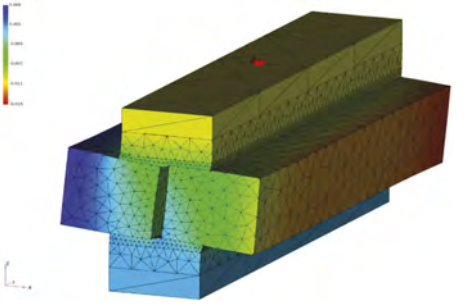

Figure 2. Calculation results. Displacement along axis Z.

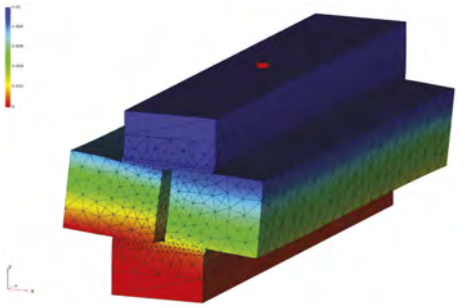

Figure 3. Calculation results. Displacement along axis X.

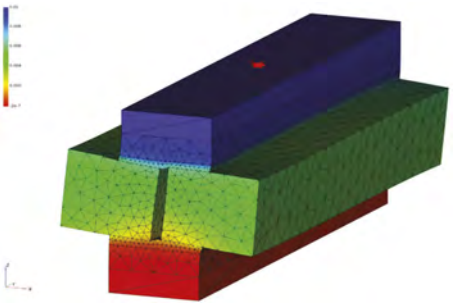

Figure 4. Calculation results. Displacement along axis Y.

Forces from the set displacements

$$N = -63035.7 \qquad Q_z = 7546.8 \qquad Q_y = 23845.0$$

Comparison with analytical solutions

Compliance of the joint according to the numerical calculation (m^3/κN):

$$\lambda_{w,z} = \frac{-\delta \cdot b \cdot s_y}{N} \cdot 10^8 = 3.17 \qquad \lambda_{w,x} = \frac{\delta \cdot b \cdot s_y}{Q_z} \cdot 10^8 = 26.50 \qquad \lambda_{w,y} = \frac{\delta \cdot b \cdot s_y}{Q_y} \cdot 10^8 = 8.39$$

Analytical solution for vertical compliance (m^3/κN):

$$\lambda_m = \begin{cases} 1.5 \cdot 10^{-3} \cdot R^{\frac{-2}{3}} \cdot t \cdot 1000, & \text{if } \sigma_m < 1.15 \cdot R^{\frac{2}{3}} \cdot 1000 = 0.00407 \\ 5 \cdot 10^{-3} \cdot R^{\frac{-2}{3}} \cdot t \cdot 1000, & \text{otherwise} \end{cases}$$

$$\lambda_m = \lambda_m . \frac{0.001^3}{0.001} \left[\mathrm{M}^3/\mathrm{kH}\right] \qquad \lambda_{m,t} = \lambda_m \, . \, (1+\phi)$$

$$\lambda_{c,pl} = \left(2 \cdot \lambda_{m,t} + \frac{h}{E_{b,p,t}}\right) \cdot \frac{b}{b_1 \cdot 2} = 0.00000003 \qquad \lambda_{c,pl} \cdot 10^8 = 3.046$$

Comparison of compliances along z as per the numerical and analytical calculations:

$$\frac{\left|\lambda_{c,pl} - \lambda_{w,z}\right|}{\lambda_{c,pl}} \cdot 100 = 4.15187828$$

Analytical solution for shear compliance (Danel 2012):

$$G_{b,t} = \frac{E_{b,p,t}}{2 \cdot (1+\mu)} = 5989583.3 \quad \lambda_r = \left(\frac{2 \cdot t}{G_{m,t}} + \frac{h}{G_{b,t}}\right) \cdot \frac{b}{2 \cdot b_1} \cdot 10^8 = 7.311$$

Comparison of compliances along y as per the numerical and analytical calculations:

$$\frac{|\lambda_r - \lambda_{w,y}|}{\lambda_r} \cdot 100 = 14.721$$

Compliance along x as per the numerical calculation is considerably higher than as per the analytical calculation:

$$\frac{\lambda_{w,x}}{\lambda_r} = 3.625$$

For the vertical direction the numerical solution is almost equal to the analytical one (the difference is less than 5%). At shear along the wall the discrepancy is a bit bigger. However, the largest discrepancy with the analytical solution occurs at shear across the wall. It is connected with the fact that the analytical solution does not consider a possibility of floor slab rotation. Meanwhile bending stiffness of slabs is quite small and resistance to such a rotation is insignificant, it can be ignored in calculations. Therefore, the value of stiffness across the slab is more adequate as per the numerical solution.

The literature does not pay any attention to stiffness of a horizontal connection of floor slabs between each other in a platform joint. Meanwhile this very stiffness defines a behavior of a floor disc at total bend of a building. This bend manifests itself at any soil-structure interaction calculation. The calculation of stiffness of floor slab fixation in a platform joint for the same parameters is given below in Figures 5-8.

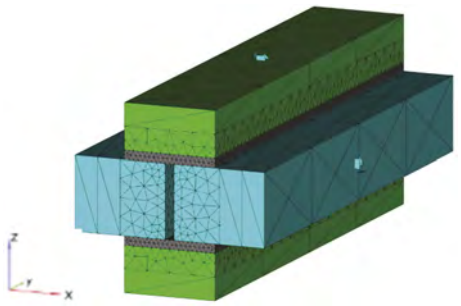

Figure 5. Calculation model.

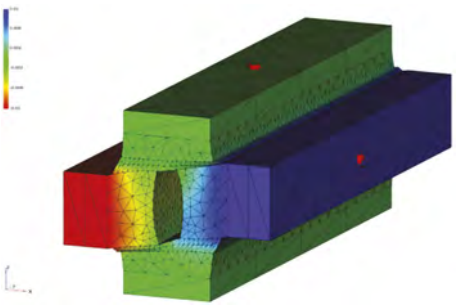

Figure 6. Calculation results. Displacement along axis Z.

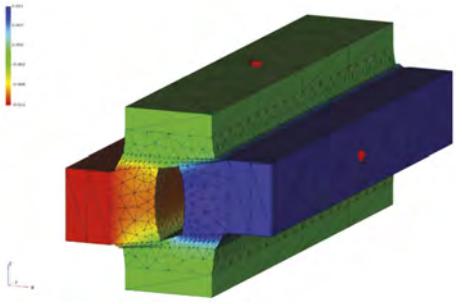

Figure 7. Calculation results. Displacement along axis X.

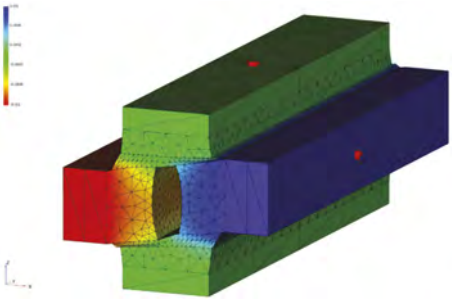

Figure 8. Calculation results. Displacement along axis Y.

Forces from the set displacements

N = 74177.7 Q_z = 101533.9 Q_y = -58653.3

Comparison with analytical solutions

Compliances of the joint according to the numerical calculation (there have been computed linear compliances, not as per an area) (m^2/кN):

$$\lambda_{p,x} = \frac{\delta \cdot s_y}{N} \cdot 10^8 = 13.5 \qquad \lambda_{p,y} = \frac{\delta \cdot s_y}{-Q_y} \cdot 10^8 = 17.0 \qquad \lambda_{p,z} = \frac{\delta \cdot s_y}{Q_z} \cdot 10^8 = 9.8$$

Analytical solution for vertical compliance (m^3/кN):

$$\lambda_{p,x,t} = \frac{t}{2 \cdot G_{m,t} \cdot b_1 \cdot s_y} \cdot 10^8 = 10.9 \quad \lambda_{p,y,t} = \lambda_{p,x,t} \quad \lambda_{p,z,t} = \frac{t}{2 \cdot E_{m,t} \cdot b_1 \cdot s_y} \cdot 10^8 = 4.5$$

One should mention that at differential strains of subsoil and considerable displacement of floor slabs in a platform joint their bearing capacity can reduce. This feature has been considered in Bakrysheva et al. (Bakrysheva 2017). In order to analyze a joint behavior there has also been addressed the modeling using the final element method but with account of nonlinear behavior of concrete and steel. As a result, there has been obtained the nature of joint failure in the form of shear fracture of an angle of wall panels. For the platform joint of 160-mm-thick panels (walls and floor slabs have the same thickness) it has been calculated the limit load applied to horizontal floor slabs – about 200 кN/m.

The calculation results of bearing capacity of platform joints at floor thickness 14 cm and panel thicknesses 14, 18 and 22 cm for different horizontal loads are given in Shapiro (Shapiro 2008).

3 CONCLUSION

The level of development of the existing standards and methods of calculation of joint stiffness for large-panel buildings does not correspond to the existing level of development of construction calculations and methods of numerical calculation.

Empirical formulae (2) и (3) are used for analytical calculation of stiffness of horizontal joints at making soil-structure interaction calculations for a large-panel building. As for the vertical direction, the numerical solution is almost equal to the analytical one (the difference is less than 5%). At shear along the wall the discrepancy is a bit bigger. However, the largest discrepancy with the analytical solution occurs at shear across the wall. It is connected with the fact that the analytical solution does not consider a possibility of floor slab rotation.

Soil-structure interaction with account of non-linear behavior of soils and structural materials

K.G. Shashkin, N.A. Evseev & V.V. Babanov
Institute "Georeconstruction", St. Petersburg, Russia

ABSTRACT: Linear-elastic finite elements are used at making soil-structure interaction calculations to describe models of reinforced concrete (RC) structures. This approach (effective stiffness method) is regarded as applicable in line with recommendations of numerous standards. The account of physically non-linear behavior of reinforced concrete is facilitated by reducing stiffness of elastic elements by conditional effective stiffness coefficients, which values largely differ in literature. The paper analyses relative differential settlements of the building at calculation of a physical non-linear RC model of a building and linear-elastic models with different effective stiffness ratios. Different approaches to assigning effective stiffness of RC lead to considerable differences in calculation results, especially considering soil-structure interaction The objective of the research is to develop a method of soil-structure interaction calculation using linear-elastic model of RC structures, so that its result were in good agreement with the calculations using a non-linear RC strain model. The paper proposes dependencies for estimating effective stiffness reduction ratios. Obtained dependencies allow considering non-linear material behavior without detailed modeling of non-linear behavior itself. It is demonstrated that a correct account of physical non-linearity of structural material is very important for soil-structure interaction calculations.

1 INTRODUCTION

The necessity to consider soil-structure interaction in order to limit differential settlements of structures in the conditions of soft soils constitutes an important feature of designing in St. Petersburg (Shashkin 2006, Ulitsky 2014). When computing settlement difference of a building it is crucial to model both non-linear flexibility of subsoil and stiffness of superstructures with account of their non-linear behavior. Incorrect setting of stiffness of elements in a model of a building due to underestimation of non-linear behavior of structures leads to its excessive stiffness and, consequently, underestimation of differential settlements. The account of physical non-linearity of RC structures, as RC structures almost do not exist without cracking, is especially relevant for calculations (Bondarenko 2004, Karpenko 1996).

In design practice due to complexity of non-linear calculations physical non-linearity of RC structures is facilitated by reducing an elastic modulus of structures in an elastic model with a help of factors, which consider non-linear behavior of reinforced concrete (Zalesov 2005, Zalesov 2007), their values are given in the regulatory documents (SP 430.1325800 and SP 63.13330). This approach is generally accepted in international design practice (Evseev 2018, Das 2019, Das 2020, Das 2021, Ngoc 2014, Zhongwen 2018). In a number of cases using standard values of stiffness reduction factors leads to overestimating stiffness of RC structures (Evseev 2018, Evseev 2017, Vasenin 2019). The objective of the research is developing a method of estimating of the linear-elastic effective stiffness of RC constructions for the finite element method of soil-structure interaction calculations, so that the results of linear-elastic calculations were consistent with physically non-linear calculations.

2 METHODS TO ASSESS BENDING STIFFNESS OF A BUILDING

Sagging of a building results in occurrence of longitudinal tensile forces at lower levels of a building and the compressive ones at upper levels. Meanwhile the stiffness of floor sections in cracking areas is considerably reduced due to compression and tension. After decreasing bending stiffness of a section due to cracking a stiffness of a structure remains almost permanent until the moment of failure. It explains the possibility of using reduction factors in calculations instead of a precise solution according to a non-linear deformation model.

Based on the calculation using a non-linear deformation model for the main types of sections of RC slabs with symmetrical reinforcement, there has been made a dependency for a coefficient of reducing bending stiffness k_1 of a section after cracking at a long-term action of a load from a complex parameter $E_s \cdot I_s / E_b \cdot I_b$ (Figure 1a). There has been also built a dependency of a coefficient of reducing bending stiffness of a section for a longitudinal force k_2 on a percentage of section reinforcement μ (Figure 1b). The diagrams show linear dependencies k_1 and k_2 on parameters $E_s \cdot I_s / E_b \cdot I_b$ and μ, respectively, which are approximated by functions shown in Figure 1 with a sufficient degree of accuracy:

$$k_1 = 1,25 \cdot \frac{E_s \cdot I_s}{E_b \cdot I_b} + 0,03 \tag{1}$$

where I_b, I_s are inertia moments for a concrete section and reinforcement, respectively, relative to a center of gravity of an element cross-section; E_s, E_b – an elastic modulus of reinforcement and an initial elastic modulus of concrete, respectively.

$$k_2 = 9,46 \cdot \mu + 0,07 \tag{2}$$

where μ is a percentage of section reinforcement, unit fraction.

The calculation was made for slabs of the following parameters: section height - 0.15…0.60 m; percentage of section reinforcement - 0.5 … 1.5%; thickness of a protective layer - 10…40 mm; grade of strength of concrete - B25…B50; reinforcement A400 at relative air humidity of the environment 75 %. As at design relative settlement differences of the model are considerably limited, compressive and tensile strains are also very negligible. In this case stiffness reduction factors for longitudinal compression and tension of the section after cracking are almost equal.

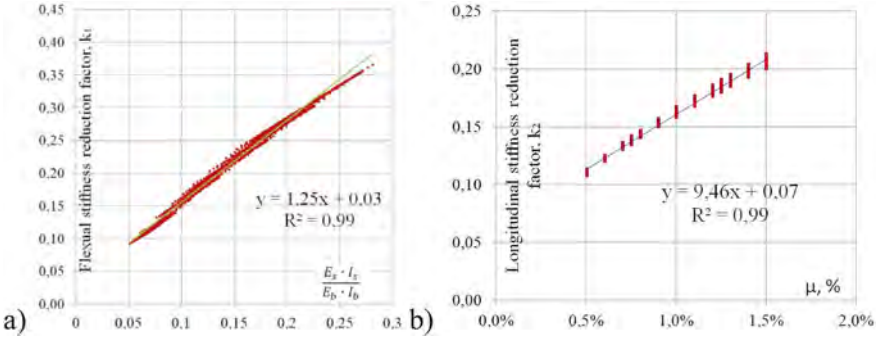

Figure 1. Reduction factors of section stiffness after cracking: a) – graph "k_1 - $E_s \cdot I_s / E_b \cdot I_b$", b) graph "$k_2$ – μ".

Stiffness of horizontal bearing structures in possible cracking areas – a span and an above-span area of floors - is taken with account of factors k_1 and k_2. There is no cracking in walls at bending of a building, their stiffness can be defined with a reduction factor of creeping for concrete.

3 USING THE PROPOSED METHODS TO ASSESS STIFFNESS OF A BUILDING AND CALCULATE DIFFERENTIAL SETTLEMENTS OF A BUILDING

There has been made a cycle of calculations of soil-structure system using elastic and non-linear deformation models for reinforced concrete. There have been considered 4 groups of schemes (Figure 2, 3): slab on elastic 600 and 400 mm – thick subsoil (without considering stiffness of superstructures, that is admissible, for example, for a flexible frame building); buildings of the wall structural scheme: "rigid" scheme (6-floor building) and more "flexible" scheme (1- floor building. Subsoil of the building was modeled with linear-elastic spatial 8-node finite elements. The building structure was modeled with 1*1 quadrangular shell finite elements. Piles were modeled as spatial road finite elements.

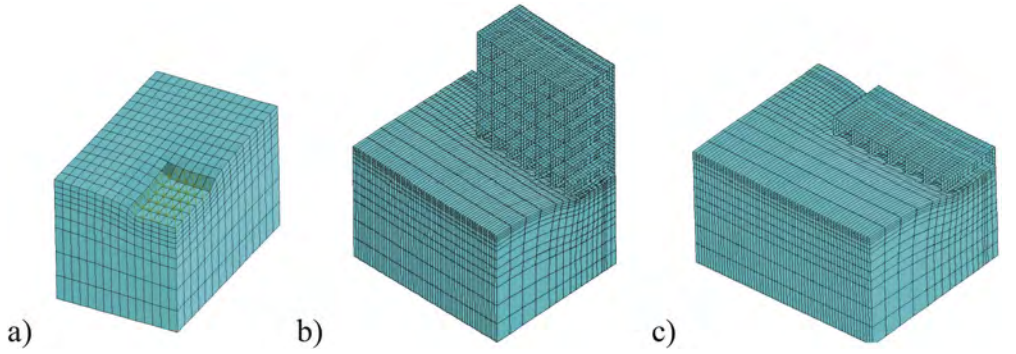

Figure 2. Deformation calculation models: a) – slab, b) – 6-floor building, c) – 1- floor building.

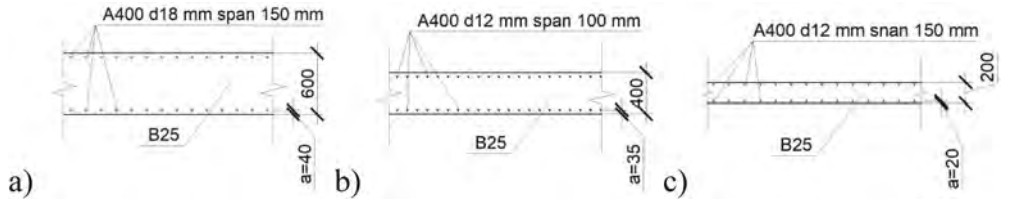

Figure 3. Structure of foundation and floor slabs in calculation models: a) – foundation slab 600 mm: k_1 = 0,127; b) – foundation slab 400 mm: k_1 = 0,141; c) – floor slab 200 mm, k_1 = 0,163, k_2 = 0,144, E_{eq} = 4056461 kPa, h_{eq} = 0,212 m.

Calculations have been made in the verified finite element method software "LIRA-SAPR" for four models of RC behavior:

a) Linear-elastic model. Reduction factors according to SP 430.1325800 relative to an initial elastic modulus of concrete: 0,6 – for walls; 0,2– for slabs.
b) Elastic model. The same reduction factor for all structures relative to an initial elastic modulus of concrete: k= $1/(1+\varphi_{b,cr})$, where $\varphi_{b,cr}$ – a factor of creeping of concrete as per SP 63.13330
c) Account of physical non-linearity of materials using deforming diagrams according to SP 63.13330: a trilinear one considering long-term action of a load at relative air humidity of the environment 75% and a bilinear one for reinforcement.
d) Account of quasi-elastic behavior of structures according to the developed methods.

The general view of the calculation model representing a one fourth of the building with soil is shown in Figure 2. Subsoil was modeled with elastic spatial 8-node finite elements. The building structures were modeled with 1*1 quadrangular shell finite elements. Piles were

modeled as spatial road finite elements. As regards soil models, there are used boundary conditions in the form of fixation at lower and lateral planes of the calculation model, that are standard for solving geotechnical problems.

Figure 4 shows graphs of dependencies of relative differences of settlements of a building on a value of maximum settlement. There has been considered a range of absolute settlements of a building which does not exceed limit values as per SP 22.13330. It was found out that a calculated difference of settlements considerably depends on methods of modeling of RC structures. A smaller difference of settlements corresponds to the calculations according to regulatory recommendations compared to the calculation according to a non-linear strain model of reinforced concrete. The difference increases together with a growth of flexibility of subsoil and reaches 30% and 50% using recommendations as per SP 430.1325800 and SP 63.13330, respectively. These differences can be rather considerable and they can influence on design solutions, for example, require increasing a length of piles for reducing a building settlement. When using the developed methods, a calculated difference of settlements is close to the values obtained by the non-linear calculation. The gap has not exceeded 5%.

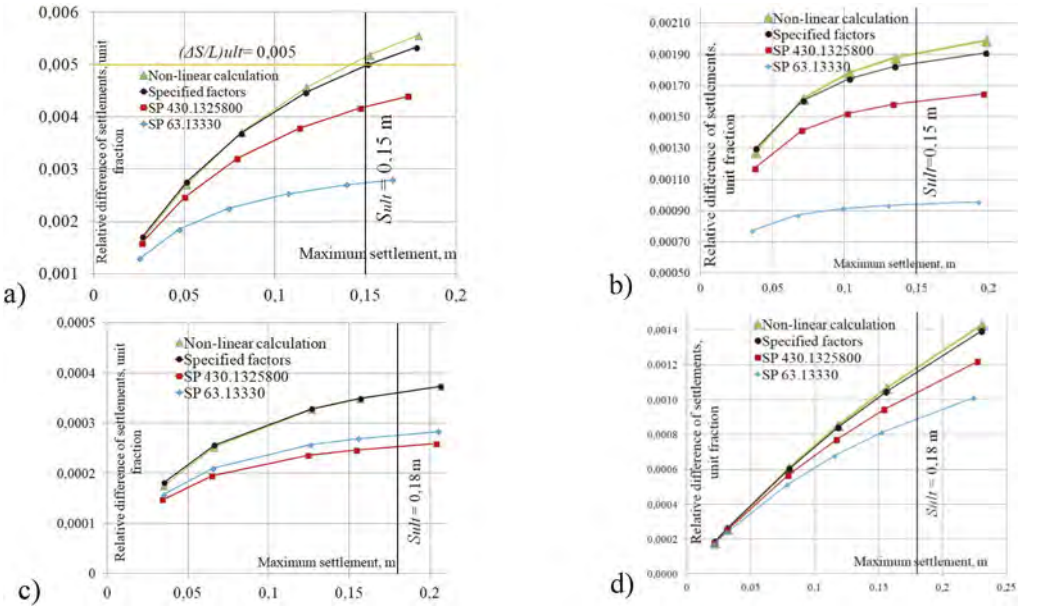

Figure 4. Dependencies of relative differences of settlements on a maximum settlement (m): a) – slab 400 mm, b) – slab 600 mm, c) – 6-floor building, d) – 1- floor building.

4 CONCLUSION

The calculation analysis has demonstrated that physical non-linear behavior of RC structures of a building exerts a considerable influence of the calculation results of the "soil-structure" system and it can affect design solutions on a construction of foundations and superstructures of a building. When computing differential settlements of a building the developed methods of facilitated estimation of reducing stiffness of RC structures of a building at the expense of physically non-linear behavior of RC structures allow reaching close consistence with the results of non-linear calculation. Facilitated approaches using standard values of stiffness reduction factors lead to overestimation of bending stiffness of a building and, consequently, underestimation of differential settlements of a building.

ABSTRACT: This study aims to identify optimal intensity measures (*IMs*) for use in probabilistic seismic demand models (PSDMs) for rectangular tunnels in three soil deposits. To this end, we performed an extended numerical parametricstudy involving two-dimensional time history analyses of selected soil-tunnel configurations to evaluate the response of the selected tunnels under transverse seismic shaking. A series of 23 *IMs* were selected and tested from motions at tunnel level deoth. The selected *IMs* were tested on several metrics, such as correlation, efficiency, practicality, and proficiency, based on an extended number of regression analyses between the IMs and the damage measure (*DM*), for the studied tunnels. The results indicate that the velocity spectrum intensity (VSI) at the ground tunnel level depth can be considered as the optimal *IM*, whereas the peak ground displacement (PGD) has the less efficient.

1 INTRODUCTION

Underground facilities are a crucial component of contemporary urban infrastructure. In the past, seismic design of tunnel structures received less attention than above-ground structures and most of them were designed and built without considering seismic effects. However, strong earthquakes have shown that even underground structures can be damaged significantly under severe seismic excitation (Hashash et al., 2001). An accurate evaluation of the seismic performance of underground structures is inevitable.

So far, several studies have investigated the correlation between *IMs* and the seismic response of the rectangular tunnel. Zhang et al. (2022) explore the optimum *IMs* for probabilistic seismic demand model (PSDM) of a three-story three-span subway station with different burial depths. Zhang et al. (2021) investigate optimum *IMs* for the performance assessment of a two-storey three-span subway station considering the effects of near-fault seismic excitations with velocity pulses, and then establish the fragility curves of subway stations using the optimum *IMs*. However, neither of the numerical models were validated against recordings. The literature review demonstrated that a study using a validated or verified numerical model to calculate the response of the rectangular tunnel has not yet been performed. Also, the more *IMs* is needed to deeply investigate the optimum *IMs* for PSDM.

The aim of this paper was to develop PSDMs for the rectangular tunnel. For that, 23 earthquake IMs are considered in developing PSDMs. The nonlinear numerical modeling of soil-tunnel configurations is constructed using FLAC^{2D} program (Itasca Consulting Group, 2011). A set of 85 ground motion records, which contain a wide range of amplitudes, magnitudes, epicentral distances, significant durations, and predominant periods, are utilized to perform nonlinear time-history analyses. Three different soil deposits are used in this study. Optimal *IMs* are recognized based on statistical indicators of PSDMs, which are the coefficient of determination, dispersion, practicality, and proficiency.

DOI: 10.1201/9781003299127-231

2 NUMERICAL MODEL AND ANALYSES

2.1 *Tunnel model*

The cross-section size is 12 m × 6 m (center-to-center width and height) and located 6 m below the ground. The thickness of side wall, top, and bottom slabs is 1 m. The center column with the cross-section of 0.4 m × 1.0 m is placed at every 3 m.

The tunnel structure was modeled using beam elements with an element size of 0.25 m. Table 1 and Figure 1 presents the properties and cross-section of the tunnel.

Table 1. Properties of the tunnel structure.

Parameters	Value
Density (kg/m^3)	2400
Young's modulus (Pa)	2.5×10^7
Poission's ratio	0.2

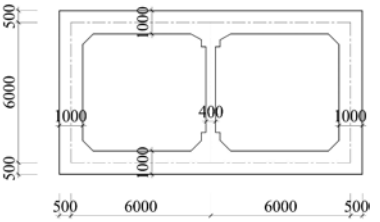

Figure 1. Cross-section of rectangular tunnels (unit: mm).

2.2 *Soil model*

The dimension of the computational model was set to 120 × 30 m (width × height) as presented in Figure 2. Three soil profiles P1, P2, and P3 corresponding to soil classes B, C, and D, according to Eurocode 8 (CEN, 2005). The density and Poisson's ratio of the soil were 1800 kg/m^3 and 0.3, respectively. The shear wave velocity profile of soil is presented in Figure 3. The soil medium was modeled using plane-strain quadrilateral elements. The element size, $\Delta l = 0.5$ m, was selected based on the following recommendation of Kuhlemeyer and Lysmer (1973). The *Sig3* model, which is available in FLAC^{2D} program, was employed to simulate the nonlinear behavior of soil.

2.3 *Soil-tunnel interface and boundary conditions*

The soil-structure interaction was simulated using the interface elements. The interface option *UNBONED* in the FLAC^{2D} program was used in this study. This contact interface can model a realistic partial-slip condition considering the gapping and the slipping phenomena between soil and tunnel under loading.

The free-field boundary was applied for lateral boundaries to absorb reflected waves. The bottom boundary was fixed to simulate the rigid boundary. The acceleration time history of the input motion was defined at the base of the numerical model.

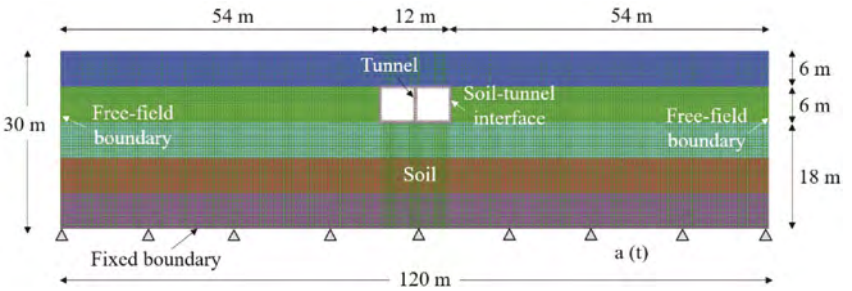

Figure 2. Soil-tunnel numerical configuration in FLAC^{2D}.

2.4 *Ground motions*

A set of 85 ground motion records are selected from historical earthquakes, which are available in the PEER center database (https://ngawest2.berkeley.edu). A wide range of earthquake amplitudes, magnitudes, epicentral distances, significant durations, and predominant periods is considered in used ground motions whose response spectra are shown in Figure 4.

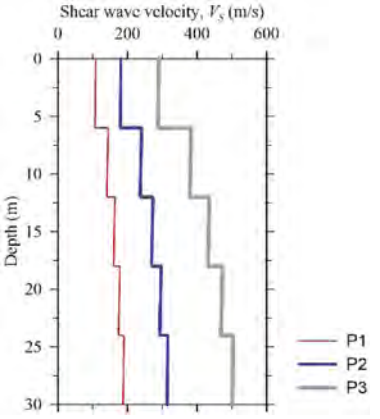

Figure 3. Shear wave velocity profiles.

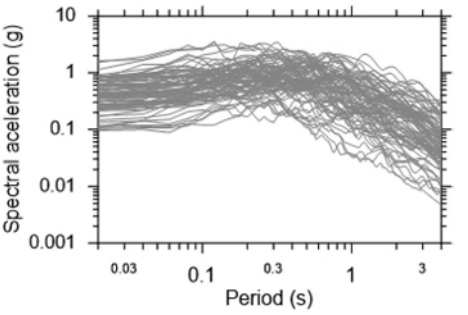

Figure 4. Input ground motions.

2.5 *The numerical validation*

The numerical model in this study was validated against the centrifuge test by (Gillis, 2015). Detail of the centrifuge test and comparison between numerical and experimental results were reported in Nguyen et al. (2022b). The compared results demonstrate that the numerical model was reliable for carrying out parametric research.

3 SELECTION OF OPTIMAL INTENSITY MEASURES

3.1 *Representative numerical results*

This study adopts the results proposed by Nguyen et al. (2022a). The representative numerical result is bending moment at the base of the center column, which is a critical section.

3.2 *Selection of examined seismic intensity measures*

This study accounts for 23 common ground motion *IMs*and these parameters are calculated for every motion record using SeismoSignal (Seismosoft, 2012). The used *IMs* are described in Nguyen et al. (2022b).

3.3 *Overview of PSDM*

PSDM, which contains the relationship between structural demand and an earthquake *IM*, needs to be appropriately established in the probabilistic performance-based seismic design. The most common expression of the relationship between seismic demand and earthquake *IMs* is the power form in Eq. (1) (Nguyen et al., 2021, Cornell et al., 2002):

$$S_D = a \times (IM)^b \tag{1}$$

where S_D is the median value of structural demand; a and b are the regression coefficients; IM is the earthquake intensity measure considered. This equation can be rewritten in forms of linear regression as follows:

$$ln(S_D) = \ln(a) + b \times ln(IM) \tag{2}$$

The conditional failure probability that the structural demand (D) exceeds its capacity for a given *IM* in the fragility analysis can be expressed as:

$$P_f = P[D \geq d|IM] \tag{3}$$

where d is the specified value, normally it is based on the structural capacity. Assuming that the structural demand and capacity follow lognormal distributions, Eq. (3) can be rewritten as:

$$P[D \geq d|IM] = 1 - \Phi\left[\frac{\ln(d) - \ln(S_D)}{\sigma_{D|IM}}\right] \tag{4}$$

The uncertainty in the seismic demand $\sigma_{D|IM}$ is approximated as the dispersion of the simulated demand with respect to the regression fit for the calculated damage data obtained from the non-linear time history analyses, as shown in Eq. (5):

$$\sigma_{D|IM} = \sqrt{\frac{\sum (\ln(d_i) - \ln(a \times IM^b))^2}{n-2}}$$

3.4 *Results of PSDM study*

3.4.1 *Correlation testing*

Figure 5 presents the regression analyses between four representative seismic *IMs* and *DM*. Notably, the *IMs* is determined from the motions at tunnel level depth. It can be observed that VSI has the strongest correlation with the *DM*, followed by PGV and HI. The correlation coefficients R^2 for the three most correlated *IMs* are 0.762, 0.754, and 0.747, respectively. Furthermore, the weakest correlation between *IMs* and *DM* is T_p with a correlation coefficient of 0.118, followed by CAV and PGV/PGA (i.e. correlation coefficients of 0.315 and 0.380, respectively).

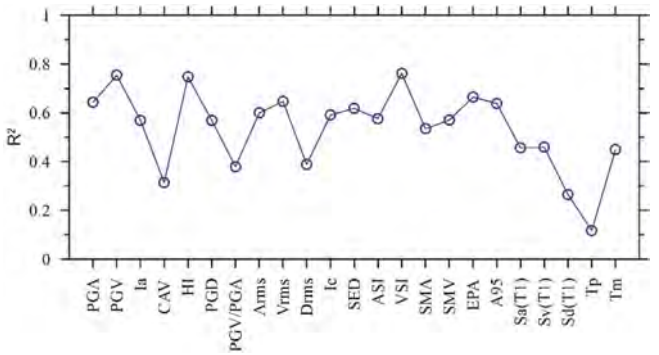

Figure 5. Regression parameter R^2 between four representative seismic *IMs* and *DM*.

3.4.2 *Efficiency testing*

The results of the efficiency analyses are depicted in Figure 6. VSI, PGV, and HI are considered more efficient measures since they have smaller standard deviations $\sigma_{D|IM}$. Among them, VSI is the most efficient *IMs* with the lowest standard deviation $\sigma_{D|IM}$, i.e. 0.194. The corresponding $\sigma_{D|IM}$ for the next two most efficient *IMs* are 0.195 and 0.197, respectively, which are slightly higher than that for VSI. The maximum standard deviation $\sigma_{D|IM}$ is observed for A_{rms}, i.e. 0.714, indicating that this measure is the least efficient. This is followed by PGA and S_d(T1). Their corresponding standard deviations $\sigma_{D|IM}$ are 0.426 and 0.404, respectively, which are lower than that for A_{rms}.

3.4.3 *Practicality testing*

Figure 7. summarises the *b* values calculated from the regression models for each *IM-DM* pair. The comparisons in Figure 7 suggest that T_m is the most practical *IMs* among others, because it has the maximum slope *b* of 0.859. ASI and EPA proved to be the second and third most practical *IMs*, with the corresponding slope *b* equal to 0.841 and 0.798, respectively. In contrast, SED is found to be the least practical *IM* among the other tested *IMs*, as it exhibits the minimum slope *b* of 0.233 for the examined cases. D_{rms} and PGD prove to be the other two least practical *IMs*, with slightly higher slope values b, i.e. 0.282 and 0.343, respectively.

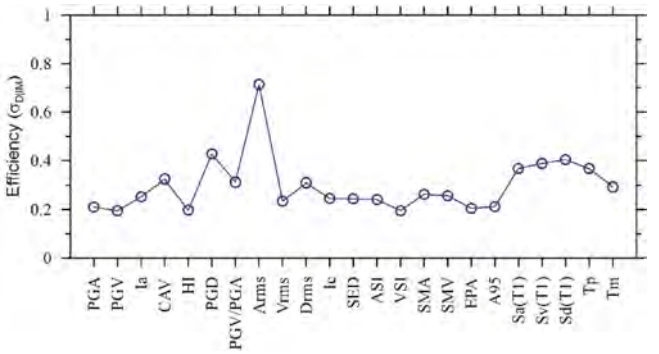

Figure 6. Regression parameter $\sigma_{D|IM}$ between four representative seismic *IMs* and *DM*.

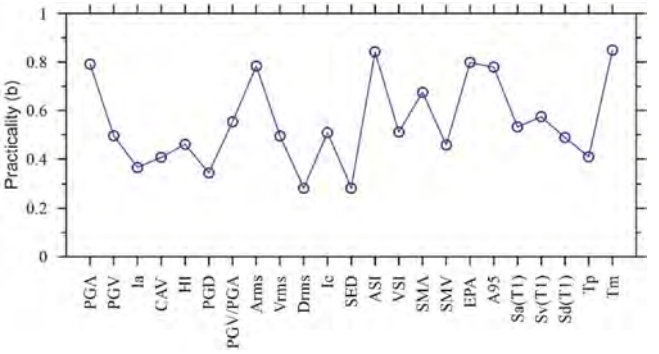

Figure 7. Regression parameter *b* between four representative seismic *IMs* and *DM*.

3.4.4 *Proficiency testing*

Padgett et al. (2008) proposed an indicator, namely proficiency, which can balance the selections between efficiency and practicality. The proficiency is defined by the ratio of dispersion ($\sigma_{D|IM}$) to the practicality (*b*), as shown in Eq. (6). The smaller value of ξ is, the more proficient is.

$$\xi = \frac{\sigma_{D|IM}}{b} \tag{6}$$

Figure 8 compares the computed ξ for the considered *DM* with regard to the 23 tested *IMs*. EPA is the most proficient *IM* due to the corresponding smallest ξ of 0.256, followed by PGA and A_{95}, which have ξ values of 0.266 and 0.273, respectively, which are quite close to the value for EPA. PGD is the less proficient measure, as it has the maximum ξ, i.e. 1.243. The next two least proficient *IMs* are D_{rms} and A_{rms}. Their corresponding values of ξ are 1.095 and 0.911, respectively, which are considerably lower than the value for PGD.

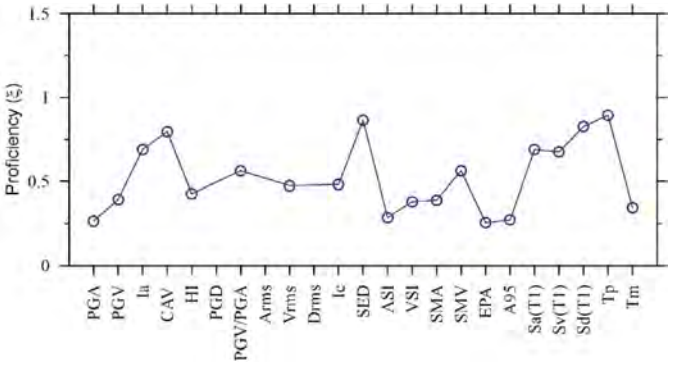

Figure 8. Regression parameter between four representative seismic *IMs* and *DM*.

4 CONCLUSIONS

This study developed PSDMs for various *IMs* and identified optimal *IMs* for the seismic performance of the rectangular tunnel structure embedded in three soil deposits. A group of 85 ground motion records and 23 different *IMs* were used in nonlinear time-history analyses. The selected *IMs* were tested using the correlation, efficiency, practicality, and proficiency metrics, with the aim of identifying the optimal *IMs* from the selected ones for the examined soil-tunnel systems. The following conclusions are drawn.

The optimal *IMs* for PSDMs of the rectangular tunnel structure are VSI followed by PGV and HI. The PSDMs with respect to these *IMs* contain higher values of R^2, lower standard deviations and proficiency values, and larger practicalities than those of others.

The less efficient *IMs* for PSDMs of the rectangular tunnel structure are PGD, D_{rms}, and A_{rms}. These *IMs* are displacement- and acceleration-based parameters.

A study on the mobilization of negative skin friction along end bearing piles installed through layered soils

F.S.A. Ansar & L.I.N. De Silva
University of Moratuwa, Colombo, Sri Lanka

ABSTRACT: This paper presents a study on the mobilization of negative skin friction (NSF) through end-bearing piles for a soil profile containing soft soils sandwiched between stiff residual soil layers. A commercially available finite element package PLAXIS 2D has been used for the analysis. The model has been validated using case study results available in the literature. The position of the neutral plane and magnitude of drag load is analyzed with the change of soil layer thickness for different pile diameters and axial loads. All results were compared with an analytical method suggested in Sri Lankan guidelines and the variation among results was less than 20%. Pile settlement and axial shortening significantly affect the mobilization of NSF whereas the magnitude of the axial load has no significant effect. It can be concluded that finite element analysis can reasonably predict the mobilization of NSF on piles installed through layered soil profiles.

1 INTRODUCTION

Negative Skin Friction (NSF) is induced whenever the soil settles more than the pile (Fellenius, 1984, Wong & Teh, 1996). Negative skin friction has two effects on the pile; The drag load which is the additional compressive axial force and the down drag which is the additional settlement (Chen et al., 2009). Drag load reduces the bearing capacity since it becomes an additional load to the pile. The drag load caused by NSF depends on the location of the neutral plane and the distribution of NSF throughout the pile. Therefore, to estimate the NSF location of the neutral plane and the distribution of NSF throughout the pile should be analysed (Liu et al., 2012, Matyas & Santamarina, 1994). The neutral plane (NP) is the place where the relative settlement is zero. Above the neutral plane, the skin friction is negative. NSF is a complex phenomenon that depends on several factors. Since NSF directly relates to soil settlement all the factors affecting consolidation affect NSF.

According to past researchers, it has been found that the relative settlement of even a few millimetres (2-5 mm) between soil and the pile would mobilize NSF (Chen et al., 2009, Kim & Mission, 2011, Matyas & Santamarina, 1994, Wong & Teh, 1996). Research had been done to evaluate the NSF of different soil types and on layered soil. Drag force and down drag would vary with soil profile (Comodromos & Bareka,2005). Thus, it is important to investigate different types of soil profiles.

Terzaghi consolidation theory overestimates the drag load and down drag since it considers the NSF is fully mobilized in the pile(Chen et al., 2009, Comodromos & Bareka, 2005). Analytical, empirical, and numerical methods have been used to evaluate the mobilization of NSF. The Finite Element Method (FEM) and Finite Difference Method (FDM) have improved the understanding of the mobilization of NSF for various soil and pile conditions (Liu et al., 2012).

When the soft soil layer is at the top of the soil profile, the depth to the neutral plane increases when the thickness of soft soil layer increases and the increase is significant for the higher thickness of the soft soil layer (Hanna & Hoque, 2008). Though there are several research conducted for a case of a soft soil layer at the top of the soil profile, a profile that is

DOI: 10.1201/9781003299127-232

sandwiched is not available in the literature. Also, the analytical and empirical methods are difficult to use in practice when the number of soil layers increases. In this research, the mobilization of NSF with the change of soft soil layer thickness, for a soil profile of soft soil sandwiched between stiff residual soil is conducted using FEM.

2 METHODOLOGY

2.1 *Finite element model*

A numerical model was developed using PLAXIS 2D (version 8.2) software. A single pile was modeled as a volumetric element using the axisymmetric model. First, the model was validated using a known case and the analysis was conducted using the same model. The thickness of the soft soil layer and the bottom stiff residual soil layer was varied to investigate the variation of NSF with the layer thicknesses. The influence of load on the pile was also investigated.

2.2 *Model validation*

The verification of the model was conducted using a known case by Indraratna et al., (1992). This case was conducted for soft Bangkok clay. The subsoil was a thick clay layer overlying a sand layer. Clay layers were categorized into three layers according to soil properties (Tables 1 and 2).

Table 1. Material properties of end bearing layer and the pile (reprinted from (Liu et al., 2012)).

Material	Depth m	Density kN/m^3	Young's modulus MPa	Poisson's ratio	Coefficient of permeability m/day
End bearing	24-28	17	28	0.33	$3.72E^{-05}$
Pile	0-27	15	3000	0.33	$1.00E^{-05}$

Table 2. Mohr-Coulomb parameters used in model validation (reprinted from (Liu et al., 2012)).

Depth m	Density kN/m^3	Young's Modulus MPa	Poisson's ratio	Coefficient of permeability m/day	Cohesion kPa	Friction angle
0-4	17	4900	0.20	$6.76E^{-04}$	3	26°
4-10	17	4900	0.33	$5.50E^{-05}$	5.9	25°
10-20	17	4900	0.33	$2.60E^{-05}$	14.7	25°
20-24	17	6370	0.20	$3.72E^{-05}$	5.9	23°

A circular pile of 400 mm in diameter and 27m long has been used for the test. A 2m high embarkment has been raised as the surcharge. The density of the embarkment material was 16.67 kNm^{-3} with 24×14 m base dimensions and side slopes of 2:1. A UDL of 33.35 kPa, with a radius of 7.4m was used as the surcharge in the model. The Mohr-Coulomb model was selected for validation. A similar procedure was used by Hanna and Sharif, (2006) and Liu et al., (2012). The analysis results are presented in Table 3 and Figure 1.

Table 3. Results of model validation.

Parameter	Actual (Indraratna, B.,1992)	Present study	% Deviation of the model from actual
Max. NSF (kN/m^2)	17.64	-21	19%
Depth at Max. Nsf (m)	13.50	10	26%
Neutral point (m)	17.50	16.9	3.4%

The model results have a good agreement with the actual case. Therefore, the same modelling procedure has been used for the analysis of NSF of a single pile.

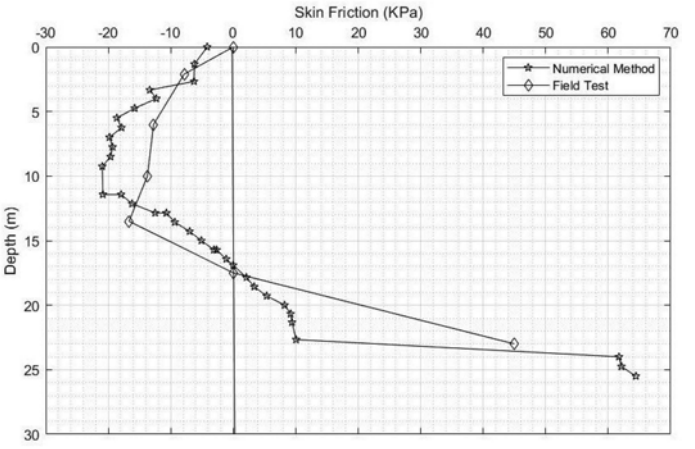

Figure 1. Comparison of model validation.

2.3 *Model details*

A circular pile with diameters 0.4 m,0.6 m, and 1 m and a length of 27 m were modelled. A model radius of 30 m and depth of 27 m was used. The mesh was formed by 15-noded elements with 'medium' global coarseness (Figure 2). The left and right boundaries were vertically free and fixed horizontally. The bottom boundary and the pile were fixed. The groundwater table was placed at the ground level. A 33.5 kPa Surcharge was applied as a uniformly distributed load (UDL).

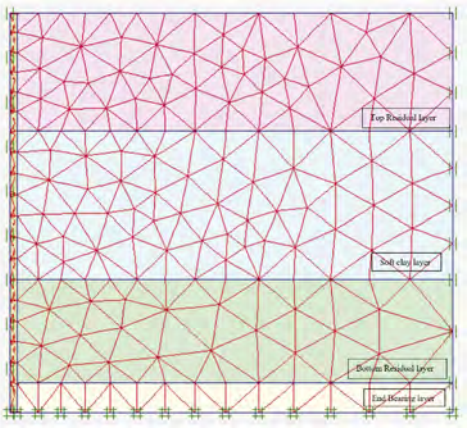

Figure 2. Finite element model with mesh.

The end bearing capacity of the rock was assumed as 5000kPa. The load which could be withstood for this end bearing capacity was applied at the top of the pile (P). An interface reduction factor (R_{inter}) value of 0.67 was used. The initial conditions of the soil are obtained by the K_0 procedure. A consolidation analysis was conducted. In the first stage, the loads and the interface were activated. Analysis results were obtained for the case of minimum excess pore water pressure, $P_{min} < 1$ kPa.

2.4 *Soil profile*

A soft soil layer was sandwiched between two stiff residual soil layers. Drained parameters were used for soil. A residual soil layer of 8m thickness was maintained at the top. The thickness of the soft soil layer and the bottom stiff residual soil layer were varied while a 2m of the

pile socket length was maintained in the end bearing layer. The soft soil layer thickness was varied as 5,7,10,12,15 m and the corresponding bottom residual layer thickness was 12,10,7,5,2 m respectively. Residual soil properties were obtained from Law et al., (2014). Soil and pile properties used for the analysis are listed in Table 4.

Table 4. Material properties used in the model.

Material	Depth m	Model	Density kN/m^3	Young's Modulus kPa	Poisson's ratio	Coefficient of permeability m/s	Cohesion kPa	Friction angle
Top residual	0-8	MC	17	$4.50E^{+04}$	0.25	$1.00E^{-05}$	5	31°
Soft clay	8-t	MC	15	1000	0.35	$1.00E^{-08}$	3	20°
Bot. Residual	t-25	MC	18	$9.00E^{+04}$	0.25	$1.00E^{-05}$	8	33°
End bearing	25-27	LE	22	$1.00E^{+06}$	0.20	$1.00E^{-10}$	-	-
Pile	0-27	LE	15	$3.00E^{+07}$	0.33	$5.04E^{-10}$	-	-

* t is the soft soil layer thickness *MC is Mohr-Coulomb model * LE is Linear Elastic model

2.5 *NSF calculations*

The shear stress along the pile-soil interface was obtained from the software and the drag load was calculated as follows.

$$\text{Total Drag Load} = \sum \Delta\text{NSF} \tag{1}$$

$$\Delta\text{NSF} = 2\pi R^{*}\Delta y^{*}\Delta\tau \tag{2}$$

where Δy = distance between selected points; $\Delta\tau$ = Average pressure between selected points and R= Radius of pile

The values obtained from the model were compared with the method proposed by the ICTAD/DEV/15 guidelines which is mostly used by the practitioners of Sri Lanka. β method is proposed in this guideline.

$$\tau_{neg} = \beta \times p(d) \tag{3}$$

where τ_{neg}= Unit skin friction; β=Negative Skin friction factor (Proposed values are given in the guideline) and p(d)= Vertical effective stress at the mid-depth of the layer that applies negative skin friction

Force due to NSF can be obtained by multiplying τ_{neg} with the associate pile area

3 RESULTS OF FEM ANALYSIS

3.1 *Scenario 01: Axial load on pile top*

First, the load which could be withstood for the end bearing capacity of the pile was applied to the pile and the layer thickness was varied as specified. NP was within the soft soil layer for each layer thickness. The position of NP was not significantly varied with the change in diameter of the pile. A linear relationship can be observed between the graph of NP/L vs T/L where T is the soft soil layer thickness and L is the pile length (Figure 3). The NP varied within 85 to 100% of the soft soil layer.

The Drag load due to the NSF was calculated using Equation 1 and the method proposed in ICTAD. The deviation among the values was less than 20% in each case.

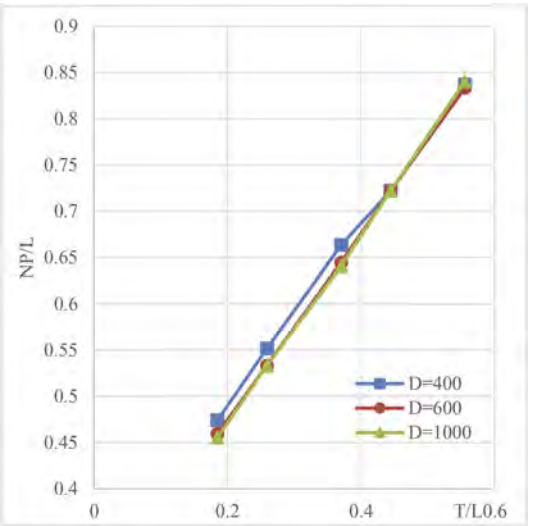

Figure 3. Relationship between soft soil thickness and neutral point (Scenario 01).

3.2 *Scenario 02: Effect of magnitude of axial load on pile*

To investigate the effect of axial load on the top of the pile, the load on the pile was varied for the 400 mm diameter pile. It was observed that the NP and the distribution of NSF don't have a significant effect on the magnitude of the load applied unless P=0. NP is deep when P=0, compared to P≠0. Figure 4 shows the variation of drag load with load applied at the top

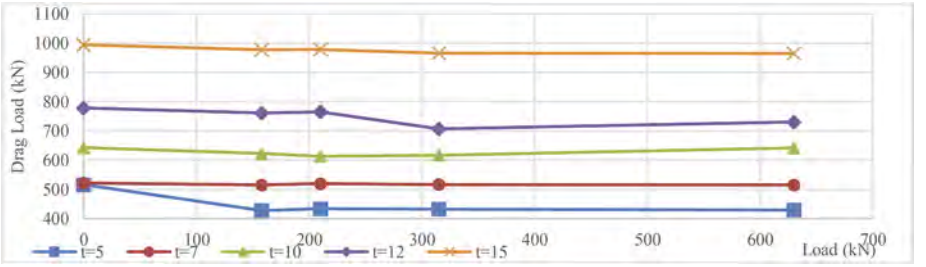

Figure 4. Variation of drag load with load applied (Scenario 02).

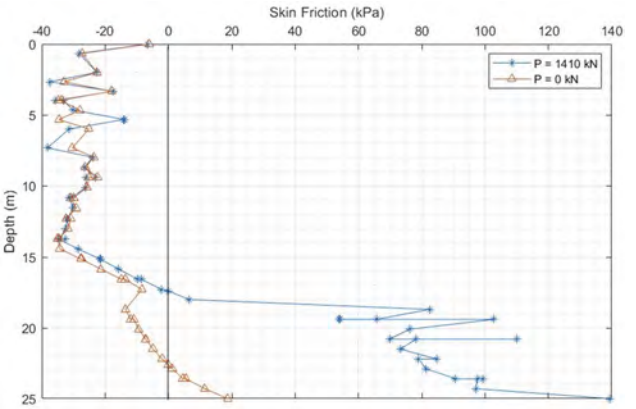

Figure 5. Variation of NSF with and without an axial load on the pile.

of the pile. Figure 5 represents the variation of NSF with depth plotted according to the analysis results for the case of soft soil layer 7 m.

4 CONCLUSION

The mobilization of Negative Skin Friction through soft soils sandwiched between stiff residual soil layers, with the change of soft soil layer thickness was analysed using the finite element software, PLAXIS 2D. The results obtained were compared with the method suggested by ICTAD (now it is called CIDA), which is mostly used by Sri Lankan practitioners.

The research was conducted under 2 scenarios by changing the load applied to the pile at the top. When a load is not applied on the pile NSF is fully mobilized along the soft soil layer while NP lies at the boundary between the soft soil and a bottom residual layer or within the residual soil layer. There is a slight variation of the NP with the change in diameter. When the diameter increases the depth to NP increases. Since the pile is fixed at the bottom the settlement of the pile can be neglected and the axial shortening of the pile is not significant as a load is not applied to the pile. So, the governing factor is the soil settlement.

When a load is applied to the pile the NP lies within the soft soil layer. NP doesn't have a significant variation with the pile diameter. The NSF mobilizes up to 85-98% of the soft soil layer. It was observed that the full mobilization of NSF happens with a small load applied to the pile. The axial shortening comes to play as a load is applied to the pile. Hence, the NP shifts up compared to the previous case. Also, the drag load has a good agreement with the method proposed by ICTAD (now called CIDA). Hence the FEM analysis can be used to predict the variation of NSF in complex cases with reasonable accuracy.

Ground Master Construction Co, Ltd, Taipei, Taiwan

ABSTRACT: The purpose of barrette pile foundations is to transmit heavy loads into the ground and are becoming the preferred underground foundation system. In general, the static pile load tests are commonly conducted to estimate the pile bearing capacity and determine the in-situ soil parameters. In this study, a three-dimensional finite element model was used to simulate the behavior of barrette piles to determine in-situ soil parameters using the load-settlement relationship, and evaluating the pile behavior simulated by the structural elements-embedded beams.

Keywords: barrette pile, underground foundation system, static pile load test, retaining structure

1 INTRODUCTION

In general, the use of piles can effectively suppress soil liquefaction, which is important for area that has frequent earthquakes, such as Taiwan. In recent years, barrette piles have become more widely used in various types of building foundations, including barrette piles and barrette piles combined with buttress walls. Besides, rectangular-shaped piles have a larger pile shaft area than round-shaped piles. Therefore, barrette piles can contribute more skin friction and support higher superstructure load, which is a favorable foundation for urban areas.

The static load test is commonly used for determining the load-bearing capacity of the pile. In this study, the three-dimensional (3D) numerical analysis was used to simulate the static axial load test of the barrette pile, which is the most basic test and involves the application of vertical load directly to the pile head. Simulation of the pile load test is conducted to provide back analysis from the load-settlement results and determine the correct soil parameters of the site. Furthermore, the pile skin friction from the results of the pile loading test on-site was also used for the structure element: embedded beam. The soil parameters and numerical method are thus used in the following simulation stages and components. The simulation of barrette piles with embedded beam can reduce the difficulty during the model configuration (compared to solid element method) and provide more accurate prediction on soil-pile interaction behaviors.

2 SITE CONDITION AND NUMERICAL MODEL

2.1 *Details of excavation site condition*

The project was located near Gong-Guan MRT station, Taipei City, Taiwan. Figure 1 shows the plan view of the site. It consists of three main buildings, which are 12, 10, and 10-story

DOI: 10.1201/9781003299127-233

buildings. Each building has a 3-story basement with a construction area of 113,162 m2. The site includes 127 individual barrette piles, 39 barrette piles combined with the buttress wall, and two groups of the barrette piles axial static load test (both in compression and tension). The dimension of barrette piles is 2700×1000 mm, and the load applied is 4050 ton-force. The CP1 (compression pile 1) pile is 46.45 m in length and near borehole no. 1. The CP2 pile is 49.45 m in length and near borehole no. 8. Figure 2 shows the soil properties in the field.

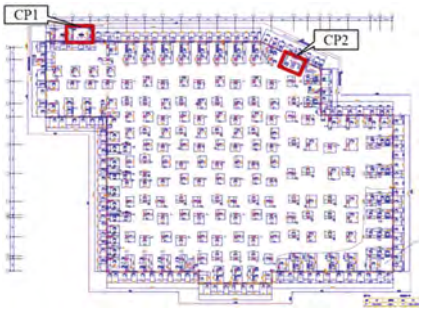

Figure 1. Location of Case Study in Taipei, Taiwan.

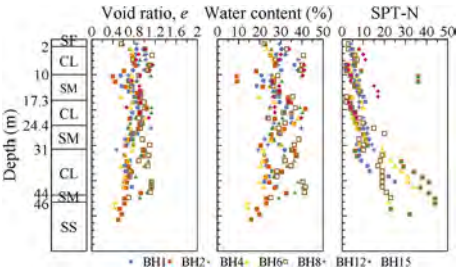

Figure 2. Soil properties at the in-site.

2.2 *Numerical model*

Three-dimensional (3D) finite element analyses were conducted to simulate the barrette piles axial load test with PLAXIS 3D v.22. The dimensions of the finite element model were 208.8 m x 208.8 m x 130.5 m. Figure 3 shows the 3D finite element model of barrette piles and generated mesh. Table 1 summarizes the detail of the PLAXIS 3D models adopted in this study.

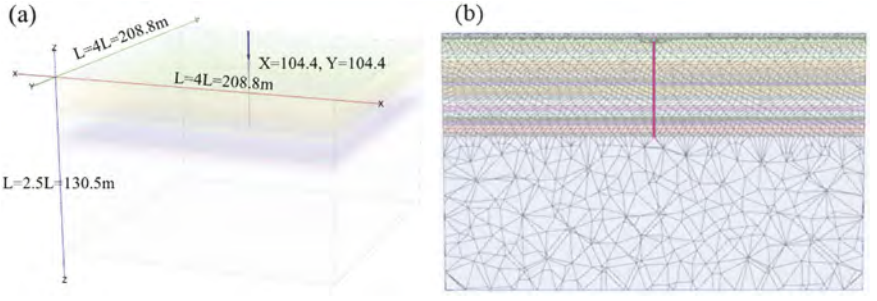

Figure 3. (a) The three-dimensional numerical model for a single barrette pile (b) 3D finite element meshing of 10-node tetrahedrons soil element.

Table 1. Adapted Models description.

Model number	Young's modulus reduction factor of pile, R_E	Model number	Young's modulus reduction factor of pile, R_E	$\gamma_{0.7}$
HS-A	R_E=0.6	HS small-A	R_E=0.6	1×10^{-4}
HS-B	R_E=0.7	HS small-B	R_E=0.7	1×10^{-4}
HS-C	R_E=0.8	HS small-C	R_E=0.8	1×10^{-4}
HS-D	R_E=1.0	HS small-D	R_E=1.0	1×10^{-4}
		HS small-E	R_E=0.7	7.5×10^{-5}

The stabilizer at the top pile was modeled as a beam element, while the barrette pile was modeled by using an embedded beam element to simulate the skin resistance of barrette piles. Hence,

the soil friction from the pile load test could be adopted for the skin friction in the embedded beam model. Table 2 shows the input parameters for structural elements. In these analyses, 21 construction stages were considered to simulate different loading conditions, as listed in Table 3.

Table 2. Input parameters for structural elements.

Structure	Type	A (m^2)	γ (kN/m^2)	I_2 (m^3)	I_3 (m^3)	E (GPa)	Axial skin resistance	Base resistance, F_{max} (kN)
Barrette (no friction)	Beam	2.7	26	1.640	0.225	35.8	-	-
Barrette	Embedded beam	2.7	26	1.640	0.225	35.8	Multi-linear	3000

Phase 21	Apply the axial load to the barrette pile from 4050 tons.

2.3 *Soil parameters*

The hardening soil model is an advanced elastoplastic constitutive model that is used for simulating both stiff and soft soil behaviors. Moreover, HS small is a modification of the hardening soil model that accounts for the increased stiffness of soils at small strains. Table 4. shows the properties of the soil layers by using HS and HS small soil models.

Table 4. Soil parameters.

Soil	Depth (m)	γ_m (kN/m^3)	e	ϕ'	SPT-N	Su (kPa)	E_{ur}^{ref} (MPa)	E_{50}^{ref} (MPa)	E_{oed}^{ref} (MPa)	G_0^{ref} (MPa)	$\gamma_{0.7}$
SF	0~2	20.6	0.7	30	3		8.2	2.7	2.7	9.6	1×10^{-4}
CL	2~10	18.3	0.9	30	3~4	19~25	65~72	21~23	15~17	76~84	1×10^{-4}

3 ANALYSIS RESULTS AND DISCUSSION

3.1 *Static load-settlement curve*

Figures 4 and 5 show the 3D FEM results and static pile load test for the Load-Settlement relationship by using HS and HS small model. The results showed that the pile settlements from the HS model decreased non-linearly, while the HS model results slightly overestimated the settlement from the monitor data at the initial working loading ($P < 2500$ Ton). It is also found that the HS and HS small model simulation had a close agreement with the monitoring data for $R_E = 0.7$ (30% reduction of pile Young's modulus).

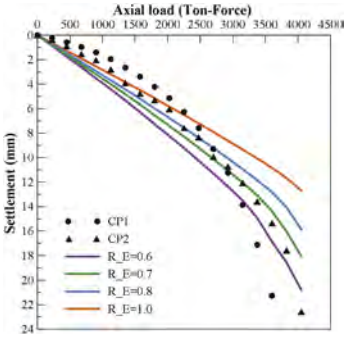

Figure 4. Simulation of Load-Settlement Curve from PLAXIS 3D HS model.

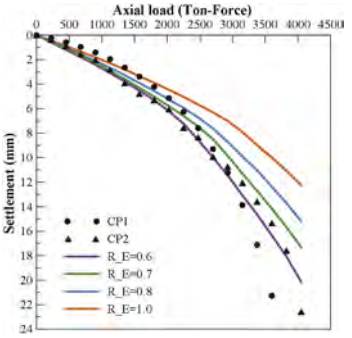

Figure 5. Simulation of Load-Settlement Curve from PLAXIS 3D HS small model.

According to Figure 6, it is found that the HS small model results could fit the monitor data, which was better than that of the HS model results. The reason is that the HS small model is a modification of the HS model, which considers the stiffness dependency of small strains. Based on the study conducted by Li (2022), the $\gamma_{0.7}$ range in Taipei city range is 1×10^{-4} ~ 5×10^{-5}. The difference in the results of changing the $\gamma_{0.7}$ is not significant because the shear strain has not yet reached 70% of $G_{0.}$ Figure 7 shows a simulation of pile behavior using the embedded beam in the HS small model. The results showed that this model could provide accurate skin friction and determine the typical loading behavior of barrette piles.

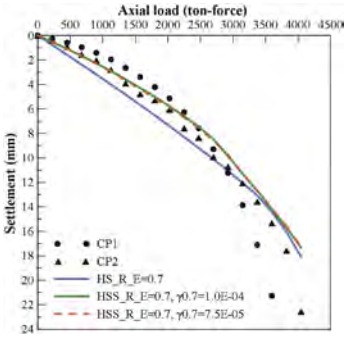

Figure 6. Comparison of load-settlement curve from PLAXIS 3D HS and HS small model.

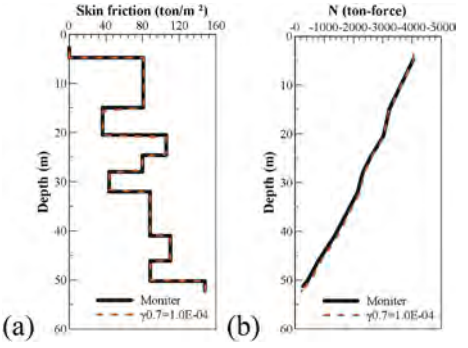

Figure 7. Simulation of pile behavior using embedded beam in HS small model: (a) Unit Shaft Resistance of Curve at CP2 (b) Distribution of Normal Stress of Curve at CP2.

4 CONCLUSION

In this paper, PLAXIS 3D was used to simulate barrette piles, and in-site pile static load tests were used to correct the soil parameters of this case. Following are some of the conclusions from the paper:

1. The pile structure element was modeled as an embedded beam in PLAXIS 3D, which can input soil-averaged pile shaft skin resistance from in-situ pile loading tests and yield more accurate pile behavior.
2. The stiffness dependency of small strain behavior could be considered by using HS small model, which could enhance the soil stiffness under small strain so that the Load-settlement curve is closer to the monitor data.

3. In the barrette pile load test, the displacement of the top pile under the large load is small, indicating that the soil is within the range of small strain. In such a case, the shear strain has not yet reached 70% of G_0, so the change of $\gamma_{0.7}$ is not sensitive to the results.

Preliminary assessment of non-conforming *u-p* elements for saturated geomaterials

V.N. Kaliakin & D. Botchway
Department of Civil and Environmental Engineering, University of Delaware, USA

ABSTRACT: To simulate the response of saturated geomaterials requires a numerical approach such as the finite element method that employs a generalized Biot formulation. Under isothermal conditions, the primary dependent variables are displacements (u) and pore pressure (p), which are suitably coupled. The stability of such "*u-p*" elements requires that the displacement approximation be one order higher than the pressure approximation. Typical elements employ quadratic and linear approximation for u and p, respectively. Since, according to Darcy's law, the velocity of flow is proportional to the gradient of the pore pressure, the approximate velocity is thus constant over an element. In slow "consolidation-type" problems the accurate computation of such velocities is not crucial, as they are generally very small. The need to accurately simulate the effects associated with rising sea levels, rapidly rising flood waters, etc., however, now requires that accurate approximate velocities be computed. Consequently, robust and computationally efficient higher-order *u-p* elements need to be used in simulating such problems. The development of such elements that are is not a straightforward undertaking. This paper explains this difficulty and, as a measure to overcome it, describes some non-conforming elements that have been recently developed.

1 INTRODUCTION

Historically, mixed finite elements have been successfully applied to three general classes of problems, namely: 1) problems involving a physical (kinematic) constraint such as incompressibility, inextensibility, etc., 2) certain physical problems involving higher-order derivatives in their governing differential equations and/or boundary conditions and 3) problems having two or more primary dependent variable fields. Formulations based on the generalized Biot theory (Biot 1941) for porous geologic media come under the third category listed above. In addition, since geomaterials exhibit the kinematic constrain of incompressibility under certain conditions, such formulations also qualify for the first category.

Under isothermal conditions, the primary dependent variables used in generalized Biot formulation are displacements (u) and pore pressure (p), which are suitably coupled. The stability of such "*u-p*" elements requires that the displacement approximation be one order higher than the continuous pressure approximation. Traditionally, such elements have employed quadratic and linear approximation for u and p, respectively. Since, according to Darcy's law, the velocity of flow is proportional to the gradient of the pore pressure, the approximate velocity is thus constant over an element.

In slow "consolidation-type" problems the accurate computation of such velocities is not crucial, as they are generally very small. The need to accurately simulate the effects associated with rising sea levels, rapidly rising flood waters, etc., however, now requires that accurate approximate velocities be computed. Consequently, robust and computationally efficient higher-order *u-p* elements need to be used in simulating such problems. Here "higher-order" implies a pressure approximation that is quadratic or higher.

DOI: 10.1201/9781003299127-234

The development of such higher-order *u-p* elements that are is not a straightforward undertaking. This paper explains this difficulty and, as a measure to overcome it, describes some non-conforming elements that have been recently developed.

2 GOVERNING EQUATIONS

This paper is restricted for two-field (*u-p*) generalized Biot formulations (Biot 1941) for a saturated deforming porous medium under isothermal, quasi-static conditions. The deformations and deformation gradients are both assumed to be infinitesimal. To facilitate the presentation, the following variables are defined (Kaliakin 2001): N_{sdim} = spatial dimension of the problem (= 1, 2 or 3), N_{dn} = number of nodes in an element at which displacement degrees of freedom exist, N_{pn} = number of nodes in an element at which pore pressures are unknown, N_{en} = total number of nodes in an element (in general, $N_{en} \neq N_{dn} + N_{pn}$), N_{nddof} = number of displacement degrees of freedom at a given node, N_{eddof} = total number of displacement degrees of freedom for a given element (= N_{dn} * N_{nddof}), N_{epdof} = total number of pressure degrees of freedom for a given element (= N_{pn}), N_{rowb} = number of stress and strain components present in the formulation. For three-dimensiona analyses (N_{sdim} = 2), N_{rowb} = 6. For torsionless axisymmetry N_{sdim} = 2 and N_{rowb} = 4. Finally, for plane strain analyses N_{sdim} = 2 and N_{rowb} = 3.

The governing equations for the aforementioned medium are first re-cast in their weak form. A Galerkin form of the weighted residual equations is next adopted. Time derivatives of displacements and pore pressure are approximated using a one-step family of methods (Hughes 1987) that are characterized by the temporal parameter θ ($0 \leq \theta \leq 1$).

Following a standard discretization process (Kaliakin 2001), the following set of discrete (approximate) element equations, written in incremental vector-matrix form, is obtained:

$$\begin{bmatrix} \tilde{\mathbf{K}}^{(e)} & \mathbf{G}^{(e)} \\ \mathbf{G}^{(e)T} & \left(\mathbf{H}^{(e)} + \mathbf{L}^{(e)}\right) \end{bmatrix} \begin{Bmatrix} \Delta \hat{\mathbf{u}}_n^{(e)} \\ \Delta \hat{\mathbf{p}}_n^{(e)} \end{Bmatrix} = \begin{Bmatrix} \Delta \mathbf{q}_1{}^{(e)} \\ \Delta \mathbf{q}_2{}^{(e)} \end{Bmatrix} \tag{1}$$

where $\Delta \hat{\mathbf{u}}_n^{(e)}$ is an (N_{eddof} * 1) vector of unknown nodal incremental absolute displacements of the porous solid, and $\Delta \hat{\mathbf{p}}_n^{(e)}$ is an (N_{epdof} * 1) vector of unknown nodal incremental values of pressure.

In equation (1) the (N_{eddof} * N_{eddof}) symmetric and positive definite element displacement sub-matrix is defined by

$$\tilde{\mathbf{K}}^{(e)} = \int_{\Omega^e} \left(\mathbf{B}^{(u)T} \mathbf{C}^{(e)} \mathbf{B}^{(u)} \right) d\Omega \tag{2}$$

where Ω^e represents the element domain. In equation (2) $\mathbf{C}^{(e)}$ is an (N_{rowb} * N_{rowb}) matrix of element tangent stiffness coefficients that, depending on the specific constitutive law, can vary with stress, strain or their history. Typically some incremental-iterative nonlinear solution scheme is thus required. In the simplest case, $\mathbf{C}^{(e)}$ is a matrix of elastic material constants.

The (N_{eddof} * N_{epdof}) element "coupling" sub-matrix appearing in equation (1) is defined by

$$\mathbf{G}^{(e)} = -\int_{\Omega^e} \left(\mathbf{B}^{(u)T} \alpha^{(e)} \mathbf{N}^{(p)} \right) d\Omega \tag{3}$$

where $\boldsymbol{\alpha}^{(e)}$ is an (N_{rowb} * 1) vector of generalized "Biot moduli" used in the definition of effective stress (Thompson & Willis 1991), and $\mathbf{N}^{(p)}$ is an (1 * N_{epdof}) matrix of pressure interpolation functions.

Unless stated otherwise, $\boldsymbol{\alpha}^{(e)}$ contains unit entries. More precisely, for three-dimensional idealizations $\boldsymbol{\alpha}^{(e)} = \{ 1 \quad 1 \quad 1 \quad 0 \quad 0 \quad 0 \}^T$, for plane strain idealizations $\boldsymbol{\alpha}^{(e)} = \{ 1 \quad 1 \quad 0 \}^T$, and for torsionless axisymmetry $\boldsymbol{\alpha}^{(e)} = \{ 1 \quad 1 \quad 1 \quad 0 \}^T$.

The (N_{epdof} * N_{epdof}) element "permeability" sub-matrix appearing in equation (1) is defined in the following manner:

$$\mathbf{H}^{(\mathbf{e})} = -\int_{\Omega^e} \left(\frac{1}{\eta^{(e)}} \mathbf{B}^{(\mathbf{p})T} \mathbf{k}^{\mathbf{d}} \mathbf{B}^{(\mathbf{p})} \right) \theta \Delta t_m \, d\Omega \tag{4}$$

where $\eta^{(e)}$ is the dynamic viscosity of the pore fluid (units of FtL^{-2}) associated with the element, $\mathbf{K^d}$ is the intrinsic or geometric permeability tensor (units of L^2), $\Delta t_m = t_{m+1} - t_m$ is a discrete time step, and θ is the aforementioned temporal parameter.

Finally, the (N_{epdof} * N_{epdof}) element "compressibility" sub-matrix $\mathbf{L^{(e)}}$ appearing in equation (1) is defined as follows:

$$\mathbf{L}^{(\mathbf{e})} = -\int_{\Omega^e} \left(\frac{1}{M^{(e)}} \mathbf{N}^{(\mathbf{p})T} \mathbf{N}^{(\mathbf{p})} \right) d\Omega \tag{5}$$

where $M^{(\mathbf{e})}$ is a material constant, commonly referred to as the "Biot modulus" (Detouenay & Cheng 1993), that characterizes the volume compressibility of the soil/fluid mixture. For $M^{(e)} < \infty$ $\mathbf{L^{(e)}}$ is symmetric and negative definite. For infinite values of $M^{(\mathbf{e})}$, $\mathbf{L^{(e)}}$ becomes the zero matrix and, depending on the magnitude of entries in $\mathbf{k^d}$ (and thus in $\mathbf{H^{(e)}}$), can make the entire element matrix *singular*. Whether or not this happens depends on the rank deficiency of $\left(\mathbf{H}^{(\mathbf{e})} + \mathbf{L}^{(\mathbf{e})} \right)$ (Hughes 1987).

The (N_{eddof} * 1) element load vector associated with the displacement degrees of freedom is defined by

$$\Delta \mathbf{q}_1^{(\mathbf{e})} = \int_{\Omega^e} \mathbf{N}^{(\mathbf{u})T} \Delta(\rho \mathbf{g}) \, d\Omega - \int_{\Omega^e} \mathbf{B}^{(\mathbf{u})T} \Delta \boldsymbol{\sigma}^{\mathbf{0}\prime} \, d\Omega + \int_{\Gamma_t} \mathbf{N}^{(\mathbf{u})T} \Delta \bar{\mathbf{t}} \, d\Gamma \tag{6}$$

where $\mathbf{N^{(u)}}$ is an (N_{nddof} * N_{nddof}) matrix of displacement interpolation functions, ρ is the *average* material mass density (i.e., the density of the soil skeleton together with the pore fluid), $\mathbf{g}$ is the gravitational acceleration, $\Delta \boldsymbol{\sigma}^{\mathbf{0}\prime}$ is an (N_{rowb} * 1) vector of initial stresses, and $\Delta \bar{\mathbf{t}}$ is a vector of known applied incremental surface tractions.

Finally, the (N_{epdof} * 1) element load vector associated with the pressure degrees of freedom is defined by

$$\begin{aligned} \Delta \mathbf{q}_2{}^{(\mathbf{e})} = & \int_{\Omega^e} \mathbf{B}^{(\mathbf{p})T} \left[(m) \left(\frac{1}{\eta} \mathbf{k}^{\mathbf{d}} \mathbf{B}^{(\mathbf{p})} \Delta \hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})} \right) \right] \Delta t_m \, d\Omega \\ & - \int_{\Omega^e} \mathbf{B}^{(\mathbf{p})T} \left\{ \left[(m) \left(\tfrac{1}{\eta} \rho^f \mathbf{k}^{\mathbf{d}} \mathbf{g} \right) (1-\theta) + {}^{(m+1)} \left(\tfrac{1}{\eta} \rho^f \mathbf{k}^{\mathbf{d}} \mathbf{g} \right) \theta \right] \right\} \Delta t_m \, d\Omega \\ & + \int_{\Gamma_Q} \mathbf{N}^{(\mathbf{p})T} \Delta \bar{Q} \, d\Gamma \end{aligned} \tag{7}$$

where $\Delta \bar{Q}$ is the known total hydraulic flux (flow per unit area) normal to the surface.

3 GRAPHICAL CONVENTIONS

In figures contained in this paper, circles depict nodes possessing displacement degrees of freedom. Black circles represent nodes with *constrained* displacement degrees of freedom; white circles represent nodes with unconstrained degrees of freedom. Nodes with pressure degrees of freedom are depicted by triangles. Transparent triangles represent nodes with unconstrained pressure degrees of freedom.

The first one- to three letters describe the type of the element used. These are followed by the number of nodes in the element at which displacement degrees of freedom exist. This number is followed by the letter "P" and the then by the number of nodes in the element at which pore pressures are unknown. The element designation terminates with the letter "c"

which indicates that the pressure approximation is continuous. Thus, the designation T6P3c represents a quadratic triangular element with six displacement nodes and three pressure nodes that are associated with a continuous (linear) pressure approximation, Q9P4c represents a quadrilateral element with nine displacement nodes and four pressure nodes, and so on.

Although interpolation function continuity requirements are somewhat relaxed in mixed formulations, for certain choices of these functions the mixed approximation will not yield meaningful results. As it turns out, this limitation is much more severe than in the irreducible formulation, where continuity and completeness criteria were sufficient to ensure a monotonically convergent form (Kaliakin 2001). In particular, from an assessment of the stability and performance of mixed formulation it is a known that the condition $N_{eddof} > N_{epdof}$ is a necessary but not sufficient condition for stability (Hughes 1987). As a result of this fact, the number of potentially stable elements is rather small.

4 "TAYLOR-HOOD" ELEMENTS

Arguably the most popular subclass of mixed finite elements with continuous pressure approximations consists of two- and three-dimensional elements possessing a displacement interpolation that is one order higher than the pressure interpolation. Such elements are sometimes referred to as "Taylor-Hood" elements, in recognition of the pioneering use of this element class by C. Taylor and P. Hood (Taylor & Hood 1973, Hood & Taylor 1974) for solving incompressible flow problems in field of computational fluid dynamics (CFD). In such elements, a quadratic approximation is assumed for the displacements in conjunction with a linear one for the pore pressure. Since "Taylor-Hood" elements are known to generally yield stable results, they have been used rather extensively in the past.

5 DISCUSSION OF POTENTIAL HIGHER-ORDER ELEMENTS

In this section, some general comments related to the development of higher-order *u-p* elements are presented. As mentioned in the introduction, "higher-order" implies a pressure approximation that is quadratic or higher.

5.1 *Triangular elements*

First consider triangular *u-p* elements. Various forms of such elements have been used in the past to simulate the response of a saturated deforming porous medium.

The first such element is the T4P3c. This conforming element adds a cubic displacement "bubble" function to the linear triangular element. To this is added a continuous linear pressure approximation. The resulting element is shown in Figure 1a. For this element, $N_{dn} = 4$, $N_{pn} = 3$, $N_{en} = 4$, $N_{eddof} = 8$ and $N_{epdof} = 3$. The conjecture behind the T4P3c is that the additional two displacement degrees of freedom associated with the interior node will yield a robust lower-order element (Kaliakin & Jiang 2009). For mesh generation software that is incapable of generating four-node triangles, these degrees of freedom must be "condensed" out of the element equations so as to yield a pseudo-linear three-node element.

The next triangular *u-p* element considered is the T6P3c. This conforming "Taylor-Hood" element combines a quadratic displacement approximation with a linear (continuous) pressure approximation associated with the vertex nodes. The resulting element is shown in Figure 1b. For this element, $N_{dn} = 6$, $N_{pn} = 3$, $N_{en} = 6$, $N_{eddof} = 12$ and $N_{epdof} = 3$.

The third triangular *u-p* element considered herein in the T7P3c. This conforming element is shown in Figure 1c. It adds a cubic "bubble function" to the quadratic T6P3c element; the two additional displacement components of $\hat{\mathbf{u}}^{(\mathbf{e})}$ are globally continuous on the element domain Ω. Similar to the T6P3c, the pressure approximation is linear. For this element, $N_{dn} = 7$, $N_{pn} = 3$, $N_{en} = 7$, $N_{eddof} = 14$ and $N_{epdof} = 3$.

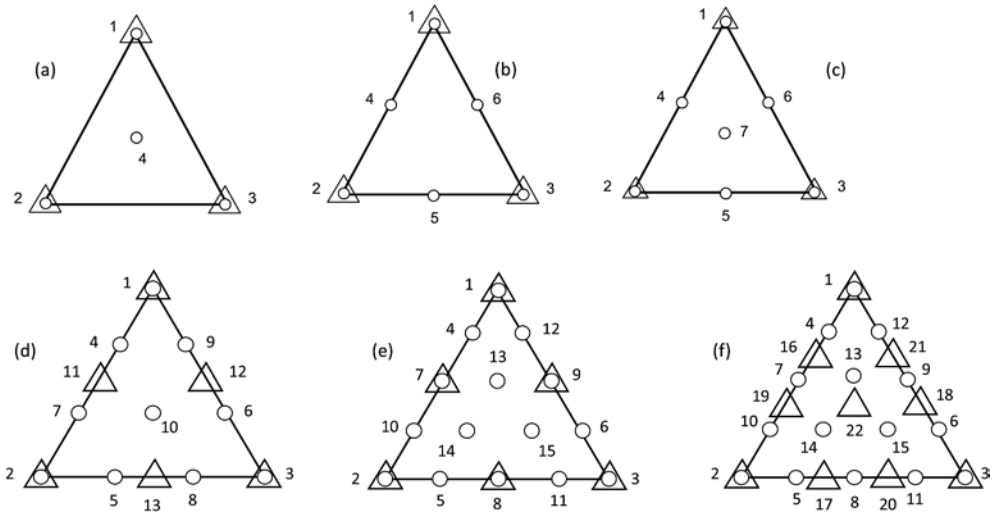

Figure 1. Triangular *u-p* elements: a) T4P3c, b) T6P3c, c) T7P3c, d) T10P6c, e) T15P6c, f) T15P10c.

Although they employ different approximations for the displacements $\hat{\mathbf{u}}^{(e)}$, the T4P3c, T6P3c and T7P3c all use a linear approximation for the pore pressure. Guided by the fact that displacement interpolation should be one order higher than the pressure interpolation (recall the discussion of "Taylor-Hood" elements in Section 4), it follows that to include a higher-order quadratic pressure approximation, the displacement approximation must be at least cubic.

The first potential conforming higher-order triangular *u-p* element is thus the T10P6c, which is shown in Figure 1d. This element combines a standard cubic (10-node) triangular element with a quadratic (6-node) pore pressure approximation. Although the vertex nodes have both displacement and pressure degrees of freedom, the remaining three mid-side nodes associated with the pressure approximation do not coincide with the mid-side displacement nodes. As such, for the T10P6c, $N_{dn} = 10$, $N_{pn} = 6$, $N_{en} = 10+3 = 13$, $N_{eddof} = 20$ and $N_{epdof} = 6$. The presence of mid-side nodes with only pressure degrees of freedom makes this element somewhat impractical. In addition, the presence of such elements would likely require special logic in mesh generation software.

A more practical conforming higher-order triangular *u-p* element is the T15P6c, which is shown in Figure 1e. This element combines a standard quartic (15-node) triangular element with a quadratic (6-node) pore pressure approximation. For the T15P6c, $N_{dn} = 15$, $N_{pn} = 6$, $N_{en} = 15$, $N_{eddof} = 30$ and $N_{epdof} = 6$. This element was used in the CRISP (Britto & Gunn, 1987) and Plaxis (2012) computer programs.

Finally, it is timely to note that another possible conforming higher-order triangular *u-p* element is the T15P10c. This element combines a standard quartic (15-node) triangular element with a cubic (10-node) pore pressure approximation (Figure 1f). Although the vertex nodes have both displacement and pressure degrees of freedom, the remaining six mid-side nodes associated with the pressure approximation do not coincide with the mid-side displacement nodes. In addition, the interior node associated with the pressure approximation does not coincide with the the location of a displacement node. As such, for the T15P10c, $N_{dn} = 15$, $N_{pn} = 10$, $N_{en} = 15+7 = 22$, $N_{eddof} = 30$ and $N_{epdof} = 10$. Similar to the T10P6c element, the presence of mid-side nodes with only pressure degrees of freedom makes this element somewhat impractical. In addition, the presence of such elements would likely require special logic in mesh generation software.

5.2 *Quadrilateral elements*

Next, consider quadrilateral *u-p* elements. Similar to some of the aforementioned triangular elements, various quadrilateral elements have been used in the past to simulate the response of a saturated deforming porous medium.

The first such element is the Q5P4c. This conforming quadrilateral element adds a quadratic "bubble" function to the irreducible bilinear Lagrangian element. The pressure is approximated using a bilinear (continuous) pressure approximation associated with the vertex nodes. The resulting element is shown in Figure 2a. For this element, $N_{dn} = 5$, $N_{pn} = 4$, $N_{en} = 5$, $N_{eddof} = 10$ and $N_{epdof} = 4$. The conjecture behind the Q5P4c is that the additional two displacement degrees of freedom associated with the interior node will yield a robust lower-order element (Kaliakin & Jiang 2009). For mesh generation software that is incapable of generating five-node quadrilaterals these degrees of freedom must be "condensed" out of the element equations so as to yield a pseudo-bilinear four-node element.

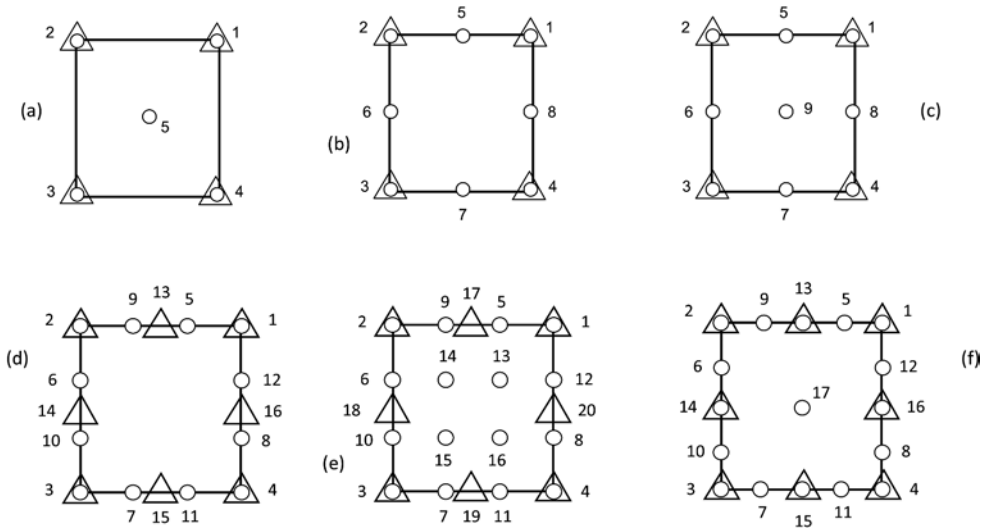

Figure 2. Quadrilateral *u-p* elements: a) Q5P4c, b) Q8P4c, c) Q9P4c, d) Q12P8c, e) Q16P8c, f) Q17P8c.

The next quadrilateral *u-p* element considered is the Q8P4c. This conforming "Taylor-Hood" element combines a bi-quadratic Serendipity displacement approximation with a linear (continuous) pressure approximation associated with the vertex nodes. The resulting element is shown in Figure 2b. For this element, $N_{dn} = 8$, $N_{pn} = 4$, $N_{en} = 8$, $N_{eddof} = 16$ and $N_{epdof} = 4$.

The third quadrilateral *u-p* element considered is the Q9P4c. This conforming "Taylor-Hood" element combines a bi-quadratic Lagrangian displacement approximation with a linear (continuous) pressure approximation associated with the vertex nodes. The resulting element is shown in Figure 2c. For this element, $N_{dn} = 9$, $N_{pn} = 4$, $N_{en} = 9$, $N_{eddof} = 18$ and $N_{epdof} = 4$.

Although they employ different approximations for the displacements $\hat{\mathbf{u}}^{(e)}$, the Q5P4c, Q8P4c and Q9P4c all use a linear approximation for the pore pressure. As in the case of triangular elements, the inclusion of a higher-order quadratic pressure approximation requires the displacement approximation to be at least cubic.

The first potential conforming higher-order quadrilateral *u-p* element is thus the Q12P8c, which is shown in Figure 2d. This element combines a standard cubic (12-node) Serendipity quadrilateral element with a quadratic (8-node) pore pressure approximation. Although the vertex nodes have both displacement and pressure degrees of freedom, the remaining four mid-side nodes associated with the pressure approximation do not coincide with the mid-side displacement nodes. As such, for the Q12P8c, $N_{dn} = 12$, $N_{pn} = 8$, $N_{en} = 12+4 = 16$, $N_{eddof} = 24$ and $N_{epdof} = 8$. Similar to the aforementioned T10P6c element, the presence of mid-side nodes with only pressure degrees of freedom makes this element somewhat impractical. In addition, the presence of such elements would likely require special logic in mesh generation software.

Another possible conforming higher-order quadrilateral *u-p* element is the Q16P8c. This element combines a standard cubic (16-node) Lagrangian quadrilateral element with a quadratic (8-node) pore pressure approximation (Figure 2e). Similar to the Q12P8c element, the vertex nodes have both displacement and pressure degrees of freedom; the remaining four mid-side nodes associated with the pressure approximation do not, however, coincide with the mid-side displacement nodes. For the Q16P8c, $N_{dn} = 16$, $N_{pn} = 8$, $N_{en} = 16 + 4 = 20$, $N_{eddof} = 32$, and $N_{epdof} = 8$. Similar to the Q12P8c element, the presence of mid-side nodes with only pressure degrees of freedom makes this element somewhat impractical. In addition, the presence of such elements would likely require special logic in mesh generation software. In addition, the presence of the four interior displacement nodes makes the Q16P8c even more impractical than the Q12P8c.

A more practical conforming higher-order quadrilateral *u-p* element is the Q17P8c, which is shown in Figure 2f. This element combines a standard quartic (17-node) Serendipity quadrilateral element with a quadratic (8-node) pore pressure approximation. For the Q17P8c, $N_{dn} = 17$, $N_{pn} = 8$, $N_{en} = 17$, $N_{eddof} = 34$ and $N_{epdof} = 8$.

6 OVERVIEW OF NON-CONFORMING QUADRILATERAL ELEMENTS

As evident from the discussion presented in the previous two sections, the robust implementation of a higher-order conforming *u-p* element requires a quartic approximation for the incremental displacement components. Since the computational effort associated with such conforming elements is non-trivial, it is natural to investigate the development of suitable non-conforming *u-p* elements. This section thus gives an overview of two non-conforming quadrilateral *u-p* elements that contain a higher-order pressure approximation. Jiang & Kaliakin (2009) give some preliminary comments regarding such elements.

In these elements, a quadratic approximation for the incremental displacement components identical to that used in either the Q8P4c (Figure 2b) or Q9P4c (Figure 2c) elements is employed; viz.,

$$\Delta\hat{\mathbf{u}}^{(\mathbf{e})} = \mathbf{N}^{(\mathbf{u})}\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})} \tag{8}$$

where $\Delta\widehat{\mathbf{u}}^{(\mathbf{e})}$ is a (2*1) vector of incremental displacement components, $\mathbf{N}^{(\mathbf{u})}$ is a (2 * N_{eddof}) vector of displacement interpolation functions, and $\Delta\widehat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})}$ is again an (N_{eddof} * 1) vector of unknown nodal incremental absolute displacements of the porous solid (recall Eq. 1).

Motivated by the development of irreducible non-conforming quadrilateral elements (Taylor et al. 1976), the pore pressure is approximated as follows:

$$\Delta\hat{\mathbf{p}}^{(\mathbf{e})} = \mathbf{N}^{(\mathbf{p})}\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})} + \mathbf{N}^{(\mathbf{p})*}\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*} \tag{9}$$

where

$$\mathbf{N}^{(\mathbf{p})} = \left\{ N_1^{(p)} \quad N_2^{(p)} \quad N_3^{(p)} \quad N_4^{(p)} \right\} \tag{10}$$

are standard bi-linear Lagrangian interpolation functions used to approximate the pore pressure, $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})}$ is an (4*1) vector of unknown nodal incremental values of pressure,

$$\mathbf{N}^{(\mathbf{p})*} = \left\{ \left(1-\xi^2\right) \quad \left(1-\eta^2\right) \right\} \tag{11}$$

is a (1*2) vector of quadratic interpolation functions that cause the element to be non-conforming, and $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}$ is a (2*1) vector of quadratic unknown nodal incremental values of pressure.

Using the above approximations along with their spacial derivatives and following a standard discretization process (Kaliakin 2001), the following set of discrete (approximate) element equations, written in incremental vector-matrix form, is obtained (compare with Eq. 1):

$$\begin{bmatrix} \tilde{\mathbf{K}}^{(\mathbf{e})} & \mathbf{G}^{(\mathbf{e})} & \mathbf{G}^{(\mathbf{e})*} \\ \mathbf{G}^{(\mathbf{e})^T} & \left(\mathbf{H}^{(\mathbf{e})} + \mathbf{L}^{(\mathbf{e})}\right) & \left(\mathbf{H}^{(\mathbf{e})*} + \mathbf{L}^{(\mathbf{e})*}\right) \\ \mathbf{G}^{(\mathbf{e})*^T} & \left(\mathbf{H}^{(\mathbf{e})*^T} + \mathbf{L}^{(\mathbf{e})*^T}\right) & \mathbf{M}^{(\mathbf{e})*} \end{bmatrix} \begin{Bmatrix} \Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})} \\ \Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})} \\ \Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*} \end{Bmatrix} = \begin{Bmatrix} \Delta\mathbf{q}_1^{(\mathbf{e})} \\ \Delta\mathbf{q}_2^{(\mathbf{e})} \\ \Delta\mathbf{q}_3^{(\mathbf{e})} \end{Bmatrix} \tag{12}$$

where $\tilde{\mathbf{K}}^{(e)}$, $\mathbf{G}^{(\mathbf{e})}$, $\mathbf{H}^{(\mathbf{e})}$, $\mathbf{L}^{(\mathbf{e})}$, and $\Delta\mathbf{q}_1^{(\mathbf{e})}$ are as previously defined.

In equation (12*)*,

$$\mathbf{G}^{(\mathbf{e})*} = -\int_{\Omega^e} \left(\mathbf{B}^{(\mathbf{u})^T} \boldsymbol{\alpha}^{(\mathbf{e})} \mathbf{N}^{(\mathbf{p})*}\right) d\Omega \tag{13}$$

has size (N_{eddof} * 2). The (4*2) augmented element "permeability" sub-matrix appearing in equation (12) is defined in the following manner:

$$\mathbf{H}^{(\mathbf{e})*} = -\int_{\Omega^e} \left(\frac{1}{\eta^{(e)}} \mathbf{B}^{(\mathbf{p})^T} \mathbf{k}^{\mathbf{d}} \mathbf{B}^{(\mathbf{p})*}\right) \theta \Delta t_m \, d\Omega \tag{14}$$

where $\eta^{(e)}$, $\mathbf{k}^{\mathbf{d}}$, Δt_m, and θ are as previously defined.

The (4*2) augmented element "compressibility" sub-matrix $\mathbf{L}^{(\mathbf{e})*}$ appearing in equation (12) is defined as follows:

$$\mathbf{L}^{(\mathbf{e})*} = -\int_{\Omega^e} \left(\frac{1}{M^{(e)}} \mathbf{N}^{(\mathbf{p})^T} \mathbf{N}^{(\mathbf{p})*}\right) d\Omega \tag{15}$$

The (2*2) augmented element sub-matrix $\mathbf{M}^{(\mathbf{e})*}$ is given by

$$\mathbf{M}^{(\mathbf{e})*} = -\int_{\Omega^e} \left(\frac{1}{M^{(e)}} \mathbf{N}^{(\mathbf{p})*^T} \mathbf{N}^{(\mathbf{p})*}\right) d\Omega \tag{16}$$

The second sub-vector appearing in the forcing vector in equation (12*)*, which has size (4*1), is given by

$$\begin{aligned} \Delta\mathbf{q}_2^{(\mathbf{e})} = & \int_{\Gamma_Q} \mathbf{N}^{(\mathbf{p})^T} \Delta\bar{Q} \, d\Gamma + \int_{\Omega^e} \mathbf{B}^{(\mathbf{p})^T} \left[{}^{(m)}\left(\frac{1}{\eta} \mathbf{k}^{\mathbf{d}} \mathbf{B}^{(\mathbf{p})} \Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})}\right)\right] \Delta t_m \, d\Omega \\ & + \int_{\Omega^e} \mathbf{B}^{(\mathbf{p})^T} \left[{}^{(m)}\left(\frac{1}{\eta} \mathbf{k}^{\mathbf{d}} \mathbf{B}^{(\mathbf{p})*} \Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}\right)\right] \Delta t_m \, d\Omega \\ & - \int_{\Omega^e} \mathbf{B}^{(\mathbf{p})^T} \left\{ \left[{}^{(m)}\left(\tfrac{1}{\eta} \rho^f \mathbf{k}^{\mathbf{d}} \mathbf{g}\right)(1-\theta) + {}^{(m+1)}\left(\tfrac{1}{\eta} \rho^f \mathbf{k}^{\mathbf{d}} \mathbf{g}\right)\theta\right] \right\} \Delta t_m \, d\Omega \end{aligned} \tag{17}$$

Finally, the third sub-vector appearing in the forcing vector in equation (12*)*, which has size (2*1), is given by

$$\begin{aligned}\Delta\mathbf{q}_3^{(\mathbf{e})} = &\int_{\Omega^e} \mathbf{B}^{(\mathbf{p})*T}\left[{}^{(m)}\left(\frac{1}{\eta}\mathbf{k}^{\mathbf{d}}\mathbf{B}^{(\mathbf{p})}\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})}\right)\right]\Delta t_m\, d\Omega \\ &+\int_{\Omega^e} \mathbf{B}^{(\mathbf{p})*T}\left[{}^{(m)}\left(\frac{1}{\eta}\mathbf{k}^{\mathbf{d}}\mathbf{B}^{(\mathbf{p})*}\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}\right)\right]\Delta t_m\, d\Omega \\ &-\int_{\Omega^e} \mathbf{B}^{(\mathbf{p})*T}\left\{\left[{}^{(m)}\left(\frac{1}{\eta}\rho^f\mathbf{k}^{\mathbf{d}}\mathbf{g}\right)(1-\theta)+\ {}^{(m+1)}\left(\frac{1}{\eta}\rho^f\mathbf{k}^{\mathbf{d}}\mathbf{g}\right)\theta\right]\right\}\Delta t_m\, d\Omega\end{aligned} \tag{18}$$

To eliminate $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}$ from the element equations, the third set of sub-matrices in equation (12) is solved as follows:

$$\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*} = \left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\left[\Delta\mathbf{q}_3^{(\mathbf{e})} - \left(\mathbf{H}^{(\mathbf{e})*T} + \mathbf{L}^{(\mathbf{e})*T}\right)\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*} - \mathbf{G}^{(\mathbf{e})*T}\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})}\right] \tag{19}$$

Substituting equation (19) into the first set of sub-matrices in equation (12) gives

$$\begin{aligned}&\left[\tilde{\mathbf{K}}^{(e)} - \mathbf{G}^{(\mathbf{e})*}\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\mathbf{G}^{(\mathbf{e})*T}\right]\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})} \\ &\quad+\left[\mathbf{G}^{(\mathbf{e})} - \mathbf{G}^{(\mathbf{e})*}\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\left(\mathbf{H}^{(\mathbf{e})*T} + \mathbf{L}^{(\mathbf{e})*T}\right)\right]\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})} \\ &\quad=\Delta\mathbf{q}_1^{(\mathbf{e})} - \mathbf{G}^{(\mathbf{e})*}\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\Delta\mathbf{q}_3^{(\mathbf{e})}\end{aligned} \tag{20}$$

Substituting equation (19) into the second set of sub-matrices in equation (12) gives

$$\begin{aligned}&\left[\mathbf{G}^{(\mathbf{e})^T} - \left(\mathbf{H}^{(\mathbf{e})*} + \mathbf{L}^{(\mathbf{e})*}\right)\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\mathbf{G}^{(\mathbf{e})*T}\right]\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})} \\ &\quad+\left[\left(\mathbf{H}^{(\mathbf{e})} + \mathbf{L}^{(\mathbf{e})}\right) - \left(\mathbf{H}^{(\mathbf{e})*} + \mathbf{L}^{(\mathbf{e})*}\right)\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\left(\mathbf{H}^{(\mathbf{e})*T} + \mathbf{L}^{(\mathbf{e})*T}\right)\right]\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})} \\ &\quad=\Delta\mathbf{q}_2^{(\mathbf{e})} - \left(\mathbf{H}^{(\mathbf{e})*} + \mathbf{L}^{(\mathbf{e})*}\right)\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\Delta\mathbf{q}_3^{(\mathbf{e})}\end{aligned} \tag{21}$$

The modified element equations thus have a form similar to equation (1*)*; viz.,

$$\begin{bmatrix}\tilde{\mathbf{K}}_{11}^{(\mathbf{e})} & \tilde{\mathbf{K}}_{12}^{(\mathbf{e})} \\ \tilde{\mathbf{K}}_{21}^{(\mathbf{e})} & \tilde{\mathbf{K}}_{22}^{(\mathbf{e})}\end{bmatrix}\begin{Bmatrix}\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})} \\ \Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})}\end{Bmatrix} = \begin{Bmatrix}\Delta\tilde{\mathbf{q}}_1^{(\mathbf{e})} \\ \Delta\tilde{\mathbf{q}}_2^{(\mathbf{e})}\end{Bmatrix} \tag{22}$$

where $\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})}$ has size (N_{eddof} * 1) and $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})}$ has size (4*1).

The sub-matrix $\tilde{\mathbf{K}}_{11}^{(e)}$ appearing in equation (22) has size (N_{eddof} * N_{eddof}) and is defined as follows:

$$\tilde{\mathbf{K}}_{11}^{(\mathbf{e})} = \tilde{\mathbf{K}}^{(\mathbf{e})} - \mathbf{G}^{(\mathbf{e})*}(\mathbf{M}^{(\mathbf{e})*})^{-1}\mathbf{G}^{(\mathbf{e})*T} \tag{23}$$

The sub-matrix $\tilde{\mathbf{K}}_{12}^{(e)}$ has size (N_{eddof} * 4) and is defined as follows:

$$\tilde{\mathbf{K}}_{12}^{(\mathbf{e})} = (\tilde{\mathbf{K}}_{21}^{(\mathbf{e})})^T = \mathbf{G}^{(\mathbf{e})} - \mathbf{G}^{(\mathbf{e})*}\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\left(\mathbf{H}^{(\mathbf{e})*T} + \mathbf{L}^{(\mathbf{e})*T}\right) \tag{24}$$

Finally, the sub-matrix $\tilde{\mathbf{K}}_{22}^{(e)}$ has size (4*4) and is defined as follows:

$$\left[\left(\mathbf{H}^{(\mathbf{e})}+\mathbf{L}^{(\mathbf{e})}\right)-\left(\mathbf{H}^{(\mathbf{e})*}+\mathbf{L}^{(\mathbf{e})*}\right)\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\left(\mathbf{H}^{(\mathbf{e})*T}+\mathbf{L}^{(\mathbf{e})*T}\right)\right] \tag{25}$$

The first sub-vector appearing in equation (22) has size (N_{eddof} * 1) and is defined as follows:

$$\Delta\tilde{\mathbf{q}}_1^{(\mathbf{e})}=\Delta\mathbf{q}_1^{(\mathbf{e})}-\mathbf{G}^{(\mathbf{e})*}\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\Delta\mathbf{q}_3^{(\mathbf{e})} \tag{26}$$

Finally, the second sub-vector has size (4*1) and is defined as follows:

$$\Delta\tilde{\mathbf{q}}_2^{(\mathbf{e})}=\Delta\mathbf{q}_2^{(\mathbf{e})}-\left(\mathbf{H}^{(\mathbf{e})*}+\mathbf{L}^{(\mathbf{e})*}\right)\left(\mathbf{M}^{(\mathbf{e})*}\right)^{-1}\Delta\mathbf{q}_3^{(\mathbf{e})} \tag{27}$$

Once $\Delta\hat{\mathbf{u}}_{\mathbf{n}}^{(\mathbf{e})}$ and $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}$ are known, $\Delta\hat{\mathbf{p}}_{\mathbf{n}}^{(\mathbf{e})*}$ is computed from equation (19).

7 CONCLUSIONS

This paper has presented some general considerations for developing conforming *u-p* elements that possess a higher-order (i.e., quadratic or higher) continuous pore pressure approximation. It was shown that the robust implementation of such a higher-order conforming element requires a quartic approximation for the incremental displacement components.

Since the computational effort associated with such conforming *u-p* elements is non-trivial, an overview of two quadratic (in displacement) *u-p* elements that contain a higher-order non-conforming pore pressure approximation was also presented. The element equations associated with such elements have the same general form as their conforming Q8P4c and Q9P4c counterparts.

Recommendation for reducing seismic subsidence deformation of structures

A.U. Tashkhodzhaev & D.N. Galieva
Tashkent Architecture and Civil Engineering University, Republic of Uzbekistan, Tashkent

ABSTRACT: This article gives recommendations for reducing the seismic subsidence deformation of structures. Solutions to ensure the seismic stability of the foundation in the absence of seismic subsidence are presented.

Keywords: seismic subsidence, strength, stability, seismic forces, soils, loads, foundations, soil friction, seismic subsidence threshold

In the Republic of Uzbekistan, most of it is composed of loess and other structurally unstable soils. Their specificity lies in the tendency to subsidence, liquefaction, deformation, curvature, uneven subsidence, etc. which can lead to the destruction of the structure, seismic subsidence threshold a_{lim} and the expected intensity of the earthquake a_c . If, as a result of such a check, it is revealed that the value of the seismic subsidence threshold turns out to be greater than the seismic acceleration, as noted above, then the soils at the base of the structure have sufficient strength and stability, and there is no seismic subsidence deformation. In such cases, existing deformations in buildings will occur as a result of poor construction quality. [1]

However, in a number of cases, we may encounter an inverse ratio of quantities, i.e. $a_{lim} < a_c$. Under such conditions, it is necessary to resort to the use of certain measures aimed at increasing the strength of the soil within the foundations of structures.

As is known, the magnitude of the maximum seismic acceleration a_c is predetermined by natural conditions. All elements of the dynamic mode (amplitude A, frequency f, period T, etc.) under these conditions are outside the sphere of human influence on them. In a completely different aspect, the issue of establishing the threshold of seismic subsidence of the soil $a_{lim\ is\ being\ solved}$.

In accordance with the above experimental studies, the seismic stability of soils at the base of structures can be increased:

– increase in strength characteristics of soils (ϕ *and* c_w)
– reducing the thickness of the core subjected to shaking (compressible thickness).

In the light of this provision, the corresponding "regulation" of the magnitude of the threshold of seismic subsidence a_{lim}, it is possible to significantly reduce the values of the calculated acceleration, thereby reducing (or reducing to zero) the values of the module of seismic subsidence. In this case, by comparing various options for measures that lead to an increase in the seismic subsidence threshold, it is possible to choose the most optimal solution that contributes to an increase in the value of a_{lim}.

The choice of one or another more effective option aimed at increasing the value of a_{lim} should be made in relation to each particular case, taking into account soil conditions and the factors influencing them by comparing and identifying the most appropriate measures. The types and forms of construction measures currently used and which could be suitable for increasing the value of the seismic subsidence threshold are very diverse.

DOI: 10.1201/9781003299127-235

Recall that an increase in the strength characteristics of the soil leads to an increase in the value of the seismic subsidence threshold a_{lim} and thus to increase the seismic resistance of the foundations and reduce the design score of the construction site. Hence, it becomes clear the importance of measures aimed at increasing the parameters of soil strength, which is confirmed by construction practice. Buildings and structures erected in seismic regions without observing the strength of the foundation soils underwent deformations in the form of tilt, curvature, uneven subsidence, and even complete destruction during the very first seismic tremors. [2]

In this regard, the criterion for the threshold of seismic subsidence a_{lim} sets the requirement that any ground conditions and foundations of structures must be stable with respect to the expected seismic force. These requirements can be met in practice by various construction measures aimed at improving the strength characteristics of the foundation soils.

Existing activities can be divided into the following groups:

a) activities carried out with the help of soil compaction with mechanical devices (surface compaction with rollers or rammers, deep compaction with short piles, hydrovibration, electrical, thermal and other methods);
b) measures aimed at reducing the porosity of the soil by introducing various chemical solutions into the pores (cementation, silicification, resinization, etc.)

It should be emphasized that the use of each of the above measures, in some cases, partially or completely, may turn out to be ineffective, especially without taking into account the seismic subsidence deformation of the soil under seismic conditions. At the same time, the cost of any engineering measure regarding soil is very high. [3]

The need for a significant investment of time for fixing and compacting soils, unacceptability in all conditions, insufficient development of technology and the need for special equipment almost completely exclude the possibility of using these measures in the mass construction of buildings of relatively small sizes.

Obviously, as a result of seismic subsidence of large masses of soil under the influence of shaking, the seismic resistance of structures erected on pile foundations cannot be ensured, even with a decrease in the load on them.

According to the definition of the threshold of seismic subsidence a_{lim} the thickness of loess moistened soils leads to a decrease in its value. From these positions, one of the conditions for increasing the seismic resistance of a construction site is to reduce the thickness of weak soils. The most effective measure in this regard is the design of buried structures or the use of pile foundations.

Deep foundations with the justification of structures on stronger rocks are used very often in construction practice. The essence of this measure is fundamentally very simple, however, it is applicable to any structures, including civil structures, bridge supports, hydraulic structures, etc.

These considerations confirm the emerging trend in construction practice to use simpler methods as anti -subsidence measures that are suitable on a wider scale and do not require any special expensive equipment. In particular, it is possible to reduce the forthcoming seismic settlement of buildings by laying their foundations deeper, according to the principle of "suspended foundations", i.e. without cutting through the entire loess layer. [4]

At the same time, the deepening of the foundations of structures, i.e. laying their soles to a certain depth from the surface of the strata will be the simplest and most effective measure to reduce the expected seismic subsidence deformation as a result of the oscillatory movement of the base.

Considering this circumstance, in 2007 we proposed a method of deepening the base of the foundation as an anti- seismic subsidence measure, which showed a fairly good effect when using it in the construction industry (see the act of implementation).

In accordance with the proposed method, the depth of the foundation of any structure (H) erected on cohesive (loess) soils, at which the seismic stability of the foundation is ensured in the absence of seismic subsidence, is determined by the formula:

$$H_0^c = \frac{p_0\,(1 + k_c e^{i\omega t})}{\gamma tg^4(45^0 - \frac{\phi}{2})} + \frac{c}{\gamma tg\phi} \tag{1}$$

For loose soils in the absence of dynamic impact, i.e. when working with non-cohesive soil under static conditions, it takes the form:

$$H_o = \frac{p_0}{\gamma tg^4(45^0 - \frac{\phi}{2})} \quad (2)$$

In expressions (1) and (2): - p_o normal stress in the soil from the weight of the structure; γ– soil density; k_c- seismicity coefficient; ω- circular frequency; t is time; φ - angle of internal friction of the soil; c-cohesion of the soil.

The expression $p_z = 0{,}2p_{np}$ has one very remarkable property. As follows from its consideration, the value h is directly proportional to p_o. In accordance with formula (1), such a dependence also exists between σ_z and p_o.

Consider the practical use of this method in examples.

Initial data: uniformly distributed load transferred to the ground under static conditions p_o \u003d 32 t/m^2, taking into account the inertial force of the seismic effect p_o^c\ u003d \$p_o(1+e^{iwt})$ u003d 45 t/m^2; soil density of natural moisture γ_w = 1.5 t/m^3; angle of internal friction of the soil -22°; soil adhesion - 3.0 t/m^2. It is required to determine the depth of the foundation in terms of ensuring the seismic stability of the foundation. [5]

*Solution***.** Substituting the values of the factors in the formula (1) we get:

H_0^c\u003d 13.5 m. The same value, excluding seismic, according to formula (1), is equal to: H_o \u003d 9.4 m. Thus, to ensure the seismic stability of the foundations under the conditions of given values, the depth of the foundation should be increased by 4.1 m.

Taeseo Ku
School of Civil and Environmental Engineering, Konkuk University, Seoul, South Korea

ABSTRACT: The coefficient of lateral stress at rest (K_0) is a very important soil parameter determining the in-situ stress states of soils. While the K_0 of soils under static loading conditions have been extensively studied, studies evaluating K_0 under repetitive loading have been very limited. This study aims at investigating the characteristics of K_0 of two granular materials with varying particle shapes during repetitive loading. The modified odeometer tests equipped with bender elements and diaphragm transducer were performed during static loading (-354.0 kPa), repetitive loading ($\Delta\sigma'$ = 176.6 kPa) and extra static loading (-706.9 kPa). The results of this study demonstrate that K_0 of tested materials increases with increasing cyclic loading number (i) though void ratio of tested materials continuously decreases with cyclic loading number. The stiffness anisotropy based on shear wave velocity measurements also confirms the finding of this study. Finally, the results of this study demonstrate that rounded granular material shows greater change in K_0 during repetitive loading compared to angular sand.

1 INTRODUCTION

The coefficient of lateral stress at rest (K_0), expressed as the ratio of effective horizontal stress to effective vertical stress, reflects the characteristics of ground and determines the in-situ stress states of soils. Therefore, K_0 is considered as the most fundamental input parameter in geotechnical analysis and design. Though a number of studies about the K_0 have been performed under the static loading conditions to evaluate the effects of composition, structure (or fabric), stress history, and loading directions on K_0 (Mitchell and Soga, 2005), studies evaluating K_0 under repetitive loading conditions have been very limited (Zhu and Clark, 1994; Mesri and Vardhanabhuti, 2007). Due to the continuous accumulation of plastic strain and the consequent internal fabric change during repetitive loading, the behavior of soils under repetitive loading is totally different from that of soils under static loading (Park and Santamarina, 2019). Therefore, this study aims at evaluating the variations of K_0 of two granular materials with different particle shapes as a function of cyclic loading number.

2 EXPERIMENTAL PROGRAM

2.1 *Tested materials and sample preparation*

Two granular materials (i.e., angular silica sand, K-7 sand and glass beads, GB) with similar median particle sizes (D_{50}) but different particle shapes were selected to determine the values of K_0 during repetitive loading (Figure 1). The index properties and grain size distributions of the tested materials are given in Table 1 and Figure 1, respectively. The dry funnel deposition

DOI: 10.1201/9781003299127-236

method was chosen for the preparation of tested specimens due to its ability to produce a wide range of relative densities. To determine the K_0 under static loading conditions (normally consolidated state), the specimens were prepared with various relative densities ranging from 20% to 80%, and the specimens under repeated loading were tested with the initial relative densities of 30% and 70%.

Table 1. Index properties.

Type	D_{50} (mm)	G_s	e_{max}	e_{min}	R	Particle Shape
K-7 sand	0.20	2.65	1.07	0.68	0.2	Angular
Glass beads	0.12	2.5	0.74	0.61	1.0	Round

Note: D_{50} = median particle size (50% passing); G_s = specific gravity; e_{max} = maximum void ratio; e_{min} = minimum void ratio; R = roundness.

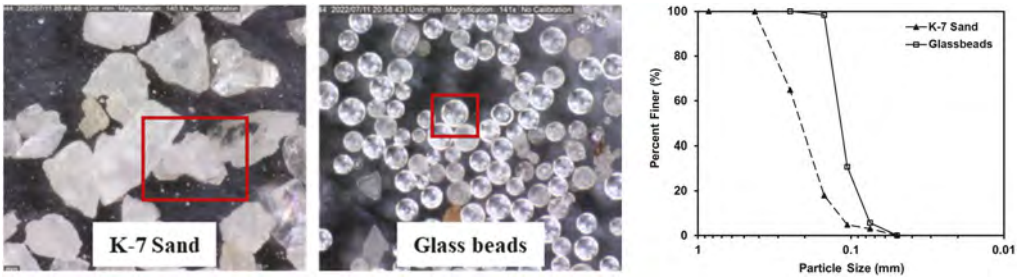

Figure 1. Grain size distributions and optical microscope images of tested materials.

2.2 *Test equipment and measurements*

The modified odeometer cell (sample diameter = 80 mm, sample height = 45mm, wall thickness = 10 mm) made of stainless steel was designed to measure the shear wave velocity and lateral stress under zero-lateral strain conditions. As shown in Figure 2, the diaphragm pressure transducer (Omega PX61V0) installed on the wall of the oedometer cell, was used to measure the lateral stress (Kim et al., 2021), and two pairs of bender elements were fitted in different configurations to measure the vertically propagating and horizontally polarized shear wave velocity, $V_s(VH)$ and horizontally propagating and horizontally polarized shear wave velocity, $V_s(HH)$. A static loading (-354.0 kPa), a repetitive loading ($\Delta\sigma'$ = 176.6 kPa), an extra static loading (-706.9 kPa), and unloading (-6.3 kPa) were applied to the prepared sample under K_0 condition. Total 100 times of repetitive loading with a period of 20 seconds to remove dynamic effects (Chong and Santamarina, 2016) were applied to the tested materials, and the lateral stress, settlement, and shear wave velocity (V_s) were measured according to loading steps and cyclic loading number.

3 RESULTS AND DISSCUSSION

The variations of the measured horizontal effective stress (σ'_h) according to the applied vertical effective stress (σ'_v) of tested two materials with initial relative density = 30% during static loading-repetitive loading-extra static loading-static unloading steps are shown in Figure 3. Glass beads (GB) shows greater σ'_h at a given σ'_v than K-7 sand, reflecting higher K_0 values of rounded GB. During the static loading, the slope between σ'_v and σ'_h remains constant value, reflecting constant K_0 values regardless of stress levels. However, in the case of repetitive loading condition, Figure 3 clearly demonstrates that the measured σ'_h at a given σ'_v continuously increases during repetitive loading. To quantify the results of Figure 3, Figure 4 shows the variations of K_0 according to cyclic loading number. Figure 4 clearly shows a gradual increase in K_0

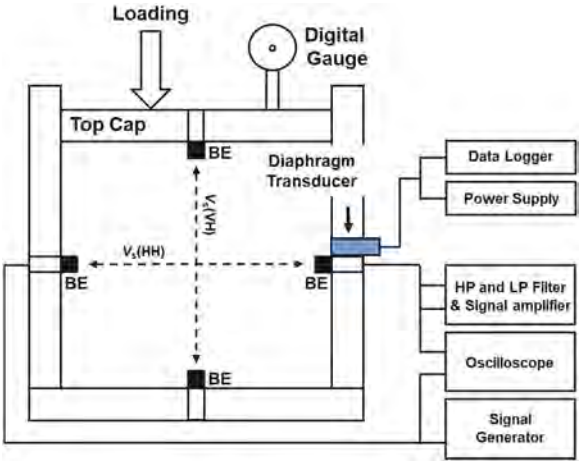

Figure 2. Experimental setup for measuring shear wave velocity and lateral earth stress.

with increasing cyclic loading number. The repetitive loading yields a continuous plastic displacement in the sample; therefore, the void ratio of tested materials continuously decreases with cyclic loading number. Because it is well-known that K_0 decreases with a decrease in void ratio, the results of Figure 4 are surprising and may be attributed to the accumulation of lateral stress locking. There should be no change in overconsolidation ratio of soils under the repetitive loading with constant stress amplitude. However, the repetition of loading-unloading steps may result in the accumulation of locked-in stress, leading to an increase in K_0 according to cyclic loading number; thus it may act as an increase in overconsolidation ratio.

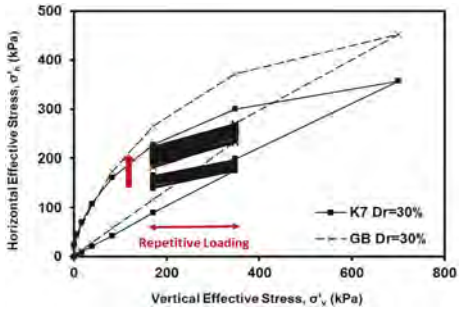

Figure 3. Relation between horizontal effective stress and vertical effective stress.

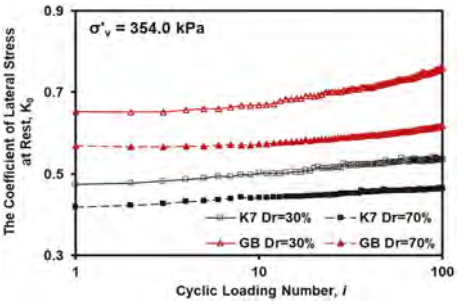

Figure 4. Variation of K_0 according to cyclic loading number.

When the 100 times of repeated loads were applied compared to the static loading conditions, the value of K_0 increased by about 5.9 % for K-7 and about 10.5 % for glass beads at an initial relative density of 30%. The effect of particle shape on the K_0 variation can be identified by directly comparing test results shown in Figure 6. It is observed that the values of K_0 measured in the static loading conditions (cyclic loading number = 0) for K-7 are lower than for glass beads, due to higher degree of angularity and interlocking of sand particles (Lee et al., 2013). Note that the higher interlocking leads to lower degrees of stress transmission in the horizontal direction. The load is more uniformly transferred to the surrounding particles when the particle is closer to a spherical shape.

The shear wave velocity is the power function of mean effective stress. Thus, V_s(VH) and V_s (HH) can be expressed as Equations (1) and (2), respectively. Based on the ratio between V_s (HH) and V_s(VH), the stiffness anisotropy of tested materials can be expressed as Equation (3).

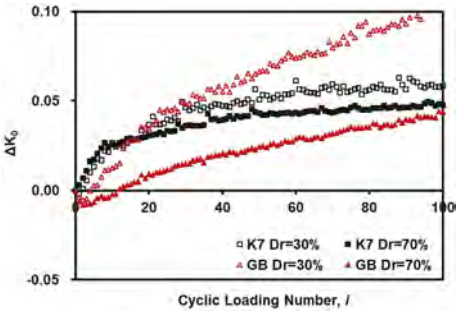

Figure 5. Variation of the coefficient of lateral stress at rest (K_0) of the tested materials.

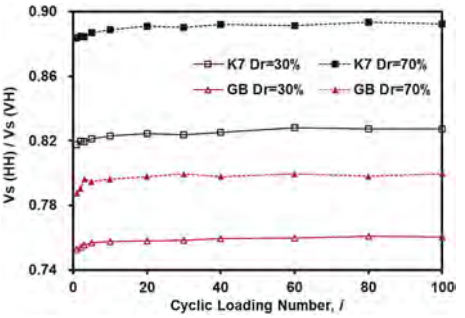

Figure 6. The ratio between V_s(HH) and V_s(VH) according to cyclic loading number (i).

Experimentally determined ratios between V_s(HH) and V_s(VH) of tested materials are shown in Figure 6. Figure 6 indicates the stiffness anisotropy, resulted from stress-induced anisotropy, decreases (or V_s(HH)/V_s(VH) increases) with increasing cyclic loading number. Most notably, Equation (3), which is function of K_0, also demonstrates that V_s(HH)/V_s(VH) should decrease with increasing K_0. Consequently, the wave velocity measurements (Figure 5) also support the finding of this study (Figure 4).

$$V_s(\mathrm{VH}) = \alpha_1 \left(\frac{\sigma_v' + \sigma_h'}{2\mathrm{kPa}} \right)^{\beta_1} = \alpha_1 \left(\frac{1+K_0}{2\mathrm{kPa}} \cdot \sigma_v' \right)^{\beta_1} \quad (1)$$

$$V_s(\mathrm{HH}) = \alpha_2 \left(\frac{\sigma_h' + \sigma_h'}{2\mathrm{kPa}} \right)^{\beta_2} = \alpha_2 \left(\frac{K_0}{1\,\mathrm{kPa}} \cdot \sigma_v' \right)^{\beta_2} \quad (2)$$

$$\frac{V_s(\mathrm{HH})}{V_s(\mathrm{VH})} = \frac{\alpha_2}{\alpha_1} \left(\frac{2K_0}{1+K_0} \right)^{\beta} \quad (3)$$

where, σ'_v = vertical effective stress; σ'_h = horizontal effective stress; α-factor = the V_s at σ'_m = 1 kPa; and β-exponent captures the sensitivity of tested materials on the applied stress.

4 CONCLUSION

This experimental investigation aims to evaluate the K_0 of granular materials under repetitive loading conditions. The results of this study demonstrate that K_0 of tested materials increases with increasing cyclic loading number (i). The stiffness ratio also supports this observation. In addition, rounded material shows greater change in K_0 compared to angular sand.

ABSTRACT: This study aims to assess the site effect of the Bukit Timah Granite area in Singa-pore via 2D dynamic numerical modeling and further comparison with previous geophysical testing results. A 3D geophysical model was created via combining geophysical investigation data with borehole data and geological maps of the region, and then several 2D geological cross-sections were extracted. Those cross-sections were used for dynamic numerical modeling of seismic ground motion and for calculating site amplification using the Universal Distinct Element Code (UDEC). The results show that the fundamental frequency (f_0) is in a good agreement between dynamic numerical modeling and horizontal to vertical spectral ratio (HVSR). Thus, the dynamic numerical models would be used for site effect analysis in the seismic hazard assessment.

1 INTRODUCTION

The local effects that amplify the seismic waves are generally due to the surface topography, the presence of an alluvial/lake, or any other soft deposits, including artificial fills (Wald & Allen, 2007). Therefore, the territory targeted is divided into several microzones to consider seismic amplification effects based on the dynamic soil properties of the site.

Site effect analyses can be conducted using information from geological investigations, borehole drilling, and geophysical surveys (Hakimov et al., 2021). Borehole drilling, an invasive method, is commonly practiced among the listed methods. Drilling will provide data on the thickness of each layer, bedrock depth and layers' stiffness. The latter data can then be empirically used for estimating shear wave velocity (V_S). Despite its popularity, the method contains huge drawbacks, such as being destructive, expensive, and time-consuming. For these reasons, their wide application is not always possible (Zhang et al., 2019, Moon & Ku, 2017), e.g., in Upper Missisipi Embayment, where the bedrock depth can reach up to 1000m (Moon et al., 2017). Geophysical surveys (e.g., multichannel analysis of surface waves (MASW) or horizontal to vertical spectral ratio (HVSR) from microtremor measurements (MM)) are practiced as a fast and cost-effective alternative to deriving dynamic soil properties.

This study aims to evaluate the site effects at the Bukit Timah Granite area in Singapore using 2D dynamic numerical modeling. 2D numerical models are selected from 3D Geomodel in such a way as to contain locations with geophysical and borehole information. The

DOI: 10.1201/9781003299127-237

numerical modeling technique generates a layered digital representation of a Bukit Timah Granite region to improve interpolated data further. The available geophysical survey data with the region's borehole data and geological maps are combined to create a 3D Geomodel. From the resulting numerical model, 2D cross-sections close to available geophysical data are selected for further data validation.

2 STUDY AREA

The Bukit Timah Granite is the most predominant rock formation in Singapore, comprising about 1/3 of the land area, and is one of the five major geological formations. Bukit Timah Granite is considered a base rock formation for the central part of Singapore. In a local context, in accordance with weathering degree, Bukit Timah Granite is graded from G(I) for hard intact rock to G(VI) for fully weathered residual soil. Bedrock depth is considered the depth of G(III), in which gradual stiffness is noticeably increased (Moon & Ku, 2017). The thickness of residual soils in Bukit Timah territory reaches 70 m, with a mean thickness of 30 m (Zhao, 1996).

Previous studies have demonstrated that the MASW test and microtremor measurement (MM) are applicable for bedrock depth estimation in the Bukit Timah Granite (Moon et al., 2019, Ku et al., 2021). Moreover, further works on HVSR inversion in Bukit Timah Granite performed with constrained borehole information resulted in V_S profiles similar to MASW test results (Abdialim et al. (2021). This work compiles the results of all the aforementioned studies for generating and demonstrating a dynamic numerical model in an example of a 2D cross-section. Figure 1 shows test site locations, including MASW results, MM, and borehole data.

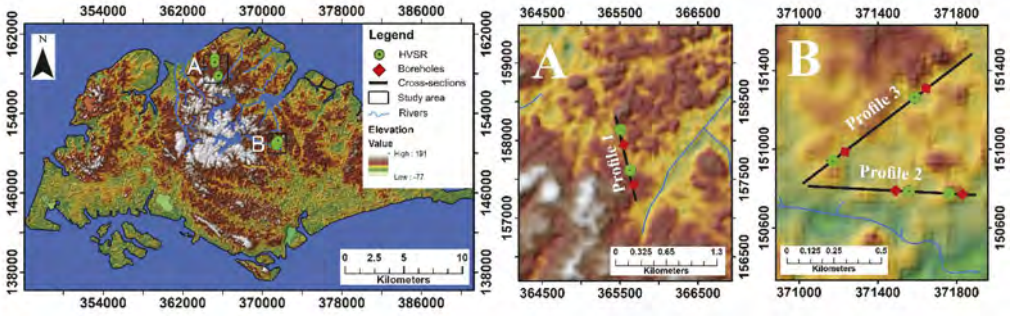

Figure 1. The study area of the Bukit Timah Granite with an indication of three 2D cross-sections (Note: Green circles indicate HVSR points on the profiles, and the red rhomboid shows borehole locations on the profiles).

3 NUMERICAL MODELLING

A 3D geomodel for the Bukit Timah area was generated based on combined MASW, HVSR, and borehole data. This model was obtained using Leapfrog Geo software (version 4.5 from Seequent Limited). The thickness of soil layers (h) susceptible to site amplification was estimated and mapped by the 1-D soil model assumption using the following equation: $h = V_S/4f_0$, where V_S = average shear wave velocity of 30m, f_0 = fundamental frequency. Since the relationship between f_0 and h assumes a high impedance contrast between two underlying layers, only clear peak HVSR curves with high amplitudes were used for Geomodel generation. 3D Geomodel was split into three layers to consider the weathering: soft layer, weathered granite layer, and granite. Thicknesses of soft and weathered layers were introduced following borehole, MASW, and HVSR information. From the 3D geomodel, we extracted three 2D cross sections from the points where HVSR

measurements were taken (Figures 1 and 2). Dynamic numerical simulations of the site effect were performed and compared with HVSR measurements. UDEC software developed by the Itasca Consulting Group was used as the distinct element method-based tool. 2D section consists of a basement, a weathered granite layer, a surface layer, and synthetic receivers. Site effect analysis was performed in an elastic domain for all profiles. Input data were selected from the literature (e.g., stiffness properties of bedrock from Zhao (1996), V_S values from MASW data, densities from Sharma et al. (1999)). Bulk and shear moduli (K and G) data converted from V_P and V_S data. Joint properties of the model, such as joint normal and shear stiffnesses (j_{kn} and j_{ks}) and joint cohesion (j_{coh}), were maximized for the prevention of deformations along the discontinuities (Havenith et al., 2003). Ricker wavelet was used as input signal at the base. Elastic properties of numerical model materials are listed in Table 1.

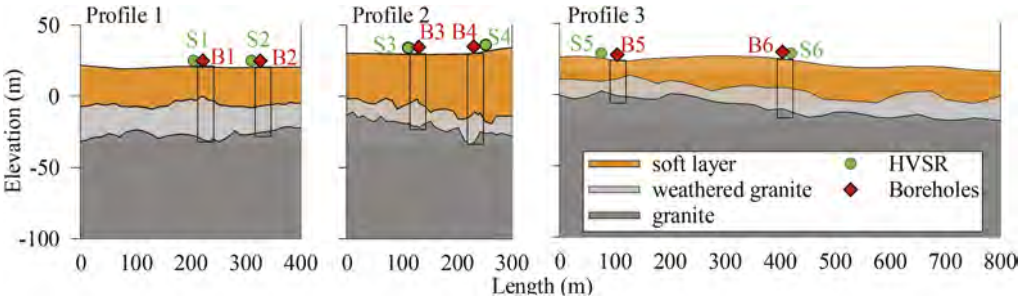

Figure 2. 2D Cross-sectional profiles taken and extracted from 3-D geomodel.

Table 1. Soil engineering properties.

	K (Mpa)	G (Mpa)	ρ (kg/m^3)	H(m)	j_{fric}	j_{tens}
Soft layer	1387	384.75	1900	10-20	–	2e20

Granite	14208	7776	2600	30-50	38	–

4 2D NUMERICAL MODELING PROCESSING

Figure 3a shows the locations of synthetic receivers for dynamic analysis. Standard spectral ratios (SSRs) were obtained for site amplification evaluation at each synthetic surface receiver by the following procedure: The acceleration-time histories generated on the surfaces were compared with those recorded on a synthetic receiver at the model's base. Signals were then multiplied by two to account for the flat surface reflection effect and filtered, respectively (Havenith et al., 2003). By gathering such time histories on the surface, synthetic three-component records were generated. The surface receivers (synthetic receivers) represent the two horizontal components in this set, and base records replace the vertical component. This synthetic data was further processed by following the HVSR analysis procedure. As a result, much like in the HVSR technique, a spectral ratio versus frequency graph would be generated.

5 RESULTS AND DISCUSSION

3D Geomodel construction relies mainly on borehole readings and geophysical test results. Among geophysical tests, HVSR measurements significantly contribute to the modeling because the relationship between f_0 and peak amplitude is directly correlated with the site amplification. For our simulation, we considered the relative changes and shape of the peak rather than the absolute amplitude value. In Figure 3b, we compared the results of simulated

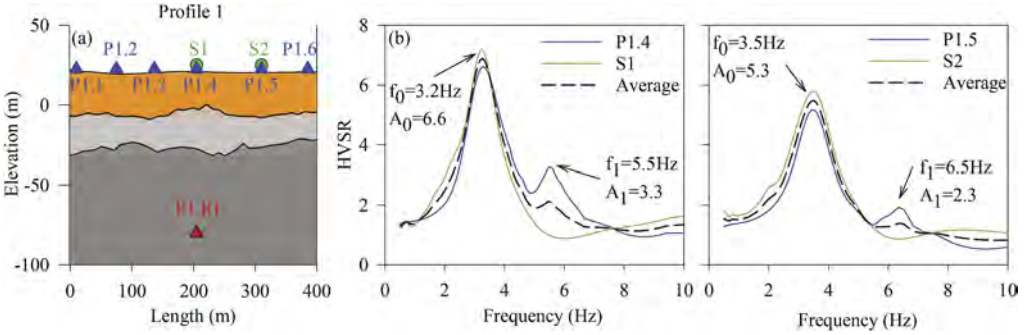

Figure 3. (a) 2D Cross-section with an indication of locations of synthetic receivers and HVSR measurements (green) at Profile 1. The base receiver (red) was a reference for surface receivers (blue). (b) Simulated SSR (P1.4 & P1.5) and HVSR measurements (S1 & S2) in Profile 1.

and real HVSR at profile 1. The comparison shows that both curves have the same trend for low frequencies, especially close to the f_0. At high frequency, simulated SSR had a low amplitude corresponding to a weathered granite layer. A peak frequency match was observed for the frequency range of 2-7 Hz. The extra peak can be because of differences in impedance contrast between weathered granite and soft soil in numerical modeling compared with actual measurements. The numerical model was generated by grouping different granite layers into "soft layer" and "weathered granite" based on weathering degree. Thus, there might be a sudden rise in impedance contrast. In reality, the number of layers will be higher with slowly increasing stiffness, resulting in the absence of an intense surge in impedance contrast between layers. Thus, we believe that this method allows us to detect the resonant frequency of deep deposits and highlight the presence of surface deposits. However, HVSR measurements have clear limitations in application: (1) HVSR data will not be able to estimate soft layer thickness, and other geophysical data, such as V_S., will be needed. (2) the interpretation of peak amplitudes: correlation between site amplification factor and HVSR amplitudes has not been fully proven. These results provide a basis for further research on Geomodel modification and implementation of more geophysical results (e.g., MASW) to minimize the limitations.

6 CONCLUSIONS

To assess the site effects of the Bukit Timah Granite region, 2D cross-sections were generated from 3D Geomodel. Response to the horizontal Ricker wavelet input signal at the base of the model was used to estimate the region's SSR and further comparison with actual HVSR data. In an example of Profile 1, it was demonstrated that both simulated and measured spectral curves had the same shape close to the f_0. It was also mentioned that only the shape of the simulated spectral curve was used for the data analysis of the curve. Moreover, simulated curves contained extra peaks at higher frequencies corresponding to the impedance contrast between the soft and weathered granite layers. A possible reason for such differences at high frequencies was discussed. Known limitations of the method can be minimized in the future by using extra geophysical data, especially when generating 3D Geomodel. The clear trend between synthetic and measured data demonstrates the possibility of using numerical modeling for seismic microzonation works at Bukit Timah Granite formation.

Comparative analysis of seismic design for shallow foundations adhering to the Kazakhstani and European approaches

A. Zhanabayeva, S.-W. Moon, J. Kim & A. Satyanaga
Nazarbayev University, Nur-Sultan, Kazakhstan

Y. Shokbarov
KazNIISA, Almaty, Kazakhstan

ABSTRACT: Starting in 2015 the transition period from the traditional seismic design to the newly developed system has been initiated in Kazakhstan. The new regulatory system involves the application of the European approach for the design of buildings and structures on the territory of Kazakhstan. This research paper aims to present a comparative analysis of the seismic design code applied in Kazakhstan (SP RK 2.03-30-2017 – Construction in seismic zones) and Eurocode 8 (EC8). One of the key aspects of the research is to understand the difficulties of the integration of the European design standards in Kazakhstan. Moreover, the problems associated with seismic design in Kazakhstan are discussed. The necessity of the application of the European approach considering geotechnical features of the country in the National Annex is defined and proved. The considered codes of practice are also compared in terms of their conservativeness and cost efficiency for seismic design based on the design problem in Almaty city.

1 INTRODUCTION

Seismic, geological, and geographical conditions of Kazakhstan's East, South, and Southwest regions represent a seismic risk for approximately one-fourth of the country's territory (Sajjad et al.). Analytical results of the research work during the Soviet times became the foundation for developing normative documentation for seismic design in Kazakhstan. Since 2006 the SNiP-based regulations have not been modified. The reason referred to the transition to the European standards, which allows the increase in safety of the designed structures under seismic actions (Zhanabayeva et al. 2023). Eurocodes with National Annexes in Kazakhstan were issued in 2016 and were recommended for application in parallel with the existing regulations (Zhanabayeva et al. 2021). For the design and construction of buildings and structures in seismic regions, SP RK EN 1998:2004/2012 identical to Eurocode, was issued. However, due to the complexity of this document, it did not receive a wide application among local specialists (Shaldykova et al. 2020).

Nowadays, the performance of construction works requires integration into a new regulatory system. The Kazakhstani designers and engineers are required to conform to both national and European codes (Zhanabayeva et al. 2022). However, the practice shows that specialists face difficulties due to significant differences between the Kazakhstani and European design approaches for seismic design. The integration issue is explained not only by different design methods but other reasons, considering the lack of the appropriate construction materials, equipment for materials' quality control, standards, technical conditions, methodologies, etc. The considerable differences between design approaches applied in Kazakhstan and European countries refer to (1) seismic magnitude scale, (2) scope of the application, and (3) soil classification.

DOI: 10.1201/9781003299127-238

This research work aims to introduce and evaluate the seismic design procedures adhering to the Kazakhstani and European codes of practice and analyze the sufficiency of the bearing resistance for designing a shallow foundation in Almaty city.

2 SEISMIC DESIGN OF FOUNDATIONS ADHERING TO THE KAZAKHSTANI AND EUROPEAN APPROACHES

Foundation systems ensure load transfer from superstructures to ground without considerable deformation. The design actions on the structures are defined based on the capacity design. This section provides a detailed design procedure for determining the seismic bearing capacity of shallow foundations when adhering to the Kazakhstani (SP RK 2.03-30-2017 2017) and European (EN 1998-1 2005) codes of practice.

2.1 *Kazakhstani approach for the design of foundations constructed in seismic regions*

Seismic design of shallow foundations under seismic actions involves determining (1) bearing capacity for the limit state analysis and (2) sliding capacity. The following condition is required to be performed to determine the sufficiency of seismic bearing capacity of a shallow foundation:

$$N_a \leq \gamma_{c,eq} \frac{N_{u,eq}}{\gamma_n} \tag{1}$$

where N_a = a vertical design eccentric load in a special combination; $\gamma_{c,eq}$ = a seismic operational conditions coefficient; γ_n = a reliability coefficient based on the purpose of the designed structure; $N_{u,eq}$ = a vertical component of the ultimate resistance of the foundation due to seismic action defined in accordance with the ratio between eccentricities e_a and e_u:

$$\text{For } e_a \leq e_u : N_{u,eq} = 0.5bl(p_b + p_0) \tag{2}$$

$$\text{For } e_a > e_u : N_{u,eq} = 0.5bl(p_b + p_o^{'}) = \frac{b1p_b}{(1 + 6e_a/b)} \tag{3}$$

Here eccentricity of the design load e_a and eccentricity of the limiting pressure diagram e_u are defined based on the following equations:

$$e_a = \frac{M_a}{N_a} \tag{4}$$

$$e_u = \frac{b(p_b - p_0)}{6(p_b + p_0)} \tag{5}$$

where N_a = a vertical component of design load acting at the foundation base under a special load combination with the consideration of seismic actions; b = a foundation width; l = a foundation length; d = a foundation depth; M_a = a moment acting at the foundation base under seismic actions; Q_I^s = a horizontal force acting on the foundation base in the design direction under a special load combination; h = a foundation height.

In Equations 2-5 p_o and p_b = the ordinates of the diagram of the ultimate pressure under the edges of the foundation base defined in accordance with the following equations:

$$\begin{aligned} p_0 &= \xi_q F_1 \gamma'_I d + \xi_c (F_1 - 1) \frac{c_I}{tg\varphi_I} \\ p_b &= p_0 + \xi_q \gamma_I b + (F_2 - K_{eq} F_3) \end{aligned} \tag{6}$$

where ξ_q, ξ_γ, ξ_c = shape coefficients; γ'_I and γ_I = design values of the unit weight of soil above and below foundation base; φ_I and c_I = design values of the internal friction angle and cohesion; d = the foundation depth; k_{eq} = a seismicity coefficient; $F_1,\ F_2,\ F_3$ = coefficients defined in accordance with the design internal friction angle φ_I value.

The sliding capacity of a shallow foundation under seismic load is defined in accordance with the following condition:

$$Q_a \leq \frac{\gamma_{c,eq}}{\gamma_n}[N_a tg(\varphi_I - \Delta\varphi_I) + c_I A] \tag{7}$$

where Q_a = a horizontal component of the load at the foundation base level taken as $Q_a = Q_I^s$; A = an area of the foundation base; $\Delta\varphi_I$ = a decrease of the design frictional angle.

2.2 *European approach for the design of foundations constructed in seismic regions*

Eurocode 8 (EC8) represents a part of Eurocodes specializing in seismic and earthquake design. EC8-5 covers a detailed procedure for the design of foundations constructed in seismic regions. Annex F of EC8-5 (EN 1998-5 2004) presents a method for the verification of the seismic bearing capacity of a strip foundation. The general expression for the check of the stability of a strip foundation against seismic bearing capacity failure combines a long-term European experience gained by field, analytical and numerical results. The stability is checked using the following equation related to the soil strength, the design action effects ($N_{Ed},\ V_{Ed},\ M_{Ed}$) at the foundation level, and the inertia forces in soil as follows:

$$\frac{(1+e\bar{F})^{c_T}(\beta\bar{V})^{c_T}}{(\bar{N})^a[(1-m\bar{F}^k)^{k'}-\bar{N}]^b} + \frac{(1-f\bar{F})^{c'M}(\gamma\bar{M})^{c_M}}{(\bar{N})^c[(1-m\bar{F}^k)^{k'}-\bar{N}]^d} 1 \leq 0 \tag{8}$$

where

$$\bar{N} = \frac{\gamma_{Rd}N_{Ed}}{N_{max}};\ \bar{V} = \frac{\gamma_{Rd}V_{Ed}}{N_{max}};\ \bar{M} = \frac{\gamma_{Rd}M_{Ed}}{BN_{max}} \tag{9}$$

N_{max} = an ultimate bearing capacity of the foundation under a vertical centered load; B = a foundation width; $\bar{F}$ = a dimensionless soil inertia force; γ_{Rd} = a model partial factor; $a,\ b,\ c,\ d,\ e,\ f,\ m,\ k,\ k', c_T, c_M, c'_M, \beta, \gamma$ = numerical parameters depending on soil type.

The ultimate bearing capacity under a vertical load N_{max} for purely cohesive soil is defined based on the following equation:

$$N_{max} = (\pi + 2)\frac{\bar{c}}{\gamma_M}B \tag{10}$$

where $\bar{c}$ = an undrained shear strength of soil for cohesive soil; γ_M = a partial factor for material properties.

The dimensionless soil inertia force $\bar{F}$ is defined as follows:

$$\bar{F} = \frac{\rho a_g SB}{\bar{c}} \tag{11}$$

where ρ = a unit mass of soil; a_g = a design ground acceleration on Type A ground ($a_g = \gamma_I a_{gR}$); a_{gR} = a reference peak ground acceleration on Type A ground; γ_I = an importance factor; S = a soil factor.

3 DESIGN PROBLEM IN ALMATY CITY

The seismic design of a shallow foundation is performed based on the design problem provided in Figure 1. The design problem requires checking the seismic design resistance of

a strip foundation with a width of 3 m located at a depth of 1.8 m below ground for Almaty soil properties obtained from (Khomyakov et al. 2013). The soil engineering properties in Almaty, the actions applied on a strip foundation, and the SP RK and EC8 parameters involved in the calculations are provided in Table 1.

Based on the performed design calculations adhering to the Kazakhstani and European design procedures for the determination of seismic bearing resistance of a strip foundation, it was identified that the calculated results of seismic bearing resistance satisfy design requirements. Adhering to the Kazakhstani approach, when substituting the values of soil engineering properties and SP RK parameters into Equation 1, it was obtained that the RHS equals 814 kN. The obtained value is greater than the design vertical load, meaning the seismic bearing resistance satisfies the design condition. EC8 also provides a safe strip foundation design when considering Almaty soil conditions, as the LHS of Equation 11 is equal to –0.08. However, the obtained value is very close to the boundary (i.e., 0). Therefore, it can be concluded that the decided width of the designed strip foundation represents a minimum dimension when adhering to the European approach. Thus, EC8 provides a more conservative seismic design than SP RK.

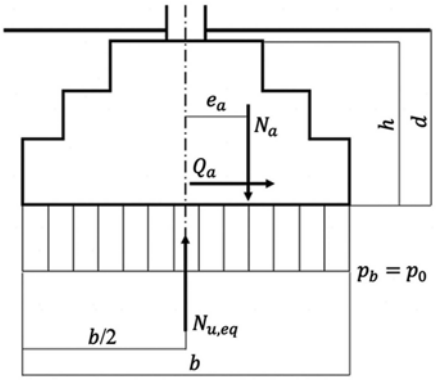

Figure 1. Design problem in Almaty city.

Table 1. Soil engineering properties in Almaty city.

Soil properties	Given data	SP RK parameters	Eurocode parameters
Silty clay:c = 33.00kPa w = 18.80% e = 0.86 E = 12.00MPa $\varphi = 19.00°$ $\gamma = 17.00\text{kN/m3}$ (obtained from (Moon and Ku, 2018))	b = 3m N_I= 700kN Q_I= 66kN M_I= 90kN ∗ m 9-degree intensity	$\gamma_{c,eq}$= 0.8,γ_n= 1.15 ξ_q=ξ_γ=ξ_c= 1 F_1= 5.63,F_2= 2.94 F_3= 9.55	a = 0.7, b = 1.29 c = 2.14, d = 1.81 e = 0.21, f = 0.44 m = 0.21, k = 1.22 $k = 1.00,\ c_T = 2.00$ $c_M = 2.00, c_M = 1.00$ $\beta = 2.57, \gamma = 1.85$ γ_{Rd}= 1.00,γ_M= 1.4

4 CONCLUSION

This research introduces the procedure for seismic design of shallow foundations when applying SP RK and EC8. A significant difference between the Kazakhstani and European approaches for seismic design exists, including the scope of the application of design codes, the application of different seismic magnitude scales and soil classification systems.

Seismic design of a strip foundation in Almaty city is performed adhering to the Kazakhstani and European codes of practice. The design problem is used to analyze the sufficiency of seismic bearing resistance of a strip foundation for the given soil engineering conditions. It is

defined that both regulations provide satisfactory results. However, EC8 provides a more conservative seismic design of a shallow foundation, which means a costlier design than SP RK.

To conclude, the SNiP-based Kazakhstani design code did not experience significant changes for a long time compared to EC8. Therefore, the European approach represents a good alternative for assessing seismic hazards and geotechnical applications in Kazakhstan.

ABSTRACT: A hybrid type reinforcement technique is proposed for application to both existing and new highway embankments for mitigating earthquake induced damages. In the proposed technique, inclined piles are installed at the top of vertical piles, and they are fixed to each other. The inclined piles are assumed to provide an additional restraining force to the vertical piles against lateral loading as well as reduce ground deformation and settlement during earthquake loading. In this study, a series of simulations were performed to determine the optimum inclination angle to achieve the best performance using the proposed technique. The numerical results suggest that a suitable angle (55–60°) between the vertical and inclined pile could effectively reduce deformation of the highway embankment during seismic loading.

1 INTRODUCTION

Sustainable Development Goals 11 (to make cities and human settlements inclusive, safe, resilient, and sustainable) focuses on minimizing the exposure to disasters and enhancing resilience and adaptive capacity. Highways play a crucial role in the connectivity and transportation of critical rescue components and relief materials during disasters. However, numerous highway embankments in Japan, which were constructed on soft soil foundations, are aging and have become susceptible to natural disasters. The highway embankment damage and retaining wall failure in Kyushu Expressway near Mashiki town were observed after the 2016 Kumamoto earthquakes (Hazarika et al. 2017). West Nippon Expressway Company Limited (2017) reported that the key cause of this embankment failure during this earthquake, such as excessive settlement and collapse, is the liquefaction of the loose sand layer underlying the embankment. To protect similar embankments from future earthquakes, an innovative low-cost hybrid type steel pile reinforcement technique was developed, consisting of the vertical and inclined piles, thereby mitigating the effects of liquefaction and reducing excessive deformation in highway embankments. In previous research, the effectiveness of this hybrid type steel pile reinforcement technique was evaluated using 1g shaking table tests (Qin et al. 2021). In this study, the deformations of the highway embankment reinforced by this technique with different configurations are analyzed to determine the optimum angle of the inclined pile using effective stress analysis.

DOI: 10.1201/9781003299127-239

2 NUMERICAL APPROACH

2.1 *Numerical model and boundary conditions*

Finite element modeling was conducted for one configuration of conventional reinforcement and six different configurations of hybrid type reinforcements, as shown in Table 1. Figure 1 illustrated a symmetric embankment 5 m high with a roadway 26 m wide and a slope of 1:2. The foundation comprised a 10 m thick saturated liquefiable sandy layer over a 10 m thick dense sandy layer. A cyclic elasto plastic model was selected as the constitutive law for the soil in the embankment and foundation. The insertion depth of the vertical 1.5 m diameter piles was 15 m, and the length of the inclined 0.2 m diameter piles was 14 m for all the hybrid type reinforcements. The hybrid beam elements for the vertical pile, consisting of conventional beam elements and elastic solid elements, were used to represent the pile volume. Joint elements were along with all the interfaces between the soil elements and piles, which shared identical displacements in the horizontal direction. The bottom of the model was set to be rigid. The drainage boundary was set on the ground surface, with the water table corresponding to the surface level. The ground model was established long enough in the x-direction to minimize the boundary influence.

Table 1. Numerical models with different configurations.

Angle between vertical and inclined piles	
Case 0	Without the inclined pile
Case 1	40°
Case 2	45°
Case 3	50°
Case 4	55°
Case 5	60°
Case 6	70°

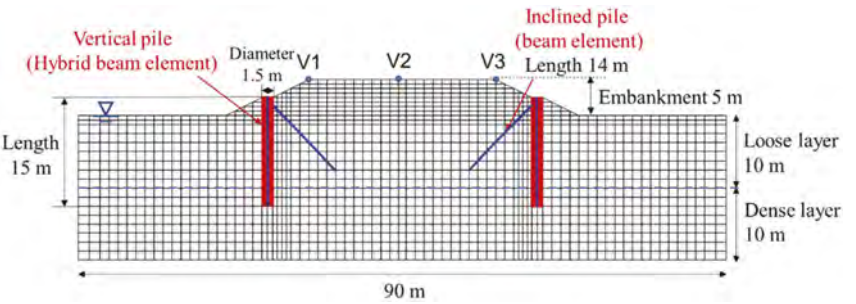

Figure 1. Finite element model for Case 2.

2.2 *Input motion*

The seismic wave from the KMMH16 station, as shown in Figure 2, was applied in the simulation. An incremental time interval of 0.001 s was adopted, while the parameters β and γ in the Newmark integration method are set respectively as 0.3025 and 0.6 to ensure numerical stability.

3 RESULT AND DISCUSSION

Figure 3 depicts the lateral displacements on left and right corners of the embankment side slopes (points A and C) for six different configurations of the hybrid type reinforcements; the locations of points A and C are shown in Figure 1. It can be clearly seen that the most

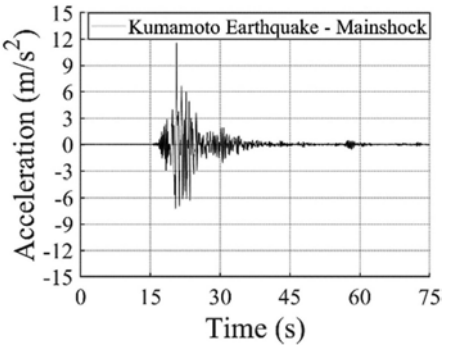

Figure 2. Seismic input motion applied in analysis (Strong-motion Seismograph Networks).

significant reduction in the lateral spreading on left and right corners of the side slopes occurred in Case 6 (angle between the vertical and inclined piles = 70°). In addition, considerable lateral spreading on the sloping sides of the embankment occurred in Case 4 (angle between the vertical and inclined piles = 55°). Figure 4 shows that the vertical displacements on points A and C were improved by the hybrid type reinforcements with six different angles. The large lateral and vertical displacements convincingly demonstrated that the hybrid type reinforcement in Case 1 (angle between the vertical and inclined piles = 40°) could not adequately enhance the embankment stability. A slight decrease in the vertical displacement was detected in Case 3 (angle between the vertical and inclined piles = 50°). Therefore, the installation of the hybrid type reinforcement in the embankment slope, as presented in Figure 1, appeared to provide limited mitigation of the embankment failure on the surface of the embankment.

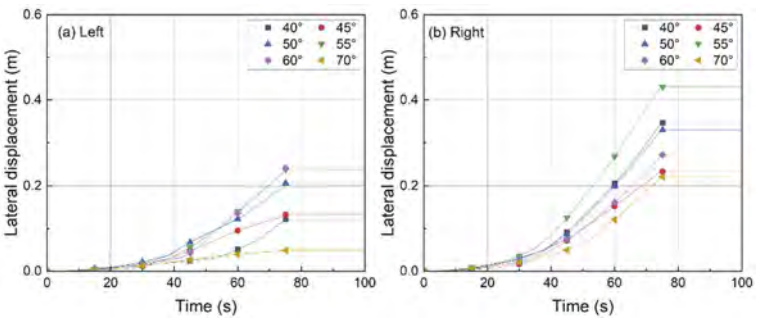

Figure 3. Time histories of lateral displacements on left and right corners of the embankment side slopes (a: point A and b: point C) for six different configurations of hybrid type reinforcements.

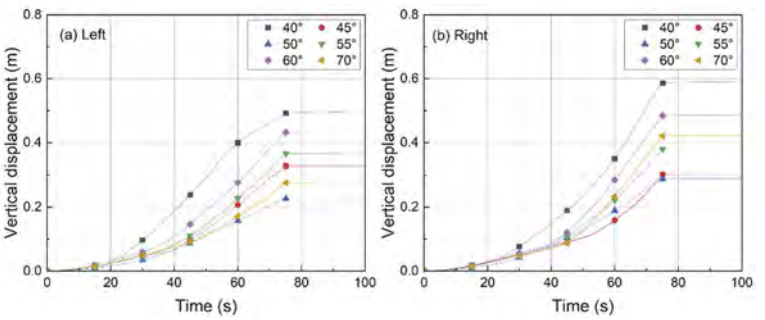

Figure 4. Time histories of vertical displacements on left and right corners of the embankment side slopes (a: point A and b: point C) for six different configurations of hybrid type reinforcements.

Figure 5 (a) shows the recorded time histories of the vertical displacements at the center of the embankment surface. For the conventional reinforcement (Case 0), the vertical displacement increased rapidly during the seismic loading. Figure 5 (b) depicts the final vertical displacements at point B for six different configurations of the hybrid type reinforcements at the end of the numerical simulations. Compared to Case 1, 2, 3 and 6, the settlements for Case 4 (angle between the vertical and inclined piles = 55°) and Case 5 (angle between the vertical and inclined piles = 60°) are less. Case 6, which reduces effectively the lateral spreading on the embankment slopes, has larger settlements than other cases.

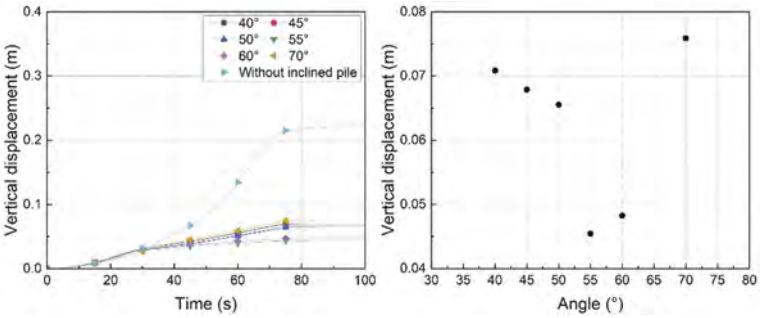

Figure 5. (a) Time histories of vertical displacements at the center of the embankment surface (point B) for six different configurations of hybrid type reinforcements and one configuration of conventional reinforcement, and (b) final vertical displacements at the same point for six different configurations of hybrid type reinforcements at the end of the simulations.

Figure 6 shows the deformed configurations of Case 4 (angle between vertical and inclined piles = 55°) and Case 5 (angle between vertical and inclined piles = 60°) at the end of the mainshock. The blue lines illustrate the locations of the vertical and inclined piles. Both side slopes of the highway embankment show significant deformation in both cases, while the surface is relatively intact after seismic loading.

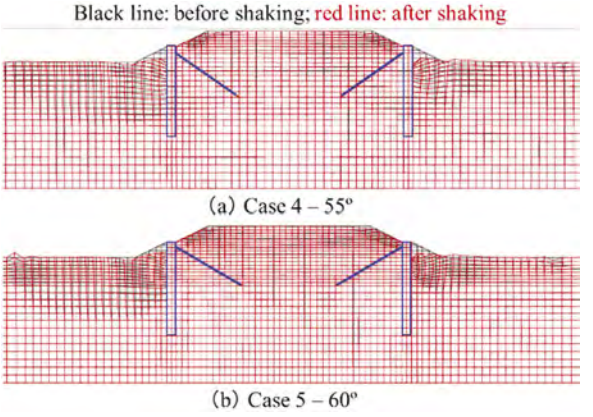

Figure 6. Deformed configurations at the end of the simulation: (a) Case 4 and (b) Case 5 (black line: before shaking; red line: after shaking).

4 CONCLUSIONS

The simulated results have proved that the highway embankment improved by hybrid type steel pile reinforcement has better performance in reducing settlement during seismic loading. In the proposed technique, inclined piles could suppress the deformation on the left and right

corners of the embankment side slopes, especially Case 6 (angle between the vertical and inclined piles = 70°) has the minimum deformation during the seismic wave. In addition, the final settlements at the center of the embankment surface were limited to an acceptable range in Case 4 and Case 5 (angles between the vertical and inclined piles are 55° and 60°). There are two possible reasons for these: (a) the complicated seismic behavior of the loose sandy layer including liquefaction; (b) the hybrid type reinforcement's range of influence. The optimum angle between the vertical and inclined piles should be in the range of 55°–60°. The inclined piles with this optimum angle range could efficiently mitigate earthquake-induced damage to highway embankments.

Validation of energy-based liquefaction prediction method for rock debris

M. Sawatsubashi & M. Ishimaru
Sustainable System Research Laboratory, Central Research Institute of Electric Power Industry, Abiko, Chiba, Japan

ABSTRACT: Under the new regulatory requirements for nuclear power plants, the evaluation of the liquefaction potential of rock debris, conventionally regarded as non-liquefiable soil, is necessary because the standard ground motion is stronger. Recently, an energy-based method was proposed for rational liquefaction prediction. In this study, to verify the applicability of energy-based liquefaction prediction to rock debris, the predicted results were compared with those of two centrifugal model tests performed on saturated rock debris under a centrifugal acceleration of 50 G. In one case, the entire layer was liquefied, and in another, the deep layer did not liquefy. In the energy-based method, the dissipated energy of each layer was calculated using nonlinear total stress analysis. The liquefaction prediction results of the energy-based method were consistent with experimental results.

1 INTRODUCTION

Liquefaction assessment is necessary to evaluate the seismic stability of ground foundations for Class S facilities, under the new regulatory requirements for nuclear power plants in Japan. The evaluation of the liquefaction potential of rock debris, conventionally regarded as non-liquefiable soil, is necessary because the standard ground motion is stronger.

Recently, an energy-based liquefaction evaluation method was proposed (Millen et al. 2020). In this method, the dissipated energy is calculated using the enclosed area of the hysteresis loop of the stress-strain relationship obtained from an undrained cyclic loading test. The dissipated energy is then compared with the energy produced by an earthquake to evaluate the liquefaction potential (Kokusho et al. 2015). The energy-based method allows a more reasonable evaluation of liquefaction compared with the stress-based method, which is currently the preferred method for evaluating liquefaction. However, most studies have focused on sandy soil, and the applicability of energy-based methods to granular materials, such as rock debris, has not been clarified.

Therefore, in this study, the characteristics of the energy-based method were analyzed to predict the increase in excess pore water pressure using a centrifugal model test on saturated rock debris.

2 TEST CONDITIONS

2.1 *Ground model and measurement items*

Figure 1 shows an illustration of the ground model and arrangement of the measuring instruments. The acceleration, ground surface displacement, and underground water pressure were measured. The ground model had a 1/50 reduction ratio, and a seismic motion was used as the input for a centrifugal force field with a centrifugal acceleration of 50 G. Table 1 lists the specifications of the centrifugal model test according to similarity laws (Kazama & Inatomi 1993).

DOI: 10.1201/9781003299127-240

Table 1. Specifications of the centrifugal model test according to similarity laws.

Parameter	Prototype	Model
Length	1	1/50
Strain	1	1
Stress	1	1
Time	1	1/50
Displacement	1	1/50
Acceleration	1	50

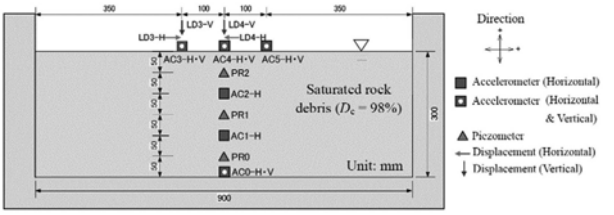

Figure 1. Ground model and arrangement of the measuring instruments (Case 2).

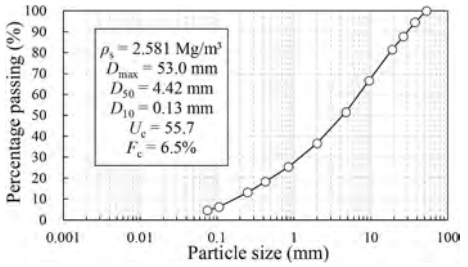

Figure 2. Particle size distribution and basic properties of rock debris.

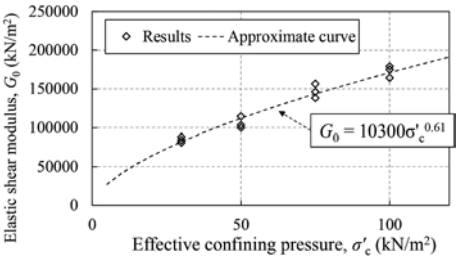

Figure 3. Elastic shear modulus and approximate curve.

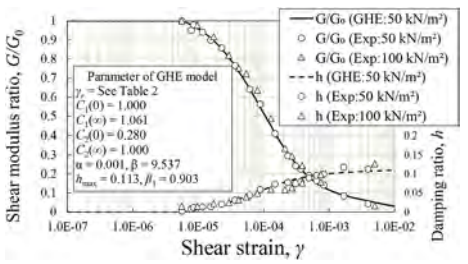

Figure 4. Dynamic deformation characteristics obtained from the cyclic triaxial tests.

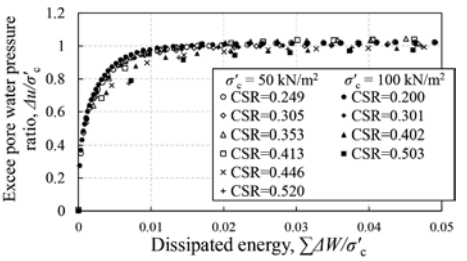

Figure 5. Relationships between the excess pore water pressure ratio and dissipated energy obtained from undrained cyclic loading tests.

The ground model was prepared using rock debris in a rigid-wall box. The ground height was 300 mm (15 m for the prototype scale) and the groundwater was at the same level as the ground surface. The ground model was prepared by compacting each layer at 60 mm intervals to achieve a 98% degree of compaction (D_c). After completion of the ground model, the box was placed in a vacuum container and saturated with deaired silicon oil (viscosity: 50 mN/m^2·s) during deairing.

2.2 *Physical properties of geomaterials*

The basic physical properties of the rock debris are shown in Figure 2. The elastic shear modulus, dynamic deformation characteristics, and liquefaction characteristics were measured via cyclic triaxial tests using specimens (diameter of 300 mm × height of 600 mm) with a D_c of 98%. With respect to the elastic shear modulus (G_0), minute cyclic loadings were performed under various confining pressures, and the relationship between the effective confining pressure (σ_c') and G_0 was obtained. Figure 3 shows the test results and approximate curve.

Figure 4 shows the dynamic deformation characteristics obtained from the cyclic triaxial tests. Cyclic triaxial tests were performed at σ_c' values of 50 and 100 kN/m^2. The test results

were fitted using a general hyperbolic equation (GHE) model (Tatsuoka & Shibuya 1992). The parameters for the GHE model were determined by fitting the experimental results, and the parameter settings are listed in Figure 3.

Figure 5 shows the relationship between the dissipated energy and maximum excess pore water pressure ratio for each cycle obtained in the undrained cyclic loading tests. The dissipated energy, $\Sigma \Delta W/\sigma'_c$, was calculated as

$$\sum \Delta W/\sigma'_c = \oint \tau(\gamma)\mathrm{d}\gamma/\sigma'_c \tag{1}$$

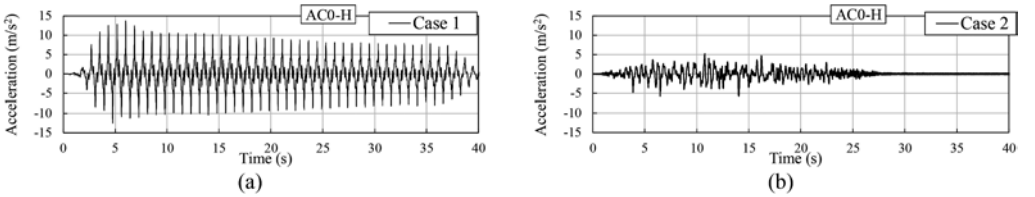

Figure 6. Input seismic motion for (a) Case 1 and (b) Case 2.

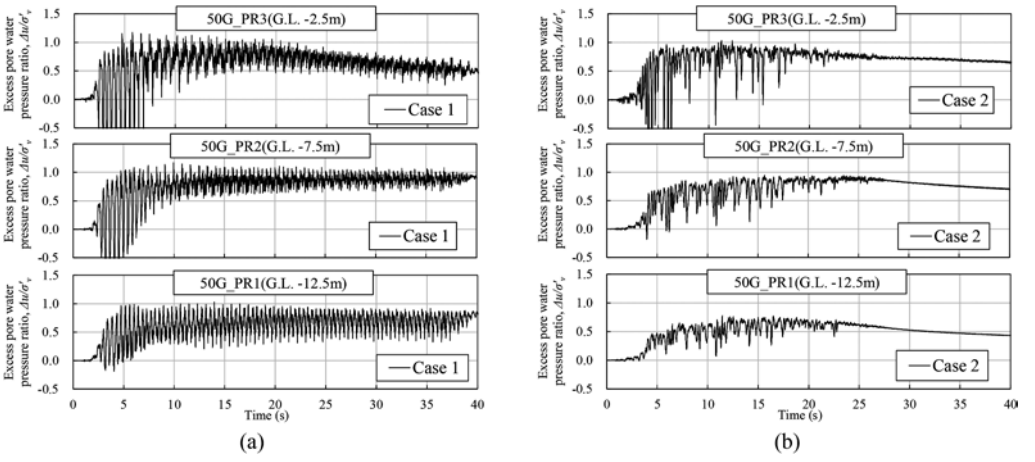

Figure 7. Excess pore water pressure ratio at each depth for (a) Case 1 and (b) Case 2.

where τ is the shear stress (half of the deviator stress), and γ is the shear strain (1.5 times the axial strain, assuming a Poisson's ratio of 0.5). The average $\Sigma \Delta W/\sigma'_c$ required to reach an excess pore pressure ratio of 95% was 0.0168 (standard deviation of 0.0078). The liquefaction resistance of rock debris, defined by an axial strain amplitude of 5% and 20 cyclic loading cycles, was 0.44 (σ_c' = 50 kN/m^2) and 0.39 (σ_c' = 100 kN/m^2).

2.3 *Input seismic motion*

Two centrifugal model tests were conducted. All subsequent data are shown as values converted to the prototype scale, based on Table 1. As shown in Figure 6, the input seismic motion was a 1.2-Hz sine wave with a four-wave taper before and after in Case 1 (PGA:13.7 m/s^2), and a simulated seismic motion in Case 2 (PGA:5.8 m/s^2).

3 TEST RESULTS

Figure 7 shows the excess pore water pressure ratio $\Delta u/\sigma_v'$ (obtained by dividing the excess pore water pressure Δu by the initial vertical effective stress σ_v') at each depth. Except for PR1 in Case 2 (G.L. −12.5 m), the $\Delta u/\sigma_v'$ of all measured layers reached 1.0 and liquefied.

4 APPLICABILITY OF ENERGY-BASED METHOD FOR LIQUEFACTION PREDICTION

4.1 *Nonlinear total stress analysis*

In previous studies, equivalent linear analysis has often been adopted to estimate input seismic wave energies. However, in the preliminary analysis, the shear strain exceeded the range of applicability of equivalent linear analysis (>1%). Therefore, a nonlinear analysis was performed. Table 2 summarizes the physical characteristics of the analysis. The ground was divided into intervals of 1-m layer thickness. The elastic shear modulus (G_0) was set using the equation in Figure 3 by assuming a coefficient of earth pressure at rest (K_0) of 0.5 and calculating the mean effective stress (σ'_c). The dynamic deformation characteristics were modeled using the GHE model, as shown in Figure 4. The values of the reference strain (γ_r) of each layer were calculated based on G_0 and the shear strength of each layer, which was calculated from the internal friction angle (47.9°), cohesion (3.9 kN/m^2), and σ'_c obtained from triaxial compression tests. The input acceleration was the horizontal acceleration measured at the bottom of the rigid-wall box during the centrifuge model experiments (Figure 6). The Newmark–β method (average acceleration method) was used as the numerical integration method. Iterative calculations were conducted to correct for disproportionate forces, and residual forces were applied in the next step.

Table 2. Physical characteristics in the analysis and results of liquefaction prediction.

* Judged liquefied.

4.2 *Liquefaction prediction using the energy-based method*

The dissipated energy ($\Sigma \Delta W/\sigma'_c$) obtained from the nonlinear total stress analysis was calculated using Equation 1. In the undrained cyclic loading tests (Figure 5), the excess pore water pressure ratio reached 0.95 when $\Sigma \Delta W/\sigma'_c$ reached an average of 0.0168. Thus, an experimental value of 0.0168 was used as the threshold for liquefaction in the energy-based method. In Case 1, all layers liquefied, whereas in Case 2, the deep layer (G.L. 12.5~14.5 m) did not liquefy. These predicted results were consistent with the test results.

5 CONCLUSIONS

The applicability of an energy-based method to centrifugal model tests with saturated rock debris was investigated. The energy-based method using nonlinear total stress analysis, can predict liquefaction in centrifugal model experiments on rock debris with relatively high accuracy.

Versatility of u-w-p formulation to instability phenomena of saturated soil

T. Toyoda
Nagoya University, Nagoya, Aichi, Japan

ABSTRACT: Numerical stability of soil-water coupling was evaluated by a spectral radius of simultaneous recursive equations comprised of ***u-p***/***u-w-p*** governing equations with time integration formulas. As a result, the numerical stability of the ***u-w-p*** formulation was confirmed for instability problems as well as highly permeable conditions. Then, the ***u-w-p*** formulation-based soil-water coupled elasto-plastic finite deformation analysis was carried out for the instability problems of saturated soil (i.e. earthquake-induced liquefaction and seepage force-induced boiling problems). Finally, we indicated the versatile applicability of ***u-w-p*** formulation-based analysis without failure of calculation even in the destabilizing stage of analysis which cannot be solved by the ***u-p*** formulation.

1 INTRODUCTION

Most of the soil-water coupled analyses based on the Biot's mixture theory employ ***u-p*** formulation (proposed by Zienkiewicz et al. 1980; hereinafter, referred to as "***u-p***"). The ***u-p*** is a method with an assumption of static pore water permeation neglecting the dynamic motion of pore water (i.e. relative acceleration/convection of pore water viewed from soil skeleton). Although the assumption contributes to reducing the number of unknown variables, the analysis fails when targeting highly-permeable soils due to the negligence of the possible dynamic motion of pore water. Therefore, the "***u-p***"-based elasto-plastic soil-water coupled finite deformation analysis developed in our research group (Noda et al. 2008) was extended to ***u-w-p*** formulation (Noda & Toyoda, 2019; hereinafter, referred to as "***u-w-p***"). The ***u-w-p*** is the scheme for considering relative acceleration/convection of pore water by solving the equation of motion of pore water directly so that the analysis for highly permeable soils exhibiting dynamic motion of pore water can be seamlessly conducted. It can be regarded as a theoretical overcome of the limitation of ***u-p*** formulation. Furthermore, the dynamic pore water motion-induced phenomena solved by ***u-w-p*** were introduced in Toyoda & Noda (2021). Besides, the applicability of the ***u-w-p*** is not limited to solving highly permeable soils with a large coefficient of permeability k, but also to solving instability problems (i.e. failure with strain localization, bifurcation, material softening, liquefaction, boiling, etc.) that requires small time increment Δt for continuing calculations with acceptable accuracy (Noda et al. 2008).

In the first half of this manuscript, the inapplicable range of the ***u-p*** was thoroughly investigated and the potential of the ***u-w-p*** for overcoming the limited applicability of ***u-p*** was empirically indicated. The possibility of the ***u-p***/***u-w-p*** calculation was evaluated using a spectral radius of a simultaneous recursive equation comprised of discretized governing equations and time integration formulas. In the latter half, the ***u-w-p*** elasto-plastic finite deformation analysis was carried out for the instability problems of saturated soil (i.e. earthquake-induced liquefaction of centrifuge model experiment of sandy ground-embankment system and boiling due to an upward local hydraulic gradient). Through these analyses, we confirmed the versatile applicability of the ***u-w-p*** analysis without failure of calculation even in the destabilizing stage of analysis (i.e. decrease of mean effective stress due to softening with pore water absorption) whose stepwise calculation cannot be continued by the ***u-p***.

2 NUMERICAL STABILITY EVALUATION OF SOIL-WATER COUPLING ANALYSIS

2.1 *Governing equation and method for evaluating numerical stability*

The governing equation of the ***u*-*w*-*p*** (Noda & Toyoda, 2019) is indicated as follows:

$$\rho_s \mathrm{D}_s^2 \boldsymbol{v_s} + \rho_f \mathrm{D}_s \mathrm{D}_f \boldsymbol{v_f} + \rho^f (\mathrm{div}\, \boldsymbol{v_s})(\mathrm{D}_s \boldsymbol{v_s} - \boldsymbol{b}) = \mathrm{div}(\mathrm{D}_s S_t) \tag{1a}$$

$$\rho^f \mathrm{D}_f \boldsymbol{v_f} = -\gamma_w \,\mathrm{grad}\, h - (\gamma_w / k)\boldsymbol{w} \tag{1b}$$

$$\mathrm{div}\, \boldsymbol{v_s} + \mathrm{div}\, \boldsymbol{w} = \boldsymbol{0} \tag{1c}$$

where Equations 1a-c represent the equation of motion of mixture, the equation of motion of fluid phase, the soil-water coupling equation, respectively; ρ, ρ_s, ρ_f, ρ^f = densities of mixture, solid phase, fluid phase, pore water, respectively; D_s, D_f = material time derivatives focusing on configurations of solid phase and fluid phase; $\boldsymbol{v_s}$, $\boldsymbol{v_f}$ = solid and fluid velocity; $\boldsymbol{w} = n(\boldsymbol{v_f} - \boldsymbol{v_s})$ = averaged flow rate of pore water; p = pore water pressure; h = hydraulic head; n, k, γ_w, $\boldsymbol{b}$, $\mathrm{D_sS}_t$ = porosity, coefficient of permeability, unit weight of volume, body force per unit mass, rate of nominal stress, respectively. Assuming static pore water permeation ($\mathrm{D}_f\boldsymbol{v}_f - \mathrm{D}_s\boldsymbol{v}_s << \mathrm{D}_s\boldsymbol{v}_s$), Equations 1a-c can be reduced to the governing equation of ***u*-*p***:

$$\rho \mathrm{D}_s^2 \boldsymbol{v_s} + \rho^f (\mathrm{div}\, \boldsymbol{v_s})(\mathrm{D}_s \boldsymbol{v_s} - \boldsymbol{b}) = \mathrm{div}(\mathrm{D}_s S_t) \tag{2a}$$

$$\left(\rho^f k / \gamma_w\right) \mathrm{div}(\mathrm{D}_s \boldsymbol{v_s}) - \mathrm{div}\, \boldsymbol{v_s} + \mathrm{div}(k\, \mathrm{grad}\, h) = 0 \tag{2b}$$

After conducting non-dimensionalization and spatial discretization of Equations 1a-c or 2a-b based on Toyoda & Noda (2019) and coalescing them with the time integration formula of Wilson-θ method, we obtain a pair of algebraic equations:

$$\text{Governing equations and Wilson-}\theta\text{ time integration:} [\mathrm{A}]\{\boldsymbol{u}\}_{n+\theta} = [\mathrm{B}]\{\boldsymbol{u}\}_n \tag{3a}$$

$$\text{Pull-back formulas of Wilson-}\theta : \{\boldsymbol{u}\}_{n+1} = [\mathrm{C}]\{\boldsymbol{u}\}_n + [\mathrm{D}]\{\boldsymbol{u}\}_{n+\theta} \tag{3b}$$

Substituting Equations 3a-b, we obtain the following simultaneous recursive equation:

$$\{\boldsymbol{u}\}_{n+1} = [\mathrm{E}]\{\boldsymbol{u}\}_n \tag{4}$$

where $\{\boldsymbol{u}\}_n$, $\{\boldsymbol{u}\}_{n+1}$, $\{\boldsymbol{u}\}_{n+\theta}$ represent column vectors listing dimensionless unknown variables at time $t = t$, $t+\Delta t$, $t+\theta\Delta t$, respectively; $[\mathrm{E}] = [\mathrm{C}]+[\mathrm{D}][\mathrm{A}]^{-1}[\mathrm{B}]$. Then, investigating the spectral radius $\rho(\mathrm{E})$ of the matrix [E] calculated as a magnitude of the minimum eigenvalues of [E], we can evaluate the numerical stability of Equation 4, i.e., $\rho(\mathrm{E}) \leq 1$ means the numerical stability of the system.

2.2 *Results of numerical stability evaluation*

In this section, the numerical stability of ***u*-*p*/*u*-*w*-*p*** was evaluated assuming the elastic and infinitesimal deformation under one-dimensional condition.

The results of numerical stability analysis changing permeability coefficient k and time increment Δt with typical parameters (θ = 1.4; ground thickness H = 1m; Young's modulus $E = 10^4$ kPa; Poisson's ratio ν = 0.30, specific gravity of soil particles G_s = 2.65; void ratio e = 1.0) are indicated in Figure 1. As for the boundary conditions, undrained fixed and drained free conditions are considered at each end of one-dimensional domain, respectively. The markers ○ and × in the figures denote the numerical stability ($\rho(\mathrm{E}) \leq 1$) and instability ($\rho(\mathrm{E}) > 1$).

In the case of ***u*-*p*** in Figure 1a, the large k/small Δt resulted in the numerical instability of calculations that was able to lead to the failure of calculations. That is, there certainly exists the inapplicable range of ***u*-*p*** formulation. Moreover, the threshold (a blue line on the figure) of the calculation possibility was not indicated as a straight line, but bent around $k = 10^{-2}$~10^{-1} m/s.

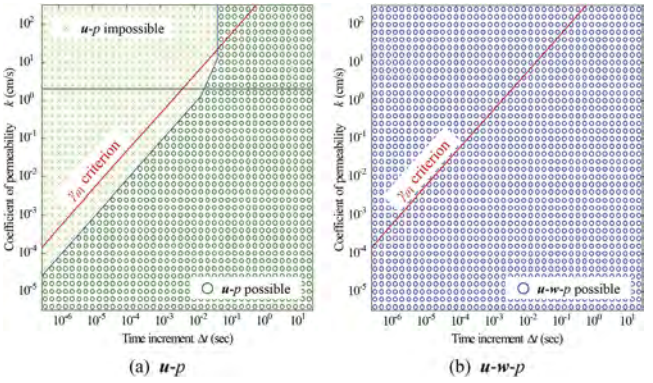

Figure 1. Numerical stability of soil-water coupling analysis evaluated by spectral radius.

Although we omitted the details here, the bending is caused by the change of eigenmodes in the theoretical solution of the one-dimensional governing equation. It could also be confirmed that the $\gamma_{\theta 1}$ criterion for estimating the possibility of ***u-p*** derived by Noda et al. (2008) was more or less valid in the low permeable range (under the horizontal black line on the figure).

In contrast, in the case of ***u-w-p*** in Figure 1b, the numerical stability was ensured even at the inapplicable range of ***u-p***. It means ***u-w-p*** has versatile applicability regardless of the settings of k and Δt. This is a potential of ***u-w-p*** for overcoming the limited applicability of ***u-p***.

It should be noted that the sufficient number of finite elements converged the value of the spectral radius, the threshold in the low permeable range does not depend on the ground height and stiffness, and the above discussion postulates $\theta > 1.37$ ensuring unconditional stability of Wilson-θ method. We've confirmed that the same trends of diagrams in Figure 1 could be obtained through two-dimensional analysis.

3 APPLICATION TO INSTABILITY PROBLEMS

In the former chapter, we confirmed that the ***u-w-p*** has strong applicability not only for highly permeable soil, but also for conditions with small time increment Δt that would usually be required in instability problems of saturated soils. In this chapter, we applied the ***u-w-p***-based elasto-plastic finite deformation analysis of saturated soil to liquefaction and boiling problems for confirming the efficacy of ***u-w-p*** to the instability problems. The targeted problems usually accompany instability caused by a lack of stiffness with a decrease of mean effective stress.

3.1 *Analysis of earthquake-induced liquefaction of sandy soil-embankment system*

Referring the centrifuge model experiment by Japan Institute of Country-ology and Engineering (2002), we prepared one/two-dimensional models in Figure 2a and input irregular wave shown in Figure 2b. The domains are entirely constituted by loosely deposited Edosaki sand whose material parameters and initial states for SYS Cam-clay model were omitted due to the space limitation. Time increment Δt (1.25×10^{-3} sec at the beginning) was changed to the smaller value when the iteration at each step did not converge.

Analysis results for the one-dimensional model with three permeability coefficients (k = 1.95×10^{-4}, 9.75×10^{-4}, 1.95×10^{-3} m/s was indicated in Figure 2c. While the case with $k = 1.95\times10^{-4}$ m/s exhibited perfect correspondence of ***u-p*** and ***u-w-p*** solutions, the case with $k = 9.75\times10^{-4}$ m/s caused a difference in the solutions. As for the case with $k = 1.95\times10^{-3}$ m/s, ***u-p*** failed at the initial stage of calculation whereas the ***u-w-p*** successfully continued the calculation.

The calculation for the two-dimensional model with $k = 1.95\times10^{-3}$ m/s based on ***u-w-p*** was indicated in Figure 2d. The ***u-w-p*** calculations were successfully continued even after the decrease of mean effective stress. Besides, we confirmed in the case of ***u-w-p*** that the occurrence of the substantial magnitude of the relative acceleration of pore water caused dynamic seepage.

3.2 *Analysis of upward seepage force-induced boiling*

Although the detailed information was abbreviated, one/two-dimensional deformation analysis applying hydraulic gradient was conducted with the same parameters of 3.1. As a result of the ***u-w-p*** analysis, we obtained not only the decreasing process of mean effective stress *p'* (softening with pore water absorption) but also the behavior after the state becomes closer to *p'*=0, i.e., surface oscillation with repeated element-wise pore water drainage/absorption in Figure 3a, concentration/disturbance of the streamline in Figures 3b-c. It should be emphasized that ***u-w-p*** calculation could be continued even at an unstable state with a lack of mean effective stress.

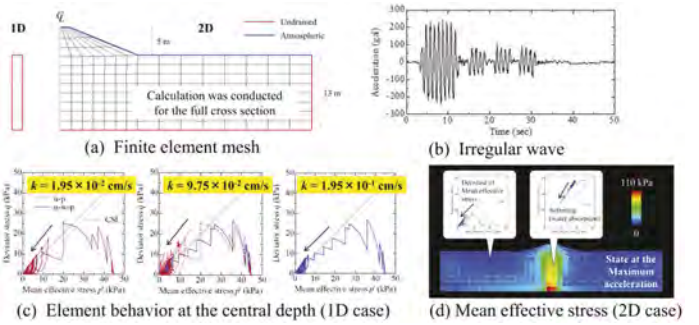

Figure 2. One/two-dimensional liquefaction analysis of sandy ground-embankment system.

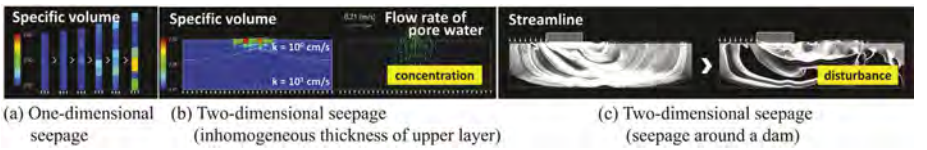

Figure 3. One/two-dimensional boiling analysis of sandy ground.

4 CONCLUSION

A versatile applicability of ***u-w-p*** has been indicated through numerical stability evaluation using a spectral radius of the recursive equations and demonstrated through its application to the liquefaction and boiling problems causing instability with a decrease of effective stress.

ACKNOWLEDGEMENTS

C.E. Ortiz
Research Center on Digital Transformation in Engineering (CITDI), Lima, Peru

ABSTRACT: In 1746, the city of Lima was impacted by an earthquake of high magnitude with a seismic intensity of X in the Modified Mercalli scale. Nowadays, a seismic event of similar magnitude has not occurred off the coast of Lima, for that reason is necessary to estimate ground response to verify if design motion of the Peruvian Earthquake-Resistant Code is appropriated. In this sense, the non-linear site response analysis was carried out in the city of Lima, for which synthetic movements in rock were generated and the deep S-wave velocity profiles were characterized. Then, the amplification of ground acceleration and spectral amplification were analyzed, as a result the spectral amplification on average was 3.0, being greater than 2.5 that is the value of the spectral amplification of the Peruvian Code. In addition, a new design spectrum for the city of Lima was proposed.

1 INTRODUCTION

The city of Lima is located in one of the regions with the highest seismic activity. According to seismic history, in the year 1746 off the coast of Lima, a strong movement occurred whose seismic intensity was X on the Modified Mercalli scale (Silgado, 1978).

In the last century, strong earthquakes occurred in 1966, 1970 and 1974 in different regions of the Peruvian coast, where seven seismic records were obtained and analyzed through normalized acceleration Spectra (Sa/PGA) to evaluate the maximum spectral amplification for rigid soil of Lima City, the result obtained was a mean maximum spectral amplification of 2.28 (Meneses & Alva, 1986). From this result and similar maximum spectral amplification values from seismic of other countries a value of 2.5 (maximum amplification) was incorporated in the E030 Peruvian Seismic-Resistant Design Code of 1997.

After several years of absence of analysis and research regarding the evaluation of spectral amplification, Soto (2016) and Soto et al. (2018) compiled the physical and dynamics characteristics of ground to obtain results for deep soil profiles (greater than 200 m). Then evaluated the site spectra by equivalent linear (EL) and non-linear (NL) site analysis, the spectra was normalized to obtain a spectral amplification value of 3.0, which is greater than 2.5, the last value was indicated in E030 Peruvian Code of 2006. In southern of Peru, in Tacna, Ortiz (2019) and Alva et al. (2020) compiled the geotechnical characteristics and conducted an extensive campaign of dynamic characterization through measurements of microtremor arrays specifically at the seismic stations. With this information it was performed the EL and NL site analysis of deep soil. The results obtained for stiff and intermediate soil the acceleration amplification were 1.0 and 1.3, respectively, and the maximum spectral amplification was 3.0 for both types of soil, again these values are higher than 2.5. On the other hand,

DOI: 10.1201/9781003299127-242

Aguilar et al. (2019) performed the NL site analysis of soil profiles with depth of 30 m to estimate the spectral amplification by ratio of soil spectrum over the rock spectrum, as result the amplification values of 3.0 for profiles with Vs30 varying from 200 m/s to 350 m/s.

Recently, Alva (2021) analyzed the acceleration records from the large earthquakes of the years 2001, 2007 and 2019. From these last earthquakes, significant amounts of seismic records were obtained. With these records, the spectral amplification for different types of soil was analyzed, in several stations. It was evidenced that spectral amplification has a maximum value of 3.0, so it is insisted to continue with the evaluation of soil amplification and spectral amplification.

Two types of amplification occur during a seismic event, the first as an increase in ground motion relative to the motion of bedrock (soil amplification factor) and the second as an increase of the motion of structure relative to the ground motion (structural amplification factor) through spectral amplification. These amplification factors could be determined by analysis of seismic records, probabilistic Seismic Hazard, Non-Linear Site Response Analysis and Seismic Design code. Since no strong motion information is available for deep soil deposits, the NL site analysis of the City of Lima was performed in this paper to evaluate the site spectral amplification by means of the normalized acceleration spectra.

2 PERFORMED SITE ANALISIS

2.1 *Analyzed sites*

The analyzed sites were eighteen seismic stations, these stations correspond to the seismic networks CISMID (Peruvian-Japanese Center for Seismic Research and Disaster Mitigation) and UNI-CITDI (Research Center on Digital Transformation in Engineering from National University of Engineering). The stations are located in zones with different seismic geotechnical characteristics, these zones were established in the Seismic Geotechnical Microzonation map (CISMID, 2014). This map was made from the physical characteristics of the ground (soil pits and drilled wells) and the dynamic characterization through the fundamental vibration period (obtained of microtremor HV spectrum). A summarized of four zones are described as follow Zone I has vibration periods less than 0.3 s, Zone II has vibration periods less than 0.4 s, Zone III shows vibration period greater than 0.4 s, and Zone IV as zone of high seismic amplification. The location of the seismic stations on Seismic Geotechnical Microzonation map is shown in Figure 1.

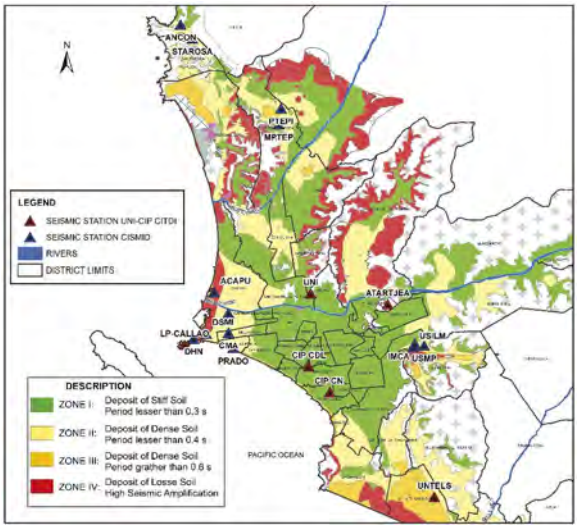

Figure 1. Locations of analyzed seismic stations.

2.2 *Physical characteristics of soil*

The City of Lima is composed of gravel and boulders, which is called Lima Conglomerate (Zone I) in whole depth, as well as the presence of sand, and silts and clays (Zone II, III and IV) superficially. According to drilling wells below 50 m depth in zones II, III and IV, the Lima Conglomerate is present (Soto, 2021).

The average unit weight for clayey and silty soils, is 14.1 kN/m^3, the moisture content is 20.8%, and the Liquid Limit (LL) varies from 1.7 % to 42.0 %. The unit weight for sandy soils is 17.2 kN/m^3, the moisture content is 8.4 %, the compactness varies from dense to very dense, also is presented in an almost dry state and certain degree of natural cementation. The unit weight for the Conglomerate, is 22.0 kN/m^3, the moisture content is 3.6 %, and these values are close to those obtained by Sanchez et al. (2016) who considered the variability of these parameters of the Lima Conglomerate, from the depth of 5 m to 30 m. For rock, it is mostly conformed by igneous and sedimentary rock whose unit weight is about 26 kN/m^3.

2.3 *Dynamics characteristics of soils*

The dynamic characteristic of soils was obtained through of the Fundamental Period (T) and the S-Wave Velocity profile (Vs). The values of T were obtained from HV spectral ratio of seismic records (HV spectrum) and the values of Vs obtained from surface waves measurements tests of the first 30 m depth (Vs_{30}) and the inversion of the HV spectrum, as mentioned by Soto (2021) and Soto & Alva (2022). The values obtained for deep Vs profile are similar to those obtained by Calderon et al (2013).

Due that Lima soil deposit has a thickness varying from 200 m to 400 m in depth, the use of Vs_{30} according to E030 Peruvian Code for site class is not sufficient, so that very thick deposit can influence the behavior during a seismic motion. Therefore, a particular criterion of Class Site (according the Vs_{30}) and Peaks Periods of the HV spectrum was adapted as shown in Table 1, where site type S1 and S2 were subdivided into two subgroups G1 and G2.

Figure 2a shows four HV spectra of the CIP CN, IMCA, LP CALLAO, and UNTELS stations, which according to peak periods T0 and T1, the mentioned stations were characterized as S1-G1, S1-G2, S2-G1, and S2-G2, respectively. From an inversion process of these HV spectra, the corresponding Vs profiles were obtained as shown Figure 2b. These profiles shows that bedrock presents a Vs value of 1500 m/s, with the exception of the IMCA station where the rock has a value almost 1000 m/s and also shows a reduction of Vs at depth of 55 m to 85 m to increase again at greater depth. For others seismic stations according to HV spectra and Vs profile were classified as shown in Table 2.

Table 1. Criterion of class site.

Class	Predominant Period	Condition	Site
S1	0.1 < T0, T1 < 1.0 s	T0<T1	S1, Group 1 (S1-G1)
S1	0.1 < T0, T1 ≤ 1.0 s	T0>T1	S1, Group 2 (S1-G2)
S2	T0≥1.0; 0.1 < T1 < 1.0	T0>T1	S2, Group 1 (S2-G1)
S2	0.1 < T0, T1< 1.0	T0>T1	S2, Group 2 (S2-G2)

T0 is the period of the highest amplitude
T1 is the period of the second highest amplitude

2.4 *Non-linear behavior of soils*

The non-linear behavior of soils was estimated using the empirical equations of normalized shear stiffness curves (G/G_o) and damping ratio curves (D) from available technical literature. For gravelly soils (including the Conglomerate), the empirical relationships of Menq (2003) were used, while for sandy and clayey soils the empirical relationship of Zhang et al. (2005) were used.

Most of empirical equations requires the physical properties such as Coefficient of Uniformity (Cu) and effective isotropic confining pressure (σ'_o) for gravels, while sandy soils and clayey soils depend of the Plastic Index (PI) and mean effective confining stress (σ'_m). For the Lima Conglomerate the Cu value was 70; for sands, the PI was 6 % for UNTELS and CMA stations and PI of 0% for other stations; and for clays, the PI was in range 6% to 21 %.

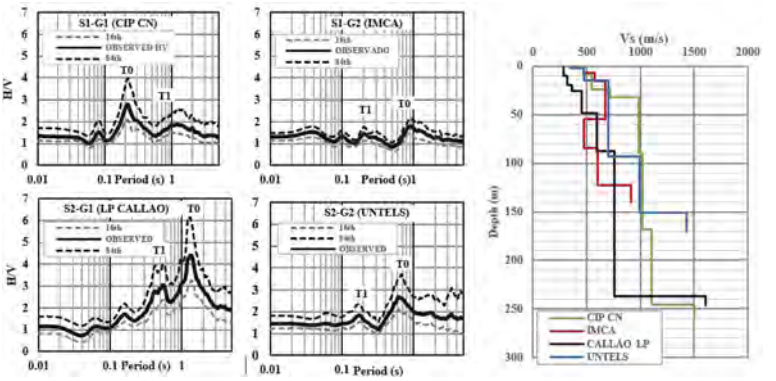

Figure 2. a) HV spectra for determine peak periods, b) Deep vs profiles.

Table 2. Dynamic characteristics for analyzed seismic Stations.

Seismic Station	Lat (°)	Long (°)	Zone	Vs_{30} m/s	Site Class E.030	Site Class ASCE	T0 (s)	T1 (s)	Group

* Stations from UNI-CITDI seismic network

2.5 *Input seismic records*

Since there are no rock acceleration records of strong motions in Peru, synthetic accelerograms were generated so that the mean acceleration spectrum is compatible to the rock design spectrum (Kottke & Rathje, 2007). The selected records were from earthquakes of greater magnitude recorded in the Peruvian territory, these correspond to interface and intraplate subduction mechanisms, and Table 3 shows the characteristics of the recorded seismic events.

The rock design spectrum (Vs30=760 m/s) was obtained from uniform hazard analysis with 10% of probability of exceedance in 50 years, same level of seismic risk of E030 Peruvian Code. Resulting in the spectral acceleration at T=0 s of 0.47 g.

The criterion for using these earthquakes was the Arias Intensity (AI) a parameter that reflects the amplitude and frequency by duration of the motion, as well as the structural damage that can be generated by ground motion. Figure 3a shows the AI for each seismic record and Figure 3b shows the compatible spectra where the mean spectrum sufficiently matches the rock spectrum.

These compatible input motions correspond to motion of the outcrop with Vs30=760 m/s, however, it has been observed that bedrock of the deep profiles has a Vs value of 1000 m/s to 1500 m/s for the site analysis. The input motion at bedrock was obtained by deconvolution for the Atarjea station, then at the specific depth where Vs varies from 1000 m/s to 1500 m/s was considered the input motion for site analysis as performed by Soto (2021). The Atarjea station belongs to UNI-CITDI and is located on rock.

* Epicentral distance

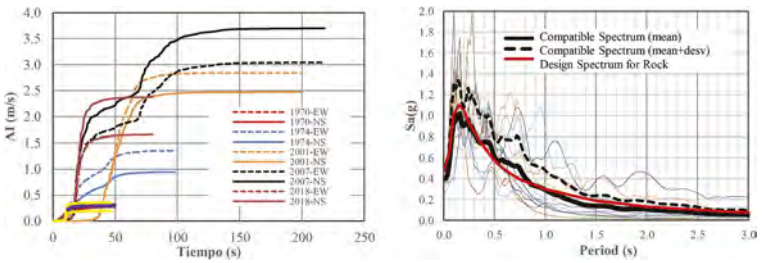

Figure 3. a) Arias intensity of seismic records, b) Compatible design spectrum for rock.

2.6 *Non-linear site analysis*

Non-linear Site Analysis was performed using DeepSoil software (Hashash et al. 2016). For each analysis, profile was discretized in layers such that the maximum vibration frequency is 25 Hz. The constitutive mode and load-unload model of soils were the MRDF pressure-dependent hyperbolic model (Phillips & Hashash, 2009).

3 RESULTS AND DISCUSIONS

3.1 *Acceleration spectra*

After performing the nonlinear analyses, on the surface of each profile, the acceleration spectra with damping ratio of 5% (Sa) were obtained as shown in Figures 4-5 for sites S1-G1, S1-G2, S2-G1 and S2-G2. These figures show the mean values and its variability (mean plus

a standard deviation), due to the high degree of variation of the input motion, however, in the following paragraphs the description and analyses were performed for the mean value of spectra as shown.

For sites S1-G1 (Figure 4a), a maximum average surface acceleration of 0.47 g was obtained, while for S1-G2 (Figure 4b) a maximum acceleration of 0.38 g was obtained. These sites superficially have a similar Vs30 value (Type S1, according E030 Peruvian Code), however the effect of depth and the variation in depth of the Vs profiles influences the seismic response at surface, as shown in acceleration spectra in Figure 4.

For sites S2-G1 (Figure 5a, b) a maximum surface acceleration of 0.40 g was obtained on average, with a notable difference in the shape of spectra, as shown in the LP CALLAO and DSMI stations, this is because the surface layers are more erratic from stations close to ocean (LP CALLAO and DHN). On the other hand, for sites S2-G2 (Figure 5c) the maximum ground acceleration was 0.60 g, this spectrum has a peak spectral acceleration in the period of 0.1 s, this is because the profile is dense in the first 50 m depth.

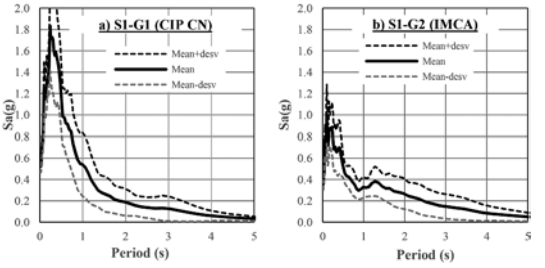

Figure 4. Acceleration spectra at surface for sites S1-G1 and S1-G2.

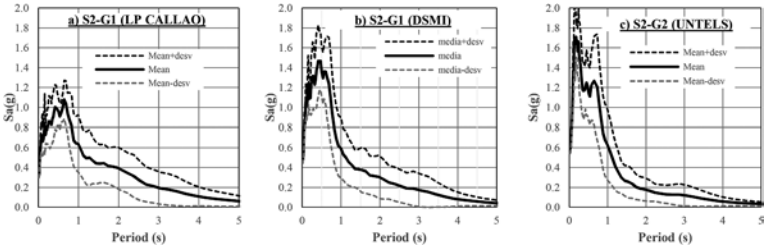

Figure 5. Acceleration spectra at surface for sites S2-G1 and S2-G2.

On the other hand, for sites S1-G1 and S1-G2 the Sa spectra present a peak acceleration in spectral periods less than 0.2 s and 0.3 s, respectively. In the range of periods greater than 1.0 s, the spectral acceleration of S1-G2 are higher than S1-G1, this is due to the behavior of the deep profile and the Vs values of S1-S2. For site S2-G1 as LP CALLAO and DMSI the Sa spectra present a maximum value that apparently are almost flat until periods of 0.9 s and 0.6 s, respectively. In the range of periods greater than 1.0 s the spectral accelerations of LP CALLO are higher than DSMI, this is due to deep Vs profile and shallow layers of both sites (Soto, 2021). For site G2-S2 shows a peak spectral in period 0.1 s, then becomes almost flat up to 0.6 s.

3.2 *Soil amplification*

The ground motion at surface is amplified or de amplified with respect to rock motion, taking into account that the response at the surface is influenced by whole ground profile, it is defined as the soil amplification (S') which is determined as the ratio of maximum acceleration of surface soil to maximum acceleration of outcrop.

From the rock uniform hazard spectrum, the maximum acceleration was 0.47 g, slightly higher than 0.45 g (for Zone 4 of Peru, according E030 code), this last value of rock acceleration is used as a reference for the design of structures in the city of Lima. The amplification was determined considering the rock acceleration of 0.45 g. The S values for sites S1-G1, S1-G2, S2-G1 and S2-G2 are shown in Table 4.

3.3 *Spectral amplification*

The ratio of the spectral acceleration to maximum ground acceleration was defined as the spectral amplification. This ratio is a simplified method that allow identifying the influence on the site over a wide range of periods regardless of maximum ground acceleration level. This ratio allowed identify how deep soil profiles influence the seismic response of the acceleration spectrum.

The spectral amplification has a peak value because the Sa spectrum has a peak value. These values do not necessarily indicate the maximum spectral amplification over the whole spectrum, so therefore a review of the site spectrum and displacement spectrum were necessary to properly define the spectral amplification. A summary of the peak values of spectral amplification (C') are shown in Table 4.

Table 4. Values of aoil amplification (S') and maximum spectral amplification (C').

Group	S'	C'
S1-G1	1.00 – 1.16	2.89 – 3.53
S1-G2	0.80 – 0.95	2.86 – 4.00
S2-G1	0.70 – 0.93	3.33 – 3.59
S2-G1*	0.80 – 1.04	2.76 – 3.09
S2-G2	0.90 – 1.20	2.94 – 3.27

* Stations (DSMI, ACAPU, RAMON, CMA, and PRADO) located in Zone II of Seismic Microzonation

3.4 *Proposed site spectrum and proposed spectral amplification*

To determine the Site Design Spectrum (S_a), in a practical manner, it was established that it is influenced by the maximum ground acceleration and the spectral amplification through the following equations:

$$S_a = ZSC \tag{1}$$

$$T \leq T_P : C = C_o \tag{2}$$

$$T_P < T \leq T_L : C = C_o(T_P/T) \tag{3}$$

$$T > T_L : C = C_o(T_P\, T_L)/T^2 \tag{4}$$

Where Z= maximum horizontal acceleration for rock; S= soil amplification factor; C= spectral amplification; C_o= maximum value of spectral amplification; T= structural period; T_P= limit period to define constant spectral acceleration; and T_L= period that define the beginning the displacement constant spectral.

To define the T_P and T_L periods of Site Design Spectrum, the variability of seismic motions was considered at surface ground, as well as the Displacement Spectrum (S_d) that is influenced at the surface due to seismic motions. The S_d spectrum is defined as $S_a\,(T/2\pi)^2$. To obtain the values of T_P and T_L, the spectra of C, S_a and S_d were analyzed simultaneously, then the same parameters of E030 code were compared.

For each site S1-G1, S1-G2, S2-G1 y S2-G2, a group of S, C_o, T_P y T_L values was proposed as shown in Table 5, where it is observed that sites S2-G1 were subdivided in two groups due to the different behavior of spectral amplification caused by the shallow layers. Then the normalized acceleration spectra was superimposed with spectral amplification (C-proposed), the NL acceleration

spectral (Sa-NL) with the site design spectrum (Sa-proposed) and E030 code acceleration spectrum (Sa-E030), and the NL displacement spectra (Sd-NL) with the site displacement spectrum (Sd-proposed) and E030 code displacement spectrum (Sd-E030) as shown in Figures 6-10.

The proposed spectral amplifications (C-proposed) for all sites (Figures 6a-10a) can be considered as acceptable because it encompassed the normalized spectra of ground motions obtained from NL analyses, with a slightly difference in pointed structural period less than T_P.

The Sa-proposed spectra, for all sites (Figure 6b-10b) encompassed acceptably the Sa-NL spectra with some pointed difference at spectral periods less than T_P, it is similar to the proposed amplifications, however, this does not influence on the displacement generated by seismic motions from the NL analysis. Furthermore, the Sa-proposed spectra are greater than Sa-E030 spectra over the whole range of structural periods.

With respect to the Sd-proposed spectra, for all sites, these are acceptably to cover the Sd-NL spectra over the range of structural periods. In addition, the Sd-proposed spectra are greater than Sd-E030 spectra in all structural periods, satisfactorily covering some upper spectral displacement that may occur due to strong influence of depth at sites. This is evidenced by the deep profile is showed for Sd-NL spectra exceed the Sd-030 spectra, therefore this shows that the C, Sa and Sd parameters of E030 Peruvian Earthquake-Resistant code (Table 5) provides values with deficiencies for deep soil deposits for earthquake design as indicated by this code.

Table 5. Summarized of proposed parameters and peruvian code parameters.

Group	Proposed Parameters				E.030 Parameters			
	(S)	(C_o)	T_P	T_L	(S)	(C)	T_P	T_L
S1-G1	1.05	3.00	0.40	2.50	1.00	2.50	0.40	2.50
S1-G2	0.90	3.00	0.50	2.50	1.00	2.50	0.40	2.50

4 CONCLUSIONS

The spectral amplification of deep soil deposits in city of Lima was analyzed using the simplified method from obtained surface ground motion of the nonlinear site response analysis.

The results shows that the deep soil deposits characterized by the HV spectrum of earthquakes and deep Vs profile show a notable influence on the shape of the normalized acceleration spectrum, the acceleration spectrum and the displacement spectrum, for which the spectral amplification (C) and Design Spectrum (Sa) were proposed in equations 1-4. A maximum value of spectral amplification (C_o) is 3.0 greater than 2.5 (value stablished by the E030 Peruvian code). On the other hand, for deep deposits the E030 code is deficient in covering the displacement spectral values that may occur for design earthquake.

An experimental investigation on ejecta-induced settlement in sand with varying fines contents and densities

M.-C. Chu
Postdoctoral Fellow, Department of Civil Engineering National Chung Hsing University

C.-C. Tsai
Professor, Department of Civil Engineering National Chung Hsing University

ABSTRACT: Ground settlement may occur due to ejecta during soil liquefaction and consequently cause damages to structures and lifelines. To investigate factors that affect the settlement induced by sand boil, an experimental investigation by the special design apparatus is conducted in this study. Sandy deposit is prepared by filling in transparent acrylic cylinder with varying densities and fines contents. An acrylic circular plate, acting as a non-liquefied layer, is placed on the top of sandy deposit (specimen). Then, the cylinder is subjected to torsional shaking to produce soil liquefaction and sand boil. Soil particles are ejected out from the gap between the circular plate and cylinder and the plate starts to sink simultaneously. The thickness of ejecta can be observed from the accumulated sand particles on the plate. The influences of varying densities and fines contents on the ejecta amount as well as the settlement are quantitatively analyzed. It is found that the larger density of clean sand deposit results in smaller ejecta amount and associated settlement. However, the influence of density on the ejecta amount of sand and silt mixture is not as obvious as that of clean sand. Moreover, the ejecta contains more silt than the prepared specimen from the sieve analysis results.

Keywords: Sand Boil, Liquefaction, Settlement, Fines content, Ejecta, Density

1 INTRODUCTION

Liquefaction settlement is an important issue in geotechnical engineering, and many researches have been conducted to evaluate the liquefaction settlement. The mechanism of liquefaction settlement has been discussed by Bray & Dashti (2014) that including three types: ejecta-induced settlement, shear-induced settlement, and consolidation settlement. The ejecta-induced settlement could be more significant compared the other two. However, the ejecta-induced settlement is hard to be captured by continuum analyses (Bray & Macedo 2017). Hence, an experimental investigation by the special design apparatus is used in this study. Effects of non-liquefied thickness, gap size, overburden weight on the amount of ejecta have been investigated in the model experiment by Tsai et al. (2022). In this study, the effects of fines and densities on the ejecta amount is further evaluated.

2 TEST PROGRAM

2.1 *Test system*

The experimental apparatus in this study is presented in Figure 1. The 2500g loading system (Figure 2) is placed on the top of soils. The laser distance transducer is installed on the top to

DOI: 10.1201/9781003299127-243

measure the total settlement. The transparent acrylic cylinder is designed to observe soil response during the test and to measure the pore water pressure changes by pore water pressure transducers installed at different depths on the cylinder. The acrylic cylinder is fixed on the shaking table during tests, and acceleration is measured by accelerometer through the tests. Torsional shaking is applied to induce liquefaction. During liquefaction, soil particles are ejected out from the 2mm gap between the loading system and acrylic cylinder (Figure 2) during the test. The ejecta amount could be observed and recorded by the monitoring camera.

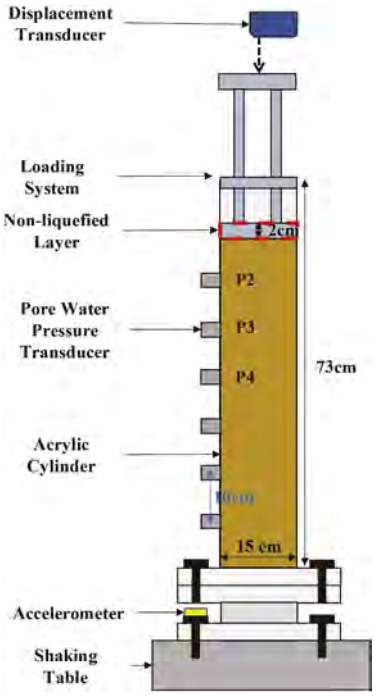

Figure 1. Testing system.

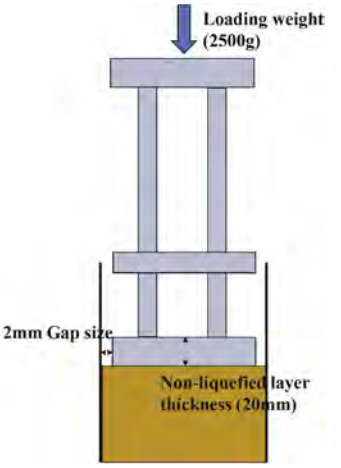

Figure 2. Loading system.

2.2 *Specimen preparation and testing procedure*

The clean sand and non-plastic silt (Figure 3) were used as the test materials in this study (Table 1). The 5% silt is added in pure sand to investigate the effect of fines on sand boils. Clean sand specimens are produced by water pluviation method which has been adopted in previous researches (Ueng et al. 2006, Tsai et al. 2022). However, water pluviation method may lead to severe segregation of coarse and fine particles in the specimens of dirty sand. On the other hand, the dry deposition method and wet tamping method may also cause non-uniformity in specimens. Therefore, a modified deposition method is proposed herein for preparing specimens with fines after Carraro & Monica (2008) with the following steps.

1. The sand is first mixed with fines in the dry condition.
2. An acrylic tube is filled with de-air water to 1/5 height of tube.
3. Mixed soil is slowly filled in tube, and water is added to until it merges the soil.
4. The rubber stoppers are installed on the rube and the tube is placed upside down for allowing air bubbles to move up toward the top of tube.
5. Extra water is added to replace the space occupied by air bubbles. Previous step could be repeated several times until no visible air bubble.

6. Plastic wrap is installed on one side of tube.
7. The tube is suspended in sedimentation apparatus, and plastic wrap is penetrated to let soils flow out the tube and deposit in the transparent acrylic cylinder.

The proposed method effectively reduces the amount of air bubbles, and improve the uniformity. A pre-test small shaking is applied to achieve the desired densities. The settlement and porewater pressure are recorded and measured through the tests.

Table 1. Basic properties of used materials.

Materials	Sand	Silt
Specific gravity of solids	2.65	2.66
Median size D_{50} (mm)	0.193	0.012
Effective size D_{10} (mm)	0.147	0.002
Coefficient of uniformity C_u	1.36	7.58
Coefficient of curvature C_d	1.1	2.07
Hydraulic conductivity k(cm/s)	0.034	0.0056
e_{max}	0.922	2.102
e_{min}	0.598	1.182

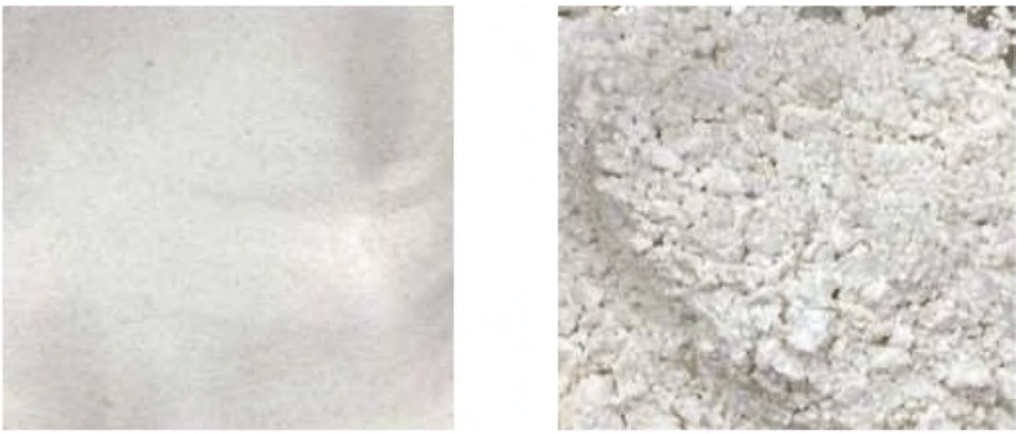

Figure 3. Photos of materials.

3 TEST RESULTS

The measured total settlement is contributed by ejecta-induced and consolidation settlement. The observed thickness of ejecta is considered as the same as the ejecta-induced settlement but is corrected to for the density difference between the ejecta and the specimen. Therefore, the consolidation settlement is estimated by the total settlement subtracting the ejecta-induced settlement.

3.1 *Density effect*

The test results on clean sand of different densities (relative densities, Drs) are collected and shown in Figure 4. As the density increases, the total settlement (Figure 4 (a)), ejecta-induced settlement (Figure 4 (b)), and consolidation settlement (Figure 4 (c)) decrease. Moreover, the total settlement is mainly contributed by the ejecta-induced settlement as the density decreases. The excess pore water pressures in tests are shown in Figure 4 (d). It could be observed that the duration of excess pore water pressure maintaining around 2kPa is longer as densities is lower.

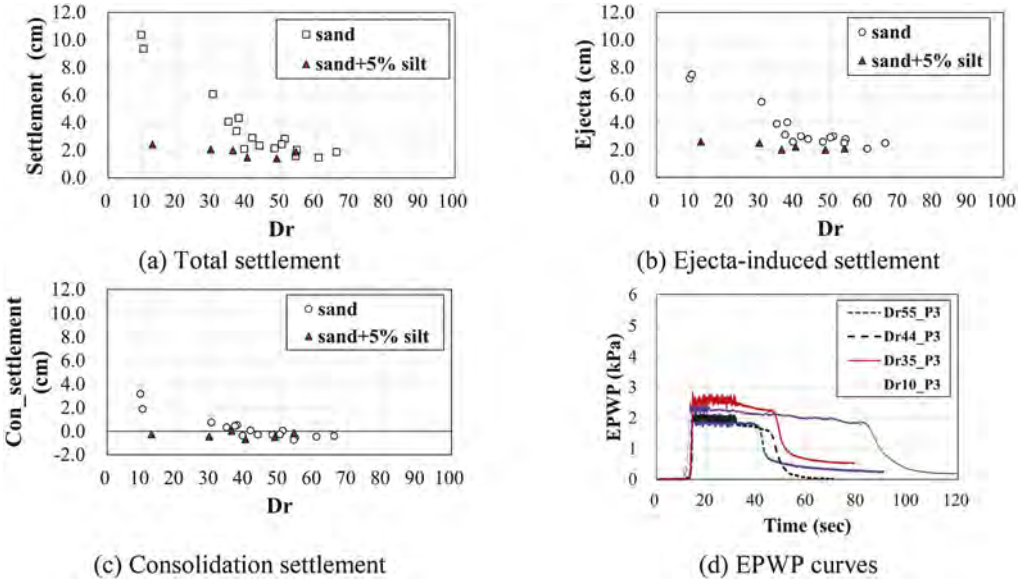

Figure 4. Test results under varying densities for clean sand and dirty sand.

3.2 *Fines effect*

Figure 4 also shows the tests results of adding fines. It could be seen that density have a more obvious influence on liquefaction settlement in clean sand than dirty sand specimens. With the similar relative density, the ejecta (Figure 4 (b)) and consolidation (Figure 4 (c)) settlement of dirty sand specimens are less than clean sand. The excess pore water pressure dissipates right after the shaking stops in the dirty sand specimen as shown in Figure 5(a). With the similar density, pore water pressure maintains (PWP time) in 2kPa is longer in the clean sand than the dirty sand. In Figure 5(b), it could be seen that the PWP time reduces with the increasing relative density. It is also found that the fines contents in ejecta is around 15% to 25%, which is higher than the fines content (5%) in designated specimens. This shows that the fines are easier to be ejected out.

Table 2. Test information.

Test Series	Test No.	e (-)	Dr (%)	Gap size (mm)	Shaking duration (s)
sand	12	0.75	54	2	20
Sand+5% silt	M2	0.71	52	2	20
	M3	0.76	40	2	20
	M5	0.73	49	2	20

4 CONDLUDING REMARKS

Through the series of test results, it is concluded that density is influential on the amount of ejecta on both clean and dirty sand specimens. As density increase, the total settlement, ejecta-induced settlement, and consolidation settlement are reduced. However, the influence is more obvious in clean sand than dirty sand. On the other hand, the excess pore water pressure dissipates right after the shaking stops in the dirty sand specimen. The PWP time reduces as the density increases, which is more profound in the clean sand than the dirty sand specimens.

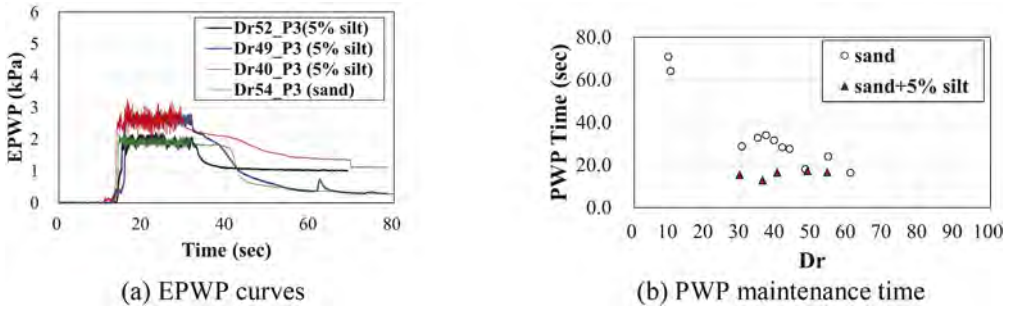

Figure 5. Test result of adding fines specimens.

Propose of design method about seismic reinforcement of embankment using soil nails and slope protection works

T. Matsumaru & S. Nakajima
Railway Technical Research Institute, Tokyo, Japan

ABSTRACT: In recent years, reinforcements of railway embankments have been conducted for increasing the seismic resistance and reinforcements using soil nails are adopted. At the slope of the embankment, slope protection works are often constructed and can also contribute to the increase of seismic performance by connection with soil nails. However, this effect has not been studied clearly. In this paper, the effects were studied through the series of shaking table tests and the calculation method with consideration of the effect was developed and validated.

1 INTRODUCTION

In recent years, severe earthquakes have often occurred, and a lot of railway earth structures collapsed (Koseki et al. 2012). Therefore, increasing seismic resistance of earth structures is important so the reinforcements of the earth structures have been conducted positively. Furthermore, the new methods of reinforcements have been established (Nakajima et al. 2021). The methods of reinforcements aimed to embankments are selected according to the prediction of their failure modes and calculations of residual settlements. In the case where the reinforcement of the embankment body is required, the reinforcement method of installing soil nails in embankment is often selected. This method has been validated from series of tests and been used in business practices with the establish of its design (Railway Technical Research Institute 2007).

On the other hands, the slope protection works on the surface of slope of embankments are often constructed in Japan for increasing resistance to severe rainfall (Matsumaru and Sato 2018) and realizing economical maintenance of slopes. When the soil nails are constructed at existing embankments with slope protection works, the top of the soil nails are often connected with the works. In this case, the soil nails will work as group and can show larger effect of reinforcement. However, the mechanism about the effect of the soil nails and the slope protection works on seismicity has not been studied and the design method has not been established.

In this paper, the series of shaking table tests of embankments with soil nails were conducted, to clarify the effect of slope protection works for the increase of seismic resistance. Then, the method considering this effect in predicting the residual displacement of embankment was developed. Finally, the validation of the proposed method was examined through the simulation analysis of shaking table tests.

2 SHAKING TABLE TESTS OF EMBANKMENT

2.1 *Test conditions*

Figure 1 Shows the illustrations of the experimental model of embankment and the slope protection works for three cases used in the shaking table tests. The dimension of the embankment was 60 cm in height and 1: 1.2 in gradient of the slope. For all cases, four soil nails with 50 cm in length were used arranged as shown in Figure 1. We conducted three cases of tests under the presence/absence or kind of the slope protection work. In Case 1, any slope protection work was not used, and the top of the soil nails were fixed with the bearing plate. In Case 2, the lattice rigid

DOI: 10.1201/9781003299127-244

frame was adopted. The tops of the nails were connected with the intersections of the frame work. Thought the region surrounded by the frame was opened, the surface of the slope was in contact with the frame. In Case 3, the small frame for keeping the distances between soil nails was used. The frame did not touch the surface of the surface of the slope so there was no effect of the small frame on retaining earth pressure of slope.

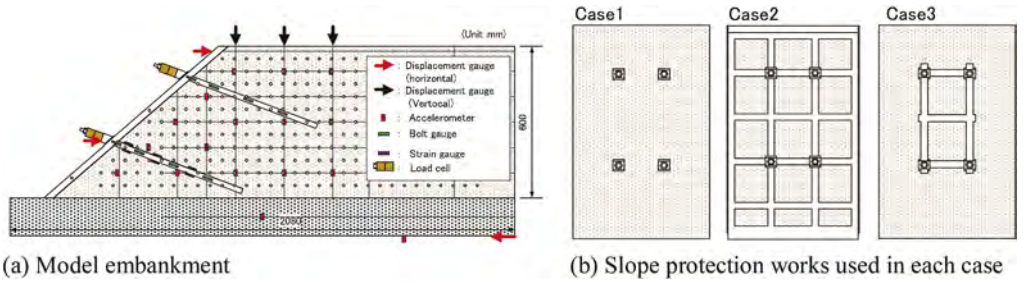

Figure 1. Model embankment and cases about presence/absence or kinds of slope protection works.

The material of the embankment was Inagi sand, whose particle density G_s was 2.723; 50% diameter on the grain size diagram D_{50}, 0.134mm; the uniformity coefficient U_c, 9.29; the fine fraction content F_c, 9.7 %; and the maximum dry density, 1.517 g/cm^3. The embankment was prepared so that the dry density and the water content would be 1.335 g/cm^3 and about 13% respectively. The ground was constructed using crushed stone for mechanical stabilization.

The measurement included acceleration, horizontal and lateral displacement at the top and the surface of the embankment, and the tensile force and the strain of soil nails for making dynamic behavior of the embankment clear. Furthermore, we photographed reference points in the embankment with a high-speed camera and analyzed the obtained data to estimate a deformation mode of the embankment. For the input motion, a sinusoidal wave of 5 Hz was used. For both the cases, the shaking table test was continued with gradual increase of the amplitude of acceleration until the embankment collapsed.

2.2 *Results and discussions*

Figure 2 Shows the relationship between the inputted acceleration and the residual vertical displacement at the shoulder of the embankment. In Case 1, the residual displacement occurred at the shaking of 700 gal and increased rapidly. In Case 3, the displacement occurred at the shaking of 800 gal, which showed similar tendency to Case 1. Even if the distance between soil nails was kept, the seismic resistance of the embankment was not largely improved. Compared to these two cases, the displacement of Case 3 showed smaller gradient of the increment against to the amount of the inputted motion. It is possible to understand that the seismic resistance was improved by soil nails with slope protection work using the lattice frame.

Figure 3 Shows the relationship between the inputted acceleration and the tensile force of the soil nail located at the lower part. In Case 1 and Case 3, the tensile forces gradually increased by increasing the amount of the inputted motion, but the value was still small after the deformation of the embankment occurred. On the other hand, the force showed larger value from the start of the shaking of Case 2. The soil nails became more effective by use with the lattice frame.

In order to clarify the mechanism of the increase of the tensile force of soil nails with the lattice frame, Figure 4 shows the enlarged time histories of the tensile force of the soil nails and displacements of the marked points at the lattice frame and the embankment close to the surface of the embankment in Case 2. When the embankment moved to the anterior direction, the tensile force increased. Focused on the time histories of displacements, it is possible to understand that the amount of displacement at each point is different. The displacements of the embankment were larger than those of the lattice frame. This tendency is remarkable at the points to close to the surface of the slope. This means that the embankment pushed the lattice frame affected by the inputted motion.

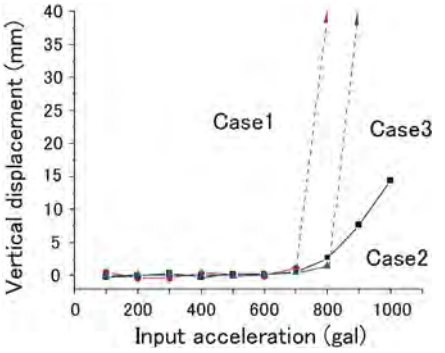

Figure 2. Residual displacement for three cases.

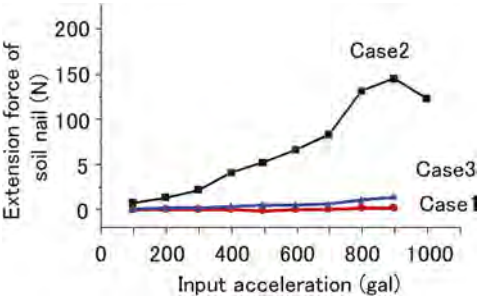

Figure 3. Extension force of soil nail for three cases.

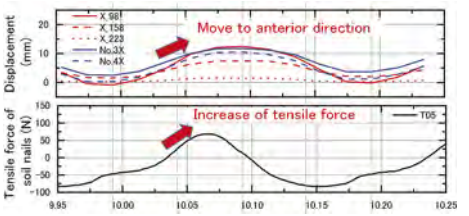

Figure 4. Time histories of extensile force and displacements.

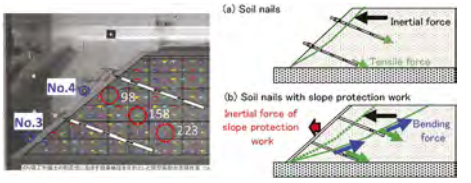

Figure 5. Effect of slope protection work.

Figure 5 Shows the illustration of the mechanism of the increase of seismic resistance by using the lattice frame. In Case 1 and 3, when the inertial force caused by the inputted motion exceeds the resistance force of the embankment at the slip surface, the embankment collapses. On the other hands, in the conditions where the tops of the soil nails are connected and the surface of the slope has contact with the slop protection work as the experiment of Case 2, the slip surface moved to deeper area and the combination of the soil nails and the slope protection work prevents from the occurrence of the severe collapse of the embankment due to the increase of the tensile force. Furthermore, the experimental results from the strain gauges showed that the soil nails were deformed with showing bending mode, so the soil nails demonstrated not only extension resistance but also bending resistance.

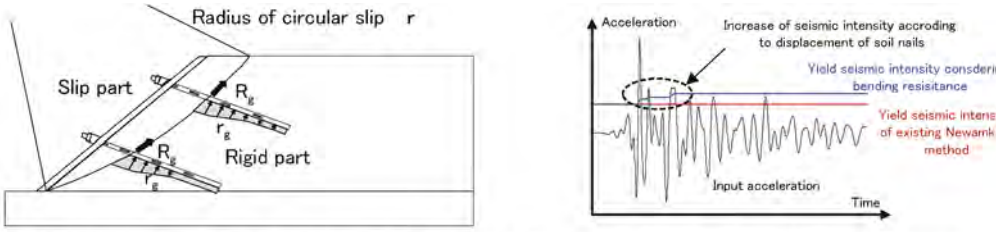
3 DESIGN METHOD OF SEISMIC REINFORCEMENT CONSIDERING EFFECT OF SLOPE PROTETION WORKS

3.1 *Proposed method*

For the evaluation of the seismic resistance of the embankment, the Newmark's sliding method (Newmark 1965) is adopted for the calculation of the residual displacement and the calculated displacement is examined by comparing with the limited value. This method is adopted for the design of railway earth structure (Railway Technical Research Institute 2007). In this method, the reinforcement effect of the soil nails is considered as the resistance force. Based on the results of the shaking table tests, the effect of the soil nails with slope protection works will be considered as shown Figure 6. As mentioned in the previous discussion, the bending resistance of soil nails were demonstrated, so this resistance is added in Newmark's method. The total value of bending resistance is considered as the increment of the resistance moment M_{RT} by using the displacement of circular slip and the ground reaction force R_g under the rigid part, as shown in Figure 6 (a), expressed by the following equation.

$$M_{RT} = \Sigma R_g \cdot r \tag{1}$$

Where r is the radius of the circular slip. Therefore, this effect is considered as increase of yield seismic intensity in Figure 6 (b). In the existing Newmark's method, the yield seismic intensity is constant. However, in the proposed method, it is possible that the intensity increases according to the displacement of soil nails, due to the increase of the moment M_{RT}.



(a) Resistance by soil nails and slope protection works (b) Increase of yield seismic intensity

Figure 6. Calculation method of residual displacement considering effect of slope protection works.

3.2 *Validation of proposed method*

By using the proposed method, the simulation analysis of shaking table was conducted. Figure 7 shows the relationship between the inputted acceleration and the residual displacement obtained by the experiment and the simulations of Case 2. The calculated result using existing Newmark's method overestimated the residual displacement obtained by the experiment. The existing method has difficulty for the case of use of the slope protection work and the tendency is similar to the experimental results for Case 1 and 3 as shown in Figure 2. On the other hands, the calculated result became largely smaller than the existing method and showed good agreement with the experimental result. So, the proposed method was validated.

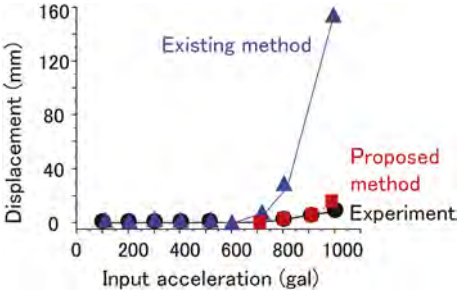


Figure 7. Calculated residual displacement of shaking table test of Case 2.

4 CONCLUSIONS

In this paper, the mechanism of the increase of seismic resistance about embankments reinforced by soil nails with slope protection works were studied. From the series of shaking table tests, it is revealed that connecting the top of soil nails with slope protection works and retaining the slope surface by the slope protection works contribute to the increase of seismicity. Furthermore, the method for calculating the residual settlement of embankments was developed by the modification of Newmark's method. The proposed method showed good agreement with the residual displacements obtained by the shaking table tests so the validation was confirmed.

Deep neural network based approach for site amplification prediction of shallow bedrock sites

Yonggook Lee, Dongyeon Lee, Jieun Kang & Duhee Park
Department of Civil and Environmental Engineering, Hanyang University, Seoul, Korea

ABSTRACT: Site amplification models have been proposed based on the empirical and simulation results and represented by the functional form with regression analysis. However, these regression models result in large differences between the results. In this study, a new site amplification model is developed by using a deep neural network (DNN) to reduce the uncertainties in site amplification predictions. The results of the linear and nonlinear site response analyses are used to train and test the model. The results of the DNN-based model are compared with those of the regression model. The DNN-based model outperforms the regression model and shows lower residuals throughout spectral periods. The DNN model can replace the regression models and reduce the uncertainties caused by simple prediction models.

1 INTRODUCTION

Predicting the local site amplification is important to design the geotechnical structures during earthquakes. One-dimensional (1D) site response analysis (SRA) has been widely performed to estimate the site amplification factors (Hashash and Park, 2001). Site amplification models have been developed and used to predict ground motion intensity measures with ground motion prediction equations (GMPEs). The 1D SRA results were performed and used to develop the site amplification models with respect to the time-averaged shear wave velocity (V_S) of the top 30 m (V_{S30}), depth to bedrock (H), site period (T_G), and other site proxies (Kamatchi et al. 2010; Derras et al. 2014; Ilhan et al. 2019, Aaqib et al. 2021). Monte Carlo (MC) simulations were also utilized to deal with a large suite of data. The site amplification models were proposed by regression analyses. However, the regression-based amplification models showed significant differences. In this study, both linear and nonlinear 1D SRA were performed and all the simulation results were used to train a deep neural network (DNN) model.

2 SITE AMPLIFICATION PREDICTION MODELS

2.1 *Site response analysis*

Linear and nonlinear analyses were performed in frequency and time domains, respectively, using 1D site response analysis software DEEPSOIL v7 [Hashash et al. 2017]. Because of the insufficient number of V_S profiles, forty baseline V_S profiles were used and twenty randomized profiles were generated by using the model of Toro (1995). The input ground motions were selected from the NGA-West2 database. The magnitude (M_w), rupture distance (R_{rup}), and peak ground acceleration of the rock outcrop motions (PGA_{rock}) range from 5 to 7.5, 0 to 100 km, and 0.01 to 0.5 g. The number of V_S profiles and recorded ground motions are 840 and 51, respectively (Figure 1). The 42,840 cases were performed for linear and nonlinear analyses, respectively. The results were used to train the proposed DNN model.

DOI: 10.1201/9781003299127-245

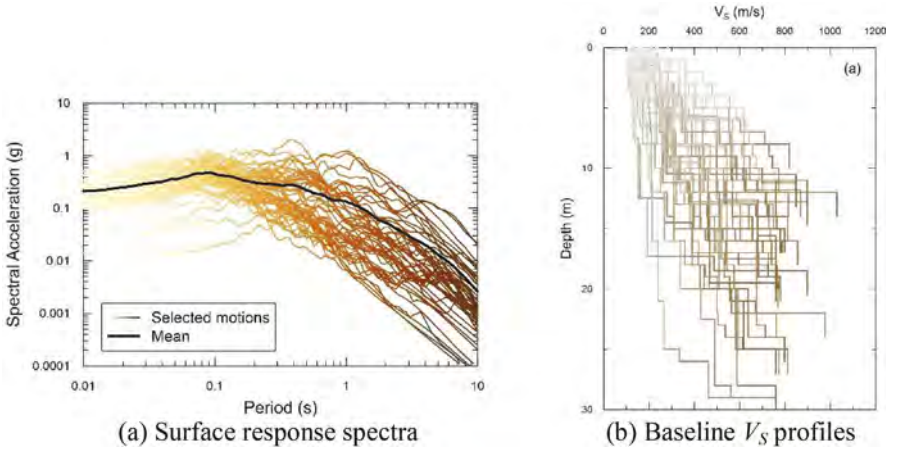

Figure 1. Input surface response spectra and V_S profiles.

2.2 *Proposed deep neural network model*

The response spectra of bedrock were used as the input features of DNN model. The thickness, V_S, unit weight, and damping ratio were also selected as input features to represent soil characteristics (Figure 2). Four hidden layers were used to extract the features of input data for the input ground motions and soil profiles, respectively. The features were concatenated and connected to four fully-connected hidden layers. The surface spectral accelerations of a 113×1 vector were labeled as output data. In all hidden layers, the rectified linear unit (ReLU) was used as an activation function (Nair & Hinton 2010). For the initialization of the model, the weights and biases were initialized by Glorot uniform initializer (Glorot & Bengio 2010) and zero, respectively. The Adam optimizer (Kingma & Adam 2015) was used as an optimization algorithm used in this study. A loss function is defined by a mean squared error (MSE). The batch size was 256 and the learning rate was selected as 0.005. The whole dataset was split into 80% of the dataset as a training set and 20% dataset as a test set.

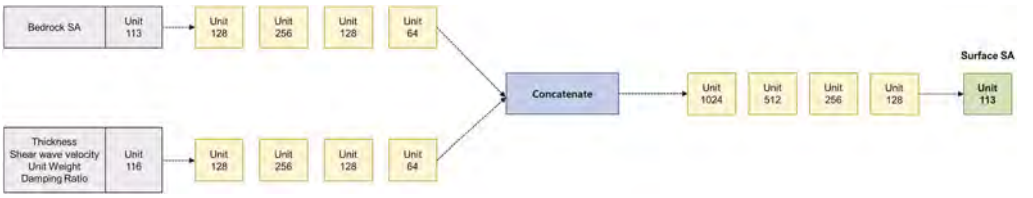

Figure 2. Proposed deep neural network.

3 RESULTS

The calculated MSE and mean absolute error (MAE) are shown in Table 1. The differences in MSE show that the proposed DNN model does not overfit. Figures 3, 4 illustrate the comparison of linear and nonlinear amplification components. The trained DNN model can predict well with the test data. To compare the results of a conventional method, a regression-based site amplification model by Aaqib et al. (2021), AEA21 model, was compared with the proposed DNN model. Because of the use of site proxies, the AEA21 model only can predict the median trends for the spectral periods. The DNN model shows exceptional performance in predicting both linear and nonlinear site amplifications.

Table 1. Comparison of MSE and MAE between train and test dataset.

Analysis	Dataset	MSE	MAE
Linear	Training	0.00056	0.01666
	Test	0.00069	0.01788
Nonlinear	Training	0.00096	0.02135
	Test	0.00131	0.02392

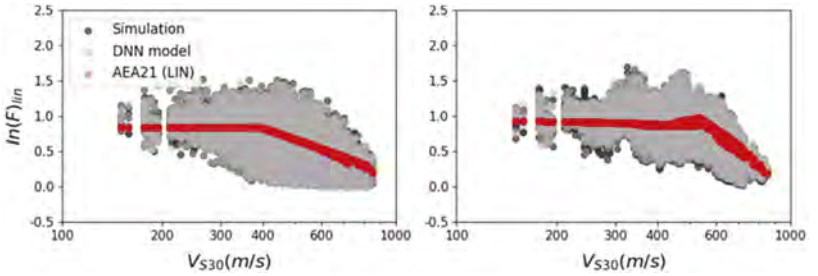

Figure 3. Comparison of linear amplifications for the spectral periods of 0.01 s (left) and 0.1 s (right).

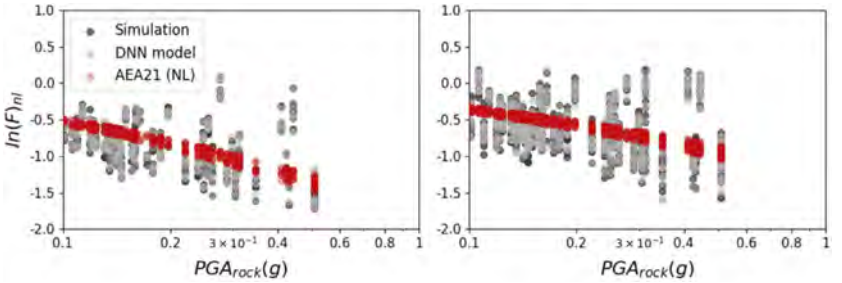

Figure 4. Comparison of nonlinear amplifications for V_S from 200 to 250 m/s (left) and V_S from 300 to 350 m/s (right) at spectral period 0.01 s.

4 CONCLUSION

In this study, site response analyses were performed to predict the site amplifications for the shallow bedrock profiles. The DNN-based model was used to train and test the site response analysis data instead of using the regression-based model. The DNN-based model can use extensive raw data excluding the use of site proxies. The 85,680 pairs of input and result data were used directly. And the database was divided into 80 and 20 % for training and test sets, respectively. As a result, the DNN-based model shows remarkable performance in reproducing the surface response spectra. The proposed DNN-based model can overcome the limitation of the regression-based model, which is caused by the use of site proxies. Future studies will be conducted by using a wide range of site characteristics as well as ground motions.

ABSTRACT: Taiwan is located at the junction of the Philippine Sea Plate and the Eurasia Plate, where earthquakes occur frequently. Soil liquefaction has often been observed during an earthquake, and the associated settlement and lateral spreading usually lead to structural damage and property loss. In this study, numerical analyses were carried out to mimic a dynamic centrifuge model test and examine liquefaction behavior due to seismic shaking. The numerical simulations were performed using two cyclic constitutive models. The constitutive modes were first calibrated against laboratory element test results. A comparison was made to evaluate the effectiveness of these two models used in the finite element analyses.

1 INTRODUCTION

Numerical simulation is often used in geotechnical engineering analysis and design, including modeling complex soil behaviors due to liquefaction. Liquefaction Experiments and Analysis Projects (LEAP) is an international collaboration on producing a series of reliable experimental data for constitutive model calibration and numerical modeling techniques for analysis and assessment of soil liquefaction. In this study, one dynamic centrifuge model test in the LEAP-2017 project (Kutter, 2017) was chosen for numerical analyses to investigate soil liquefaction under slight sloping surfaces due to seismic shaking, where the specimen model is a 4-meter thick Ottawa F-65 sand with a surface slope of 5 degrees in a rigid box.

The study aims to verify two constitutive models (UBC3D-PLM and PM4Sand) in predicting centrifuge model test results. Firstly, model parameters and constants for both constitutive models were calibrated individually by fitting the experimental data of the cyclic direct shear tests, including shear stress versus shear strain, shear stress versus mean effective stress, mean effective stress versus shear strain, and excess pore pressure ratio versus the number of cycles. The calibrated parameters and constants were then used for numerical analyses in PLAXIS, which were applied to mimic a dynamic centrifuge model test and examine the liquefaction behavior due to seismic shaking.

2 CONSTITUTIVE MODEL

2.1 *Introduction*

There are 13 and 15 parameters (including primary and secondary) in the constitutive models of PM4Sand and UBC3D-PLM, respectively. The material properties with physical meanings

DOI: 10.1201/9781003299127-246

include the critical friction angle and elastic moduli, where the critical friction angle of φ_{cv} is 33° for both models. According to the relationship between elastic moduli, the parameters PM4Sand (G_0) of and UBC3D-PLM (K_G^e & K_B^e) can be determined by

$$G = \frac{E}{2(1+\upsilon)} \tag{1}$$

$$G = K\frac{3(1-2\nu)}{2(1+\upsilon)} \tag{2}$$

where the elastic modulus (Young's modulus E) for granular material (Dr=72.6% of dense sand was considered in this study) is about 70 MPa based on Obrzud & Truty (2012), and the Poisson's ratio (υ) was taken as 0.3. The other parameters for both models are calibrated using the best fits from cyclic direct shear tests. These tests were carried out at an initial confining pressure of 100 kPa with 8 cyclic stress ratios (CSR = 0.075, 0.085, 0.095, 0.105, 0.12, 0.125, 0.13, and 0.15), were taken from the LEAP-2017 Project. The calibrated model parameter sets of the PM4Sand and UBC3D-PLM model are presented in Table 1 and Table 2.

2.2 *PM4Sand model*

PM4Sand model can successfully simulate the behavior of sand under dynamic loading, pore pressure variation, liquefaction, and post-liquefaction phenomena. This model was extended by Dafalias & Manzari (2004), incorporating stress ratio control, critical state compatibility, and bounding surface plasticity. PM4Sand version 3.1, developed by Boulanger & Ziotopoulou (2017), has been implemented in PLAXIS2D. The elastic response is described by the elastic shear moduli as given by:

$$\mathrm{G} = G_0 p_A \sqrt{\frac{p}{p_A}} \tag{3}$$

where G_0 is the shear modulus coefficient, p_A is the atmospheric pressure, and p is the mean effective stress. A detailed description of the default values of the primary and secondary parameters of PM4Sand can be found in Boulanger & Ziotopoulou (2017).

2.3 *UBC3D-PLM model*

The UBC3D-PLM model is developed by Tsegaye (2010) for the liquefaction behavior of sand under seismic loading, which is an improvement on the UBCSAND model. UBCSAND was developed by Puebla et al. (1997) and Beaty & Byrne (1998) and is one of the advanced constitutive models commonly used to evaluate liquefaction problems. The UBC3D-PLM model has been successfully implemented in PLAXIS (Petalas & Galavi 2013).

The UBC3D-PLM model involves two yield surfaces (principal stress pace for primary loading and simplified kinematic hardening rule for secondary loading) using the Mohr-Coulomb yield functions. The elastic response is described by the shear and bulk moduli given by:

$$G = K_G^e p_A \left(\frac{p}{p_A}\right)^{ne} \tag{4}$$

$$K = K_B^e p_A \left(\frac{p}{p_A}\right)^{me} \tag{5}$$

where K_G^e and K_B^e are the factors of elastic shear and bulk moduli, respectively, p_A is the atmospheric pressure, p is the mean effective stress, and me and ne are rates of stress-dependency of elastic modulus. A detailed description of the default values of the primary and secondary parameters of UBC3D-PLM can be found in Petalas & Galavi (2012).

2.4 *Inspection of element tests*

Figure 1 shows the respective numerical simulations for both models compared to the experimental data in different spaces: shear stress vs. shear strain, shear stress vs. mean effective stress, mean effective stress vs. shear strain, and excess pore pressure ratio vs. the number of cycles. The simulations using the same set of parameters for each constitutive model in the simulations of cyclic resistance curves are shown in Figure 2. Both models demonstrate good agreements against laboratory element test results.

3 NUMERICAL ANALYSIS

3.1 *Model mesh and boundary conditions*

Figure 3 shows the configuration of the centrifuge test and the instrumentation layout. The deformation boundary in the static phase was set up to (a) fully fix (in the X and Y direction) at the bottom, and (b) X direction was fixed for both vertical sides. The dynamic boundaries, in Figure 4, were assigned as a compliant base at the bottom of the model. Free-field boundaries were used on both sides of the model to minimize the seismic reflection. According to the study by Vilhar et al. (2018), when the PM4Sand model is used in PLAXIS, it is recommended to add drainage zones with the free-field boundary on both sides, as shown in Figure 4b.

The initial geostatic stress was calculated in the first stage by the gravity loading procedure. In the second stage, the acceleration history was added to the bottom of the model and simulated using dynamic calculations type.

3.2 *Comparison between simulation and experimental result*

According to sections 2.2 and 2.3, two constitutive models are used for the numerical analyses of a dynamic centrifuge test. This study compares horizontal accelerations and pore pressures at the specified positions (i.e. the accelerometers of AH4, AH6, and AH10 and the piezometers of P2, P5, and P7, as shown in Figure 3 and Figure 4). Despite the fact that the position of the measuring points may not be 100% the same between simulations and tests, the differences are negligible.

In Figure 5 and Figure 6, the horizontal acceleration results show that the PM4Sand produced more oscillated acceleration than the UBC3D-PLM in some periods. In addition, in Figure 7, it can be seen that the PM4sand has a better pore water pressure prediction for the experimental results of P2 and P5 compared with the UBC3D-PLM. However, by evaluating the effectiveness of these two models in the results of acceleration and pore water pressures, both models can mimic the dynamic centrifuge test well.

4 CONCLUSION

PM4Sand and UBC3D-PLM are used separately in the finite element simulation of a centrifuge model test. The model parameters of PM4Sand and UBC3D-PLM models are firstly calibrated by cyclic direct shear tests with different CSRs. It can be seen that the PM4Sand model can perform softening behavior much better than the UBC3D-PLM after the number of cycles. It can also been seen that by checking the first few loops in the hysteresis plot, the UBC3D-PLM model always shows a high stiffness before the soil is liquefied. In the

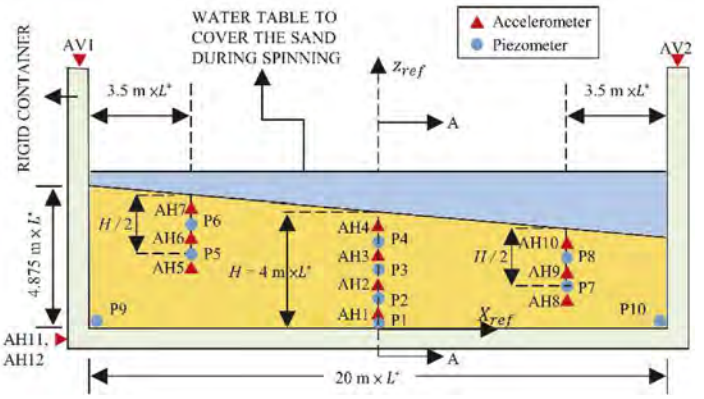

Figure 3. Configuration of centrifuge test and instrumentation layout (redrawn after Kutter et al. 2019).

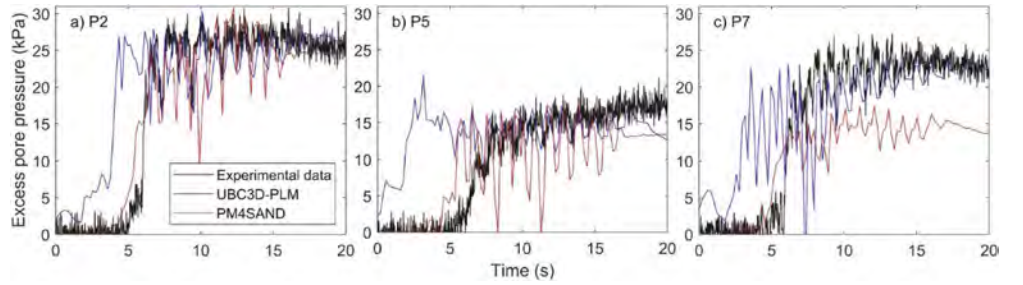

Figure 7. Excess pore pressure versus time for three piezometers of P2, P5, and P7.

simulation of the shear stress-shear strain curve, it was observed that the PM4Sand model simulates the stress-strain curve more effectively than the UBC3D-PLM model.

It is noted that the initial geostatic stress could be inaccurate when using the UBC3D-PLM and PM4Sand models under the gravity turn-on phase in PLAXIS. It is advised to use another soil model (Mohr-Coulomb herein) for the initial geostatic stress calculation. In the inspection of the centrifuge test, both constitutive models can capture the behavior of the centrifuge tests very well and achieve good agreement in the simulation of soil liquefaction. However, it can be observed from the results of pore water pressure that PM4Sand is more suitable for predicting pore water pressure than the UBC3D-PLM model. A comparison of displacement versus time in the centrifuge test is not inspected due to the lack of data from existing laboratory data. To further understand these two constitutive models, future investigation can be focused on predicting displacement and dissipation of pore water pressure for post-liquefaction.

ABSTRACT: Deep soil mixing is an effective mitigation strategy that reduces the devastating impacts of liquefaction hazards. These strong columns decrease the induced damage to the substructures while there are still lots of uncertainties about the design assumptions of DSM configurations in the liquefiable areas. Considering the practical concerns, a series of fully nonlinear numerical simulations are conducted and the effect of interaction of DSM grids and liquefied subsurface layer on the ground shaking motions is evaluated. Effect of DSM pattern and mechanical properties on the response of system were examined and results compared with those analytical methods proposed in the literature. Reduction of excess pore water pressure near the columns was obvious.

1 INTRODUCTION

Liquefaction triggering during seismic events in loose soil strata could induce destructive damage to the superstructure. Correct estimation of liquefaction triggering, the performance of foundations during liquefaction, and hazard mitigation strategies were favorable topics during the last decades.

Improvement procedures using stone columns and pile columns were proposed by Asgari et al. (2013). By employing 1g shaking table tests, Rasouli et al. (2015) proposed a sheet-pile wall as an effective method for reduction of settlements of foundation in a liquefiable soil layer. Rayamajhi et al. (2015) stated soil cement columns after liquefaction remains intact and will support the superstructure. Also, it was reported that columns with floating piles had a negligible effect on the reduction of excess pore water generation.

Hasheminezhad and Bahadori (2019) employed 3D numerical simulation and studied the efficiency of single DSM columns in the reduction of excess pore water pressure during seismic scenarios. Shaking table modeling was employed by Bahrampour et al. (2018) to investigate effect of the DSM column on the remediation of liquefaction. Boulanger et al. (2018) reported the performance of soil-cement walls on improvement of liquefaction for an embankment based on centrifuge and numerical modeling. The installation of soil cement walls reduced potential of ground displacement. Zhang et al. (2021) conducted a series of shaking table tests and reported that the presence of cement columns will have direct effects on acceleration amplification, fundamental periods, and pore water pressure. Tong et al. (2018) used DSM method to a reduction of liquefaction hazard of caisson walls. The findings of Demir and Ozener (2020) revealed that the current design method based on strain compatibility overestimates the seismic shear stresses reduction

Khosravi et al. (2017) performed a series of centrifuge tests modeling and examined the performance of structures found on a soil cement grid. The results of physical modeling showed

DOI: 10.1201/9781003299127-247

that during shaking events, soil-cement grids are useful to control the settlement in a soft clay layer. Nguyen et al. (2013) proposed an analytical procedure for designing a DSM grid for liquefaction reduction. The results were extracted based on some linear elastic finite element models. DSM walls were introduced as shear stress reduction elements and the design method was developed based on an assumption of strain compatibility.

Although some efforts have been conducted to recognize the effectiveness of DSM columns and grids in the reduction of liquefaction risk, there are still practical issues regarding the implementation of proposed methods. In this regard, a series of 3D non-linear FEM models are conducted in the present study, and the effect of both DSM columns and grids on the redistribution of excess pore water pressure is investigated properly.

2 FEM MODELING

The three-dimensional fully non-linear dynamic method is employed for numerical simulation of a liquefiable soil deposit using PLAXIS 3D version 2021 finite element-based software. The centrifuge tests results obtained by Ramirez et al. (2017) were modeled in the prototype scale to match the FEM modeling

2.1 *Geometry*

The centrifuge tests conducted by Ramirez et al. (2017) were used for the calibration of the numerical model. Three soil layers with different dry densities were modeled at the free field condition. The lower soil layer was prepared by a dense Ottawa sand with and thickness of 10 m and D_r of 90%. The same soil material with D_r=40% was placed at the middle layer with a thickness of 6m. Finally, a 2m layer of Monterey sand and D_r=90% were constructed at the top layer. The soil body was modeled with 29-noded triangle elements. A view of the model is depicted in Figure 1.

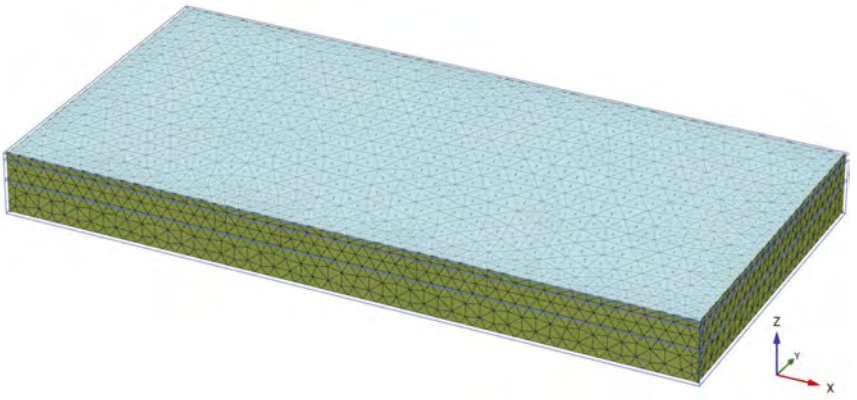

Figure 1. Model mesh view.

2.2 *Constitutive model*

The UBC3D-PLM model which has been developed by Tsegaye (2010) and implemented as a user-defined model in the PLAXIS software was used for modeling the behavior of soil layers. The formulation of the soil model is based on hyperbolic strain hardening and the Duncan-Chang approach. Based on previous contributions this constitutive model predicts the excess pore pressure with a good degree of accuracy while the prediction of settlements is questionable. The calibrated soil parameters are presented at the Table 1.

Table 1. Soil properties.

	me	ne	np	φ_{cv}	φ_p	$(N_1)_{60}$
Monterey sand	0.5	0.5	0.4	38	45.5	35
Ottawa dense	0.5	0.5	0.4	38	45.5	35
Ottawa loose	0.5	0.5	0.4	31.3	32	7

2.3 *Boundary conditions*

A free field boundary condition was introduced at the side walls to absorb reflected waves along the boundary to reduce the radiation damping effect. A compliant base boundary condition was also defined for the bottom of the model.

2.4 *Validation*

Numerical modeling was employed to simulate the outcomes of centrifuge tests. Kobe L seismic motion with peak ground acceleration (PGA) equal to 0.34 g imposed to the base of models in X direction according to Ramirez et al. (2017). Figure 2. Shows the FEM model and experimental outcomes in terms of pore pressure. Based on the results it can be concluded that the proposed FEM model matched the centrifuge outcomes with an acceptable degree of accuracy.

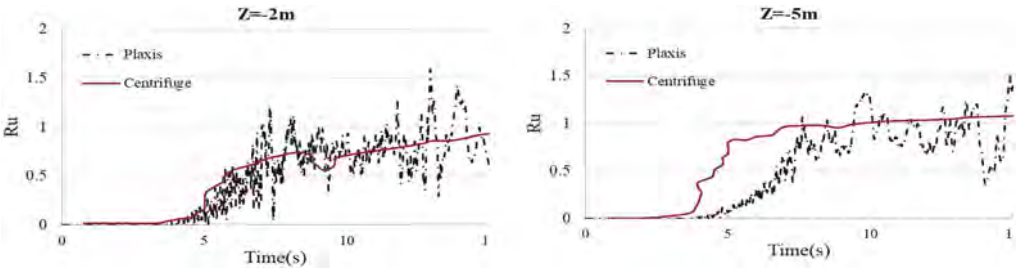

Figure 2. Validation of excess pore water pressure.

3 RESULTS

3.1 *Single column*

First, single columns with a diameter of 1.6m and qu=1,2 and 3MPa were placed and the response of the system was captured. The Ru contours are achieved as illustrated in Figure 3.

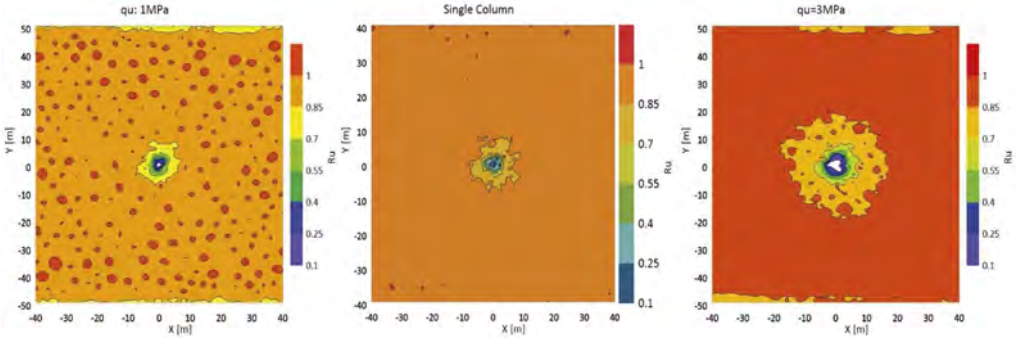

Figure 3. Ru contour for single pile with different USCs at the middle of the liquefiable layer.

It is obvious that the effective radius that reduces the Ru, is increased by enhancing the stiffness of the column. These radiuses are 1.7, 2.7m, and 3.5m for columns that their values of USC are 1MPa, 2MPa, and 3 MPa, respectively.

3.2 *Grids*

For assessing the effect of the DSM grids on liquefaction remediation, the procedure proposed by Nguyen (2013) was employed. Based on that method and the condition of soils used in the model, using a DSM grid with a length of 15 for columns with a diameter of 1.6m will improve factor of safety against liquefaction to the desired state. The procedures are implemented to consider different methods of liquefaction susceptibility based on the available methods in the literature. Some parts of the used in-house app are depicted in Figure 4.

Figure 4. Calculation of liquefaction susceptibility based on analytical solutions.

The same configurations were modeled in the FEM models. The Ru contours are depicted in the Figure 5. The results of modeling showed that using DSM grids will reduce the Ru both with this dimension still high magnitude of excess pore water pressures were captured in some points. These observations showed that designing only based on simplified methods needs to be verified by numerical models for clarifying the doubts.

Also, the magnitude of acceleration in the middle of the liquefiable layer is recorded at the time 8s. Higher magnitudes of accelerations are captured near the DSM grids. It can be attributed to the fact that large strain due to the liquefaction caused higher damping and resulted in a considerable reduction in the magnitude of acceleration while the stiff column sensed smaller damping.

3.3 *Effect of grid size*

2 different size grids including 5m and 10m with a diameter of 80cm have selected and the effect of DSM grids on the redistribution of pore water pressure was investigated. The results are depicted in Figure 5

It shows that small DSM grids significantly reduced the excess pore water pressure and proper design of DSM grids will be a beneficial option for mitigation of liquefaction. The contour of liquefaction in the model is also depicted in Figure 7.

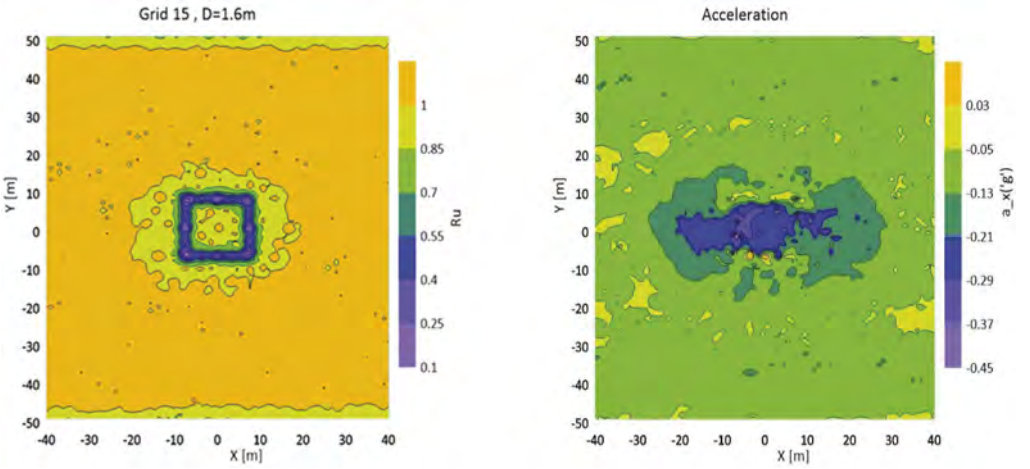

Figure 5. Ru and acceleration contour for the grid of DSM in the middle of the liquefiable layer.

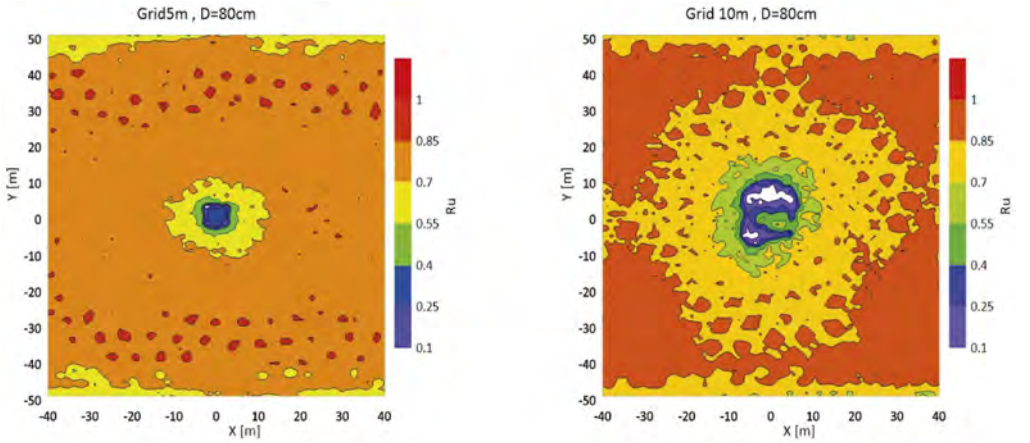

Figure 6. Effect of grid dimensions on the development of pore water pressure.

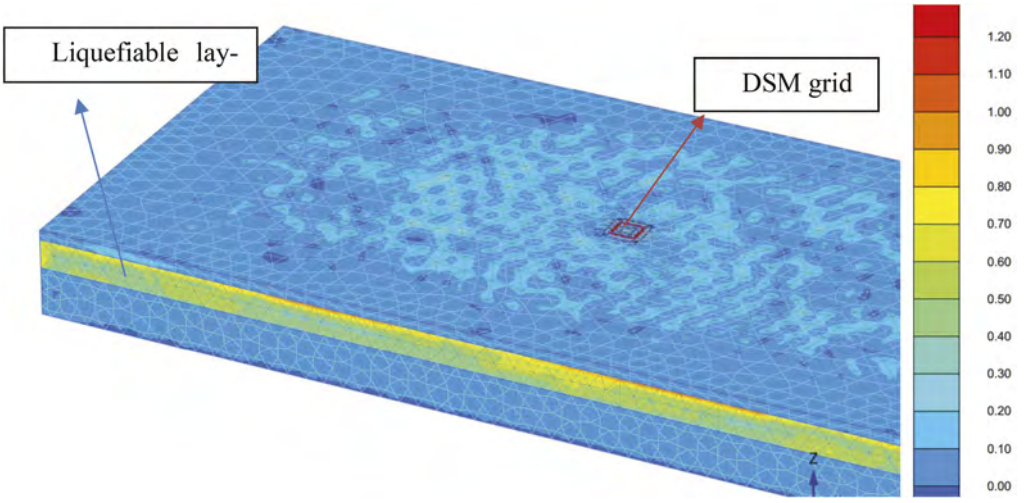

Figure 7. Pore water pressure contours of FEM model.

4 CONCLUSION

A series of FEM models were conducted for the evaluation of the effects of DSM columns and grids on the liquefiable layer. The main findings are summarized as the following:

1. An acceptable prediction of excess pore water generation during earthquakes can be achieved by the UBC3D-PLM model.
2. Depending on the stiffness of the columns, a clear reduction of Ru was observed around the columns.
3. Using DSM grids will reduce the excess pore water pressures but for large grids still, some liquefiable points in the middle of grids were observed.

Seismic risk assessment of USBRL project in Jammu and Kashmir: Implications towards earthquake resilient infrastructure in the Himalaya

Abdullah Ansari, KS. Rao & AK. Jain
Department of Civil Engineering, Indian Institute of Technology Delhi, Hauz Khas, New Delhi, India

ABSTRACT: Jammu and Kashmir in the northwestern part of the Himalayas witnessed many moderate to large magnitude frequent earthquake events. In the last two decades, the progress of infrastructure projects is boomed in this region. Earthquake-resilient design of structural elements of any development project is very challenging, especially in seismic-prone zones. In this paper, an attempt has been done to develop the seismic fragility functions for various tunnels located in three phases of the Udhampur Srinagar Baramulla Rail Link (USBRL) Project. The outcomes of this study reveal that most of the tunnels in Phase 1 of this project are subjected to extensive damage. Near-field active tectonic sources, weathered rock conditions, high seismicity, and landslide vulnerability all contributed to portal damage and significant lining failure at such sites. This study will assist design engineers in advocating for earthquake-resistant tunnels and underground facilities in Jammu and Kashmir. It will pave the way for earthquake-resistant design of infrastructure projects in the Himalayas.

1 INTRODUCTION

The development and progress of any region require a well-established transportation network as a prerequisite for overall economic growth. Tunnels are built as part of infrastructure projects or upgraded transportation networks. Any seismic damage to them might disrupt the overall serviceability of road or railway transit, causing socioeconomic disruption and perhaps disastrous outcomes. Jammu and Kashmir (J&K) is one of India's fastest-growing union territories, with continuing infrastructural developments to support economic development (Ansari et al. 2022). The Indian government proposed a 345 km Udhampur Srinagar Baramulla Rail Link (USBRL) Project connecting the Kashmir Valley with the Indian Railways network to offer J&K an easy way of transportation option.

The alignment of the USBRL project track and neighbouring active tectonic sources are shown in Figure 1. The construction of a new railroad line in the Indian subcontinent has never been more challenging than this one. The young Himalayas that is full of geological surprises and myriad issues are traversed by the terrain. In the present study, an attempt has been done to assess the seismic risk of the USBRL project. The fragility curves provided will serve as a valuable tool for increasing public awareness and directing track operations in the event of a major earthquake that occurs in or near J&K in the future.

2 OVERVIEW OF USBRL PROJECT

The main concept behind the proposal of the USBRL project is to work on the traffic issues in the Jammu and Kashmir. The project has been divided into 4 subsections for execution

DOI: 10.1201/9781003299127-248

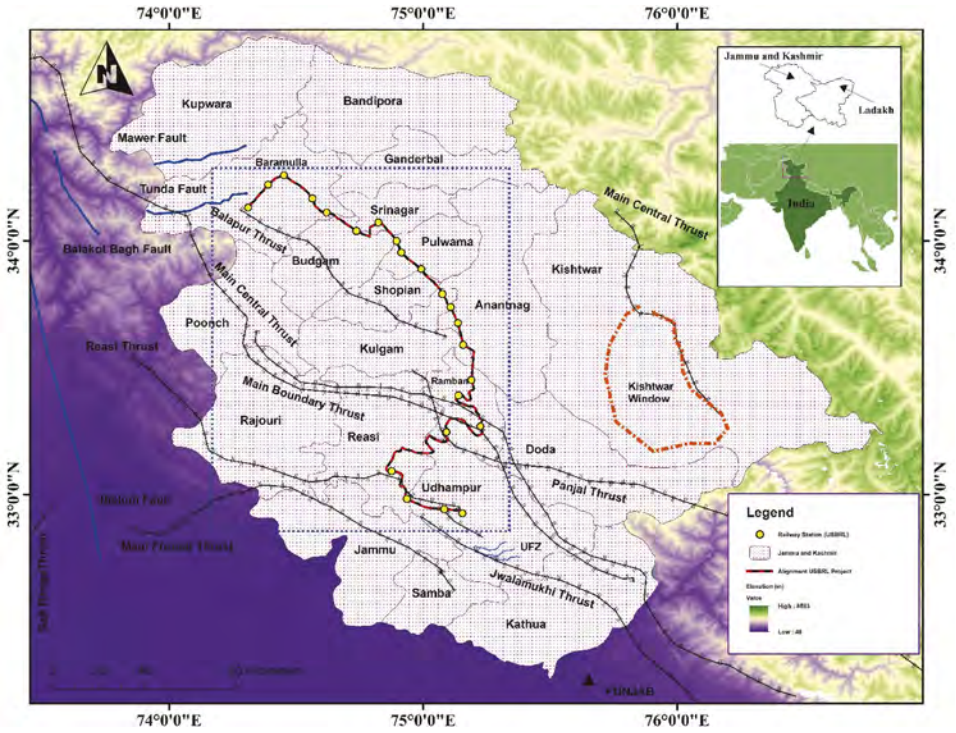

Figure 1. Location of the Udhampur Baramulla Srinagar Rail Link (USBRL) Project.

purposes. The alignment and structural details for each subsection are mentioned in Table 1. The Chenab Bridge and Anji Bridge are located in the Reasi and are the two main bridges under the subsection between Katra to Banihal. The Chenab Bridge is one of the engineering marvel structures in Reasi. The Anji Khad Bridge is the first cable-stayed bridge by the Indian Railways located in Reasi which acts as a connecting chain between Tunnel T2 and Tunnel T3.

Most of the tunnels under this project are located near the major tectonic sources including MBT, MCT, PT, and BT (Ansari et al. 2022b). The Tunnels T2, T49, and T80 are the main tunnels of this route. The total length of Tunnel T49 is 12.75 km which is going to become India's longest tunnel. The Tunnel T80 is known as the Pir Panjal tunnel passing through the Pir Panjal ranges and acts as a gateway to KV. This is the only tunnel in Banihal to Quazigund (BN-QZ) subsection with maximum overburden of 1300 m.

Table 1. Comprehensive detailing of the subsections of the USBRL Project.

	Subsections			
Parameters	Udhampur-to-Katra (UD-KT)	Katra-to-Banihal (KT-BN)	Banihal-to-Quazigund (BN-QZ)	Quazigund-to-Baramulla (QZ-BR)
Total Stations	3	10	1	15
Route length (km)	25	111	18	118
Total Tunnels	10	27	1	0
Length (km)	11	164	11.21	0

3 MAJOR GEOLOGICAL CHALLENGES

The Himalayas have the world's most difficult ground conditions from the standpoint of tunnelling. One of the prime reasons for this is that they are the youngest of the mountain chains. Slope instability issues resembling landslides and debris flows were seen in the vicinity of Tunnel T1, Tunnel T5, and Tunnel T11. The presence of a shear zone offers a particularly favourable environment for cavity formation at the tunnel crown.

The cavity formation observed on the left side that stretched to the crown of Tunnel T40/41 (Wani and Alamgir 2017). During the excavation process of T50 in Ramban, a chimney formed at the collapsed tunnel face (Srivastav et al. 2022). The tunnel T74R consists of Main Tunnel; parallel Escape Tunnel; nineteen cross passages and one Adit (Yusoff and Adhikari 2017). Cracks of 5-8 mm were observed at junctions. Due to weak rock mass condition (RMR less than 40), over the break of strata had been observed at various sections along the tunnel.

4 SEISMIC RISK ASSESSMENT

Seismic fragility functions are important tools since they define the damage probabilities of tunnels in both pre and post-earthquake stages (Hashash et al. 2001; Tsinidis et al. 2020). According to the mid-term theory, the efficiency of the resultant complex is distributed in the form of Lognormal if the structural capacity and seismic demand are two variables with a Normal or Lognormal distribution. As a result, the probability density function indicates the probable distribution described in the fragility curves (Argyroudis and Pitilakis 2012; Wang et al. 2020). As shown in Eq. (1), the fragility functions are represented by fragility curves with a lognormal distribution, assuming that all database uncertainty can be stated just by median uncertainty.

$$\boldsymbol{P[DS \geq DS_i |\ IM] = \emptyset(ln\ IM - ln\ IM_{DS_i}/\beta_{total},\ DS_i)} \tag{1}$$

where $\boldsymbol{DS}$ is the type of damage state in the tunnel lining.
$\boldsymbol{\beta_{total}}$ is estimated using the Eq. (2) considering the cumulative effect of $\boldsymbol{\beta_C}$, $\boldsymbol{\beta_D}$, and, $\boldsymbol{\beta_{DS}}$.

$$\boldsymbol{\beta_{total} = \sqrt{\beta_C{}^2 + \beta_D{}^2 + \beta_{DS}{}^2}} \tag{2}$$

The Probabilistic Seismic Hazard Analysis (PSHA) technique, which considers both spatial and temporal uncertainty, was utilised to define the seismic hazard. The central part of Udhampur, the bedrock level PGA is estimated as 0.34 g (Ansari et al. 2022a). The Reasi and Ramban have shown the maximum PGA of 0.4 g due to the combined seismic influence of Main Boundary Thrust (MBT), Main Central Thrust (MCT), and Reasi Thrust (RT). The probability of experiencing extensive damage to the North Portal of Tunnel T2 is 0.92 for PGA of 0.6 g, as shown in Figure 2a. The highly jointed and weathered dolomite rock mass at the South Portal of Tunnel T5 indicates the 85% risk of extensive damage, which corresponds to 0.8 g as bedrock PGA produced at RT. The near-site shear zone and strong seismicity characteristics of MCT enhance the risk of both portals of the Tunnel T13 suffering moderate damage. For the Tunnel T40/41, the chance of extensive damage gradually increases when PGA > 0.5 g (Figure 2b). Due to landslide-prone zones, the chances of extensive damage ($\boldsymbol{DS_3}$) of tunnel portals is very high for the tunnels in P2 among all three major phases. For the Tunnel T44/45, minor damage is twice as likely to occur for the same level of seismic intensity as moderate damage.

As illustrated in Figure 2c, there is a considerable decline in the damage probability from $\boldsymbol{P[DS \geq DS_1 \mid PGA = 0.7g] = 0.89}$ to $\boldsymbol{P[DS \geq DS \mid PGA = 0.7g] = 0.32}$, respectively at the North Portal of Tunnel T80. The vicinity of Tunnel T78 in Phase 33 is extremely vulnerable to slope failure, and debris flow indicates an equal probability of moderate and extensive damages. The Tunnel T80 is around 22.5 km from MCT and MBT, where PGA is anticipated to be more than

0.7 g. From the perspective of structural safety for T80, the tilting of the hazard scenario towards greater PGA and the proximity of the Himalayan thrusts are not looking good. The damage contribution of Tunnel T77D and Tunnel T78 under Phase P33 increases the likelihood of a portal collapse by 50%. The probability of minor damage ($\boldsymbol{DS_1}$), moderate damage ($\boldsymbol{DS_2}$), and extensive damage ($\boldsymbol{DS_3}$) are propounded in Table 2.

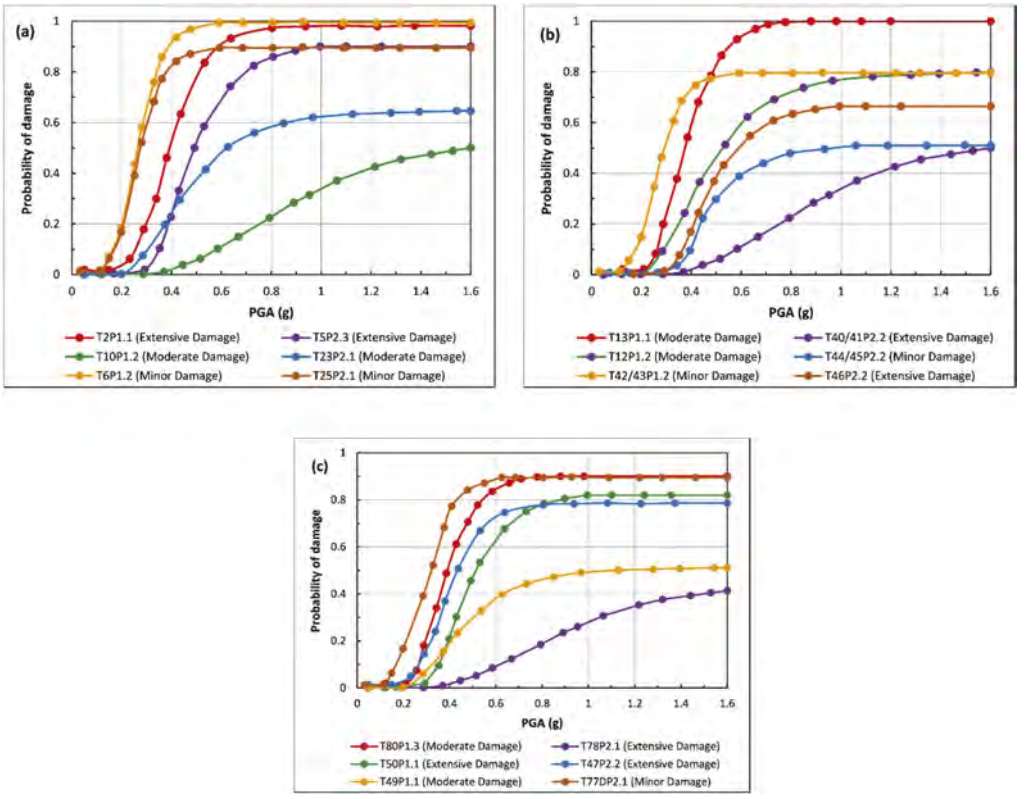

Figure 2. Seismic fragility curves for tunnel sections along the USBRL track located between the railway stations (a) Udhampur to Reasi (b) Reasi to Sangaldan, and (c) Sangaldan to Quazigund.

5 CONCLUSIONS

- The 345 km long route of USBRL Project, which starts in Udhampur and finishes in Baramulla, traverses highly weather and jointed rock masses, folded and faulted tectonic features, shear zones, unstable sloping terrain, and landslide-prone areas. The construction of tunnels and bridges alongside railway tracks is a challenging task that presents significant geological difficulties.
- At Tunnels T2, T5, T40/41, T50, and T74R, excavation-related phenomena including cavity development, face wall deformation, squeezing, chimney formation, and water leakages were noted. Phase P1, Phase 2, and Phase 3 are classified as accessible, accessible with moderate repair, and inaccessible.
- The Tunnels in the Katra-Banihal (KT-BN) subsection of this project have demonstrated a significant propensity for extensive damages. Adverse seismic behaviour of tunnels, Phase 2 is no longer in an accessible state. Due to the effects of a high degree of seismicity, landslide susceptibility, weathered rock mass, and close source characterization, Phase 3 is the riskiest track in terms of post-seismic functionality.
- The seismic performance of Tunnels T48, T74R, and T80 has been triggered by the presence of shear zones, the proximity of the Panjal and Balapur thrusts, and the highly weathered and fractured rock mass beyond the Sangaldan railway station. All associated phases were transferred into an inaccessible category due to the high probability of damage. The tunnel designers, engineers, and risk management authorities may use this study to better understand how different components of the USBRL project will work in post-seismic situations.

Analysis of the dynamic stability of the base, taking into account the peculiarities of the distribution of the liquefaction potential over the depth of the soil mass

E. Sobolev & G. Anzhelo
Federal State Budget Educational Institution of Higher Education
"National Research Moscow State University of Civil Engineering" (NRU MGSU),
Moscow, Russian Federation

ABSTRACT: The present study was carried out in order to improve the prediction of the stress-strain state of the soil foundations under dynamic influence based on the assessment of the liquefaction potential. The influence of the distribution of the potential of soil liquefaction over the depth of the soil mass is investigated, a hypothesis is put forward about the need to consider the potential of liquefaction with mandatory reference to the depth of the soil and the inadmissibility of using the concept of "average" liquefaction potential for the entire layer, regardless of its capacity, which leads to an unreasonably optimistic assessment of the stability of the soil mass. The tests were carried out for an engineering survey site composed mainly of sandy soils, shallow and dusty, loose and medium density, water-saturated, prone to dynamic instability. The predicted seismic impacts are taken on the basis of direct measurements made at the site of engineering surveys. The research was carried out on the basis of special laboratory studies of soils under conditions of dynamic triaxial compression. Samples of fully water-saturated soil were tested to determine shear stresses at the time of dynamic liquefaction. Then the liquefaction potentials were calculated in the first case on average for the entire soil layer, in the second case taking into account the distribution over the depth of the layer. As a result of the studies performed, the initial hypothesis was confirmed. For the studied sandy soils, the use of the "average" value of the liquefaction potential is not correct, since part of the studied soil is characterized as dynamically stable, while the other part is prone to liquefaction. If only the average value of the liquefaction potential is calculated, a false statement of the stability of the entire layer will be obtained. The conducted research complements and expands the current understanding of the assessment of the dynamic stability of soils under seismic influences and can be used to predict the stress-strain state of buildings and structures in complex engineering and geological conditions.

1 INTRODUCTION

Analysis of the dynamic stability of the foundations of buildings and structures is carried out, as a rule, in seismically hazardous areas. The presence of complex engineering and geological conditions has a significant impact on dynamic stability. From the point of view of dynamic stability, bases are considered weak, which are characterized by the presence of dusty and fine sandy water-saturated soils and sandy-clay soils with high fluidity. The magnitude of the predicted seismic impact also plays an important role, since it is obvious that under equal ground conditions, a stronger impact is more likely to cause a loss of dynamic stability of the soil mass. The main parameter characterizing the dynamic stability of the base is the liquefaction potential. In the physical sense, the liquefaction potential is a coefficient showing the ratio of dynamic strength to the maximum shear stresses arising in the soil mass during seismic action. The liquefaction potential can be determined both on the basis of laboratory tests of soils, and directly at the research site by field methods. None of the possible methods has decisive advantages, so they are all used equally in the global geotechnical practice.

DOI: 10.1201/9781003299127-249

This article deals with the problem of assessing the dynamic stability of the base based on the determination of the liquefaction potential in laboratory conditions. In geotechnical practice, it is often necessary to face the problem of misunderstanding the results of research in this area. The liquefaction potential is a parameter rigidly linked on the one hand to the specific soil for which it is determined, and on the other hand to the sampling depth for which the test was performed. The magnitude of the dynamic strength and the maximum shear stresses at which destruction occurs in the dynamic mode depend on the magnitude of the natural pressure, and, consequently, on the depth of sampling. Thus, it is incorrect to say that for the same engineering-geological element, it is possible to take samples from different depths, conduct dynamic tests to determine the liquefaction potential and determine a certain "average" value of the liquefaction potential for the entire layer as a whole.

At this stage, one may wonder about the statistical reliability of the research. If it is impossible to determine the average value based on tests of the same soil taken from different depths, then how can the reliability of the studies performed be ensured? The answer to this question lies in the need to take several samples of the same soil from the same (or comparable) sampling depth from one or neighboring engineering-geological workings (boreholes). Thus, a series of tests (from three to six) will be performed for each selected sampling depth to ensure the specified statistical reliability of the results.

The purpose of this study is to prove the hypothesis that for the same soil, a situation may arise in which the "average" liquefaction potential will indicate the stability of the soil layer to the predicted dynamic impacts, while the analysis of the liquefaction potential based on the reference to the depths of soil sampling shows that part of the layer will be it is stable, but the other one is not.

It should be mentioned that the construction regulatory documents in force in Russia do not define this issue. A lot of regulatory documents in the field of engineering surveys for construction and geotechnics establish the need to perform a dynamic stability forecast, test methods and processing of the results. However, there is still no full-fledged regulatory document dedicated to the process of analyzing dynamic stability under seismic impacts.

2 MATERIALS AND METHODS

The analysis of the dynamic liquefaction process is carried out by comparing the shear stress caused by the seismic load and the shear stress required to start soil liquefaction, or the level of shear strain amplitude, which is considered unacceptable for design.

To determine the liquefaction potential, the results of special laboratory studies of soils by dynamic triaxial compression were used. The equipment manufactured by Antriebs-, Pruf- und Steuertechnik (APS) GmbH "Wille Geotechnik" (Germany) was used for testing, which is a servo-hydraulic load frame with a maximum axial force of 63 kN, a triaxial compression chamber of type "A", a servo-hydraulic drive control unit, a data processing unit coming from pressure and displacement sensors, air pressure control unit and control computer. The general view of the installation with the assembled camera is shown in Figure 1.

Soil samples were Quaternary deposits of proluvial genesis, represented by silty sands, loose, saturated with water. The thickness of cover sands varies from 0.5 to 2.0 m. The average density of dry soil was 1650 kg/m^3.

The formation of samples from samples of the disturbed structure was carried out by the method of dry layer-by-layer filling into a cylindrical detachable form. Water saturation of the initially dry soil was carried out directly in the chamber of the device. The preparation made it possible to obtain fully water - saturated samples with the Skempton parameter $\beta \geq 0.95$. A comprehensive pressure equal to household pressure was applied to the sample at a given depth and a consolidation stage was carried out in open drainage conditions.

After the consolidation was completed, a vertical dynamic load was applied to the sample. The frequency of dynamic action was assumed to be equal to 0.5 Hz, the number of cycles for each amplitude was 10. The amplitude of dynamic vertical loading increased in increments from 0.10 to 0.25 MPa until the criteria for the destruction of the soil sample.

At the initial stage, the soil sample was compacted under the action of an isotropic pressure σ'_0. The initial compression pressure corresponded to the natural pressure at the depth of soil

sampling. The natural pressure was equal to the product of the specific gravity of the soil and the free fall acceleration. Then the initial static shear stress σ_s was applied to it, in these tests 10 kPa was accepted – the minimum permissible value due to the technical features of the test installation. Then a predetermined number of shear stress cycles were applied sequentially to the sample, while performing several series of homogeneous axial loads under untrained conditions with increasing amplitude. Series of loadings with increasing amplitude were repeated until the criterion for determining the dynamic strength was reached. Dynamic loading was carried out either before destruction (visible destruction of the sample or the achievement of axial deformation of more than 10%).

Figure 1. General view of triaxial compression equipment with dynamic loading.

The magnitude of the cyclic shear stress at any point under the horizontal ground surface during an earthquake when a shear wave passes from below is determined by the formula:

$$\tau_{\max} = \frac{a_{\max}}{g} \cdot r_d \cdot \gamma \cdot z, \tag{1}$$

where $a_{\max}$ is a peak value of horizontal acceleration on the ground surface; g is an acceleration of free fall; γ is specific gravity of the soil; r_d is a stress reduction coefficient; z is a depth of soil sample.

Taking into account the distribution of total σ_z and effective stresses σ'_z in a soil column, the formula (1) takes the following form:

$$\frac{\tau_{\max}}{\sigma'_z} = \frac{a_{\max}}{g} \cdot r_d \cdot \frac{\sigma_z}{\sigma'_z}, \tag{2}$$

where $\sigma_z = \gamma \cdot z$ is a full vertical stress.

Using formula (2), the cyclic stress acting under a given seismic action is calculated, and the strength of the soil under dynamic action is determined by the results of soil tests in dynamic triaxial compression devices.

Having expressed the relative magnitude of the applied stresses in terms of the relative equivalent stress τ_{av}/σ'_z, then the corresponding strength is determined in terms of the relative equivalent stress $\tau_{av,l}/\sigma'_z$. At the same time, τ_{av} is the average amplitude of the cyclic action,

which is 0.65 of the maximum shear stress τ_{max}. Thus, the liquefaction potential k_s of the soil layer is estimated through the expression:

$$\frac{\tau_{max,l}/\sigma'_z}{\tau_{max}/\sigma'_z} = \frac{\tau_{av,l}/\sigma'_z}{\tau_{av}/\sigma'_z} \tag{3}$$

The relative level of shear stresses operating in the soil τ_{av}/σ'_z is called cyclic stress ratio CSR and the value of cyclic strength $\tau_{av,l}/\sigma'_z$ is called the cyclic resistance ratio CRR.

The calculation of CSR is considered as an impact from an earthquake and is determined by the formula:

$$\mathrm{CSR} = 0.65\frac{\sigma_z}{\sigma'_z}a_{max}r_d \tag{4}$$

where 0.65 is a specific factor introduced by Sid to calculate the number of cycles of uniform stresses necessary to create pore pressure, as in the case of uneven displacement of the ground during an earthquake; σ_z is total vertical stresses at the appropriate depth; σ'_z is effective vertical stresses at the appropriate depth; a_{max} is maximum horizontal acceleration in the soil mass, units of measurement g (acceleration of gravity); r_d – the coefficient of stress reduction in depth in accordance with a certain function (NCEER, 1997/1999).

Computational and experimental methods for assessing the possibility of liquefaction are based on comparing CTR and CTR values to determine the liquefaction potential:

$$k_s = \frac{\mathrm{CRR}}{\mathrm{CSR}} \tag{5}$$

Liquefaction is possible if $k_s < 1$. Water-saturated soils are non-liquefied at $k_s > 1.15$. When determining the depth after which dynamic liquefaction is impossible, the normative coefficient of 1.15 was taken into account. That is, the depth of the zone of dynamic soil liquefaction should be determined at values corresponding to $k_s \leq 1.15$.

3 RESULTS

For the analysis of dynamic stability, the following parameters of seismic impact are adopted: the maximum acceleration in the horizontal direction is PGA a_{max}=3.43m/s^2; the moment magnitude of the earthquake is M_s=6.3; the frequency of dynamic impact is 0.5 Hz; the number of cycles for each amplitude of dynamic impact is 20 pcs. The test results of a series of seven soil samples are presented in Table 1.

The analysis of Table 1 shows that the average value of the liquefaction potential for all tests indicates the stability of the studied soil to dynamic liquefaction. At the same time, it should be noted that samples taken from a depth of 0.4 m to 1.0 m have a liquefaction potential of less than 1.15, which indicates their dynamic instability.

The obtained results are presented in the form of a graph of the dependence of the liquefaction potential on the depth of soil sampling (Figure 2).

4 DISCUSSION AND CONCLUSIONS

The analysis of the performed special laboratory studies of the dynamic stability of samples of sandy fully water-saturated soils allowed us to confirm the hypothesis put forward at the beginning of the study. It is a mistake to assume that the average value of the liquefaction potential can be used as a fundamental assessment of the dynamic stability of a particular soil under given parameters of dynamic impact.

For the studied sandy soils, the use of the average value of the liquefaction potential is incorrect, since part of the studied soil is characterized as dynamically stable, while the other

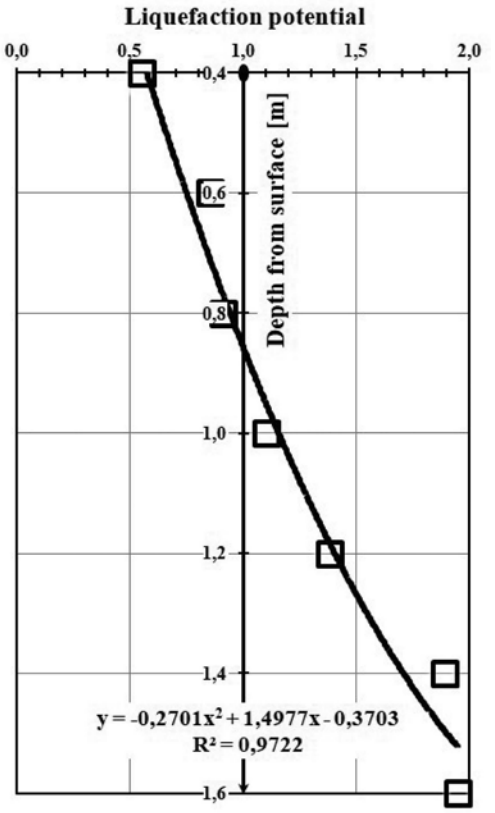

Figure 2. Experimental dependence of the liquefaction potential (fractions of a unit) on the depth of soil sampling (m).

part is prone to liquefaction. If only the average value of the liquefaction potential is calculated, a false statement of the stability of the entire layer will be obtained.

The performed studies clearly show that the layer, generally considered stable, should be divided into two zones in depth. The first zone is at a depth of 0.4 m to 1 m, where this layer is dynamically unstable and is characterized by liquefaction potential values less than 1.15. The second zone is at a depth of 1 m to 1.6 m, where this layer is dynamically stable and is characterized by liquefaction potential values of more than 1.15.

The conducted research complements and expands the current understanding of the assessment of the dynamic stability of soils under seismic influences and can be used in predicting the stress-strain state of buildings and structures in complex engineering and geological conditions.

The specifics of soil friction against a retaining wall under seismic load

O.P. Minaev
Military Academy of Logistics named Army General A.V. Chrulev, The Russian Federation

ABSTRACT: For the first time ever, the author of the paper has found that the classical quasi-static analysis of a retaining wall for seismic load provides indirect evidence of the wave nature of the impact the sandy backfill soil exerts on the rear surface of the retaining wall. In order to prove this, the paper presents the comparative results of the calculations of a gravity retaining wall with and without consideration of soil friction under operational static and seismic loads. The calculations are based on the given dimensions of the retaining wall and the characteristics of sandy backfill soils laying on weak clay foundation soils. Thus, we obtained the dependence for measuring the angle of soil friction against the rear surface of the retaining wall under seismic load of different intensity. It seems quite convincing that the retaining wall can be designed for a seismic load of 9 points without taking into account the soil friction because soil slips on the surface of the retaining wall in case of such seismic impact. The evidence is given that the calculation results are quite consistent with the research data on the behavior of sandy soils in the base of the plate under dynamic wave loads.

1 INTRODUCTION

It is well-known (Ivanov 1991, Budin 2014) that the soil friction on the rear surface of the retaining wall significantly affects the results of the design carrying capacity and stability under static load of the retaining wall.

According to many researchers, e.g. Prof. A.Ya. Budin (Budin 2014), calculations conventionally assume that the angle at which soil frictions against the retaining wall is equal to the angle φ of internal friction of the backfill soil or to its half $\varphi/2$.

Given the wave character of the dynamic effect on the retaining wall, it seems that such a convention in determining the angle of internal friction of soil against the retaining wall is not likely to be applicable for calculating seismic loads and here is why.

Headed by Prof. P.L. Ivanov (Ivanov 1991) the Soil Mechanics Laboratory of the Department of Underground Structures, Foundations and Bases, Peter the Great St. Petersburg Polytechnic University conducted numerous studies of the effect produced by dynamic wave load on the friction of sandy soil on the surface of a vibrating plate installed on its surface. In the experiments with a vibrating plate for in-plane shear, in addition to the static stresses from the weight of the plate and the vibrator, the mechanical vibrator added dynamic stresses from the rotation of the vibrator cams that acted according to the harmonic law. The vertical mechanical vibrator varied the stresses raging within the values of $\pm\Delta\sigma$**.** The dynamic pressure amplitude was controlled by changing the eccentricity of the vibrator cams while the frequency was adjusted by their rotation speed. The shear resistance considered according to the Coulomb dependence in the form of $\tau = (\sigma\text{-}\Delta\sigma)tg\varphi$ indicates a periodic shear of the plate on the sand surface.

As a result of the tests it has been found that within the range of vibration acceleration up to 1.0 g the angle of internal soil friction does not change while the decreasing shear resistance should be taken into account through changing normal stresses at the plate bottom. Thus, in case of vibration and seismic effects the shear stability of structures has to be tested given the

DOI: 10.1201/9781003299127-250

dynamic component of stresses at a constant value of the angle of internal soil friction, imposed on the static tests.

Therefrom, the author obtained a dependence for determining the angle ω of soil friction against the retaining wall at various values of force E_a^c of active lateral soil pressure at seismic load, in the form

$$\omega = arctg\left(2 - \frac{E_a^s}{E_a}\right) tg\phi \tag{1}$$

where E_a is the force of active lateral soil pressure on the retaining wall under the operational static load, kN; E_a^s is the force of active lateral soil pressure on the retaining wall under seismic pressure, including the force of lateral soil pressure under operational static load; φ is the angle of internal friction of the backfill soil.

In case the expression in brackets has a negative value, the angle ω of soil friction against the retaining wall is taken to be equal to 0. In this case, with wave dynamic impacts occurring at a time when the force of soil pressure is directed away from the rear surface of the wall during soil vibrations from seismic action, the backfill soil can shift (slip) along the wall surface due to the gravity of the soil and payload. We consider this factor as there is no soil friction against the retaining wall during seismic action.

Figure 1 shows a characteristic graph of the dynamic wave action on the retaining wall.

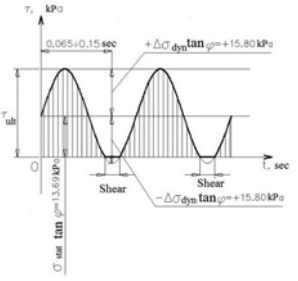

Figure 1. Graph of dynamic wave impact on the retaining wall at seismic intensity of 9 points.

The paper presents the results of comparative calculations of retaining walls with and without regard to the soil friction on the rear surface for seismic load intensity of 9 points. The results confirm the wave nature of the impact on the retaining wall during seismic action.

2 THEORETICAL DEPENDENCIES

The coefficient of active lateral pressure λ_a^s given the angle ω of soil friction against the retaining wall under seismic impact is determined according to Equation 1:

$$\lambda_a^s = \frac{cos^2(\varphi - \varepsilon)}{(1 + \sqrt{z^2}\cos\varepsilon} \tag{1}$$

where in Equation 1:

$$z = \frac{\sin(\varphi - \varepsilon)\sin(\varphi + \omega)}{\cos(\omega + \varepsilon)} \tag{2}$$

According to the standards applicable for a retaining wall calculated for seismic load (Stavnitser 1991, Savinov, Uzdin, Belash 1995), the most hazardous is the horizontal direction of the seismic pressure of soil.

For this case the dependence has the form of Equation 3:

$$\gamma^s = \frac{\gamma_i}{\cos \varepsilon} \tag{3}$$

where $\varepsilon = arctgAK_1$ is the angle of deviation from the vertical of the specific gravity equilibrium γ_i of soil and seismic force $y_i^s AK_1$, A is the coefficient whose values are taken equal to 0.1; 0.2; 0.4 respectively for the seismic intensity of 7, 8 and 9 points, K_1 is the coefficient that considers the admissible damage to buildings and structures, taken equal to 0.25 for hydraulic structures.

In the case the lateral active pressure of water-saturated soil on the retaining wall under seismic effects is determined, the weight of suspended soil y_{sb} should be introduced into the formulas, just as in case of operational load. The seismic force $y_{satur}AK_1$ should be determined according to the density of saturated soil y_{satur}. In this case, the deviation angle of the resultant is determined by the following formula in Equation 4:

$$\varepsilon_{satur} = arctg\frac{\gamma_{satur}}{\gamma_{sb}}AK_1. \tag{4}$$

The well-known dependencies are used to check the stability of the retaining wall for sliding under in-plane shear of the base and for in-depth shear under seismic load.

The theoretical dependences for calculating the retaining wall using this methodology are discussed in more detail in the following publications (Minaev 2019a, Minaev 2019b, Minaev 2019c).

3 INITIAL PARAMETERS AND LOADS

The calculations were carried out for a reinforced concrete retaining wall with a front cantilever. The total height of the retaining wall was 7.4 m, the water depth $h_в$ next to the embankment was 6.1 m and the height of wall elevation h_0 above water level was 1.3 m. Average sand with specific weight γ = 18.4 kN/m^3 and humidity W = 14% was taken as backfill soil. The foundation of the retaining wall is composed of water saturated clayey soils (highly plastic clay-bearing soils) having specific weight γ = 20.0 kN/m^3 and humidity W = 24 %. The humidity of clayey soils at liquid limit W_L = 0.30 and at plastic limit W_p = 0.16. The design angle φ of internal friction of sandy soils was 32°, and that of clayey soils was 17° with cohesion c = 16.67 kPa. The elastic modulus E of sandy soils was 31 MPa and that of clayey soils was 17 MPa.

The value of the useful load q on the surface of the base (on the cordon) was 29 kPa.

Initially, the values of active lateral pressure under operational and seismic load of 7, 8 and 9 points were estimated without considering soil friction and at the angle of soil friction against the rear surface of the retaining wall being equal to the angle φ of internal friction of backfill soil or to its half $\varphi/2$.

For all of these cases, we calculated the width of the retaining wall bottom.

Further comparative calculations on the bearing capacity and stability of the retaining wall for a maximum seismic load of 9 points did not consider soil friction. The angle of soil friction against the rear surface of the retaining wall was equal to the angle φ of internal friction of backfill soil or to its half $\varphi/2$.

We used the results of these calculations for analyzing the behavior of soils under dynamic wave loads.

Tables 1, 2 and 3 show the coefficients of active lateral pressure λ_a^s calculated according to Equations 1 – 4 for seismic intensity of 7, 8 and 9 points, respectively.

The calculations show that the width of the retaining wall bottom under operational load is 7.2 m without considering the friction against the rear surface of the wall. Considering the soil friction against the wall, the width of the retaining wall bottom goes down to 6.8 m for both design cases at the angle of soil friction against the wall $\varphi/2$ and φ.

The calculations for seismic load of 7 and 8 points show that the width of the retaining wall bottom is 8.3 and 8.6 m, respectively without considering the soil friction against the wall.

Table 1. The coefficients of active lateral pressure for seismic intensity of 7 points.

Item No.	Angle of soil; friction against the wall, ω	The coefficient of active lateral pressure of soil on the wall		
		Operational load, λa	Seismic intensity	
			above water, $\lambda^s_{a_1}$	under water, $\lambda^s_{a_2}$
1	**2**	3	**4**	**5**
1	0	0.307	0.321	0.336
2	**φ** /2	0.278	0.293	0.308
3	**φ**	0.277	0.293	0.311

Table 2. The coefficients of active lateral pressure for seismic intensity of 8 points.

Item No.	Angle of soil; friction against the wall, ω	The coefficient of active lateral pressure of soil on the wall		
		Operational load, λa	Seismic intensity	
			above water, $\lambda^s_{a_1}$	under water, $\lambda^s_{a_2}$
1	**2**	3	**4**	**5**
1	0	0.307	0.336	0.365
2	**φ** /2	0.278	0.308	0.340
3	**φ**	0.277	0.311	0.347

Table 3. The coefficients of active lateral pressure for seismic intensity of 9 points.

Item No.	Angle of soil friction against the wall, ω	The coefficient of active lateral pressure of soil on the wall		
		Operational load, λa	Seismic intensity	
			above water, $\lambda^s_{a_1}$	under water, $\lambda^s_{a_2}$
1	**2**	3	**4**	**5**
1	0	0.307	0.365	0.431
2	**φ** /2	0.278	0.340	0.412
3	**φ**	0.277	0.347	0.434

Considering the soil friction against the wall, the width of the retaining wall bottom reduces from 8.3 m down to 7.9 and 8.0 m under seismic load of 7 points and from 8.6 m down to 8.3 m and 8.4 m under seismic load of 8 points, respectively at the angle of soil friction against the wall $\varphi/2$ and φ.

Similar calculations for seismic load of 9 points show that the width of the retaining wall bottom is 9.1 and 9.3 m respectively at the angle of soil friction against the wall $\varphi/2$ and φ. In the latter case it is equal to the width of the retaining wall bottom if the calculation does not consider the soil friction against the wall.

Figure 2 presents a common active pressure diagram drawn for the vertical plane led through the front of the retaining wall, under a seismic load of 9 points.

In further calculations of the retaining wall for bearing capacity and stability, the seismic intensity was assumed to be 9 points.

4 RESULTS OF BEARING CAPACITY AND STABILITY CALCULATIONS

The results of the verified calculations of the base soils resistances show that the construction of a retaining wall of this type directly on natural base soils is possible.

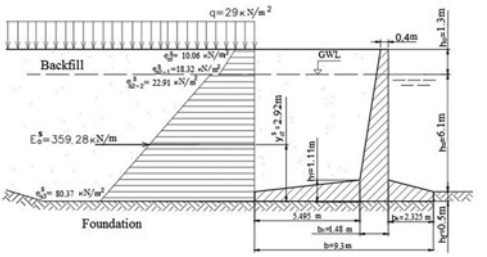

Figure 2. Diagram of active lateral pressure on a reinforced concrete corner retaining wall under seismic load of 9 points.

A diagram of isolines with highlighted areas of plastic deformations was built according to the methodology suggested by Prof. Kirillov, V.M. (Minaev 2019a). It was found out that the deformations spread to a depth of 6.63 and 6.66 m, respectively, while the angle of soil friction against the wall is $\varphi/2$ and φ (and φ=0).

Due to the plastic deformations at the base of the retaining wall, the weak soils of the base had to be substituted for a sand backfill cushion. The soils were compacted with the common vibro-dynamic compacting methods (Minaev 2011, Minaev 2014).

At the right edge of the wall, the the sand cushion width is set equal to 0.7 of the maximum depth y_{max} of the areas to which plastic deformations spread. In terms of design, it is taken as its half at the left edge of the wall, which corresponds to values equal to 4.34 (2.32) m at the angle of soil friction against the wall being $\varphi/2$and 4.66(2.33) m at φ (and φ=0).

We verified the stability of the retaining wall for in-plane shear slip under seismic load. The values of stability coefficient $K^{\text{in-psb}}$ for in-plane shear are 1.08, 1.04 and 1.05, respectively for the angle of soil friction against the wall $\varphi/2$, φ and φ=0.

Thus, the stability of the wall to the in-plane shear in the wall base is not ensured, as the value $K^{\text{in-psb}}$ (the same as K^{deep}) must be equal to 1.15 at least.

The calculations show that with the sand cushion layer being 2.32 (2.33) m thick, the stability coefficient rises to 1.23 for all design cases.

The results of calculations of the retaining wall for in-depth shear, show an even greater decrease in the stability coefficient K^{deep} with values of 1.02, 0.99 and 0.97 respectively at the angle of soil friction against the wall $\varphi/2$, φ and φ=0.

At the same time if a 2.32 and 2.33 m thick sand cushion was built, the stability coefficient could increase from 1.02 to 1.18 and from 0.99(0.97) to 1.15 respectively at the angle of soil friction against the wall $\varphi/2$ and φ (and φ=0).

In the base of the reinforced concrete retaining wall, 81, 87 and 83 piles are required per 10 linear meters of the retaining wall, respectively, at the angle of soil friction against the wall $\varphi/2$, φ and φ=0.

In the case of a pile foundation, the resistance of the wall to deep shear increases a lot up to the values of K_{deep} over 2.

5 ANALYSIS OF CALCULATION RESULTS

Based on the studies of soil behavior under dynamic wave loads in (Ivanov 1991), the author of this paper analyzed the results of the calculations of the retaining wall for seismic load.

According to the calculations, the force E_a^s of lateral active pressure on the retaining wall under seismic impact of 9 points amounts to 341.65, 357.89 and 359. 28 kN/m at the angle of soil friction against the wall $\varphi/2$, φ=0 and φ. The proportionate force E_a of lateral active pressure on the retaining wall under operating static load is 172.52, 190.56 and 171.98 kN/m.

The comparison of the design value shows that the additional force ΔE_a^s of active lateral pressure on the retaining wall on seismic impact is either insignificantly lower than the force E_a of active lateral pressure under operational static load or exceeds it. The verification of the

dependence to Equations 1 indicates that on seismic impact the angle ω of soil friction on the rear surface of the retaining wall is either insignificant or absent at all.

Figure 1 presents a typical graph of dynamic wave action on the retaining wall when the active lateral pressure force under seismic load exceeds the pressure under operational static load.

In support of the above we can refer to the experimental studies of Kazakh scientists (Khomyakov 2015). Their experiments included a table, on top of which was a tray with a retaining wall and sand. The table was subjected to multidirectional horizontal displacements to simulate wave vibrations of soil under seismic load. The wave vibrations of the soil even made the backfill soil separate and slip along the rear surface of the retaining wall.

In addition, at the seismic intensity of 8 point, the lateral active pressure force E_a^s on the retaining wall reduces to 283.49, 304.53 and 289.05 kN/m while at seismic intensity of 7 point it decreases even further down to 257.47, 280.93 and 259. 81 kN/m respectively at the angle of soil friction against the wall $\varphi/2$, $\varphi=0$ and φ. It can be defined from Equation 1 that at seismicity of 7 and 8 points, the angle ω of soil friction against the rear surface of the retaining wall is 0.569 φ and 0.440 φ**.**

6 CONCLUSION

1. For the first time ever the author of the paper used Equations 1 for defining the angle of soil friction on the rear surface of the retaining wall under seismic load of various intensity given the wave character of the dynamic impact on the retaining wall.

2. This research proves that Equations 1 can be practically applied for computational justification of the retaining walls that are designed on natural foundation and pile foundation soils in seismic areas.

ABSTRACT: Recent research have shown that the liquefaction potential of saturated sand can be drastically reduced if the sand is made slightly unsaturated. By introducing gas into the saturated sand, one can lessen the degree of saturation. However, injecting gas uniformly into sand is a challenging task. This paper describes the studies conducted to generate gas bubbles by introducing non-pathogenic denitrifying bacteria. The produced bio gas is tiny, chemically inert, less soluble, and has less impact on the environment. Triaxial cyclic tests are conducted on both saturated and partially saturated sand, as well as sand containing nitrogen gas bubbles created by bacteria to evaluate the effectiveness of this method towards liquefaction resistance. When the degree of saturation of the specimens is reduced from 100 to 90%, the excess pore water pressure generation and the liquefaction potential of sand under cyclic loading are found to be significantly reduced.

1 INTRODUCTION

Soil liquefaction is a phenomena that occurs when soil loses its shear strength and acts like a fluid due to an increase in pore water pressure. Liquefaction is commonly accompanied with significant soil deformations and can have catastrophic effects on structures and human life. Granular soils have a high drainage capacity and negligible pore pressure accumulation under static loads. Due to the rapidity of the seismic event, a completely saturated granular deposit may exhibit undrained behavior under dynamic stress. These factors can cause liquefaction of the soil. There are successful conventional soil liquefaction mitigation strategies, such as soil densification, cementation, and groundwater table lowering. However, these methods are typically expensive and inapplicable to existing buildings. Ordinary constructions and buildings cannot afford a suitable remedy for soil liquefaction. Consequently, many older buildings and infrastructure remain vulnerable to soil liquefaction. We require a solution that is economical, eco-friendly, and technically sound. According to particular experimental data, decreasing the degree of saturation can enhance the strength and resistance to liquefaction of sand (Yoshimi et al. 1989; Okamura 2006; Wang et al. 2016; Mele et al. 2019; Tsukamoto 2019). It has been demonstrated that a significant liquefaction resistance effect can achieve if the saturation level of sand reduced up to 5 %. On the basis of this hypothesis, a new mitigation strategy dubbed Induced partial saturation was recently presented. In the Induced partial saturation method, the presence of air or gas bubbles reduces the bulk modulus of the pore fluid, allowing the soil to conserve energy by reducing its volume and limiting the generation of further pore pressure due to cyclic loading. Desaturation can be done by decreasing the groundwater table or injecting gas into the soil pores (Yoshimi et al. 1989). The former is more intrusive and produces a high degree of desaturation; the latter is less invasive and produces a different degree of saturation. Several techniques have been adopted to achieve the purpose, including air injection

(Ishihara et al. 2003; Yasuhara et al. 2008; Okamura et al. 2009, 2011; Raghunandan et al. 2014; Marasini et al. 2015; Zeybek et al.,2016, 2017; Amanta et al. 2021; Flora et al. 2021), electrolysis and drainage recharge method (Yegain et al., 2007), chemical method (Bayat et al. 2013, 2020; Nababan et al. 2016), biogenic desaturation (Rebata -Landa et al. 2012; He et al., 2016; Pham et al. 2016; Donnell et al. 2017a, 2017b; Mousavi et al.,2019;2021; Peng et al. 2021), inducing microbubbles (May et al. 2010).In recent years, attempts have been made to use microbiology to geotechnical engineering, with an emphasis on either increasing shear strength or decreasing soil permeability by inducing calcite crystallisation through the microbial hydrolysis of urea. The generation of small gas bubbles by a microbial denitrification process is yet another possible use of biotechnology. The primary purpose of this method is to create and evenly disperse gas bubbles. This method has been named as "Microbial induced partial saturation" or MIPS. In this investigation, denitrifying bacteria were injected and examined for their ability to create bio gas bubbles. Later liquefaction resistance is evaluated by conducting cyclic triaxial tests on microbially-treated, nitrogen-bubble-containing soil

2 GAS PHASE DISTRIBUTION IN PARTIALLY SATURATED SOIL

Depending on the arrangement of the gas phase, soil is often classified as fully saturated, partially saturated, or unsaturated zones (Tsukamoto 2018). In fully saturated zones, the interparticle pores of the soil are filled with water and contain no gas phase. A sample of soil subjected to an isotropic increase in total stress, denoted by $\Delta\sigma$. It exhibits a rise in pore pressure under undrained condition, with Δu equal to the total stress increment if the fluid is assumed to be nearly incompressible. This makes the pore pressure coefficient B equal to 1 ($B = \Delta u/\Delta\sigma$). In unsaturated zones, matric suction caused by water surface tension interacts with soil grains to generate additional compressive normal stresses between soil particles, hence enhancing soil shear strength (Tsukamoto2018). Under a rise in total stress, pore air pressure and pore water pressure increase at distinct rates, which may be determined by specializing the pore pressure parameters, which are always less than 1, as $B_a = u_a/\Delta\sigma$ and $B_w = u_w/\Delta\sigma$. Since the gas phase is continuous below 80% saturation, the pore water pressure increases faster than the pore air pressure, resulting in a decrease in matric suction (Tsukamoto et al. 2014). Soils that are partially saturated separate the two forms. While the liquid phase is continuous, air bubbles are blocked in the pore spaces of the grains. There is no air-grain contact because air bubbles are confined in the void of the soil skeleton. Therefore, there is no mobilization of shear strength, matric suction is low, and effective stresses are still utilised to depict mechanical behaviour. Occluded gas bubbles only increase the compressibility of the pore fluid without influencing the interlocking forces between grains. When partially saturated soils are subjected to an increase in confining stress, the gas phase becomes discontinuous and the difference between liquid and air pore pressures becomes negligible, making the two pore pressure parameters equal to $B_a \approx B_w$ (Kamata et al. 2009). Thus, the pore pressure parameter can be unique.

3 MICROBIAL DENITRIFICATION PROCESS

Denitrification, or the dissimilatory reduction of nitrate, was the source of nitrogen gas in the biogas process (Figure 1). The biological denitrification mechanism gradually converts nitrate (NO_3) to nitrogen gas (N_2).In this work, heterotropic denitrification has been considered. The overall equation for the process with ethanol as the electron donor is

$$5C_2H_5OH + 12KNO_3 \rightarrow 10CO_2 + 6N_2 \uparrow + 9H_2O + 12KOH \quad (1)$$

CO_2, H_2, CH_4, and N_2 are the most abundant biogenic gases in near-surface soils. Carbon dioxide (CO_2) is very soluble in water and has a short residence time, but hydrogen (H_2) and methane can burn. One of the numerous benefits relevant to this inquiry is that nitrogen gas (N_2) is neither combustible nor a greenhouse gas. Nitrogen gas is having the property of extremely

low solubility, which is 0.014 l of gas per litre of water at 250°C and atmospheric pressure, is its most notable quality (He and Chu 2014). There are a few constraints to microbial denitrification. According to certain research, a high quantity of nitrate might produce a buildup of nitrite, resulting in incomplete denitrification (Paassen et al. 2010). Other limiting variables include pH, temperature, the presence of oxygen, etc. Previous research demonstrated that a neutral to moderately basic pH environment is optimal for high activity and complete denitrification (Saleh-Lakha et al. 2009). Denitrification by microorganisms is a natural process that is common in soil environments. Conditions for its occurrence in soil are quite simple to satisfy.

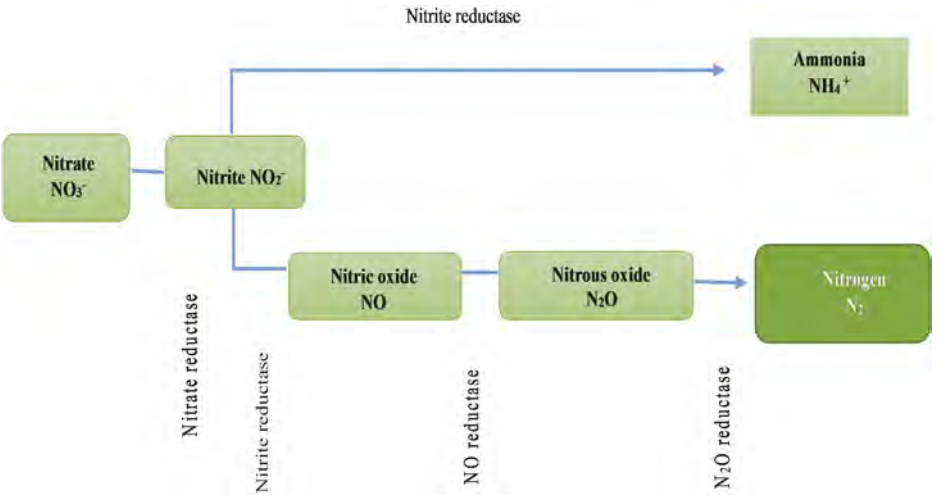

Figure 1. Nitrate dissimilatory reduction, enzymes, and products (Kraft et al., 2011).

4 LABORATORY EXAMINATION

4.1 *Material classification*

The tested soil is a liquefiable silty sand collected from a place in Chidambaram, Tamil Nadu, India. The soil is designated as poorly graded sand (ASTM D2487) and enclosed inside the limits of extremely prone to liquefiable soil (Tsuchida, 1970) (Figure 2). Pseudomonas stutzeri was chosen to conduct the experiment on soil desaturation. Pseudomonas stutzeri (MTCC 863) was obtained and cultivated on nutrient agar-stabilized Petri dishes. It is a mesophilic organism that can grow at temperatures as low as 4°C and as high as 44°C, but grows optimally at temperatures about 35°C. This bacterium doubles in around 53 minutes when cultured in lysogeny broth (LB) medium ($MgSO_4.7H_2O$ 0.2 g, KNO_3 2 g, K_2HPO_4 1 g) at 32 °C.

4.2 *Soil desaturation test*

The bacteria solution has been combined with a broth containing nitrates, which stimulates the metabolism. We must understand the biogas production regulation process in sand in order to obtain the necessary level of saturation for a given concentration. As seen in Figure 3, a basic soil desaturation experiment is conducted using a bacterial solution using a basic setup. A syringe was filled with a sample of sand that had been combined with denitrifying bacteria and nutrients. The syringe was attached to a burette. As a result of the formation of gas bubbles in the sand sample, a part of the sand's water was replaced, causing the water level in the burette to increase. Changes in the water level in the burette reflect the quantity of gas production. The saturation level is

determined by the phase relationship. Four different initial nitrate concentrations, including 146,198.6, 300.7, and 370 mg/L, were utilized during the experiments. As shown in the table, the degree of saturation begins to decrease as nitrate concentration increases. The appropriate level of soil saturation can be achieved by altering the amount of nitrate added to soils. The reaction rate was slowed by five days, while the maximum change was noticed between two and three days. During the course of monitoring, regular bubble production was observed. On the third or fourth day, bubbles form, and their density increases. Regardless of the nitrate concentrations, the gas production rates are comparable across all samples. As indicated in Table 1, the pH values of all three samples increase as well. This increase in pH is consistent with the reaction depicted in Equation 1, which shows that hydroxyl is one of the process byproducts.

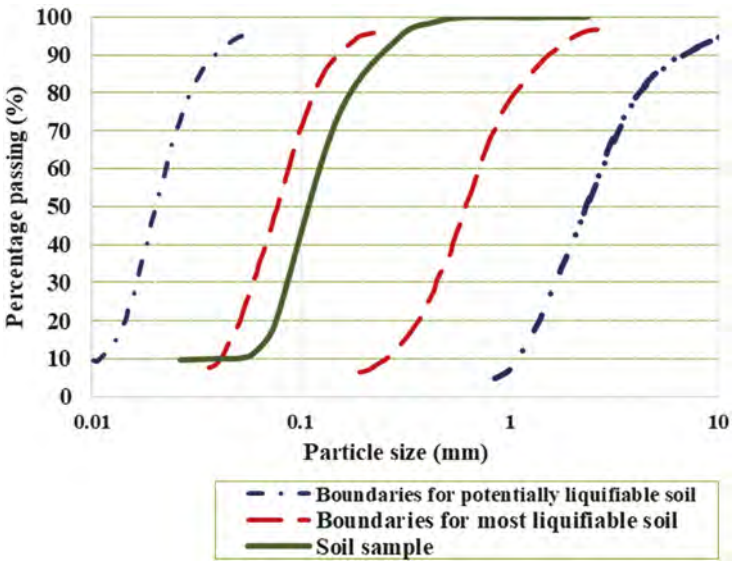

Figure 2. Particle size distribution of sand used in this study.

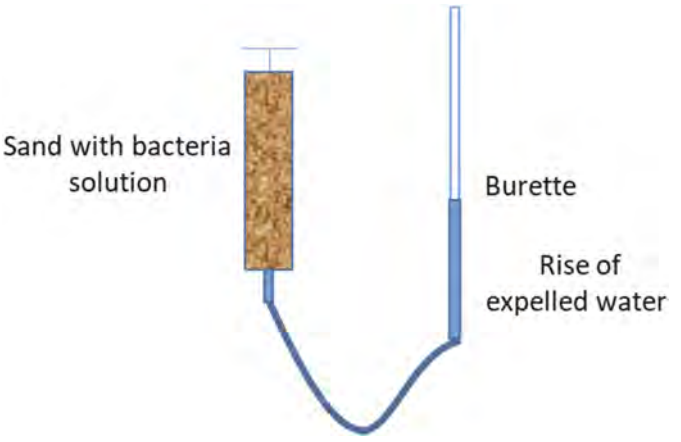

Figure 3. Setup of soil desaturation test.

Table 1. Result of soil desaturation test.

Void ratio (e)	Initial Nitrate concentration mg/L	Degree of saturation (S_r%)	pH
0.702	146.00	92.40	7.65
0.702	198.66	90.12	8.1
0.702	300.75	80.25	8.16
0.702	370.20	75.00	8.2

5 LIQUEFACTION BEHAVIOR OF UNTREATED SAND MICROBIALLY TREATED SAMPLE

5.1 *Testing procedure*

A modified cyclic triaxial setup is used to determine the liquefaction resistance of fully saturated and microbially-induced partially saturated sand during the test. A closed burette linked to the drainage value was added to the standard triaxial arrangement as a volume measuring method. The apparatus for measuring volume can measure the volume of water evacuated. The moist pluviation is produced immediately in the solution of bacteria and nitrates. With a 30% D_r sample of loose relative density and confining pressures of 50, 75, and 100 kPa and cycle stress ratios(CSR) of 0.1, 0.2, 0.3, and 0.4, consolidated undrained tests were conducted.

5.2 *Testing results and discussion*

The variation of deviatoric stress and excess pore pressure (r_u) (EPP) with the number of loading cycles, deviatoric stress with axial strain, and Cyclic stress ratio (CSR) with the number of loading cycles were obtained for fully saturated and partly saturated samples. All samples displayed identical behaviour. The Figure 4 illustrates typical graphs exhibiting the variation at 0.2 CSR and 75 kPa confining pressure. Figure 4 (a) depicts the variation of EPP with loading cycles (N_L). The soil liquefaction failure criteria for EPP ratio is found when r_u equals one. The samples with a greater 'N' value are more resistant to liquefaction. As the number of loading cycles (N_L) increases, so does the r_u, indicating the accumulation of EPP. The saturated sample displayed early liquefaction at a lower number of loading cycles than the partly saturated sample, as seen by the Figure 4a,b. Partially saturated sample look more number of loading cycles to reach maximum pore pressure ratio (r_u) of 0.46 (Figure 4b). Comparing the resistance to liquefaction of both samples in terms of loading cycles, it is obvious that the partially saturated sample displayed greater resistance to liquefaction. In terms of deviatoric stress, the initiation of liquefaction can be defined when the deviatoric stress reaches zero. The soil is completely liquefied and approaching almost zero after seven cycles for the fully saturated sample (Figure 4c). Since the partially saturated sample is not liquefied, the deviatoric stress ranges between about 37 kPa with increasing number of loading cycles. (Figure 4d). As observed in the Figure 4e, the deviatoric stress against axial strain loop becomes flatter as the deviatoric stress decreases continuously with increasing loading cycles (N_L). This clearly indicates the reduction in soil stiffness for the completely saturated sample compared to the partially saturated sample (Figure 4e,f). Figure 4g, h shows the CSR and N_L trends for untreated and MIPS-treated specimens at an effective confining pressure of $\acute{\sigma_c}$ 75kPa. No sample of partly saturated sand exhibited a pore pressure ratio (r_u) of 0.9 or 1. Under all combinations of stress conditions, the r_u is restricted to a maximum of 0.6. As CSR magnitude increases, the number of cycles necessary to achieve liquefaction reduces for both saturated and partially saturated samples.

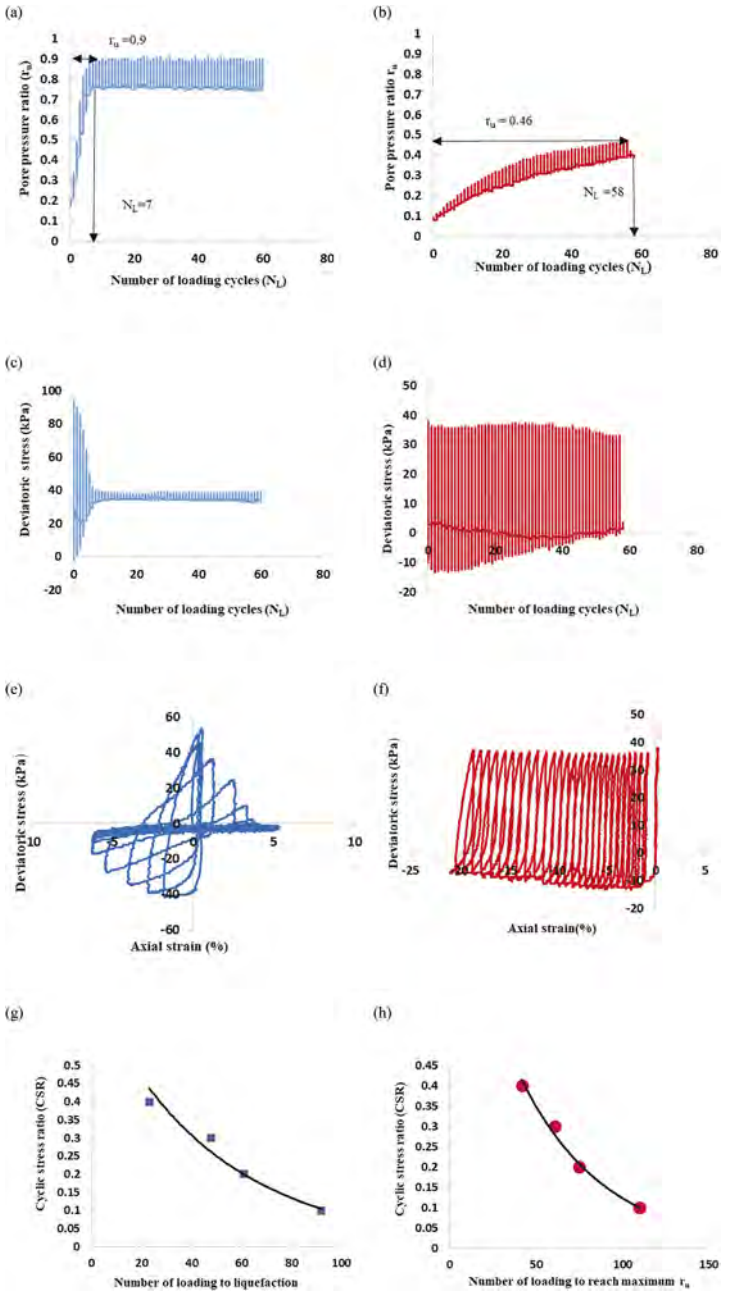

Figure 4. Undraind cyclic response of saturated and desaturated loose sand (D_r 30%) at 0.2CSR, effective confining stress of σ_c' 75kPa(a) Pore pressure ratio with number of loading cycles (N_L) (untreated sample) at degree of saturation (S_r) 99 %. (b) Pore pressure ratio with number of loading cycles (N_L) (treated sample) at degree of saturation (S_r) 93.74 % (c) Deviatoric stress vs. number of loading cycles of untreated sample at S_r 99% (d) Deviatoric stress vs. number of loading cycles of treated sample at S_r 93.74% (e) Deviatoric stress vs. strain of untreated sample at S_r 99% (f) Deviatoric stress vs. strain of treated sample at S_r 93.74% (g) Cyclic resistance curve of untreated sample at S_r 99% (h) Cyclic resistance curve of untreated sample at S_r 93.74%.

6 CONCLUSIONS

In this research, partial saturation generated by denitrifying bacteria metabolism has been evaluated, as well as the liquefaction behaviour of the treated sample. The desaturation test proved that the microbial denitrification process may create nitrogen (N_2) gas in sand, resulting in the sand desaturation. By changing the nitrate content of the soil, a saturation level of less than 80% can be reached. The cyclic triaxial test reveals that reducing the saturation level of sand from 100 % to 90% can greatly reduce its liquefaction potential. Saturated sands lose their stiffness much more rapidly than partially saturated sands when subjected to cyclic loading, as evidenced by the less number of cycles necessary to produce early liquefaction in the saturated samples. After inducing partial saturation with the MIPS approach, the soil's resistance to liquefaction increases rapidly. This suggests that induce partial saturation of sand by this technique can be a highly effective countermeasure against liquefaction.

ABSTRACT: The effect of biopolymer-based soil treatment (BPST) on the liquefaction resistance of loose sand was investigated in this study. Cyclic simple shear (CSS) apparatus was used to assess the cyclic responses of untreated (natural) and gel-type biopolymer-treated sand specimens. Laboratory test results show that BPST is effective on improving both cyclic shear stress ratio (CSR) and cyclic shear resistance ratio (CRR) where BPST could be considered as a new ground improvement method for seismic mitigation and anti-liquefaction purposes.

1 INTRODUCTION

Natural disasters such as earthquakes generally accompany geotechnical engineering instability issues including slope failure, retaining wall collapse, ground liquefaction, sink holes, and so on.

Among others, in general, ground liquefaction occurs when saturated loose sand is subjected to repeating cyclic motion where the excess pore water pressure generation induces intergranular effective stress decrease (Akhila et al., 2019). In geotechnical engineering, ground liquefaction is an important concern where it directly affects the ground bearing capacity. Thus, numbers of research have been conducted to improve the liquefaction resistance of sandy soils, including replacement, compaction, or chemical ground improvement with cement or lime (Adalier and Elgamal, 2004, Xiao et al., 2018, Bao et al., 2019, Sharma et al., 2021).

Liquefaction resistance may generally be achieved by repeated direct shear testing and triaxial tests. The cyclic load is normalized to the effective payload (effective normal stress and effective average stress). The cyclic shear stress ratio (CSR) is defined as the normalized cyclic load, and the cyclic stress (Eq. 1), while resistance ratio (CRR) is defined as the CSR in the number of cyclic shear stress loads (N) when liquefaction occurs in the experiment. CRR is defined as the ground's liquefaction resistance (Seed and Idriss, 1971).

$$CSR = \frac{\tau_{cyc}}{\sigma'_{vc}} \tag{1}$$

where τ_{cyc} = shear stress; σ'_{vc} = confinement

DOI: 10.1201/9781003299127-252

A series of repeated shear experiments were carried out in this study to explore the suitability of biopolymer, an eco-friendly ground reinforcement new material, to replace the present structure installation and ground reinforcement method using cement.

2 MATERIALS AND METHOD

2.1 *Jumunjin sand*

The test sample was constructed using Jumunjin sand, a non-stick standard sand in Korea. The USCS classifies it as SP low-grade sand. The following Figure 1 and Table 1 are the particle size distribution characteristics of Jumunjin sand.

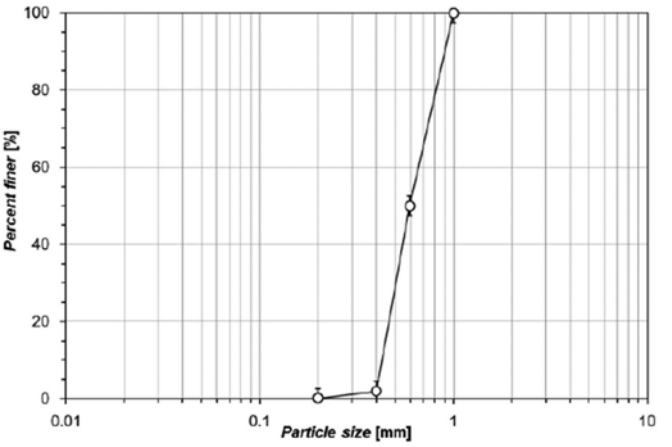

Figure 1. Characteristics of particle size distribution of Jumunjin standard sand.

Table 1. Basic geotechnical engineering properties of Jumunjin standard sand.

C_u	C_c	e_{max}	e_{min}	G_s	USCS
1.94	1.09	0.89	0.64	2.65	SP

2.2 *Biopolymer: gellan gum*

Gellan gum (In this study, gellan gum is referred to as GG), a high molecular weight polysaccharide generated by Sphingomonas elodea bacterium, was employed in this study. Gellan gum is an eco-friendly new material with heat-gelling capabilities that has lately gained notice. It has a limited solubility at low temperatures, but it dissolves evenly when combined with water to create a gellan gum solution at temperatures over 90 degrees (Chang et al., 2016).

Biopolymers have recently been shown to be useful as a geotechnical engineering ground reinforcement material. Biopolymer-based soil treatment (BPST) improves ground shear strength, friction angle, and decreases permeability. It also serves as an environmentally friendly construction material by improving groundwater retention, avoiding desertification, and promoting plant growth (Chang et al., 2015, Qureshi et al., 2017). Laboratory specimens were prepared using research grade gellan gum (Merck; CAS: 71010-52-1) in this study.

2.3 *Sample preparation*

Samples for cyclic simple shear test were prepared by mixing dry sand and heated gellan gum solution at a designated biopolymer-to-soil content and water-to-soil content in mass. The gellan gum-to-soil content in mass was set as 1%, while the water content was set as 20%. Thus a 5% gellan gum solution was prepared by dissolving 5 g of gellan gum into 95 g of

deionized water heated over 90ºC. Sand and gellan gum solution was quickly mixed above a hot plate to maintain the temperature and avoid thermo-gelation before sample molding. Hot and moist gellan gum-sand mixtures were shaped into a disk (63.5 mm in diameter and 20 mm in height) having a relative density (Dr) of 60%. Then samples were cooled down to the room temperature to allow thermo-gelation.

2.4 *Cyclic simple shear test*

A cyclic simple shear test was used in this study to compare the resistance to cyclic stress of samples made of normal sandy soil and biopolymer-treated sandy soil. In the cyclic simple shear test, a shear stress is repeatedly delivered to the sample at a fixed frequency to produce deformation in the presence of a constant overhead load. Geocomp's ShearTrac-II equipment was employed (Figure 2).

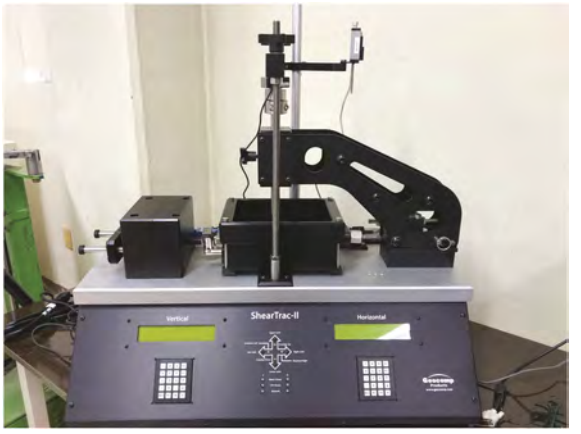

Figure 2. Overview of cyclic simple shear testing machine.

The experiment is carried out in phases. Consolidation is accomplished in the first phase of repeated simple shearing by increasing the restraining pressure on the top of the sample to 100 kPa. Following that, in step 2, shear stress is applied to the sample at a uniform frequency of 1 Hz, and the experiment is repeated until the sample's shear displacement in both directions reaches 7.5% (Vaid and Sivathayalan, 1996).

3 RESULTS AND DISCUSSION

3.1 *Experimental results: CRR (Cyclic Resistance Ratio) Comparison*

The shear strain of the sample is increased uniformly in both directions in the cyclic shear test, and the surplus pore water pressure is increased until the effective vertical stress approaches 0 kPa, causing liquefaction. Seed (Bolton Seed et al., 1985) employed the CSR at the time of 15 repeated loads based on an earthquake magnitude of 7.5 to estimate the CRR in this research. Figure 3 shows the CSR graph for each cycle of each sample collected in the experiment, and the CRR values are summarized in Table 2.

4 CONCLUSION

A cyclic direct shear test was used in this work to evaluate the liquefaction resistance of sandy soil treated with gellan gum. The liquefaction time of the gellan gum treated sample was delayed relative to the untreated sample because of the experiment, and the CRR value of each sample was inferred from the CSR graph generated from the experiment. The gellan gum-treated sample had a CRR of 0.3, which was around 0.2 greater than the untreated

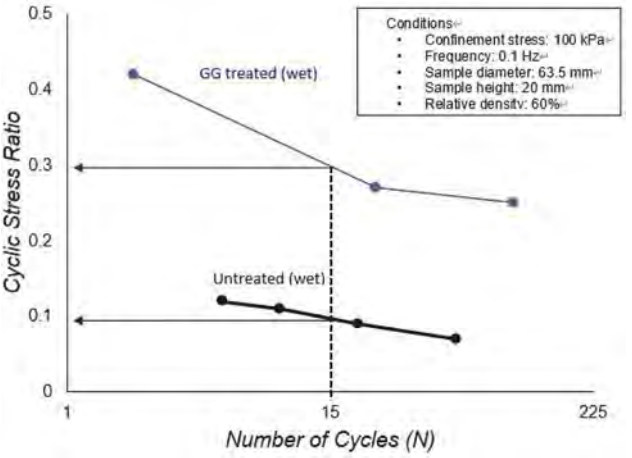

Figure 3. CSR graph according to shear cycle.

Table 2. CRR table for each case.

Case	BP (%)	Condition	10^{th} cycle CSR(CRR)
Untreated	0	Wet	0.1
GG treated	1.0	Wet	0.3

sample's CRR of 0.1, showing that the gellan gum biopolymer helps to increase liquefaction resistance. Experiments on the basic physical properties of biopolymer-treated samples, as well as the correlation between shear modulus and damping ratio, are also required.

Extremely long coseismic flow of sandy slopes and its mathematical modelling

I. Towhata
Kanto Gakuin University, Yokohama, Japan

ABSTRACT: This paper addresses coseismic landslides in gentle sandy slopes wherein the displacement exceeded 500 m and claimed hundreds of deaths in destroyed houses. This extent of displacement was substantially greater than what happened during past earthquakes. Aiming at mathematical reproduction of this extreme event, the study reviews the reconnaissance findings and then refers to field surveys. Accounting for the loss of shear resistance under the surface crust, a mathematical theory was developed on the basis of gravity-induced compression of the crust in the slope direction induced by high ground water pressure underneath and loss of shear resistance. Consequently, the passive failure of the crust was found to have shortened the length of the slopes, thus triggering the extreme downslope displacement as occurred in the field.

1 INTRODUCTION

Liquefaction-induced lateral movement in gentle sandy slopes has been known during past earthquakes. In 2018, a profoundly striking movement was triggered by an earthquake of Mw=7.5 in Palu, Sulawesi Island, Indonesia, in which the lateral displacement exceeded 500 m and was in a clear contrast with those of several meters during the 1964 Niigata, the 1983 Nihonkai-Chubu and the 1994 Northridge earthquakes. Many houses on the moving slopes were transported with the ground movement and were destroyed at the terminus where moving materials deposited and hundreds of residents were killed under debris.

After this disaster, JICA (2021) conducted a comprehensive field study on the details of this slope disaster and published a report. As one of the study team, the author picks up the information on the displacement mechanism from the report and presents its mathematical modelling.

Figure 1. Head scarp of Balaroa site; see spring water in the foreground.

Figure 2. Accumulation of earth and debris at the terminus of Balaroa slope failure.

DOI: 10.1201/9781003299127-253

2 FINDINGS DURING FIELD RECONNAISSANCE

Major slope failure occurred at four sites which are namely Balaroa, Petobo, Jono Oge and Sibalaya, accompanied by a few smaller events. Figure 1 illustrates the head scarp of the Balaroa event, which is a typical example, accompanied by PGA=281 cm/s^2 recorded in the vicinity. Many lateral cracks were found beyond the scarp, implying tensile stress there. In the base of the landslide plane, water springs were still visible six weeks after the disaster. Figure 2 shows the terminus of the lateral movement where house debris and soil got accumulated.

The JICA study inquired the eyewitnesses on what they experienced during the seismic shaking and slope movement (Figure 3). Among many issues, it is interesting that water ejection (possibly liquefaction) started during or immediately after the end of strong shaking. Ground started to move shortly (typically 20 seconds) after the end of shaking and some eyewitnesses felt several meters of depression, followed by uplift. These phenomena had been hardly experienced during past earthquakes.

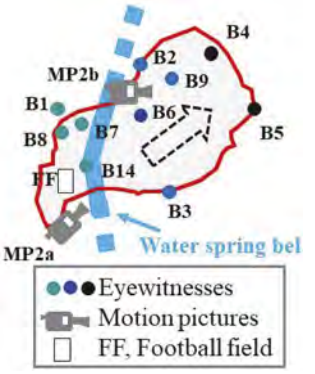

Figure 3. Location of eyewitnesses in Balaroa.

3 DISCUSSION ON BEHAVIOUR OF SUBSOIL UNDERGONG LONG-DISTANCE FLOW

Because the observed flow distance in 2018 was extremely longer than the past experiences, researchers sought for some 'special' conditions in the study areas. The effects of water leakage from the unpaved irrigation channel beyond the head scarp called attention (e.g., Nurdin et al. 2018) but this leakage is not the major cause because the Balaroa site did not have any water channel at its head. Similar to the other three sites of major slope failure, the Balaroa slope rested on a belt of water springs (Figure 3) that are common at the bottom end of alluvial fans; see water spring in Figure 1 as well.

Very loose sand exhibits strain softening during undrained shear, sometimes leading to total loss of shear strength. In the JICA study, this phenomenon was removed from the possible cause of the observed slope movement because the collected undisturbed sand samples did not behave in this manner. Another idea was the formation of water films between the surface soil crust and the underlying liquefied sand, meaning that the overlying crust can move freely along this frictionless 'water film'. This mechanism likely occurs at many places in alluvial planes and is considered not to be sufficiently 'special' to the Sulawesi sites.

The third possibility is the outbreak of underground aquifers triggered by earthquake shaking. This idea comes from the fact that the long-distance slope movements occurred in relatively low gaps between bigger and older fans (Figure 4). The low gap has less overburden and likely allows outbreak of pressurized water. Then, the last possibility is the water ejection from a tectonic origin. This idea stems from the fact that the site is a pull-apart basin formed by the very active

Palu-Koro strike-slip fault (annual displacement = 30-40 mm). It is recalled that the Matsushiro earthquake swarm was triggered by upward flow of tectonic water (Nakamura 1984) and this flow triggered three landslides. To date, no single mechanism has been decided on.

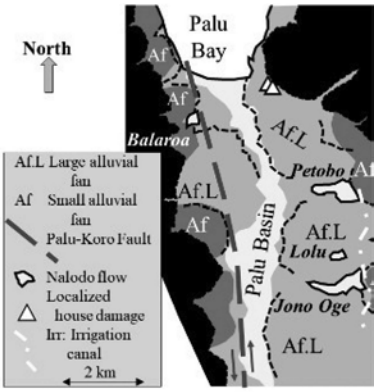

Figure 4. Sites of slope failure (called Nalodo here) between bigger fans (Af.L).

4 MECHANISM OF LONG LATERAL DISPLACEMENT OF SURFACE CRUST

In contrast to the preceding discussion on source of water pressure, the consideration on the surface crust is simple. Figure 5 schematically shows the crust resting on water. It does not matter whether this water stands for water film, outburst of pressurized water aquifer or tectonic water. Without shear stress in the lower face of the crust, the gravity force increases the longitudinal stress, σ_1, with the distance, x, from the head scarp. In case that the slope is long, this longitudinal stress exceeds the passive earth pressure and triggers shear failure as illustrated in this figure.

Figure 6 indicates the idealized stress state in which the principal stresses are given by

$$\sigma_1 = 2\rho_s g x \frac{z}{H} \sin i$$

in the longitudinal direction, and

$$\sigma_3 = \rho_s g z \cos i \tag{1}$$

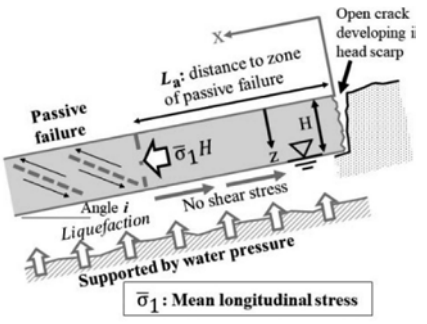

Figure 5. Surface crust subject to gravity-induced longitudinal compression.

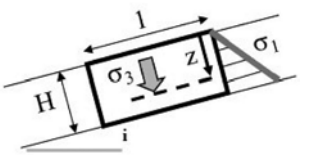

Figure 6. Idealization of stress state in the dry surface crust.

Where $\rho_s g$ stands for the unit weight of soil, and i means the slope angle. Accordingly, the mean longitudinal stress, $\overline{\sigma_1}$, satisfies the force equilibrium without base friction;

$$\overline{\sigma_1} H = \rho_s g H x \sin i \tag{2}$$

At a long distance (x=L_a) from the open crack at the top (Figures 1 and 6), the two principal stresses satisfy the passive failure conditions. Therefore, the distance from the top of the slope to the first passive failure (Figure 5) is given by

$$L_a = \frac{H}{2 \tan i} tan^2 \left(45^\circ + \frac{\phi}{2} \right) \tag{3}$$

Suppose that the soil thickness, H, = 3-5 m, the frictional angle, φ, = 30 degrees in loose sand, and tan$i$=0.02, the distance to the passive failure is L_a= 225-375 m (Figure 5), which is substantially long and accounts for the reason why passive failure and long-distance flow did not occur in shorter slopes during past earthquakes. Figure 7 illustrates the idealized model of surface crust beyond the passive failure point. The upriding of blocks occurs in the direction of 45°-φ/2 and the forces between blocks are the normal force, N, and the shear force, S=Ntanφ, whereas the contact force, N_p, with the floor becomes null at limit equilibrium after upriding. Following geometrical and force equilibrium calculations, the values of a and b are determined;

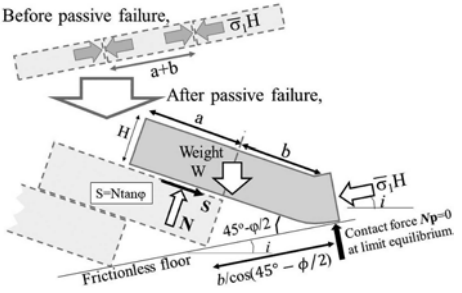

Figure 7. Surface soil blocks riding up on adjacent blocks as a consequence of passive failure.

$$\begin{gathered} a + b = sin\, i \frac{cos(45^\circ + \frac{\phi}{2})}{sin(45^\circ + \frac{\phi}{2} - i)} x \ and \\ b = H / \tan(45^\circ - \phi/2) \end{gathered} \tag{4}$$

This means that a soil block of the slope-parallel length = a+b rides up on an adjacent one (obduction) and the new longitudinal length per block decreases to b/cos(45° - φ/2). This shortening is calculated over the entire zone of passive failure and the slope displacement is worked out. The shortening ratio is defined as 'shortening' / 'original length' which is equivalent with compressional strain in continuum mechanics. Note that a fixed boundary condition is assumed at the foot of the slope as evidenced by the soil accumulation (Figure 2). It attracted attention that this theoretical study revealed negative shortening ratio near the top of the slope, suggesting a formation of big void under the upriding blocks and elongation in this part of the slope. Because formation of a big void is not realistic, the present calculation ignores this negative shortening.

5 EXAMPLE CALCULATION OF LATERAL DISPLACEMENT

Displacement was calculated by considering the shortening ratio to be equivalent with 'strain' and integrating it along the slope length. Figure 8 shows the results in which the realistic combination of H=3m and the slope length, L, =1000-2000 m gives the maximum displacement (see ○ in the

figure) of 100-700 m, which is consistent with reality. Note that the slope has to be longer than 500 m for this parameter combination in order to trigger the passive failure mechanism. This is the chief reason why the long distance flow did not occur in shorter liquefied slopes during past earthquakes. Further, the upriding of blocks and its collapse account for the substantial depression and uplift as mentioned by eyewitnesses. Figure 9 illustrates the effects on the maximum displacement exerted by the slope gradient and the friction angle in the surface crust. Within the range of calculation, the friction angle is less important than the slope gradient.

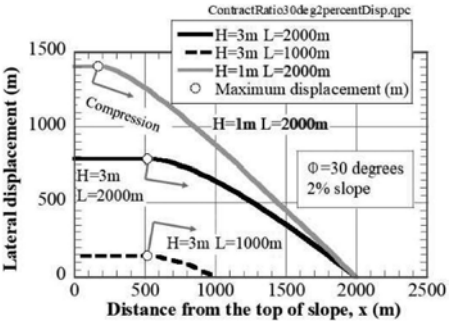

Figure 8. Calculated lateral displacement.

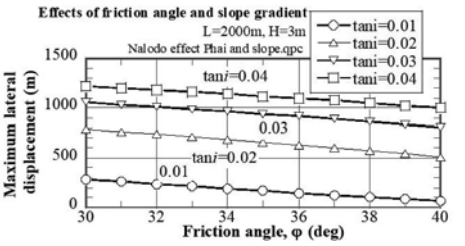

Figure 9. Maximum displacement affected by slope gradient and friction angle in the surface crust.

6 CONCLUSIONS

In response to the 2018 landslide disaster in Sulawesi, Indonesia, a predictive method was developed on the long-distance flow of gentle slopes. The major conclusive points are listed below.

1. As suggested by sand ejecta and water springs inside the landslide area, high ground water pressure presumably promoted the long-distance flow. The present study supposes that this high pressure erased the effective stress under the surface soil crust, and the loss of shear resistance underneath allowed extremely long lateral movement.
2. The gravity of the crust has a component in the slope-parallel direction that increases the longitudinal stress in the crust.
3. When the slope is long enough, the accumulated longitudinal stress becomes high enough to cause passive failure, causing upriding of the blocks in the surface crust.
4. An analytical method was developed that considers the above-mentioned mechanism and gives the displacement which is consistent with the observed displacement.

ACKNOWLEDGEMENT

Deep appreciations are expressed by the author to Mr. H. Furuichi of Yachiyo Engineering Company and the research team of the landslide disaster that was organized by JICA.

Collapse behavior and microstructure of loess soils in middle Asia

C. Boley
Institute for Soil Mechanics and Geotechnical Engineering, Bundeswehr University Munich, Germany

C. Meier
Boley Geotechnik GmbH, Munich, Germany

ABSTRACT: Mazar-e-Sharif is located in northern Afghanistan in a basin with thick alluvial sediment (loess). In its dry state, loess is rock hard, however, with an increase in water content (rainfall events), the dry soil structure collapses and sags. This leads to massive problems for construction projects.

Previous research focusses on collapse-criteria, solely for qualitative estimates on sagging potential due to the increase of water concentration (hydroconsolidation). A new method of prediction, also with a quantitative estimate, is presented by determining the influencing factors on the sagging like clay and lime percentage, pore space and macro-/microstructure of the soil in transition from semi-stable to compact. The results enable the formulation of an empirical-deductive method to predict the collapse-like deformation due to hydroconsolidation.

The intent is a practice-orientated and applicable design method that approximates the behavior of meta-stable soil structures in the event of an earthquake or the effects of weapons-related explosions.

1 INTRODUCTION

Loess and loess-like deposits cover more than 10% of the earth's surface and represent the most widespread deposit of the Quaternary period (Pécsi 1996). As an aeolian or fluvial sediment, loess belongs to a group of soils that have a high degree of strength and load-bearing capacity when they are earth-moist. The increase in water content leads to a loss of the high stability and to a qualitative change in the soil-mechanical behavior (Feda 1966) as a result of rearrangement of the grain structure. The reduction in volume associated with this rearrangement is generally referred to as sagging.

The structure of the examined loess soil, before the subsidence occurs, is described as meta-stable if the following soil characteristics occur simultaneously (Rogers 1995):

- geologically recent or recently altered sediments
- high porosity
- open pore structure
- high sensitivity to changes in water content
- weak interparticle binding forces

The Afghan loess soils of the Hindu Kush region around Mazar-e-Sharif and Kunduz considered here show all the characteristics mentioned above and, according to Rogers 1995, lead to a classification as soil prone to subsidence, i.e. soil prone to collapse.

In addition to geochemical investigations to determine the mineral composition and the water solubility of individual components, the empirical determination of the subsidence, i.e. collapse potential under static load, was the focus of the investigations. The aim was to formulate a new empirical prognosis method for estimating the collapse deformation of a recently formed loess soil (Meier 2011).

DOI: 10.1201/9781003299127-254

2 STRESS-STRAIN BEHAVIOR UNDER STATIC LOAD

The experimental determination of the deformation to be expected as a result of hydroconsolidation is not standardized in Germany. However, international normative regulations such as the Russian standard "GOST 23161-78" or the Chinese set of rules "GBJ 123-88" describe a method for examining the hydroconsolidation behavior. This is a modification of the one-dimensional compression test described in the German standard DIN EN ISO 17892-5. This was carried out using the test setup and procedure described below to determine the deformation behavior under static load.

2.1 *Research methodology*

In order to study the sensitivity of the loess soils in Mazar-e-Sharif to water, collapse tests were performed in laboratory according to Chinese Standard GBJ 123-88 (Boley 2009). For the tests, undisturbed loess samples with natural water content were compressed at first in an oedometer under different vertical pressures p. For the modified, one-dimensional compression tests, undisturbed soil samples, with in-situ water content and density properties, and with a diameter of 71 mm and a height of 14 to 24 mm were used. Since only natural samples were used, the determination of the influence of the examined parameters (clay content, pore content and lime content) was carried out exclusively based on the range of the respective parameter occurring in the naturally grown soil. That means, that the parameters were not varied, for example by adding clay or lime.

Before installing the sample, the top and bottom surfaces of the sample were machined flat and fitted with a filter plate. This filter plate ensures saturation of the sample from above as well as from the underside of the sample (Figure 1).

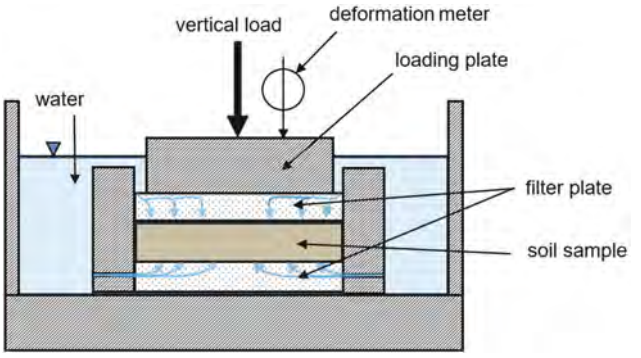

Figure 1. Experimental setup for saturation in consolidation press.

Five specimens with the specified dimensions were obtained from a special specimen. The specimens were gradually loaded in the axial direction via the loading plate. The vertical stresses applied were applied in the following increments: σ_v = 15, 50, 100, 150 and 200 kN/m².

The vertical stresses were only increased once the settlements from the previous load increment had subsided. After the deformation was complete, the samples were saturated, with the level of saturation being different for each of the five samples. The first specimen was saturated after the settlements from the first load increment (σ_v = 15 kN/m²) had subsided. All other samples went through the first load increment without a change in water content. Similarly, the second sample was only saturated after the settlements of the second load increment had subsided. The saturation of the remaining samples followed accordingly. The deformation that takes place as a result of loading and watering can be represented as a function of the effective stress. Figure 2 shows a schematic load-settlement curve for the test setup shown in Figure 1.

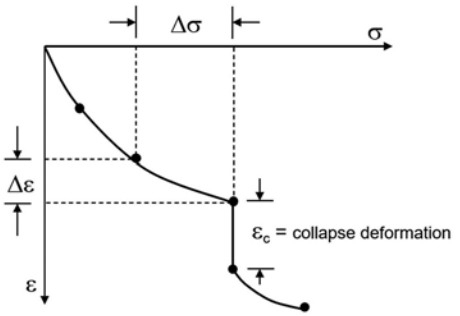

Figure 2. Deformation behavior of a collapsible loess soil.

2.2 *Study of various influencing parameters*

The test setup and procedure described for the modified compression tests was used to investigate the deformation behavior of Afghan loess soils as a result of hydroconsolidation. The study of various parameters and their influence on the average collapse deformation ε_{cav} was the focus of the study. In addition to the influence of the vertical stress (load level) and the soil density (pore content) described below, the influence of the natural clay content and lime content was also examined. The related relevant results can be found in Meier 2011.

The vertical stress σ_v acting on the soil at the time of saturation largely determines the degree of collapse-like deformation that occurs. Figure 3 shows the mean collapse deformation ε_c (index av = average) as a function of the vertical stress. The almost linear progression of the graph results from the connection of the marked points. These in turn characterize the mean collapse deformations for the five load levels σ_v = 15, 50, 100, 150 and 200 kN/m².

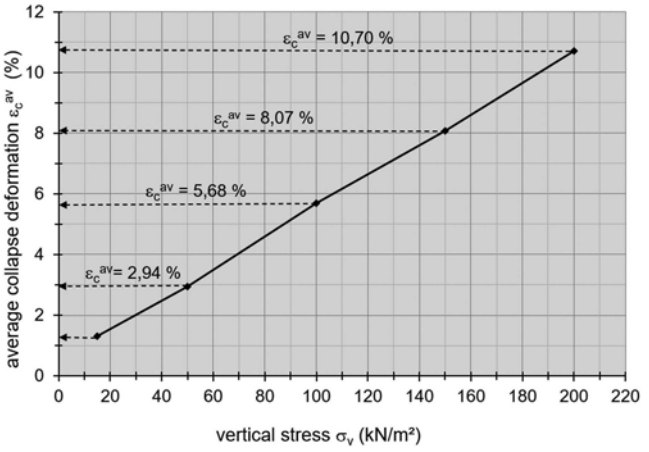

Figure 3. Influence of vertical pressure on collapse deformation.

In addition to the load level, the soil density and thus also the content of the pores in the soil are of particular importance regarding the deformation behavior. Figure 4 shows the influence of the porosity, of the natural soil on the subsidence behavior due to hydroconsolidation at a vertical stress of 200 kN/m². The porosity of the tested sample material was in the range $0.7 < e < 1.0$. As expected, the collapse strain increases with increasing porosity. This increase was shown to be linearly proportional in all tests. The metastable soil structure loses its strength due to the reduction in apparent cohesion due to changes in water content. Due to the collapse of the structure, the soil goes into a denser and therefore more stable structure. This behavior makes the pore content and thus the number of pores e, in addition to the vertical stress σ_v, the decisive parameter in hydroconsolidation.

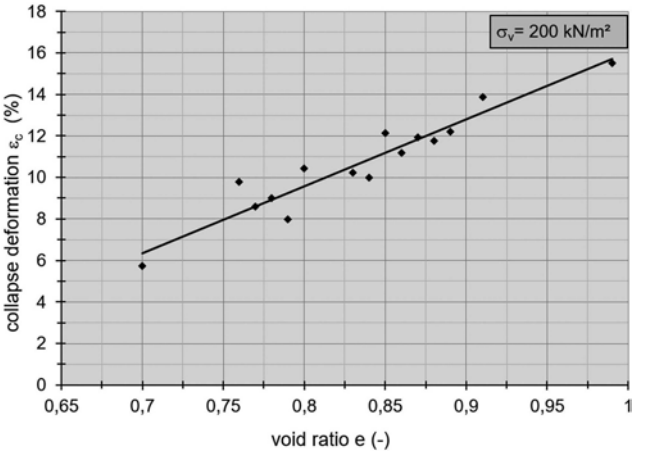

Figure 4. Influence of void ratio on collapse deformation, vertical pressure σ_v = 200 kN/m².

3 CONCLUSIONS

The study used the modified compression tests to determine the influence of various parameters on the collapse deformation ε_c. The results showed that both the clay content and the proportion of lime (calcite CaCO3) have no clear influence on the collapse deformation (Meier 2009 and 2011). Therefore, it does not make sense (for the Afghan loess soil) to use clay or lime content when predicting the expected subsidence due to hydroconsolidation. The influence of the void ratio on the other hand, proved to be a clear indicator in all tests, since the collapse deformation was always linearly proportional to the number of pores. In addition to the void ratio, the vertical load applied when changing the water content also has a major influence. Thus, the subsidence occurring as a result of hydroconsolidation is largely determined by the in-situ prevailing density, i.e. the void ratio, as a function of the applied load.

The verification of the applicability of existing forecasting methods to the Afghan loess soil examined in the work by Meier 2011 makes it clear that, despite the existing approaches, there is a need for a reliable and practice-oriented method for the quantitative determination of hydroconsolidation behavior. Based on the results obtained from the modified, one-dimensional compression tests, a new empirical forecasting method was presented (Meier 2011). This enables a quantitative estimation of the collapse deformation for recently formed fluvial and aeolian loess soils.

Characteristics of liquefaction strength for sandy soil

K. Ishii & S. Kamao
Department of Civil Engineering, Nihon University, Japan

ABSTRACT: Liquefaction has also been reported in soils containing fine grains, and studies have been conducted on the liquefaction characteristics of fine-grained sands. Evaluation of liquefaction strength using skeleton void ratio and fine-grained void ratio focusing on the skeletal structure of the soil has been studied. However, it is difficult to evaluate the liquefaction strength of sands containing fine grains with different plasticity index based only on the skeleton void ratio and fine fraction void ratio. In this study, fine-grained Toyoura sand with different plasticity index was mixed with the sand to make specimens, and repeated undrained triaxial tests were conducted. The objective of this study is to understand the characteristics of fine-grained sand on liquefaction strength.

1 INTRODUCTION

Liquefaction has also been reported in soils containing fine grains, and studies have been conducted on the liquefaction characteristics of fine-grained sands. Evaluation of liquefaction strength using skeleton void ratio (Sato 1997, Wen 2021, Ishii 2022) and fine fraction void ratio (Sato 1997, Wen 2021, Ishii 2022) focusing on the skeletal structure of the soil has been studied. Ishii et al. have conducted undrained cyclic triaxial tests using soil mixtures with a constant void ratio e and varying fine-grain content from 0 to 40%. (1) In the region where the skeleton void ratio e_s does not exceed the maximum void ratio e_{max} of sand alone ($e_s < e_{max}$), the liquefaction strength R_{20} is uniquely related to the skeleton void ratio e_s regardless of the type of fine fraction. (2) With a skeleton void ratio e_s above the maximum void ratio e_{max} for sand only ($e_s > e_{max}$), the liquefaction strength R_{20} has a good correlation with the "Fine fraction void ratio e_{ff}" in the region where the fine fraction is predominant. (3) In the region with skeleton void ratio e_s exceeding the maximum void ratio e_{max} of sand alone ($e_s > e_{max}$), liquefaction strength tends to be different depending on the plasticity index I_p of fine fraction. However, it is difficult to evaluate the liquefaction strength of sands containing fine grains with different plasticity index based only on the skeleton void ratio and fine fraction void ratio. In this study, fine-grained Toyoura sand with different plasticity index was mixed with the sand to make specimens, and undrained cyclic triaxial tests were conducted. The objective of this study is to understand the characteristics of fine-grained sand on liquefaction strength.

2 EXPERIMENT OVERVIEW

2.1 *Sample*

The samples used were Toyoura sand as coarse-grained soil and kaolin clay as fine-grained soil. Fujinomori clay and Kasaoka clay, which have a higher plasticity index than kaolin clay, were also used to examine the effects of the different properties of the fine-grained soil. The mixing ratio was determined as a percentage of the dry mass of the fine-grained fraction to the total dry mass, ranging from 0 to 60%. Each mixed soil is referred to as K5 (kaolin-mixed soil

DOI: 10.1201/9781003299127-255

with 5% fine-grain content), F10, or KS20, depending on the initial letter of the name of the fine-grained soil and the mixing ratio. Main soil property values and particle size distributions of each sample are shown in Tables 1 and 2, Figure 1.

Table 1. Main soil property values ofcoarse-grained soil.

	Soil particle dencity	Mean grain size	Clay fraction	Fine fraction	Plasticity index
Coarse-grained soil	P_s (Mg/cm^3)	D_{50} (mm)	CC (%)	FC (%)	I_p
Toyoura sand	2.64	0.161	0	0	NP

Table 2. Main soil property values of fine-grained soil.

	Soil particle dencity	Mean grain size	Clay fraction	Fine fraction	Plasticity index
Coarse-grained soil	P_s (Mg/cm^3)	D_{50} (mm)	CC (%)	FC (%)	I_p
Kaolin clay (K)	2.714	0.003	64	100	13.7
Fujinomori clay (F)	2.535	0.009	37	92	20.4
Kasaoka clay (KS)	2.710	0.006	46	100	30.8

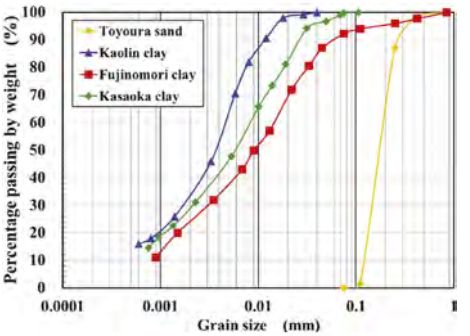

Figure 1. Grain size accumulation curves the sample.

2.2 *Experimental method*

The specimen is a cylindrical sample of 5cm in diameter and 10 cm in height. The specimens were divided into ten equal parts and then divided into ten layers, each layer of which was solidified with a rammer. After the specimens were prepared at a predetermined density, the specimens were first allowed to stand on their own at a constraint pressure of 20 kPa and were saturated by aerating carbon dioxide, passing sufficient degassed water, and then saturated by applying 200 kPa of backpressure, which is about three times the volume of the specimens. Subsequently, consolidation was performed with effective constraint pressure σ_c' = 100 kPa. The consolidation time was set as shown in Table 3 for each sample, considering that the consolidation could be completed sufficiently. After the consolidation was completed, the B-value was measured to confirm the saturation, and the backpressure was further applied to make the B-value more than 0.95. After confirming that the B-value was more than 0.95, the material was repeatedly loaded with a sinusoidal wave of 0.1 Hz frequency at the prescribed cyclic stress ratio R(= $\sigma_d/2\sigma_c$'). The test conditions for each sample are shown in Table 3.

Table 3. Test conditions for cyclic triaxial.

Sample	Density () indicates D_r (%)	Initial void ratio e_0	Consolidation time t (hour)	Cyclic stress ratio $R = (\sigma_d/2\sigma_c')$
Toyoura	Loose (40)	0.828	0.5	0.12, 0.13, 0.15
	Medium (60)	0.757	0.5	0.16, 0.17, 0.18

KS60	Medium	0.757	72	0.22, 0.26, 0.27

In this study, the most densely packed sand is called "Dense", the most loosely packed sand is called "Loose", and the sand with a density in between is called "Medium". When only Toyoura sand was used, to consider the effect of density change, the relative densities were adjusted in three ways: D_r = 40% (Loose), D_r = 60% (Medium), and, D_r = 80% (Dense). When the same test was conducted using mixed soil, the density was controlled so that the initial void ratio e_0 was e_0 = 0.828(Loose), e_0 = 0.757(Medium), and e_0 = 0.684 (Dense), respectively, which was the same value as the initial void ratio e_0 when the density was adjusted using only Toyoura sand.

3 EXPERIMENT RESULTS

3.1 *Relationship between fine fraction content and liquefaction strength*

As an index of liquefaction strength, the cyclic shear stress R at which both amplitude strains DA = 5% after 20 cycles of cyclic loading was used as the "liquefaction strength R_{20}. Figure 2 shows the relationship between the liquefaction strength R_{20} and the fine-grain content FC calculated from the liquefaction strength curves of each sample. Figure 2 shows that the liquefaction strength R_{20} of each soil mixture decreases with increasing fine-grain content, and

then R_{20} begins to increase around FC = 20%. Furthermore, as the fine-grain content increases, the difference in liquefaction strength due to the type of fine-grain content becomes more pronounced.

3.2 *Skeletal structure of mixed soils*

In this study, the effect of the fine fraction on liquefaction properties was considered using "Skeleton void ratio e_s" and "Fine fraction void ratio e_{ff}". The skeleton void ratio e_s is the void ratio when all fine fractions are considered as pores while the skeleton void ratio e_s is the void ratio. The fine fraction void ratio e_{ff} is a void ratio that ignores the volume of coarse-grains and focuses only on the fine fraction content, which is an indicator of how well the fine fraction content is plugged. The void ratio can be calculated by the following Equations (1) and (2). Equations (1) and (2) use the symbols shown in Figure 3.

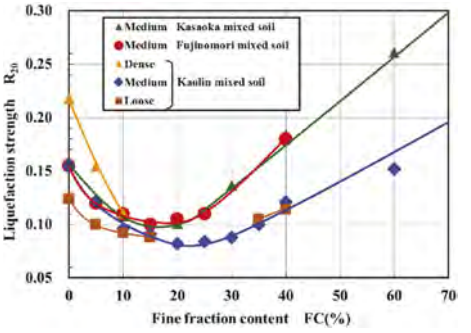

Figure 2. Effect of fine fraction content FC on liquefaction strength R_{20}.

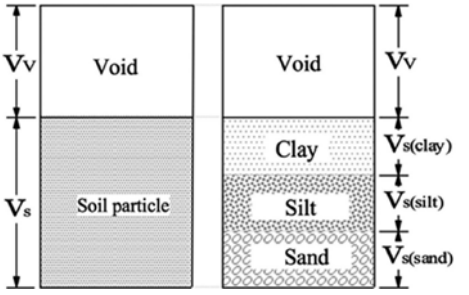

Figure 3. Schematic of mixed samples.

$$\text{Skeleton void ratio } e_s = \frac{V_v + V_{s(silt)} + V_{s(clay)}}{V_{s(sand)}} \tag{1}$$

$$\text{Fine fraction void ratio } e_{ff} = \frac{V_v}{V_{s(clay)} + V_{s(silt)}} \tag{2}$$

3.3 *Relationship between skeleton void ratio and liquefaction strength*

The relationship between the skeleton void ratio e_s and the liquefaction strength R_{20} of each soil mixture is shown in Figure 4. Previous studies have shown that (Ishii 2022) the

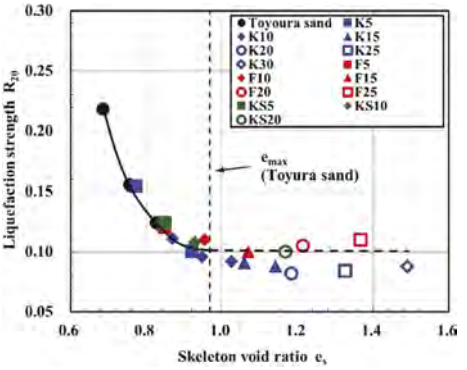

Figure 4. Relationship between Skeleton void ratio e_s and Liquefaction Strength R_{20}.

liquefaction strength increases with the plasticity index of fine-grained soil when the skeleton void ratio e_s is larger than the maximum void ratio of sand, and the liquefaction strength of fine-grained soil increases with the plasticity index of fine-grained soil when the skeleton void ratio e_s is larger than the maximum void ratio of sand. The figure focuses only on the non-plastic mixed soil and plots only the data for the non-plastic mixed soil. For the Toyoura sand only, the skeleton void ratio e_s is on the same curve as R_{20} regardless of the type of fine-grained soil, indicating a good relationship between the skeleton void ratio e_s and R_{20}. This indicates that in the range smaller than the sand-only e_{max}, the skeletal structure of the soil is formed by the sand content, and the fine-grain content has no effect on R_{20}, and R_{20} is determined by the skeleton void ratio e_s. In the range where the skeleton void ratio e_s is larger than the maximum void ratio e_{max} of sand only, the liquefaction strength R_{20} is approximately equal to the liquefaction strength when the skeleton void ratio is equal to the maximum void ratio of sand. In the range where the maximum void ratio of sand only, e_{max}, is larger than the skeleton void ratio, e_s, the sand becomes the sand becomes misalighed and the influence of fine grains gradually increases, but the liquefaction strength does not increase significantly because the soil is a non-plastic mixture.

3.4 *Relationship between fine fraction void ratio, plasticity index and liquefaction strength*

In the range where the skeleton void ratio e_s is larger than the maximum void ratio e_{max} of sand, R_{20} is considered to be influenced by the skeletal structure and soil properties of fine grains, and is considered to be closely related to the fine fraction void ratio e_{ff} and the plasticity index I_p. The relationship between the fine fraction void ratio e_{ff} and liquefaction strength R_{20} is shown in Figure 5. Figure 5 shows that the liquefaction strength increases as the fine fraction void ratio e_{ff} decreases, but the results are divided between kaolin mixed soil (blue dashed line) and other mixed soil (green dashed line) due to the difference in the plasticity index of fine-grained soils. Therefore, the relationship between the plasticity index and liquefaction strength of mixed soils with fine fraction content in the range where the skeleton void ratio e_s is larger than the maximum void ratio e_{max} of sand is examined as shown in Figure 6. The liquefaction strength tends to increase as the plasticity index increases, even at the same fine fraction content. Therefore, it can be said that there is a better relationship between the plasticity index I_p and liquefaction strength R_{20} in the range where the skeleton void ratio e_s is larger than e_{max} than the fine fraction void ratio e_{ff}.

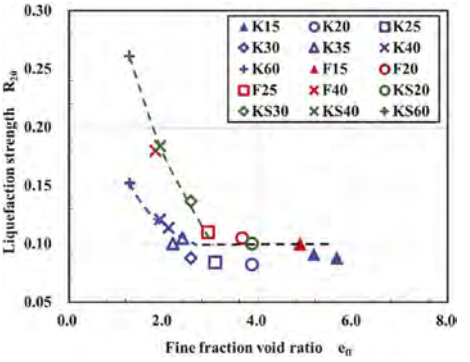

Figure 5. Relationship between Fine fraction void ratio e_{ff} and liquefaction strength R_{20}.

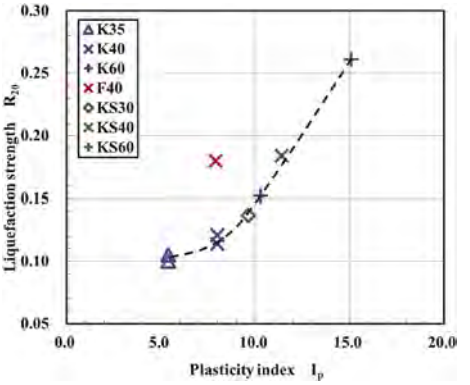

Figure 6. Relationship between plasticity index I_p and liquefaction strength R_{20}.

4 CONCLUSION

(1) The liquefaction strength R_{20} was found to have a good relationship with the skeleton void ratio e_s regardless of the type of fine-grained soil in the range of skeleton void ratio e_s less than the maximum void ratio of sand only ($e_s < e_{max}$).
(2) In the range of skeleton void ratio e_s greater than the maximum void ratio of sand only ($e_s > e_{max}$), the liquefaction strength R_{20} tends to be approximately equal to the liquefaction strength R_{20} when the skeleton void ratio e_s is equal to the maximum void ratio of sand when the mixed soil is unplasticized.
(3) The plasticity index I_p of the mixed soil tends to show a better relationship than the fine fraction void ratio e_{ff} in the range ($e_s > e_{max}$) where the maximum void ratio of sand only is greater than the skeleton void ratio e_s.

Investigation of dynamic response of sand-tire derivatives mix for geotechnical applications

A.S. Amanta
Postdoctoral Fellow, IIT Bombay, Mumbai, India

S.M. Dasaka
Professor, IIT Bombay, Mumbai, India

ABSTRACT: Disposal of used tires is a major global challenge. Used tires are recommended for usage in a variety of sectors due to their durability. The usage of derivatives out of used tire is reported in many recent researches for a variety of civil engineering applications. For potential use in liquefaction countermeasure techniques, the current study examines the dynamic characteristics and liquefaction resistance of sand, sand-tire chips, and sand-tire crumbs mixes. A number of cyclic triaxial tests were conducted in strain controlled condition, considering variables like all round pressures and strain. The present report includes description of the dynamic characteristics and liquefaction resistance for each mix in terms of excess pore pressure ratio. The findings indicated that the mix made with tire crumbs has the best damping behavior and is the most resistant to liquefaction, but it has a lower modulus than the mix with tire chips.

1 INTRODUCTION

Tire disposal is a huge global issue. Due to their longevity, used tires are suggested for use in many industries. A number of recent studies have proposed the use of scrap tire derivatives as light weight filler material in embankments (Tweedie et al. 1998; Shrestha et al. 2016),, drainage materials (Edil et al. 2004; Reddy et al. 2010) and use for vibration mitigation (Tsang 2008, Hazarika et al. 2010).

These tire derivatives are divided into three categories in accordance with ASTM D6270-17. Tire derivatives with sizes less than 12 mm, between 12 mm and 50 mm, and more than 50 mm are referred to as tire crumbs, tire chips, and tire shreds, respectively. Secondly, tire shreds are expected to have both fiber and metal reinforcements of the tires, while tire crumbs are not permitted to have any reinforcements.

The present study investigates the dynamic properties and liquefaction behaviour of sand, sand-tire chips, and sand-tire crumbs mixes for potential application in liquefaction countermeasure approaches.

2 MATERIALS AND EXPERIMENTAL PROGRAM

The present study considered sand and tire derivatives for the investigation. The sand used, had a specific gravity of solids as 2.62. The soil was poorly graded. Tire chips and crumbs are used in the study. The specific gravities of chips and crumbs were 1.14 and 1.02, respectively. The scrap tires that were available locally were shredded into tire chips, whereas the tire crumbs were commercially available. The tire chips had regular dimensions with largest particle size passing through 19 mm sieve and retained in 9.5 mm sieve. The used tire crumbs, however, were well graded, with a mean diameter of 1.87 mm and a maximum particle size of 9.5 mm. list further information about the tire chips, tire crumbs and sand. The maximum and minimum dry density of sand was 1.74 g/cm^3 and 1.44 g/cm^3, tire chips was 0.65 g/cm^3

DOI: 10.1201/9781003299127-256

and 0.51 g/cm^3, and tire crumbs was 0.57 g/cm^3 and 0.38 g/cm^3, respectively. Sand and tire derivatives were uniformly mixed together in a 4:1 weight ratio to uniform mix. M1 stands for sand-tire chips mix, and M2 for the sand-tire crumbs.

Twenty-seven number of strain-controlled, undrained, cyclic triaxial experiments (CTX) were conducted to examine the dynamic properties and liquefaction resistance of the sand-tire derivative mixes. In line with ASTM D3999-91 and D5311-92, the tests were conducted. Additionally, experiments were conducted at confining pressures of 50 kPa, 75 kPa, and 100 kPa; and strain amplitudes of 0.11%, 0.19%, and 0.26% to examine the impact of all round pressure and strain the liquefaction and dynamic response of the mixes. Experiments were done at 1 Hz frequency and 60% relative density. The cylindrical sample used for the CTX testing has dimensions of 100 mm by 200 mm. Dry pluviation was used to prepare the samples for analysis. Various test parameters were continuously recorded as the experiments progressed.

The dynamic parameters discussed in the paper were damping ratio (D) and shear modulus (G). These characteristics were determined using the stress-strain curve from the CTX tests. The excess pore pressure ratio (R_u), which is the ratio of the generated excess pore pressure (EPP) to the initial confining pressure, was used to compare the liquefaction behavior of the mixes. Liquefaction is said to have occurred when this R_u is close to unity.

3 RESULTS

Stress-strain plot is observed for all the CTX tests. For each of the three mixes taken into consideration in the study, a similar hysteresis loop is seen. The stress-strain plot flattens out as the loading cycles proceed, showing a decrease in the stiffness of the material. These hysteresis loops serve as the basis for the dynamic properties presented in this research.

The variation of the G for each of the three mixes is shown in Figure 1. It can be seen that among the three mixes, sand and M2 have the highest and lowest G values. Even though the proportion of tire derivatives in M1 and M2 is the same, the particle sizes vary. Even the M1 mix had tire derivatives with fiber reinforcement which must have contributed to the increase in the total stiffness of the sample.

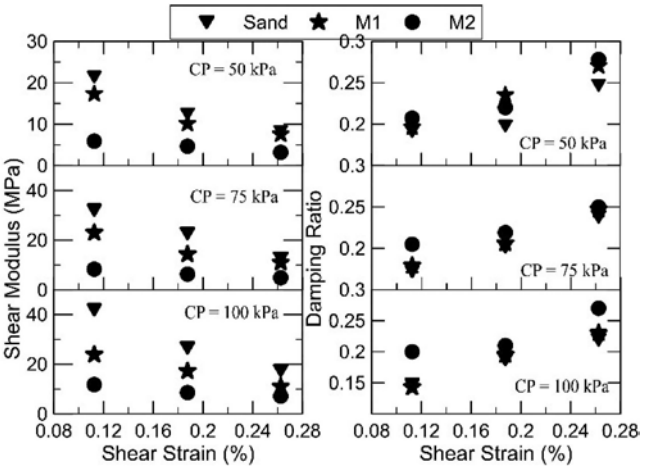

Figure 1. Dynamic properties of different mixes tested under different conditions.

The D values for all the mixes are also shown in Figure 1. It should be observed that even though tire derivatives only make up 20% of the weight of the mixes M1 and M2, the D of the sand was significantly impacted by them. As can be observed, the damping characteristics showed a tendency that was the reverse of G. Comparing the three combinations, the one with

tire crumbs consistently demonstrated the maximum damping. Of the three, the sand displayed the least damping. This damping characteristic of the mixes can be linked to the nature of the tire derivatives to deform easily when compared to the stiffer sand particles. Sand particles have a greater resistance to deformation.

Additionally, it can be seen in Figure 2 that strain amplitudes significantly affect the dynamic properties of all the mixes. The G value fell as the D value rose with increasing strain amplitude.

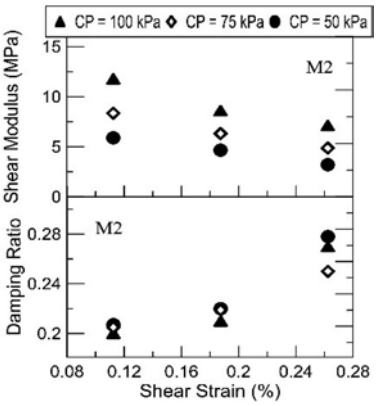

Figure 2. Effect of shear strain on G and D.

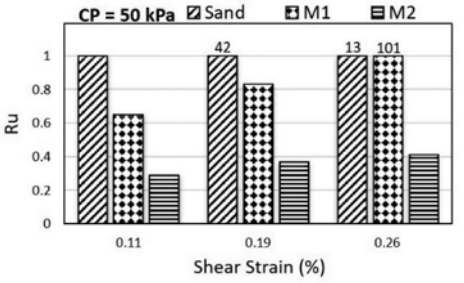

Figure 3. Variation of R_u with shear strain at confining pressure of 50 kPa.

The impact of confining pressures on the dynamic properties of all three mixes can be seen in Figure 2. It is evident that as confining pressure is increased, G increases while D decreases. This may be due to the fact that higher confining pressures would have produced a stronger matrix, increasing the stiffness of the sample and, consequently, its G value. This would have also led to a sample that was more resistant to deformation, which would have decreased the D values at confining pressures.

The liquefaction behavior of each mix in terms of R_u is described in this section. The R_u value after 200 loading cycles for specimen tested with 50 kPa confining pressure is shown in Figure 3. The number of cycles at which the sample reported liquefaction is also noted in the figure for samples that liquefied in less than 200 cycles. Three samples of sand liquefied out of the nine tests depicted in the figure. The three samples got liquefied at 0.19% and 0.26% shear strains for 13 to 101 number of loading cycles.

The figures show that for all mixes, the R_u value increases with increasing shear strain. Additionally, as confining pressures are raised, the R_u value decreases, making the samples more resistant to liquefaction. Similar results were obtained for tests carried out with confining pressures 75 kPa and 100 kPa.

The behavior of pore pressure generation is observed for all mixes. M2 has the lowest R_u value of the three mixes and did not liquefy in any of the circumstances taken into account. Despite having a similar amount of tire derivatives as M2, M1 displayed far higher R_u values than M2, and in every instance, the R_u value for M1 was found to be greater than double that of M2. Even with a confining pressure of 50 kPa and a strain amplitude of 0.26%, M1 achieved liquefaction after 101 cycles. The sand sample, in contrast to the mixes M1 and M2, reached liquefaction in all but two cases.

For the case where the confining pressure was the lowest i.e. 50 kPa and the strain amplitude was maximum i.e. 0.26%, the sand sample reached liquefaction after only 13 loading cycles. M1 mix liquefied at the same conditions at 101 cycles, which is nearly eight times than sand, whereas M2 barely reached a R_u value of 0.41.

4 CONCLUSIONS

The key conclusions from the current investigation are as follows:

- Among the three mixes studied, sand samples had the lowest D and the highest G.
- Sand has a lower G but a higher dampening characteristic when tire derivatives are included.
- Among the two mixes considered, tire chips exhibited higher modulus with sand but tire crumbs displayed stronger damping behavior.
- Liquefaction resistance was enhanced remarkably by the tire derivatives addtion.
- Among the three mixes, those containing tire crumbs demonstrated the greatest resistance to pore pressure generation.
- With increasing strain amplitudes, all of the mixes displayed a decrease in modulus and an increase in damping.
- For all the combinations, the increase in confining pressure increased G and decreased D.

Experimental study of uplift of buried pipe liquefiable soil at different depths

M. Hajialilue-Bonab
Professor of Geotechnical Engineering, Faculty of Civil Engineering, University of Tabriz, Tabriz, Iran

S. Bahram Ghannad
MSc. Student, Faculty of Civil Engineering, University of Tabriz, Tabriz, Iran

ABSTRACT: Many buried structures, including tunnels and lifelines, have been severely damaged in recent earthquakes. It is noteworthy that the phenomenon of soil liquefaction has played a significant role in the occurrence of these damages. Damage caused by the uplift of lifelines has motivated the study of the uplift of buried structures. Therefore, in this study, an attempt has been made to experimental study of the uplift of buried pipes in liquefiable soils by physical modeling at different depths. The soil used in this study is Gum Tape sand and shaking table has been used to simulate seismic load. Buried pipe at three depths: 1.5, 2.5 and 5 times the diameter of the pipe has been subjected to seismic load and the degree of elevation and deformation mechanism have been investigated. The results show that with decreasing the buried depth of the pipe, due to the relatively high pore water pressure in the lower depth of the soil, the overpressure created after dynamic loading tends to be wasted and flows towards the low-pressure points (surface part). And because in the surface areas, the flow is upward, so the uplift continues to some extent. Also, the displacement vectors on the sides of the pipe are in the form of circular rings that try to raise the pipe.

1 INTRODUCTION

Today, the increase in population and, consequently, the increase in demand, has highlighted the role of lifelines in human life.

Natural disasters such as earthquakes can cause damage to these lines. According to statistics, the rise of pipes is one of the obvious failures that the occurrence of which will lead to other damages [1, 2]. Therefore, it is important to find out the cause of uplift.

What makes the conditions more suitable for the occurrence of soil liquefaction is three factors: 1- Loose sand soil 2- High groundwater level 3- Earthquake that aggravate the conditions for its occurrence. It is worth noting that liquefaction is one of the destructive factors of lifelines that has been studied in this study. Loose sand soils have high permeability, but if this type of soil is saturated and subjected to seismicity, despite the high permeability, due to high loading speed and tendency to reduce soil volume, the opportunity for water exit is not provided and undrain condition governs the problem [3]. As a result, with the occurrence of undrain condition, the role of effective stress, as a representative of soil resistance due to increased water pressure will be diminished, and as a result, the soil loses its shear strength and will behave like a liquid. In other words, it can be stated that the soil has become liquefied [4]. By reducing the shear strength, the soil does not tolerate the maintenance of the buried pipe and the conditions for the rise of the pipe are provided [5, 6].

In the 1995 Kobe and 1999 Jiji earthquakes, the failure of water transmission lines due to liquefaction led to the failure of firefighters to contain the fire and caused irreparable damage

DOI: 10.1201/9781003299127-257

[7-9]. Examples of earthquakes that have caused soil liquefaction include the 1995 Kobe Earthquake [10], the 2004 Chuetsu Earthquake [11], the 2010 Chile Earthquake [12], and the 2011 Tokyo Earthquake [13].

In the study of Tokida et al. [14], the effect of liquefiable soil thickness under buried substructure and the width of the structure on the amount of uplift caused by liquefaction has been investigated experimentally and shaking table has been used to simulate the earthquake load. The results show that by stopping the applied load, deformation and uplift also stop and by reducing the thickness of liquefied soil and the thickness of the buried structure, the amount of uplift decreases. Also in this research, a kind of wall around the underground structure has been used to reduce the amount of overhang. Laboratory study of the effect of buried depth and diameter on the elevation of buried structures has been done by Chian et al. [5], the results have been indicated that with increasing the diameter and buried depth of the pipe, its elevation has decreased. The elevation of sewer pipes due to the liquefaction of the embankment behind the pipe has been investigated by Koski et al. [15]. In this research, shaking table has been used to model the seismic load. By considering the relative density of soil as the studied variable, it was concluded that the amount of uplift in the samples with loose sand at the beginning of the experiment was 5 to 15 mm, while there is no significant change in dense samples. However, at the end of seismic loading, the elevation of dense specimens increased significantly (about 100 mm = buried depth). The elevation of subway stations as a result of soil liquefaction was studied as numerical modeling (finite difference-finite element) by Ji-Lei et al. [16] and the results showed that liquefaction because of seismic load can initiate elevation but cannot be main reason. The uplift starts gradually from the first stage of liquefaction and increases with the amount of liquefied area, and finally with the complete liquefaction of the area, the amount of uplift occurs more intensely. It should also be noted that with the seismic stop, the simultaneous ascent does not stop. The seismic behavior of shallow foundations located on liquefiable soil was investigated numerically by Hasheminezhad et al. using flac software. In this study, soil columns have been used to improve the soil properties against liquefaction and the amount of liquefaction has been investigated by changing the geometric characteristics of the foundation and soil columns. With increasing the width of the foundation, the amount of overpressure of the pore water pressure has decreased [17]. In a study conducted by Nourzadeh et al., The vulnerability of Tehran gas facilities to liquefaction was evaluated. In this study, the phenomenon of liquefaction and vulnerability of buried pipes has been investigated by numerical and laboratory modeling. The results indicate that in some areas of Tehran there is a possibility of damage to lifelines that can be reduced by improving the soil characteristic [18]. Reduction of gas pipe vulnerability by Castiglia, et al. Has also been investigated by shaking table. A new method proposed to reduce gas pipe vulnerability in this study is the use of sandbags buried in the lower or upper part of the pipe [19]. Another method to deal with liquefaction and reduce the damage caused by it is the use of geogrids or geocomposites, which by Bahadori et al., Proved that the impact of geocomposites is more than geogrids [20]. In the study of Papadimitriou et al., The behavior of steel pipes buried in the riverbed that are affected by lateral slip has been investigated. In this study, numerical modeling of finite element has been performed with the aim of finding the maximum ground surface motion (PGD). The results showed that by increasing the thickness of the walls of the buried pipe, the allowable movement of the ground surface can be increased [21]. In a numerical study conducted by Sudevan et al., The elevation of structures buried in the soil has been investigated. In finite element software with Mohr Columbus behavioral model combined with Finn model, liquefied soil modeling has been performed[22]. According to Wu et al., The elevation of buried pipes at deep and shallow depths has been investigated. The result of this study is the dependence of the critical depth of buried pipes on the density of sand [23]. In order to reduce the uplift due to liquefaction, numerical modeling of liquefaction in FLAC software was performed by Mahmoud et al. As a result of this study, drainage around the structure and a layer of impermeable material under it is one of the methods to reduce uplift [24]. Huang et al. [25] believed that the rise of the pipe stops when the loading is complete. Therefore, in this research, the stopping time of the uplift will be evaluated in proportion to the loading.

2 MATERIALS AND METHODS

2.1 *Material properties and dimensional analysis*

Due to the presence of relatively large impurities, sifted soil has been used. The type of soil used in the experiments is Gum Tape sand, the properties of which are given in "Table 1".

Table 1. Properties of sand soil.

parameter	value
G_S	2.66
D_{10}	0.21 mm
D_{30}	0.3 mm
D_{60}	0.43 mm
Unified Soil Classification System	SP
C_C	1
C_u	2.05
$\rho^d_{\min}$	1.49 gr/cm^3
$\rho^d_{\max}$	1.72 gr/cm^3

It should also be noted that for physical modeling, it is necessary to perform dimensional analysis in order to maintain the behavior of soil and structure. In this study, Lai modeling law [26] has been used. The dimensional analysis used is similar to the dimensional analysis used in the study of Otsubo et al. [27], in this study, liquefaction and strategies to diminish it, were examined. It is noteworthy that in the modeling of the Otsubo study, the law of Lai modeling has been used for dimensional analysis. In Lai modeling law, dimensional analysis for physical modeling is performed using equilibrium equations and boundary conditions governing the problem. Lai stated that in shaking table models, due to the limited modeling space, it is necessary to scale the model to small dimensions, so by using this scale, other parameters that affect soil behavior can be scaled. In the present study, as in the Otsubo study, a scale of 1 to 5 (laboratory model to the main model) has been used.

According to Lai modeling law, the relative density of the original model (DrP) has been reduced by 15% to obtain the relative density of the laboratory model. Therefore, it can be stated that the relative density scale specified by NDr is equal to DrP-15%. The reason for the decrease in relative density is that in laboratory modeling the limiting pressure is reduced and in order to achieve the same dilatation angle and softening behavior at large strains, it is necessary to reduce the relative density by 15%. "Table 2".

Table 2. Dimensional analysis.

variable	parameter	Shaking table modeling	Value in current study
Geometry	N_G	1/5	(cm)100(length)* (width) 62* (height)64
Relative density	N_{Dr}	Dr_P-15%	30%
frequency	N_f	5	8 Hz
Pipe diameter	N_{dp}	1/5	6 cm

2.2 *Shaking table*

The reason for using shaking table in physical modeling is the need to apply seismic loading to create liquefaction in the soil. For this reason, the shaking table of Tabriz University, which was inaugurated in2016, has been used "Figure 1a".

The University of Tabriz shaking table has up-to-date equipment that allows dynamic simulation of experimental studies. Dynamic excitation like an earthquake is transmitted by the stimuli to the base of the model and simultaneously the seismic response of different points of the model is recorded by sensors and by analyzing and interpreting the records, the dynamic behavior of the real structure can be evaluated. The test platform of the shaking table is a rectangle with dimensions of m2 × m3, which is made of steel sheet and the capacity of the shaking table is up to 6 tons. The shaking table of Tabriz University has 1 degree of freedom and has a displacement range of 100 mm. The frequency designed for seismic operation is 0-20 HZ and the input movement enters the test platform through a horizontal hydraulic actuator. The test box is of rigid type with dimensions of 100 m (length) * m62 (width) * 64 m (height) "Figure 1b".

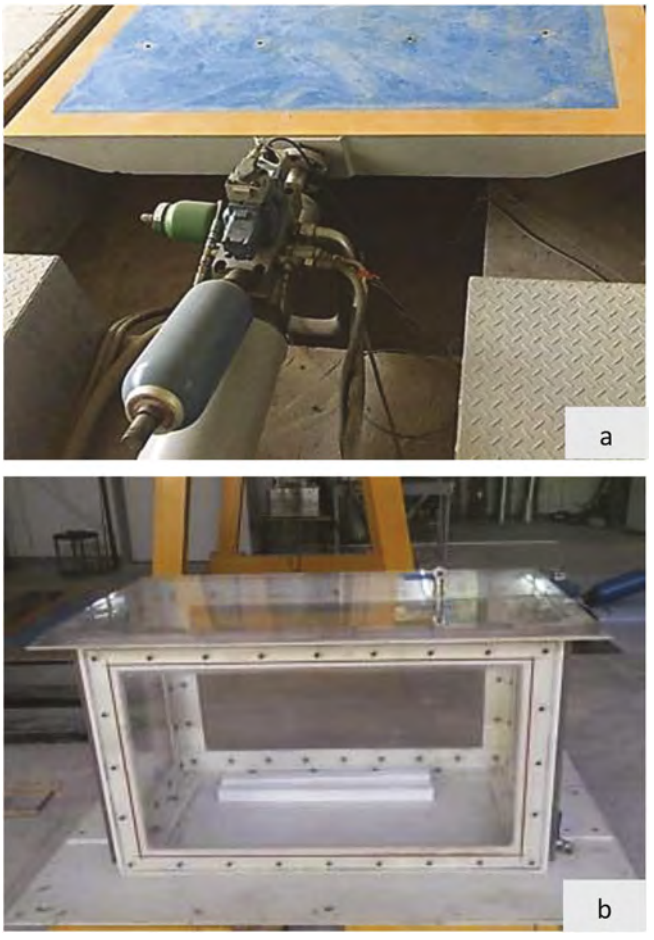

Figure 1. A) Shaking table b) rigid box.

2.3 *Properties of buried pipe, sensors, loading*

In this study, a hollow PVC pipe with an outer diameter of 6 m and a length of 61 cm and a density of 39 gr/cm3 was used to simulate the buried structure. Also, due to the lack of modeling of the water inside the pipe, both sides of the pipe are blocked so that water cannot enter the pipe.

In this study, an accelerometer has been used to control the applied seismic acceleration and a pressure gauge has been used to detect the excess pressure of the pore water during liquefaction. Relevant data can be recorded by connecting the accelerator and pressure gauge to the data logger.

Hatami et al. [28] After numerical study of the seismic response of concrete retaining walls, concluded that the seismic response of the retaining wall under the influence of different characteristics of ground input movements such as: dominant frequency, maximum ground velocity, earthquake intensity, earthquake duration and Also, the applied inputs of the recorded data of the earthquake accelerometer are real or applied in the form of harmonic motions. Also, many experimental studies on simpler physical systems have shown clear evidence of turbulent response with non-uniform correlations for various motion parameters that affect model behavior (such as range of motion and amount of final settlement). However, the most important purpose of model experiments in this study is to obtain information on the behavior of soils under dynamic loading. This goal can also be achieved by applying inputs from the earth's motion that do not reflect real seismic motion [29]. Therefore, in seismic experiments, instead of using the actual data of recorded earthquakes, simplified and harmonic loads can also be used to study the seismic behavior of soil and structures.

2.4 *Sample preparation*

In the case of soil liquefaction, soil saturation is a requirement. To prevent from Obstruction of Side valves, almond-shaped coarse grains are used at the bottom of the box to the top of the valves and a layer of geotextile is used to distribute the water evenly into the soil. The relative density of the tested soil is 30% which sand pluviation method has been used b to achieve this goal "Figure 2".

Figure 2. Sand pluviation device.

It should be noted that the load applied to the seismic is in the form of displacement over time. The sinusoidal load considered in this study is represented in "Figure 3".

Figure 4 is a photo of the model before the test. The cause of the bulge in the middle part is the presence of the pipe and due to the effect of the relative density of the sand precipitation device, there is no manual change in soil height in the middle part. In this study, in order to investigate the effect of buried depth of the pipe, three physical models were performed according to Table 3. In this table, the buried depth of the pipe with parameter H, the diameter of the pipe with parameter D, and the relative density of the sample with parameter Dr are specified.

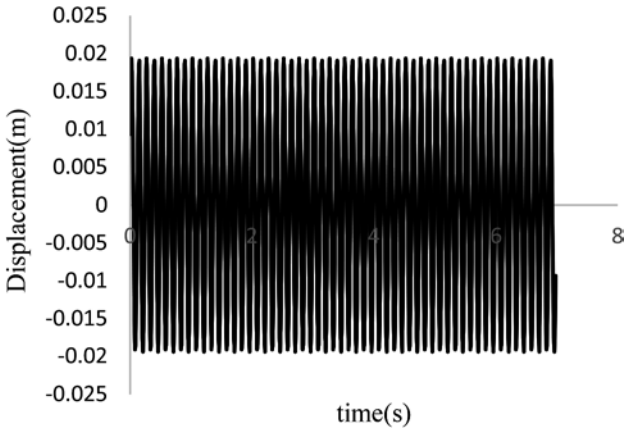

Figure 3. Seismic load.

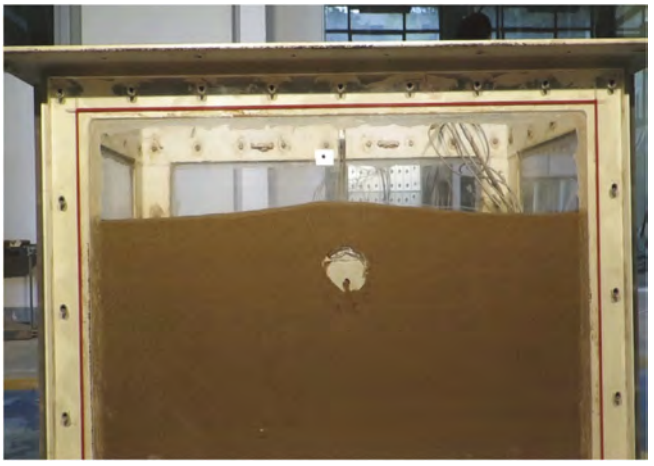

Figure 4. Laboratory physical modeling.

Table 3. Test program.

Modeling	frequency	acceleration	Dr	H/D
Model 1	Hz 8	g 0.5	30 %	1.5
Model 2	Hz 8	g 0.5	30 %	2.5
Model 3	Hz 8	g 0.5	30 %	5

3 RESULTS AND DISCUSSION

Due to the reduction of soil shear strength due to liquefaction and as a result of increasing pore water pressure, the stability of the pipe is difficult. As a result of soil liquefaction, the pipe buried in the soil prone to liquefaction will be transformed, which can be seen in "Figure 5b", the vertical movement of the pipe in an earthquake with a frequency of Hz8 and acceleration of 0.5 g at different buried depths. Also, the relationship between the buried depth of the pipe and the degree of elevation of the pipe is shown in "Figure 5a". It is worth

mentioning that the vertical axis parameter ($\frac{\Delta h}{D}$) represents the ratio of uplift to the pipe diameter and the horizontal axis parameter ($\frac{H}{D}$) represents the ratio of buried pipe depth to pipe diameter. In order to achieve the amount of elevation at different buried depths, a relationship has also been proposed as a correlation between the elevation and the buried depth of the pipe.

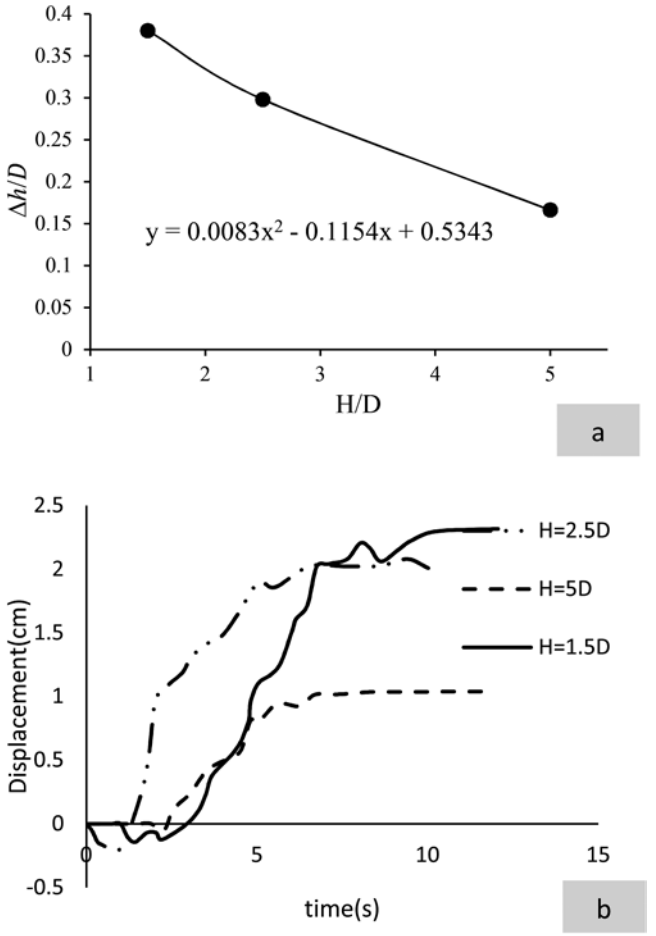

Figure 5. A) Relationship between elevation and buried depth of pipe b) Displacement of buried pipe in liquefiable soil in different buried depths.

As can be seen from the diagram, the amount of uplift decreases with increasing depth, so that when the depth of the pipe becomes 3.33 times, the ratio of the uplift of the pipe to the diameter of the pipe decreases by 56%. The reason for this can be attributed to the increase in resistive force due to the weight of the soil above the pipe. As the buried depth of the pipe increases, the amount of soil mass above the pipe, which acts as an uplifting force, increases, and as a result, the overpressure of the pore water as one of the driving forces will not be able to lift the pipe. Also, in general, first the pipe moves downwards, then, due to the elasticity in the sandy soil, the upward movement occurs and causes the pipe to reach its initial level first and then continue to rise. According to many researchers, the elevation of pipes buried in liquefied soil follows the seismic load. In this way, with the start of loading, the uplift starts

and with its end, the uplift stops [13, 30]. In order to study the beginning and end of the uplift, the diagrams of the input load, the excess of the pore water layer and the uplift are examined in "Figure 6". As can be seen from "Figure 6", the onset of uplift occurs when excess water pressure forms inside the soil. It is also important to note that uplift does not stop with the end of the load, although it continues in small amounts. Therefore, it can be concluded that seismic load is not only the initiator of uplift in buried structures during liquefaction, and the excesses pore water pressure also plays a role in this phenomenon. It is noteworthy that in order to getting Dimensionless axes of the diagram, the excess water pressure is divided into the initial effective stress and is expressed as $\frac{\Delta u}{\sigma}$ that is available at each stage of the experiment with Pressure indicator and indicates the degree of liquefaction. In relation to the pore water pressure diagram, it can be noted that due to the return wave application, the pore water pressure increases with each return wave and some of the water pressure surplus until the return wave is applied to the sample. Excesses pore water pressure disappear and the same process continues in the next wave. Also, "Figure 7" shows the relationship between the buried depth of the pipe and the excesses pore water in order to find out the effect of the buried depth of the pipe on the excesses of the pore water. It is noteworthy that when the buried depth of the pipe increases 3.33 times, the ratio of the excesses pore water pressure to the effective stress is reduced by 75%.

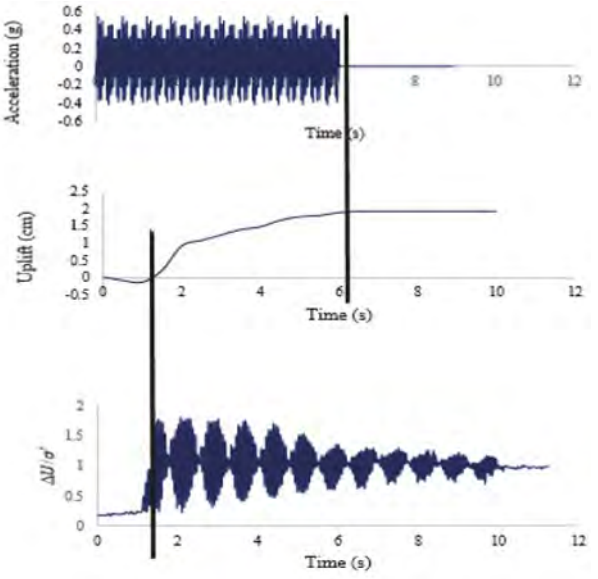

Figure 6. Acceleration, pipe uplift and degree of liquefaction charts in terms of time in the second experiment of the present study.

Figure 6. Demonstrates the time histories of selected measurements during shaking. The uplift of the pipe initiated after the surrounding sand layer had attained liquefaction. Uplift displacement proceeded at nearly constant rate mainly during shaking. Although pore pressure after shaking maintained the value equal to that during shaking uplift displacement rate decreased after shaking. There for, it is suggested that uplift displacement be affected by shaking intensity in addition to pore pressure.

According to this diagram, it can be seen that when the buried depth increases, the pore water pressure around the pipe has decreased. So, in order for the lifelines to be safe from the excesses pore pressure and as a result of the uplift caused by it, it is necessary to place them in the deep depths of the earth.

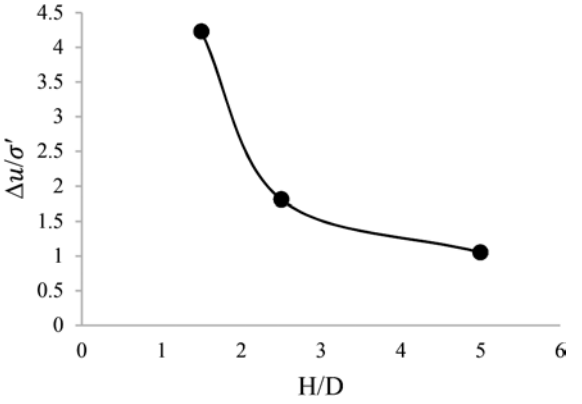

Figure 7. Relationship between excesses pore water pressure and buried depth of pipe.

4 CONCLUSION

The elevation of structures buried in liquefiable soil has been one of the important geotechnical issues due to irreparable damage. Therefore, in this study, through physical modeling, the elevation of the buried pipe has been investigated. Various parameters are effective in the uplift of the pipe, including: applied acceleration, loading frequency, relative soil density, buried depth of the pipe, etc., what is considered as a variable parameter in this study is the buried depth of the pipe. Therefore, an attempt has been made to check the elevation of the pipe by changing the buried depth of the pipe. In order to study this subject, shaking table, rigid Plexiglas box, loose sand, sand pluviation device, pressure gauge and accelerometer, deaired water device and vacuum have been used.

1. In this study, when the buried depth of the pipe increases 3.33 times, the ratio of the excess pore water pressure to the effective stress decreases by 75%. With increasing the buried depth of the pipe, due to the increase in the amount of resistive force caused by the soil mass above the pipe, the amount of uplift of the pipe has decreased. It should be noted that due to the stability of other influential parameters, the reason for the decrease in the elevation of the pipe can be attributed to the increase in the buried depth of the pipe.
2. When the buried depth of the pipe decreases, the rising of the pipe continues even after the loading is completed. Due to the high excesses pore water pressure in the lower depths of the soil, the excesses pressure created after dynamic loading tends to be wasted and flows towards the low pressure points (surface area) and because in the surface areas, the flow is upward, so the uplift It goes on to some extent. It is noteworthy that with 3.33 times the buried depth of the pipe, the ratio of uplift to pipe diameter decreases by 56%.
3. Excesses pore water pressure during seismic loading is one of the most important and effective variables in the elevation of buried pipes. The results show that the prerequisite for uplifting is reaching the excesses pore water pressure to a certain amount.

ABSTRACT: Under the influence of the wet-dry cycles, the dynamic properties of expansive soil in railway subgrade tends to be more complex. In this study, the effects of wet-dry (WD) cycles, dynamic loading and moisture content are investigated by dynamic triaxial tests. The results show that these factors have significant effects on the dynamic properties of expansive soils. In the different deviator stress conditions, soil deformation shows different trends. The expansive soil was stable as the deviator stress was less than the critical dynamic stress. Conversely, the expansive soil was destroyed as the deviator stress exceeded critical dynamic stress. With the increase of wet-dry cycles, the critical dynamic stress decreased and the accumulated strain increased. The cumulative deformation increased rapidly when the wetted time was from 0 to 1, and the increase rate slowed from 2 to 3. The results reveal the cumulative deformation law of expansive soil under the combined action of repeated wetting and dynamic load. It is expected to provide theoretical support for the construction and long-term performance evaluation in the expansive soil area.

1 INTRODUCTION

Expansive soil is characterized by expansibility, fissure and strength attenuation due to its water sensitivity. During the change in moisture content, its volume and microstructure will change significantly. In the seasonal wet and dry environment, clay minerals in the soil will expand and contract repeatedly, leading to soil structure damage and soil strength reduction. However, in the construction of railway, highway and railway projects, it is inevitable to reshape the expansive soil. Therefore, the mechanical characteristics of expansive soil under the action of wet and dry cycles affect all aspects of infrastructure construction (Ajdari et al. 2013; Tripathy et al. 2002; Vilar and Rodrigues 2011; Lu and Godt 2012; Zha et al. 2013; Zhang et al. 2015).

Current research shows that wet-dry (WD) cycle has a significant impact on the static characteristics of expansive soil. The shear strength of expansive soil decreases with the increase of the number of WD cycles, and finally tends to be stable. The stability value of strength and the number of WD cycles required for stability decrease with the increase of the change range of moisture content (AlTaie et al. 2016; Dan et al. 2018; Estabragh et al. 2015; Yarba et al. 2020). The expansion and contraction deformation of the sample in the normal WD cycle

DOI: 10.1201/9781003299127-258

gradually tends to be stable with the increase of the number of cycles. The expansion and contraction characteristics are obviously affected by the drying and shrinking paths, and the expansion rate increases with the increase of the WD cycles. The expansion rate of the sample in the process of WD cycle depends on the moisture absorption capacity to a certain extent (Gaspar et al. 2022; Yazdandoust et al. 2010). The reason why the performance of expansive soil was weakened under the condition of WD cycle is investigated from the microscopic perspective. These results indicate that the cohesion of expansive soil will be seriously lost in the first three WD cycle process, and the total pore volume will increase. Repeated WD cycles will lead to irreversible fatigue damage of microstructure and micro-crack growth (Ajdari et al. 2013; Chittoori et al. 2018; Dao et al. 2020; Liu et al. 2021).

With the development of high-speed and heavy haul traffic construction in expansive soil areas, people gradually pay attention to the dynamic characteristics of expansive soil, such as dynamic elastic modulus, dynamic resilience modulus, critical dynamic stress, cumulative strain characteristics (Yang et al. 2019; Wang et al. 2012; Zhou et al. 2019). But the dynamic characteristics of expansive soil under WD cycles still needs deeper investigation.

Most areas in southern China are in the typical WD environment. Therefore, the moisture content of expansive soil in the railway subgrade changes significantly in different seasons. In order to simulate the wet-dry process of the expansive soil under train road, the influence of dynamic stress amplitude, WD cycle and moisture content on the dynamic characteristics of compacted expansive soil is analyzed through the dynamic triaxial tests. The results reveal the cumulative deformation law of expansive soil under the action of repeated wetting and dynamic load.

2 SAMPLES PREPARATION

2.1 *Samples properties*

Expansive soil samples from Chengdu, Sichuan Province of China were selected as the test objects, which were taken from 1.5-2m below the surface. This sampling depth range was chosen because it is below the depth of maximum impact of superficial weathering. In order to determine the physical parameters of the soil samples, the moisture content, relative density, particle size distribution and related properties are tested. The results are shown in Table 1. The mineral compositions mainly include quartz, feldspar, and some clay minerals, which were obtained by X-ray diffraction (XRD) analysis (in Table 2).

Table 1. Physical properties of expansive soil.

				Atterberg limits			Particle size distribution		
Nature moisture content	Dry density	Specific gravity	Free swelling rate	Liquid limit	Plastic limit	Shrinking limit	Clay	Silt	Sand
22.7%	1.6g/cm3	2.73	82%	30.5%	52.8%	82%	50.26%	40.77%	8.77%

Table 2. Mineral compositions wt. %.

Illite	Chlorite	Quartz	Feldspar	Calcite
0.69	0.38	95.03	2.10	1.80

2.2 *Sample preparation*

All basic geotechnical tests were performed based on American Standard Test Method (ASTM). The dynamic triaxial test and backpressure saturation are carried out on dynamic triaxial instrument (DYN77S) that was made by GDS Instruments of the UK (Figure 1). In

this test, the density of the samples was controlled to be 1.6 g/cm^3. Soil and water were mixed according to the moisture content. The sample is divided into 5 layers of compaction, with a diameter of 50 mm and a height of 100 mm. The moisture content of the soil sample is controlled within 10% ~ 25%. In order to study the effect of WD cycle on dynamic characteristics, dynamic triaxial tests of 0~3 WD cycles were carried out. In each cycle, three moisture content (ω = 10%, 17%, 24%) were selected as control points. Backpressure saturation was obtained by GDS instrument. The temperature was controlled at 40°C to simulate the dehumidification process by the oven. The moisture content of the samples was measured by weighing method at the interval of each 1 hour during the early drying process. The measurement frequency increased when the moisture content was close to the target moisture content. After the moisture content drops to the control point, the sample is sealed and cured for 24h to make the moisture distributed uniformly.

3 DYNAMIC TRIAXIAL TEST SCHEME

The dynamic triaxial test adopts stress-controlled loading mode. A half-sine curve load is set to simulate the traffic load (Figure 2). The lateral pressure of railway subgrade surface was 20 ~ 60 kPa (Han et al., 2002), so the confining pressure was 50 kPa and all samples were consolidated by isobaric pressure. The frequency range of train vibration is usually F≤2.35 Hz (Liu et al. 2009). Considering that frequency is not used as a variable factor in the test, 1Hz is selected as the simulation frequency. The test is ended as the dynamic loading reaches 10000 times or the axial cumulative plastic strain of the sample is greater than 10%. The parameters in the test scheme are shown in Table 3.

Figure 1. DYN77S dynamic triaxial test apparatus.

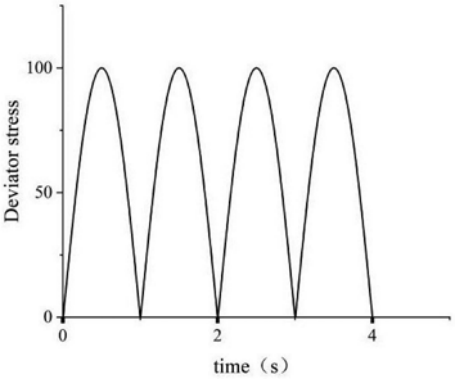

Figure 2. Curve of cyclic loading.

Table 3. Dynamic triaxial test scheme.

Moisture content (%)	Confining Pressure (kPa)	Vibration Frequency (Hz)	Number of wet-dry cycles (n)	Deviator stress (kPa)
15	50	1	0	150
			0	90, 150, 200, 250, 300
17	50	1	1	90, 150
			2	90, 150
			3	90, 150
19	50	1	0	150

4 RESULTS AND DISCUSSION

4.1 *Dynamic deformation characteristics of expansive soils*

The axial strain changes with the number of vibrations (lg N) with a confining pressure of 50 kPa and a moisture content of 17% at different stress amplitudes as shown in Figure 3(a). This curve can generally be divided into three types according to its development mode: plastic stability type, plastic creep type and incremental damage type (Perez et al. 2006; Xiao et al. 2017). For the plastic stability type, as the deviator stress are 90kPa and 150kPa, the cumulative plastic strain under cyclic loading increases rapidly and stabilizes at fewer vibration times. The cumulative plastic strain is 1.11% and 1.05% after 2000 vibrations, respectively. For the plastic creep type, as the deviator stress is 200kPa, the cumulative plastic strain increases rapidly at the initial stage under cyclic load, then slows down but keeps growing. Finally, the cumulative plastic strain reaches 3% at 1000 vibration times and continues to increase slowly. The characteristic of the incremental damage curve is that the cumulative plastic strain increases rapidly under cyclic load, and reaches 10% of the strain of the termination test when the number of vibrations is less than 100 as deviator stress is 250 kPa and 300 kPa. The reason is speculated that the relative slip between the particles in the sample results in the rapid growth of the cumulative plastic strain of the sample at the initial stage of loading. At the same time, the impaction and occlusion between internal particles are relatively enhanced, and the ability of the specimen to resist external loads is enhanced. Therefore, the curve shows that the cumulative strain rises rapidly and then becomes stable. When the deviator stress is 90 kPa or 150 kPa, the dynamic load is less than the strength of specimen, so the state of the sample is characterized by elastic deformation after the internal particles impaction and occlusion. As the deviatoric stress increases to 200 kPa, the specimen changes from elastic state to plastic state, and the cumulative strain increases slowly. When the deviatoric stress increases to 250 kPa, the strength of the specimen is significantly insufficient to resist the effect of the current dynamic load. As a result, the specimen with rapid growth of cumulative plastic strain was destroyed after less than 100 times of vibration.

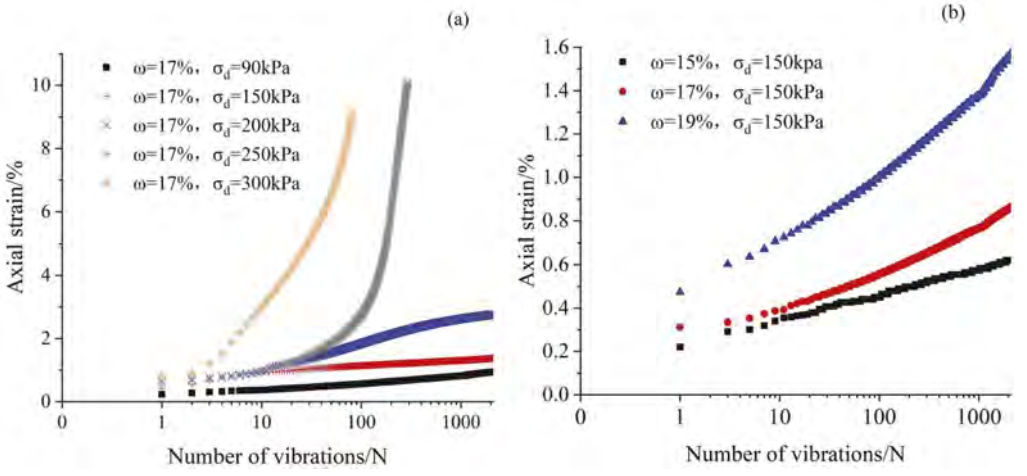

Figure 3. Permanent deformation curve under different deviator stress and moisture content.

The result of permanent deformation of the expansive soil varies with different moisture content as shown in Figure 3(b). The axial strains are 0.58%, 0.85% and 1.4% after 1000 vibrations as the moisture contents are 15%, 17% and 19%, respectively. It is obvious that the permanent deformation of the soil specimens increases with the increase of moisture content. It can be deduced that the critical dynamic stress of the expansive soil would decrease during this process. As a result, if the expansive soil is used as the roadbed filler in the railway construction, it should pay attention to the arrangement of waterproofing and drainage facilities.

4.2 *Impact of the number of wet-dry cycles on the dynamic deformation*

The relationship between cumulative axial strain and vibration number of the expansive soil with the moisture ω=17% at different dynamic stress and WD cycles is shown in Figure 5. It is obvious that the number of WD cycles has a great influence on the expansive soil deformation. After expansive soil experienced at least one time WD cycles, the axial strain was about two times than that of soil samples without WD process. The reason is speculated that the percent of grain size of clay grade increases and that of silt and sand grades decreases, which could cause the soil structure to decompose partially (Rao et al. 2001; Yazdandoust et al. 2010). Nevertheless, the axial strain increases slightly with the increase of WD cycle since the one time WD cycle. Besides, the dynamic stress has a certain influence on the axial strain as well. The axial strain of soil samples at σ_d=150kPa is about 34% higher than that of soil samples at σ_d=90kPa. However, the overall change tendency is almost the same for all samples at different dynamic stress. It is indicated that the WD cycles have a significant influence on the dynamic properties of the expansive. The effect of WD process is essentially caused by the migration of pore water. This effect not only brings additional deformation but also causes changes in physical and mechanical properties of expansive. The mechanism of dynamic strength decreases needs further study in the view of microstructure.

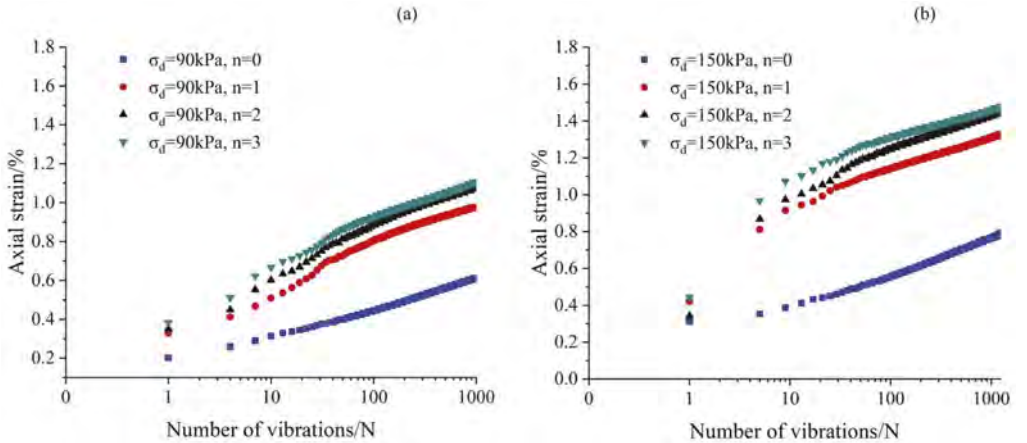

Figure 4. Relationship between axial strain and vibration number under different dynamic stress and WD cycles.

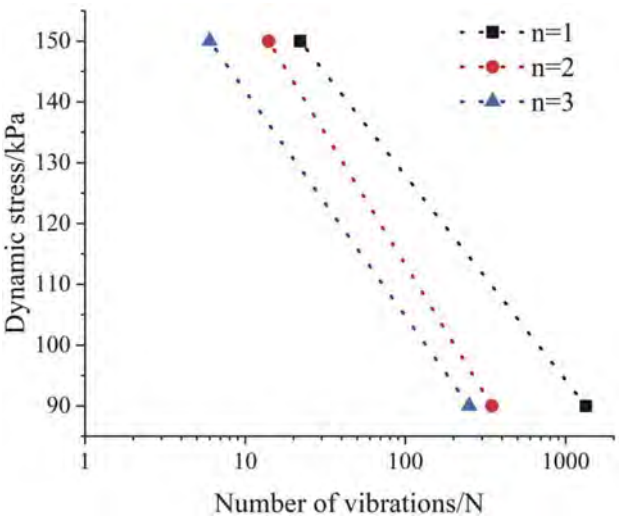

Figure 5. Dynamic strength curve of different WD cycles.

Dynamic strength of soil refers to the dynamic stress of soil under dynamic load vibrations according to the failure criterion. When the axial cumulative plastic strain reaches 1%, the failure criterion is taken into account (Wu et al., 1998). Based on the deformation characteristics of soil in Figure 4, the dynamic strength of expanding soil under different WD cycles is shown in Figure 5. It is indicated that the more WD cycles performed, the fewer times of vibration required to achieve the failure standard under the same stress condition. The numbers of vibrations required to attain the failure standard are 1339 and 346 as the deviator stress is 90kPa but the WD cycle is 1 and 2, respectively. The descending percentage of vibration number is close to 75% after one more time WD cycle. Furthermore, the vibration number decreased from 22 to 14 as the deviator stress is 90 kPa and WD cycle increased from 1 to 2. In this condition, the descending percentage of vibration number is about 36%. It is obvious that the wet-dry process has significant influence on the dynamic strength of expanding soil, especially under the higher deviator stress.

4 CONCLUSION

In this paper, the dynamic properties of the expansive soil in Chengdu city, China were investigated by dynamic triaxial tests. The following conclusions were obtained.

(1) The permanent deformation curve under different deviator stress can generally be divided into three types according to its development mode: plastic stability, plastic creep and incremental damage types. All three types showed a rapid increase in cumulative strain in the first stage. The plastic stability type entered the elastic stability stage after a rapid increase. The plastic creep type entered the plastic slow deformation stage after a rapid increase. The deformation of incremental damage type continues to increase until it is destroyed.
(2) The permanent deformation of the soil specimens increases with the increase of moisture content.
(3) Wet-dry cycles have a greater influence on the dynamic properties of expansive soils. Under the same dynamic stress amplitude, the permanent plastic strain of expansive soil specimens increases significantly with the increase of the number of WD cycles. The dynamic strength of expansive soil specimens decrease with the increase of number of WD cycles under certain confining pressure.

Dalia Ali Abdul Hussein
M.Sc. in Geotechnical Engineering, Civil Engineering Department, University of Technology, Baghdad, Iraq

ABSTRACT: Due to the position and the high importance of Baghdad city as the capital of Iraq with its very high population of about 10 million, and its subjection to frequent earthquakes in the last decade. This study tries to assess the factor of safety against liquefaction potential indices (LPI) for the most critical seismic situations under the effect of seismic loading during earthquakes. Huge data were used for 630 boreholes represent 200 site location points for many different types of projects spread all over the city has been chosen and analyzed using special soft wares. Input data of the studied sites represent soil geotechnical properties at different depths such as the total borehole depth, the ground water level, standard penetration number (N), unit weight, and fines content. Six earthquake magnitudes with 0.5 interval (M_L=4, 4.5, 5, 5.5, 6, and 6.5) have been chosen to analyze the data. Only 121 points show susceptibility to liquefaction. Three mathematical equations were proposed for analyzing the studied ten factors. Three equations with their accuracy were proposed for points with high percent of clay, points with high percent of silt, and points with high percent of sand. The probability of ground failure (P_G) and the calculated LPI was considered for assessing liquefaction risk. As the probability of liquefaction (P_L) and the probability of ground failure (P_G) are considered to be better measure of liquefaction potential than the factor of safety, so they were determined using the factor of safety and L.P.I.

Keywords: Earthquakes, Soil liquefaction potential index, probability of ground failure (P_G) and probability of liquefaction (P_L), Baghdad soil

1 INTRODUCTION

In this work, the potential of liquefaction damage will be quantified by an averaged index property, i.e., the liquefaction potential index (LPI), which was originally proposed by Iwasaki et al. (1978 and 1982) has been subsequently used and calibrated by many investigators. Many researchers performed a number of studies on liquefaction and liquefaction-induced ground failures.

Soil liquefaction is a catastrophic occurrence takes place in saturated soils that is generated by seismic events or dynamic shaking. It is considered to be an earthquake-related phenomenon. This phenomenon happens owing to the incapability of soil to dissipate pore water pressure that buildup under abrupt loading. The unexpected increase in pore water pressure in addition to dynamic-induced stresses can carry the soil structure to an unstable condition (Kramer, 1998; Fattah et al. 2002).

*Corresponding author: 40062@uotechnology.edu.iq

DOI: 10.1201/9781003299127-259

The liquefaction potential index (LPI defined by Iwasaki et al. (1978) combines depth, thickness, and factor of safety of liquefiable material inferred from a CPT sounding into a single parameter (Toprak and Holzer, 2003).

The potential for liquefaction to occur at certain depth at a site is quantified in terms of the factors of safety against liquefaction (F.S.) (Dixit et al., 2012). The factor of safety less than 1 at a certain depth indicates that the soil layer at that particular depth is likely to liquefy. The F.S. values for a particular depth can be seen to be decreasing with the increase in the magnitude of earthquake. This shows that the increase in the susceptibility of liquefaction with the increase in intensity of seismic events.

Liquefaction phenomenon has been registered and developed in many parts of the world where ground vibration is repeated and soils consist of loose fine sand under water table. Iraq involving the capital Baghdad is in general an alluvial deposits consisting of fine sand and silt deposits with shallow ground water table in most places. Although the older alluvium is less susceptible to liquefaction, the recent deposits along the river flood plains may liquefy during a severe earthquake. Thus, any structure, if not properly designed for liquefaction, may lead to its failure or sustain excessive cost through conservative design. No study has so far been achieved to show liquefaction possibilities at local levels in Iraq. In the absence of a definite knowledge of liquefaction probabilities at various localities, difficulties arise in accomplishing design of many important structures. This adds to the construction time and cost. It has been, therefore, felt necessary to undertake a study to develop a liquefaction potential map of Baghdad city.

Further related studies concerning Baghdad city is that accomplished by Karim and Schanz (2006) who analyzed the data of 44 sites within the city. This study found that 8 sites only show liquefaction zones mainly occurring in the first 15 m from ground surface, with total settlements $\leq$20 cm. Later, Karim et al. (2010) evaluated some geotechnical properties and liquefaction potential for 14 sites in Iraq from seismic parameters. To investigate the liquefaction potential of soils, two selected sites have been studied using the computer program. The application shows a total settlement for saturated and dry sand of 32 mm for the first site while no settlement has been indicated for the second site. Lastly, Karim and Wadaa (2017a and b) assessed liquefaction potential of Baghdad soil under earthquakes effect with analyzing Baghdad soil geotechnical properties. Data for 630 boreholes were used in both studies representing 200 sites. Only 121 points show susceptibility to liquefaction.

This article is concentrated on the assessment of soil liquefaction potential index using probability concept For Baghdad City, Iraq and to calculate the applicability of the LPI equations in evaluating damage severity in Baghdad city.

Evaluation of the Liquefaction Potential Index (LPI) using probability concept

Determination the probability of ground failure (P_G) and probability of liquefaction (P_L)

Using the factor of safety and L.P.I, another two determinations will be produced, the probability of ground failure (P_G) and the probability of liquefaction (P_L). Those are considered to be better measure of liquefaction potential than the factor of safety.

Based on the Bayes' theorem the relationship between the probability of ground failure (P_G) and the calculated L.P.I. can be established:

$$P_G = \frac{1}{(1 + e^{(4.9 - 0.73 * L.P.I.)})} \tag{1}$$

Table 1. Probability of liquefaction-induced ground failure (Li et al. 2006).

Probability	Description of the risk of liquefaction-induced ground failure
$0.9 < P_G$	extremely high to absolutely certain
$0.7 < P_G \leq 0.9$	high
$0.3 < P_G \leq 0.7$	medium
$0.1 < P_G \leq 0.3$	low
$P_G \leq 0.1$	extremely low to none

Using Bayes' theorem as outlined by Juang et al. (1999 and 2002), the probability of liquefaction (P_L) is calculated as follows:

$$P_L = \frac{1}{\left(1 + \frac{F.S.}{0.85}\right)^{5.54}} \quad (2)$$

Thus P_G and P_L for liquefied points with different earthquake magnitudes can be calculated.

2 RESULTS AND DISCUSSION

In this study, SPT N-values, along with other necessary geotechnical properties adopted for 630 boreholes and are representing 200 site location points (105 in Rusafa and 95 in Karkh) for different kinds of projects of Bahgdad City, were used to assess the liquefaction potential of the geological materials of the city using simplified procedure to determine the factor of safety against liquefaction.

Input data of the studied sites represent soil geotechnical properties at different depths such as the total borehole depth, the ground water level, standard penetration number (N), unit weight, and fines content. Six earthquake magnitudes with 0.5 interval (M_L=4, 4.5, 5, 5.5, 6, and 6.5) have been chosen to analyze the data. Only 121 points show susceptibility to liquefaction.

To assess the liquefaction potential, the LiqIT software was used (GeoLogismiki, 2006), which enables LPI estimation from the combination of observations (i.e.…. In this work, liquefaction hazard is quantified and mapped in terms of an averaged index called the LPI, initially proposed by Iwasaki et al. (1978) and Iwasaki et al. (1982).

The 200 site points are mapped using geographical information system (ArcGIS10.3.). The GIS techniques were used to show the first map, which is spatial locations and distributions of site point's location of Baghdad City as shown in Figure (1).

The depth of the studied boreholes has been adopted to only 30 m, the soil layers were grouped into each 2m, where 15 layers studied. The factor of safety is taken according to Adriss and Seed with F.S. =1.5.

Applying Excel software, six tables evaluated with six different earthquake magnitudes have been constructed using specific the above two equations in order to show the values of P_G and P_L of soil for Baghdad City. Table 1 represents the values of P_G and P_L values for the liquefied points with earthquakes magnitude 4.

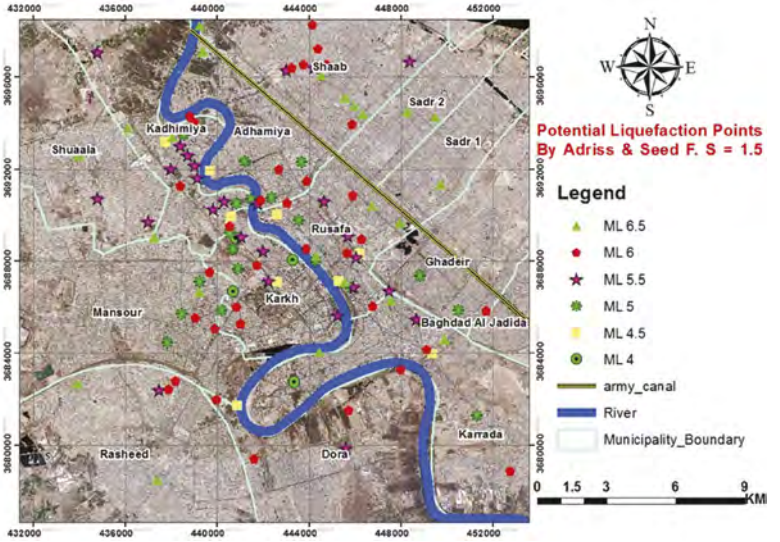

Figure 1. Liquefaction potential site point's location according to the considered option.

The significance of the relationship between the probability of ground failure PG and the calculated LPI relation is for assessing liquefaction risk.

The P_G values for M_L=4 are ranging between 0.012 (extremely low to none) - 0.373 (medium), but most the values are <0.1. P_L values are ranging between 0.272-0.45 (Table 2).

The probability of ground failure (*PG*) and probability of liquefaction (P_L) values have been constructed as digital interpolation maps and as digital combined contour–interpolation maps.

Table 2. P_G and P_L for liquefied points with earthquake magnitude =4.

maps have been constructed for earthquakes magnitudes M_L=4-6.5 and for each P_G and P_L,for digital combined contour–interpolation map for liquefaction potential index (Figures 2) (Figures 3).

The P_G values in the maps for M_L=4-5 are ranging between 0.026-0.244 (Figure 2- a). Higher values are located in the northern part of Baghdad city, besides some parts in the southwestern part. While lower values are located in the southeastern part. According to the risk description of liquefaction-induced ground failure indicated that the probability values of the risk is of very low-none ($P_G \leq 0.1$) to low ($0.1 < P_G \leq 0.3$). Concerning the probability of liquefaction (P_L) for M_L=4-5, their values are ranging between 0.305-0.379 (Figure 3- a). As in the P_G maps, higher values of P_L values (0.38) are located in the northern part and southwestern parts of Baghdad city, with low values (0.3) in its southern and southeastern parts. Comparing P_G and P_L values with that of LPI values, it seems that there is coincidence between the two maps particularly in their northern parts where high values of LPI are found to reach LPI>10.

Regarding the P_G values in the maps for M_L=5.5 are between 0.05-1.283 (Figure 2- b), where high values (>1 reaching 1.2) are located in the NW part with intermediate (0.5) in the SE part to low values (< 0.1) in the middle (NE-SW) parts. Consequently, the risk appears to be extremely high to absolutely certain in the northwestern part, medium in the SE part, with extremely low-none in the in the middle (NE-SW) parts. Regarding P_L values, they are ranging between 0.27-0.50 (Figure 3- b) where high values are assigned to NW and SE parts with 0.5 while lower values (<0.3) are located in the NE-SW parts. In comparison between P_G and P_L values with LPI values for M_L=5.5, it is clearly shown the full coincidence between the three maps, where high values of LPI are found in the north western half (>23) with low values (3-8) in the middle parts to medium (8-13) in the SE part of Baghdad city.

The P_G values for M_L=6 are ranging between 0.01-0.203 (Figure 2- c), where higher values (0.2) are assigned to the center parts surrounded by lower values (~ 0.01). Therefore, the risk description of liquefaction-induced ground failure indicated that the probability values of the risk appears to be medium in the center parts to extremely low to none for the rest areas. The P_L values are ranging between 0.245-0.375 (Figure 3- c) with high values in the northern part reaching >0.3 with lower values for the rest areas. In comparison with LPI map with P_G and P_L, there is similarity between LPI and P_G where both have high values in the north eastern and central parts surrounded by lower values for the rest parts. While, some similarity is found between LPI and P_L maps.

The P_G values for M_L=6.5 are ranging between 0.022-0.756 (Figure 2- d), where higher values (>0.17) are assigned to the third part of northern part, while lower values (<0.17) are assigned to the middle and southern parts of the city. Subsequently, the risk description of liquefaction-induced ground failure is indicated to be medium risk (>0.3) in the upper third part of north to low- none risk (<0.18) for the rest area. For the probability of liquefaction (P_L) for M_L=6.5 (Figure 3-d), their values are between 0.152-2.563 with higher values (>0.4) reaching 2.5 in the western and southern

parts, while lower values (<0.4) for the rest parts of the city of Baghdad. Comparing P_G values with that of LPI values, it looks that there is some coincidence between them, with higher values of LPI (>20) in the NE part associated with high values of P_G while low-intermediate values of LPI (≤ 20) in the NW and southern parts associated with low P_G values. Comparing $P_{L\ values}$ with that of LPI values, it looks that there is also some coincidence between them, with higher values of LPI (>20) and low values (0.15) of P_L in the NE part and lower LPI values (<20) in the NW and southern parts, while high P_L values are indicated in the NW part.

3 CONCLUSIONS

The main conclusion for the aassessment of soil liquefaction Potential index using probability concept For Baghdad city can be summarized in the following remarks:

1. The probability concept can be considered a new encouraging approach can be implemented to develop liquefaction potential evaluation criteria.
2. Three mathematical equations were proposed for analyzing the studied ten factors. The three final equations with their accuracy were proposed for points with high percent of clay, points with high percent of silt, and points with high percent of sand.

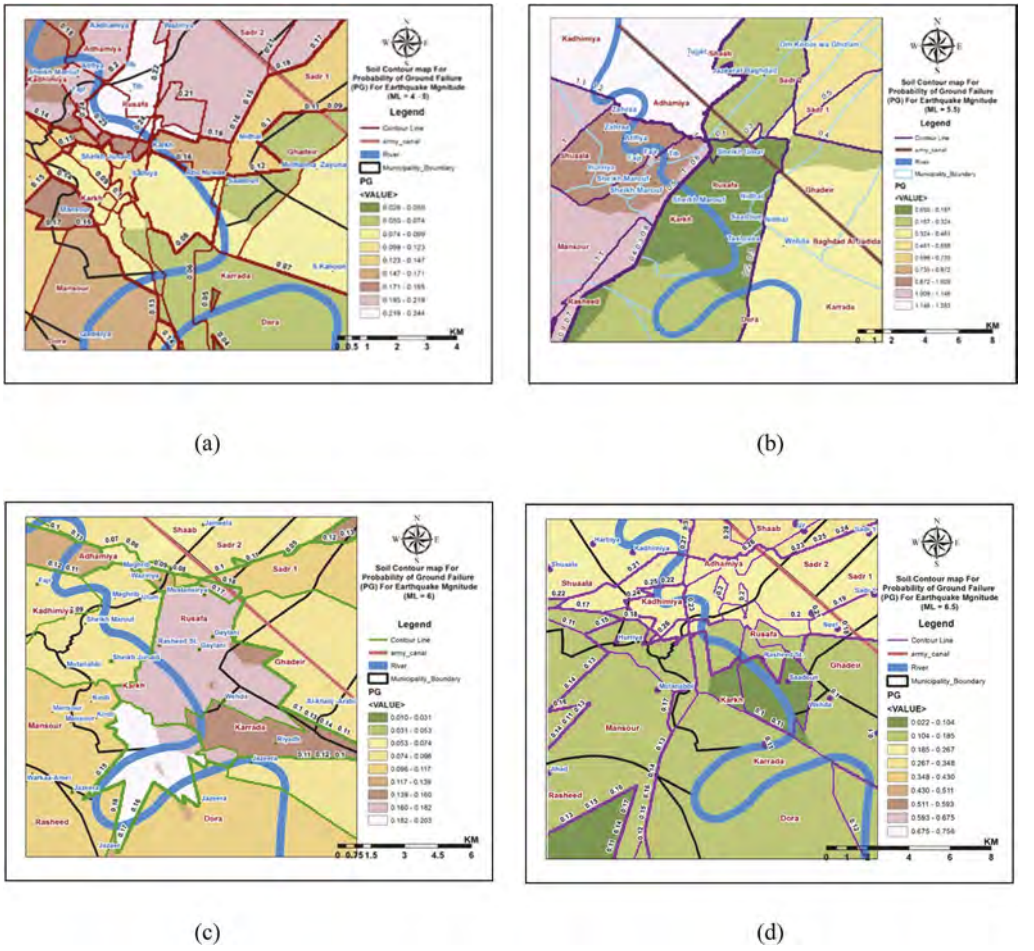

Figure 2. Digital combined contour-interpolation map for the probability of ground failure (*PG*) with different ML values: (a) ML=4-5, (b) ML= 5.5, (c) ML=6, (d) ML=6.5.

3. It was found that LPI is generally effective in predicting moderate-to-severe liquefaction manifestations, but its utility diminishes for predicting less severe manifestations.
4. The probability of ground failure (P_G) and the calculated LPI was calculated for assessing liquefaction risk. As the probability of liquefaction (P_L) and the probability of ground failure (P_G) are considered to be better measure of liquefaction potential than the factor of
5. safety, so they were determined using the factor of safety and L.P.I.

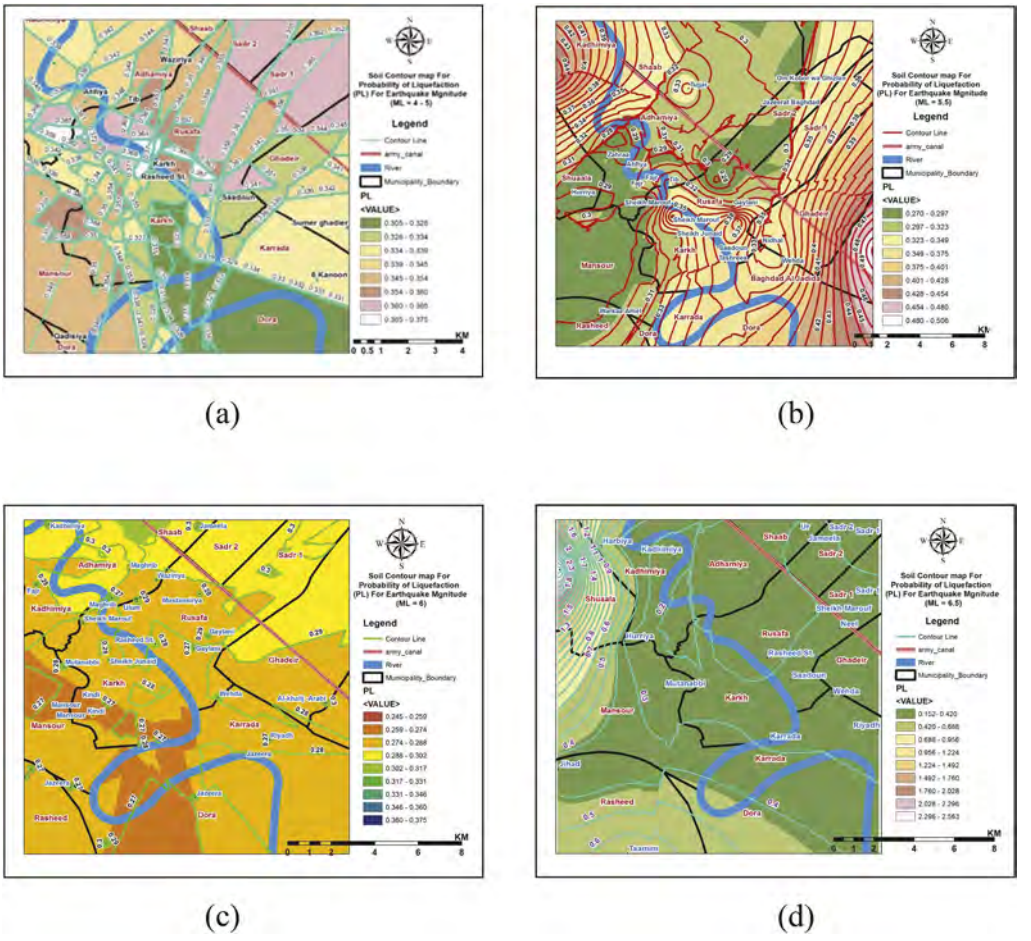

Figure 3. Digital combined contour-interpolation map for the probability of liquefaction (*PL*) with different ML values: (a) ML=4-5, (b) ML= 5.5, (c) ML=6, (d) ML=6.5.

ABSTRACT: In this study, cyclic torsional shear tests were conducted under experimental conditions of density, fine-grain fraction, and static earth pressure coefficient in order to quantify the liquefaction countermeasure effect of the compaction improved. Liquefaction properties were evaluated as liquefaction strength ratio and normalized accumulated dissipation energy. We concluded that the static earth pressure coefficient, in addition to density, has a significant effect on liquefaction properties. The denser the specimen, the stronger the mutual effect was. The estimated equations obtained from multivariate analysis using the test condition as parameters showed a high correlation with the experimental data.

1 INTRODUCTION

The 1995 Great Hanshin Earthquake and the 2011 Great East Japan Earthquake caused ground disasters in Japan owing to liquefaction in a wide area of young, reclaimed land. However, Yasuda et al. (1996, 2012) reported less liquefaction damage in areas where the ground was improved by compaction. They thus concluded that compaction was effective as a liquefaction countermeasure. The effect of compaction is hypothesized to be an increase in the coefficient of static earth pressure and density of the original ground. However, reclaimed land is more heterogeneous than alluvial ground. Additionally, the effects of material properties, density, and static earth pressure coefficient on the liquefaction potential have not been quantitatively determined previously. It is expected that quantifying the effects of these parameters will lead to more advanced design of the improved compaction method.

In this study, liquefaction tests were carried out on specimens having variable fine-grain content and densities. Isotropic and anisotropic stress conditions using adjusted specimens that simulate the process of reclamation were tested to evaluate the effects of these parameters on the liquefaction strength ratio and normalized accumulated dissipation energy.

2 TEST PROCEDURE

2.1 *Material properties*

Three types of sandy soil with different fine-grained content were used as soil samples. The sandy soil was collected from Chiba Prefecture, Japan. It was classified by water plunging and remixing in a 2 m high acrylic cylindrical container to simulate reclamation. After 24 h, the sandy soil with low fine-grain content was deposited in the lower layer and fine-grain soil with low sand content was deposited in the upper layer. The material properties of each sample and the grain size distribution curves are shown in Figure 1. The maximum void ratio e_{max}

DOI: 10.1201/9781003299127-260

was obtained using the JGS 0161-2009, a Japanese Geotechnical Society standard. The minimum void ratio e_{min}* was defined as the maximum dry density obtained from the soil compaction test (JGS 0711-2009), as followed by Ishihara et al (2016).

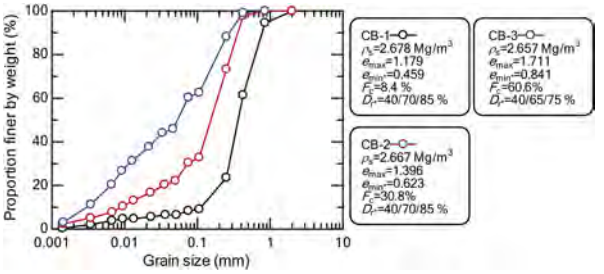

Figure 1. Grain size distribution curves and the material properties.

2.2 *Cyclic torsional shear test method*

The specimen was a hollow cylinder with an outer diameter of 100 mm, inner diameter of 60 mm, and height of 100 mm. The density of the specimens was set as per the relative densities shown in Figure 1. The three types of specimens were defined as loose, medium, and dense. They were prepared using a dry vibration method. The sides of the mold were tapped with a wooden hammer, and the height of each layers was controlled by dividing the specimen height into five sections. Once the specimens were prepared, their saturation was checked based on the pore water pressure coefficient B using CO_2 and de-aerated water. The value of B was confirmed to be greater than 0.95. Consolidation was carried out for 30 min at each confining pressure. Three static earth pressure coefficients K_0 of 0.5, 1.0, 1.5, were used for the confining pressure, based on a mean effective principal stress σ'_m of 130 kN/m^2. In anisotropic stress conditions, cyclic undrained shear tests were performed by correcting the axial displacement of the specimen to reproduce the plane strain conditions, as performed by Tatsuoka et al (1982). The loading method is a shear stress control with a 0.1 Hz sine wave.

3 TEST RESULT

3.1 *Characteristics of number of cycles and shear stress*

In this study, liquefaction is defined the condition when the double amplitude shear strain γ_{DA} = 7.5 % is reached in the soil patch under analysis. Figure 2 shows the relationship between the number of cycles to liquefaction and the cyclic shear stress ratio normalized by the vertical effective stress. In the figure, from left to right, CB-1, CB-2, and CB-3 are divided by their fine-grain content. The plots show difference in the coefficient of static earth pressure. The colors indicate the density of the specimens, where red, green, and blue indicate loose, medium, and dense specimens, respectively. The numbers in the figure are the average relative density of each specimen after consolidation. The liquefaction strength curve of CB-1, with a low fine-grain content, is characterized by an upward shift as the density and static earth pressure coefficient increase under the same confining pressure conditions and density conditions, respectively. The same trend is observed for CB-2, which contains a moderate amount of fine grains, and CB-3, which is highly fine-grained.

Figure 3 shows the relationship between the number of cycles to liquefaction and normalized accumulated dissipation energy. The accumulated dissipated energy can be obtained by calculating the hysteresis area for each cycle from the stress-shear-strain relationship of each specimen and accumulating it over the liquefaction time, as calculated by Kokusho (2013). The accumulated dissipation energy was then divided by the vertical effective stress to obtain the normalized accumulated dissipation energy. The normalized accumulated dissipation energy during liquefaction in the loose conditions for CB-1 and CB-2 is similar. The marginal variation observed is due to the difference in the static earth pressure coefficient. However, when the specimen density moves towards dense form medium, the normalized accumulated

dissipation energy becomes larger than the loose state. It also increases because the static earth pressure coefficient is not as significant under the same density conditions. The cause of these observations is hypothesized to be due to an increase in the shear strain before the excess pore water pressure reaches the effective confining pressure in fine-grained soils. This tendency is characteristic to fine-grained soils, unlike CB-1 and CB-2.

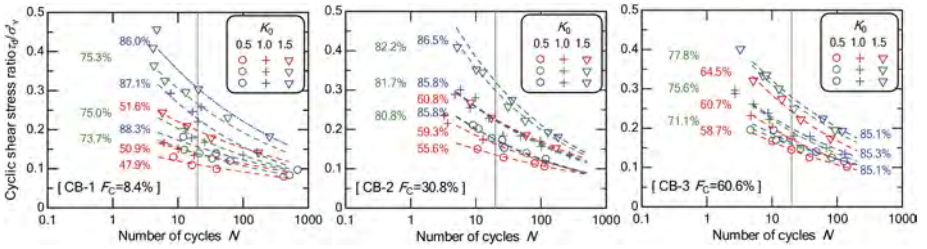

Figure 2. Liquefaction strength curves for each sample.

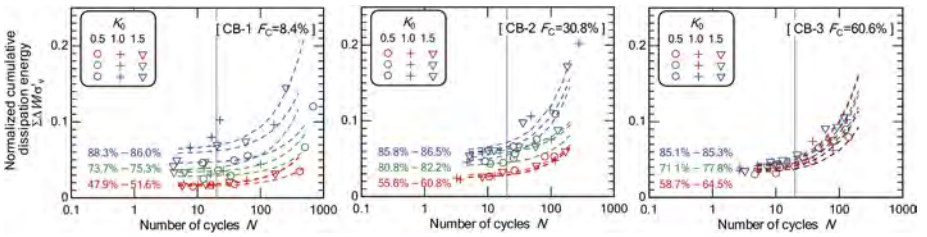

Figure 3. Normalized accumulated dissipation energy vs. number of cycles.

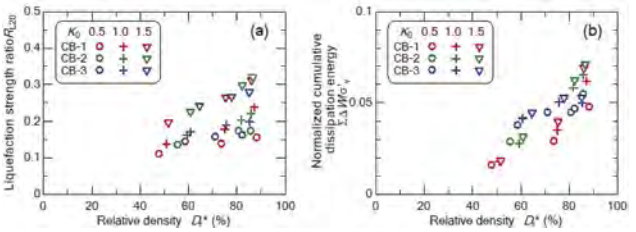

Figure 4. Relative density vs. liquefaction strength ratio (a) or normalized accumulated dissipation energy (b).

3.2 *Characteristics of liquefaction strength ratio and liquefaction potential*

From the liquefaction strength curves for each test condition in Figure 2, the cyclic shear stress ratio over 20 cycles was used to derive the liquefaction strength ratio. Similarly, the normalized accumulated dissipation energy over 20 cycles from Figure 3 was used to derive the liquefaction potential of the specimen in Figure 3. The relationship between the average relative density and the liquefaction strength ratio and normalized accumulated dissipation energy for each test condition is shown in Figure 4 (a) and (b), respectively. The liquefaction strength ratio and static earth pressure coefficient increase with an increase in the relative density. Additionally, the increase in the static earth pressure coefficient under dense conditions is significant. The effect of the fine grains is not as significant as that of the density and static earth pressure coefficient. This may be because the specimens were reconstructed and therefore did not include the effect of aging. Additionally, the normalized cumulative dissipation energy corresponding to its liquefaction strength ratio for a material is shown to be unique and variable for loose and dense relative density conditions, respectively. The normalized cumulative dissipated energy is also found to vary with the amount of fine grain in the soil sample. This suggests that evaluating liquefaction properties with normalized accumulated

dissipation energy may allow for the consideration of more details of the soil such as the effects of material properties, density and static earth pressure coefficient.

The liquefaction strength ratio and the equivalent normalized accumulated dissipation energy are mutually influenced by the relative density, static earth pressure coefficient, and amount of fine-grain. Therefore, a multivariate analysis was performed using the liquefaction strength ratio and the equivalent normalized accumulated dissipation energy as objective variables and the test conditions as explanatory variables. Figure 5 compares the experimental values with the estimates derived from the multivariate analysis. The figure shows that the coefficient of determination R_2 between the experimental and estimated liquefaction strength ration is 0.95, indicating a high correlation. The root mean square error (RMSE) is 0.014. Similarly, the R_2 between the experimental and estimated normalized accumulated dissipation energy is 0.92, and the RMSE is 0.0046. They also show a high degree of correlation. The estimated equation obtained from the multivariate analysis are shown in Figure 5.

Using this correlation equation, liquefaction potentials can be evaluated for different fine-grain content, density, and static earth pressure coefficient. However, since the correlation equation is based on a reconstructed sample, the compatibility with the actual ground conditions needs to be confirmed in the future.

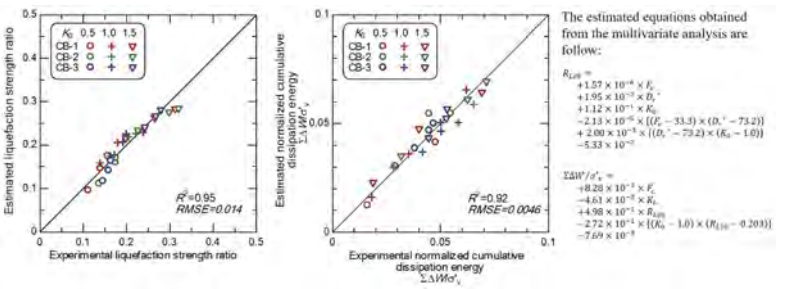

Figure 5. Comparison of experimental and estimated liquefaction strength ratios and normalized cumulative dissipation energies.

4 CONCLUSIONS

In this study, liquefaction strength ratios and normalized accumulated dissipation energy were obtained from cyclic torsional shear tests. The parameters considered during the test were material properties, density, and static earth pressure coefficient of the specimens. We concluded that the static earth pressure coefficient, in addition to density, has a significant effect on liquefaction properties. The denser the specimen, the stronger the mutual effect was. The estimated equations obtained from multivariate analysis using the test conditions as parameters showed a high correlation with the experimental data.

ABSTRACT: The dynamic impedance function is presented for massless rigid foundations, which is possible to obtain the dynamic response of foundations for different frequencies. This study investigates the dynamic impedance functions using physical model tests on sandy soil subjected to two-way horizontal harmonic loading. The tests were carried out inside a steel container which was filled with Babolsar sand. A 10 cm thickness sawdust was employed between the container and sand to simulate infinite half-space. Also, concrete slabs of 15 cm thickness were applied to simulate the bedrock beneath the sandy layer. The selected foundations were square and circular and investigated to determine the effects of foundation shape and embedment ratio to impedance function. The results show that dynamic stiffness and damping coefficient increase with increasing embedment ratio. Also, the dynamic response of square and circular foundations is different due to wave propagation, which depends on foundation geometry.

1 INTROUDUCTION

One of the fundamental problems in dynamic soil-structure interaction is the characterization of the dynamic response of surface foundations resting on a soil medium under time-dependent loads. In modern methods of machine foundation analysis, impedance functions are used frequently. Consequently, the most critical step in machine foundations' current dynamic analysis method is to determine dynamic impedance functions. Impedance functions are ratios of applied interfacial force or moment to induced displacement or rotation angle of foundation.

In recent years, a large and growing body of literature has examined numerical methods to predict the response of shallow foundations to harmonic and seismic loadings (Li et al. 2019, Zeolla et al. 2022). Large-scale experiments are performed to assess the impedance function of surface foundations. Typically, the large-scale testing results are the best data for verifying numerical modeling (Cheney et al. 1990, Amendola et al. 2021). However, there are limited studies conducted on small-scale experiments. As the example is Nii (1987) who carried out an extensive investigation on the impedance function of a rigid rectangular surface foundation under viscoelastic homogeneous half-space conditions. By considering a high expenditure of in-situ tests and lack of control over the soil parameters, researchers became interested in physically modeling this issue in the laboratory. A few important studies have been performed in this regard on surface foundations by Erden (1974), Nii (1987), and Pak & Guzina (1995). In these studies, a surface footing was placed in a container box, and a dynamic load was applied to it. However, all of these researches investigated foundation response to vertical vibration. Jafarzadeh & Ghassemi (2011) investigated the shallow foundation response to one-way horizontal direction loading by physical model tests in half-space model conditions.

DOI: 10.1201/9781003299127-261

Keeping above observations, the investigation of impedance functions for a foundation exposed to two perpendicular co-phase horizontal loading has yet to be investigated. So, this study examines the dynamic foundation response to two-way horizontal loading using physical modeling in a rigid base model condition.

2 PREPARATION OF THE MODEL

In the present research, using physical modeling, dynamic response of shallow foundations on homogeneous rigid base model was studied. Soil medium was built in a 1 by1 by 0.8 m^3 steel box whose interior walls were covered by a 0.1 m thick layer of sawdust (a material with high damping). For separation, a wooden frame by a thin plastic layer (0.1 mm) was placed all around the container. Also, a concrete slab with a thickness of 15 cm was placed at the bottom of the container to simulate the bedrock conditions (Figure 1-a).

In this study, "Babolsar" sand obtained from coastal city of Babolsar in the south of Caspian Sea. This soil, according to the USCS standard, is classified as SP. The soil properties are calculated where e_{max}, e_{min} and e_{ave} are the maximum, minimum and average of the void ratio of the model 0.775, 0.547 and 0.51, respectively. Furthermore, G_s that is the specific gravity of the sandy soil determined 2.753. Also, Babolsar sand particle-size distribution curve is displayed in Figure 1-b. Using the sand-raining method, uniform unit weight of the soil was poured into a steel container. In this method, by controlling falling height and sand flux (by using a sieve with proper holes diameter) desired density of sand can be achieved. The soil was prepared in layers and resembled the condition of soil layers in nature. In this study, air pluviation technique was used, and sand was dropped from 70 cm height by a sieve with opening sizes of 6 mm and formed layers with a thickness of 5 cm making a soil with relative density of about 54%.

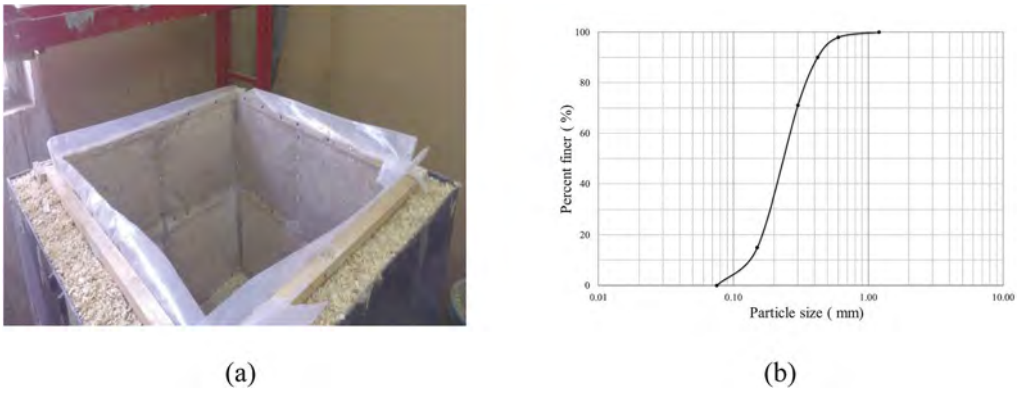

Figure 1. A) Steel box, wood frame and sawdust, and b) Particle size distribution for Babolsar sand.

3 TEST SETUP

Two different footing shapes: square and circle with equal surface area were used in this research. The dimensions were chosen such that the footing was protected against slipping. The foundation was joined to a steel column with a height of 20 cm, and it was connected to the signal generators. After the preparation of the soil-foundation system, the footing and column were placed on the center of the soil surface with an embedment depth of zero and was subjected to the two-way of co-phase horizontal directions of loading vibrations. Next, a loading system consisting of a shaker, metal rod, harmonic signal generator, and an amplifier was connected to the model. Harmonic loading with specified amplitude and frequency was produced by signal analyzer and amplified by power amplifier and was applied using two shakers in the horizontal direction through the column on the footing. The shakers received a horizontal harmonic signal generated by the signal generator from the amplifier. The signal passed through the two metal rods and finally transmitted to the column.

The excitation frequency range was chosen as 50-900 Hz, compatible with frequency range of most industrial machines, for observing the dynamic response of various types of structures. It included the frequency limits of large foundations, e.g. turbines, large silos, as well as large and relatively rigid footings in power plants. The loading duration was 16 seconds consisting of sinusoidal harmonic cycles at a specific frequency. Also, 20 Hz steps were used for tests as uniform intervals.

The force amplitude was recorded via two load cells located between the column and string. The amplitude of the horizontal load was maintained approximately constant by changing the voltage gain of the signal analyzer unit as frequency increased. The foundation displacements in horizontal and vertical directions were recorded via accelerometers mounted on them. These sensors were piezoelectric-type and were connected to a signal analyzer. Two accelerometers were placed on the foundation in the vertical direction. These sensors enabled the measurement of vertical displacement of the footing. These accelerometers were strain gauge type and were connected to a data logger, which transmitted data to a computer for later processing. In addition, using these recorded data, calculating the rotation angle of the footing was possible. The schematic cross section of the model and the loading system are shown in Figure 2.

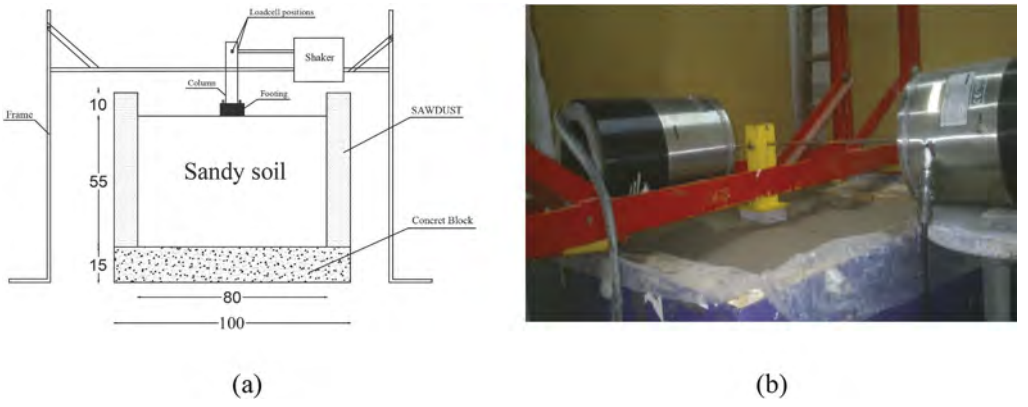

Figure 2. Physical model, (a) Schematic experimental setup (measurements are in centimeters), and (b) Real side view.

4 COMPLEMENTARY TESTS

Travel time tests were conducted in order to measure the compressional and shear wave velocities of the models. Two accelerometers were installed inside soil models 0.4 m apart from each other vertically. One footing was set on the soil model, and body waves were generated using a specific hammer, in the vertical direction. By knowing the distance and delay time, the compressional wave velocity was calculated. Next, by repeating this procedure, and putting accelerometers 0.4 m apart from each other in the horizontal direction, the shear wave velocity of the soil medium was measured. So, the compressional and shear wave velocities being calculated as 116 m/s and 54 m/s; respectively. The minimum and maximum dry unit weight of Babolsar sand are measured as 15.45 (kN/m^3) and 17.8 (kN/m^3); respectively. Using data in Table 1 and formula given by Gazetas (1983) static stiffness is calculated:

$$k_h = \frac{8GR}{2-\upsilon}\cdot\left(1+\frac{R}{2H}\right) \qquad (H/R > 1) \qquad (1)$$

Where: k_h = horizontal static stiffness; G = shear modulus; R = footing radius (or equivalent radius); υ = Poisson's ratio; and H = soil layer thickness.

Table 1. Physical model properties.

Parameter	Unit	Value
Maximum dry density	kN/m^3	17.8
Minimum dry density	kN/m3	15.45
Dry density	kN/m3	16.65
Relatively density (D_r)	%	54
Compressional wave velocity (V_c)	m/s	116
Shear wave velocity (V_s)	m/s	54
Elastic modulus (E)	MPa	13.2
Shear modulus (G)	MPa	4.8
Poisson's ratio (υ)	-	0.36

5 BASIC RELATIONS

The foundation response to the dynamic loading can be obtained by considering a soil-foundation system. In the case of foundation vibration, displacement proportional to vibration will occur in the soil. Impedance functions are defined as ratios of the total interfacial load (force or moment) at the soil-foundation interface to induced displacement or rotation angle of foundation, which are function of frequency. It is common to introduce complex notation and to express each of the impedances in form below:

$$K = K_1(\omega) + K_2(\omega) = K(K_h + \omega C_h i) \tag{2}$$

in which both real component K_1 and imaginary component K_2 are functions of the circular frequency ω. Also, K is typically referred to as the static stiffness, K_h is horizontal dynamic stiffness, and reflects the stiffness and inertia effects of the supporting soil. In imaginary component, C_h is the dashpot coefficient showing the radiation and material damping generated in the system (due to energy carried by waves spreading away from the foundation and energy dissipated in the soil by hysteric action; respectively). Alternatively, a dimensionless frequency number is often introduced:

$$a_0 = (\omega B)/(v_s) \tag{3}$$

where B = half width of the foundation; ω = circular frequency of vibration; and V_S = shear wave velocity in soil medium. Rewriting Equation 2:

$$K = K_1(a_0) + K_2(a_0) = K(K_h + a_0 C_h i) \tag{4}$$

So, in this study, the results are given in the form of figures that include parameters k and c against dimensionless frequency, a_0.

A dynamic horizontal loading to the soil-foundation medium will appear in a horizontal force and rotation on the foundation surface. The two degrees of freedom of motion will result in four impedance equations, i.e. horizontal, rotation, rotation combined with horizontal, and horizontal combined with rotation. This approach is problematic since only two independent responses, i.e. horizontal sliding and rotation, can be measured, while four unknown impedances are to be determined. In this research, to solve the problem, the following method is used (Dunn 2010). By assuming that coupled impedances are negligible, the horizontal impedance can be calculated using Equation 5:

$$S_h = F_s/U_h \tag{5}$$

where, F_s is a function of the applied horizontal force and the inertia of the footing and U_h is the maximum horizontal displacement of the footing bottom interface with the soil. For calculating F_s, it is necessary to consider changes in the sliding force due to the foundation rotation and any structure attached to the foundation. So, it can be computed by Equation 6:

$$F_s = F_T + \omega^2(M_0U_b - M_0b_2\phi_b) + \omega^2[1]^T[M]\{U\} \quad (6)$$

where: F_T = applied horizontal force to the column (or footing); M_0 = footing weight; U_b = the total motion of the instrumentation measuring horizontal motion; b_2 = the distance from the instrumentation to the gravity center of the foundation; φ_b = the maximum rotation of the footing; [1] = the unit matrix; [M] = the matrix of point masses; and {U} = the maximum horizontal displacement corresponding to the matrix of point masses. The first part of Equation 6 describes the horizontal force exerted to the column (F_T), the second part shows the foundation movement, and the third part considers the structural effect on the foundation. When calculating this effect, the structure is separated to individual points, each with mass properties. This separation is done as the column and frame may not be considered rigid. Each point is employed as a point that will move a unique magnitude and impart a force on the foundation. Regarding the column as rigid, the third part of Equation 6 can be assumed zero. Therefore:

$$F_s = F_T + \omega^2(M_0U_b - M_0\ b_2\ \phi_b) \quad (7)$$

On the other hand, Equations 8 and 9 are used to calculate U_h and Φ_b:

$$U_h = U_b - 2b_2\varphi_b \quad (8)$$

$$\varphi_b = (v_1 + v_2)/2B \quad (9)$$

In this study, the contact between the column to footing was considered rigid and attached through bolts together. Thus, Equation 7 was used to calculate the horizontal impedance function.

6 TEST RESULTS

The tests were done in rigid base conditions for square and circular footings. The test program was designed such that minimum disturbance occurred in the soil-foundation system. In these experiments, influential parameters, including footing shape and embedment ratio, were chosen to examine their influence on impedance functions.

According to Figure 3, in square footing, the dynamic stiffness coefficient of the square footing grows with the increase in the embedment ratio (D/h; D, embedment and h, footing thickness). The dynamic stiffness at the embedment ratios 0 and 1 showed almost a similar trend. Also, the dynamic stiffness fluctuations were observed at the dimensionless frequency, $a_0 \leq 4.5$. This fluctuation may be due to the sharp edges of square footing affecting the wave propagation into the soil. Further, upon elevation of the buried ratio, the distance between the bed of the square foundation and the rigid bed decreases. Distance reduction can cause higher level reflection, which significantly affects the results. Both test results show a peak at a_0=3.5. Furthermore, in the square footing, dynamic damping coefficients grow with the rise in the embedment ratio with similar trends.

As illustrated in Figure 4, in the circular footing, upon D/h increase, the dynamic damping at $a_0 \leq 2$ is almost unchanged, while at higher values, it fluctuates. On the other hand, the dynamic damping of the circular footing showed a similar trend, where the embedment ratio of 1 resulted in a higher value than 0. Also, by comparing the circular and square footing results, it is noticed that the results are more regular in the circular footing than the square ones. These results confirmed the general rule that a higher embedment ratio could increase the impedance functions.

Figure 5 indicates that the dynamic stiffness of the square footing has higher values of circular footing. Also, it can be noticed that circular footing has a smooth trend in front of the square footing, which may be from the sharp edges of the square footing. Damping of circular and square footings follows relatively similar trends at the lower frequency range of $a_0 \leq 3$. In higher a_0, the square footing shows higher damping values.

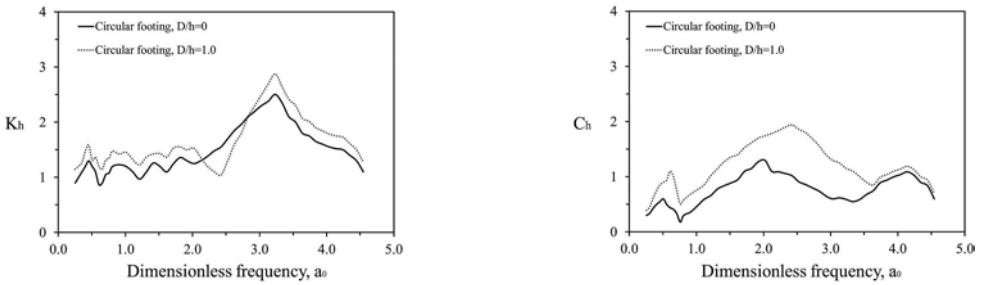

Figure 4. Comparison of the effect of embedded ratio on dynamic stiffness and damping of circular footing.

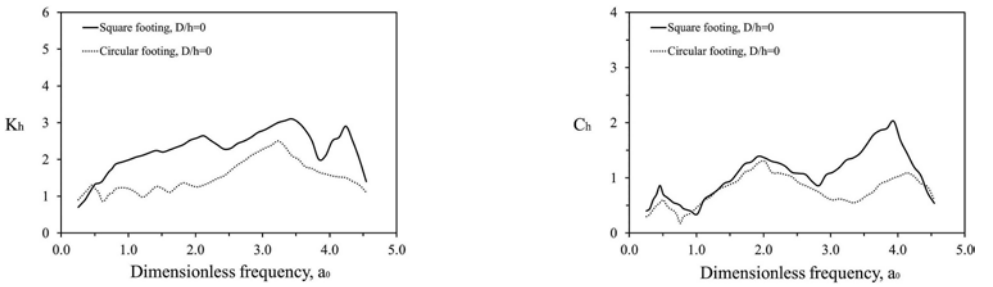

Figure 5. Comparison of the effect of footing shape on dynamic stiffness and damping.

7 CONCLUSION

The main goal of the current research was to determine the dynamic response of surface footings by physical tests to two-way horizontal harmonic loading. For this purpose, a systematic experimental investigation was conducted to obtain the impedance functions in sandy soils. Tests were performed in a rigid base model condition. The relative density of the models was 54%, and the shear wave velocity was 54 m/s. These tests were conducted in dimensionless frequency limits of 0.3 to 4.5 and for two footing shapes: square and circular. From the results, it can be found that complex and unpredictable behaviors were observed in the rigid base model condition due to the propagation and reflection of waves inside the soil. Also, upon elevation of the embedment ratio, dynamic stiffness and damping increased. It was also marked that the circular footing had a smoother response than square foundations.

1g shaking table tests for small scale superstructure - pile groups in sandy soil

Sumin Song & Sangseom Jeong
Yonsei University, Seoul, South Korea

ABSTRACT: In this study, 1g shaking table tests were performed with a superstructure supported group pile to investigate the dynamic response of soil-structure interaction with rigid base and deep foundation. The super and sub structure were modeled as a 1/25 scaled 6-story steel-framed building, 2x2 group pile with the end bearing pile, fixed and hinge pile head condition, and embedded in dense SP soil. An experimental program had sweep tests performed to assess the natural period of the structure with different foundation conditions, and the dynamic behavior of the earthquake in Korea was analyzed using the sinusoidal wave. The test results showed that the natural period was longer in the case of pile-supported structures than structure without pile, and it was found that the pile head hinge condition have a longer natural period. The lateral displacement also showed that the hinge condition was larger, and the largest lateral displacement occurred at the frequency near the natural period.

1 INTRODUCTION

The dynamic response of building structures depends on its natural period of vibration and the natural period is widely used in the design codes. Matsumoto et al. (2004) performed the shaking table tests on piled-raft model embedded in dry sand with varying the height of the superstructure structure. J. Roy et al. (2018) described that the natural frequencies of piled-raft foundation with superstructure effect by using numerical analyses.

In this study, the dynamic response of pile-supported superstructure was investigated in dense sand conditions(relative density, D_r = 80) from 1g shaking table tests.

2 1G SHAKING TABLE TESTS

2.1 *Test apparatus*

Dynamic tests on small scaled piles and superstructures were carried out from 1g shaking table tests. The platform width and length of the shaking table are 1,500 mm and, 1,500 mm, respectively.

2.2 *Test soil and small-scaled pile-supported structure*

This study used Jumunjin standard sand according to the Unified Soil Classification System-(USCS) as SP(Poorly graded Sands), with a specific gravity(G_s) is 2.65 for 1g shaking table tests. The properties of the test soil are shown in Table 1.

The prototype piles are assumed to be general steel pipe piles with a diameter of 0.5 m, a thickness of 0.05 m, and a length of 12.5 m. In this study, the small-scale model pile has a hollow circular portion with a 2.0 cm outer diameter as the scale factor, 25, and the 50 cm

DOI: 10.1201/9781003299127-262

embedment depth to consider the long pile condition based on the pile conditions theory. The 1g shaking table test devices are summarized in Figure 1.

Table 1. Physical properties of test soil.

USCS	γ_{max} (kN/m^3)	γ_{min} (kN/m^3)	Gs	D_{10} (mm)	D_{30} (mm)	D_{60} (mm)	C_u	C_C
SP	16.2	13.6	2.65	0.38	0.49	0.49	1.59	0.99

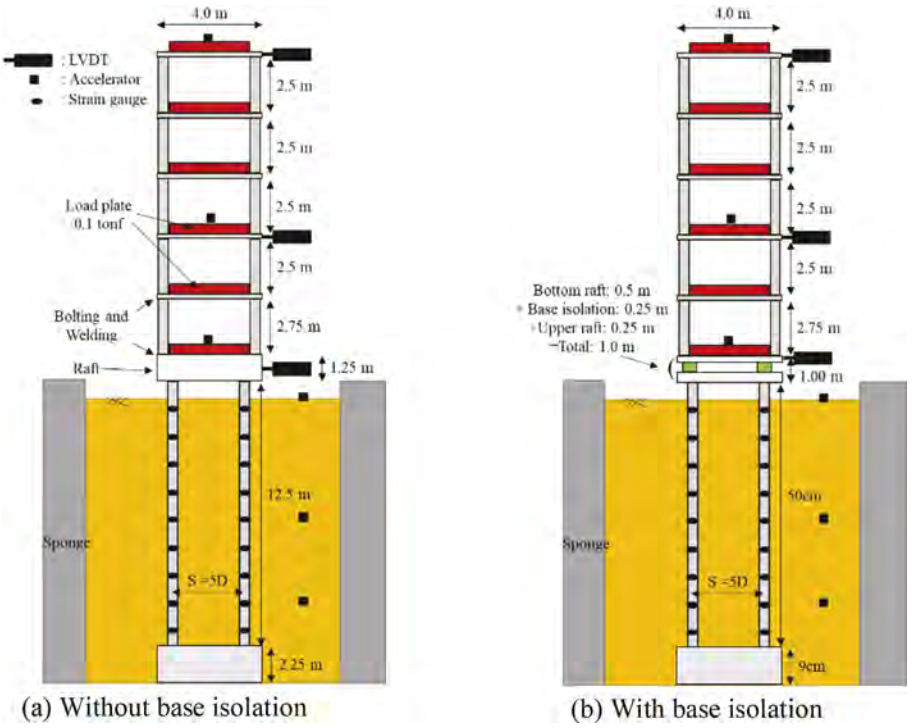

Figure 1. Illustration of the pile-supported structure in this study.

2.3 *Test programs*

In phase 1, this study conducted sweep tests to assess the natural frequency structure systems under various input sinusoidal acceleration. In phase 2, the sinusoidal acceleration test conducted with a specific natural frequency(f_r). The test programs are summarized in Table 2, 3.

Table 2. Sweep tests of Phase 1.

Case	Stories	Foundation	Pile head condition	Input acceleration	
				Peak acc. (g)	Frequency(Hz)
1		Pile	Fixed		Sweep test
2	6		Hinge	0.05	1 – 30 Hz
3		Footing	-		

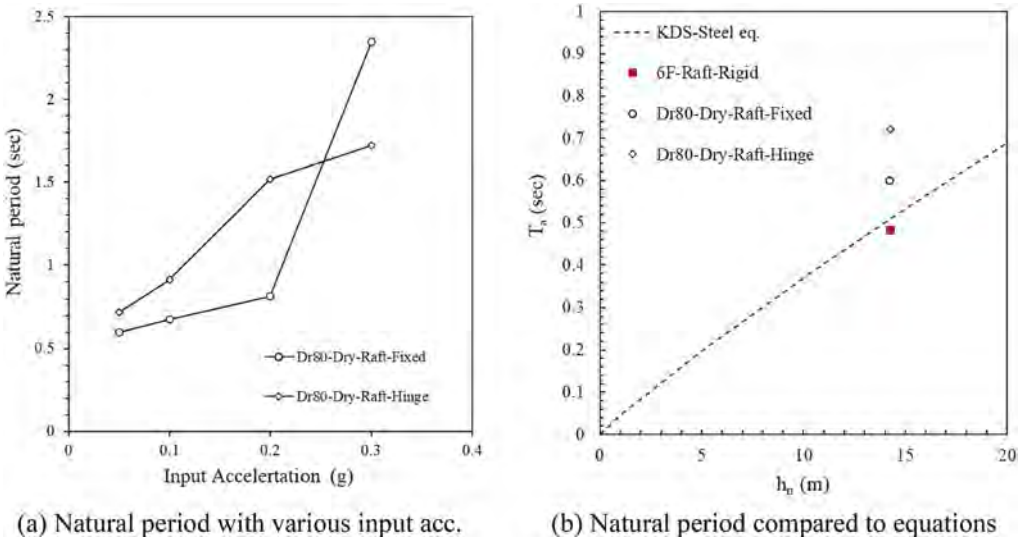
Table 3. A sinusoidal test case of Phase 2.

Case	Stories	Foundation	Pile head condition	Input acceleration	
				Peak acc. (g)	Frequency(Hz)
4	6	Pile	Fixed	0.1	0.37
				0.2	0.96
5			Hinge	0.3	1.65
				0.4	

3 TEST RESULTS AND ANALYSES

Figure 2 (a) shows test results of the natural period with varying input acceleration. The natural periods were calculated from the 6th-floor acceleration by using FFT(Fourier Fast Transformation). The results show that as increasing of input acceleration, the natural period of pile-supported superstructure increases. Figure 2 (b) shows the natural period of pile-supported superstructure compared to the natural frequency equation for steel-framed buildings in KDS. It is shown that the natural period of the rigid(direct) foundation show almost similar value but increased in the cases of pile-supported case. The hinged pile head condition recorded longer natural period than fixed condition because of increase lateral displacement of superstructure (Figure 3).

Figure 3 shows the lateral displacement of superstructure in varying input acceleration. The largest lateral displacement of superstructure at the Hinged pile head condition. Hinged pile head condition showed more lateral displacement than fixed condition, but fixed condition recorded larger lateral displacement in Figure 3.



(a) Natural period with various input acc. (b) Natural period compared to equations

Figure 2. Test results of the natural period.

4 CONCLUSIONS

In this study, shaking table tests of pile supported superstructure on cohesionless sand were carried out by considering soil-structures interaction. The key conclusions obtained in this study as follows:

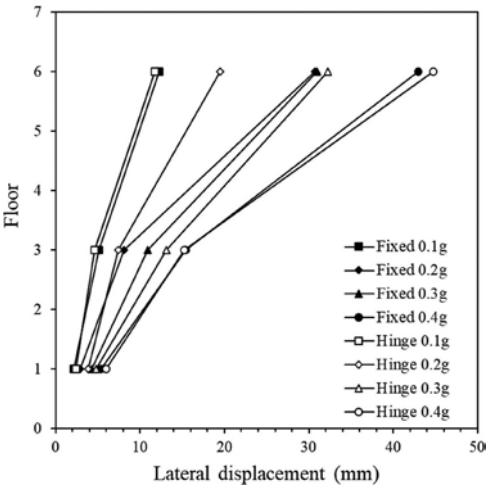


Figure 3. Lateral displacement of superstructure in various input acceleration.

1. All pile-supported superstructures got larger natural periods than without pile conditions. As increase the input acceleration, the natural period of pile-supported superstructure increases.
2. The lateral displacement of superstructure in various input acceleration showed low frequency domain case, and fixed condition showed larger lateral displacement than in 0.96 Hz case.

Ground motion predictions based on soil properties using convolutional neural network

P.T.H. Nguyen, Byongkyu Bae & Jaehun Ahn
Department of Civil and Environmental Engineering, Pusan National University, Republic of South Korea

ABSTRACT: Earthquakes are among the most devastating natural disasters. In the past few decades, neural networks and other machine learning models have had significant success in geotechnical earthquake engineering. This paper studies the Convolutional Neural Network (CNN) model in predicting ground motion based on acceleration history measured in bedrock and soil properties. A CNN model is proposed; then, the model was trained and tested for 500 seismic events obtained from the Kiban Kyoshin Network (KiK-net, NIED 2016). When the predictions were compared with the baselines (actual measurements), the proposed CNN model presented good agreements.

Keywords: Earthquake, Convolutional neural network, Spectral acceleration, Soil properties, Source characteristic

1 INTRODUCTION

When natural disasters such as earthquakes occur, human and huge economic damages are caused (Green et al. 2011; Lee et al. 2012). To reduce the damage caused by earthquakes, models are developed to predict earthquakes and create preventative measures. As a result, earthquake ground response analysis contributes significantly to seismic design reliability (Kramer 1996; Phanikanth et al. 2011). During earthquakes, the waves propagate from the seismic source through rocks eventually to ground surface. This paper proposes a prediction model based on Convolutional Neural Network (CNN) for estimating the acceleration response spectrum of ground motion.

2 DATA IN ANALYSIS

2.1 *Site information and earthquake events*

Detailed information on earthquake sites and events in Japan as well as measured acceleration histories are shown in the seismograph network Kiban Kyoshin Network (KiK-net, NIED 2016). In this study, a total of five sites named FKSH18, FKSH19, IWTH02, IWTH05, and IWTH12 were selected from KiK-net. In order to perform modeling, out of 100 earthquake input and output datasets each site, 80 earthquake events were used for the training, and 20 earthquake events were used for the testing.

2.2 *Soil properties*

In the prediction model, shear wave velocity (Vs) and P-wave velocity (Vp) profiles were used together with input seismic signal. An example of the wave velocity profiles used in the analysis is presented in Figure 1.

DOI: 10.1201/9781003299127-263

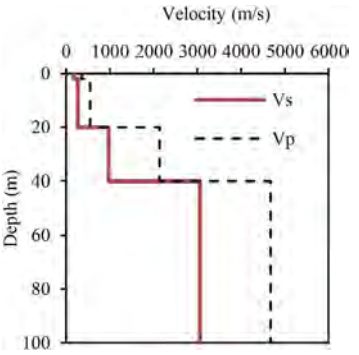

Figure 1. Shear wave and P-wave velocity profiles for the site FKSH19.

3 DEEP LEARNING MODEL

3.1 *Spectrogram*

This paper used the spectrogram representation of acceleration history motion as the input of models. The spectrogram is a three-dimensional representation of changes in the content of a signal over frequency and time. The acceleration was transformed into the FFT spectrogram by using Matplotlib as a Python calculation option.

3.2 *Convolutional neural network*

This study proposed a CNN model to estimate the effect of soil properties based on the acceleration measured at the bedrock for predicting seismic ground responses. Acceleration spectrogram, shear wave velocity (Vs), and P-wave velocity (Vp) are used as input data for the model. The CNN model structure was shown in Figure 2. A CNN has a convolutional layer at the input and a fully connected layer at the output. In the hidden layers, there are a number of convolutional layers and a number of pooling layers. The CNN model applied 20, 40, 80, and 160 filters for each layer respectively with MaxPooling size 2x2 and stride of 2. Figure 3 represented the overview of the proposed procedure based on CNN. Also, the errors are represented as mean squared errors (MSE).

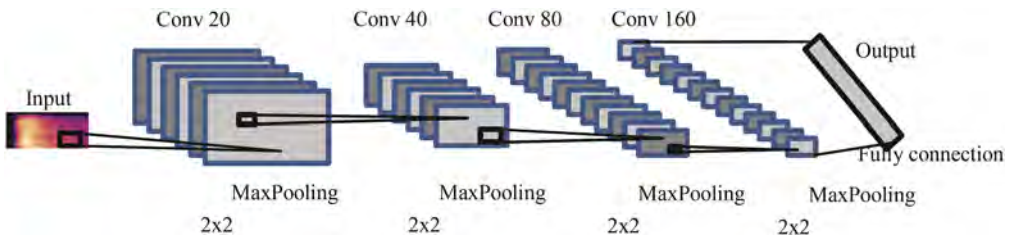

Figure 2. Scheme of the process of Convolutional Neural Network (CNN).

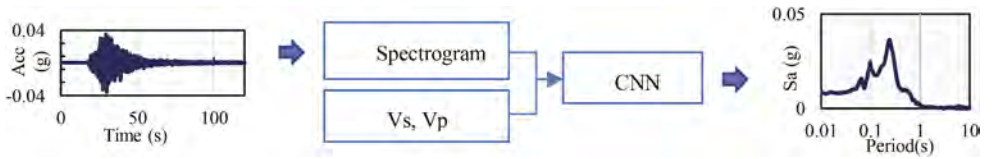

Figure 3. The overview of the proposed procedure is based on CNN.

4 RESULTS

4.1 *Prediction*

In the five-site earthquake dataset, models for the site were trained. Among the results, the response spectra of 4 sample results each site are presented in Figure 4. Most of the predictions show good agreements with the baselines.

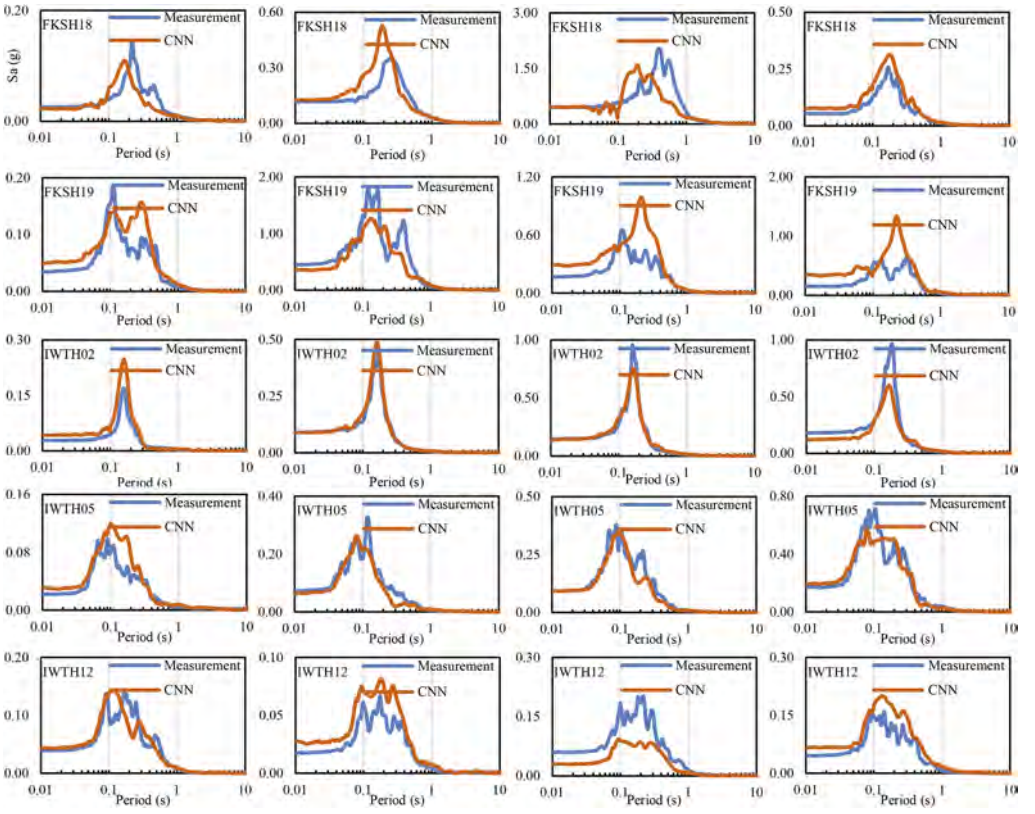

Figure 4. Spectrum acceleration response prediction.

4.2 *Prediction errors*

The errors of the estimation of five sites are calculation by Equation (1) and plotted in Figure 5. The training and testing loss value of the CNN model were calculated based on MSE and shown in Table 1.

$$\text{Error\_each} = \text{Sa\_measured} - \text{Sa\_predicted} \tag{1}$$

where Sa_predicted is the estimation by the CNN model, and Sa_test is the ground motion measurement.

Table 1. Training and testing mean square error loss.

Dataset	MSE
Train	4.3815e-04
Test	0.00498

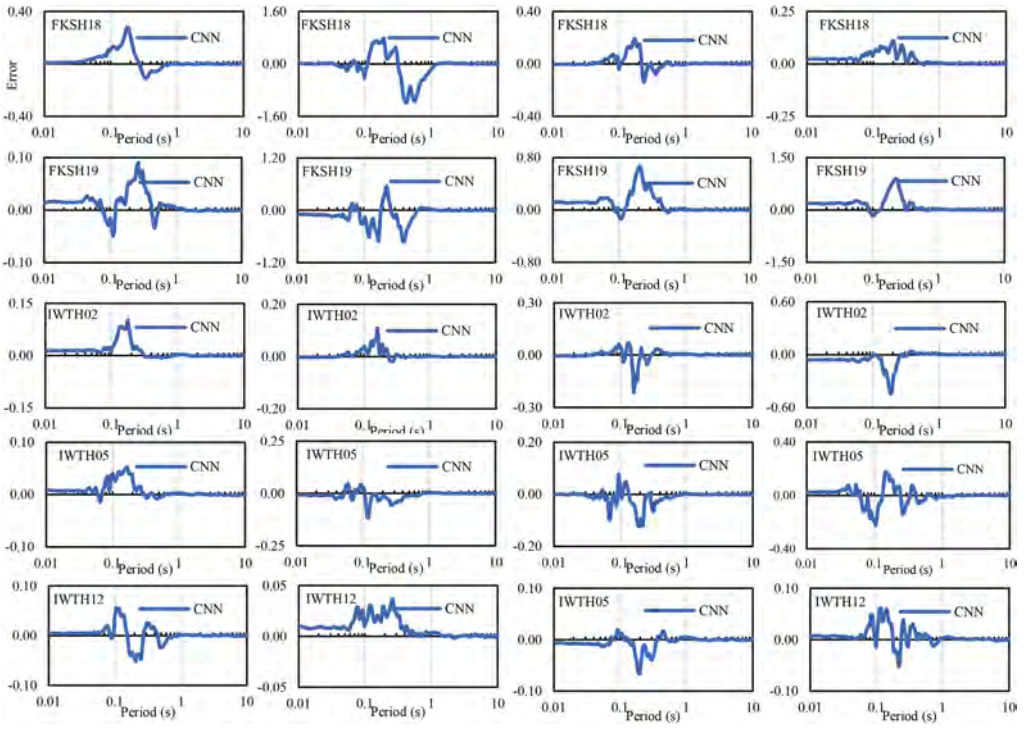

Figure 5. The errors of the ground motion prediction.

5 CONCLUSIONS

The study proposed a model to predict the seismic response spectrum based on CNN. Among the 100 datasets for each site, 80 sets were used for the training, and 20 sets were used for the testing for 5 sites in the KiK-net database. The ground response spectrum prediction result was affected by soil properties. Developing future research results requires to implement the other characteristic of soil used in the deep-learning model for seismic response prediction.

Development of liquefaction judgment methods in Japan and future problems

S. Yasuda & K. Ishikawa
Tokyo Denki University, Saitama, Japan

ABSTRACT: Since damage due to liquefaction occurs every year or two in Japan, liquefaction potential is considered in the design of most structures in the country. Simple methods based on the SPT *N*-value and particle size are used to judge liquefaction potential. More than 10 methods are used, depending on the type of structure. A method to judge liquefaction potential was introduced into a design standard in 1970, and since then, the simple judgment methods for each structure have been revised several times based on the results of cyclic triaxial tests and case studies of earthquake damage. Nevertheless, there are still some issues to be noted in the application of current judgement methods and several problems to be studied in the future.

1 INTRODUCTION

Methods using the *N* value of the standard penetration test are widely applied all over the world to estimate the liquefaction potential. However, the SPT *N* values is merely ground parameters, not direct indicators of liquefaction strength. Therefore, it is necessary to indirectly estimate the liquefaction strength by incorporating other indicators, such as particle size. Various simple formulae for this estimation have been proposed, and different simple formulae are used in each country. In Japan, different simple formulae are used for each type of structure design standard (JGS, 1998). As there are more than 10 types, overseas engineers wonder why so many simple formulae are used. In Japan, a method to judge liquefaction potential was introduced in the design standards for port facilities in 1970, and different simple judgment methods have been introduced in other structures. After that, an earthquake that produced liquefaction occurred every year or two, and the validity of the judgment methods was verified based on case studies. Subsequently, based on cyclic triaxial tests on undisturbed samples, each judgment method has been revised.

2 LIQUEFACTION JUDGMENT METHOD AT THE BEGINNING OF DEVELOPMENT

In Japan, the 1964 Niigata Earthquake triggered widespread research on liquefaction. The soil condition in Niigata City was investigated just after the earthquake based on existing and newly conducted boring data. Then, a simple liquefaction prediction method based on critical *N*-value was derived by several researchers. In 1970, liquefaction potential was first taken into consideration in the code for harbor facilities. A consideration of liquefaction was also introduced in the design codes for highway bridges in 1972 and for railways and buildings in 1974. After that, this method was changed to the "F_L value method", described later, for highway bridges, building foundations, and railway structures, but it was revised to make the same judgment as the F_L value method by modifying the critical *N* value method for port structures. The critical *N* value method was also introduced in the design codes for oil tanks and LNG tanks.

After Seed et al. started research on liquefaction potential based on laboratory tests in the United States after the 1964 Alaska Earthquake, similar experiments were started in Japan

DOI: 10.1201/9781003299127-264

around 1970. For example, Ishihara et al. conducted cyclic torsional tests to investigate the influence of seismic load and anisotropic confining pressure. In addition, around 1975, the procedure for taking undisturbed samples from the field and conducting cyclic triaxial tests began. Using the results of cyclic triaxial tests conducted on undisturbed samples and the N values at the depths of the samples, a method to estimate the liquefaction resistance ratio (also called cyclic strength ratio) R_L from the N value and particle size was proposed by Tatsuoka et al. in 1978 as follows:

$$\begin{cases} R_L = 0.0882\sqrt{N/(\sigma'_v+0.7)} + 0.225\log_{10}(0.35/D_{50}) & (0.04 \le D_{50} < 0.6\ \text{mm}) \\ R_L = 0.0882\sqrt{N/(\sigma'_v+0.7)} - 0.05 & (0.6 \le D_{50} \le 1.5\ \text{mm}) \end{cases} \quad (1)$$

However, since this R_L is a liquefaction resistance ratio obtained by cyclic triaxial tests with isotropic confining pressure and sine wave load, it was necessary to convert to the liquefaction strength ratio R (or CRR) when receiving seismic load in the anisotropic confining pressure in the in-situ soil. Then the following correction was made. C_1 and C_2 are correction coefficients for confining pressure and seismic load, respectively.

$$R = C_1 \times C_2 \times C_3 \times C_4 \times C_5 \times R_L \cong R_L \quad (2)$$

Next, they decided to use the simple formula proposed by Seed and Idriss in 1971 as a method for estimating the shear stress ratio L (or CSR) generated in the ground during an earthquake.

$$L = r_d\ (\alpha_{max}/g)(\sigma_v/\sigma'_v) \quad (3)$$

where, r_d is the reduction coefficient in the depth direction, α_{max} is the peak ground acceleration, σ_v is the overburden pressure, and σ'_v is the effective overburden pressure. Seismic response analysis with six input waves was performed on two ground models to obtain the depth distribution of r_d. Then the following formula was proposed as an average relationship.

$$r_d = 1 - 0.015z \quad (4)$$

where, z: depth (m).

In 1980, the F_L value method (determined as liquefaction resistance factor $F_L = R/L$) based on these was introduced in the specification for highway bridges. For railway structures, the F_L value method was introduced in 1986 and was then modified for dense soils and for soils with large amounts of fine particles.

Tokimatsu and Yoshimi (1983) conducted cyclic triaxial tests using samples taken by the freeze sampling method and by the normal sampling method, and obtained a relationship in which the liquefaction strength increased sharply when the relative density was high. Next, using the relationship between the Dr and the N value proposed by Meyerhof, a method for estimating the R_L from the N value and the fines content F_C was derived. In addition, the method in Equation (4) was used for the shear stress ratio in the ground, and the relational expression of 0.1 (M-1) was used to convert to sine wave loading. In 1986, the F_L value method was introduced in the design of building foundations in consideration of the liquefaction data at the time of past earthquakes.

3 BACKGROUND OF REVISION OF JUDGMENT METHOD

After the introduction of different methods to judge liquefaction potential for different design standards, as described above, the applicability of each method has been continuously examined and the judgement method for each design standard has been revised several times.

For highway bridges, cyclic triaxial tests on undisturbed samples were added and revised in 1990 to add the influence of the F_C as the third item in Equation (1). As the 1995 Kobe

Earthquake caused a very strong shaking, it became necessary to judge liquefaction potential under such strong ground motion (called Level 2 seismic motion), and an appropriate revision was made in 1996. Since Level 2 seismic motion may cause liquefaction even in dense ground, cyclic triaxial tests were conducted by sampling ground with an N value of about 20 to 30 by the freeze sampling method. Then, the liquefaction strength was corrected for medium-dense-to-dense ground. A formula for gravel soil has also been added. In addition, since Level 2 seismic motion is divided into Type I (plate boundary type) and Type II (inland type), the correction coefficient C_W (a combination of C_1 to C_5 in Equation (2)) was set for each type. After that, it became necessary to correct R_L for soil with a small N value due to a relatively large amount of fines content. In 2017, R_L was revised based on the results of cyclic triaxial tests conducted on samples with relatively large amounts of fine particles taken using the tube sampling method, as shown in Figure 1.

For the design of building foundations, since there was no contradiction with the liquefaction/non-liquefaction phenomenon during the 1995 Kobe Earthquake, the 1988 version of the method to judge liquefaction potential was retained in the 2001 revision. However, the coefficient of the N value of gravel ground was corrected, and the cone penetration test and cyclic triaxial test for undisturbed samples were recommended for soil with a small N value and a high fine particle content. There was no big change in the 2019 version as shown in Figure 2, but soil layers with small N values, even in diluvium, are now subject to liquefaction potential judgment.

In the design standards for railway structures, the 1999 revision included new judgment methods for Levels 1 and 2 seismic motions. It was recommended to obtain R by a cyclic triaxial test, but if it is difficult to carry out the test at Level 1, a simple formula estimated from the N value and F_C (different from 1986) could be used. For Level 2, it was recommended to conduct a cyclic triaxial test and seismic response analysis.

Initially, in the technical standards for port and harbor facilities, soil was divided into two types according to the grain size distribution curve, and the relationships between maximum acceleration and the critical N value to cause liquefaction for each soil type were set. This was revised in 1990 to judge the susceptibility to liquefaction in four stages.

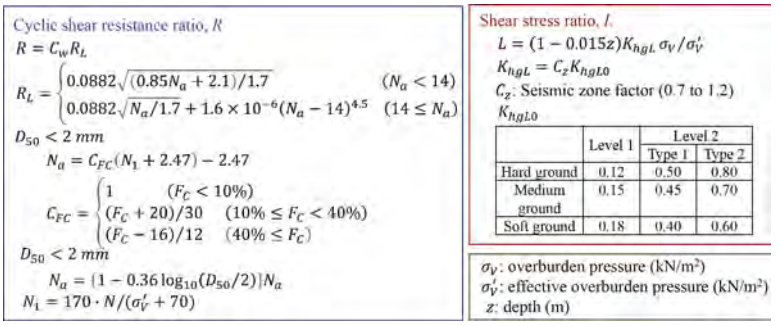

Figure 1. The method used in the specification for highway bridges (2017).

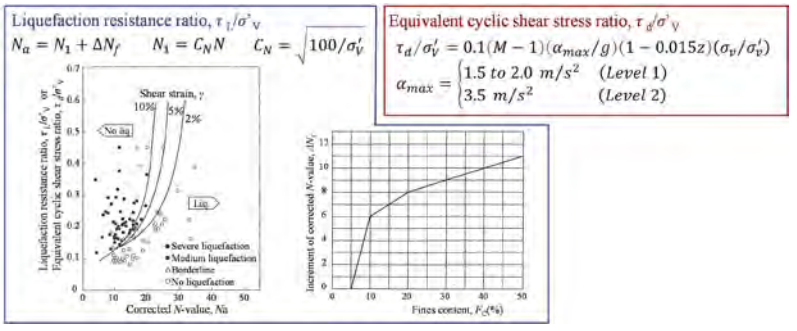

Figure 2. The method used in the recommendation for design of building foundations (2019).

4 POINTS TO NOTE WHEN APPLYING CURRENT METHODS AND FUTURE PROBLEMS

As described above, since the judgment of liquefaction potential began to be incorporated into design standards in 1970, each standard has been revised many times. For example, under certain conditions, the R_L calculated by the highway bridges formula has changed as shown in Figure 3. However, problems remain to be solved. Below, we present the issues and points to note when using the current judgment methods and future studies needed

(1) Since the N value is not directly related to the liquefaction strength, a judgment based on the N value inevitably contains an error. As stated in the standard for railway structures, it is desirable to determine the liquefaction strength by cyclic triaxial tests. These tests must be conducted on samples with little disturbance. In many design standards, Equations (3) and (4) are used to estimate the L and r_d, respectively. However, since the variation in r_d is large, the error is also large in the estimation of L. Half a century before these formulae were proposed, computers were not yet easy to use, but now, seismic response analysis can be performed easily with a personal computer. L should be obtained by seismic response analysis.

(2) When the liquefaction potential of a certain ground is judged by different methods, it is usually not the same. When only the R_L was compared from three judgement methods, the results shown in Figure 4 are obtained. As can be seen in the figure, the shape of the $N - R_L$ relationship from the three methods is similar for soil with a small amount of fine particles, such as Fc = 5%, but differs for soil with large amounts of fine particles.
Since the reclaimed land along Tokyo Bay liquefied extensively during the 2011 Tohoku Earthquake, many institutions estimated the liquefied depth by each method after the earthquake. However, since the reclaimed soil contained a large amount of fine particles, it was difficult to determine the depth where liquefaction occurred (Ishikawa and Yasuda, 2020). There may be considerable error in the estimation of R_L in sandy soil with a large amount of fine particles.
Furthermore, in several cases, the judgment method yielded a result that was opposite the finding that the alluvium soil at the bottom had liquefied without liquefaction in the reclaimed layer. It is known that R_L and N increase with time after soil deposition due to soil aging. However, it is not known whether the R_L of soils with different sedimentary ages can be determined by the same simple formula. Research is needed to consider the aging effect in the simple judgment methods.

(3) When creating a liquefaction hazard map, the characteristics of local soil cannot be reflected simply by applying the nationally uniform judgment methods. For such soil, it is desirable to take undisturbed samples, conduct tests, and propose an appropriate evaluation formula for R_L.

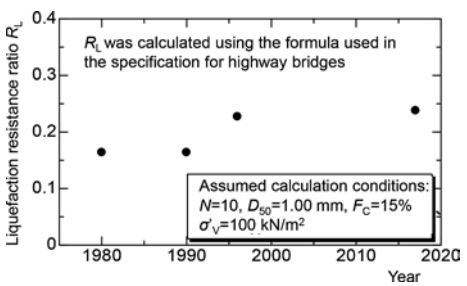

Figure 3. An example of change in R_L calculated by the formula of the highway bridges.

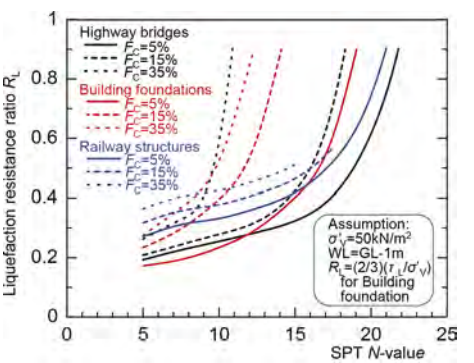

Figure 4. Relationships between N and R_L estimated by three methods.

5 CONCLUSIONS

Methods to judge liquefaction potential using *N*-value differ by country. In Japan, their validity has been tested during past earthquakes, and they have been revised several times. Even so, it is still quite difficult to accurately predict liquefaction because the *N* value does not directly express liquefaction strength. Therefore, judgement methods based on the *N* value contain some errors. It is desirable to conduct cyclic triaxial tests and seismic response analyses.

Response of buried pipeline in soil slopes to surface blast loading

T. Lodh & K. Chatterjee
Department of Civil Engineering, IIT Roorkee, Roorkee, Uttarakand, India

ABSTRACT: Precise modelling and simulation of the effects of blast occurrences, especially in or around the slope, is of interest in this study. Applications include minimizing casualties and improving buried pipeline survivability from attacks using improvised explosive tools. In the present study, coupled Eulerian-Lagrangian capability in FEM-based computer program ABAQUS/ Explicit was used to simulate experimental tests in which the structural response to the detonation of a surface charge was characterized. Soil has been modeled as a three-phase porous media to accommodate various degrees of saturation. Lagrangian representation was used for the pipe, while Eulerian representation was used for the soil, explosive, and ambient air.

Detonation products were modeled using the Jones-Wilkins-Lee equation of state. The blast design parameter PPV (peak particle velocity) has been obtained for input parameters. The simulations agree favorably with the test results and produce higher adherence solutions than traditional analytical or empirical blast models.

1 INTRODUCTION

Blasting vibrations may be an activating figure for soil movement developments and avalanches. A quantitive assessment is of need to serve this purpose. Evaluation is generally done in terms of peak particle displacement (PPD), peak particle velocity (PPV), or peak particle acceleration (PPA). But due to the scarcity of PPD and PPA-related established existing papers, analysis is performed referring to PPV only. Lu *et al.* (2005) gave the conceptual overview of the fully-coupled method with a comparative study of the buried structure. An attempt was made by Newmark and Kuesel (2015) for the seismic design of buried pipelines which are likely to be damaged by earthquakes or distant explosions. Malachowski *et al.* (2018) used the ALE method and applied blast load to the pipes with and without a protective cover. A combined Eulerian-Lagrangian method was used by Mokhtari (2015) to study the response of buried steel pipelines to the explosion and generally concerns with finding a safe distance of explosion where the pipeline deformation does not reach to the plastic stage. Adib *et al.* (2017) studied the effects of mass charges pipeline thickness on pipeline deformation using the Drucker-Prager resistance equation for soil. Similarly, other researchers used the finite element method along with the finite-difference method or individually each of them to solve the blast-related problems.

The present study explores the reaction of buried pipelines subjected to impact waves numerically. The numerical modeling technique is one of the alternatives to study the dynamic response of underground structures subjected to blast load because a very high cost is associated with the full-scale field blast test. A self-assertive Lagrangian-Eulerian strategy was embraced to create a full-coupled 3D finite component demonstration. The analysis performed here is in Abaqus/Explicit program for dry soil only. In choosing legitimate fabric models, the speed and push of the pipeline, and the impact of buried depth were examined within the investigation. The outcomes from the study can be utilized for improvement in the defensive plan of steel pipelines.

DOI: 10.1201/9781003299127-265

2 PROPOSED METHODOLOGY

The objective is to implement a fully-coupled demonstration that can handle the impact wave engendering through the air, the impact wave interaction with the structure, and the related primary reaction of the system and would be perfect for showing everything from the ground up.

2.1 *Geometry and material assigning*

Beginning with the geometry as shown in Figure 1 below, a 1m diameter and 0.01m thick embedded pipeline is used in the analysis. The soil slope was maintained at 45°.

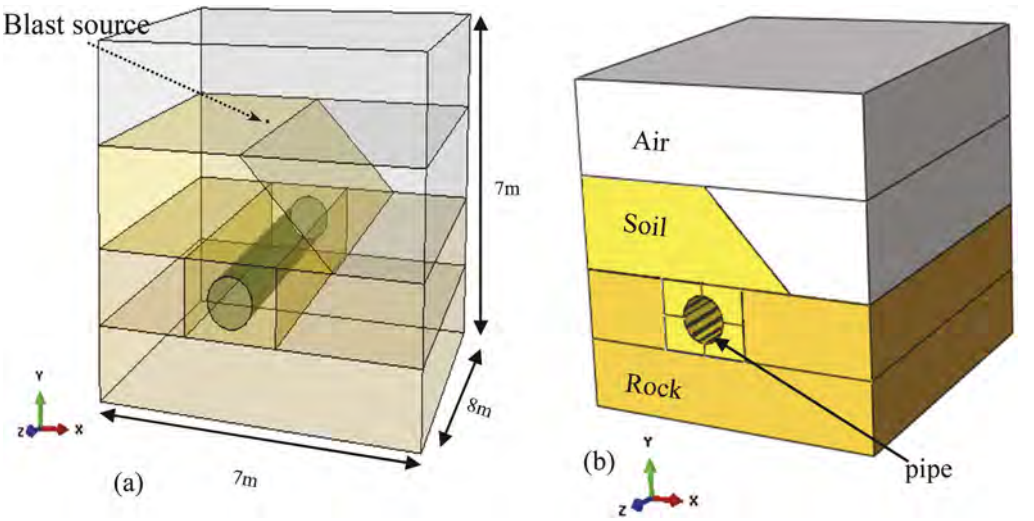

Figure 1. (a) Model geometry (b) Material assigned view of the model.

2.2 *Material properties*

According to the Abaqus/Explicit manual requirements, the material parameters used in the present study are adopted from Tang *et al.* (2021). The Mohr-Column material model was adopted for the soil layer. The model of the sandstone and ductile iron gas pipeline assumes the user input elastic-plastic material model by giving elastic, plastic, and density parameters as tabulated below in Table1.

Table 1. Input parameters used in the present analysis.

	Values		
Properties	Soil	Rock	Pipe
Density (kg/m^3)	1920	2500	7850
Elastic Shear modulus (*GPa*)	3.85	-	-
Elastic modulus(*GPa*)	-	30	150
Yield Strength (*Pa*)	-	2580	3000
Poisson ratio	0.32	0.3	0.3
Cohesion (*Pa*)	5000	-	-
Friction angle (°)	10		

Blast material is modeled by selecting EOS (Equation of State) in the mechanical module in which the JWL type is taken. In the sub-option EOS of Abaqus/Explicit, detonation

coordinates and time are mentioned. The concerning parameters of explosive detonation products are shown in Table 2 below. The relationship between specific volume and pressure in the model is mentioned in equation (1) and the process of explosive by detonation is simulated using the JWL equation of state.

$$P = A\left(1 - \frac{W}{R_1 V}\right)e^{-R_1 V} + B\left(1 - \frac{W}{R_2 V}\right)e^{-R_2 V} + \frac{wE_0}{V} \quad (1)$$

In equation (1), P is pressure; A, B, $R1$, $R2$, and W are material parameters; V is relative volume; E_0 is initial specific internal energy. The material of air is defied by the ideal gas equation of state, which is one of the simplest forms of the equation of state of a gas. The equation of state was used for the gas with uniform initial conditions and can be written as in Equation (2):

$$Ph = (\gamma - 1)\rho e \quad (2)$$

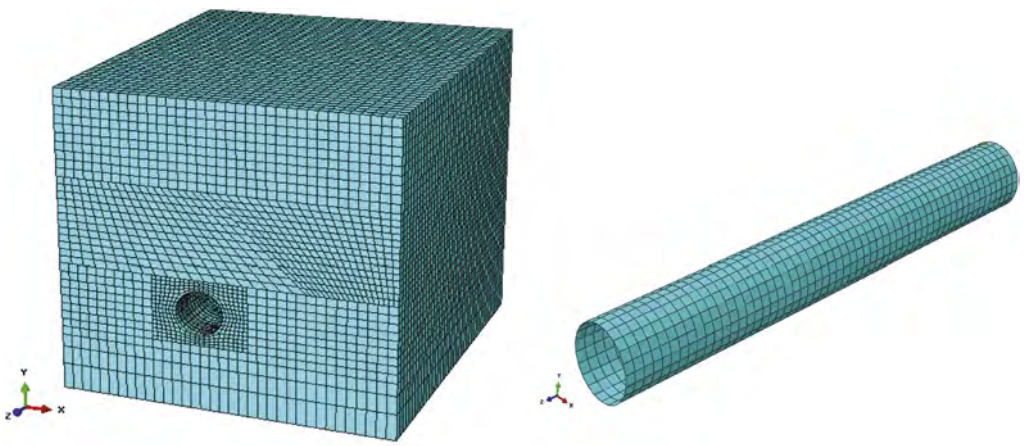
In equation (2), ρ is density, e is specific internal energy, γ is the adiabatic index and P_h is hydrostatic pressure. These are tabulated in Table 3.

Table 2. JWL parameters used in the present study.

Properties Density	Detonation (kg/m^3)	Density Velocity (m/s)	A (MPa)	B (MPa)	Omega	R_1	R_2	Detention Energy Density	Pre-detonation Bulk Modulus
Values	1100	3500	47600	524	0.3	3.5	0.9	6e6	**0**

Table 3. Air parameters used in the analysis.

Properties	Density (kg/m^3)	Specific volume ($J/kg\ k$)	Temperature	Adiabatic Exponent
Values	1.225	0.3	288.2	1.4



(a) (b)

Figure 2. Meshing view of the (a) full model (b) pipe.

2.3 *Meshing and contact properties*

General contact explicit definition was used in the contact module of Abaqus/Explicit. Eulerian elements were used in soil, air, rock, and blast parts since these will undergo large deformations. Lagrangian elements were used for the pipeline. After performing a variety of convergence studies and doing proper seeding in edges along with that required partitioning and meshing were done effectively. Meshing is liner near the pipe and blast and coarser as one moves far from the pipe and blast source, as indicated in Figure 2.

2.4 *Boundary conditions*

The bottom of the model was fixed and the non-reflecting boundary was applied on all other sides of the model. Acceleration due to gravity of 9.81m/s^2 was applied to all the materials.

3 RESULT AND DISSCUSSION

Analysis for input parameters mentioned in earlier Tables was carried out and results have been discussed in this section. All the computation part is done using Abaqus/Explicit solver for evaluating the influence of surface explosion in different positions such as soil surface, soil slope, and buried pipe. The stress contours on the pipe after the blast indicates that the stress effect of the blast first reached the zone immediately below the pipe. In a short span of time, the stress wave propagated radially along the pipe and total stress dissipation happened in a short span of blast time (almost in 5 milliseconds), as illustrated in Figure 3.

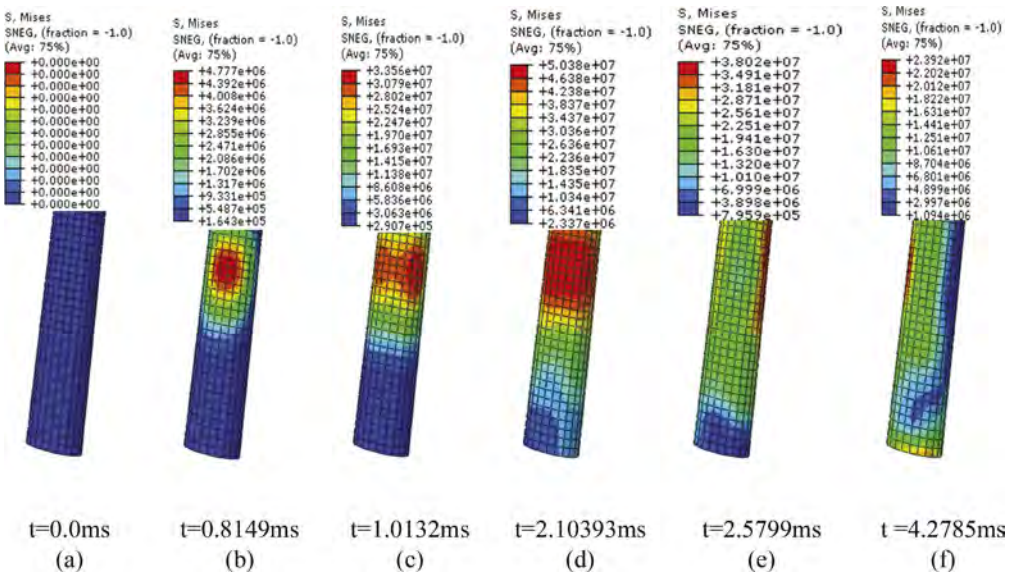


Figure 3. Stress propagation at different time intervals on pipe immediately after the blast (t=0ms-4.27ms).

Tables 4 and 5 show the peak particle velocity at various positions of the soil slope and pipeline for different quantities of blast load. It is observed that with an increase in horizontal distance the peak particle velocity decreases significantly, i.e., for 100g TNT, when the observation point changes from G_1 to G_2, PPV changes by almost 67.37%, as illustrated in Figure 4.

3.1 *Effect of slope on PPV*

It was observed that slopes are more vulnerable to blast as PPV values are on the higher side than direction despite the higher distance, as the surface of the slope is free on one side. For 100gm TNT the PPV values initially decrease at a slower rate of 8.36%-15.91% and followed by a higher rate of 38.26%-56.52% at the bottom of the slope. The variation becomes higher if the blast load is increased to 200gm TNT. Moreover, the trend of results in the present study compares well with the field test results of Tang *et al.* (2021) that were carried out at a test site located in Wuhan city and tabulated in Table 4.

Table 4. Comparison of the present numerical results with the field results of Tang *et al.* (2021) for varying weight of explosive charge.

Explosive charge	Position	Field Results (cm/s)	Numerical Results (cm/s)	Error (%)
100g	G_1	8.04	8.72	+8.46
	G_2	4.83	5.21	+7.87
	G_3	1.98	2.09	+5.56
	P_1	2.79	3.10	+11.11
	P_2	1.45	1.64	+11.59
	P_3	0.88	1.02	+15.91
200g	G_1	10.50	11.98	+14.09
	G_2	7.76	7.85	+1.16
	G_3	2.88	3.09	+7.29
	P_1	4.17	4.51	+8.15
	P_2	2.25	2.68	+19.11
	P_3	0.97	1.01	+4.12

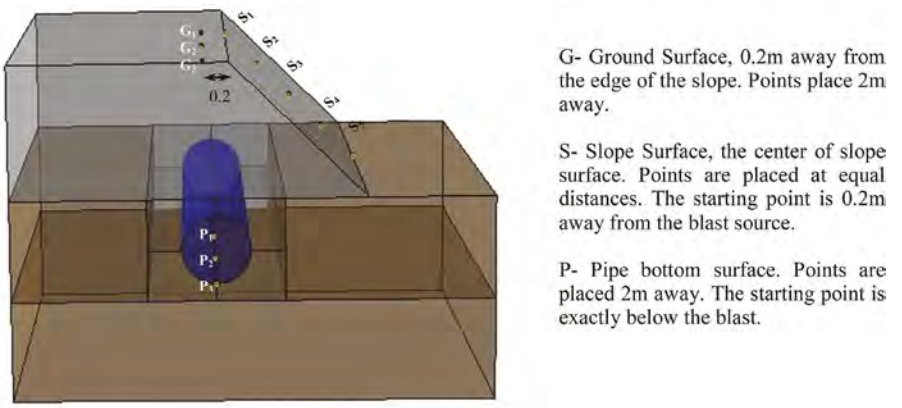

Figure 4. PPV measuring positions on ground (G), pipe bottom (P) and slope (S).

It is seen from Table 4 that there is a variation of 5.56%-15.91% between the field test results and developed numerical model. This may be attributed to various influencing

Table 5. Variation of PPV at different points of the slope for different amounts of explosives.

	100gm TNT					200gm TNT				
Position	P_1	P_2	P_3	P_4	P_5	P_1	P_2	P_3	P_4	P_5
PPV (cm/s)	9.98	9.18	7.92	5.06	3.65	12.58	11.73	9.89	6.46	4.97

parameters acting in the complex modeling which need a separate discussion but are not elaborated in the present study.

Five equally spaced points were taken along the slope, as shown in Figure 4 and the PPV of corresponding points were measured separately for both 100g and 200g TNT. It is seen that the PPV values increase with depth from the top of the slope. In the top portion, the variation is almost 26.05% and, in the bottommost portion the variation is 36.16%.

4 CONCLUSIONS

The major conclusions that can be made from the present study are as follows:

- At starting phase just after the blast (1-2 milliseconds), there is maximum influence on PPV value then gradually it gets reduced to zero in the next few milliseconds, in case of TNT blasting.
- PPV on the ground surface is a lot higher than the PPV in the pipe.
- With increased horizontal distance and burial depth PPV gets reduced significantly.
- Slope is vulnerable to the blast and PPV values are decreasing significantly at the bottom of the slope, which gives a conclusion that special care should be taken in case of a blast around the slope.
- Free surface of slope may be one of the probable reasons for higher PPV in slopes.
- A robust analysis is needed to give absolute judgment regarding slope stability.

ACKNOWLEDGEMENT

Comparative analysis of dynamic vibration dampers

M.B. Zhumamuratov
JSC Kazakhstan Highway Research Institute, Astana, Kazakhstan

ABSTRACT: This article provides an overview and analysis of methods for calculating the structures of dynamic dampers designed to reduce aeroelastic vibrations of continuous girder bridges. The article also outlines the main provisions for determining the parameters of an alternative design of a hydrodynamic damper, which is used to reduce the vibrations of bridges.

In the "conflict" between external loads and bridges, one of the most important problems is the instability of aerodynamics, which is characterized by the possibility of aeroelastic vibrations in the structural elements of the structure from strong wind currents. Aeroelastic vibrations as a phenomenon, is one of the types of instability of aerodynamics, are largely found on large-span flexible structures: hinged and cable-stayed bridges, pipeline crossings and, as the practice of recent decades has suddenly demonstrated, on continuous girder bridges, as well as so-called "Skyscrapers".

In order to ensure aerodynamic stability in the processes of interaction of structures with wind flows, an intensive study of this topic began in the middle of the twentieth century, in order to determine further branches of the study of aerodynamics with new types of solutions.

At the beginning of the twentieth century in the USSR, and in particular in Kazakhstan, the problems of different types of structures with the interaction of wind flows on them were developed. N. Rynin was the first to study the issues of aerodynamics of building structures and structures, on the basis of his studies of models of buildings and structures, the flow spectra, the acting forces of aerodynamics, as well as the issues of redistribution of wind pressure on the surface of structures were studied [1]. In the study of the physical foundations of the interaction of structures and structures with wind pressure, a significant contribution was made by the Russian teachings of K.A. Bunkin and A.M. Cheremukhin.

Soviet researcher E. Retter invented a special wind tunnel with unique scientific and technical requirements to determine the possible degree of turbulence of the air flow and wind pressure.

In different years, the work of L. Gandin, G. Fomin, M. Barstein, A. Bernstein, A. Zeitlin, N. Popov, K. Fedyaevsky, M. Kazakevich, L. Devnin, G. Savitsky, A. Lugovtsev, V. Mugalev, E. Solovieva, S. Gorlin, G. Khudyakov, V. Samsonov was devoted to the problem of interaction of structures with wind flow, S. Herzenstein, I. Nekrasov, A. Ordanovich, V. Nazarenko, K. Strelkov, M. Berezin and other scientists [2].

Experimental work on the study of air flow around buildings and structures was done by foreign scientists Irminger in 1891 and Stanton in 1903. J. Sermak studied all possible nuances in modeling the interactions of wind flow and pressure with various structural elements [3].

As indicated in the literature review, methods of dynamic vibration damping are used to eliminate aeroelastic vibrations and ensure safe operation of bridge structures. Structurally, this is due to the installation of passive adaptive mass dampers. The calculation of such dampers is based on the use of a spring pendulum - a mechanical analogue of a beam on two supports. The additional mass of the vibration damper is attached to the beam by means of an

DOI: 10.1201/9781003299127-266

elastic coupling (dynamic damper without damping) or an elastic coupling and a viscous component (dynamic damper with damping).

The disadvantage of using dynamic vibration dampers is that each dampener reduces vibration only of a certain frequency.

Vibration dampers are most effective when used to reduce vibration in mechanisms with stable vibration frequencies, such as turbo generators, pumps and power units. Vibration dampers are also very effective for reducing the vibration of chimneys in high-rise buildings (300-400 m). To reduce the vibration of the chimneys caused by the wind load, loads of different weights are suspended on cables inside the chimney to act as vibration absorbers with different natural frequencies [4].

The natural frequency of the vibration damper is selected in accordance with the frequency of the wind load. The high reliability and efficiency of vibration dampers for chimneys is confirmed by many years of experience.

The vibration absorption (vibration damping) method is used to reduce the vibration of the housing and other sheet metal components, such as fences.

The vibration absorption method involves coating the vibrating surface with an elastic body (rubber, plastic or anti-vibration rubber) with high internal friction. By allowing this elastic body to absorb vibration energy, the vibration of the structural component can be reduced. As a result, the vibration energy is converted into heat, and the vibration amplitude is significantly reduced, especially in the resonant mode.

Vibration-absorbing membranes are effective when the length of the absorbing layer corresponds to several wavelengths of bending vibration. If the length of the absorbing membrane is small, the bending vibration force decreases slightly. This should be taken into account when using absorbing membranes on structures with low vibration frequencies, where the wavelength reaches several meters.

Vibration absorption is ineffective for reducing the intensity of longitudinal waves with high frequency and high vibration energy. To reduce such vibrations, it is effective to provide a vibration isolation gap between individual structural elements. These gaps must be filled with a wave-resistant material (for example, rubber bands, air layers, etc.), different from the material of the machine. The material of the vibration-absorbing membrane and its dimensions are selected depending on the vibration range. Vibration-absorbing membranes are used in places with the highest vibration amplitude, determined on the basis of studies of the vibration rate at various points of the structure. The use of vibration-absorbing membranes can significantly reduce production noise, especially in high-frequency ranges. Reduction of the noise level (dB) during vibration of metal surfaces lined with a vibration-absorbing coating can be approximately calculated by formula 1:

$$\Delta L = 20 \lg \left[\frac{n_1 - n_2}{n_2} \right]$$

Formula 1 – determination of approximate noise reduction.

where n_1 is the loss coefficient of the vibration—absorbing surface before applying the vibration-absorbing layer;

n_2 - is the loss coefficient in the presence of a vibration—absorbing layer.

Depending on the dynamic modulus of elasticity, vibration-absorbing coatings are divided into hard (Ed = 109 Pa) and soft (Dc = 107 Pa). Hard coatings are effective for reducing vibrations of low and medium frequencies, soft coatings are used to reduce the intensity of high-frequency vibrations.

Sheet plastic materials (for example, vinyl, foam) are used as soft coatings that are glued to thin metal surfaces, such as casings, fences and ventilation ducts. Special mastics consisting of synthetic resins and fillers are used to cover surfaces of complex shape with vibration-absorbing materials.

Polyacrylic and biponite composite absorbing materials, which consist of a layer of hard plastic or metal and a layer between layers of polymer materials, have high efficiency. The optimal thickness of the vibration-absorbing membrane is 2. 3 thicknesses of the coated structure [5].

To obtain higher efficiency, the damper must have parameters close to optimal by preliminary analysis of the structure on which it will be installed. The correct setting of the pendulum damper is ensured by choosing the length of the pendulum suspension. As a rule, one or more stranded cables are used as a suspension.In the event that the fastening of the cable at the suspension point is rigid, the frequency of oscillation of the pendulum damper, taking into account the action of the tensile force N in the cable, can be determined by the formula 2:

$$\omega^2 = \frac{\beta^3 ch\beta}{\beta ch - sh\beta} \times \left(\frac{EI}{Ml^3}\right)$$

Formula 2 – determination of the oscillation frequency.

where l is the length of the suspension of the damper with a mass of M; EI is the bending stiffness of the cable, $\beta = 1(N/EI)^{1/2}$

The energy absorption coefficient in such a extinguisher can be found by the formula 3:

$$\psi = \frac{\psi_0}{\left[\frac{2(\beta ch\beta - sh\beta)^2}{\beta(sh\beta ch\beta - \beta)}\right]}$$

Formula 3 – determination of the energy absorption coefficient

where ψ0 is the energy absorption coefficient in the cable during bending deformations

The analysis of this equation shows that with an increase in the tensile force of the cable, the attenuation of the extinguisher decreases, and with an increase in the bending stiffness of the cable, the attenuation of the extinguisher increases accordingly. Therefore, to increase the attenuation of the damper, it is necessary to use a cable with high internal friction and design a damper with as little β as possible.

Deepankar Choudhury
Prof. T. Kant Chair Professor and Head, Department of Civil Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

ABSTRACT: Numerous researchers have carried out seismic microzonation of India using various criteria. Seismic zonation was conducted at the national and regional levels using the conventional approaches i.e., either a probabilistic or a deterministic approach. Between the computed peak ground acceleration and the real peak ground acceleration observed during the seismic event, significant differences have been detected. Different approaches (conventional and new) have been used in the literature to conduct seismic hazard analysis and site-specific analysis of India in order to address this issue. The goal of the current work is to evaluate critically various researchers' approaches to seismic hazard analysis and compare those to Indian codal provisions already in place with a highlight of need for further research and modifications.

Keywords: Hazard Analysis, Peak Ground Acceleration, Seismic microzonation, India

1 INTRODUCTION

A natural phenomenon that results in the instant loss of life and property is an earthquake which results in the abrupt release of energy. Although deemed to have a low chance, earthquakes pose a significant risk to society. Large earthquakes have caused extremely significant damage and fatalities throughout history worldwide as recorded by USGS such in 1960 Chile (M_w of 9.5), 1964 Southern Alaska (M_w of 9.2), 2004 Sumatra (M_w of 9.1), 2011 Japan (M_w of 9.1), 2010 Chile (M_w of 8.8), 2018 Indonesia (M_w of 7.5), 2020 Turkey-Greece (M_w of 7.0), 2022 Afghanistan-Pakistan (M_w of 6.2) etc.

India is regarded as one of the world's earthquake-prone countries. India has experienced earthquakes since the prehistoric times. Devastating earthquakes in India have resulted in disasters in terms of property destruction and fatalities, including those in 1819 Kutch, 1897 Assam, 1905 Kangra, 1934 Bihar & Nepal, 1950 Assam, 1967 Koyna, 1991 Uttarkashi, 2001 Bhuj, 2005 Kashmir, 2011 Nepal, 2015 Nepal. The majority of reported fatalities are attributed to building and structure collapses brought on by the seismic events.

It is extremely important to study the insight of earth tectonics for the region given the size and severity of the hazard capability of earthquakes. India can be divided into three seismotectonic regions based on its seismic activity: the stable continental region (SCR), subduction zones, and shallow crustal region. The northwest part of the Indian plate i.e., the southern Tibetan Plateau and the Himalayas are examples of shallow crustal regions that are tectonically active. Among the subduction zones are the Indo-Myanmar arc in the northeast, the Andaman-Sumatra seismic belt in the southeast, and the Hindukush-Pamir in the northwest part of India. Due to its intraplate seismicity and low to moderate seismic activity, peninsular India is referred to as the SCR or Stable Continental Region (Nath & Thingbaijam 2012, Sitharam et al. 2014).

DOI: 10.1201/9781003299127-267

2 METHODOLOGY

Seismic Hazard Analysis is generally carried out by the conventional way and a new earthquake hazard technique considering the regional rupture characteristics which is also known as Rupture Based Seismic Hazard Analysis (RBSHA).

In conventional way, Deterministic seismic hazard analysis approach (DSHA) and Probabilistic seismic hazard analysis approach (PSHA) can be used to conduct the seismic hazard assessment. According to DSHA, the greatest possible earthquake happens at the nearest possible location. Whereas, PSHA is based on the integration of all potential earthquake effects anticipated to occur over a certain time period at various sites while taking uncertainty into account. These studies would concentrate on the regional seismic risk over the long term, but they do not account for the impacts of seismic wave attenuation or amplification caused by local, site-specific variables.

For the purpose of designing future infrastructures, the majority of traditional evaluations of seismic hazard take into account historical earthquake location, size, and frequency on the fault or in the area. Large to moderate earthquakes must have enough energy to rupture the faults. The amount of time needed to accumulate the necessary energy to produce moderate to big earthquakes varies by region. As the strain energy accumulated on faults get released during earthquakes, the future earthquakes in a particular area are more certain to occur in places with low or no recent seismic activity (Kramer 1996). The time between two successive earthquakes in the same place is therefore large, yet it is inadequately taken into account by traditional hazard analysis techniques. Additionally, this conventional method does not take into consideration the probability of destructive earthquakes occurring in other places or sources. Anbazhagan et al. (2011) presented a novel seismic hazard analysis approach, known as Rupture Based Seismic Hazard Analysis (RBSHA), to consider the likelihood of earthquake occurrence in the regions different from the locations of previously catastrophic earthquakes. The rupture features of the local faults and lineaments are taken into account in the RBSHA method. This method can be employed to determine the maximum probable earthquake magnitude. This method of M_{max} estimate could simulate the worst-case earthquake in the future. The Ground Motion Prediction Equations (GMPE) chosen in this method will use weights together with the statistical techniques like the Log Likelihood (LLH) approach and Data Support Index (DSI) values. The full methodology or the steps for this rupture-based approach can be found in the study of Anbazhagan et al. (2011).

3 DETERMINISTIC SEISMIC HAZARD ANALYSIS (DSHA) STUDIES

Pervez et al. (2003) provided a nationwide seismic hazard map using a deterministic approach that divided entire India into forty seismic zones. Seismic hazard maps were presented for the Indian territory in terms of D_{max}, V_{max}, and Design Ground Acceleration (DGA) by computing realistic synthetic seismograms. DGA ranged from 0.3g to 0.6g in Assam, Andaman-Nicobar Islands, and the central and western Himalayas. Using the Iyengar & Raghu Kanth (2004) attenuation relationship, Boominathan et al. (2008) assessed the earthquake hazard taking into account local site impacts for microzonation studies of Chennai metropolis. Peak Ground Acceleration value for that area was in the range of 0.004g - 0.106g. Using data from remote sensing to locate lineaments in the Bangalore region, Sitharam et al. (2006) had computed the peak horizontal acceleration (PHA) for Bangalore City. They made use of the attenuation correlation provided for south India. For the city, PHA ranged from 0.005g to 0.13g. Sitharam et al. (2006) performed DSHA for Bangalore city using the empirical equation provided by Wells & Coppersmith in 1994. PHA varied depending on the method from 0.001g - 0.146g. Sitharam & Anbazhagan (2007) evaluated the Peak Ground Acceleration for Bangalore City using the attenuation relationship developed by Iyengar & Raghu Kanth (2004) and the Wells & Coppersmith (1994) by RLD approach for cross validation. The PGA value was observed to be 0.146g & 0.159g when using the DSHA method & RLD approach, respectively. Raghu Kanth et al. (2009) used the enhanced 1-D stochastic simulation model developed by Boore (1983) to simulate ground motion in Imphal city. For the Imphal city, the PGA varied between 0.12g and 0.2g at rock level. PGA value at the surface ranged from 0.14g to 0.24g. Desai & Choudhury (2014) carried out DSHA for the Greater

Mumbai region. They took into account 7 GMPEs in the logic tree analysis to calculate the PHA and S_a values (0.1s and 1s) at the bedrock level. The PHA values varied from 0.076g to 0.328g. Shukla & Choudhury (2012) conducted DSHA for the 5 major cities of Gujrat. For the seismic hazard analysis, 7 ground motion prediction equations were used in the logic tree to calculate the PGA values for each of the cities. PGA values for the five cities were 0.13g (Ahmedabad), 0.15g (Surat), 0.64g (Bhuj), 0.14g (Jamnagar), 0.20g (Junagadh). Kataria et al. (2013) carried out DSHA of the Andaman and Nicobar Islands taking into account seven seismogenic source zones. GMPEs applicable for subduction zones and shallow crustal earthquakes in active tectonic regions, respectively, had been employed. In that study, the PGA value was in between 0.27g – 0.58g. Naik & Choudhury (2014) carried out DSHA for Goa state of India. 7 attenuation equations (GMPEs) were utilized to calculate the PGA value for the state. PGA map developed for Goa shows high hazard values in the central Goa part compared to the other parts of the state. Rao & Choudhury (2021) carried out DSHA for the North-Western part of Haryana. As an important structure like Nuclear Power Plant (NPP) is going to come up very soon, proper seismic hazard analysis was necessary. Seismic hazard maps were developed for the region by taking into account 3 scenarios. PGA values for the 3 scenarios considered were found to be 0.088g, 0.110g and 0.151g respectively. Anbazhagan et al. (2023) carried out seismic hazard analysis of Tripura (NE India) using both conventional and rupture-based approach. Seismic hazard maps obtained by both the approaches for the state of Tripura was provided as the results of the study. The Peak Ground Acceleration value was found to be in the range of 0.05g – 0.58g.

4 PROBABILISTIC SEISMIC HAZARD ANALYSIS (PSHA) STUDIES

Bhatia et al. (1999) generated a seismic hazard map of India and surrounding areas using the probabilistic approach. The key geological characteristics and seismicity trends were used to define 86 possible seismic source zones. This investigation used the Joyner & Boore (1979) attenuation relationship. The projected PGA values for the Tibetan plateau were 0.25g, 0.35g – 0.4g for the North-East and North-West Himalayan regions, 0.1g for the Indian Shield, and 0.2g for the Koyna region. Nath & Thingbaijam (2012) conducted PSHA of India using 16 ground motion prediction equations (GMPE) with equal weights for the hazard computation. Plots of PGA and PSA for several cities were shown at 0.2 and 1 seconds. Based on 104 regional seismic source zones in India, Sitharam & Kolathayar (2013) conducted a seismic hazard study of the nation utilising areal sources. They took into account four attenuation relationships for the analysis. PHA and S_a (Spectral Acceleration) values (for durations of 0.1 and 1 s) were analysed at rock level for the entire country for probabilities of exceeding 10% and 2% in 50 years. Desai & Choudhury (2014) assessed the seismic hazard for the Mumbai region and provided PGA and S_a. Seven attenuation equations for shallow crustal intraplate regions developed for the other parts of the world had been applied. From the hazard map, it was revealed that Panvel, JNPT, Vashi and Belapur of Navi Mumbai were high hazard places compared to the other parts of Mumbai. Das et al. (2016) carried out PSHA for North-East India into 9 seismogenic zones. PGA and S_a values for the region were calculated and seismic hazard maps were presented for the region at the bed rock level. From the maps, it was seen that there was a significant spatial variation locally unlike the constant value of PGA given in IS code. Coefficient of Variation (COV) map had also been provided along with the hazard map for the region. For the city of Bangalore, Sitharam et al. (2006) took into account 52 faults and lineaments, and seismic hazard analysis used the attenuation relationship of Iyengar & Raghu Kanth (2004). For that area, PHA ranged from 0.001g – 0.146g. Shukla & Choudhury (2012) conducted PSHA of two of the most important ports of India located in the state of Gujrat. Uniform Hazard Spectra (UHS) for the two ports (Kandla and Mundra port) was developed by using 7 GMPEs. For the site characterization, soil profiles were obtained from the investigations carried out at the two ports. It was concluded that UHS amplitude depends heavily on local site conditions and cannot be described properly by IS code. Using the Poisson method, Anbazhagan et al. (2008) carried out PSHA for the city of Bangalore. In their analysis, the attenuation relation for a rock site in Peninsular India developed by Raghu Kanth

(2005) was applied. For the city of Bangalore, the PGA value was in the range of 0.17g – 0.25g. Mohanty & Yanger (2008) used a quasi-probabilistic methodology to calculate the seismic hazard for Kolkata city while taking five seismic source zones into account. The attenuation relationship of Toro et al. (1997) was applied in the study. From the south-eastern to the eastern parts of Kolkata, PGA varied from 0.10g – 0.34g. The estimate of the seismic hazard for the Delhi region was done by Agrawal & Chawla (2006). Contour maps of the entire region were used to display the results. The PGA ranged from 0.12g – 0.17g for the study area. Kumar et al. (2013) conducted Lucknow's seismic hazard analysis taking into account nearby and active seismic gaps. PGA ranged for 10% and 2% risk of exceeding in 50 years are 0.04g – 0.07g and 0.07g – 0.13g, respectively. Patil et al. (2014) carried out PSHA for Himachal Pradesh and its surrounding area. Two cases (constant b and varying b value) were considered to find out PGA values at bedrock level. PGA values ranged between 0.14g to 0.37g and 0.07g to 0.24g for the two cases respectively. Rout et al. (2015) conducted PSHA for the North-Western and Central Himalayas by dividing the area into 22 seismogenic source zones. Considering the varying b value case, PGA values at bed rock level was ranging from 0.06g to 0.65g.

5 RUPTURE BASED SEISMIC HAZARD ANALYSIS (RBSHA) STUDIES

The seismic hazard map of Coimbatore was presented by Anbazhagan et al. (2012), who also highlighted 8 likely places called the probable locations where earthquakes might be anticipated soon. They also compared the hazard map developed using the Rupture based approach with the map developed using the conventional DSHA approach. Anbazhagan et al. (2023) conducted the rupture based seismic hazard analysis of Tripura state of North-East India. They have provided the hazard maps of the state developed with this new method. It showed that Tripura state can experience higher PGA values than as mentioned in IS 1893: Part 1 (2016).

6 DISCUSSIONS

The examination of papers mentioned above demonstrates the many methods used to calculate the PGA value at both the national and regional levels.

Agrawal & Chawla (2006) provided PGA values for Delhi that are comparable to Bhatia et al. (1999) and that ranged from 0.12g to 0.17g for 10% risk of exceeding in 50 years, although the IS code zone factor is larger for Delhi than the value provided by Agrawal & Chawla (2006). The PGA values recommended by Boominathan et al. (2008) varied from 0.004g – 0.106g, that is comparable with the zone factor of 0.16g for Chennai specified in IS 1893: Part 1 (2016). Comparing the zone factor for Kolkata in IS 1893: Part 1 (2016) to the regional PGA value provided by Mohanty & Yanger (2008), the zone factor was understated as 0.16g. The IS code zone factor for Lucknow is 0.16g, however the PGA value ranged from 0.07g – 0.13g for 2% likelihood (2475 years) of exceedance in 50 years provided by Kumar et al. (2013). In comparison to Sitharam et al. (2006) & Anbazhagan et al. (2008) for Bangalore region, IS 1893: Part 1 (2016) underestimated the PGA value of zone II as 0.10g. Andaman and Nicobar are classified as being in zone V according to IS 1893: Part 1 (2016), which is an underestimation compared to the PGA value provided by Kataria et al. (2013). Nath & Thingbaijam (2012) for Andaman and Nicobar recommended PGA values between 0.30g and 0.60g while taking the DSHA technique into consideration, which is similar to the PGA values stated in Khattri et al. (1984). The PGA value reported for the same in Bhatia et al. (1999) was 0.15g to 0.30g, which is less than the PGA value stated in Khattri et al. (1984). Anbazhagan et al. (2023) reported PGA value for the state of Tripura in the range of 0.05g – 0.57g which is much higher than 0.36g given in IS code. Both conventional and rupture-based approach was used in the study. PGA map was provided for the state and it was revealed from the study that there was a spatial variation within the small area of the state. Also, the reported values of PGA across the state were deviating from the constant value given in the IS code for the state. Few of these comparisons made above shows a fair deviation from the value given in the IS code. For instance, PGA value for the whole North-East India as given

by IS code is constant (0.36g). But it is not true as observations from the studies of different researchers tells us a different story. These deviations in the hazard values obtained by the different researchers shows the importance of carrying out micro level hazard estimation in which use of different seismic hazard methodologies plays an important role.

7 CONCLUSIONS

India is split into four zones, with zone factors in the range of 0.10g - 0.36g, according to IS: 1893: Part 1 (2016), but the site geology and criteria for identifying these soils are not entirely given. These data have been compared, and it was discovered that the Indian Standard code overpredicts PGA values for hard rock sites, while underpredicting values for soil locations. Therefore, site-specific research is crucial by taking into account the local, geological, geophysical, seismotectonic and rupture characteristics of the area. It has also been seen that most researchers use predictive relationships in hazard analyses without considering if they are valid for the region being studied. Therefore, one of the most crucial factors in the seismic hazard analysis is the right selection or development of a predictive relationship for a location. Some studies have employed a variety of methods to categorize seismically active regions, including the zone-wise approach, the fault-based approach, and the grid-based technique. However, thorough study of these methodologies is crucial for future research. Also, since there are not many studies done using the RBSHA methodology, seismic hazard analysis in the national or regional level can be performed using this approach by formulating new GMPE equations for any region or considering the nation as a whole. IS code needs also be updated considering the scientific approaches and should provide PGA values obtained from microzonation analysis.

ACKNOWLEDGEMENT

Authors would like to express sincere thanks to Dr. Ranjit Das, Assistant Professor, Universidad Catolica del Norte, Chile, for his valuable and constructive suggestions during the planning and development of this review manuscript.

ABSTRACT: The article presents the results of long-term geodetic observations of deformations of blast furnace bases at the Karaganda Metallurgical Combine and the main provisions of the development of the elastic-plastic clay model for soils of Central Kazakhstan. The results of experimental studies of clay soils and numerical analysis of the forecast of basement sediments are presented.

1 INTRODUCTION

For more than 60 years, geodesic monitoring has been carried out for the precipitation of structures of the Karaganda Metallurgical Plant. During the construction of the foundations of blast furnaces No. 1-4, coke oven batteries No. 1-4 and chimneys with a height of 250 m, reference points were installed (according to the project requirements), which still record deformations of the foundations of structures. It is known that the main precipitation occurs during the construction of the structure and during the first few years of its operation, and in clay soils, precipitation stabilization occurs much later than in sandy soils. In this regard, it is very important to monitor the deformations of the base, starting from the moment of foundation construction, i.e. from the very beginning of load transfer to the base. It should be noted that the ground water level is at a depth of 23.0 meters and the ground at the base of the foundations is wet. In 1982, there was a need for a complete replacement of the blast furnace No. 1, its overhaul after 20 years of operation. During the dismantling period, elastic deformations of the base were recorded, the value of which was 32 mm. After the blast furnace was built and fully loaded, the sludge stabilized in 2 months. A similar pattern was observed during the reconstruction of all blast furnaces.

2 ANALYSIS OF THE RESULTS OF ENGINEERING AND GEOLOGICAL SURVEYS

Analysis of the results of engineering and geological surveys shows that most buildings and structures They are built on soils, mainly of Quaternary age (systems). Soils of the Quaternary system are characterized by the variability of their physical state, complexity, and variety of mechanical properties. Therefore, as part of the object (geotechnical system), the forecast of

DOI: 10.1201/9781003299127-268

precipitation of industrial structures 'foundations on clay soils of Central Kazakhstan was chosen as the subject of research. The main factors that lead to changes in the properties of clay soils of foundations are, first of all, man-made (technical and technological) and climatic (precipitation infiltration). The negativity of the process lies in the fact that the factors that lead to changes in the properties of the base soil are irreversible and are primarily associated with human engineering activities. Therefore, taking into account these factors that directly affect the stress-strain state of soils is necessary for a reliable forecast of foundation precipitation. Figure 1 shows the distribution of the porosity and density coefficients over depth on clay substrates. Analysis of the graphs shows that the porosity coefficients vary in depth from 0.6 (15.0 m) to 1.1 (1.0; 10.0; 25.0 m) and the density values - from 1.75 to 2.1 g/^{cm3}.

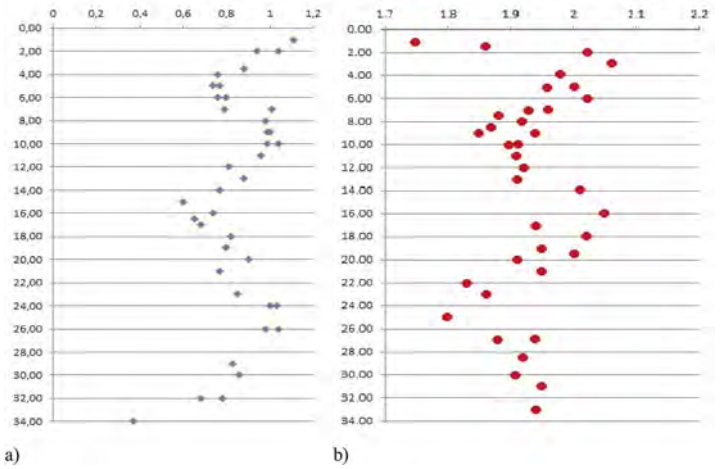

Figure 1. Depth distribution of physical properties of clay soils. (a. porosity coefficient b. density).

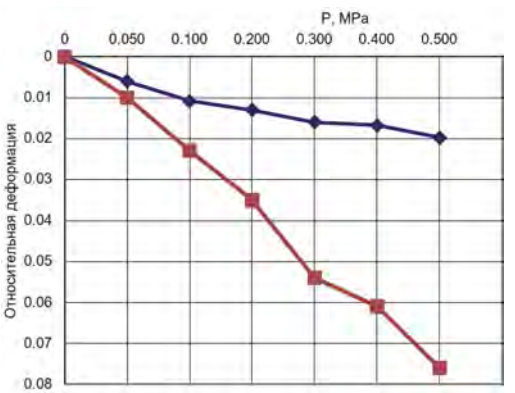

Figure 2. Compression graphs before and after soaking clays.

Figure 2 shows the results of testing clays in a compression device with the initial data: W=14.3, p=1.85 g/^{cm3}, e=0.695, While the results are obtained: natural humidity-m $_0$ = 0.045 MP a, E $_k$=17.8 MP a, E $_{od}$=44.4 MP a and at soaking – m0=0.254 $_{MP}$ a, ek=6.0 MP a, E $_{od}$=7.5 MP a. The analysis shows that the compression module is 2.9 times smaller when soaked than in the natural state, and the odometric module is 5.8 times smaller.

To study the stress-strain state and forecast the sedimentation of foundations of structures, an improved elastic-plastic model of clays based on the tent model of Professor T. Tanaka is

presented [3,7,8]. Tent (deformation) models are the most developed for describing the deformation of clay soil bases [3]. When applying this model for clays, we consider the incremental relationship between stresses and deformations when testing soils on triaxial compression devices. The analysis of the results is carried out in stresses, since clay soils of the base are moist and not fully compacted in their natural state:

$$p = 1/3(\sigma_1 + 2\sigma_2) И\, q = \sigma_1 - \sigma_2, \tag{1}$$

and deformations:

$$_{ei} = {}_{e1+}\, 2e2 \text{ and } \gamma = 2/3\ (_{e1} - e2), \tag{2}$$

where σ_1, σ_2, ε_1, ε_2 - stresses and deformations.

A graphic representation of the tent model is shown in Figure 3.

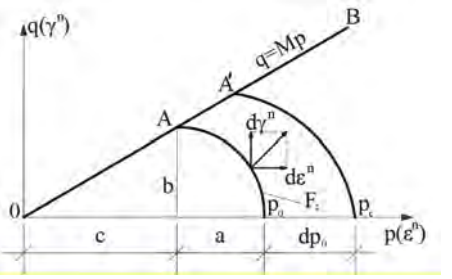

Figure 3. Graphic representation of the elastoplastic model.

Line with the equation:

$$Mp = q, \tag{3}$$

in Figure 3: the line with the equation $q = Mp$ is the limit line of this soil,

where M = constant is a coefficient that varies within 0.7÷1,2, which corresponds to the internal friction angles from 18 ° to 30 °.

When solving the problem, the following model assumptions are made::

- isotropic compression under pressure – P_o forms the elastic zone OAR_0 and within this zone the change in the stress state is accompanied only by small elastic deformations. Beyond the boundary of the yield surface AP_0 is accompanied by the appearance of plastic deformations $d\gamma^n$ and dfe^n;
- the yield surface AP_0, this is the surface of the plastic potential and, in accordance with the associated flow law, the total vector of plastic deformations is normal to the yield surface.

An increase in stresses, accompanied by the accumulation of plastic deformations, will lead to an expansion of the elastic region and the yield surface (tent) will occupy a new position A'P *C*. At the same time, the volume plastic deformation at any point of the new tent will be independently constant and equal to the deformation by which the soil is deformed under isotropic compression from pressure P_0 and P_C. Experimental compression parameters for implementing the model – λ and decompressions – k were obtained from compression curves in semilogarithmic coordinates (Figure 4). In this case, changes in the soil porosity coefficient linearly depend on the logarithm of the external pressure change.

Then the equation of the compression curve has the form:

for the load branch

$$e_i = e_0 - \lambda \ln\left(\frac{P_i}{P_0}\right), \tag{4}$$

for the unloading branch

$$e_i = e_0 - k \ln\left(\frac{P_i}{P_0}\right), \tag{5}$$

where e0 and P0 are the initial porosity and pressure coefficients; *ei and* Pi *are the porosity coefficient and pressure corresponding to the* i*-th* load stage; λ – compression ratio; k – decompression ratio.

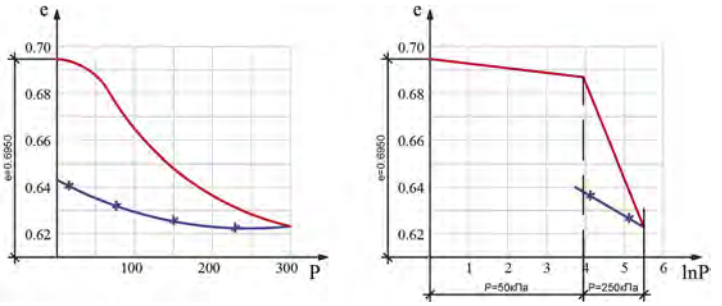

Figure 4. Compression graphs for determining load parameters-λ and unloading – k.

Compression ratios λ and decompression k is the tangent of the angle of inclination of the semi-logarithmic curve to the pressure axis, numerically equal to the difference in the porosity coefficients. If *Pi = e*, this condition should be taken into account in *Pi = e ln pi = 1* [3,4]. These coefficients are dimensionless and characterize the compressibility of soils in a large pressure range [5].

Bearing in mind that the total increase in volume deformation consists of elastic and plastic parts, the total deformation is defined as:

$$d\varepsilon_{ij} = d\varepsilon_v = d\varepsilon_{ij}^v + d\varepsilon_{ij}^n = d\varepsilon_v^v + d\varepsilon_v^n. \tag{6}$$

Increments of the elastic strain component are related by linear relations of the generalized Hooke's law with stress increments:

$$d\varepsilon_{ij}^v = \left[(1+v)d\sigma_{ij} - 3v\delta_{ij}d\sigma_{cp}\right]/E, \tag{7}$$

where δ_{ij} is the Kronecker symbol.

The increment of plastic deformation components that occurs under active loading at a regular point on the loading surface is determined by the ratio:

$$d\varepsilon_{ij}^n = dk\frac{\partial \Phi}{\partial \sigma_{ij}}, \tag{8}$$

the use of which implies the construction of the loading surface *F=const,*
where *dk* is a scalar infinite multiplier; *F is* the loading function.
Loading function in the elastic domain at *F < 0* in matrix form:

$$d\varepsilon = \ d\varepsilon^{y} + s \cdot d\varepsilon^{n} = D^{y-1} d\sigma + s\lambda B, \tag{9}$$

plastic deformations from experimental graphs are determined by:

$$\varepsilon_{ij}^{n} = \ \frac{\lambda - k}{1 + e_0} \frac{1}{2.3} \ln\left(\frac{-3P}{-3P_0}\right), \tag{10}$$

where: *-3P = P_s*
then:

$$\varepsilon_{ij}^{n} = -A \ln(-P_C) + B, \tag{11}$$

$$A = \frac{1}{2.3} \frac{\lambda - k}{1 + e_0} \text{И}\, B = -A \ln(-3P_0), \tag{12}$$

coefficients A and B are constant

$$P_c = \exp\left(\frac{B - \varepsilon_{ij}^{n}}{A}\right), \tag{13}$$

The yield surface equation for an isotropic medium in the stress space is written as:

$$f(\sigma) = 0, ij, \tag{14}$$

where *f is* the yield function in the elastic region *f < 0*.
In the case of an elastic-plastic medium *F = f*, then (8) takes the form:

$$d\varepsilon^{y} = dk \frac{\partial f}{\partial \sigma_{ij}}, \tag{15}$$

It should be noted here that if the guiding cosines of the normal to the loading surface are proportional, then the ratio (8) means the vector of increment of plastic deformation at a regular point directed along the normal to the loading surface-F_2 in any direction of the loading vector. In this case, only the value of the vector depends on the loading vector . The loading surface is used to establish the relationship between stresses and deformations in the pre – limit state of the soil, and the yield surface is used in the limit state.

In general, the yield function is defined as:

$$f = \alpha I_1 + \frac{J_2^{1/2}}{g(\theta)} - K = 0, \tag{16}$$

At: *f (σ, k) = 0; df = 0;*
Then we have

$$\text{a}^{\ t}\ d\sigma - A\lambda = 0, \tag{17}$$

$$A = -\frac{1}{\lambda} \frac{\partial f}{\partial k} dk, \text{a} = \frac{\partial f}{\partial \sigma}, \text{b} = \frac{\partial \Phi}{\partial \sigma}, \tag{18}$$

the final element area coefficient is defined as follows:

$$S = \frac{Fb}{Fe}, \tag{19}$$

where fb is the area of the final element after shear or deformation; $_{F}\, e\, _{is\ the\ area}$ of the final element at the beginning of the calculation.

Formula (9) is an equation for the relationship between strain increments and stresses for the accepted model. And also the proposed model considers the OM line as the limit line of normally compacted soil and defines:

$$\alpha_{cs} I_1 + \frac{I_3^{\frac{1}{2}}}{g(\theta)} = 0 \text{ or } \alpha_{xs} P_0 + \frac{b}{g(\theta)} = 0, \tag{20}$$

where: $b = -\alpha_{cs} P_0 g(\theta)$ and $\alpha = R(-\alpha_{cs} P_0 g(\theta))$,

Then

$$P_c = P_0 - a = P_0[1 + \alpha_{cs} g(\theta) R], \tag{21}$$

where α_{cs} – critical condition coefficient;

In this model, the associated yield surface and plastic potential for normally compacted clays ($F_2 = f$ or AP_c) is a section of an ellipse described by the equation:

$$\frac{(I_1 - P_0)^2}{a^2} + \frac{I_2}{b^2} = 1, \tag{22}$$

where a and b are geometric parameters of the ellipse,$a/b = R = const;$ P0 is the center of the ellipse.

The yield surface is described by the equation:

$$f = F_2 = b^2 (I_1 - P_0)^2 + \frac{a^2 I_2}{(g(\theta))^2} - a^2 b^2 = 0, \tag{23}$$

or

$$f = F_2 = b^2 (P_c P_0)^2 + - a^2 b^2 = 0, \tag{24}$$

Given the Mohr-Coulomb law, we define:

$$g(\theta) = \frac{\cos\frac{\pi}{6} - \frac{1}{\sqrt{3}} \sin\frac{\pi}{6} \sin\varphi}{\cos\theta - \frac{1}{\sqrt{3}} \sin\theta \sin\varphi} = \frac{3 - \sin\varphi}{2\sqrt{3}\left(\cos\theta - \frac{1}{\sqrt{3}} \sin\theta \sin\varphi\right)}, \tag{25}$$

where θ - parameter: e;

$$\sin 3\theta = -\frac{3\sqrt{3} J_3}{2 J_2^{\frac{3}{2}}}, \tag{26}$$

The given invariants are determined by the well-known formulas.

The position of the ellipse is determined by two constants a and b and a function that relates the position of the tent to the bulk plastic deformation-$e\ v^{\,p}$.

$$P_c = F_2(\varepsilon_v^n), \tag{27}$$

It should be noted that the theoretical stress increase is defined as:

$$n\ v\ \varepsilon^{\,Kd} - y\ dp_{=}^{\ dp} \text{ and } dq = dq^{\,y} - 2\ G dq^{\,n}, \tag{28}$$

where dqy and dpy are the elastic stress increment; $K,\ G\ are$ the secant modules of bulk strain and shear.

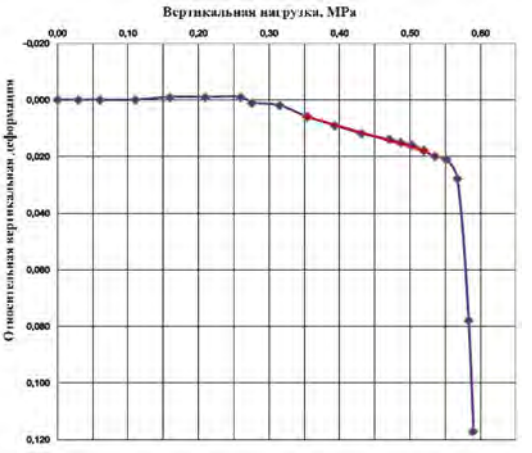

Figure 5. Results of triaxial clay tests.

Thus, to study the stress-strain state in an elastoplastic model, it is necessary to determine the strain modulus, Poisson's ratio, and secant strain modulus. Figure 5 shows that the results of triaxial tests of clays were obtained at the initial clay data-W=14.3%, p=1.85 g/^{cm3}, e=0.695, modulus of deformation-E = 13.8 MPa; Poisson's ratio-v = 0.21; secant modulus of deformation-E =7.2 MPa.

We will make a forecast of basement sediment using the Nonsolan applied geotechnical program (Japan) using the finite element method in the elastic-plastic formulation-application-Soil Creep. To construct a system of finite element equations, we use the condition that the powers of contour forces at displacement velocities and internal stresses at strain velocities are equal. Also, the forecast of basement sediment requires consolidation and creep parameters, which are determined using compression tests of clays (Figure 6).

To determine $_{C}v$ *and Ca* by the logarithmic method, we construct $_{a}$ consolidation curve in the coordinates: relative strain ε (ordinate) - logarithm of time *lg t* (abscissa). The curve should be used to find the strain corresponding to 100% primary compression at a given load. For this purpose, a tangent is drawn to the final section of the curve $\varepsilon = f(lg\ t)$. Then draw a tangent to the steepest part of the curve (Figure 6).

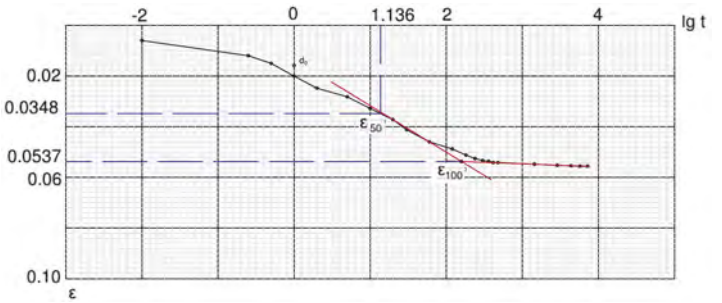

Figure 6. Consolidation charts for determining calculated consolidation parameters and creep.

Filtration consolidation coefficient-C_{v} (^{cm2}/year), calculated by the formula:

$$Cv = T_{50}h^2/t_{50}, \tag{29}$$

where T_{50} is the coefficient (time factor) corresponding to the degree of consolidation of 0.5;

50_t – time corresponding to 50% primary compression, min.

The creep coefficient- C_a (dimensionless value) is determined by the tangent of the angle between a straight line parallel to the abscissa axis and a straight line segment of the curve in the secondary consolidation section using the formula:

$$C_a = tg_a = \varepsilon(t_2) - \varepsilon(t_1)/lg\ (t_2) - lg\ (t_2), \tag{30}$$

where $\varepsilon(t2)$ and $\varepsilon\ (t1)$ are the values of the sample deformation at the secondary consolidation site; *t1* and *t2* are the time corresponding to the deformations $\varepsilon(t2)$ and $\varepsilon\ (t1)$, min.

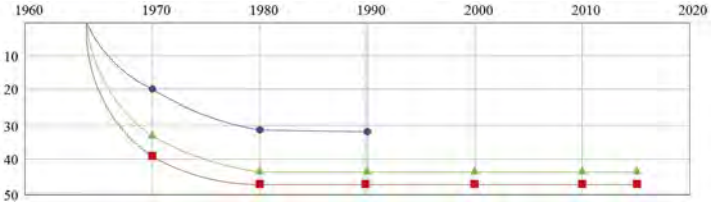

Figure 7. Graphs of basement sediments (experimental "round – elastic", "triangular – full-scale" and theoretical ones using the elastic-plastic model).

3 CONCLUSION

It was found that the total draft for the blast furnace was 43.0 mm. Elastic precipitation due to soil compaction was 32.0 mm and creep precipitation – 12.0 mm.

To compare the calculated foundation precipitation with the actual and maximum permissible values, the foundation precipitation was recalculated. The draft was determined for the design load: for a blast furnace-300 t/^{m2}, with the dimensions of slab foundations: 27.0 m in diameter, with a depth of 3.5 m. Precipitation was calculated using the methods recommended by the regulatory literature. Comparison of calculated, actual, and maximum permissible precipitation showed that the actual precipitation of blast furnace foundations is several times less than the calculated precipitation recommended by the regulatory literature. The actual precipitation of the blast furnace is many times less than the calculated and limit values. Calculations of the forecast of basement precipitation using the Nonsolan applied geotechnical program (Japan) using the finite element method in the elastic-plastic formulation showed that the discrepancy between the actual and theoretical precipitation is no more than 15%.

Comparing the results obtained, we come to the conclusion that it is necessary to conduct additional studies to accumulate and systematize new data and make amendments to the generally accepted formulas for determining basement sediments.

Adjustments and corrections of the main calculation formulas will allow us to approximate the obtained data on the depth of propagation of the main compressive stresses, the amount of precipitation, and the calculated soil resistances under the base of foundations obtained theoretically to the practical values revealed by construction practice and long-term observations of deformations of buildings and structures in operation.

More accurate (real) calculated values will reduce the total cost of construction, since the design of building foundations is carried out with a large margin of safety, which entails unnecessary labor and material costs.

Freeze-thaw shrinkage potential in fine-grained soils

S. Nishimura & K. Yamaoka
Hokkaido University, Sapporo, Japan

ABSTRACT: Fine-grained soils cause permanent volume reduction when subjected to freeze-thaw cycles, even when obvious ice-lensing and other meso-/macroscopically inhomogeneous structures do not appear. The volume reduction amount is dependent on the stress level. The envelope of the eventual states reached after many freeze-thaw cycles is defined as Freeze-Thaw Residual Line (FTRL), and its characteristics are investigated for fine-grained soils with different plasticity. Possible correlations between FTRL parameters and plasticity index are indicated. Comparison between natural and reconstituted samples is also made, which revealed that natural soil structure was not easily lost after multiple freeze-thaw cycles.

1 INTRODUCTION

The volume reduction seen in fine-grained soils due to freeze-thaw cycles can be an engineering concern in many contexts. The effective stress and hence the shear strength are reduced immediately after thawing and before the pore water pressure dissipation (Nixon & Morgenstern 1973). In longer term, this will lead to thaw consolidation and can result in uneven settlement or ground distress. Both in natural and artificial ground freezing, therefore, an analytical model based on sound understanding of the physical processes behind freeze-thaw-induced volumetric straining is desired. The first author (Nishimura 2021) proposed a Thermo-Hydro-Mechanically (THM) coupled model for describing mesoscopic plastic volumetric strain associated with freezing and thawing processes by upscaling smaller-scale internal water transfer driven by inhomogeneity in water potential at subzero temperature. The model is formulated in a rate form, and can therefore be adopted in incremental, nonlinear numerical analysis based on continuum mechanics, such as finite element analysis.

The first part of this paper provides a summary of the model. It will be shown that the Freeze-Thaw Residual Line, defined as a characteristic line in the volume – effective stress space, and the parameters to represent it are at the core of the model. The second part of this paper presents experimental exploration of these parameters by testing fine-grained soils with different plasticity. The eventual aim is to correlate the degree of plastic straining, or the shrinkage potential, due to freeze-thaw cycles to such indices as plasticity index, I_p.

2 MODEL FOR FREEZE-THAW-INDUCED PLASTIC VOLUMETRIC STRAIN

2.1 *Freeze-Thaw Residual Line (FTRL)*

When normally consolidated fine-grained soils are subjected to one-dimensional, closed-system freeze-thaw cycles under constant stress, the volume reduction accumulates and converges to a limit value. If the soil specimen is small and freezing rate is high such that the internal water transfer to frozen fringe is minimal, this volume change is uniform across the specimen, and can hence be regarded as behaviour of mesoscopically representative element (Nishimura et al. 2020). Figure 1 shows example of the experimental results on high-plasticity Kasaoka clay, involving five cycles of freezing to –20 °C and thawing to +24 °C under the vertical stress of 100, 200, 400 or 800 kPa. By extrapolating the results to an infinite number of cycles, the residual states are defined by a line in the specific volume v – the vertical effective

DOI: 10.1201/9781003299127-269

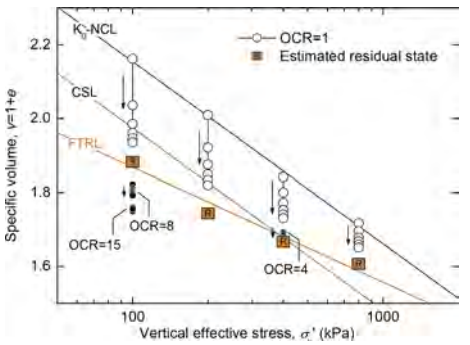

Figure 1. Freeze-thaw-induced volume changes in kasaoka clay (after Nishimura et al., 2020).

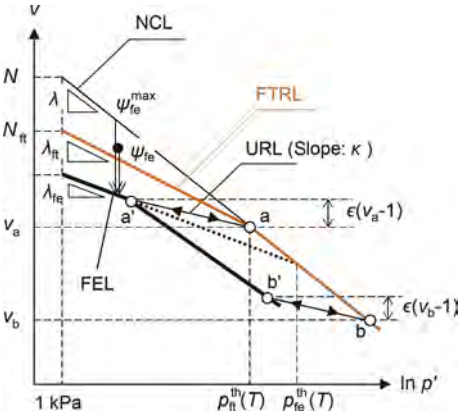

Figure 2. Definitions of FTRL, FEL and ψ_{fe} (after Nishimura, 2021).

stress σ_v' space. This line is defined as the Freeze-Thaw Residual Line (FTRL). It is straightforward to identify this line from experiments, and the two parameters are deduced; λ_{ft} for its slope and p_{ft}^{th} for its intersect with the Normal Compression Line (NCL) for a given freezing temperature T. In addition to such standard material parameters as λ, κ and N, these parameters are used in the proposed model. Here, λ: slope of the NCL, κ: slope of the Unloading-Reloading Line (URL), and N: the intercept of NCL at $\sigma_v' = 1$ kPa. Five freeze-thaw cycles are usually sufficient to estimate the FTRL.

2.2 *Freeze Equilibrium Line (FEL) and shrinkage potential ψ_{fe}*

The FTRL only describes the state after the thawing, and the state during freezing, where the effective stress σ_v' is not clearly defined, remains unclear. The proposed model, following Nishimura & Wang (2019), assumes that the state during freezing is where the URL should have started to bring the post-thaw state onto the FTRL. As Δv during thawing and κ can be measured, the URL can be followed back from the FTRL. The frozen state after many freeze-thaw cycles estimated this way is on the Freeze Equilibrium Line (FEL), as schematically shown in Figure 2. Nishimura (2021) explained the meaning of the FEL based on an idealised micromechanical soil structure consisting of two distinct micro-domains with different water retentivity. It corresponds to a state reached at prolonged freezing, where any internal imbalance of water potential disappears.

It is difficult in reality to directly observe the FEL. However, its geometric relationship with the FTRL allows it to be determined from λ_{ft} and p_{ft}^{th} as:

$$\lambda_{fe} = \frac{(1+\epsilon)k\lambda_{ft}}{k+\lambda_{ft}\epsilon} \tag{1}$$

$$p_{fe}^{th}(T) = p_{fe}^{th}(T)\exp\left\{\frac{\epsilon\lambda_{fe}-\kappa}{\kappa\lambda-\lambda_{fe}}(N-1-\lambda\ln p_{ft}^{th}(T))\right\} \tag{2}$$

where ϵ is the volume expansion factor for undrained freezing, and the other parameters are as defined in Figure 2. The proposed mode uses ψ_{fe}, the excess of v over the FEL at given σ_v', as a potential to cause the plastic volumetric strain arising from the internal water equilibration. By considering Darcian flow in freezing porous media between the micro-domains within the assumed soil structure (see Nishimura 2021, for detail), the plastic volumetric strain rate, $\dot{v}_p$, is expressed as:

$$\dot{v}_p = -\frac{1}{\rho_1 g}\frac{\alpha}{L^2}ks\frac{\langle\psi_{fe}\rangle}{\psi_{fe}^{max}} \qquad (\langle\psi_{fe}\rangle = \psi_{fe} \text{ for } 0 \le \psi_{fe},\ \langle\psi_{fe}\rangle = 0 \text{ for } \psi_{fe} < 0) \tag{3}$$

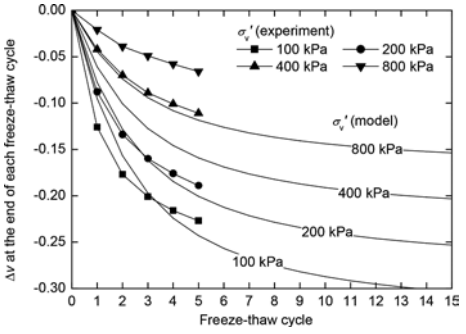

Figure 3. Simulation of freeze-thaw-induced volume changes in Kasaoka clay (after Nishimura, 2021).

Table 1. Tested clays (LL: liquid limit, PL: plastic limit).

Sample	LL (%)	PL (%)	λ
Kasaoka clay	62	28	0.216
Kaolin	46	32	0.087
Kibushi clay	73	38	0.192
Fujinomori clay	44	27	0.093
Higashi-Osaka clay 1	88	33	0.212
Higashi-Osaka clay 2	110	49	0.242
Tuffaceous clay	61	25	0.153
Atsuma clay	48	23	0.101

where $\rho_l g$ is the liquid water unit weight, k is the hydraulic conductivity and s is the cryogenic suction. A parameter α/L^2 is related to the characteristic scale of the problem, to be determined by fitting the model to experimentally observed volume – freeze-thaw cycle number curves. Equation 3 forms the core of the proposed model. Of course, these equations alone are not sufficient to describe the freeze-thaw behaviour. They are meant to be coupled with other THM equations representing, for example, soil-water characteristics curve, soil skeletal constitutive relationship, liquid saturation-dependent hydraulic conductivity, effective stress equation, etc. Examples of these additional equations are given by Nishimura (2021), but other equations may be used. Figure 3 shows examples of modelled volumetric changes due to freeze-thaw cycles, in comparison to the experimental results. The trend is well described by the model.

3 SHRINKAGE POTENTIAL OF FINE-GRAINED SOILS

3.1 *Experimental investigation: Correlation of FTRL parameters with plasticity*

The key model parameters λ_{ft} and p_{ft}^{th} can be determined by experiment in relatively straightforward manners. However, it will be helpful to have guiding knowledge of the parameter values expected for soils within a typical plasticity range. An experimental program has been undertaken in which eight reconstituted soils with different plasticity are tested, as shown in Table 1. They were subjected to five freeze-thaw cycles between +24 °C and –20 °C, following the method by Nishimura et al. (2020). The plasticity index range was 14–61, all tested at σ_v' = 100-800 kPa. In the following, p_{ft}^{th} values cited are all for –20 °C.

Figure 4 shows the observed value of λ_{ft} and p_{ft}^{th} plotted against the soils' plasticity. Here the parameter λ_{ft} is normalised by λ to make the non-parallelism between the FTRL and NCL clearer. There is a weak correlation, with higher I_p leading to lower λ_{ft}/λ. At I_p = 14 (Kaolin), λ_{ft}/λ = 1, meaning that the FTRL and NCL are parallel to each other, and therefore p_{ft}^{th} (their intersection) cannot be defined. Nishimura et al. (2020) discussed this phenomenon observed for low-plasticity soils, and attributed their volume changes to soil skeletal deformation hysteresis, rather than the water potential equilibration – i.e. a mechanism different from that assumed in the model. In any case, the offset of the FTRL from NCL is very small for low-plasticity soils, and the freeze-thaw-induced strain is minor. The correlation between p_{ft}^{th} and I_p seems weaker still, scattering between about 2,000 and 10,000 kPa. Data are not shown where p_{ft}^{th} cannot be defined for the above reason. At low to medium stresses, the NCL-FTRL distance was generally greater for lower I_p.

3.2 *Influence of natural soil structure*

A limited number of natural samples were also tested to understand the influence of natural structure, which is characterised by a curved NCL located outside the reconstituted, 'intrinsic' NCL (Burland, 1990). Both natural and reconstituted samples of Atsuma clay and Higashi-Osaka clay 1 and 2 were tested to make comparison. All the samples of each clay were taken from a single

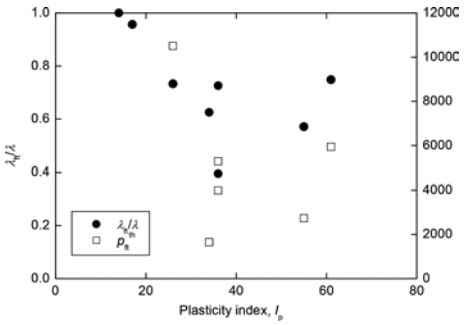

Figure 4. Correlation of FTRL parameters λ_{ft} and p_{ft}^{th} with plasticity index I_p.

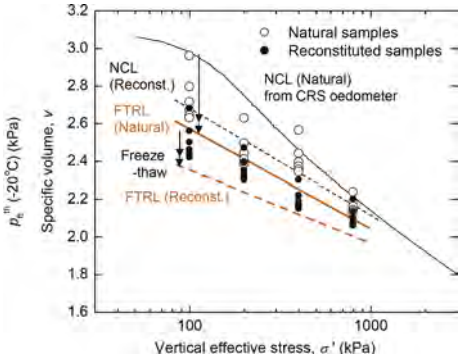

Figure 5. State changes by freeze-thaw cycles in natural and reconstituted Higashi-Osaka clay 2.

borehole core of 100 mm in height and 76 mm in diameter, without re-using. This was possible because the experiment uses very small specimens, with 20 mm in height and 20 mm in diameter. Figure 5 shows the NCLs and FTRLs for both types of samples of Higashi-Osaka clay 2. A continuous compression curve obtained by a constant-rate-of-strain oedometer test on the natural sample is also shown in the same figure, as connecting individual test origins from freeze-thaw cycle tests does not always reveal the compression curve clearly. Despite the significant plastic volume compression, the eventual states of the natural sample after five freeze-thaw cycles do not appear to be asymptotic to the reconstituted FTRL. The natural soil seems as if it has its own FTRL, and the plastic strain due to the freeze-thaw cycles were not sufficient to cause sufficient destructuration that would bring the FTRL of natural sample to that of reconstituted soil. This is despite the fact that the amount of compression after five cycles at, for example, $\sigma_v' = 100$ kPa (from $v = 2.96$ to 2.63, or 11% strain) corresponds to mechanical compression well over the apparent yield stress seen around 100-150 kPa. This investigation is still preliminary, and more tests with a larger number of freeze-thaw cycles may be necessary to reach more definitive conclusions. However, the results hint at relatively robust natural structure against freeze-thaw action.

4 CONCLUSIONS

This paper firstly provided a digest of the model proposed by Nishimura (2021) for describing freeze-thaw-induced plastic volumetric strain. One of the key components is the Freeze-Thaw Residual Line (FTRL) defined in the volume – effective stress space. The two parameters needed to define the FTRL were obtained for reconstituted fine-grained soils with different plasticity. Correlations were recognised between the model parameters and the plasticity index, I_p, which may be useful in estimating soil's shrinkage potential against freeze-thaw cycles in early stages of ground investigation. Natural soils seem to have their own FTRLs that are not easily disturbed and do not coincide with reconstituted FTRLs even after significant compression.

ABSTRACT: In cryolithozone the problem of buildings and structures adaptation to the increasing climate warming is relevant. Solutions based on thermal insulation of permafrost are being developed. The purpose of this study was to evaluate the effectiveness of a foamed polyethylene (FP) insulation in the base of a building on a pile foundation. For 2022-2092, taking into account the climate warming, a forecast of the temperature in the soil base and piles bearing capacity was carried out in the Frost 3D software. Results shows that FP installation keeps the base in a frozen state and reduce the rate of the seasonally thawed layer increase (in 2052, it's 2.7 m more outside the building). However, the average annual permafrost temperature raises (by 1°C in 2042). The piles bearing capacity increases up to 10% and 50% (improper building maintenance in last case) with FP installed.

1 INTRODUCTION

The Earth's climate is changing and global warming occurs according to the most pessimistic scenario: the intensity and speed of changes are much greater than the previous estimates of the scientific community suggested. In 2010-2019, there was a global increase in surface air temperature by 0.9-1.2 °C. Temperature growth is observed in almost all regions. Warming in the Arctic region is predicted to be twice as strong as the global average (IPCC, 2021).

An urgent issue is the adaptation of buildings and structures located in the cryolithozone to current and predicted climate changes. Solutions based on the use of thermal insulation materials are common. Installation of thermal insulation on permafrost soils is used in railways (Ashpiz et al. 2008) and highways (Bessonov et al. 2022), industrial and civil construction (Ilyichev et al. 2003; Alekseev, Konash, Khrustalev 2018; Nikiforova & Konnov 2022), in mining (Goncharov & Belchenko 1998).

There are solutions for the I principle of construction on permafrost soils (preserving the frozen state) with the use of strip foundations on sand embankment with thermal insulation (Alekseev, Konash, Khrustalev 2018).

The purpose of this study is to evaluate the effectiveness of a foamed polyethylene (FP) insulation in the base of a building on a pile foundation.

Advantages of FP are low average density and thermal conductivity, high elasticity, sufficient strength characteristics, resistance to aggressive media. This material is suitable for use in systems operating at low (up to -60 ° C) and alternating temperatures (Semenov et al.

DOI: 10.1201/9781003299127-270

2018). FP is steam- and moisture-proof (Zhukov, Ter-Zakaryan, Bessonov et al. 2018). A heat-reflecting foil layer can be applied to its surface, increasing its resistance to ultraviolet radiation, protecting it from moisture ingress under the insulation and mechanical damage.

2 RESEARCH METHOD

The forecast of the temperature distribution in the soil base was carried out numerically using the Frost 3D software for thermal calculations of soils (Kovalenko, 2013; Gordiychuk, 2017).

The study used the results of engineering geological investigations and temperature measurements of the soil to a depth of 15 m at construction site in the Oktyabrsky district of Yakutsk. Soil thermal properties are given in Table 1. The soil profile of the model is presented in Figure 1.

Table 1. Soil thermal properties.

Soil type	Volumetric heat capacity, kcal /m^3 °C		Thermal conductivity coefficient, kcal/ h m °C		Freezing point $T_{bf,}$ °C
	unfrozen soil C_{th}	frozen soil C_f	unfrozen soil λ_{th}	frozen soil λ_f	
Anthropogenic soil fine sand, strongly saline	670	510	1.85	2.05	-2.1
Lean and silty clay soft, moderately saline	720	520	1.25	1.35	-1.2
Sand fine and medium, moderately saline	750	560	2.15	2.35	-0.7
Silty clay frozen, weakly saline	800	560	1.55	1.60	-0.7
Sand fine frozen, weakly saline	720	520	1.65	1.85	-0.3
Sand medium frozen, weakly saline	750	560	2.15	2.35	-0.6
Sand fine frozen	660	490	1.65	1.85	-0.2

Zero heat flux (q=0) was set at the lower and lateral boundaries of the calculated area. The dimensions of the calculated area were selected from the condition that the temperature distribution at the lateral boundaries should be similar to the distribution obtained during the calculation without taking into account the thermal effects of the modeled objects. A soil mass with a depth of 15 m (according to Russian standard SP 446.1325800.2019 "Engineering geological investigations for construction. General rules" and results of investigations) and a plan size of 26 x 32 m was modeled.

Modeling was carried out on the basis of the concept developed by TEPOFOL company to protect the pile foundation of a building designed according to I principle of construction on permafrost (preserving its frozen state) with the FP insulation. This concept assumes installation of a horizontal FP layer under a residential building with an open ventilated space and beyond its borders. At some distance from the building along its perimeter to the permafrost at 2,1 m depth, a vertical layer of FP is arranged (Figure 1). The insulation is installed out of rolls, its edges are sealed with a lock joint, which is sticked together with a construction fan. A protective layer of soil is provided above the insulation.

When modeling the FP, the following thermophysical properties were set, provided by TEPOFOL company: thermal conductivity coefficient $\lambda_{th} = \lambda_f$ = 0,039 Вт/(м·°С), ρ = 25 kg/m^3. Volumetric heat capacity was $C_{th} = C_f$ = 33,5 kJ/(m^3·°C).

A time interval of 70 years was modeled, starting from 2022 to 2092. Climatic conditions affecting heat exchange on the ground surface were set for Yakutsk according to long-term

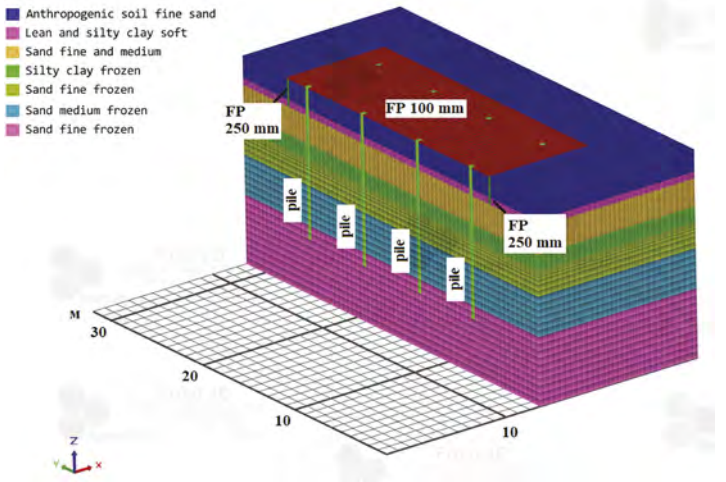

Figure 1. Cross section of the calculated area in the YZ plane.

observations given in SP 131.13330.2020 standard and the Climate of Russia reference book (Razuvaev et al. 2020).

Taking into account the small size of the studied area, a regional climate model of future climate changes in Russia of the Voeikov Main Geophysical Observatory was chosen as the source of the predicted temperature values (Kattsov et al. 2016,2019; Shkolnik & Efimov 2015). This model is characterized by a high spatial resolution (25 km). The trend of increasing surface air temperature for Yakutsk was determined according to the forecast map of anomalies of the Roshydromet Climate Center, based on ensemble calculations using this model, under the scenario of changes in the content of greenhouse gases and aerosols in the atmosphere RCP 8.5.

The prediction of changes in the bearing capacity of piles over time due to climate warming with installation of FP thermal insulation was made by numerical method in the Frost 3D software module called Frost.Pile. In this module the calculation of the bearing capacity of piles is implemented, according to SP 25.13330.2020 and SP 24.13330.2011 (in the case of thawed soils) Russian standards on the basis of the forecast thermal calculation performed in the Frost 3D. Within the problem considered in the article, the technology of pile construction was not taken into account in the thermal calculation. Calculation of the bearing capacity of piles in Frost.Pile is made in accordance with the SP 25.13330.2020 formula:

$$F_u = \gamma_t \gamma_c (RA + \sum_{i=1}^{n} R_{af,i} A_{af,i}) \quad (1)$$

where γ_t – a temperature coefficient that takes into account changes in the temperature of the base soils due to random changes in the outdoor temperature; γ_c – coefficient of working conditions of the base; R – calculated resistance of frozen soil under the lower end of the pile, kPa; A – the cross-sectional area of the pile, m^2; $R_{af,i}$ – calculated shear strength along the lateral freezing surface of the pile within the i-th soil layer, kPa; $A_{af,i}$ – the freezing surface area of the i-th soil layer with the side surface of the pile, m^2; n – the number of layers of permafrost soil selected in the calculation.

In the Frost.Pile module, the load-bearing capacity of a bored precast reinforced concrete pile located under the middle of the building was calculated. The pile is b = 0.35x0.35 m in size with a tip at the depth of 10 m. The load on the pile is 80 tons.

When calculating the bearing capacity of the pile, a constant value of the temperature coefficient γ_t = 0.851 was used, given in the work of Khrustalev L.N., Emelyanova L.V. (2013) for Yakutsk.

3 RESULTS

The installation of the FP layer (horizontal with a thickness of 100 mm and vertical – 250 mm at 2.1 m depth) in an open ventilated space under a building allows to keep its soil base in a frozen state. After 30 years the soil base begins to thaw under the influence of climate warming. In 2052 the thickness of the seasonally thawed layer (STL) outside the building will be 3 m, under the building – 0.3 m (Figure 2).

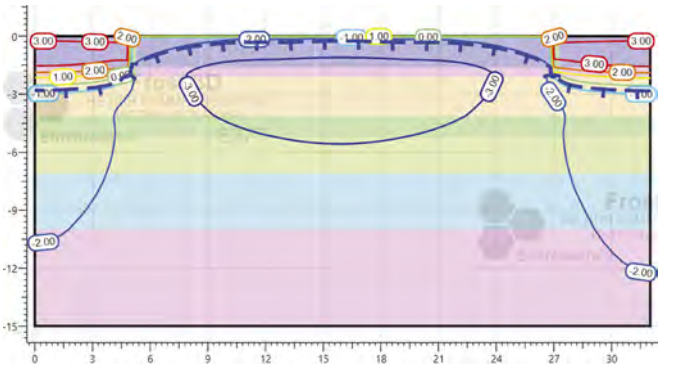

Figure 2. Temperature distribution in the soil mass for 2052 (for a building with an open space under it after 30 years of operation) in the warm season (September) with the FP layer (the thickness of the horizontal layer is 100 mm, the vertical layer is 250 mm to a depth of 2.1 m).

The horizontal layer of the FP reduces the cooling effect of the ventilated space under a building on its soil base in winter. The average annual temperature of permafrost soil is increasing. In 2042 for the base of a building with an open ventilated space, it will be -3.4 °C without the FP installation and -2.4 °C with its installation.

The load-bearing capacity of piles of a building with an open ventilated space under it varies slightly when installing the FP. For a building which has a closed ventilated space with blowouts, the FP usage increases the bearing capacity of piles to 10% (Figure 3).

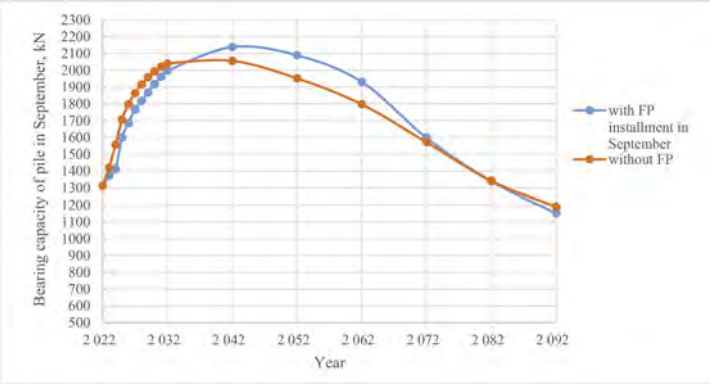

Figure 3. The bearing capacity of the pile in September for 70 years of a building operation (space under a building with blowouts closed for the summer) the thickness of the horizontal FP is 100 mm, the vertical one is 250 mm to a depth of 2.1 m.

The bearing capacity of piles was calculated based on the temperature distribution in the soil mass for the case when there is improper maintenance of a building with an open ventilated space and a snow cover is formed over the insulation. With the FP installed, a significant increase in the bearing capacity of piles (up to 50%) was obtained (Figure 4), which allows

extending the life of a building and reducing the designed number of piles. This increase in load-bearing capacity will be especially evident for existing buildings with the specified improper maintenance. The use of FP for existing buildings is the subject of further research.

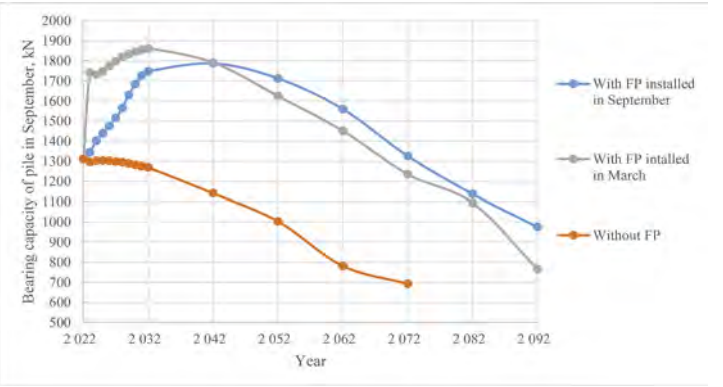

Figure 4. The bearing capacity of the pile in September for 70 years with improper maintenance of a building in winter (snow builds up in open space under it) with a thickness of the horizontal layer of the FP 100 mm, vertical – 250 mm to a depth of 2.1 m.

The installation time of the FP (September or March) in the first 10 years leads to a difference in the bearing capacity of piles from 20 to 10% (larger values are for March). In subsequent years of the building operation, the time of FP installation basically does not affect the temperature distribution in the soil mass and, accordingly, the bearing capacity of piles (the difference is up to 7%).

4 CONCLUSION

Numerical modeling of the soil temperature regime in the Frost 3D software with thermal insulation made of foamed polyethylene (FP) in geological conditions of Yakutsk showed the following:

1. The installation of the FP layer under a building with an open ventilated space allows to keep its soil base in a frozen state. After 30 years the base begins to thaw under the influence of climate warming; in 2052 the thickness of the seasonally thawed layer outside the building will be 3 m, under it - 0.3 m. Horizontal layer of the FP reduces the cooling effect of the ventilated space under a building on its soil base in winter. The average annual temperature of permafrost soil is increasing. In 2042 for the base of a building with an open ventilated space, it will be -3.4 °C without the FP installation and -2.4 °C with it.
2. The load-bearing capacity of piles of a building with an open or closed ventilated space with blowouts varies slightly when installing the FP (up to 10%). For the case when there is improper maintenance of a building (snow builds up in ventilated space) a significant increase in the bearing capacity of piles (up to 50%) is obtained, which allows extending the life of a building and reducing the designed number of piles.
3. The installation time of the FP (September or March) in the first 10 maintenance years of the building leads to a difference in the bearing capacity of piles from 10 to 20% (with larger values in March), but later the difference decreases.

Composite anti-frost heaving pile

A.V. Boyarintsev, K.M. Astashkevich & S.V. Lanko
Saint Petersburg State University of Architecture and Civil Engineering, Saint Petersburg, Russia

ABSTRACT: Frost heave is a widespread phenomenon for northern countries, especially for Russia. The soil increases its volume and influence the foundation of building during soil freezing. This effect is most dangerous for low weight buildings. The using of anchoring is most effective solution for protection the building foundation against frost heave force impact. In this paper, the new solution for protection of building foundation is shown. This solution is composite anti-frost heaving pile. The main idea is described. The results of researches show effectiveness of using this type of piles.

1 INTRODUCTION

The Far North, Siberia and the Far East are the main development regions of the Russian Federation. The wealth of these regions with natural resources, minerals and the tourism potential, encourage the government of the Russian Federation, as well as the management of large companies to develop these territories. The success of regional development directly depends on the reliability for buildings and structures erected in these territories.

The soil conditions of Russia, as in any other countries, have some features due to the history of the origin of soils, climate and other factors. One of such features that Russian geotechnical engineers must consider is the phenomenon of frost heave, which is widespread throughout the country. Freezing to depths of 0.5 meters in the southern regions, up to 3.5 meters in the Far North and Far East, the soils increase in volume and affect the structures immersed in them. According to studies (Boyarintsev 2019), frost heave in 20% of cases is the cause of accidents of civil buildings located on frozen soils, and in 35% - of infrastructure facilities. According to Russian Railways reports (Tsvigunov 2018), 48% of the pylons of catenary system operated on the Far Eastern railway are in disabled condition, and one of the main reasons is frost heave.

Thus, the development of structures that effectively resist frost heave is one of the key factors to increase the reliability of buildings and constructions, and, as a result, the successful development of these regions.

2 METHODS OF FROST HEAVE PREVENTION

Copy All methods of frost heave prevention can be divided into three main groups: thermal, ameliorative and constructive (Karlov 2007).

The most effective and popular are constructive ones that allow to change the parameters of the foundation structure so that the intensity of shearing heaving stresses decreases, and the efficiency of their acceptance increases. The main types of constructive methods are the reduction of an adfreezing area, sprinkling, reduction of adfreezing strength between the freezing soil and the foundation material, anchoring of underground structures in soil layers that are not subject to freezing and the device of inclined faces.

DOI: 10.1201/9781003299127-271

According to the previously mentioned report (Tsvigunov 2018), 80% of deformed buildings have a post footing, and only 8% are piled foundation. Thus, using piled foundations, a constructive method of protecting the foundation from the impact of shearing heaving stresses is implemented, namely anchoring. In addition, in practice, two or three constructive methods can be implemented simultaneously, and such piles are called anti-frost heaving piles.

Nowadays there are several options for the construction of anti-frost heaving piles. They are concrete pile covered with polymer compound; concrete and steel piles covered anti-frost heaving lube oils BAM-3 and BAM-4 or heat-shrinkable modified polyethylene (Alyavdin et al. 2013) in the area of contact with the active layer.

To upgrade the anchoring properties, any of the known methods of increasing the total bearing capacity of piles can be applied, for example: screw piles with one or more screws, welding of scrap metal (Iospa et al. 2015) or screws (Noskov & Svidersky 2019) for steel piles and transverse ribs with a certain fin pitches for concrete piles. The dimensions of these transverse ribs are larger than pile shaft. The ribs are made when concreting piles by filling cavities on the inner surface of a special formwork with concrete (Naberezhny & Savvina 2016).

Pyramidal concrete double-tapered piles (Figure 1a) are also anti-frost heaving ones. Their peculiarity is the variation of face slope across the length. So, in the zone of the active layer, the pile widens from top to bottom, thereby implementing a constructive method of frost heave prevention, and further, below the active layer, it narrows, which provides an increase in the bearing capacity under the compressive load (Dobrynin et al. 2004, Dobrynin & Yushkov 2013). A similar principle is realized in a steel anti-frost heaving pile (Figure 1b).

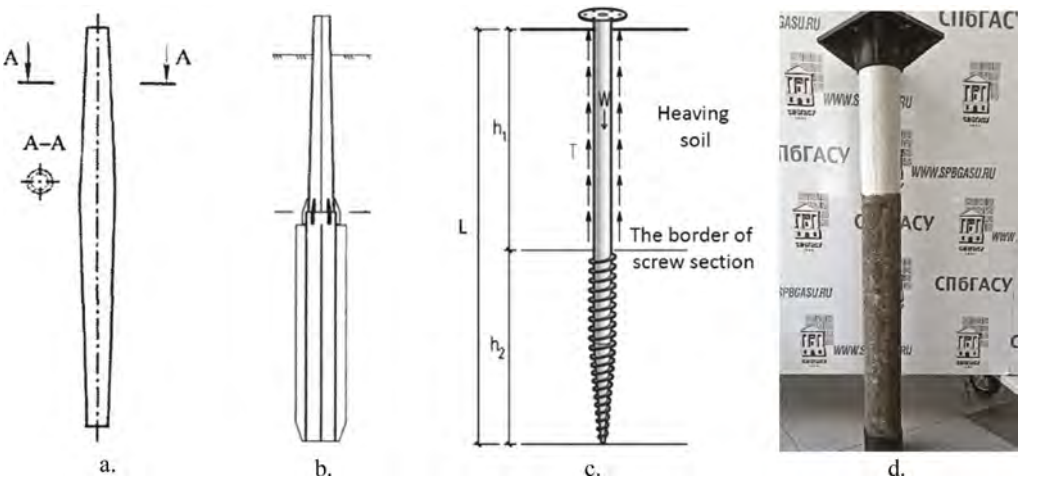

Figure 1. Caption of a typical figure. a. Pyramidal double-tapered pile (Dobrynin & Yushkov 2013) b. Steel anti-frost heaving pile (Romanov & Kasatkin 2018) c. Screw tapered pile (Noskov & Svidersky 2019) d. Composite anti-frost heaving pile (Boyarintsev 2020b).

Despite the effectiveness of countering shearing heaving forces, the described designs have some disadvantages: the lube oils BAM-3 and BAM-4 are difficult to fix on the pile shaft securely; heat-shrinkable anti-frost heaving hoses have insufficient adhesion to the pile material; concrete piles are not always economical, since pyramidal double-tapered and ribbed piles are labour-consuming in manufacturing.

Analyzing the shortcomings of the described solutions, the author proposes a new design of an anti-frost heaving pile which preserves all the principles of present structures and is devoid of their main disadvantages (Boyarintsev 2020b) (Figure 1. d). The main difference of the

proposed pile is that its body is made of composite pipe. As a material, it is proposed to use a pipe made by filament-winding technique or pultrusion (Galinovsky et al. 2019) of a polymer composite material (PCM) such as glass-fiber or basalt-fiber reinforced polymer or a combination of them.

Due to the increased corrosion resistance, the internal space of the pile can remain empty, and all external loads will be supported by the composite pipe. If the pipe's own strength and rigidity are insufficient, the interior space can be filled with concrete or reinforced concrete.

The mechanical properties of a composite pipe are enough to perceive an axial compressive load, as demonstrated by an experiment in which a composite hollow pipe, a concrete cylinder and a composite pipe filled with concrete were tested. The results show that the ultimate compressive stress supported by the composite pipe is 132 MPa, and the use of a composite shell as an external reinforcement of a concrete cylinder contributes to an increase in the ultimate compressive load on a concrete sample from 30 to 62 MPa.

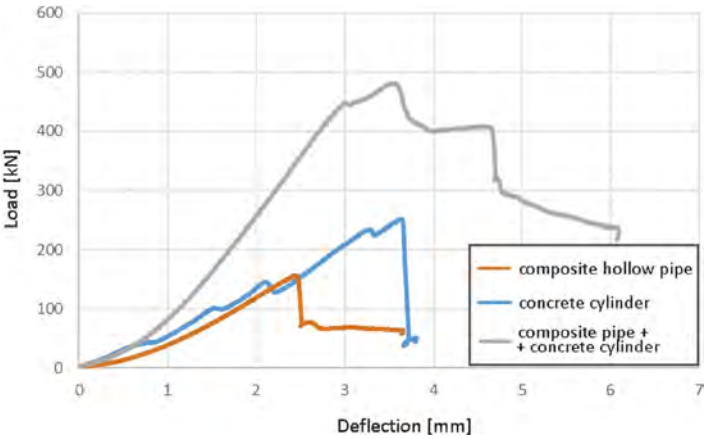

Figure 2. Testing samples for axial compression.

The recommended method of pile driving in permafrost soils is drilling - the most common method of pile placement in in permafrost. It is recommended to fill the spaces between the hole and the pile with sand-cement mortar, or with drilled sludge.

The anti-frost heaving properties of the pile are achieved through the simultaneous application of three methods of countering shearing heaving forces: reduction of the adfreezing strength of the soil and pile in the active layer; anchoring in the soil layers below the active layer; reducing the frost depth.

The decrease in adfreezing strength from the use of polymers is also confirmed by the author's experiments (Boyarintsev & Lanko 2019b). 6 samples of fiberglass, in the form of rings with a diameter of 100 mm and a height of 50 mm, made by pultrusion, and 8 samples of steel hot-rolled seamless tube, were accepted for comparison. The samples were filled with the same clay soil, frozen and then tested according to the method (Boyarintsev 2020a). The experiment was carried out conditionally instantly, with a stem shifting speed of 5 mm per second. The test results show that adfreezing strength of fiberglass samples is 28% lower in relation to steel, and 42% lower in relation to concrete.

The improvement of the anchoring properties of the pile can be achieved by increasing its bearing capacity in the ground by the method (Boyarintsev & Lanko 2019b). In continuation of the experiment described earlier, 6 fiberglass samples were tested, the inner surface of which was covered with sand with a particle size of at least 2 mm. The test results show that adfreezing strength of these samples is 30% higher than adfreezing strength of steel and is comparable

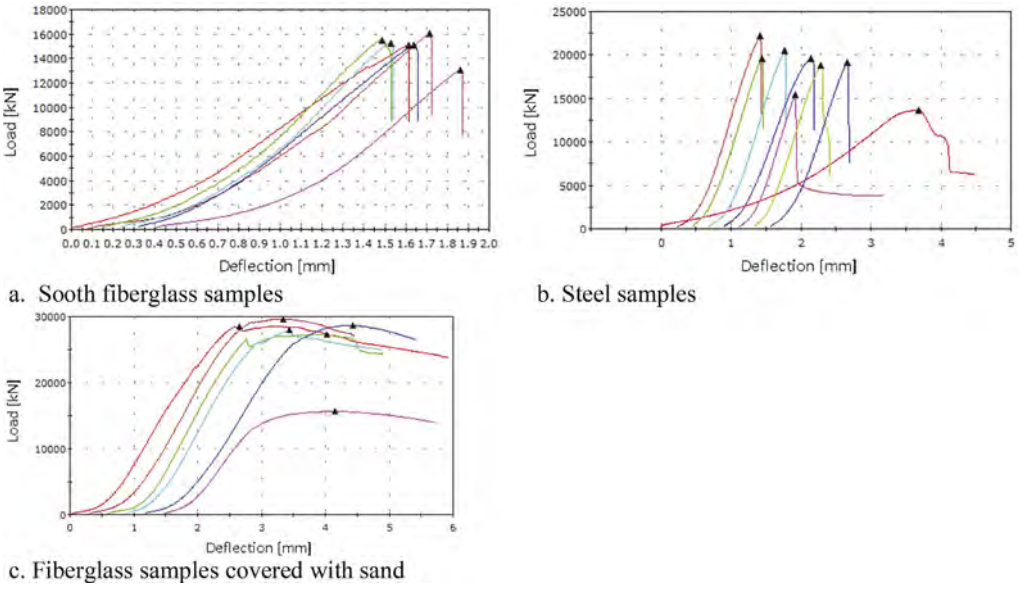

Figure 3. Adfreezing strength results.

to concrete. At the same time, the cut occurred not on the surface of the material-soil, but soil-soil, as evidenced by the nature of the test curve (Figure 3).

3 ADVANTAGES OF ANTI-FROST HEAVING PILES

Numerical simulation of the soil freezing process around single fiberglass and steel piles shows that a funnel of frozen soil is formed around the steel pile, the height of which varies from 20 to 5% of the freezing soil depth over a period of negative temperatures, while this funnel does not form at all around the anti-frost heaving composite pile (Boyarintsev & Zybtseva 2019) (Figure 4). This is because the fiberglass thermal conductivity is less than the soil thermal conductivity, and significantly less than the steel one. Thus, the use of composites helps to reduce the freezing depth, and, accordingly, the shearing heaving stresses. In addition, the curvature of the freezing front towards the pile contributes to the migration of moisture to the material surface, which is confirmed by numerical calculations (Kudryavtsev 2004). Water fills all voids at the pile-ground boundary, which entails an increase in adfreezing strength when it freezes. If the funnel does not form, the described effect is also excluded.

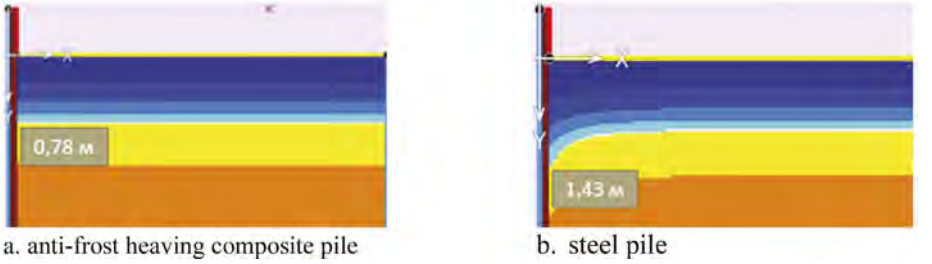

Figure 4. Distribution of soil temperatures around.

Thus, the use of the anti-frost heaving composite pile eliminates the need to apply additional material that reduces adfreezing strength in active layer, since the composite already has the necessary properties; it increases anchoring properties without requiring complex and expensive technological operations and also excludes the occurrence of a funnel from the frozen or thawed soil around the pile, which complicates the process of analytical assessment of heaving.

The advantage of anti-frost heaving composite pile compared to traditional pile materials is their strength–to–unit weight ratio. So, for concrete grade B25, this coefficient is 0.74, for steel 4.37, and for fiberglass 13.17. This ratio can affect the reduction of costs when delivering materials to the construction site, which becomes most relevant when building in hard-to-reach areas of the Far North and the Far East. Corrosion resistance of composite piles will extend the service life of the buildings erected on them and reduce the operating costs for maintaining the structure in a working condition.

4 CONCLUSION

Anti-frost heaving pile is an effective tool in protecting the foundations of buildings from the negative effects of frost susceptible soils. Its effectiveness is realized due to three features of structure and properties of the materials used. The first of them is the low thermal conductivity of the composite which the pile body is made of. This property allows the pile to prevent the intensive advance of cold into the soil mass and reduces the contact area of the pile with the frost susceptible soil. The second one is the hydrophobic properties of polymer which is the basis of the composite used. It allows to reduce adfreezing strength, which is applied to the pile in the active layer zone. And the third feature is a high roughness of the pile surface in the anchor zone, which increases the bearing capacity. In addition to the above, it should be noted such beneficial properties of polymer composites as corrosion resistance, low unit weight and significant strength. Due to these aspects, anti-frost heaving piles are prospective for implementation in geotechnical construction.

ABSTRACT: Artificial ground-freezing method is an advanced ground improvement technique. It uses artificial freezing to improve soil strength and impermeability. The cold source can be divided into brine and liquid nitrogen (LN_2). However, most studies focus on brine systems, the LN_2 method utility and the frost heave are still not well understood. To explore the applicability and frost heave of LN_2 freezing technology, a field test with LN2 freezing system is conducted. The freezing behavior and frost heave were observed according to the ground settlement and inclinometer deformation. Numerical simulations on soil frost heave were performed by PLAXIS with Frozen and Unfrozen soil model (FUS), the monitoring results are compared with numerical analysis and geophysical explorations. The results show that the LN_2 methods can effectively and quickly form frozen soil walls. The thickness of the frozen soil wall reaches 1.2m in 6 days through PLAXIS FUS model back analysis. Moreover, subsurface temperature and media changes are detected by geophysical exploration, explaining the freezing results.

1 INTRODUCTION

Artificial ground-freezing (AGF) is a particular temporary ground improvement method (Alzoubi et al., 2020). It involves introducing coolant into underground pipes to freeze groundwater in the soil. The frozen soil contacts together to form the frozen walls. The coolant of the AGF is divided into two types, brine and liquid nitrogen (LN_2). The brine freezing method is relatively low cost and long construction period. The circulating system (closed system) is used in this method with brine at -30 to -40°C. The LN2 freezing method uses a much lower temperature coolant, which is -196°C, with a direct expansion system (open system).

Although the AGF technology has been developed for decades, most research still focuses on the brine freezing method. The LN2 method utility and the frost heave displacement prediction are still not well understood. Moreover, the estimated development of underground frozen walls in the past was inferred by the trend of temperature change, which didn't consider

DOI: 10.1201/9781003299127-272

the mechanical behavior of frozen soil. To tackle these problems, the Norwegian University of Science and Technology (NTNU) and Plaxis B.V. cooperative developed a new numerical model, the Frozen and Unfrozen soil (FUS) model. Haxaire et al. 2017 first applied the FUS model to simulate the frost heave phenomenon caused by the chilled pipelines. Korshunov et al. 2020 calibration of the FUS model according to laboratory tests and in-situ monitoring results. Tuohion et al. 2021 modeled the effect of freeze-thaw on low-volume roads.

The main objective of this research is to explore the applicability and frost heave of LN2 freezing technology. Therefore a field test using an LN2 freezing method is conducted. The freezing behavior and frost heave were monitored and recorded according to ground settlement and inclinometer deformation. Numerical simulations on soil frost heave were performed by FUS mode, and the monitoring results were compared with numerical analysis and geophysical explorations.

2 FIELD TEST: LIQUID NITROGEN FREEZING METHOD

The profile of the field test is shown in Figure 1(a). The field test was conducted for a week in Yilin, Taiwan. The test location was next to the pond to ensure the stability of the groundwater level. The LN2 was supplied by a tank car. The white smoke position was the discharge end of the LN2 system. The site soil consisted of a 1.8 m cobbles backfill near the surface and a silty clay layer below 1.8 m. The groundwater level was at a depth of 1.6 m.

In the test, nine vertical freezing pipes were installed in a row. The length of the pipes was 8 m. The four PT100 thermometers, twenty ground settlement points, and three inclinometers were set up around the pipes. The arrangement details are shown in Figure 1(b).

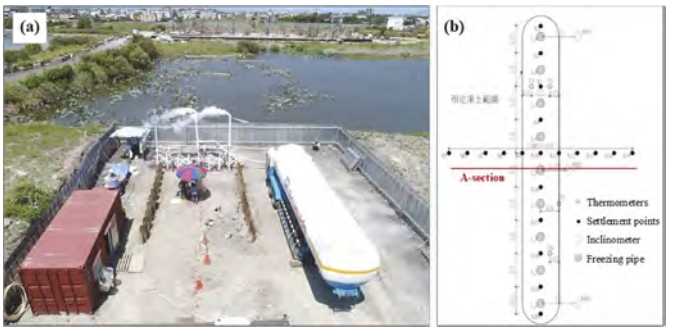

Figure 1. The liquid nitrogen freezing method field test (a) the profile, (b) the instrument arrangement details.

3 NUMERICAL SIMULATION: FUS MODEL

The FUS model is a critical-state elasto-plastic mechanical soil model. It was developed from the Barcelona Basic Model, which changed the idea of the unsaturated soil states to frozen/unfrozen states. The stress behavior is based on the mutual control of the cryogenic suction and the solid phase stress. In the FUS model, there were 28 input parameters. The parameters could be divided into four classifications. There were responsible for general, solid strain, suction strain, and the coupling effects between solid stress and cryogenic suction, respectively.

Because the FUS model was the PLAXIS 2D finite element code, the simulation was performed for the A-section in Figure 1(b). Depending on the results of the geological boring, the simulated soil layers were cobbles backfill and silty clay layer. Since the primary frost heave behavior occurs in the soil layer with sufficient water, the FUS model is used for the particle backfill and silty clay layer below the groundwater level. Most of the backfill layer was simulated using the MC model. The FUS model parameters in Table 1 were used in numerical simulation.

Table 1. The FUS model parameters were used in numerical simulation.

Parameter	Unit	Description	Backfill	Silty clay
G_0	N/m^2	Unfrozen soil shear modulus	1.33E6	2.1E6
κ_0	-	Unfrozen soil elastic compressibility coefficient	5.19E-3	4.7E-2
$E_{f,ref}$	N/m^2	Frozen soils Young's modulus at a reference temperature Tref	36E6	5.68E6
$E_{f,inc}$	$N/m^2/K$	Rate of change in Young's modulus with temperature	54E6	8.2E6
ν_f	-	Frozen soil Poisson's ratio	0.35	0.35
m	-	Yield parameter	1	1
γ	-	Plastic potential parameter	1	1
$(p^*_{y0})_{in}$	N/m^2	Initial pre-consolidation stress for unfrozen condition	120E3	150E3
p^*_c	N/m^2	Reference stress	100E3	100E3
λ_0	-	Elasto-plastic compressibility coefficient for unfrozen state	0.02	0.07
M	-	Slope of the critical state line	0.78	0.78
$(S_{c,seg})_{in}$	N/m^2	Initial segregation threshold	3.38E6	3.38E6
κ_s	-	Elastic compressibility coefficient for cryogenic suction variation	8E-3	8E-3
λ_s	-	Elasto-plastic compressibility coefficient for cryogenic suction variation	0.1	0.8
k_t	-	Rate of change in apparent cohesion with cryogenic suction	0.1	0.1
r	-	Coefficient related to the maximum soil stiffness	0.6	0.6
β	$(N/m^2)^{-1}$	Rate of change in soil stiffness with cryogenic suction	0.8E-6	0.8E-6

4 RESULTS AND DISCUSSION

4.1 *Analysis results*

Comparing the simulation result to monitoring the inclinometer displacement is shown in Figure 2(a). On the first day, the monitoring showed that the frost heave hadn't happened yet. Conversely, the cryogenic suction caused the water flow to slightly move the inclination tube. The FUS model accurately simulated this phenomenon. The output showed the direction of the water flow towards the inclination. The frost heave started occurring on the second day. In the last three days, the simulation value became little more than the monitoring, especially at a depth of 6 m. On day 6, the maximum monitoring value, 62 mm, was observed at a depth of 5.6m, and the maximum displacement of the simulation was 60 mm at 4.2 depth.

Figure 2(b) is shown the frozen soil walls' evolution below the groundwater level during the field test by numerical simulation. On the first day, the frozen walls appeared from the bottom of the freezing pipe, and the thickness was approximately 10 cm. From the second day, the frozen walls were produced on a large scale. The profile shape of the frozen walls was rectangular. The thickness reached 120 cm on the 6th day.

4.2 *Geophysical explorations discussion*

The numerical results showed that the simulation value at a depth of 6m is significantly larger than the monitoring result. The inclinometer monitoring displacement presented a double peak type. The discontinuity phenomenon was difficult to explain by numerical simulations. Thus, the geophysical exploration technique was used to investigate the underground situation. Through geophysical exploration, a large groundwater flow flowed 6m below the surface. Because the groundwater flow was at high speed and temperature, the frozen walls were difficult to produce. It reasonably explained the more significant displacement of the simulation.

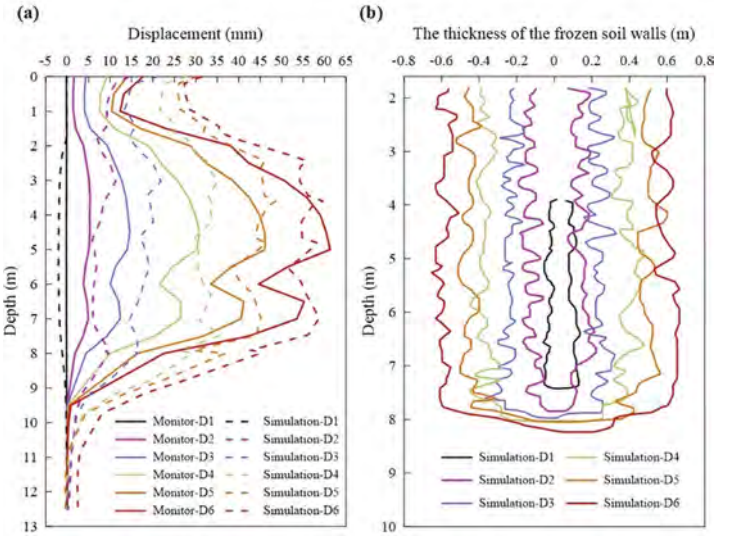

Figure 2. The simulation result (a) comparing the simulation result to monitoring the inclinometer displacement, (b) frozen soil walls' evolution below the groundwater level.

5 CONCLUSION

In this paper, the frozen soil behavior of the liquid nitrogen freezing method was studied using a field test and the FUS model in Plaxis 2D. The results show that the LN2 method can effectively and quickly form frozen soil walls rather than the traditional brine freezing method. The frozen soil walls provided strength and impermeability but also caused frost heave.

The FUS model was proven to be able to model complex multi-physical phenomena. It played a key role in understanding the LN_2 method utility and the frost heave. The thickness of the frozen soil wall reaches 1.2m in 6 days through PLAXIS FUS model back analysis. The inaccurate simulation was also reasonably explained by geophysical exploration. In summary, the utility of the liquid nitrogen method can be anticipated in the future, and reliable behavioral predictions will be obtained through the FUS model.

Detailed hydrogeological models to evaluate the risk of reactivating contaminations when re-construction harbor areas in urban environments

T.R. Andersen, A.B. Medhus & S.E. Poulsen
R&D center for Built Environment, Energy, Water and Climate, VIA University College, Horsens, Denmark

ABSTRACT: The increasing population density often leads to the development of areas previously omitted due to construction risks such as e.g., harbours. Typically, the redevelopment includes establishing both green, blue, and grey infrastructure components. However, city planners are faced with multiple challenges as the reconstruction of the harbour areas in conjunction with insufficient knowledge about the geological and hydrological setting introduces significant uncertainties in the groundwater level. They can potentially mobilize existing soil contamination previous considered less critical and immobile due to a location above the groundwater table. The study aims to use borehole data, geophysics, and GIS information to construct high-resolution hydrogeological models. The models serve as the basis for simulating the contamination transport in relation to the new harbour constructions. This paper presents the results of such modelling for the area of Horsens harbour as an example for inspiration.

1 INTRODUCTION

In 2050 UN estimates that more than 65 % of the world's population will live in urban areas. As cities expand, former industrial areas such as harbors are being urbanised due to the social and economic opportunities they present (Andersen et al., 2020; Cen et al., 2020; Loures, 2018; Weng et al., 2019). Horsens, like many other small to medium size coastal cities, are developing the harbor area. Traditionally harbor areas were the key infrastructure and the perfect location for industries depending on external resources. This former use has left many harbors area highly contaminated. As the value of a view to the sea has increased tremendously and a location near city centers is considered attractive the former industrial harbor areas are in many places converted to attractive residential areas. This is also the case for the Horsens harbor area. In this transformation the sins of the past must be assessed in order to make sure the contaminants will not get in contact with the new residents. Prior to construction works, the subsoils are investigated, and the location and concentrations of contaminants are mapped. This mapping provides a picture of the actual situation at the time of construction. In the evaluation, though, it is often forgotten that construction works alter the subsurface situation potentially changing the hydrological situation in the area which may cause contaminants to become mobile and hence affect new areas. In the Horsens Harbor case, due to the new construction, the entire sheet pile made of wood was changed to an impermeable steel sheet pile wall and a canal was excavated inland. The location of the canal is shown in blue in Figure 1.

This paper presents the result of contaminant transport modeling for the contaminated area of Horsens harbor recently transformed from an industrial to a residential area, Figure 1. Calculations were carried out for two scenarios:

- The original situation prior to construction, renovation and remediation works
- The situation after construction, renovation and remediation works

DOI: 10.1201/9781003299127-273

The purpose was to assess the impact of the development of the Horsens harbor area on the location and flow of contamination in the area.

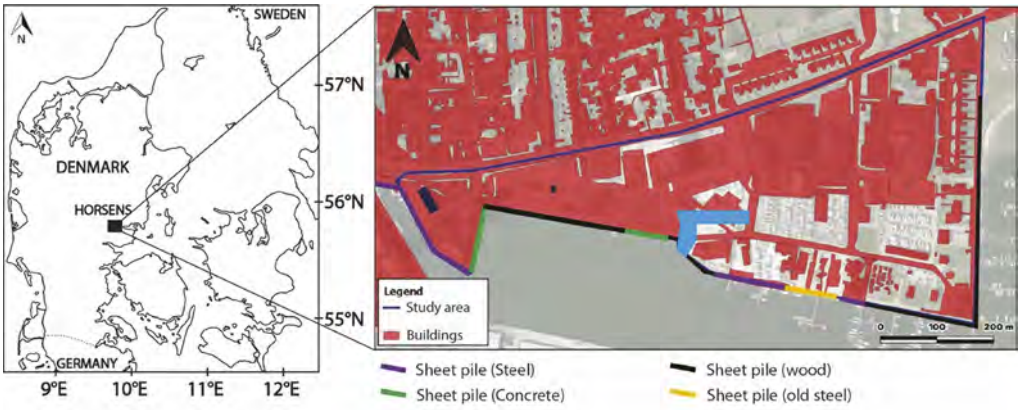

Figure 1. Overview map.

2 DATA AND METHODOLOGY

2.1 *Data*

Data included for interpretation of the hydrogeological model is shown in Figure 2. A detailed elaboration of the data can be found in Andersen et al. 2020.

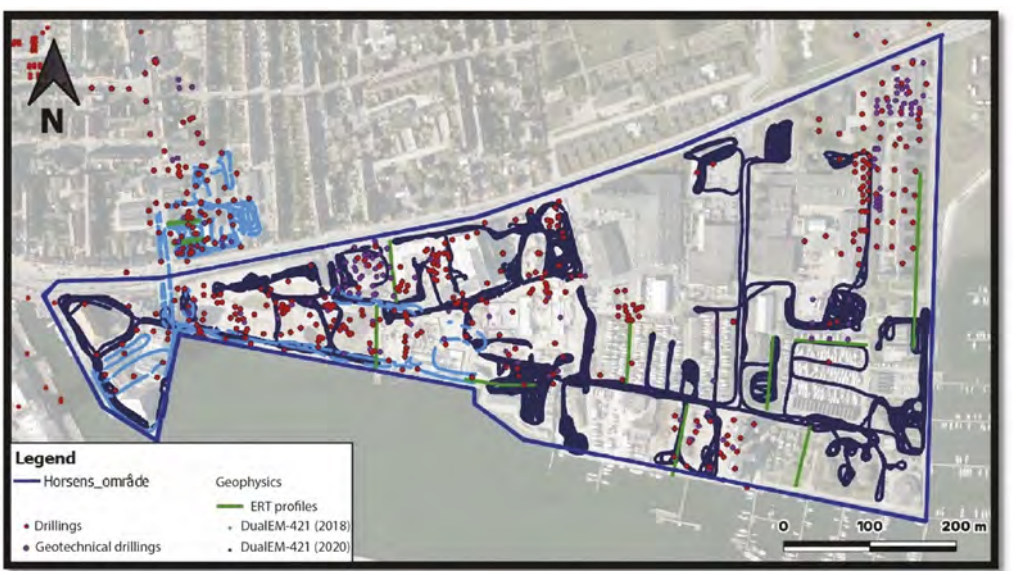

Figure 2. Input data for the hydrogeological model. The blue polygon outlines the area of investigation. dark blue and light blue dots which appears connected as lines shows where Dual-EM data has been collected. Green lines outline ERT profiles collected. Red dots represents borehole information collected from the Jupiterdatabase, while purple dots identifies boreholes from the database belonging to the Central Region of Denmark.

3 RESULTS AND DISCUSSION

3.1 *Hydrogeological model*

Based on lithology information from boreholes and geophysical data a hydrogeological model was created. Initially, the general geological layers of the model were interpreted as a layer model. Then it was converted to a voxel model, with cells sizes of 1x1m along the horizontal axes and 0.5m in the vertical direction, to be able to add more details. Pipes and buildings were added to the voxel model and the model was re-evaluated along gridlines and voxels updated to represent lenses of different lithology within layers as identified from the boreholes. Furthermore, abrupt changes in the fill materials that were difficult to obtain with interpolated layers were updated.

The shallow geology of the Horsens harbor area consists of glacial and postglacial marine layers overlain by fill materials. The hydrological model identifies an uppermost layer in the area consisting of mixed fill materials with abrupt thickness variations typically 0-2m but often thicker towards the harbor front. Underneath the fill material gyttja is present in most of the area, but pinching out to the northwest. The greatest thickness of gyttja is found in the southeastern corner of the harbor area. In one borehole a thickness of 6.1m of gyttja is encountered. Where it has not been removed or remolded by construction processes a relatively thin, typically up to 1m of marine sand is found underneath the gyttja. Below this, to the depth of interest for the modeling, moraine clay with lenses or layers of sand is found in the western part of the area while sand layers with lenses or layers of clay dominate in the southeast.

3.2 *Contaminant transport model*

The transport of various contaminants was modelled using the FEFLOW software based on the hydrogeological model, estimated extents and concentrations of contaminants, available information on groundwater levels, infiltration, and assumptions on hydraulic conductivities.

Information on different contaminants in the area was collected. These included preconstruction reports on accredited analyses for contaminants (soils, groundwater, and pore air). All test location information was georeferenced and added to the same GIS workspace in order to obtain an overview of the entire area including connections between contaminants across the cadasters often representing boundaries of single reports. Contamination in the area is mainly located at depths 0-3 mbgl. From the resulting overview, the mobile compounds that could have a negative impact on humans, animals or recipients were selected. This implies that e.g. heavy metals which are quite immobile have not been included in the mapping, since no change in extent is expected. Furthermore, contaminants entering from areas outside the study area are also excluded from the assessment. Thus, the results of this study show relevant changes related to a different hydraulic situation but cannot be applied for a general assessment of the contamination situation of the area.

For the selected compounds a polygon defining the contaminant extent was interpreted and assigned with a representative concentration based on sample analyses. In cases where only soil sample analyses were available fugacity calculations based on the present soil types were applied for estimating the groundwater concentrations. Diffuse concentrations of cyanide and tar present over a large part of the area are omitted in this study. The presence and concentration of contaminants differ between the pre-and post-construction works because some contaminants were required to be removed/reduced during construction works. Such contaminants have also been removed/reduced in the post-construction transport modelling. In the contaminant transport modelling, the concentrations of contaminants have been held constant. E.g., degradation has not been considered.

The results of the hydrological model can be observed on Figure 3

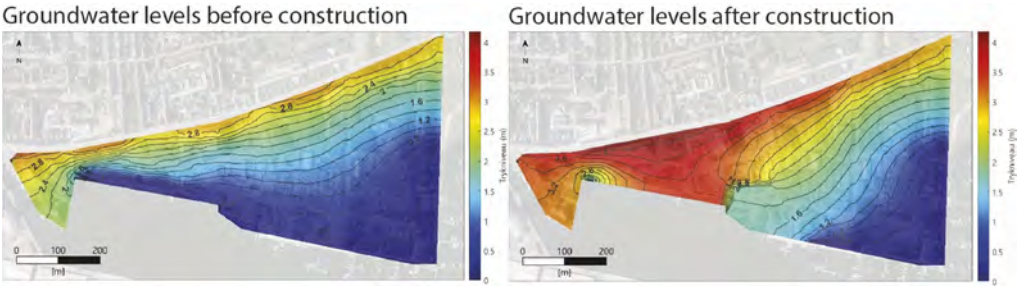

Figure 3. Modelled hydrostatic pressure before and after harbor front renovation and construction works.

In the case area of Horsens harbor addition of impermeable steel sheet walls along the harbor front and along an artificial stream, added to drag in the blue areas for recreational value, determines the flow direction. As expected, the impermeable walls toward the sea significantly alter the flow. Drainage happens at one location in the western part of the area, but it is not enough to account for the reduced outflow along the long stretch. Consequently, groundwater is expected to raise and introduce a risk of flooding from below. The increased amount of infiltration doesn't make the situation any better but has a lower contribution to the problem compared to the hindered outflow. As the eastern part of the area remains permeable the groundwater flow direction change from mainly north to south oriented to become more west to east flowing along the harbor front. The changing flow direction in combination with the higher groundwater level affects the transport of soluble contaminants in the area. The new transport situation causes contaminants to generally extend further east from the current hot spots which leads to unforeseen pollution of new areas and increased washing into the sea.

4 CONCLUSIONS

By carrying out a detailed mapping and contaminant transport modeling it has been possible to foresee the changes in the extent and discharge of contaminants in the Horsens harbor area prior to construction. This potentially allows for remediation measures and assessment of what should be taken care of in the process or as a consequence of the alterations. The modeling clearly shows that the condition of the harbor front is the main parameter affecting the flow pattern. Thus, an impermeable wall will permit contaminants to enter the sea. An impermeable wall will keep in the contaminants in the harbor area, where they may be distributed to new areas. Further, the lack of outflow options increases the risk of flooding from below as groundwater levels are already close to the surface. This may potentially bring contaminants to the surface.

Hydraulic characteristics of granular bentonite amended with hydroxy methyl cellulose under adverse chemo-mechanical loadings

Sharad Dadhich, Himanshu Yadav & Tadikonda Venkata Bharat
Indian Institute of Technology Guwahati, Guwahati, Assam, India

ABSTRACT: Granular bentonite base clay liners are widely used in landfills as hydraulic barrier because of their low hydraulic conductivity and self-sealing ability. Recent studies reported that the hydraulic conductivity of Granular bentonite has significantly increased due to the presence of different inorganic cations (i.e., Na+, K+, and Ca++), which causes the mechanical instability. This subsequently results in ground water contamination due to leachate migration from the liners. To address this problem, a composite mixture of granular bentonite and hydroxy methyl cellulose at different proportions (2-10% HMC) has been tested in the laboratory under extreme chemical (0.50M $CaCl_2$) and mechanical (20-100kPa) loadings. The performance of different mixtures is evaluated in terms of hydraulic conductivity and volume change. It is found that the mixture of granular bentonite and 10% hydroxy methyl cellulose has attained lower hydraulic conductivity (10^{-11}-10^{-9}m/s) than the critical hydraulic conductivity (10^{-9}m/s) under extreme chemical and mechanical loadings.

1 INTRODUCTION

Bentonite has been extensively used in landfills as liner material because of its low hydraulic conductivity, high swelling potentials, self-sealing ability, and higher absorption capacity (Benson, Zhai and Wang, 1994; Bharat, 2014; Chen et al., 2016). It prevents the permeation of various organic and inorganic contaminants into the ground water (Hornsey et al., 2010). Geosynthetic clay liners (GCL) have replaced the conventional thick clay liners due to the ease of handling in production and installation (Bouazza, 2002). GCL consists of 10mm thick bentonite layer sandwiched between geotextile layers. The granular bentonite is commonly used now a days because of its self-sealing ability (Yadav and Tadikonda, 2022). The self-sealing ability plays a vital role in filling the gaps between the blocks in nuclear repositories and healing the puncture after the placement in the field (Parastar et al., 2017a; Rowe and Li, 2020; Das and Bharat, 2021; Rowe and AbdelRazek, 2021). The self-sealing ability refers to the filling of the macro-voids, because of the disintegration of coarser particle into finer particle during the process of hydration (Yu, El-Zein and Rowe, 2020). The disintegration phenomenon can be considered as the results of the double diffuse layer formation and existence of the repulsive inter particles forces, which ultimately lower down the hydraulic conductivity to a limiting value (10^{-9}m/s) (Darde et al., 2021) and retard the process of diffusion (Lee and Shackelford, 2005; Bharat, Sivapullaiah and Allam, 2009). The municipal solid waste disposal landfills generate inorganic leachate consists of sodium, potassium, and calcium ions due to slat laden waste from chemical, electronic industries and demolition waste (Weber et al., 2002; Yeheyis et al., 2013; Turkyilmaz et al., 2019; Colman et al., 2020). Recent studies reported significant decrease in osmotic potential and lack of sealing ability under different chemo-mechanical loading thus, allowing the ease of contamination (Parastar et al., 2017b; Salemi et al., 2018; Wang et al., 2019). Polymeric compound base GB are currently being explored to

DOI: 10.1201/9781003299127-274

enhance the performance of GB under severe chemo-mechanical loadings. Several synthetic polymers either straight or crosslinked has been investigated in the literature (Onikata, Kondo and Kamon, 1996; Fehervari et al., 2016; Tian, Benson and Likos, 2016; Tian, Likos and Benson, 2019). The mechanism of polymeric compound with GB can be understood by long range columbic interaction and short-range ion-dipole interaction, cation bridging and hydrogen bonds(Ashmawy et al., 2002; Deng et al., 2006).

In the present study, hydraulic characteristics of granular bentonite (GB) amended with hydroxy methyl cellulose (HMC) has been investigated. The optimal proportion of HMC amended with GB has been identified for application in place of conventional GB based GCL under adverse mechanical loadings (20-100kPa) and 0.50M potassium chloride and 0.50M calcium chloride solutions.

2 MATERIALS AND METHODS

2.1 *Materials*

Granular bentonite used in this study has been extracted from commercially available GB based geosynthetics clay liner. The material is first characterized in the laboratory. The properties of GB are presented in Table 1. The hydraulic and volume change behavior of GB under different chemical and mechanical loading conditions is discussed in details in the results section.

Table 1. Characterization of granular bentonite.

Property	Method	Value
Specific Gravity	Density Bottle (BIS 1980)	2.78
Liquid Limit	ASTM D4318-17el	658
Plastic Limit		48
Specific Surface Area (in m^2/gm)	Methylene Blue sorption	648
Cation Exchange Capacity (in meq/100gm)		152.67
Na+	Flame Photometer and Atomic Adsorption Spectrometry	86.1
K+		0.87
Ca++		42.2

The hydroxy methyl cellulose is purchased from AKSHAR CHEM company. It is gelatinous compound, extracted from the cellulose, which is hydrophobic in nature. It helps in hydrophilization (Pramono et al., 2019) of Granular bentonite under high ionic salt concentration to accelerate the disintegration of the granule.

The calcium chloride dihydrate ($CaCl_2.2H_2O$, M_w = 147.02gm) and potassium chloride (KCl, Mw = 74.55gm) are purchased from Sisco Research Laboratories, which is minimum 99.50% pure. The solutions of 0.50M concentration are prepared in the laboratory as per the standard procedure.

2.2 *Methods*

To study the hydraulic conductivity and volume change characteristics of composite mixture the oedometer test setup is used with slight modification (Yadav and Tadikonda, 2022). The mould is fabricated from solid acrylic cylinder with an opening at bottom periphery to accommodate a burette for maintaining the hydraulic head upto 60cm. The modified mould has inner and outer diameter of 53 and 60mm, respectively. It can accommodate a 10mm thick compacted sample sandwiched between 5mm thick porous stones. A filter paper (A 42-grade) is placed at top and bottom side of soil specimen to avoid the clogging of the porous stones.

The soil sample is compacted at dry density of 1.20gm/cm^3 as per the density of GB in GCL (Das and Bharat, 2021). The mould is placed on the load assembly and a dial gauge (Least count = 0.002mm) is placed at the top of the mould for measuring the axial strain under chemo-mechanical loading. A burette containing the 0.50M calcium chloride solution is connected at bottom of the mould. The valve of the burette is opened immediately placing the mechanical loading (20kPa, 50kPa, and 100kPa) to simulate the in-situ loading conditions. The permeation rate is estimated using the principle of variable head permeability test and the volume change is recorded in terms of normalized thickness using dial gauge readings (Yadav and Tadikonda, 2022).

3 RESULTS AND DISCUSSION

3.1 *Influence of Polymer proportion*

The fluid permeation rate of 0.50M calcium chloride solution through GB alone and different proportions of HMC amended with GB under 50kPa mechanical loading is presented in Figure 1 (a). The permeation rate of GB alone is found to be much higher than the limiting permeation rate, which confirms the inability of GB in sealing the macro-voids in the presence of 0.50M calcium chloride solution. A decreasing trend in the permeation rate is observed at equilibrium with increase in the proportion of the HMC. The 2HMGB sample completely fails to seal the macro-void at equilibrium. The 5HMGB sample initially seals the macro-void at 480 minutes but it starts leaking around 1000 minutes. However, 10HMGB sample completely seals the macro-void at 240 minutes and the permeation rate continue to fall down till the equilibrium.

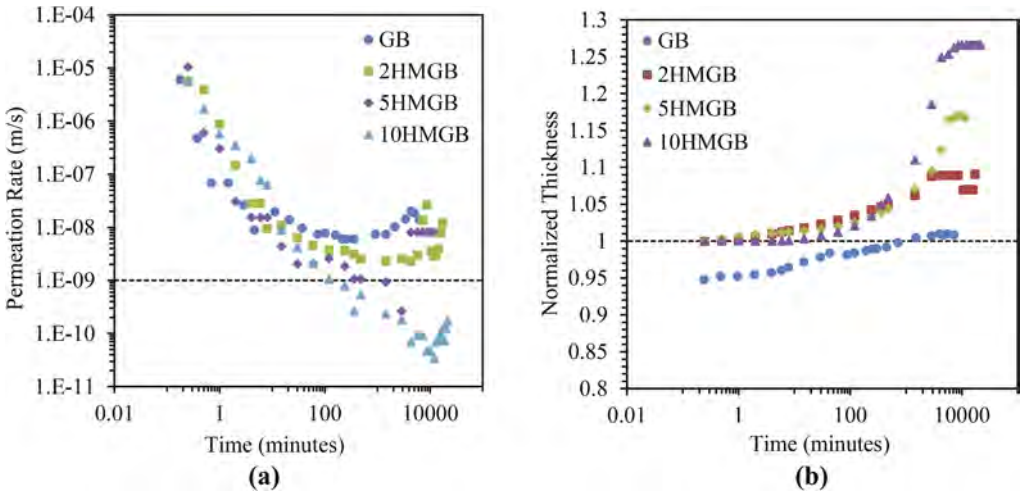

Figure 1. Temporal Variation of (a) Permeation rate and (b) Normalized Thickness for different samples with Calcium Chloride (0.50M) solution under 50kPa mechanical loading.

The volume change behavior of GB alone and different proportions of HMC amended with GB under 50kPa mechanical loading with 0.50M calcium chloride are presented in Figure 1 (b). A significant collapse in GB is observed under the applied chemo-mechanical loading. The collapse is slightly reducing with the time because of the formation of the diffused double layer as the hydration progresses. Initially, the diffused double layer formation is slow, which may be because of the limited presence of water. An insignificant collapse is noted for GB amended with HMC initially, which confirms that the HMC resist the collapse. The normalized thickness shows increasing trend with the proportion of HMC. The maximum normalized thickness is observed for 10HMGB sample (H_N = 1.28), indicating the swelling of the soil specimen.

3.2 *Performance of composite mixture under mechanical loadings*

The fluid permeation rate of 0.50M calcium chloride solution through GB amended with 2% HMC under different mechanical loadings (20-100kPa) is shown in Figure 2 (a). The 2HMGB sample fails to seal the macro-void for each mechanical loading. However, the permeation rate is slightly lower with respect to the GB alone.

The volume change behavior of GB amended with 2% HMC under different mechanical loading (20-100kPa) is shown in Figure 2 (b). A slight collapse is observed initially for 20kPa mechanical loading, which is further vanished with the time as the hydration increase. At equilibrium significant swelling is observed under different mechanical loadings (20-100kPa). It confirms the diffused double layer formation, which is primarily responsible for self-sealing behavior of GB. The maximum swelling (H_N =1.18) is observed under 20kPa.

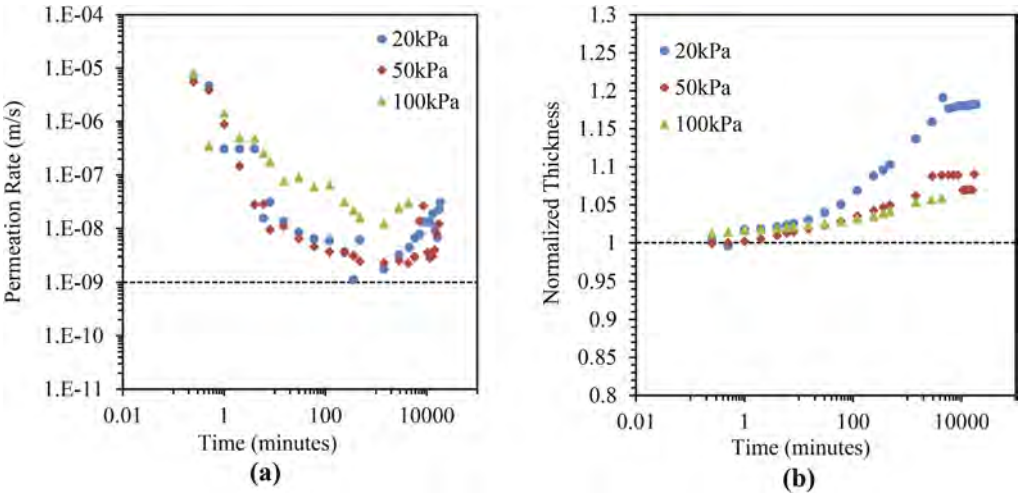

Figure 2. Temporal Variation of (a) Permeation rate and (b) Normalized Thickness for 2HMGB sample with Calcium Chloride (0.50M) solution under different mechanical loading (20-100kPa).

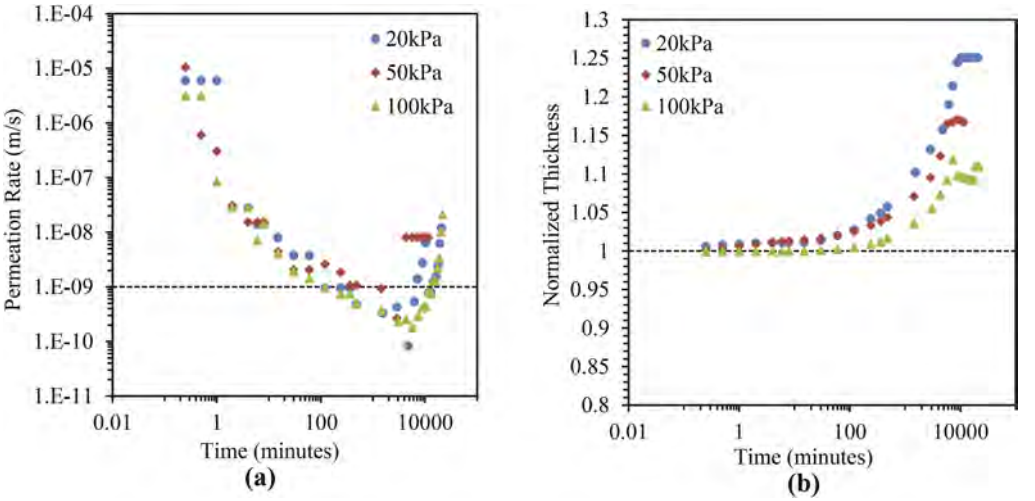

Figure 3. Temporal Variation of (a) Permeation rate and (b) Normalized Thickness for 5HMGB sample with Calcium Chloride (0.50M) solution under different mechanical loading (20-100kPa).

The fluid permeation rate of 0.50M calcium chloride solution through GB amended with 5% HMC under different mechanical loading is drawn in Figure 3 (a). Initially, the 5HMGB seals the macro-void in time intervals 240-360 minutes. As the time progresses the seal-ability goes on increasing up to a certain time and starts decreasing afterwards. Thus, permeation rate starts increasing and 5HMGB sample fails to seal the macro-void for each mechanical loading at equilibrium. However, the permeation rate is still slightly lower with respect to the 2HMGB.

The volume change behavior of GB amended with 5% HMC under different mechanical loadings (20-100kPa) is shown in Figure 3 (b). An insignificant collapse is observed initially for 20kPa mechanical loading, which is further vanished with the time as the hydration increase. At equilibrium significant swelling is observed under different mechanical loading (20-100kPa). It confirms the diffused double layer formation, which is primarily responsible for self-sealing behavior of GB. The maximum swelling (H_N = 1.25) is observed under 20kPa loading.

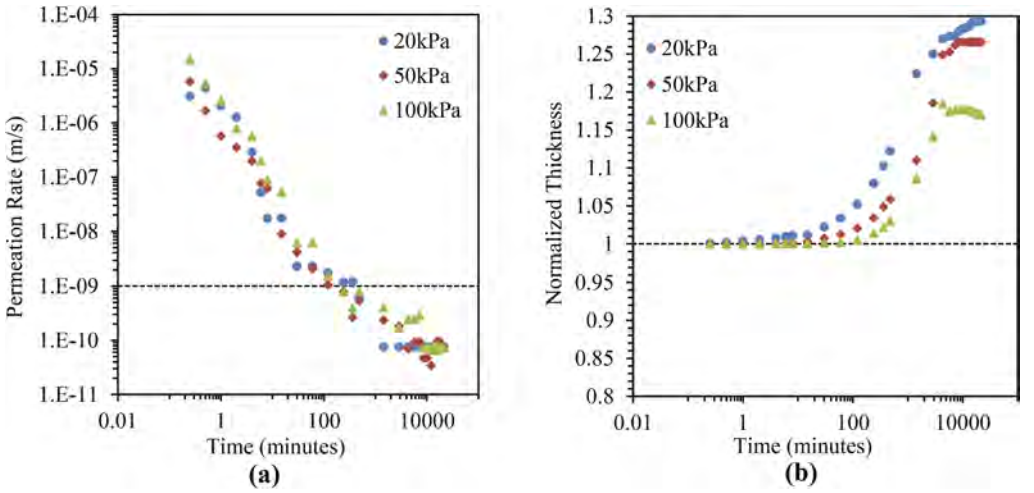

Figure 4. Temporal Variation of (a) Permeation rate and (b) Normalized Thickness for 10HMGB sample with Calcium Chloride (0.50M) solution under different mechanical loading (20-100kPa).

The fluid permeation rate of 0.50M calcium chloride solution through GB amended with 10% HMC under different mechanical loading is drawn in Figure 4 (a). The 10HMGB seals the macro-void in 240-480 minutes and the permeation rate goes on decreasing with the time. The average permeation rate at equilibrium for each load is found to be in order of 10^{-11}m/s which is manifolds lower than the limiting permeation rate (10^{-9}m/s).

The volume change behavior of GB amended with 10% HMC under different mechanical loadings (20-100kPa) is shown in Figure 4 (b). At equilibrium significant swelling is observed under different mechanical loading (20-100kPa), which confirms the diffused double layer formation. The maximum swelling (H_N = 1.30) is observed under 20kPa loading at equilibrium.

3.3 *Influence of cation type*

The fluid permeation rates of 0.50M potassium chloride and 0.50M calcium chloride solutions through GB amended with 10% HMC under 100kPa mechanical loading are drawn in Figure 5 (a).

The 10HMGB seals the macro-void in 240-480 minutes and the permeation rate is slightly higher for $CaCl_2$ solutions. This slight increase is because of the divalent Ca^{++} cation, which limits the formation of diffused double layer (Bharat and Das, 2017). The average permeation rate at equilibrium for each load is found to be in order of 10^{-10}m/s which lower than the limiting permeation rate (10^{-9}m/s).

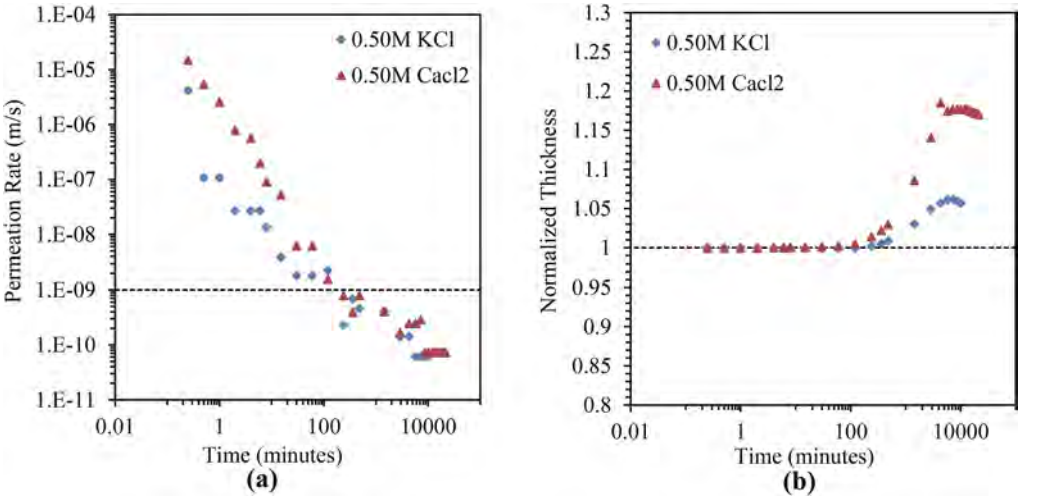

Figure 5. Temporal Variation of (a) Permeation rate and (b) Normalized Thickness for 10HMGB sample with Potassium Chloride and Calcium Chloride (0.50M) solutions under 100kPa mechanical loading.

The volume change behavior of GB amended with 10% HMC under 100kPa mechanical loading under different salt solutions (0.50M KCl and 0.50M $CaCl_2$) is shown in Figure 5 (b). At equilibrium significant swelling is observed under different salt solutions. The swelling is less for KCl solution than the $CaCl_2$ solution which may be result of the thin diffused double layer formation because of low osmotic suction.

4 CONCLUSIONS

In this study, hydraulic and volume change behavior of granular bentonite amended with hydroxy methyl cellulose is studied. The following conclusions are drawn from the study:

- Volumetric collapse was observed in the GB under adverse chemo-mechanical loading and the GB alone was found to be inefficient to seal the macro-voids.
- The inclusion of the HMC minimize the collapse in the GB and allows the formation of the diffused double layer under the high ionic salt concentration, which enables the GB to disintegrate into smaller particles and sealing the macro-voids.
- The optimal proportion of the HMC amended with the studied GB was found to be 10% HMC (w/w) for use in the GCL liners.

ABSTRACT: The development of industries has contaminated the soil both below and above the water table. Although extensive research has been conducted on the contaminant transport through saturated domain, the knowledge about the mechanism of contaminant transport in the vadose zone is rather limited. Therefore, this study aims to introduce an instrumented soil column to study bio-logical methods as an eco-friendly approach to remove soil pollutants. The soil column is equipped with moisture measuring sensors and sampling ports. Therefore, the new apparatus can be used to monitor flow of water and contaminant because soil moisture distribution affects the microbial degradation of hydrocarbons. The performance of new device is explored and dis-cussed via conducting a preliminary bioremediation test on a compacted soil column initially contaminated with 7% (w/w) of diesel. The results in terms of microbial activity are interpreted based on the temporal and spatial variations in the total petroleum hydrocarbon (TPH).

1 INTRODUCTION

Oil pollution is a global problem causing the contamination of soils. Oil spilled during production, transportation and exploitation causes toxic hydrocarbons such as long-chain alkanes and polycyclic aromatic hydrocarbons to pollute the soil. These hydrocarbons change the structure and metabolic activities of soil micro-organisms and they have a negative impact on the soil ecosystem (Liu et al. 2020; Gao et al. 2022). Hydrocarbon pollutants in the leachate of landfills also penetrate the underground water and pollute it (Hedayati-Azar & Sadeghi, 2021; 2022).

Some petroleum products such as diesel are light non-aqueous liquid phase pollutants (LNAPL). These pollutants penetrate the bridges of capillary menisci and hence distributed in the vadose zone. In the unsaturated zone, the fluctuations of underground water and precipitation cause LNAPL migration (Dobson et al. 2007). However, changes in the underground water level cause air to be entrapped as an additional source of oxygen for the microorganisms decomposing the pollutants (Zuo et al. 2021). As a result, changes in water content are effective for bio-logical activities and natural degradation of hydrocarbons. The main goal of this study is hence to develop a bioremediation soil column to explore the microbial activity through measuring the distribution of petroleum hydrocarbons in a polluted soil column at various water contents.

DOI: 10.1201/9781003299127-275

2 METHODS

Soil columns were made of PVC with a height and diameter of 90 cm and 10 cm, respectively. Each column had sampling ports at six different depths first one at 7.5 cm from the top and the others having equal 15 cm intervals (Figure 1). The parameters monitored for the laboratory experiments included moisture content, total petroleum hydrocarbon (TPH), and total heterotrophic count (THC). The flow rate chosen for the test was 54 ml/h, which is considered a high flow rate (Li et al. 2009). The flow rate was maintained by Mariotte bottle (Sadeghi, 2016). In addition, soil sampling was conducted at the initiation of the test and on days 14, 28, 42, and 60 afterward.

It is also mentioned that fertilizers diluted in water were used for sample preparation. These nutrients were added at a ratio of 100:10:1: of carbon, nitrogen, and phosphor (CNP) (Chaineau et al., 2005). The initial average TPH concentration in the soil samples was 7% (w/w). The nitrogen (N) source was supplied from $CO(NH_2)_2$, and the phosphorus (P) source was supplied from KH_2PO_4. The soil samples were collected from a contaminated site in plastic bags and transported to the laboratory. The soil used in the experiment was silty sand (Sadeghi & Nasiri, 2021). The soil samples were left to dry in ambient conditions for approximately three days. The samples were then sieved using a 2-mm sieve mesh to remove any unwanted large aggregates or particles (Sadeghi et al., 2019). After sieving, the samples were placed into storage containers and cooled down to 4 °C before the experiments so that microbial activities be minimized before initiation of the column tests. After the application of each treatment, the soils inside the test columns were sampled using a manual hand-auger set for both TPH and THC. All samples were then refrigerated at 4 °C and transported to the chemical laboratory for further analyses.

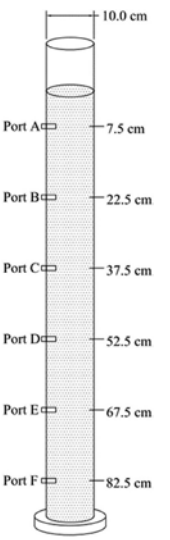

Figure 1. The schematic diagram of soil column.

3 RESULTS

The total petroleum hydrocarbons at the beginning of the experiment was equal to 4250 mg/kg, which at the end of 60 days of the experiment in A and C ports reached 3322 and 2320 mg/kg, respectively. With the increase of depth around Port A and C, the amount of TPH decreases by 21.8% and 45.4%, respectively.

At the beginning of the experiment, the population of different bacteria was equal to 1.5×10^5 CFU/g soil this amount increased during the experiment at all depths, and the

maximum was on the 28th day of the experiment (Figure 2). However, the amount of bacterial population decreased after 28 days until the end of the experiment. The bacterial population was 7.4×10^5 CFU/g soil in Port A on the 28th day of the experiment. These results are consistent with what Chaudhary et al. (2021) and Zhang et al. (2020) reported. The increase in the population of some microbial com-munities against petroleum hydrocarbons has increased the amount of bacteria at the beginning of the experiment (Zhang et al. 2020).

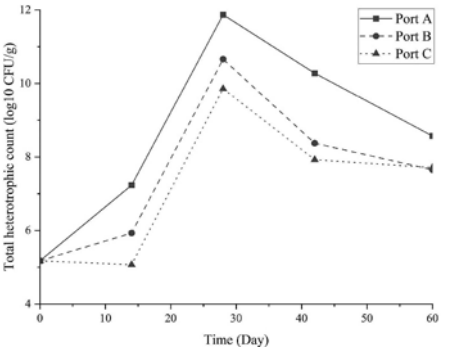

Figure 2. Variations in the bacterial population at different time steps and depths.

Changes in volumetric water content are shown in Figure 3. With the increase in depth, the volumetric water content was increased (Kolahdooz et al., 2020). High moisture caused an increase in the removal of oil pollutant, as also reported in the results of Liu et al. (2020). This phenomena can be attributed to the increase of some oil-degrading bacteria. While in the research of Lee et al. (2018), it was revealed that the increase in moisture causes a decrease in the oxygen diffusion coefficient and, as a result, a decrease in the amount of oil pollutant removal.

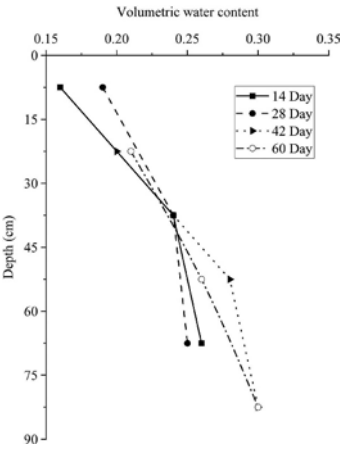

Figure 3. Distribution of the volumetric water content with depth.

4 CONCLUSIONS

The results of bioremediation of soil column systems showed that the decomposition rate of petroleum hydrocarbons changes with depth. The changes in the bacterial population vary according to the changes in moisture and the distribution of the amount of pollutants in the depth. Over time, the bacterial population first increased and then decreased. The maximum bacterial population at a depth of 7.5 cm was 7.4×10^{11} the same on the 28th day.

ABSTRACT: Wind erosion is a natural phenomenon that has been widening due to anthropogenic activities. One-third of the global land area suffers from wind erosion and its prevention is a critical issue in many arid regions of the world. Crusts on soil surfaces are well recognized for wind erosion control. In the last two decades, the use of biotechnological methods for crust formation on the soil surface has been developed. This paper presents the results of the wind tunnel experiments and the penetrometer tests conducted on a biocrust created by *Microcoleus vaginatus* cyanobacterium and a biocemented sand crust induced by precipitation of calcium carbonate by *Bacillus megaterium* bacterium. The biocemented sand crust had more resistance than the biocrust against wind erosion; however, both crusts reduced the amount of erosion several thousand times.

1 INTRODUCTION

Wind erosion is a natural phenomenon of soil degradation in which particles of different sizes are detached from the surface, transported, and redeposited by wind (Shao, 2008). In recent decades, anthropogenic activities such as overgrazing, inordinate agricultural practices, drainage of arable land, construction, and mining operations have increased the frequency and intensity of wind erosion even in non-arid areas of the world (Middleton and Kang, 2017; Goudie, 2018). Approximately 30% of the global land area suffers from wind erosion (Gemma et al., 2016). The largest area of wind erosion is located in the northern hemisphere and is known as the 'dust belt' extended from the west coast of North Africa, through the Middle East and Central and South Asia, to China (Gemma et al., 2016). Figure 1 shows the geological map of the 'dust belt' and its 11 main dust sources.

Sand and dust storms (SDS), the primary consequence of wind erosion, are of the most serious environmental issues threatening economic and human health globally (Gemma et al., 2016; Duniway et al., 2019; World Bank, 2019). Of impacts of SDSs are loss of agricultural productivity, damage to infrastructures, pollution of air, and deterioration of water supplies (Duniway et al., 2019). A single SDS event can damage hundreds of millions of dollars; for an instance, in northeast Asia in March 2021, a major SDS event canceled hundreds of flights in China, caused health problems to people in South Korea, killed 200,000 livestock, and destroyed 121 animal shelters in Mongolia (FAO, 2022). Table 1 presents other examples of the economic impacts of SDSs in a number of Asian countries.

DOI: 10.1201/9781003299127-276

South Korea	2002	1	Health, cleaning, air transportation	5600	Jeong (2008)
China	2000	1	Agriculture, construction, manufacturing	485.8	Ai & Polenske (2008)

Multitude conservation methods have been proposed/implemented to control wind erosion. These practices can be divided into two main categories, including methods to reduce wind erosivity by use of diverse elements as windbreaks with a proper arrangement (Xu et al., 2018) and methods to reduce soil erodibility by use of various organic or inorganic compounds to form a crust on the soil surface (Zang et al., 2015).

Recently, biotechnology has made possible the application of microorganisms for soil stabilization. Using this technique, a soil crust is created/developed within a few millimeters of the soil surface by inoculating microorganisms, including heterotrophic bacteria (Stabnikov et al., 2013; Tian et al., 2018; Fattahi et al. 2020a, 2021a,b), phototrophic cyanobacteria (Fattahi et al., 2020b,c), fungi and lichens (Burri et al., 2013), or mosses (Zhao et al., 2016) on the soil surface.

This study aims to examine the erodibility and strength of a desert sand stabilized by inoculation of *Microcoleus vaginatus* cyanobacteria and biocemented by precipitation of calcium carbonate by *Bacillus megaterium* bacteria.

2 MATERIALS AND METHODS

2.1 *Materials*

The sand used in this study was non-plastic and poorly graded (according to USCS) with, D_{50}, of 180 μm, 3% passing the #200 sieve, Cu, of 2.3%, G_S of 2.65, γ_d of 15.7

kN/m^3, and porosity of 0.4. This study used *Microcoleus vaginatus FACHB-1854* cyanobacterium and *Bacillus megaterium* BNCC 336739 heterotrophic bacterium to form *respectively* interparticle polysaccharide bonds and $CaCO_3$ bridges (based on Equation 1) on the sand surface.

$$Ca(C_2H_3O_2)_2 + 4\ O_2 \rightarrow CaCO_3 \downarrow + 3\ CO_2 \uparrow + 3\ H_2O \quad (1)$$

Where $Ca(C_2H_3O_2)_2$ is calcium acetate.

2.2 *Methods*

Table 2 presents concisely the steps involved in the biomasses and samples preparation. The Active culture of *M. vaginatus* and freeze-dried cells of *B. megaterium* were grown respectively in the BG-11 and 0002 liquid media. For the preparation of the required samples, a number of stainless-steel cube boxes (10 cm × 10 cm × 10 cm) filled with the sand was used. Three groups of samples, including samples with untreated sand, samples treated by the biomass of *M. vaginatus*, and samples treated by the biomass of *B. megaterium*, were prepared according to the steps of Table 2. The amount of biomass sprayed on each sample was 40 mL. Figure 2 shows the photographs of the samples.

Table 2. Steps of the microorganisms' culture and sample preparation.

Step	Task	*M. vaginatus*	*B. megaterium*
1	Mass cultivation	Diluting the algal liquid with BG-11 medium and maintaining the biomass in an incubator for 14 days	Adding 5 mm^3 of bacterial biomass from the solid medium to the liquid medium and maintaining liquid biomass in a shaker incubator for 36 h
2	Preparing biomass and spraying it on the soil surface	Resuspending algal liquid, adding 0.05 % xanthan to the algal liquid and spraying the bacterial suspension on the surface of the samples	Adding 0.05 % xanthan to the bacterial suspension, adding 20 g/L calcium-acetate to the bacterial suspension, spraying the bacterial suspension on the surface of the samples
3	Curing samples	Maintaining the sample in a greenhouse in the culture condition, watering the samples 2 mm per day for 21 days	Maintaining the sample in a greenhouse at a temperature of 23 °C until the sample dries

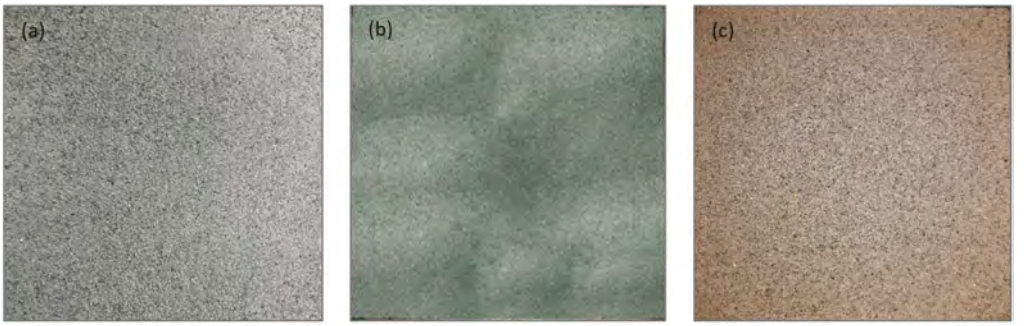

Figure 2. Photographs of the samples; a) untreated sand, b) treated by the *M. vaginatus* biomass, c) treated by the *B. megaterium* biomass.

The wind tunnel experiments were conducted in triplicate on the samples with five different wind velocities of V = 6, 10, 15, 20 and 25 m/s for 5 minutes. In order to measure the strength of the surface of the samples, this study employed the penetrometer test (Fattahi et al., 2020d), in which crusts were penetrated perpendicularly by a flat-tip stainless-steel needle with a diameter of 0.6 mm. The rate and maximum depth of penetration were 158 μm/s and 5 mm, respectively.

All of cultivation processes of the microorganisms, wind tunnel tests were conducted in the Key Laboratory of Mechanics on Disaster and Environment in Western China, Lanzhou University.

3 RESULTS AND DISCUSSION

Figure 3 presents the average force (F_P) – depth (D_P) penetration curves obtained from the penetrometer tests carried out on the samples. F_P of untreated sand did not exceed 0.03 N. For the samples treated by the *M. vaginatus* biomass, F_P showed a moderate climb, but F_P of the samples treated by the *B. megaterium* biomass experienced a sharp increase during penetration.

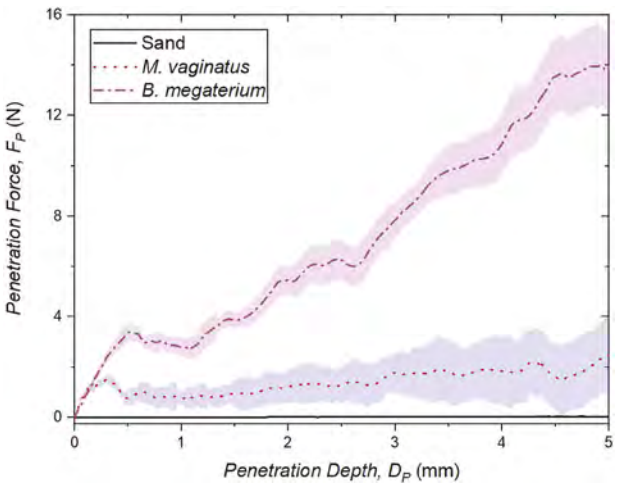

Figure 3. Force (F_P) – depth (D_P) penetration curves of the untreated sand, sand treated by the *M. vaginatus* biomass, and *B. megaterium* biomass.

Figure 4 presents the rate of erosion, E_R, in terms of kg/(m^{2}h) and in the logarithmic scale for the samples. E_R was calculated based on the eroded masses from the surfaces of the specimens in 5 minutes. As expected, E_R of untreated sand was remarkably high at all of the wind velocities and increased with the rise of V. The erosion rates of the samples treated by the *M. vaginatus* and *B. megaterium* biomasses were zero up to V=25 m/s at which the ratio of E_R of these samples over E_R of untreated sand were 7.5 $\times 10^{-5}$ and 5.6×10^{-5}, respectively.

In this study, the erodibility of the samples was obtained by subjecting the samples to different wind velocities for a short time of 5 min; hence, in contrast to the crusts' strength, the erosion rates of the crusts had no remarkable difference. In case of exposure of the crusts to wind flow for a long time, the *M. vaginatus* biocrust may deteriorate faster than *B. megaterium* biocemented sand crust due to its weaker interparticle bonds.

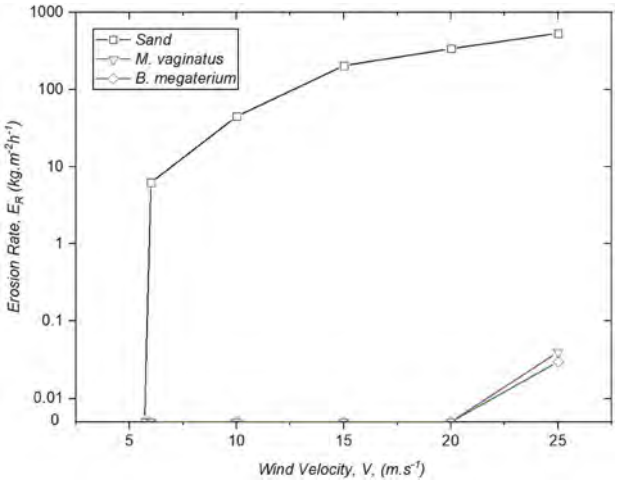

Figure 4. Erosion rates of the untreated sand, sand treated by the *M. vaginatus* biomass, and *B. megaterium* biomass at different wind velocities.

Table 3 compares the advantages and disadvantages of the cyanocrust and biocemented sand crust. The quick biocementation reaction, no water requirements for formation, and high strength are the merits which turn the biocemented sand crust as a favorite choice for quick (even emergency) controlling of wind erosion and dust emission from mine tailings, containing harmful materials, and drylands with highly erodible deposits (e.g., dunes and sand seas). In order to benefit from the advantages of the biocrust (i.e., releasing O_2, enhancing soil fertility and biological conditions, and self-recovery), protecting the biocrust at the time of its early stages of development and finding proper scientific and technical methods to reduce water necessities (especially in areas with dry climates) for the cyanocrust development is vital. The costs of the required raw materials for the biocrust and biocemented sand crust formation are about 1500 and 750 US$/ha, respectively.

Table 3. Comparison of the biocrust created by *M. vaginatus* and biocemented sand crust created by *B. megaterium.*

Crust	Advantages	Disadvantages
Biocrust	- Release of O_2 in the photosynthesis process - Enhancing soil fertility and biological conditions* - Self-treatment	- High water requirement for the formation - Long creation time - Low strength
- Biocemented sand crust	- Quick biocementation reaction - No need to water - High strength	- Release of CO_2 during biocementation process

* Fattahi et al. (2020c)

4 CONCLUSION

In order to assess the efficiency of biotechnological methods for wind erosion control, this study subjected a biocrust formed by *Microcoleus vaginatus* cyanobacterium and a biocemented sand crust created by *Bacillus megaterium* to wind flow with five different velocities. This study also measured the strength of the crust by the penetrometer test. The biocemented sand crust was relatively stronger and showed less erosion than the biocrust; however, both of them provided good protection against wind erosion for the highly erodible sand by diminishing the erosion rate several thousand times.

Cementation effect on swelling and permeability properties of bentonite considering microscopic structural evaluation

D. Ito & H. Komine
Waseda University, Tokyo, Japan

ABSTRACT: Bentonite buffer material in the geological disposal of high-level radioactive waste would be subjected to high temperatures and pressures for a long period, which may cause alteration through cementation and changes of swelling and permeability characteristics. In this study, bentonite ore was used to simulate the cemented buffer material, and effects of cementation on swelling and permeability properties were evaluated. As results, swelling pressure of undisturbed specimens was about half that of reconstituted specimens, while hydraulic conductivity was almost in the same order. To elucidate mechanism from microstructural viewpoint, SEM and XRD was utilized. SEM observations showed the undisturbed specimens had more complex structure at same dry density. XRD analysis indicated that undisturbed specimens had smaller montmorillonite basal spacing at same water content. Therefore, cementation may reduce permeability by complexity of structure, and inhibit water absorption and swelling of montmorillonite interlayers, resulting in almost no change in hydraulic conductivity.

1 BACKGROUND

In the geological disposal of high-level radioactive waste, bentonite is planned to be used as a buffer material surrounding the waste in many countries (Pusch, 1992; Sellin & Leupin, 2013). Bentonite has high swelling capacity and low permeability, so it can delay contact between radionuclides and groundwater. The properties of bentonite at the initial condition of disposal have been investigated experimentally and theoretically in many countries (Alonso & Gens, 1999; Komine & Ogata, 2004; Garitte et al., 2017), and repository design proposals have been established (Ogata et al., 1999). On the other hand, because of the long half-life of radionuclides, buffer material is required to maintain their integrity for tens of thousands of years. However, because the buffer material may be subjected to high temperatures and pressures and inflow of groundwater containing salts, there is concern that cementation would occur and properties such as swelling and low permeability will deteriorate. It is difficult to reproduce and evaluate such long-term alteration phenomena only by laboratory experiments. In this study, we focused on natural analogues, a geological research method, and used raw ore from bentonite deposits that has undergone diagenesis in the natural ground as a simulated buffer material.

In this paper, to quantitatively evaluate the effect of cementation on swelling and permeability properties of bentonite, measuring swelling pressure, and hydraulic conductivity experiments were conducted, and microscopic structural evaluation was performed using SEM and XRD.

2 SAMPLE USED IN THIS STUDY AND TESTING APPARATUSES

2.1 *Fundamental properties of bentonite ore and specimen preparation*

Na-bentonite ore from the Tsukinuno Mine in Yamagata, Japan (Tsukinuno ore) was used. Fundamental characteristics of the ore are shown in Table 1. The bentonite ore used in this study is shown in Figure 1.

To evaluate the cementation effects on swelling and permeability properties, undisturbed and reconstituted specimens were prepared by the following method. The undisturbed specimens were

DOI: 10.1201/9781003299127-277

formed from ore using cutter rings, trimmers, knives, and were made into specimen sizes (28 mm in diameter × 10 mm in height for swelling pressure test and 28 mm in diameter × 2 mm in height for permeability experiment). The reconstituted specimens were prepared using a crusher with grain sizes of ~0.425 mm, 0.850 to 2 mm, and 2.00 to 4.75 mm, and then compacted to an arbitrary dry density by applying static load. All grain sizes were used in the swelling experiments, while only specimens with grain diameters of ~0.425 mm was used in the permeability experiments.

Table 1. Fundamental characteristics of bentoniteore.

Soil particle density (Mg/m^3)	2.77
Liquid limit (%)	419.1
Plastic limit (%)	29.2
Plasticity index	389.9
Montmorillonite content (%)	44.7
Leached cation (Na^+) (cmol(+)/kg)	43.7
Leached cation (Ca^+) (cmol(+)/kg)	5.6
Leached cation (K^+) (cmol(+)/kg)	Lower than detection limit
Leached cation (Mg^{2+}) (cmol(+)/kg)	0.9
Accessory minerals	Quartz, Plagioclase
Approximate geological age	Ten million years

Figure 1. Appearance of bentonite ore.

2.2 *Testing devices of swelling pressure and hydraulic conductivity test*

Figure 2 shows the experimental apparatus. Lateral deformation of the specimen was restrained by a stainless ring, and vertical deformation was controlled by tightening the clamp knob in the swelling pressure experiment. Evaluation is based on the relationship between the value obtained when the increase in swelling pressure converges after a certain period (maximum swelling pressure) and the dry density at that time.

Figure 3 shows the hydraulic conductivity apparatus. This apparatus is for falling head hydraulic conductivity test, and burettes are connected to both the inlet and outlet sides and air pressure is applied to add hydraulic gradient. Details of the experimental setup and procedures are described in Ito et al., 2022. Tests were conducted under conditions of a hydraulic gradient of 4000- 20000 during the test period, and in this range of hydraulic gradients, proportional relationship between flow flux and hydraulic gradient was observed which follows Darcy's law. Average hydraulic conductivity was taken for each measurement period in a similar way as Ito et al. (2022a).

3 TESTING RESULTS ON SWELLING AND HYDRAULIC PROPERTIES

Figure 4 shows relation between maximum swelling pressure and dry density of specimen. For the reconstituted specimens, maximum swelling pressure tended to be higher with higher dry density, and the effect of grain size before compaction was small. On the other hand, the undisturbed specimens showed a variation in pressure values, but all of them were only about half of those of the reconstituted specimens of similar dry density. These results indicate that swelling pressure of undisturbed specimen is reduced by cementation, although the effect of cementation might be small when the samples are crushed before compaction.

Figure 5 shows the relation between hydraulic conductivity and dry density of specimens, as well as theoretical calculation using equations proposed by Komine (2008). Hydraulic conductivities of the undisturbed and reconstituted specimens were all in the order of 10^{-12} to 10^{-13}, which are similar to the calculation results.

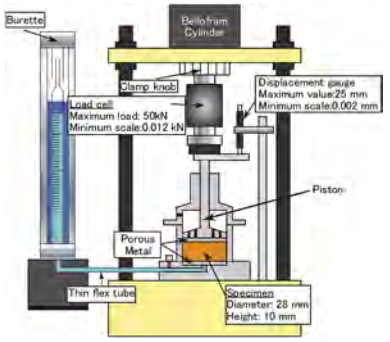

Figure 2. Swelling pressure test apparatus.

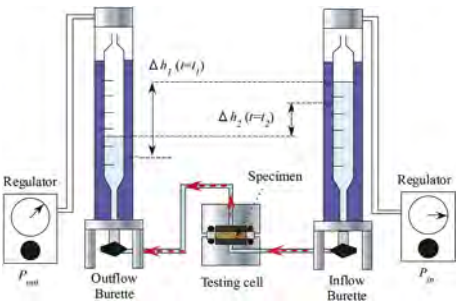

Figure 3. Hydraulic conductivity apparatus.

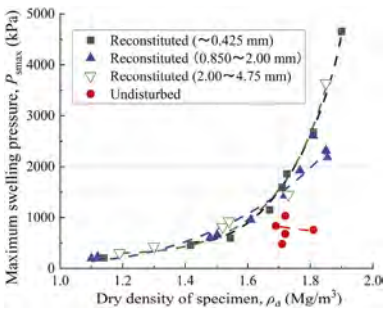

Figure 4. Relation between maximum swelling pressure and dry density.

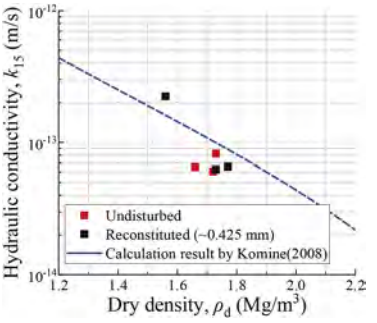

Figure 5. Relation between hydraulic conductivity and dry density.

4 MICROSTRUCTURAL OBSERVATION RESULTS BY SEM AND XRD

The differences in the shape and skeleton of the soil particles in the undisturbed and reconstructed specimens were observed using SEM (S-4500, Hitachi). When making observed sample, undisturbed and reconstituted specimens (∅ = 28 mm × h = 10 mm) of similar dry density (ρ_d = 1.7 Mg/m^3), and then the specimens were broken to expose fresh internal sections and formed to a size of 5 mm × 5 mm. Figure 6 shows appearance of SEM observation sample.

Figures 7 and 8 show observation results of undisturbed and reconstituted samples, respectively. Undisturbed sample had a complex soil particle shape, and reconstituted sample had larger pores that were not seen in undisturbed sample. From these results, the more complex soil skeleton because of cementation in undisturbed specimens might affect lower water permeation.

Also, XRD measurements were performed on the undisturbed and reconstituted specimens after water absorption and swelling pressure measurements. Montmorillonite basal spacing and adsorption state of water molecules were evaluated from the peak shapes obtained by XRD. Details of this measurement and devices are described in Ito et al. (2022b).

Figure 9 shows peak shape comparison of undisturbed and reconstituted specimen at water content of 17.0% and 18.8%. From these results, in reconstituted specimen, peak of water molecule three-layer hydration (2θ=4.7 deg) is dominant, whereas in undisturbed specimen, two-layer hydration peak (2θ=5.8 deg) remains beside the three-layer hydration peak. Undisturbed specimen has fewer water molecules between montmorillonite crystalline layers because of cementation. In undisturbed specimens, pore outside montmorillonite interlayer remains, rather than only between the montmorillonite layers which dominate the low permeability of bentonite. The combination of two factors, which complexity of skeleton and inhibition of swelling of montmorillonite layers, is assumed to be the reason why the permeabilities of the undisturbed and reconstituted specimens were not significantly different.

Figure 6. SEM observation sample.

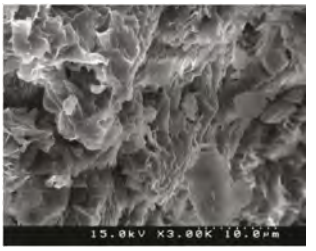

Figure 7. Observation on undisturbed sample (×3000).

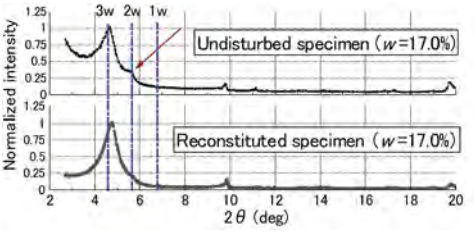
Figure 8. Observation on reconstituted sample (×3000).



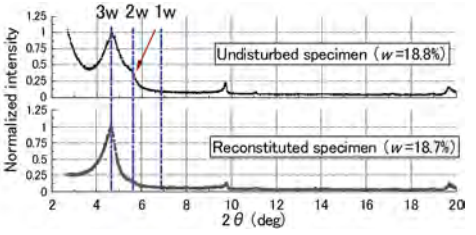


Figure 9. XRD peak shape comparison of undisturbed and reconstituted specimen at water content of 17% and 18.8%.

5 CONCLUSION

1. Because of cementation, swelling pressure of undisturbed specimen was almost half of that of reconstituted specimen, on the other hand, hydraulic conductivity was in the same order.
2. From SEM observation, undisturbed specimen has more complex soil particle structure. From XRD analysis, montmorillonite interlayer in undisturbed specimen is inhibited swelling and has less water molecules. From these factors, while undisturbed specimens decrease in swelling, the hydraulic conductivity remained almost the same.

ACKNOWLEDGEMENTS

This research was supported by the Ministry of Economy, Trade, and Industry of Japan. This study was part of JSPS KAKENHI 21K04260. XRD and SEM tests were conducted at the Materials Characterization Central Laboratory, Waseda University (Izutani et al. 2016).

Numerical study on fluid transport with viscosity reduction due to diffusion in porous materials

J. Yang & T. Mukunoki
Kumamoto University, Kumamoto, Japan

ABSTRACT: The purpose of this study is to elucidate the flow phenomena of a highly viscous fluid in sandy soil for the recovery of heavy oil using the vapor extractor (VAPEX) method. In this study, the diffusion of heavy oil into a solvent is investigated. Syrup and distilled water are used as model to simulate the behaviors of heavy oil and organic solvents. The numerical model is validated by coupling the Navier–Stokes equation with the advection–diffusion equation. Subsequently, the concentration distribution of the fluid with a constant diffusion coefficient (D) is compared with that with a variable D, which is due to viscosity reduction in a porous geometry obtained from X-ray computed tomography images.

1 INTRODUCTION

Oilsands refers to sand that contains heavy oil with high viscosity or bitumen components without fluidity at room temperature. The mainstream methods of recovering oilsands are opencast mining and steam-assisted gravity drainage (SAGD). These methods require significant amounts of energy and water during production; in fact, the fuel cost constitutes more than one-half of the production cost. These methods are primarily limited by their high production cost.

Heavy oil can be recovered using organic solvents instead of heat from steam. The vapor extractor (VAPEX) method, which involves viscosity reduction via the diffusion of organic solvents into heavy oil, has garnered significant attention in recent years (Lin *et al.* 2014). To understand flow behavior in a porous structure, it is important to evaluate the pore structure quantitatively. Then, samples of the oilsands core are difficult to obtain, and investigation regarding the pore structure of the core and fluid flows in pores in the undisturbed state are few. In this study, to investigate heavy oil recovery using the VAPEX method, the flow of high viscous fluids in a porous material is analyzed. First, the behaviors of syrup and distilled water as heavy oil and solvent, respectively, are simulated owing to their similar viscosity. Their pore structure geometries can be obtained from X-ray computed tomography (CT) images. Subsequently, their flow and concentration in the pore are analyzed using the finite element method in 2D.

2 RELATION AMONG VISCOSITY, DIFFUSION COEFFICIENT, AND CONCENTRATION

The viscosity of syrup was measured by the viscosity measuring instrument shown in Figure 1. The viscosity measuring range of the experimental device is 0.015–200 Pa·s. The initial viscosity of syrup measured is 34 Pa·s, and the volume is approximately 400 mL. An appropriate amount of water is added to the syrup from the initial concentration state, and after it is completely stirred and mixed, the concentration change is measured using a saccharimeter. Subsequently, the viscosity change is measured after mixing is performed using a viscometer. After the measurement is performed, an appropriate amount of water is added again. After fully mixing and stirring the solution, the measurement is repeated until the viscosity is reduced to the minimum viscosity.

DOI: 10.1201/9781003299127-278

The diffusion coefficient (D) of matter in a liquid varies with the viscosity of the liquid. It is generally believed that D is inversely proportional to the viscosity of liquid. In this study, Wilke–Chang's formula was applied to calculate the D in liquid.

$$\mathrm{D} = 7.4 \times 10^{-8} \times \frac{(xM)^{1/2} T}{\mu V^{0.6}} \tag{1}$$

where x is the association parameter of the pure solvent (when solvent is water, x = 2.6), M the molecular weight of the solvent (g/mol), μ the viscosity (Pa·s), c the concentration, V the molar volume of the solute (cm^3/mol), and T the temperature (°K). The parameters of the syrup (as shown in Table 1) are used in this study. Figure 2 shows the profile of the diffusion coefficient–viscosity obtained using Wilke–Chang's formula and the viscosity measured at different concentrations using the setup shown in Figure 1. When the diffusion coefficient is lower than 1Pa·s, the diffusion coefficient is almost unchanged. Meanwhile, the viscosity remains almost unchanged when the concentration is lower than 65%.

Table 1. Wilke–Chang's parameters.

Molecular weight of the solvent (g/mol)	18	Molar volume of the solute (cm^3/mol)	244.5
Viscosity of the solvent (Pa·s)	0.001	Temperature (K)	293.15

Figure 1. Viscosity measuring instrument.

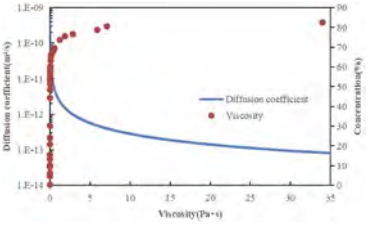

Figure 2. Viscosity–diffusion coefficient-concentration.

3 NUMERICAL ANALYSIS

3.1 *Numerical model*

Authors prepare a container model which is upper is free (i.e. no pressure and no inflow). Therefore, the Navier–Stokes (NS) equation and hydrostatic pressure condition are expressed by only the upper-end open boundary condition.

$$\frac{dV_i}{dt} = \frac{\partial V_i}{\partial t} + u\frac{\partial V_i}{\partial x} + v\frac{\partial V_i}{\partial y} + w\frac{\partial V_i}{\partial z} = -\frac{1}{\rho} gradP + \frac{\mu}{\rho}\nabla^2 V_i + F \tag{2}$$

$$P = \rho g z \tag{3}$$

Here, V_i is the velocity in the pore; $i = x, y;$ t is the time; u and v are the velocities for each dimension; ρ is the fluid density; P is the pressure; μ is the viscosity; F is the body force. The velocity V_i is substituted into the advection term of the advection–diffusion equation. For the analysis, the diffusion of syrup in the pore into water is expressed by the following advective–diffusion (AD) equation:

$$\frac{\partial c}{\partial t} = D \cdot \nabla^2 c - V_i \cdot \nabla c \tag{4}$$

c is the concentration. The parameters as shown in Table 2. To evaluate the variable D, two cases are prepared. One is using a constant D of 5.1 × $10^{-1\circ}$ (m^2/s). And the other case is that in the

analysis, the viscosity can be deduced by Figure 2, and then the deduced viscosity can be used in equation (1) to get diffusion coefficient D and both parameters are use in equation (2) at each time step. The flow of fluid in granular material models with different particle shapes and sizes is only affected by gravity. The calculation time is 2000 s, and the outputs are obtained every 10 s. Figure 3 shows three different meshes in a 4.5 mm × 3.5 mm area obtained from an X-ray CT image. To investigate the relationship between the fluid behavior and pore structure, silica sand 5, glass beads (GB), and crushed glass beads (CGB) are prepared as three different types of particles. Table 3 shows the settings of the meshes. The pore is filled with the syrup, and water is filled in the bottom reservoir. For the initial condition, the concentration at the top is set as c = 82.5%, and the concentration of water at the bottom of the model is set as c = 0%. The hydrostatic pressure condition is used in the Navier–Stokes equation. To elucidate the relationship between the pore structure and the advection–diffusion phenomenon, the authors analyzed the advection–diffusion of three types under the effect of gravity only. All calculations were performed using computational fluid dynamics (CFD) simulation and the surface flow modules in COMSOL 5.3a.

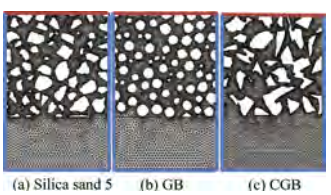

Figure 3. Geometry from numerical analysis.
(Red line: open boundary, without velocity; blue line: without velocity)

3.2 *Analysis results*

Figure 4 shows the pore size distribution curve of the three grains obtained from the method of Mukunoki *et al.* (2016). The average pore diameters of silica sand 5 and GB are similar, i.e., 0.13 mm. In addition, the average pore diameter of CGB is 0.17 mm. Figure 5 (I) and (II) show the concentration distributions calculated using (I) a constant D and (II) various D values at 1000 s for each material, respectively. The concentration obtained using the D from Wilke–Chang's equation shows that the diffusion layer becomes thinner as the concentration gradient increases. As shown in Figure 2, the D at high concentrations is small; therefore, the flow change at high concentrations on the upper region is extremely slow. Figures 6 (I) and (II) show the concentration at 2000 s. The results based on the constant D show that diffusion occurs faster as compared with those based on variable D values, as shown in Figure 6 (I). The change in D with the viscosity confirms almost no progress in dissolution in the upper interstitial region, as shown in Figure 6 (II). When D changes because of the viscosity, the syrup at the top of exhibits high viscosity and less fluidity; therefore, D is less than 10^{-12} m^2/s and water cannot diffuse into the syrup. Comparing between silica sand 5 and GB, although their porosity diameters are the same as that shown in Figure 4, the diffusion of syrup is different. The concentration of syrup in GB is distributed uniformly, but the diffusion on the left region of silica sand is faster than that on the right. The analysis shows in all cases, the syrup is trapped in the yellow circle shown in Figure 6. Figure 7 shows the concentration and velocity profiles at the black

point indicated in Figure 6. Compared among silica sand 5, GB, and CGB, at the initial state of the position where the syrup appears trapped, the liquid flow speed is low, and the transport of syrup is primarily governed by diffusion. Furthermore, the liquid flow velocity in the pores of GB is 10 times faster than those of silica sand 5 and CGB, and the diffusion speed of syrup is relatively fast. When the syrup concentration reaches a certain concentration and the fluidity of syrup increases significantly, the migration speed is expected to be high.

4 CONCLUSIONS AND ACKNOWLEDEGMENT

In this study, authors focused on the flow and concentration of syrup in granular materials are analyzed using 2D-FEM coupled NS and AD equations with/without change of the diffusion and viscosity coefficients with concentration change of syrup in water. When the syrup concentration reaches a certain concentration, the fluidity of the syrup increases significantly because of increase of diffusion coefficient and reduction of viscosity. The area where water and syrup contacted has concentration change so that the changing speed of diffusion and viscosity coefficient become fast locally. The liquid flow rate in the pores of GB is 10 times that of silica sand5 and CGB under same porosity condition. This indicates that pore structure affects fluid migration.

In the end, authors would like to acknowledge that this research has been supported by Fund for the Promotion of Fostering Joint International Research(B) (19KK0109). We also appreciate China Scholarship Council about financial support for Chinese students.

Scaling effects on lead release from excavated hydrothermally altered rock

X. Du, T. Inui & S. Ogata
Osaka University, Suita, Osaka, Japan

ABSTRACT: Excavated hydrothermally altered rocks naturally contain hazardous elements. When these rocks are exposed to the environment, they generate leachates containing toxic elements like lead and arsenic exceeding the environmental regulations. In this study, column percolation tests were performed for crushed hydrothermally altered acid rock sample at various particle sizes and column dimensions to assess the leaching of lead. Both the larger particle size and larger thickness lowered the pH values of the effluents and promoted the leaching of Pb, almost proportional to the specific surface area of the samples and the retention time in the column. pH values influenced by the particle size and layer thickness were found to have a significant correlation with Pb concentrations. This finding supports that the scaling effects arising from particle size and column dimensions on Pb leachability can be accounted for by the pH alternation.

1 INTRODUCTION

Hydrothermally altered rocks contain certain amounts of non-anthropogenic toxic metals and metalloids such as lead and arsenic due to their geological histories. Although these toxic elements could remain stable in the rock mass under an anaerobic depositional environment, they become mobile and might contaminate the surrounding soil and groundwater when they are excavated, since an increased specific surface area, exposure to water and air, and wetting-drying processes promote their leachability.

Column percolation test is one of the most common methods used to evaluate the leaching behaviors of toxic elements in geomaterials (e.g. ISO/TS 21268-3 2019). Currently, most column experiments employ a particle size of less than 2 mm or so to prepare the specimens, mainly due to the limitations in dimensions of columns adopted to ensure the sample homogeneity and prohibit the preferential flow (Inui et al. 2017). The scaling effects resulting from particle size and column size on the leaching behavior are apparent but still not fully understood and should be evaluated quantitatively to appropriately interpret the laboratory testing results into the in-situ leaching behavior. To address these issues, column percolation experiments were performed for a hydrothermally altered rock with two different particle size distributions and two column thicknesses. Changes in pH and the evolution of Pb were continuously monitored to evaluate the scaling effects arising from both particle and column sizes.

2 MATERIALS AND METHODS

2.1 *Materials*

The hydrothermally altered rock in this study was collected around a tailing dump of a copper-lead mine in Japan. Rock samples were collected randomly by hand shovels with varying original sizes from 20 to 100 mm. After being transported to the laboratory, these rocks were air-

Table 1. List of column experimental conditions.

Case	Particle size (mm)	Inner diameter (mm)	Thickness (mm)	Dry density (g/cm^3)	Porosity	Flow rate (cm/day)	Specific surface area (cm^2/g)
S	2-9.5	50	280	1.55	42.6%	3.06	2.41
M	2-26.5	150	280	1.55	42.6%	3.06	1.03
L	2-26.5	150	560	1.55	42.6%	3.06	1.03

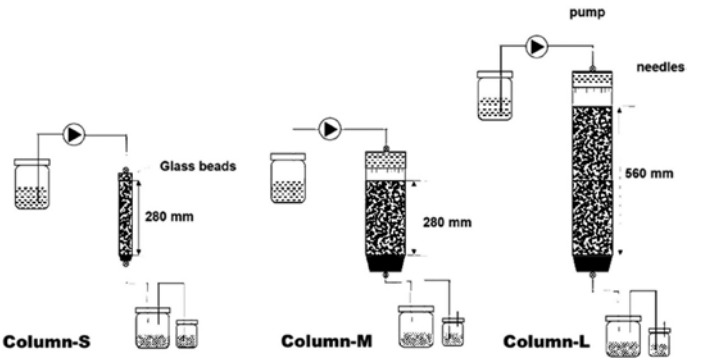

Figure 1. Schematic diagram of the column experimental setup.

dried, manually crushed by a hammer, and sieved into 4 fractions: 2-4.75 mm, 4.75-9.5 mm, 9.5-19.5mm, and 19.5-26 mm. Then these four fractions were remixed to 2-9.5 mm (2--4.75 mm×50 wt.% +4.75-9.5 mm ×50 wt.%) and 2-26.5 mm (2-4.75 mm×12.5 wt.% +4.75-9.5 mm ×12.5 wt.%+ 9-19.5 mm ×25 wt.% + ×19.5-26.5 mm×50 wt.%), both of which were used to pack the columns. The X-ray diffraction (XRD) analysis revealed that the main mineral compositions of the rock were quartz, chlorite, and mica. The bulk chemical composition of the altered rock samples primarily includes SiO_2 (wt. 59.91%), Al_2O_3 (wt. 15.62%), Fe_2O_3 (wt.15.23%), and PbO (wt. 0.05%). Pb concentration obtained from the test method Japanese Environment Agency Notification No.46 in 1991 was 35 μg/L.

2.2 *Column percolation tests*

Table 1 and Figure 1 show the column setup and experimental conditions. Three columns were set up. In Column S, the particle size was 2-9.5 mm while particle size was 2-26.5 mm in Column M and L. Column S and M shared an identical thickness of 280mm, but Column L had as twice the thickness(560mm) as that of Column M. For standardization, rock samples were packed to a dry density of 1.55 g/cm^3 in all three columns. Deionized water was introduced at a flow rate of 3.06 cm/day through three peristaltic pumps and allowed to flow by gravity. Effluents were collected every other day in the sampling bottles at the bottom of each column. The pH of the effluents was measured. Then, effluents were filtrated through 0.45μm filters and the filtrates were acidified and refrigerated. Pb concentration was analyzed by a Microwave Plasma Atomic Emission Spectroscopy (MP-AES) (4210 MP-AES, Agilent Technologies, Inc.).

3 RESULTS

3.1 *Effect of particle size distribution on the leaching of lead*

Figure 2 shows the evolution of Pb concentrations in the effluents from the columns with 2-9.5 mm (Column S) and 2-26.5 mm (Column M) in particle sizes. The ratio of the SSA (specific surface area) of Column S to that of Column M was 2.3. Pb concentrations of Column

S showed a fluctuating pattern during the first 90 days and then stabilized at around 50 μg/L, while Pb concentrations of column M fluctuated at 20 μg/L after a decline during the first 10 days. Leaching concentrations of Pb in both cases exceeded the Japanese standard for groundwater (10 μg/L). Cumulative mass of released Pb with the cumulative flow volume in the liquid to solid ratio (L/S), shown in Figure 3, revealed that the final cumulative Pb leachability in Column S was 2.7 times that in Column M, which is almost equivalent to the ratio of the SSA.

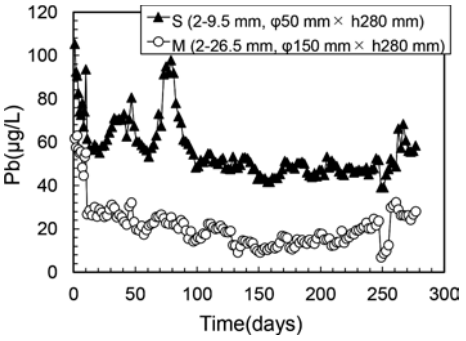

Figure 2. Particle size effect on Pb concentration.

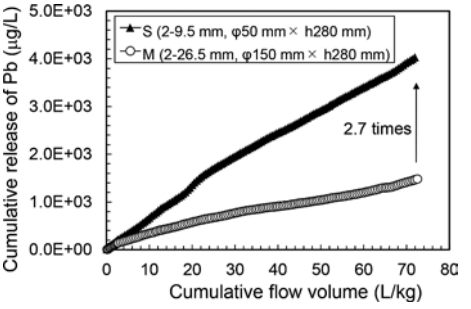

Figure 3. Particle size effect on cumulative Pb release.

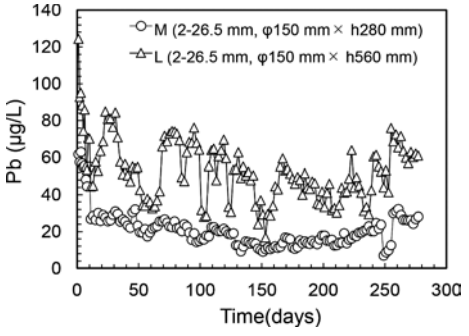

Figure 4. Thickness effect on Pb concentration.

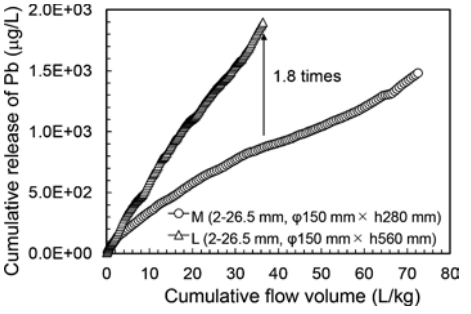

Figure 5. Thickness effect on cumulative Pb release.

3.2 *Effect of column thickness on the leaching of lead*

Figure 4 shows the evolution of Pb concentrations in columns with 280 mm (Column M) and 560 mm (Column L) thicknesses. Pb concentrations of Column L fluctuated strongly at around 50 μg/L after a sharp drop within the first 10 days and were1.5-5 times those of Column M. To compare the leaching under the same L/S ratio, Pb accumulative releases were plotted with the cumulative flow volume in the L/S ratio (Figure 5). The cumulative Pb leachability of the 560 mm thickness column was almost twice (1.8 times) that of the 280mm column except for the initial stage. This increase in Pb leachability proportional to the thickness could be attributed to the lower pH in the 560mm column, which will be further discussed in the section below.

4 DISCUSSION

Figure 6 shows the profiles of effluent pH in the three columns. The lowest pH values among the three columns occurred on the first day and then all pH values increased in the successive 20 days prior to stabilization. After 140 days, all pH values started to rise again and eventually

stabilized around 5.0, 5.4, and 5.2. Except for the initial 20 days, pH values in the fine-sized Column S were about 0.4 pH units lower on average (i.e. 2.5 times in H^+ concentration) than those in coarse-sized Column M and pH values in the thick Column L were about 0.25 pH unit lower in average (i.e. 1.8 times in H^+ concentration) than those in thin Column M over the entire experimental duration, although the fluctuations of pH values in the coarse-sized column, particularly in Column L, were greater than that in fine-sized Column S. This observation support that the pH values also correlated quantitatively to the SSA and the column thickness.

To evaluate the pH effect on Pb leaching in column percolation tests, concentrations of Pb obtained in the three column tests were plotted with respect to the effluent pH values in Figure 7, which indicates that the lower pH values, associated with the higher reactivity of the fine particles and the longer retention time of the leachate in the column, enhanced the Pb leaching. This relatively high correlation between Pb and pH values indicated that pH was the dominant factor in Pb leaching in column experiments regardless of the various particle size and column thicknesses.

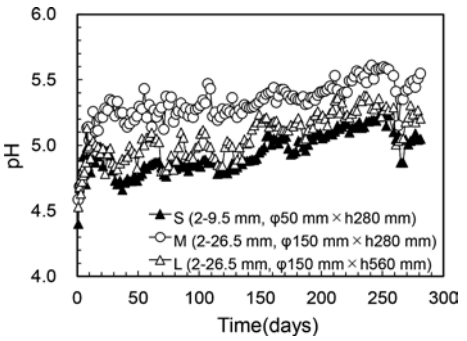

Figure 6. Evolution of pH values with time.

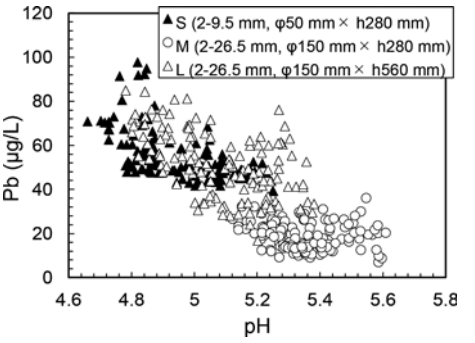

Figure 7. Relations between pH and Pb concentrations.

The accordant fluctuations in pH and Pb concentration, particularly in the 560mm column, also supported this deduction (Figures 4 and 6). The high pH-dependency of Pb leaching may primarily be explained by the adsorption-desorption of Pb onto Fe-oxyhydroxide and the dissolution-precipitation of carbonate minerals cerussite ($PbCO_3$) and hydrocerussite ($Pb_2(CO_3)_2(OH)_2$) (Gadde et al. 1974; Godelitsas et al. 2003; Tabelin et al. 2012). As pH becomes more acidic, Pb-carbonates become more soluble and Fe-oxyhydroxides/oxides become more positively charged, which could release more Pb into the solution.

5 CONCLUSIONS

The scaling effects on non-anthropogenic Pb leaching from the hydrothermally altered rock, triggered by the particle size and layer thickness, were investigated by performing column experiments with two particle size ranges and two thicknesses. The main findings of this study are summarized as follows;

(1) Both the larger SSA of the rock sample and layer thickness led to the lower effluent pH values and the higher Pb release with respect to the cumulative water flow in the L/S. They quantitatively correlated well with each other.
(2) A significant correlation between pH and Pb release demonstrated that pH values could account for the Pb leaching from the acidic hydrothermally altered rock, influenced by the particle size and column dimension. Further research is necessary to evaluate the scaling effects on the leaching of other typical toxic elements such as arsenic.

Swelling deformation and unloading curve of compacted bentonite in saline solution

Y. Watanabe & E. Yoshikawa
Central Research Institute of Electric Power Industry, Chiba, Japan

ABSTRACT: The swelling deformation of compacted Na-bentonite using NaCl solution was investigated. A higher concentration resulted in a lower swelling rate. Upon unloading the void ratio increased along the normal consolidation line, however the unloading curves for deionized water (DW) and NaCl solution differed after a threshold void ratio. The unloading curve in DW gradually increased its slope, whereas that in NaCl seemed to reach upper value. It is indicated that the osmotic effect basically dominates the swelling deformation in lower confining stress and the crystalline swelling of montmorillonite controls the limits of volumetric change in saline solution.

1 INTRODUCTION

The design of most geological disposal facilities for radioactive waste is based on the multibarrier concept, which involves natural host rocks and engineered barriers. Owing to the low permeability, compacted bentonite can be used to inhibit the migration of radioactive nuclides. Swelling deformation of the material is important in terms of the self-sealing, which fills the primary space caused by construction difficulties, and the self-healing, which fills the gap generated by material erosion and gas migration after saturation (Pusch, 1992, NUMO, 2013). According to the environmental condition, the saline solution, such as seawater (SW), infiltrates the engineered barrier. The change in swelling property is a key issue on the evaluation of self-sealing and healing.

The swelling pressure and deformation have been discussed on the basis of the void ratio–effective stress, *e*-*p*', relationship (Sridharan et al., 1986, Wang et al., 2012). The osmotic swelling likely characterizes the consolidation-swelling behavior of the compacted bentonite, specifically upon unloading process (Kyokawa et al., 2020). Higher ionic concentration of porewater declines the osmotic effect. It is significant to understand the swelling deformation of the compacted bentonite in saline solution in relation to the ordinal consolidation-swelling test result on *e*-*p*' plane.

This study investigated the swelling deformation of compacted Na-bentonite using NaCl solution. After the equilibrium swelling pressure was measured, the swelling deformation was measured by unloading the confining stress in steps. The unloading curves in deionized water (DW) and saline solution were compared and the difference was discussed.

2 EXPERIMENTAL PROCEDURE

2.1 *Sample preparation and specimen production*

Na-bentonite (Kunigel-V1, Kunimine Industries Co., Ltd.), mined from Yamagata Prefecture in Japan, was used. The physicochemical properties of the bentonite are listed in Table 1. The leachable cations, which approximately correspond to the exchangeable cations, were identified by leaching with a 1-mol/L NH_4Cl solution. Leachable Na ions were dominant in the bentonite. The amount of methylene blue absorbed was measured according to the Japanese Industrial Standard

DOI: 10.1201/9781003299127-280

(JIS Z 2451). Assuming that the methylene blue absorbed on to the pure montmorillonite in the bentonite was 140 mmol/100g, the montmorillonite content was estimated to be 51.4%. According to X-ray diffraction analysis, other than the montmorillonite, the bentonite contained quartz, feldspar, clinoptilolite, calcite, pyrite, and dolomite (Watanabe and Tanaka, 2022).

The compacted bentonite was produced by static compaction. The target dry density of the specimen was 1.6 Mg/m^3. The specimen was 20 mm in height and 60 mm in diameter, including a center hole of 6.0-mm diameter. A noncontact-type displacement gauge of 6.0 mm in diameter was inserted the hole and the small-scale deformation of the specimen was directly measured.

Table 1. Physicochemical properties of the Na-bentonite used in this study.

Particle density of soil (Mg/m^3)		2.674
Methylene blue adsorbed (mmol/100g)		72
Total amount of leachable cation (meq/100g)		106.7
Amount of leachable cation (meq/100g)	Na	57.9
	K	1.9
	Ca	44.1
	Mg	2.8

2.2 *Swelling deformation test*

Figure 1 depicts the swelling deformation test apparatus equipped with controls for the application of a small strain and loading pressure. First, the swelling pressure was measured under constant constraining condition by controlling small strain using the stepping motor during the hydration by DW or NaCl solution (0.5 mol/L and 1.0 mol/L), because the slight deformability of specimen during saturation influences the equilibrium swelling pressure (Watanabe and Tanaka, 2022). The small strain control was turned off after the equilibrium swelling pressure was measured, and a vertical pressure equal to the equilibrium swelling pressure was applied to the specimen. Subsequently, the vertical pressure was unloaded, and the swelling deformation was measured. The vertical pressure was reduced in steps, and the swelling deformation was measured when it approximately converged to a constant value at each stage. The swelling rate was defined as the ratio of the incremental height of the specimen to the initial height of the specimen.

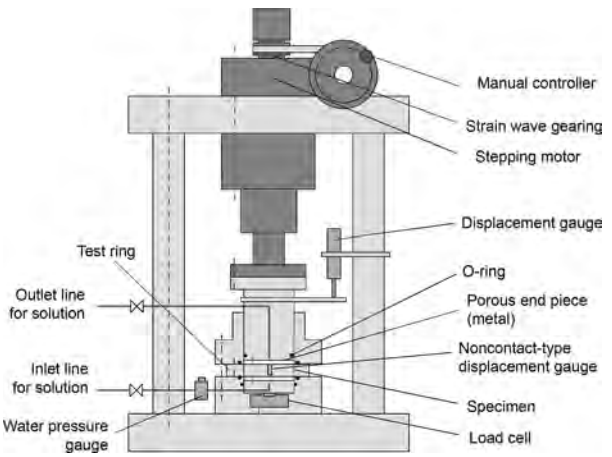

Figure 1. Apparatus for swelling deformation test.

3 RESULT AND DISCUSSION

3.1 *Swelling pressure and swelling deformation*

The relationship between the equilibrium swelling pressure and NaCl concentration is shown in Figure 2. The equilibrium swelling pressure was exponentially decreased along the increase in NaCl concentration. The equilibrium swelling pressure in 1.0 mol/L-NaCl solution was approximately 62% of that in DW.

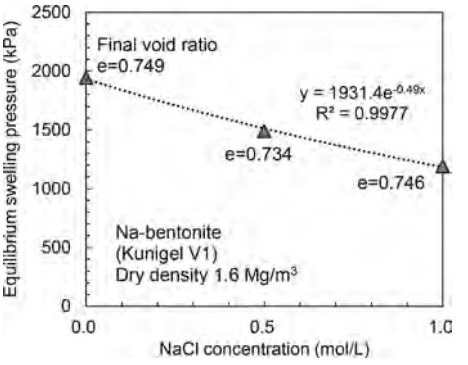

Figure 2. Relationship between equilibrium swelling pressure and NaCl concentration.

The relationship between the vertical pressure and the swelling rate is depicted in Figure 3. A smaller vertical pressure resulted in a larger swelling rate of the compacted bentonite. Furthermore, a higher NaCl concentration showed a lower swelling rate. The swelling rate in NaCl solutions when 26–28 kPa of the vertical pressure was 24–29%, which was consistent with the result in SW, considering the ionic strength of SW.

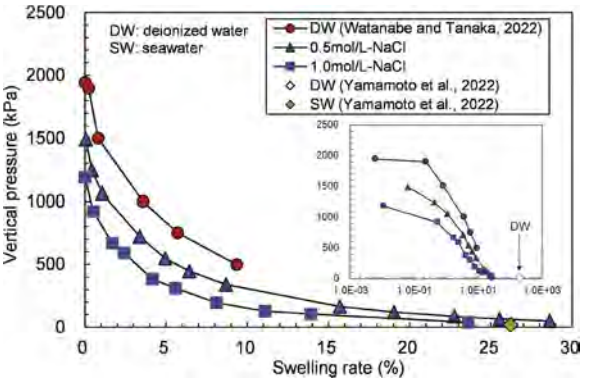

Figure 3. Relationship between vertical pressure and swelling rate.

3.2 *Unloading curves in the swelling deformation for deionized water and saline solution*

The void ratio after swelling deformation in each vertical pressure was compared to the normal consolidation line (NCL) in Figure 4. Upon unloading of the specimen saturated using DW, which had no consolidation history, the specimen swelled, and the void ratio increased along the NCL (Watanabe and Tanaka, 2022). The unloading curves for DW and NaCl solution differed after a threshold void ratio. In lower vertical pressure for DW, afterwards, the void ratio greatly exceeded from the extrapolated values of the NCL in the high-pressure range. It was close to the swelling pressure calculated based on the diffuse double

layer (DDL) theory (Komine and Ogata, 2004). It is suggested that the lower vertical pressure, as a threshold around the void ratio of 1.0, causes a significant non-linearity of the unloading curve through that the electrostatic swelling becomes more dominant. The clay particles would more disperse in the specimen, and the microstructure might be reconstructed.

For NaCl solution, the unloading curve was approximately same as that in DW, although it included a slight nonlinearity. Stepped unloading after constant volume saturation was expected to lead to approximately the same void ratio as when the material was swollen from unsaturated to saturated in saline solution. However, the swelling deformation seemed to be stopped around 1.2 of void ratio in the saline solution. This is because that the diffuse ion layer growth on montmorillonite is curtailed in the saline solutions (Rao et al., 2013), and it was surmised that only crystalline swelling was operative on swelling deformation in that condition. The crystalline swelling would be a key to estimate the swelling rate of compacted bentonite in higher ion concentration condition, that osmotic effect cannot work.

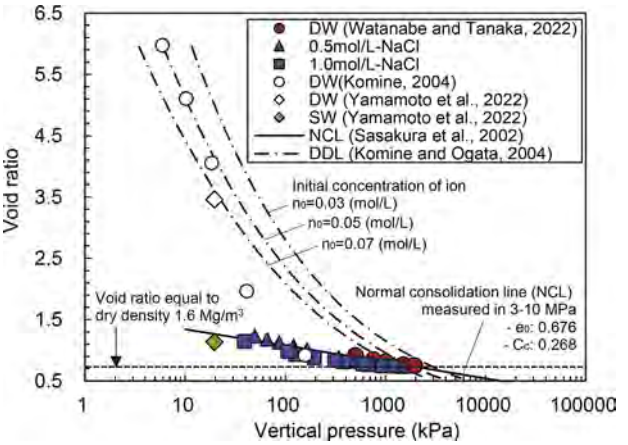

Figure 4. Relationship between void ratio and vertical pressure.

4 CONCLUSIONS

This study investigated the swelling deformation of compacted Na-bentonite (1.6 Mg/m^3) using NaCl solution, comparing some literature values. The void ratio of the compacted bentonite increased along the NCL for a while after unloading. The unloading curve in DW gradually increased its slope after a threshold void ratio, whereas that in NaCl seemed to reach upper value. It should be noted that the limit of swelling rate changes according to the ion concentration. Further study needs to infer the limitation by considering the crystalline swelling of montmorillonite.

Elevated temperature on leaching of arsenic and boron from excavated rocks

T. Kato, A. Takai, L.W. Gathuka & T. Katsumi
Graduate School of Global Environmental Studies, Kyoto University, Kyoto, Japan

Y. Xie
Graduate School of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: This work evaluated the leaching behaviors of geogenic arsenic and boron of two excavated rocks under different temperatures. Excavated rocks with geogenic contamination are expected to be used in embankments with proper countermeasures. Their leaching behaviors might change because of seasonal and daily changes in ground temperature. However, the effect of temperature on leaching behaviors has not been well examined. Column tests at temperatures of 20 and 40°C were performed using rock samples. Elevated temperatures led to the release of greater amounts of arsenic and boron. The largest arsenic concentrations obtained from the column tests were 0.53 mg/L at 40°C, while at 20°C was 0.15 mg/L for one rock sample. The largest concentrations of arsenic and boron obtained at 40°C were at most 3.5 times larger than at 20°C. Boron concentrations decreased as electric conductivity decreased. Electric conductivity can be one index to predict the leaching behavior of boron.

1 INTRODUCTION

Large volumes of excavated soils and rocks were generated from construction projects. As a result, a certain percentage of the soils and rocks contain contaminants derived from geological processes. Geogenic contaminants, such as arsenic (As) or boron (B), are widely distributed in Japan (e.g., Tabelin et al., 2018). Such soils and rocks are expected to be used in embankments as a part of ongoing efforts to achieve sustainable soil management. However, their proper utilization is sometimes a concern, especially because contaminants can be released from the soils and rocks. Given the importance of developing economical and effective utilization methods for geogenically contaminated soils and rocks, evaluating the leaching behaviors is essential.

When excavated materials are utilized in embankments or other shallow geostructures, the effect of ground temperature on the leaching behavior of toxic elements becomes a technical concern. The daily and seasonal temperature changes in the shallow ground can be much more significant than those in the deep ground. Temperature near the ground surface can be elevated because of solar radiation. The ground temperature was often more than 30°C (Menberg et al., 2013). However, laboratory leaching tests are usually conducted at room temperature (approximately 20°C). Since leaching behaviors of geogenic contamination can be affected due to thermo-mechanical-chemical interactions, the effects of elevated temperature on leaching behaviors need to be clarified from a geoenvironmental perspective.

This work evaluated the leaching behaviors of As and B from two excavated rocks with geogenic contamination using column tests under different temperatures. Column tests were less applied to evaluate the leaching behaviors of geogenic contaminants under different temperatures, while several researchers investigated using batch leaching tests (Saito et al., 2016; Takai et al., 2020). Although batch tests have advantages in simple experimental protocol with a short testing time, the applicability of this test may be limited. Since the solute kinetics under the flow conditions can be evaluated, column tests can evaluate closer to the in-field condition than batch tests (Kato et al., 2021).

DOI: 10.1201/9781003299127-281

2 MATERIALS AND METHODOLOGY

2.1 *Materials*

Two types of rocks used in this work were excavated from tunnel construction sites. The rocks were crushed to particles smaller than 2 mm for the experiments. The rock samples were stored in sealed plastic bags to prevent their oxidation by air. Table 1 highlights the fundamental physical properties of the rock samples. In addition, the total amount of As and chemical compositions of the rock samples were measured. The rock samples were air-dried at room temperature and ground into a powder with a diameter smaller than 75 μm. The samples were evaluated by X-ray fluorescence (XRF) analysis using a Shimadzu EDX 720 energy-dispersive X-ray spectrometer.

Table 1. Physical and chemical properties of rock specimens.

Parameter	Rock 1	Rock 2
Particle density, ρ_s	2.686 g/cm^3	2.749 g/cm^3
Water content, w	1.4%	4.7%
Particle size distribution		
Sand fraction [0.075–2 mm]	83%	62%
Fines fraction [<0.075 mm]	17%	38%
Average particle size	0.85 mm	0.25 mm
As content	51 mg/kg	87 mg/kg

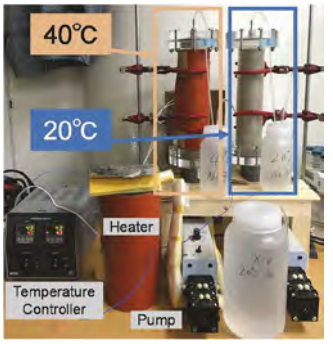

Figure 1. Setup of the column test.

2.2 *Column tests with temperature control system*

Column tests were conducted using acrylic columns (ϕ 5 cm × h 30 cm) as shown in Figure 1. A rock sample was placed in the column. Each specimen was compacted in the acrylic column in five layers with equal heights. A 125-g rammer was dropped freely from a height of 20 cm during compaction. This method was based on the corresponding ISO 21268-3 (2019). The specimen was placed between filter papers to prevent channel clogging due to fine soil particles. The dry density of the specimen for Rocks 1 and 2 were approximately 1.3 and 1.4 g/cm^3, respectively. Then distilled water was percolated in an up-flow direction using a peristaltic pump at a flow rate of approximately 15 mL/h until the specimen reached saturation. Finally, percolation was interrupted for 15 hours to achieve a saturated condition. After 15 hours, distilled water was percolated in an up-flow direction via a peristaltic pump at 15 mL/h. Leachate was collected from the outlet of the column. Column tests were conducted until the liquid-to-solid ratio (a volume of permeated solution to a dry mass of soil ratio) was larger than 10.

Temperatures of 20 and 40°C were applied to account for possible temperature changes (Menberg et al., 2013). Tests under 20°C were conducted in a constant temperature room, while 40°C were conducted by wrapping the column with rubber heaters. The temperature of the rubber heater was controlled using a controller (MTCD, Misumi Corporation). Distilled water was pre-heated to 40°C using a constant temperature bath. Tubes connected to the column were covered by glass wool (DK-089, Yamawaki Sangyo) to prevent heat dissipation. A non-contact thermometer measured the temperature of the column surface to confirm whether 40°C was achieved.

For leachate, centrifugation at 3000 rpm for 10 min and filtration with a 0.45 μm membrane filter was conducted. The filtrate electric conductivity (EC) and pH were measured using a pH/EC meter (Horiba F-54). Arsenic concentration was measured using an atomic absorption spectrophotometer (Shimadzu GFA-7000). Boron concentration was measured using an inductively coupled plasma optical emission spectrometer (Agilent Technologies ICP-OES 710).

3 RESULTS AND DISCUSSION

3.1 *Arsenic concentration and pH*

Figure 2 shows the profiles of As concentrations with pore volumes of flow (PVF) obtained from column tests. Since PVF is calculated as the volume of a permeated solution divided by a void volume, 1 PVF means one pore water is exchanged. As shown in Figure 2(a), the largest As concentration at 40°C was 0.53 mg/L, while at 20°C was 0.15 mg/L. The largest concentration at 40°C was approximately 3.5 times greater than at 20°C. As shown in Figure 2(b), As concentrations also once increased and decreased at both 40 and 20°C. The largest concentration at 40°C was 3.94 mg/L, while at 20°C was 3.19 mg/L. The largest concentration at 40°C was approximately 1.2 times greater than that at 20°C. Results show that leaching As concentration might increase as the temperature raised.

Herein, As concentrations at 1 PVF is discussed. Arsenic concentrations once increased and decreased at both 40 and 20°C. If the leaching concentration drastically decreased before 1 PVF, most contaminants flowed out as one pore water was replaced, and the leaching was considered to diminish immediately. However, even though PVF > 10, As was leached at more than 0.1 mg/L, which was 10 times larger than the regulatory limit in Japan for both rock samples. These results imply that As leching might continue relatively longer. For both Rock 1 and 2, the largest leaching concentrations were obtained after 1 PVF. Shapes of the concentration profile might not be different, but the value of the concentration might be greater at elevated temperatures.

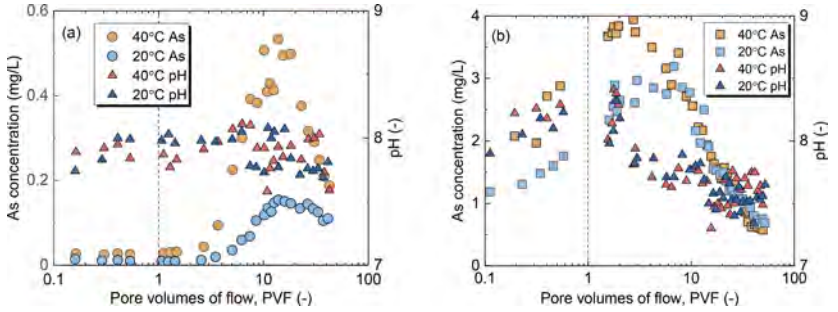

Figure 2. Arsenic concentrations and pH obtained from (a) Rock 1 and (b) Rock 2.

Figure 2 shows the profiles of pH with PVF. Alkaline pH between 7-9 was obtained from both rock samples. As shown in Figure 2(a), similar pH values were obtained regardless of temperatures, while As concentrations differed. The elevated temperature might affect not pH but As leaching behavior. According to XRF analysis, both rock samples contained some amounts of sulfide minerals. More acidic pH values should be obtained if the dissolution of sulfide minerals is promoted under elevated temperatures. However, such trends cannot be observed. Since geogenic As is usually contained in the sulfide minerals such as pyrite, dissolution of sulfide minerals is considered one of the major mechanisms of As leaching (Tabelin et al., 2018). The leaching behavior of As from these rock samples might not be related to the dissolution of sulfide minerals. In future work, the mineral composition of the rock samples and the state of the surface charge should be analyzed to investigate the leaching mechanisms of As affected by elevated temperature.

3.2 *Boron concentration and EC*

Figure 3 shows the profiles of B concentrations with PVF. Boron concentrations generally decreased as PVF increased at both 40 and 20°C. For Rock 2, the largest B concentration at 40°C was 0.14 mg/L, while at 20°C was 0.079 mg/L. The largest concentration at 40°C was approximately 1.8 times greater than at 20°C. Results show that leaching B concentration might increase as the temperature raised. In contrast to As, the largest B concentrations were obtained

before 1 PVF for both rock samples. Boron leaching might diminish more immediately than As. For B contamination, even if column tests are conducted in a short period (e.g., < 1 PVF), enough to evaluate the leaching behavior because the largest concentration can be measured.

Figure 4 shows the profiles of EC vs. B concentrations. Electric conductivity decreased drastically before 1 PVF. Generally, B concentrations decreased as EC decreased. These results mean most ions in the pore water were drained by 1 PVF. Therefore, most B might be leached with other ions as one pore water was replaced. Since measuring EC is much easier than B concentration, the EC value can be helpful indices to predict B leaching behavior approximately.

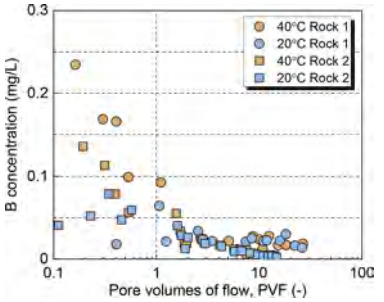

Figure 3. Boron concentrations.

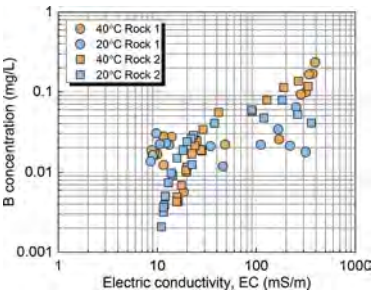

Figure 4. EC vs boron concentration.

3.3 *Geotechnical considerations for leaching behaviors under elevated temperature*

As shown in Figures 2 and 3, the largest concentrations of As and B at 40°C were at most 3.5 times larger than at 20°C. Elevated temperatures led to the release of greater amounts of As and B, but the increase was not drastic. Leaching concentration obtained from column tests is used as the boundary condition when solute transport analysis is conducted to evaluate the contamination. Since the in-situ ground temperature used by excavated materials is not always at 40°C but sometimes below 20°C, column tests conducted at 40°C may be safe side. If the solute transport analysis is performed using the As or B concentration supposed to be several times larger than obtained from the tests at room temperature, a safe prediction may conduct considering the effects of elevated temperature.

4 CONCLUSIONS

The leaching behaviors of As and B from two excavated rocks with geogenic contamination were investigated under elevated temperatures. Herein, column tests were performed at 20 and 40°C. The results support the following conclusions.

Elevated temperatures led to the release of greater amounts of As and B. The largest As concentrations obtained from the column tests were 0.53 mg/L at 40°C, while at 20°C was 0.15 mg/L for one rock sample. The largest concentrations of As and B obtained from the column tests at 40°C were at most 3.5 times larger than at 20°C. Boron concentrations decreased as EC decreased. Since measuring EC is much easier than B concentration, the EC value can be helpful indices to predict the leaching behavior of B.

Observations on deformations and pore pressures of a bentonite-sand mixture caused by heating application

T. Nishimura
Department of Civil Engineering, Ashikaga University, Tochigi, Japan

ABSTRACT: The variation in both dry density and temperature caused by the heating of a compacted, unsaturated bentonite-sand mixture tends to be the most important factor in the engineering of radioactive waste disposal barriers. The thermal effort of the bentonite-sand mixture is a significant trigger fac-tor in the coupling phenomena. Several previous experimental studies using different dry densities have reported that the most affected properties are pore pressure and expansion deformation. However, most reports lack experimental data on determination of deformation and measurement of associated pore pressures owing to a progressive increase in temperature. This study aims to establish the connection between the basic deformation properties and pore pressures produced under heating conditions and the effect on hydro-mechanical properties of a bentonite-sand mixture. This study investigated the shrinkage/expansion behavior for temperatures up to 100°C and considered the occurrence of pore pressure in the void structure for a variety of temperatures.

1 INTRODUCTION

The structural design of deep geological repositories for high-level radioactive waste consist of a barrier system using a material of hard stiffness as the sealing material (Delage et al. 2010). Some couple behavior was recognized as thermo-hydro-mechanical (THM) loadings to bentonite-sand, and THM behavior was widely studied, conducted out on previous works. Prospective designs of geological repositories for high level radioactive waste generally include an engineered berried consisting of bentonite around the waste stiffens canisters (Gens et al. 2010). As one of complex couple phenomena, a number of interacting thermal, hydraulic, mechanical and chemical phenomena produced that have a series of efforts on growing and long-term. The purpose of this study is to establish the connection between the deformation properties and the pore pressures produced under heating conditions for a bentonite-sand mixture. This study applied reliable determination of shrinkage/expansion behavior and considered the occurrence of pore pressure in void structure for a variety of temperatures.

2 TEST PROCEDURE

2.1 *Soil material and specimen*

Kunigel V1, a sodium bentonite, was used in a series of two testing programs to confirm the hydro-mechanical properties of previous experimental laboratory studies. Owing to its high montmorillonite content, the bentonite had a fines content greater than 95 %. In this testing program all of specimens mixed a silica sand, named Iitoyo No.4, into the bentonite, which had a uniformity grain size distribution. The air-dried bentonite and silica sand were humidified by spraying deionized water to reach the desired water content, which was 17.0 % in this test. All specimens had a diameter of 38 mm and a height of either 76 mm or 66 mm. The initial specimens had the following physical properties: a dry density of 1.600 Mg/m^3, void ratio of 0.710, and degree of saturation of 65.61 %. The prepared specimen size was relatively small.

DOI: 10.1201/9781003299127-282

Figure 1. Deformation test in heating.

Figure 2. Mold installed two sensors.

2.2 *Apparatus for this study*

To measure the pore fluid pressures, an improved steel mold was used, as shown in Figure 1, with two pore pressure sensors placed on the upper and lower portions of the lateral surface area. Iso-tropic heating action was supplied indirectly to the specimen through the mold. The sensors had a maximum temperature capacity of over 100°C. A steel mold without sensors was used to measure deformation in the axial direction, as shown in Figure 2. The specimen was contained by the mold, and the height of the specimen was 66 mm, which is smaller than the height of the steel mold at 76 mm.

2.3 *Series of testing program*

In the heating-deformation test, the steel mold and a thermostat chamber were used, as shown in Figure 2, and the dry densities were selected as 1.600 Mg/m^3, 1.400 Mg/m^3 and 1.200 Mg/m^3. The temperatures were 20, 60, 80 and 100°C. Only the dry density of 1.600 Mg/m^3 was used in the unconfined compression test, which was conducted after the specimen reached equilibrium at each temperature. The pressure exerted on the pores is affected by the heating effort. Therefore, to compare the pore pressure behaviors, the pore pressures were measured at both the upper and lower portions.

3 TEST RESULTS

3.1 *Deformation and unconfined compressive strength*

This study investigated the behavior of unsaturated bentonite-sand specimens with three different dry densities under increasing temperatures. Prepared heating control condition had a rage from 20°C to 100°C, and all specimens were free to deform (by shrinking or expanding) in the axial direction. All specimens exhibited expansion deformation, but the specimen with the largest deformation of 1.75 % had a dry density of 1.600 Mg/m^3, as shown in Figure 3. All specimens experienced shrinkage regardless of their dry densities at 60°C. As the temperature was incrementally and progressively increased, the shrinkage became more pronounced. The linear tendencies were verified between 60°C and 100°C, and the incline was approximately 0.01 percent per degree Celsius. Most of the shrinkage deformations occurred for the specimens with a dry density of 1.600 Mg/m^3. Subsequent to the evaluation of deformations, unconfined compression tests were conduct-ed, and the stress strain curves are shown in Figure 4. All specimens achieved peak strengths at small axial strains of less than 2.0 %. The obtained unconfined compressive strengths in order of dry densities are as follows: 563.1 kPa, 1056.9 kPa, 1121.6 kPa, and 1426.0 kPa. This verifies that the unconfined compressive strength clearly increases with increasing temperature. The black narrow symbols in Figure 4 describe the failure phenomena by unconfined compressive strength and axial strain. Considering that the performance in terms of compression stresses is a fundamental mechanical property, four straight lines were established along the data points until peak strength. The incline of the straight line clearly depends on the temperature and the determined unconfined

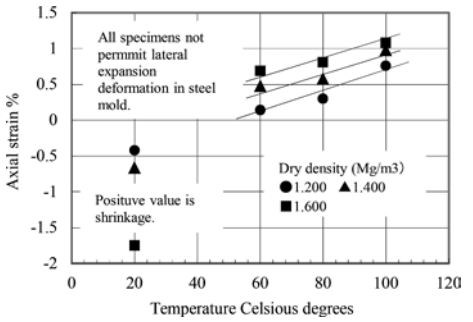

Figure 3. Change of axial strain with temperature.

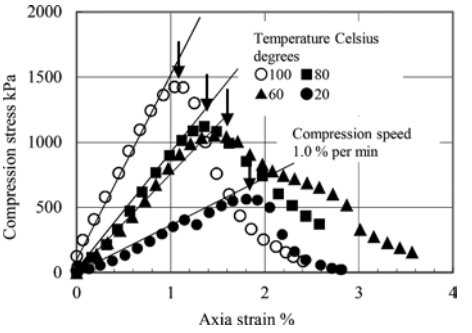

Figure 4. Stress-strain curve for dofferent temerature.

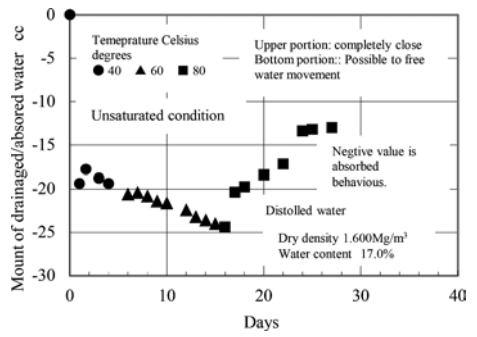

Figure 5. Change of drainaged/absorbed water.

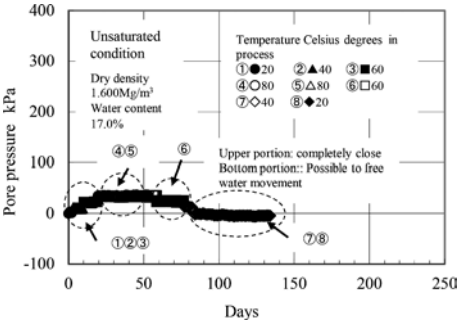

Figure 6. Measured pore pressure at upper portion.

compressive strength. The modulus of rigidity for artificial barrier structures is calculated based on the safety of predicted situations at high level radioactive waste disposal systems as follows: 170 MPa and 32 MPa for specimen temperatures of 100°C and 20°C, respectively. In addition, as the modulus of rigidity has been proven to increase with temperature, it is interesting to establish quantitative solutions.

3.2 *Hydraulic-mechanical properties under heating*

Engineered barriers are exposed to heat transfer from the radioactive waste canisters, and it is reasonable to assume that a complex coupling phenomenon is established. This phenomenon is investigated in this study by observing the change in soil moisture movement in an unsaturated bentonite-sand specimen of a constant volume in a steel mold. The hydration process and the temperature increments are shown in Figure 5. The temperature of the initial condition was 20°C. First, 40°C was applied and increased up to a maximum of 80°C. The soil moisture movement corresponding to the temperature increment was measured successfully. The soil moisture movement investigation of the unsaturated specimen, using the aforementioned heating process, described how the soil moisture movement differs for different temperature magnitudes. Almost all data sets showed the phenomenon of absorption (i.e. increased soil moisture) when the temperature was increased to 60°C. Beyond 60°C, the movement of moisture caused a drainage phenomenon, and the outflow was accurately measured. The accumulation of fluid in the small voids and the increase in pore fluid pressure causes excess soil moisture. It is possible to predict the soil moisture movements in an unsaturated bentonite-sand specimen subjected to variations in temperature.

To further understand the hydration behavior associated with soil moisture movement, pore fluid pressure measurements were also carried out. The pore pressure test was performed using two pressure sensors, which were in-stalled at the upper and lower portions of the lateral surface

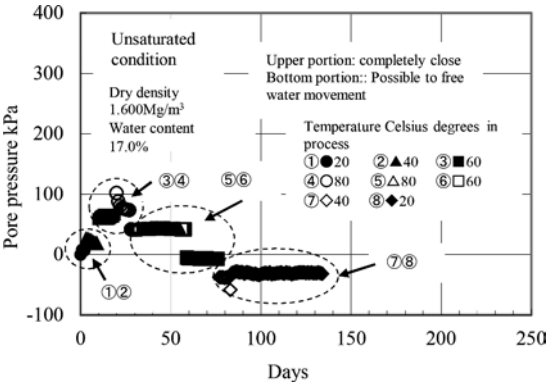

Figure 7. Measured pore pressure at bottom portion.

area of the steel mold. The temperature control process was applied at increments of 20°C with a maximum temperature of 80°C. After the temperature had reached 80°C, cooling was carried out to investigate the influence of heating-cooling hysteresis on pore pressure. At the start when the temperature was under 20°C, the specimens had different drainage conditions, which were maintained up to 80°C. The measured pore pressures of the upper portion, which remained in the completely closed condition, are shown in Figure 6. Figure 7 shows the variation in pore pressure at the lower portion, which remained in a free-draining condition. The pore fluid pressure obviously in-creased due to the temperature exceeding 40°C. The change in pore pressure according to temperature increment further varied with time. In the upper portion, the measured pore pressure reached 35 kPa at 80°C, after which the cooling process commenced. The pore pressure behavior in the cooling process was opposite to that in heating process, which is a decrement to the phenomenon. At end of test, the temperature was 20°C and the pore pressure was zero. It can be verified that the increase in pore pressure is governed by an increase in temperature by heating. The pore pressure behavior measured at the lower portion, as shown in Figure 7, is similar to that shown in Figure 6. The maxi-mum pore pressure was 102 kPa at a temperature of 80°C. In the cooling period, the pore pressure decreased smoothly to minus 30 kPa; however, the negative pore pressures contradict the pore pressure properties defined by the upper portion.

4 CONCLUSIONS

The conclusions are summarized as follows:

(1) Axial strain measurements and unconfined compression tests for different dry densities and temperatures confirm that shrinkage deformation and unconfined compressive strength are completely governed by temperature. Both the coefficient of deformation with temperature and the modulus of rigidity from stress strain properties were established and quantified.
(2) It is further clear that soil moisture movement as a hydraulic property depends on temperature. When the temperature approached 100°C, the pore fluid pressure increased and caused an out-flow of fluid.
(3) It can be verified that the pore pressures were created as a result of the applied heat, and that this pressure obviously decreased with the decrease in temperature through cooling.

Dry density effect on water diffusivity of compacted bentonite

H. Wang
Waseda University, Tokyo, Japan

H. Kyokawa
The University of Tokyo, Tokyo, Japan

ABSTRACT: This paper studied the effect of dry density (ρ_d) on water diffusivity (D) of compacted bentonite based on the distribution of volumetric water content (θ) during wetting. Four ρ_d cases with a range from 1.14 to 1.62 Mg/m^3 were conducted. The θ- D relation was obtained with an updated equation to fit the relation between a time coefficient and θ. With the θ- D relation numerical calculations (finite differential method) were conducted for specimens with different ρ_d. Both experimental and numerical results suggest that ρ_d would have minor effect on the θ- D relation, that is, the time to reach full saturation are very similar for specimens within the tested density range though there are some differences at the beginning of water diffusion.

1 INTRODUCTION

As a candidate material for the geological disposal system proposed to dealing with the high level radioactive waste (HLW), bentonite has been studied extensively in terms of swelling pressure, swelling deformation, hydraulic conductivity etc., however, water diffusivity (D) has not been concerned so much. One possible reason is that in simulations to predict bentonite behaviors, most of the numerical simulations were used hydraulic conductivity data to observe movement of water in bentonite. However, the hydraulic conductivity data for unsaturated bentonite are practically obtained from diffusivity data (i.e. unsteady state method) due to the difficulties, such as controlling high suction, in the steady state method of permeability test (Klute 1972, Masrouri et al. 2008). This paper studied the effect of specimen dry density (ρ_d) from distribution of volumetric water content (θ) of compacted bentonite during wetting. D value was obtained by updating the fitting equation proposed by Wang et al. (2020). Additionally, one dimensional numerical prediction was also conducted using finite differential method to visualizing difference of time histories of the degree of saturation (S_r) induced by the difference of the θ- D relation.

2 TEST PROGRAM AND METHODOLOGY

The commercial bentonite Kunigel V1 (K_V1), a candidate material for use in the Japanese geological disposal project, was used. Its specific gravity is 2.8±0.03, room gravimetric water content (w) is about 6-8% (relative humidity: ~50% and temperature: ~23 °C), montmorillonite content is 53%, liquid limit is 505%, plastic limit is 45%, and cation exchangeable capacity is 71.9 meq/100g with extractable Na+, Ca2+, Mg2+ and K+ of 53.8, 35.5, 1.6, and <1.0 meq/100g, respectively (Wang et al. 2022a, 2022c, Shirakawabe 2021, 2022).

Specimens with a diameter of 28 mm and thickness (h_{sp}) of 10 mm or 20 mm were prepared by means of static compaction using an oil jack. Four ρ_d cases with a range from 1.14-1.62 Mg/m^3 were conducted and two or three specimens were prepared for each case. The ρ_d, initial θ (θ_i) and saturated θ (θ_{sat}) are shown in Table 1; note that these values are average values with slight variations. After specimen preparation, the specimen was installed in the apparatus shown in Figure 1a, where the specimen was sandwiched between two stainless steel plates and fixed by four M5 bolts. Though a pressure transducer with capacity of 7MPa was glued at the center of the top plate, the measured

DOI: 10.1201/9781003299127-283

pressure data were not shown due to space limitation. Water was supplied from the top plate and transported to the specimen through a membrane filter (Wang et al. 2017). Note that porous metal was not installed to simplify apparatus design, however, the apparatus and testing method has been verified by Wang et al. (2022b). After a certain wetting period (t) shown in Table 1, the specimen together with the specimen ring was moved to the push-out device (Figure 1b). The specimen was pushed out and sliced every 1 mm from the wetted end. Note that for some cases with relatively small t, the last 2-3 mm could not be well sliced, for which it was regarded as one slices. Immediately after each slicing, water content (w) was measured using a balance with a solution of 0.1 mg.

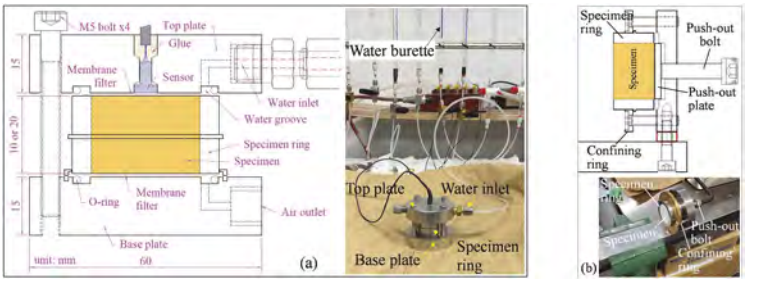

Figure 1. (a) Testing apparatus, (b) push-out device.

Table 1. Testing program and simulation parameters.

ρ_d Mg/m^3	θ_i %	θ_{sat} %	t (h_{sp}) h (mm)	Parameters A	B	C
1.14	7.30	59.3	2.73 (20), 6.13 (10)	4.70	1.12	7.28
1.33	8.67	52.5	1.77 (10), 18.5 (10), 17.3 (20)	4.85	1.25	8.44
1.48	9.94	47.1	2.00 (10), 18.3 (10), 16.9 (20)	5.07	1.36	8.89
1.62	11.2	42.1	2.45 (10), 18.2 (10), 22.6 (20)	5.23	1.45	8.66

3 TEST RESULTS AND DISCUSSIONS

Figure 2 Presents the relation between θ and the distance from water absorption side (z) for tested four cases. The θ_i range and θ_{sat} for each case were indicated by gray bars. Apparently,θ increases as z is smaller and t is longer. In some cases, θ of the slice closest to the water absorption surface exceed θ_{sat}, which is physically not possible. One possible reason is the dry density becomes smaller during to swelling deformation locally, while the pore water density larger than 1 Mg/m^3 is another possible reason (Wang et al. 2022c).

With the θ distribution shown in Figure 2, the movement of water in the specimens can be described in terms of water diffusivity (D) by combining the extended Darcy equation for unsaturated soil and the conservation of mass (Richards 1931, Klute 1972) as shown in Equation 1, where gravity potential was ignored. Bruce and Klute (1956) and Jackson (1964) used the Boltzmann transform to solve Eq. 1, of which D was set as a function of time coefficient $\lambda=z/\sqrt{t}$. With the initial condition: $\theta=\theta_i$ at $z>0$ and $t=0$ and the boundary condition $\theta=\theta_{sat}$ at $z=0$ and $t>0$, they obtained Equation 2. Note that the middle part of right-hand side of Equation 2 is the slope of λ-θ relation at θ, and rightest part is integral of λ from θ_i to θ. Wang et al. (2020) proposed a fitting equation (Equation 3) to describe the λ-θ relation and derived Equation 4 to calculate D, where A and B are fitting parameters. However, the λ-θ relation often could not be well matched if θ_i of tested specimen was assigned to θ_i in Equation 3. Thus, herein, θ_i is changed to C as the third parameter (Equation 5), by which D can be obtained by Equation 6.

$$\frac{\partial\theta}{\partial t}=\frac{\partial}{\partial z}\left(D\frac{\partial\theta}{\partial z}\right) \tag{1}$$

$$D(\theta) = -\frac{1}{2}\left(\frac{d\lambda}{d\theta}\right)_{\theta}\int_{\theta_i}^{\theta}\lambda d\theta \tag{2}$$

$$\lambda = A - B\ln(\theta - \theta_i) \tag{3}$$

$$D(\theta) = \frac{AB}{2} - \frac{B^2}{2}(\ln(\theta - \theta_i) - 1) \tag{4}$$

$$\lambda = A - B\ln(\theta - C) \tag{5}$$

$$D(\theta) = \frac{B(A+B)(\theta-\theta_i)}{2(\theta-C)} - \frac{B^2\ln(\theta-C)}{2} + \frac{B^2(\theta_i - C)}{2(\theta-C)}\ln(\theta_i - C) \tag{6}$$

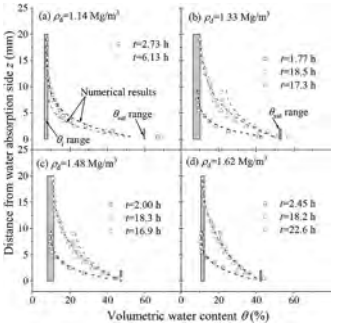

Figure 2. Relation between θ and z.

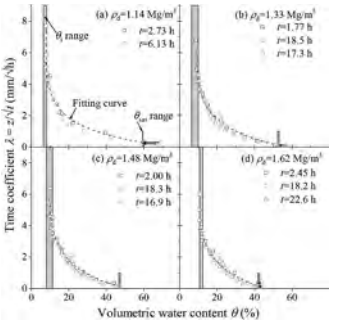

Figure 3. Relation between θ and λ.

Dash lines in Figure 3 are fitting results for each case with Equation 5 and parameters were put in Table 1. Note that some data with values very close to θ_i (pink color) were not considered in fitting since apparently θ at some z positions keeps its initial conditions if z is large enough or t is short enough. Additionally, θ_{sat} was assigned to data that numerically exceed θ_{sat} (horizontal arrows in Figure 3). Then, D as a function of θ was calculated by Equation 6 using parameters A, B and C obtained and shown in Figure 4, in which results obtained by Takeuchi et al. (1995) with ρ_d of 1.6 Mg/m^3 and Wang et al. (2020) (Equation 4) with ρ_d of 1.53 Mg/m^3 were also added. The U shape curve from Takeuchi et al. (1995) seems to be a result of the specific method they used. When θ closes to θ_i or θ_{sat}, denominator (slope of θ, $\partial\theta/\partial z$) of their equations to obtain D would approach zero resulting in unstable values. For Equation 4 used by Wang et al. (2020), D also approaches infinite when θ closes to θ_i, however, it is expected from Equation 2 and by physical sense that D would be 0 when θ equals θ_i (i.e. $\int_{\theta i}^{\theta}\lambda d\theta$=0) or θ_{sat} (i.e. dλ/dθ=0). Equation 6 produces D =0 at θ_i and a small value at θ_{sat} since setting dλ/dθ=0 at θ_{sat} in Equation 5 causes reduction of one parameter. Nevertheless, D values by Equation 6 seems to be very close for specimens with different densities when θ >20%. To visualize this difference, Equation 1 was changed to Equation 7 and numerically solved using finite differential method (Equation 8), where i and j represent space and time steps, and k and h are intervals between space and time steps, respectively.

$$\frac{\partial\theta}{\partial t} = \frac{\partial D}{\partial\theta}\left(\frac{\partial\theta}{\partial z}\right)^2 + D\frac{\partial^2\theta}{\partial z^2} \tag{7}$$

$$\theta_i^{j+1} = \theta_i^j + \frac{k}{4h^2}\frac{dD}{d\theta}\left(\theta_{i+1}^j - \theta_{i-1}^j\right)^2 + \frac{k}{h^2}D\left(\theta_{i+1}^j - 2\theta_i^j + \theta_{i-1}^j\right) \tag{8}$$

Dash lines in Figure 2 show numerically calculated θ distribution with the initial and boundary conditions of θ=θ_i at z >0 and t=0, θ=θ_{sat} at z=0 and t>0, and dθ/dz=0 at z=h_{sp} and t>0. As expected, the results are very close to testing results. Figure 5 shows the predicted average S_r time history for specimens with thickness of 10 mm with the same boundary and

initial conditions. It is shown that the average S_r becomes very close though there is about 10% difference initially, which implies that the time need to reach saturation is very similar regardless specimen density in the tested range.

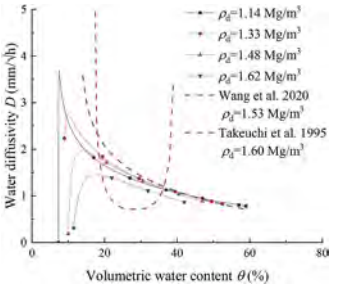

Figure 4. Relation between θ and D.

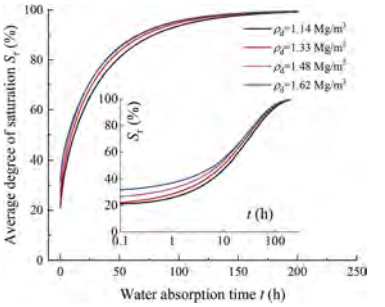

Figure 5. Time history of calculated S_r.

4 CONCLUSIONS

The effect of dry density (ρ_d) on water diffusivity (D) of compacted bentonite was studied. An updated equation to fit the relation between a time coefficient and volumetric water content (θ) was proposed. Results suggest that ρ_d would have minor effect on the θ- D relation.

Actual evaporation reduction rate considering the pore structure of sandy soils

J.G. Hussary, A. Alowaisy, N. Yasufuku & R. Ishikura
Kyushu University, Fukuoka, Japan

ABSTRACT: The falling rate stage of evaporation (Stage 2) is dominant in drylands and responsible for most water loss in the field. Therefore, predicting its evaporation rates is of a great importance. Through an experimental approach and using Fick's law of diffusion, a new determination method of the actual evaporation reduction rate during Stage 2 is proposed in this study. The model indicates that the water flux during Stage 2 is controlled by the receding rate of the vaporization plane, which is in turn dependent on the pore properties of the soil profile.

1 INTRODUCTION

Drylands cover over 41% of the Earth's surface. Alowasiy et al. (in press) mentioned the importance of acquiring new design criteria to avert soil degradation and desertification. Water evaporation from soil profiles is considered the dominant flux in drylands. The literature extensively studied the Actual Evaporation (AE), yet, accurate determination of its rate has been challenging.

Evaporation from fully saturated bare soil profiles is divided into three stages. During Stage 1 (Constant rate stage), water is sufficiently supplied to the surface by capillary liquid flow, maintaining a high AE rate. However, when the drying front, saturated-unsaturated interface, reaches a specific depth, the hydraulic connection with the surface is disrupted (Lehmann et al. 2008). Consequently, a new vaporization plane (VP) is formed below the surface, topped with an air-dry layer announcing Stage 2 (Falling rate stage). During this stage, water transports by capillarity from the drying front to the VP through water-filled pores (film region). Then continues by vapor diffusion through the air-dry layer (Shokri et al. 2009). The AE rate drops instantly and continues receding throughout the stage. Subsequently, the AE rate converges to a low and constant value announcing the diffusion-controlled Stage 3 (Residual rate stage).

Stage 1 is relatively short in drylands due to the arid climate and lack of water availability. Consequently, Stage 2 becomes dominant and responsible for most water loss. Therefore, it is essential to accurately determine its AE rate and investigate its controlling factors. Hussary et al. (2022) confirmed that Stage 2's AE reduction rate is almost linear and is controlled by the VP receding rate following Fick's law of diffusion. Moreover, the paper introduced a new Pore Size Distribution Index (I_{PSD}) that shows a strong correlation with the characteristics of Stage 2. Accordingly, the present study proposes a new determination method of the AE reduction rate during Stage 2 based on Fick's law and the I_{PSD} considering homogeneous sandy soil profiles.

2 MATERIALS AND METHODOLOGY

Homogeneous drying soil column tests were conducted. The columns were initially fully saturated to capture Stage 1 and Stage 2, while testing was stopped at the onset of Stage 3. The column's preparation and saturation were done following Hussary et al. (2022, in press).

DOI: 10.1201/9781003299127-284

A 1-D evaporation flow was allowed from the profile's top, at which the atmospheric conditions were unified at 27±1 °C, relative humidity of 47±3%, and wind speed of 2±0.2 m/s. The columns were mounted on a digital balance to determine the AE rates. Besides, TDRs (moisture sensors) were attached alongside the columns to capture the saturation profiles during drying.

Four textures of sandy soil silica sand were used; K-7, K-6, K-5, and K-4. Their particle size distribution curves are delineated in Figure 1a. The columns were compacted at different relative densities; 70, 80, and 90%. A summary of the tested columns' physical properties is shown in Table 1. Figure 1b delineates the samples' Soil Water Characteristics Curves (SWCCs) determined using the continuous pressurization method (Alowaisy et al. 2020). The Pore Size Distribution curves (PSD), Figure 1c, were inferred from the SWCCs as in Hussary et al. (2022). The scatter plots delineate the calculated pore diameters while the smooth lines show their lognormal distribution fitting. The I_{PSD} (1/μm) was adopted as the main parameter in the proposed AE determination method. Therefore, it was calculated as follows (Hussary et al. 2022):

$$I_{PSD} = \left(\frac{1}{d_1} - \frac{1}{d_2}\right) \times CV \tag{1}$$

where $(1/d_1)$ - $(1/d_2)$ corresponds to the width of the PSD. d_1 and d_2 are the smallest and largest capillaries, corresponding to the residual and air-entry suction values, respectively. CV is the coefficient of variation of the fitted lognormal distribution.

3 ACTUAL EVAPORATION REDUCTION RATE

Hussary et al. (2022) reported that the vapor diffusion transport is dominant during Stage 2, and the VP controls its AE rate. Therefore, the proposed method adopts Fick's law under the following assumptions: (1) water flows upwards under steady-state conditions (the capillary flow in the film region equals the diffusion flow in the air-dry layer); (2) water evaporates by diffusion only at the VP (bottom of the air-dry layer); (3) diffusion occurs in 1-D under isothermal conditions; (4) the change in water vapor density (∂C) is constant under unified atmospheric demand; (5) vapor diffusion coefficient (D) is constant for the homogeneous air-dry layer with constant concentration. Thus, the normalized AE reduction rate during Stage 2 (ΔNAE/Δt) is expressed as follows:

$$\frac{\Delta NAE}{A\Delta t} = \frac{D\partial C\left(\frac{1/\Delta L}{\Delta t}\right)}{AE_i} \tag{2}$$

$\Delta NAE/\Delta t$ ($1/s.m^2$) is the AE reduction rate (ΔAE) over the AE rate in Stage 1 (AE_i). The diffusion area ($A=1\ m^2$) is constant for 1-D flow. $D = D_o\, b\Phi^m$ (m^2/s) by Campbell (1985). D_o is the free air vapor diffusion coefficient, Φ is the soil porosity, while b=0.66 and m=1 are Penman's constants. ∂C (g/m^3) is the difference between the vapor densities at the VP, assumed fully saturated (C_{sat}), and at the soil surface (C_∞). $(1/\Delta L)/\Delta t$ is the inverse of the VP receding rate with time during Stage 2 (1/s.m), where L is the VP depth (diffusion distance), and it is calculated as follows:

$$\frac{1/\Delta L}{\Delta t} = -3.2 \times 10^{-6} I_{PSD} - 0.00013 \tag{3}$$

This formula was found by tracing the VP from the saturation profiles in Figure 2, where each line indicates a TDR location. The VP was assumed to reach a TDR once its reading converges to a constant residual value. Stage 2 duration was found from the AE curves (Figure 4), while the VP depth at a specific time was collected for two points once the saturation converges to residual (Figure 2). The results were plotted with the I_{PSD} in Figure 3 to deduce the formula. The strong correlation confirms that the diffusion distance dynamics highly depend on the soil pore properties.

Pore size distribution index	I_{PSD}	(10^{-4}/μm)	1.96	0.37	14.52	7.88	1.29	0.87	0.14

4 RESULTS AND DISCUSSION

The proposed determination method was used to find the ΔNAE/Δt for all the tested profiles. The values were then compared with the experimental ΔNAE/Δt for validation. The latter was found from the normalized AE curves, delineated in Figure 4. Figure 5a depicts the relationship between the I_{PSD} and the determined and experimental ΔNAE/Δt. In addition to the strong correlation, the results showed very close patterns for both values, confirming the method's validity. However, despite the I_{PSD}, the ratio between determined and experimental ΔNAE/Δt was almost constant for all profiles, around 0.015 ±0.005. This discrepancy might be related to the simplicity of the method and the diffusion coefficient. Therefore, the determined values were multiplied by the average ratio ($R_{E/D}$), and the results were delineated in Figure 5b. Accordingly, it can be concluded that the proposed determination method is reliable for determining ΔNAE using $R_{E/D}$.

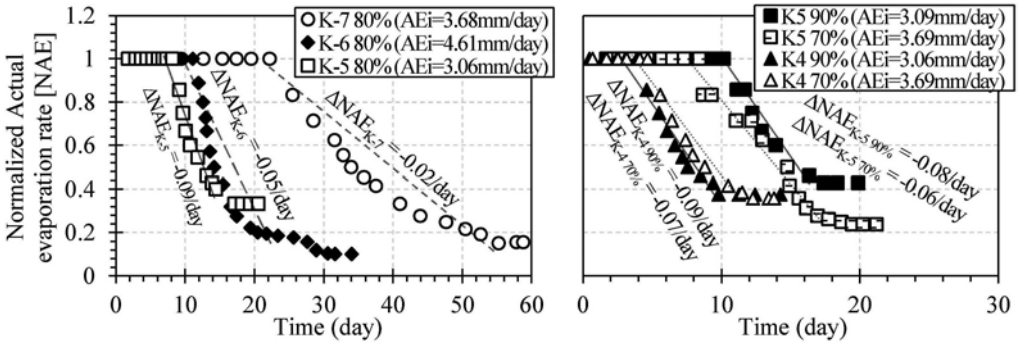

Figure 4. Actual evaporation curves showing the experimental ΔNAE/Δt.

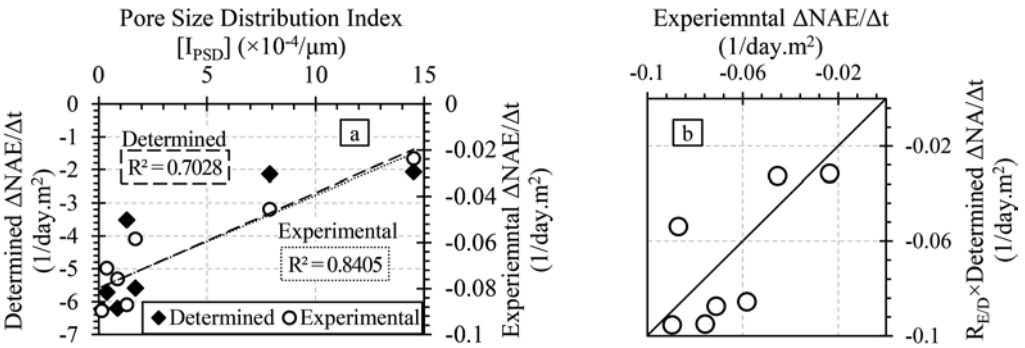

Figure 5. Comparison between the determined and experimental ΔNAE/Δt.

5 CONCLUSIONS

A new determination method of the normalized actual evaporation reduction rate during Stage 2 was proposed for homogeneous poorly-graded sandy soil profiles under unified conditions. The method adopts Fick's law of diffusion and assumes a linear reduction in the actual evaporation rates during Stage 2. Moreover, it was confirmed that the change in the vaporization plane depth depends on the pore properties, and its receding rate can be empirically found

using the Pore Size Distribution Index (I_{PSD}). The findings are believed to improve the evaporation prediction in drylands, thus finding innovations to combat droughts and desertification.

Application of biomass-added masa soil to ground materials

T. Hyodo, T. Yoshizaki & T. Terasako
Toyama Prefectural University, Imizu, Japan

N. Tatta
University of Toyama, Toyama, Japan

H. Nagai
Hazama Ando corporation, Tokyo, Japan

ABSTRACT: In Toyama Prefecture of Japan, which has abundant nature, the primary industry is thriving, but a lot of waste-based biomass is generated in the manufacturing process, and we are having a hard time disposing of it. Therefore, the authors wondered if these and Masa soil could be mixed and used as a ground material. In this study, compaction test, CBR test, and repeated triaxial compression test were conducted to examine whether biomass mixed soil can be applied to simple pavement. In all the samples conducted in this study, CBR was 3% or more, so it was found that they can be generally used not only for simple pavement and pedestrian pavement but also for roadbed materials. In addition, as a result of repeated non-drainage triaxial tests using biomass-mixed Masa soil, the liquefaction strength increased when 10% of crab and bamboo powder were mixed.

1 INTRODUCTION

One of the goals of the Sustainable Development Goals (SDGs) adopted by the United Nations General Assembly in 2015[1)] is to significantly reduce waste generation by preventing, reducing, recycling and reusing waste. In Toyama Prefecture, heavy snowfall area of Japan, primary and secondary industries are thriving, and a large amount of waste-based biomass is generated in the process of production and processing. This waste-based biomass incurs a large amount of disposal cost and has a strong psychological negative image, so it is difficult to take it out of the prefecture for disposal. Therefore, waste-based biomass is required to be locally produced for local consumption and consumed in large quantities at low cost. In previous studies, it was confirmed that the uniaxial compressive strength was increased by reducing the amount of cement added and mixing fine powder of industrial by-products in the biomass pavement [2)]. As one, it was proposed to prepare mixed soil from soil samples and biomass used as ground materials and use them as construction materials. On the other hand, many damages due to liquefaction have been reported in Japan, which is an earthquake-prone country. In particular, during the Hyogo-ken Nanbu Earthquake (1995, i.e. the 1995 Southern Hyogo Prefecture Earthquake), Masa soil (Decomposed granite soil), which was previously thought to be difficult to liquefy, was liquefied at Kobe Port Island, which was used as a landfill material for artificial islands. Therefore, in order to use biomass as a construction material, it is necessary to understand the dynamic behavior during an earthquake.In this study, arbitrary proportions of biomass were added to the soil, and the compaction characteristics were investigated in order to investigate whether it was suitable for the work to be carried out. In addition, repeated triaxial compression tests were carried out to investigate the dynamic characteristics of the biomass mixed soil.

DOI: 10.1201/9781003299127-285

2 MATERIALS

As the samples used in this test, waste-based biomass samples (hereinafter referred to as biomass) include rice husks from agriculture, rice husk ash incinerated from them, wood ash from forestry, wood ash from incinerated bark, bamboo chips, and thinned wood. Bottom ash, which is the main ash consisting of silica sand and ash, which is generated during biomass power generation using the above, and from the fishery industry, the shells of Benizuwai crab were sufficiently oven-dried at 110°C and crushed into powder. As the soil sample, we selected Masa soil from Hyogo prefecture. For soil-based pavement used for simple pavement and pedestrian pavement, this sample was adopted because it is often used as a pavement material because it has excellent harmony with the landscape and shock absorption. Table 1 shows the physical characteristics of Masa soil.

Table 1. Physical characters of masa soil.

e_{max}	e_{min}	$\rho_s(g/cm^3)$	U_c	Fc(%)
1.019	0.562	2.638	90	13.3

3 COMPACTION CHARACTERISTICS OF BIOMASS MIXED SOIL

3.1 *Testing method*

A soil compaction test (JIS A 1210) was carried out by compacting with Masa soil and mixed soil with a mass ratio of 5% and 10% for each biomass. n addition, a CBR test (JIS A 1211) was conducted to determine the bearing capacity of the mixed soil based on the optimum water content ratio obtained from the compaction test. Seven kinds of samples were selected based on the compaction curve obtained in the compaction test, and the test was carried out with mixed soil having a mass ratio of 5% for each biomass. For those with a CBR value of more than 10%, the mixing ratio was increased to 10% and the test was conducted. This time, assuming the case where the construction was carried out in the densest condition, the sample was compacted at the optimum water content and was not flooded.

3.2 *Test results*

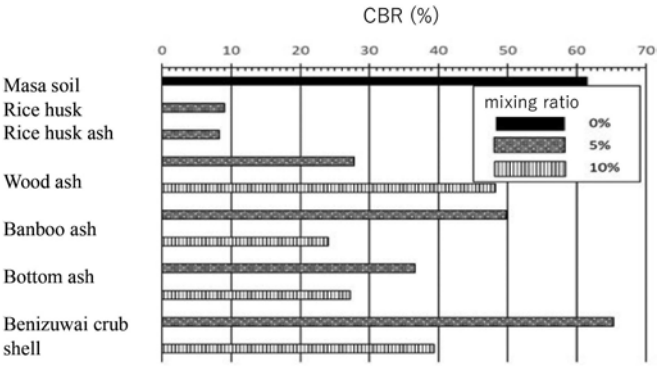

Figure 1. CBR of each sample.

Figure 1 shows the CBR of each mixed soil obtained in the CBR test. The CBR was the highest compared to the soil sample, Masa soil, and the only sample with a larger CBR than Masa soil was Benizuwai crab shell 5%. On the contrary, the CBR of 5% of rice husks and 5% of rice husk ash did not exceed 10%, which were relatively small values. In wood ash, CBR was larger in 10% mixed soil than in 5% mixed soil. Next, the correlation diagram of the relationship between CBR, maximum dry density, optimum water content, and each is shown in Figures 2 and 3.

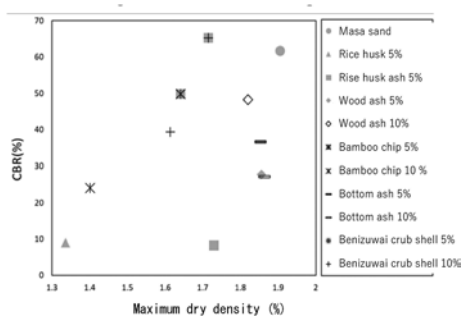

Figure 2. Relationship between CBR and maximum dry density.

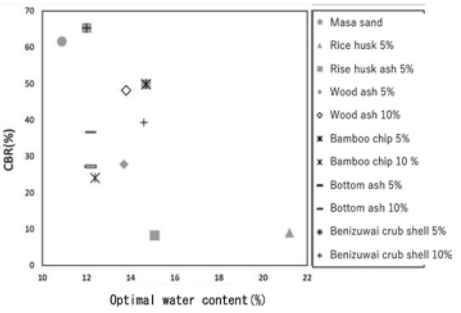

Figure 3. Relationship between CBR and optimal water content.

3.3 *Applicability as a paving material*

According to the design guidelines[4] stipulated by the Hokuriku Regional Development Bureau of the Ministry of Land, Infrastructure, Transport and Tourism, the design CBR was 3% or more as a regulation of bearing capacity for the entire roadbed. In all the samples conducted in this study, CBR was 3% or more, so it was found that they can be generally used not only for simple pavement and pedestrian pavement but also for roadbed materials. However, when actually applying it as a pavement material, it is necessary to investigate the water absorption expansion test assuming the worst water content due to rainfall, the chemical properties, and the long-term durability.

4 DYNAMIC CHARACTERISTICS OF BIOMASS MIXED SOIL

4.1 *Testing method*

In this section, as in the previous section, masa sand was used as the base material. In the repeated non-drainage triaxial test of soil, the amount of Masa soil that passed through a 2 mm sieve was used. In this test, a non-drainage triaxial test was repeatedly conducted using a mixed soil containing only bamboo soil at a mixing ratio of 0% and a mixed soil containing bamboo powder and crab powder at a mass ratio of 10% each. In this test, a non-drainage triaxial test was repeatedly conducted using a mixed soil containing only bamboo soil at a mixing ratio of 0% and a mixed soil containing bamboo powder and crab powder at a mass ratio of 10% each.The dimensions of the specimen were 50 mm in diameter and 100 mm in height. The specimen was prepared by using the aerial drop method so that the initial target relative density Dr = 50%. After preparing the specimen, CO_2 and degassed water were flowed in this order to saturate the specimen, and after confirming that the B value was 0.95 or more, isotropic consolidation was performed. After the completion of isotropic consolidation, a repeated load was applied under non-drainage conditions, and a repeated non-drainage triaxial test was carried out. After the test was completed, the fine particle content Fc (%) of each specimen was examined. As a result, it was 15.6% when the mixing ratio was 0%, 17.2% when the bamboo was mixed, and 19.1% when the crab was mixed.

4.2 *Test result*

Figure 4 shows the liquefaction intensity curve when the excess pore water pressure ratio is 0.95. The liquefaction strength ratio Rl_{20} was used as the repeated stress amplitude ratio at 20 times of repeated loading, and comparison was performed. As a result, when crab and bamboo were mixed, Rl_{20} increased. In the previous study[5], the liquefaction strength ratio increased with the increase in the fine particle content, and the same tendency was seen in this study.

Photo 1 shows the skeleton of crab and bamboo powder taken using SEM. As a result, when observing the particles, it was found that large and small pointed crab shells and rough

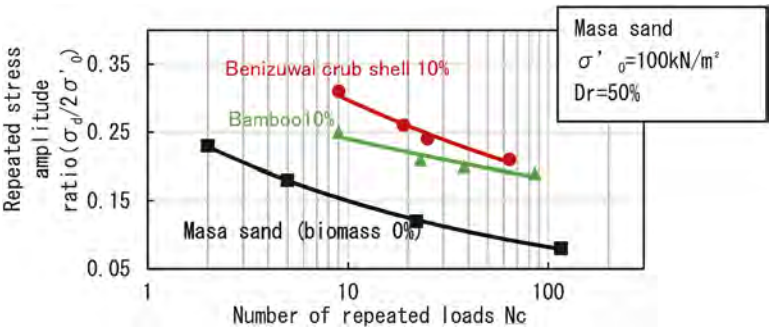

Figure 4. Liquefaction strength curve at excess pore water pressure ratio 0.95.

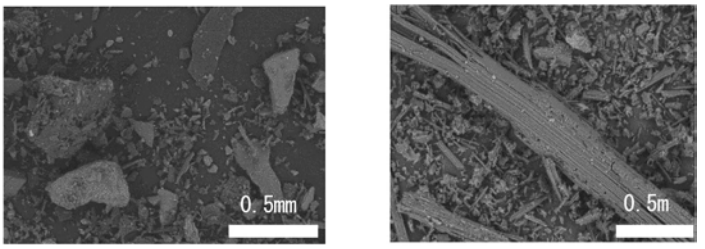
surface crab shells were mixed. It is considered that the addition of crab powder exerted an interlocking effect due to the engagement of the particles and increased the liquefaction strength. In addition, large and small elongated bamboos were mixed in the bamboo powder. It is considered that they played a role as a staple fiber tensile reinforcement and the resistance to liquefaction increased due to the increased toughness.



(a)Benizuwai crab powder (b) Bamboo powder

Photo 1. Observation of the skeleton of each biomass by SEM.

5 CONCLUSIONS

In this study, we investigated whether biomass could be used as a ground material by adding it to masa sand. As a result of various laboratory tests, the results are as follows.

1) It was found that mixing 5% of Benizuwai crab shell with masa sand increased CBR, and mixing 5% of rice husk and rice husk ash significantly decreased CBR. In addition, CBR is considered to be more influenced by the mechanical properties and particle size of biomass than the compaction properties and soil particle density. All the samples conducted in this study have a CBR of 3% or more, and it can be said that they can be generally used as road-bed materials.
2) As a result of repeated non-drainage triaxial tests using soil mixed with biomass, it was found that mixing 10% of crab and bamboo powder increases the liquefaction strength and suppresses the sudden occurrence of axial distortion. In addition, the liquefaction strength increased as the fine particle content increased. However, it was found that the liquefaction strength of the biomass-mixed soil is greatly affected by the surface and shape of the skeleton.

ABSTRACT: Soil erosion and shallow landslides are the most common forms of instability encountered during the life cycle of earthworks. It is generally well established that vegetation can contribute towards minimization of the risks associated with instability on earthworks slopes, although holistic consideration of geo-environmental conditions and connection with hydro-meteorological hazards is still lacking. The aim of this study is to investigate the link between the vegetation planted on earthwork slopes and the likelihood of failure of the earthwork in form of erosion or shallow landslide. To achieve this aim, experiments on vegetated and fallow earthwork slopes in contrasting geo-climatic conditions were carried out. These included setting up, monitoring, sampling and testing under simulated rainfall and dry conditions. The results of this study will help designers, engineers, land use planners, and landscape architects in reaching decisions that consider multi-disciplinary approach to earthwork design and construction.

1 INTRODUCTION

Although the contribution of the vegetation in the reduction of erosion and shallow landslides has a long both empirical and scientific documented history, there is still a lack of coupled consideration of geo-environmental conditions and connection with the hydro-meteorological hazards. For that purpose, parallel investigations have been started in Scotland and N. Macedonia, where the influence of planted vegetation on stability of earthwork slopes under different atmospheric conditions has been monitored. These were carried out in-situ and in laboratory, where tests on both vegetated and fallow earthwork slopes for two contrasting geo-climatic regions of Europe were performed. Complex equipment was set up, enabling continuous monitoring within the soil. Unlike the field work, the fluctuating atmosphere conditions in laboratory had to be simulated.

Having in mind the experiences and risks of infrastructure instability and the wide range of associated topics/factors, e.g.: erosion and shallow landslide typology and processes ((aggregate) stability, erodibility, soil strength, slope angle/cover, etc); hazards/risks for earthworks, climate change drivers (environmental and hydro-meteorological); hazard/risk mitigation, the aim of this study was to investigate a limited set of environmental and hydro-meteorological hazards and their effects on earthworks with a view of proposing a mitigation approach that involves vegetation as a stabilisation agent.

DOI: 10.1201/9781003299127-286

2 APPLIED MATERIALS AND MODELS

Within this very limited scope, the objectives of the research were as follows: a) for the case study in Scotland, to set up and monitor the effects of hydro-meteorological hazards on the erosion and shallow landslide risk on a major live linear infrastructure construction site; b) for the case study in N. Macedonia to model variable hydro-meteorological hazards in laboratory environment for the purpose of slope design and monitor development of erosion and/or shallow landslide and parameters in the soil before, during, and after simulated rainfall events.

2.1 *Description of the site in Scotland*

- Motorway cutting (Slope 1; Figure 1) formed in mineral podzols near Luncarty (NO 09252 29729); slope length 445 m; slope angle 1:2; slope height: 6.0 – 8.5 m; aspect: west-facing.
- In situ testing from 12 locations on 5 occasions between July and January: moisture content, shear stress (peak and residual), penetration resistance.
- Bulk samples were collected but not analysed and the monitoring was curtailed as a result of the Covid-19 pandemic (site closed).

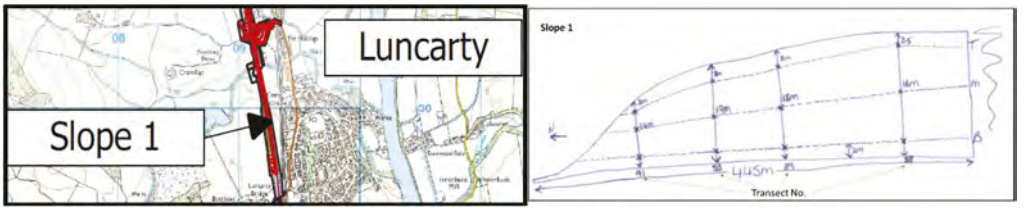

Figure 1. Case study area location in Scotland (left) and the general earthwork arrangement with monitoring point location (right).

2.2 *Description of site and laboratory model in Macedonia*

- Cutting formed in silty (sandy silt, marked as 1) and sandy (silty sand, marked as 2) materials on express road in process of construction; slope length 340 m; slope angle 1:1; slope height: 6.0 - 8.0 m; aspect: south-facing (Figure 2a).
- Two containers were prepared LxWxD=100x50x25 cm, where materials 1 and 2 were separately placed. Drainage is enabled both at the surface and at the bottom end, through a pipe.
- Sensors placed at middle depth of each soil layer, at two positions along model: sensors 1 (at upper part) and 2 (nearby toe) in mat.1, while sensors 3 (upper) and 4 (toe) in mat.2 (Figure 2b).
- Local hydro-meteorological reports were analyzed for modelling rainfalls *via* sprayers.
- Tests were performed for cases of bare soil and vegetated slope, and with dried vegetation when a heater was used to simulate the effect of the sun (Figures 2c–2d), while eroded material, run-off water and filtered water through soil were collected with dishes placed below each container.

3 RESULTS AND ANALYSIS

3.1 *Highway slope (Scotland)*

The shear strength of the exposed cutting did not change significantly with the changes in moisture content near the crest and at mid-slope (Figure 3a). However, the shear strength decreased with the increase in moisture content near the toe of the slope. While the shear

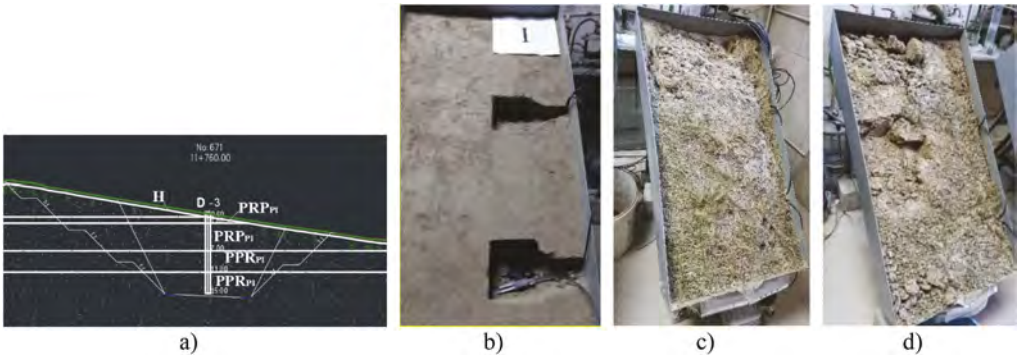

Figure 2. a) Geotechnical profile of case study area in Macedonia (PPR – sandy silt and PRP – silty sand); b) Placing sensors; final lookout of slopes after test with dry vegetation: c) material 2 (sampling nearby the sensor 3); d) material 1 (sampling in the upper part, nearby the sensor 1).

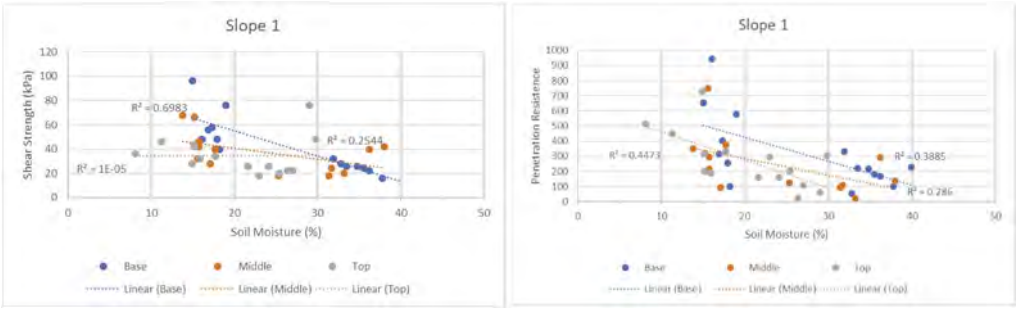

Figure 3. Relationship between the soil moisture (%) and: a) shear strength; b) penetration resistance (N) at different locations on the slope during monitoring.

strength of the exposed slope averaged approximately 40 kPa across the slope, there were a number of readings below 20 kPa during the monitoring period.

The penetration resistance of the exposed cutting showed a decreasing trend with the increase in moisture content of the soil but these trends, although similar across the slope, were not statistically significant. In general, the penetration resistance appeared to be the lowest near the crest and the highest near the toe of the slope (Figure 3b).

3.2 *Laboratory model for slope (Macedonia)*

The testing program in the laboratory considered simulating rainfalls with 30 l/m^2/h. The first test was performed on a bare soil on 30.11.2020. Planting of vegetation begun on 05.12.2020, and rainfalls were simulated on a slope with thriving vegetation on 08.01.2021. In the next period, the grass was left to dry, but for simulating prolonged sunny periods, daily heating of the surface was conducted. The final test was performed on 01.04.2021 on a slope with dry vegetation.

The sensors installed in the model continually registered the soil suction (Figure 4). As could be noticed, the sensors near the toe (No.2 and No.4, respectively) exhibit lower suction. This means that the lower part of the slope, despite the surface runoff and the underground piped drainage, contains more water than the upper part and it is exposed to lower shear strength.

Furthermore, after the initial rainfall on fallow soil, the sensors in both slopes registered sudden reduction in soil suction. Subsequent drainage and drying enabled slight increase in

the suction, with a gradient slightly increased after planting the vegetation - this was probably due to evapotranspiration of the vegetation – after which it appeared that the suction reached a constant value. The rainfall event on green slope did not significantly decrease the suction, which may be a result of both the above- and below-ground vegetation parts, preventing the drops to reach the soil and absorbing the water that has infiltrated the soil. Moreover, as long as the vegetation was green, the suction was constant, forming conditions for long term stability - an effect even more visible in the sandy material. As the vegetation dries out, this positive effect decreases and disappears.

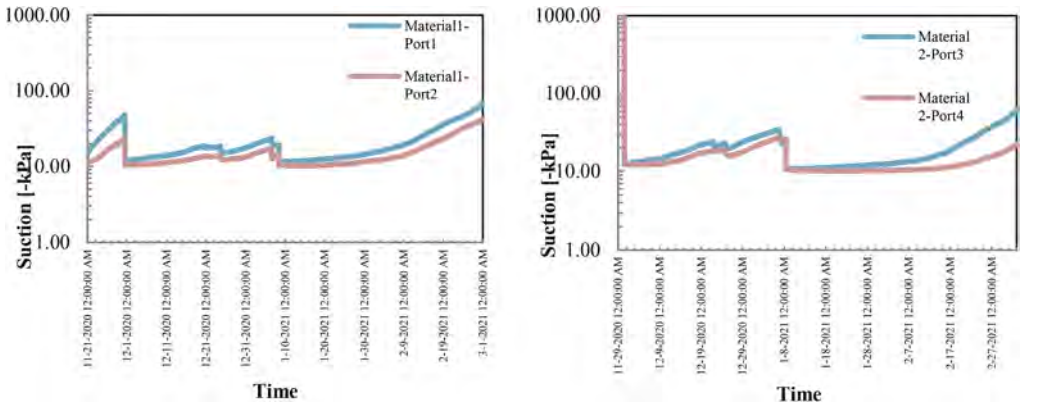

Figure 4. Measured suction during the laboratory experiment.

4 DISCUSSION AND CONCLUSIONS

Natural variability was recorded in soil strength across the slope in Scotland with locations where the strength dropped below 20 kPa due to the hydro-meteorological conditions (rainfall, water retention capacity), or disturbances during earthwork operations. The soil behavior at the toe of the slope appeared to be connected to the drainage (wetter soil at toe) but may pose a risk if the soil is shown to loose strength due to increase in moisture.

Longer-term monitoring is needed to ascertain any significant connection between the penetration resistance and soil moisture content. A decrease in penetration resistance would allow for better conditions for the vegetation to grow and an increase in moisture content would also provide for the physiological needs of the root systems.

The relationship between the shear strength and penetration resistance across the slope gives a rise to a concept of biodiversity employed in the context of slope protection and stability against shallow landslides and erosion: the crest of the slope may be a better environment for grasses and low vegetation to thrive due to low penetration resistance (slope protection from erosion initiation and rill formation due to the surface runoff and sediment entrapment) while the toe of the slope may be better suited for shrubs and trees (providing toe support and arching effect, while their strong structural roots anchoring the slope).

The aim of the laboratory experiment was to model the typical life cycle of a slope in transportation infrastructure: bare soil, slope with vegetation and slope with dry vegetation, at realistic climatic scenarios. These models showed the many very positive influences of the vegetation system, but also suggested that there may be a requirement of a suitable irrigation system during the maintenance and operation stage of a transportation project in regions with extreme conditions such as cyclic change of heat waves and intense rainfall, which are expected to be frequent.

Although these findings highlighted similar trends in contrasting environments, the limitations posed by the pandemic restricted the breadth and depth of the envisaged research. Both experiments, however, demonstrated the importance of relevant monitoring and testing.

While there were complex multi-organizational relationships on site which made getting support for monitoring/testing challenging, the laboratory experiment had challenges related to the reproducibility and applicability which could have been solved only with verification in situ. Additional to demonstrating good practice of carrying thematic laboratory and *in situ* testing in parallel, this study also showed that specific vegetation-related monitoring and testing have to form part of the earthwork design from the onset of a geotechnical project. Future work will see the development of relevant sampling, testing, and monitoring protocols which will incorporate vegetation and its effects on the soil properties and lead to more sustainable and resilient geotechnical design.

Numerical modeling in the calculations of tailings dumps based on approaches in soil mechanics

A.K. Bugrov, A.B. Ponomaryov & V.A. Melnikov
Peter the Great St. Petersburg Polytechnic University, Saint Petersburg, Russia

ABSTRACT: The paper discusses the problems of construction and reconstruction of existing tailings and the development of modern computational methods and programs. In order to improve the calculations of tailing dams the authors suggest complex accounting of deformation, strength, filtration properties of soils and probability reliability of structures. Up-to-date methods and programs have been developed. The example of the calculations of the unique tailing dam "Teghout" erected in Armenia is given in the paper.

Keywords: tailing dump, consolidation, basic design model, stability, anisotropy of properties, probabilistic reliability, numerical program

1 INTRODUCTION

Currently, the tailings dumps of large mining and processing enterprises and combines (GOPs, GOKs) have a height of 200 m or more, and the volumes of waste storage ("tailings") transported in the form of pulp reach tens of millions of m3. With the continuous operation of the concentrator, the construction and operational periods of the tailings dump practically coincide in time.

The purpose of the study is the substantiation of the design and construction of the tailings dump with the use of modern apparatus and means of continuum mechanics, soil mechanics and computer technology capabilities. An indispensable condition for ensuring proper reliability of calculations is an experimental study of the physical and mechanical properties of the soils of the tailings dump and its foundation with the determination of statistical characteristics of properties - values of mathematical expectation, standard, coefficient of variation, etc. [20, 21, 22], which is also of great practical importance.

2 BASIC APPROACHES TO SOLVING THE PROBLEM

To solve the problems of the construction of new and reconstruction of existing structures in the NIL "Soil Mechanics and stability of tailing dumps" SPbPU has been actively developing computer programs (TFCOMPL, GRUNTUS, etc.) since the 1980s, allowing for comprehensive calculations of tailing dumps [1]. At the same time, the experience of the operation of the Sever-ZM program (1980) was used - the first program in the USSR to calculate a tailings dump growing in height [2].

The TFCOMPL program is used to calculate and evaluate structures operated in harsh climates and permafrost [27]. However, at present, most of the continuously growing tailings dumps remain in a thawed state even in winter, so now the GRUNTUS program is the most in demand [3].

DOI: 10.1201/9781003299127-287

The GRUNTUS program uses the theory of consolidation developed by prof. V.A. Florin within the framework of the soil model, which he called the "basic calculation model", to assess the stress-strain state (VAT) of water-saturated soils of the tailings dump in time [4]. Based on this model, consolidation equations for plane and spatial problems were obtained, which are partial differential equations of parabolic type. The derivation and analysis of the equations are given in the fundamental works of Florin [4, 5, 26].

Calculations of the consolidation and stability of the tailings dump and its base are carried out, as a rule, according to the scheme of flat deformation in vertical section, since the planned dimensions, the length of the thrust prisms are many times higher than the height of the tailings dump, even at its height of 200 m or more.

For the flat problem of compaction of tailings storage soils under the assumption of complete water saturation (two-component soil), the use of soil characteristics with filtration anisotropy and in the absence of skeleton creep and initial pressure gradient, the consolidation equation has the form [4,5]:

$$\frac{\partial H}{\partial t} = \frac{1}{2\gamma_B} \cdot \frac{\partial \theta^*}{\partial t} + \frac{(1+e)(1+\xi)}{2\gamma_B a} \left[k_{\phi x} \cdot \frac{\partial^2 H}{\partial x^2} + k_{\phi z} \cdot \frac{\partial^2 H}{\partial z^2} \right] \quad (1)$$

where $\theta^* = \sigma_x^* + \sigma_Z^*$ are stabilized stresses, $\gamma_в$ is the specific gravity of water; e, ξ are porosity and lateral pressure coefficients; a, $k_{\phi x}$, $k_{\phi Z}$ are soil compaction and filtration coefficients along the X and Z axes.

3 RESEARCH METHODS

The GRUNTUS program [3] adopted the integro-interpolation method of finite differences when approximating partial derivatives by difference relations according to an explicit scheme. Moreover, the time step is determined automatically from the condition of mathematical stability of the design scheme. With a strongly pronounced nonlinearity of the coefficients of the consolidation equation, additional splitting of time steps is provided to ensure the reliability of the calculation scheme.

Detailed in-situ and laboratory studies of the properties of alluvial deposits of various zones of tailing dumps formed as a result of fractionation of soils during alluviation [8,9] allowed us to establish the most significant properties and characteristics, which are necessary to take into account when calculating tailing dumps. These, first of all, are the nonlinear change in deformability and permeability from the stress state and filtration anisotropy. In particular, experimental graphs $e = e\ (\sigma)$, $k_f = f(\sigma)$ are used, which allow determining the values e, k_f, $a = \partial e / \partial \sigma$ in equation (1) for the moment $t + \Delta t$ based on the results of calculating the stress-strain state for the moment t [10,11].

As a result, the finite difference method makes it quite easy to take into account when calculating consolidation the technology of construction and the design features of the structure (the presence of drainage devices, anti-filtration curtains, etc.), the significant properties of the soils of the zones of heterogeneity of the tailings and its base and change (if necessary) the partition grid in accordance with the deformations of the soil massif. Note that well-known software systems using the finite element method (Plaxis, Cosmos, etc.) do not allow to fully reflect these features of the calculation of tailings. These software complexes, as a rule, carry out calculations of the bases of unchanged geometry without taking into account deepening or vice versa extension [7].

The calculated values of the pore pressure calculated according to the "Consolidation" block were repeatedly compared with the data of field measurements and their coincidence was noted. At the same time, it was shown that neglecting excessive pore pressure when calculating consolidating soil masses (dams, tailings ponds) can lead to their damage and even destruction [1,5,13,24].

The composition and volume of the initial information for the work of the GRUNTUS program on the calculation of consolidation and subsequent determination of stability are presented in [3].

The "Consolidation" block of the program determines overpressure $p = \gamma_w \cdot H$, pressure H, and automatically sends it to the "Stability" block. If necessary, the results of the consolidation calculation are printed out for the characteristic moments of the construction of the structure.

To assess the stability of the tailings dump, the GRUNTUS program implements a calculation under the assumption of a shift along a circular cylindrical sliding surface (CCPS) of radius R in the conditions of a flat problem. The coefficient of stability margin K_3 is determined by the formula of *K*. Terzagi:

$$\kappa_3 = \frac{R}{M_{\text{акт}}}\left[\Sigma(q_i + g_i - p_i)b_i cos\alpha_i \; tg\varphi_i + \Sigma\frac{c_i b_i}{cos\alpha_i}\right], \tag{2}$$

in which: *qi+gi* is the vertical pressure created on the base of the *i-th* element (column) by an external load and the weight of the water-saturated soil;

pi is the boundary pressure in the water along the sliding curve, including hydrostatic pressure and excessive pore pressure of consolidation;

ai is the angle of inclination of the base of the i-th element to the horizontal x axis;

φi,ci - characteristics of the strength of the soil of the base of the *i-ro* element;

M act is the moment of active forces, including seismic forces (for a special combination of loads), which are taken into account as additional horizontal forces.

The program provides an automatic search for the most dangerous sliding surface using the Gauss-Seidel method, which consists in alternately varying the parameters of the shear curve (radius *R*, coordinates of the center of rotation *Xo, Zo*) and determining the shear curve with a minimum coefficient of stability margin K_{3min} [3].

4 THE OBJECT OF THE STUDY AND THE MAIN RESULTS

To illustrate the possibilities of the GRUNTUS program, detailed results of calculations of consolidation and stability of the unique tailings storage facility of the Tehut copper-molybdenum combine are given below. The tailings storage facility is located in the north of Armenia in a seismic zone and is a typical example of a mountain-type storage facility.

Design studies (2014) were performed for the first stage of the tailings dump with a crest mark of 780 m (Figure 1a) and a maximum height of 110 m in cross section *x≈450 m*. Alluvial deposits are represented by loam (zone 1), sandy loam (zone 2) and powdery sand (zone 3).

The primary dam with a height of ~ 50m is made of a stone outline (zone 5) and has a screen along the upper slope (zone 4). The base is composed of blocky-clastic soil (zone 6) and fractured rock (zone 7). The construction of the tailings dam is carried out (according to the project) in 5 years, while the pond is filled up to the crest of the dam ($\nabla 715m$) in 1 year, and the next 4 years the construction is increased to the level of 780m with an intensity of 16m per year. The position of the depression curve in Figure 1a was determined by filtration calculations.

When calculating the consolidation for the soils of zones 1-3, the experimental dependences *e=e(σ), kf=f(σ),* shown in Figure 1b,B. The calculation results are presented in Figure 1g by the pore pressure plot $p = \gamma_w$ H vertically x = 350m (vertical V-V in Figure 1a). The plot is constructed at the time of the tailings ridge exit at the level of 780m. Above the depression curve and at the base (zones 6, 7), excess pressure $p = 0$.

The coefficient of stability margin was determined by the formula (2) under the assumption of a shift in the CCPS. According to the experimental data, the calculated characteristics of soil strength are assigned: zone 1 -φ = *25* °, c = 0.01 *MPa*; zone 2 - φ=29°, c = 0.01 *MPa*; zone 3-φ=30 °, c = 0.01MPa; zones 4, 5 - φ= 34 °, c =0.006MPa; zone 6 - φ=36°, c=0. Calculation

results: for the main combination of loads K_{3min} =2.09, R=265m, Xo=207m, Z_O=293m (shear surface - k.shift. in Figure 1a); for a special combination including seismic impact, K_{3min} =1.75, R=264.7m, X_O=207m, Z_O=294m. The sliding surfaces mostly pass through sandy loam (zone 2), as expected.

According to the above scheme, the calculation of the tailings storage of the Natalkinskoye field (Russia), given in [3], was carried out in a similar way.

5 CONSIDERATION OF SOIL ANISOTROPY IN THE CALCULATION OF TAILINGS

Above, the problems of calculating VAT, consolidation and stability of tailings dumps and their bases were considered, in solving which the characteristics of deformability and strength of soils are used under the assumption of their isotropy [28]. At the same time, equation (1) of the Florin consolidation theory takes into account filtration anisotropy, the manifestation of which in ground structures has been recorded since the XIX century.

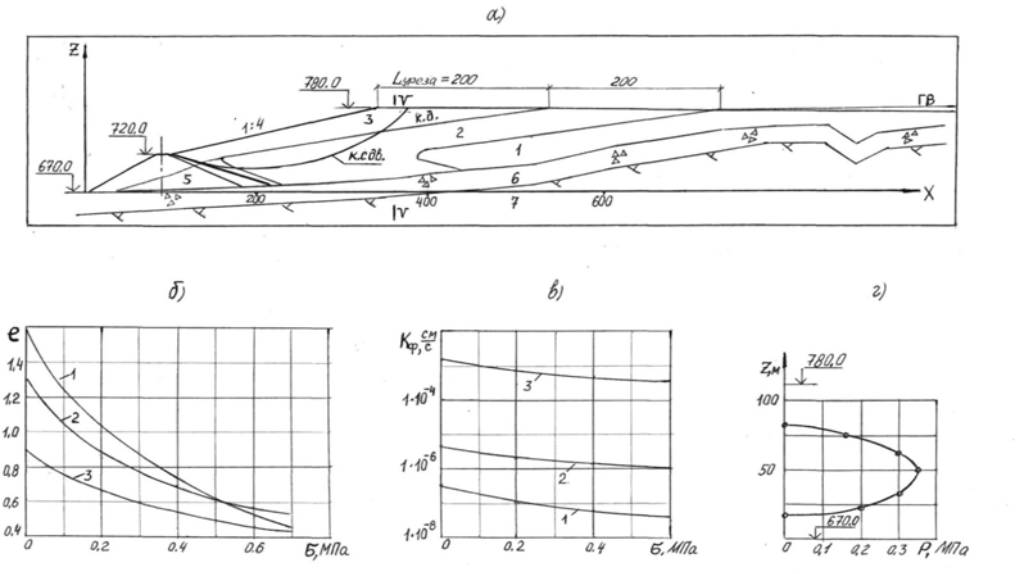

Figure 1. Calculation scheme and results of calculations of consolidation and stability of the Teghutsky MMK tailing dump.

The study of the anisotropy of other properties began later. To date, based on a review of numerous original studies, it has been established that soils - natural and man-made - have, as a rule, anisotropy of all properties at the same time - deformation, strength, filtration, etc. [7, 12, 13, 23].

As part of the improvement of consolidation calculations in the GRUNTUS program, along with filtration ($Kfx \neq Kf_Z$), consideration of deformation anisotropy ($a_x \neq a_z$) is introduced when determining the compaction coefficients a_x, a_z based on the results of compression tests of soil samples horizontally and vertically oriented in the array. The account of deformation anisotropy is easily carried out if in equation (1) the second term of the right part is represented as part of (7):

$$\frac{(1+e)(1+\xi)}{2\gamma_B a}\left[k^*_{\phi x}\cdot\frac{\partial^2 H}{\partial x^2}+k_{\phi z}\cdot\frac{\partial^2 H}{\partial z^2}\right] \tag{3}$$

where $a = a_z, k^*_{\phi x} = k_{\phi x}\cdot\frac{a_z}{a_x} = k_{\phi x}\cdot\frac{a_z}{a_x}$ is a fictitious filtration coefficient in the direction of the x axis, taking into account, along with filtration, deformation anisotropy.

Since the ratios of K_{fh}/K_{fz} and az/ax practically coincide in magnitude for the soils of tailings dumps [12] and, accordingly, we obtain $k*fx=kfz$, then the use of an isotropic model is fully justified in the calculation of consolidation, which was carried out above for the Teghutsky tailings dumps.

The strength anisotropy inherent in the soils of the base and body of the tailings dump in the GRUNTUS program is proposed to be taken into account in the "Stability" block. Detailed data on the strength anisotropy of the natural soils of the bases are given in [6, 7, 12]. It is especially pronounced in layered soils, for example, in ribbon clays, where the shear resistance tz across the layering is 5-10 times greater than t_x along the layering. For alluvial sandy soils and tailings storage materials close to them, according to Filimonov V.A., Nabokov I.M. et al., t_z/t_x =1,2-1,3 [12].

The Casagrande-Carrillo dependence is used in soil mechanics to describe the change in the strength of anisotropic soil to shear over various sites

$$\tau_\alpha = \tau_x + (\tau_z - \tau_x)sin^2\alpha, \tag{4}$$

in which α is the angle of inclination of the shear site to the X axis [12].

Since the Coulomb law $\tau = \sigma\cdot tg\varphi + c$ is laid down in the formula (2) for the stability margin coefficient, it is recommended to take the strength characteristics of $tg\varphi$ and "c" in the form of dependence (4) when taking into account strength anisotropy.

An increase intg φ_α *and* c_α with an increase in the angle α certainly provides higher values of K_3 when taking into account strength anisotropy. For gentle sliding curves (CCPs), this increase will be insignificant, for steeply inclined to the X-axis CCPs, the increase will be very noticeable. For example, for the sliding curve (Figure 1a), the margin coefficient, according to our calculations, will increase from K_3min =2.09 (isotropic soils) to K_3min= 2.25, taking into account the strength anisotropy characterized by the ratio t_z/t_x = 1.2. As a result, taking into account the anisotropy of the strength of the soils of the body of the tailings dumps allows to one way or another to increase the steepness of the slopes and, accordingly, the volume of the tailings dumps while meeting the requirements of the current standards for stability.

6 APPLICATION OF PROBABILISTIC CALCULATION MODELS

Currently, in geotechnics, further improvement of calculations of foundations and ground structures (dams, tailings dumps, waste accumulators) is associated with the use of probabilistic calculation models [14-17].

The most developed version of the theory of reliability of structures and foundations is the so-called parametric theory of reliability (PTN), which represents a probabilistic interpretation of calculations of stability, deformability, etc. [16].

In particular, the stability of the tailing dump according to the PTN is provided if the following condition is fulfilled:

$$Y1 \geq Y2 \; or \; Y1 - Y2 = Y \geq 0 \tag{5}$$

where: $Y1$ is an external factor characterized by a calculated reserve coefficient K_3min when assessing stability; $Y2$ is an internal factor (the potential capabilities of the system) characterized by a normative (permissible) stability reserve coefficient [K_3]; Y is a cumulative factor.

Taking into account the random (probabilistic-statistical) nature of the factors *Y1, Y2, Y,* the probability *P* of not reaching the limit state, determined by the dependence, is taken as a quantitative indicator of reliability

$$P[Y \geq 0] \; = \; 1-Fy(Y), \tag{6}$$

where: *Fy* is the distribution function of the value of *Y*.

There are various methods for determining the probability of R. The most common is the method of statistical tests (Monte Carlo method), especially effective in solving nonlinear problems. In particular, this method was used to assess the reliability (probability) of elastic-plastic foundations of structures based on sediment [14].

With a limited number of random variables characterized by a normal distribution law, an approximate way of representing the function F_y by the Charlier series is proposed in the monograph [18]. Taking into account the first terms of the series, which is quite sufficient when calculating the tailings, we obtain [19] an approximate dependence for probability (reliability) in the form [18]:

$$P \cong \frac{1}{2}\left[1 + \Phi\left(\frac{1}{\upsilon_y}\right)\right], \tag{7}$$

in which: υ_y is the coefficient of variation Y associated with the values m_y and σ_y by the dependence

$$\frac{1}{\upsilon_y} = \frac{m_y}{\sigma_y}, \tag{8}$$

where my is the mathematical expectation of *Y*; at the same time

$$\boldsymbol{m_y} = \boldsymbol{m_{y_1}} - \boldsymbol{m_{y_2}}, \tag{9}$$

σ_y – standard deviation (standard) Y; related to the Y_1 and Y_2 standards by dependency

$$\sigma_y^2 = \sigma_{y_1}^2 + \sigma_{y_2}^2, \tag{10}$$

$\Phi\left(\frac{1}{\upsilon_y}\right)$ is the probability integral for the value $\frac{1}{\upsilon_y}$.

As an example, we give an assessment of the level of reliability (probability) The stability of the Teghutsky tailing dump for the main combination of loads, for which K_3min =2.09 was obtained (Figure 1a.). We accept the standard reserve coefficient [K_3] = 1, 2. We assign the coefficients of variation of soil characteristics according to the recommendations [15, 18].

As a result, the dependencies (4-6) obtained: $\frac{1}{\upsilon_y} = 4,45$, F = 0.9927 and the estimated probability P = 0.9963.

Currently, a systematic assessment of the calculated reliability is carried out, as a rule, for particularly responsible unique structures (nuclear power plants, offshore platforms, etc.) [24]. The maximum permissible value of probability (reliability) according to the limit states for these structures is assumed to be *Rpr* ≥ 0.999. For tailings dumps, even with a height of *H*≥100m, the reliability of *Rpr* =0.99 seems to be sufficient [25].

7 CONCLUSION

1. Modernization of the original computing program GRUNTUS and improvement of the methodology of numerical calculation of tailing dumps have been carried out.

2. Further development of calculations is proposed, taking into account the anisotropy of the properties of the soil of the tailing dump, using probabilistic calculation models to assess its reliability.
3. The use of probabilistic models to assess the reliability of tailing dumps as hydraulic structures of increased responsibility is proved.
4. Considering the extreme complexity of the tasks to be solved, the comments of the forthcoming discussion will be taken into account in the future.

Obtaining light technogenic soil in the process of sulfur-alkali waste disposal

V.G. Ofrikhter, A.S Grishina, A.A. Ketov, Y.A. Ketov, Y.I. Vaisman & E.I. Korolev
Perm National Research Polytechnic University, Perm, Russian Federation

ABSTRACT: The article deals with an innovative light technogenic soil obtained by utilization of sulfur-alkali desulfurization waste. The environmental safety of the lightweight technogenic soil has been proved. The granulometric composition of the product, its density, moisture and compaction ability in comparison with natural soils have been studied. Based on the determination of physical and mechanical characteristics, the conclusion about the possible use of the obtained material as a technogenic soil was made. The most important advantage of the product is its density, which is on average 30% lower than the density of natural disperse soils. Also noteworthy is the increased strength properties of the lightweight soil established in laboratory tests.

Sulfur-alkali wastes are formed during cleaning of pyrolytic gases from hydrogen sulfide and carbon dioxide with sodium hydroxide solution. The effluents are formed in a number of processes: during the purification of liquefied gases, the production of lower olefins, the purification of kerosene and gasoline fractions and some other petrochemical processes. The resulting sulfur-alkali wastes are aqueous solutions of usually yellow-brown color with a pungent bad smell and alkaline reaction of the medium. From the chemical point of view, sulfur-alkali waste contains, in addition to sodium sulfide, a complex mixture of polysulfide, mercaptide and carbonate sodium salts, sodium phenolates, as well as mechanical impurities and various oil products in the dissolved or colloidal form.

Thus, sulfur-alkali wastes pose a dual environmental hazard: they contain toxic sulfur (II) compounds, mainly of the sulfur-organic type, and have a high pH due to the high content of sodium hydroxide in the solution

1 PRODUCTION OF LIGHT TECHNOGENIC SOIL

1.1 *Choosing the sulphur-alkali waste disposal method*

There are various methods for the decontamination of sulfur-alkali waste (Budnik et al 2019, Ksandopulo et al 2009), the most acceptable of which are physical or reagentless, chemical, and integrated treatment methods. As a result, sulfur (+2) compounds are usually concentrated and converted to less toxic compounds. Thus, oxidation of sulfur-containing odorants by ozonation allows us to utilize them, obtaining less dangerous compounds (Neretin et al. 2016).

In some cases, the technical solution involves the utilization of sulfur-alkali wastes as a single material, without sequential conversion into safe products of sulfur compounds and an alkaline component. An example is the production of a mineral additive based on sulfur-alkali waste to improve the properties of concrete (Badikova et al. 2020). The introduction of such a mineral additive from sulfur-alkali waste significantly improves the properties of concrete compositions, as well as reduces the consumption of resources for the production of concrete mixture and structures based on it (Murtazaev et al 2017, Batrakov 2006).

However, the necessity to utilize significant volumes of sulfur-alkali waste requires searching for a form of the obtained stuff that allows for a safe disposal of the resulting multitonnage product in the environment (Vaisman et al. 2018). For this reason, the technology of

DOI: 10.1201/9781003299127-288

waste recycling into anthropogenic soils, which minimizes the migration ability of ecotoxicants while creating an equilibrium and durable structure of the resulting material, has a long-term perspective. It has been proposed to utilize sulfur-alkali wastes using amorphous trepel oxide and obtaining a cellular silicate material (Knat'ko et al. 2015). It was shown that as a result of heat treatment, sulfur (II) from sulfur-organic compounds oxidized to sulfur (IV), and after water detachment, sodium hydroxide was a part of the obtained glassy cellular silicate material. Therefore, the purpose of this work was to study the characteristics of the resulting product as a man-made soil, and to determine the fundamental possibility of applying it for the erection of earthworks in difficult geotechnical conditions, on weak soils. After the first studies of physical and mechanical characteristics, of additional interest was the density of the obtained technogenic dispersed soil, which was on average 30% lower than that of natural soils, and its significant strength properties. The material obtained by the thermal treatment of sulfur-alkali desulfurization solution and trepel was chosen as the object of the study. Earthen structures erected from such a man-made soil will significantly reduce the load on the environment by decreasing the load on the underlying soils and downsizing the geometric dimensions of the structure due to steeper slopes, which will require a smaller area to accommodate such a bulk structure.

1.2 *Selecting the initial product composition and the utilization process parameters*

Industrial sulfur-alkaline effluent was used for the research; according to the chemical analysis, it contains 8.6 wt.% sodium hydroxide and 1.4 wt.% sulfur (II). The density of the solution is 1.094 kg/m^3.

Silica gel KSKG was selected to study the possibility of binding sulfur-alkali effluents into a silicate. Trepel with an average chemical composition (wt.%): SiO_2 - 76.16; Al_2O_3 - 9.33; Fe_2O_3 - 4.10; CaO - 1.05; MgO - 1.01 and SO_3 - 0.31 was used as a natural analog of amorphous silicon oxide.

The toxicity class of water and aqueous extracts was determined according to the "Methodology for determining the toxicity of water and aqueous extracts from soils, sewage sludge and wastes by mortality and changes in the fecundity of daphnia", Federal Register (FR) FR.1 .39.2007.03222 and in accordance with the "Methodology for determining the toxicity of water, water extracts from soils, sediments, sewage and wastes by changes in chlorophyll fluorescence and algae cell number", Federal Register (FR) FR.1.39.2007.03223.

At the first stage, the task was set to determine the conditions for obtaining an environmentally safe product. Samples of pellets heat-treated at different temperatures were subjected to the standard procedure of biotesting. As a result, it was found that heat treatment of pellets at temperatures above 700°C allows obtaining a material with zero toxicity and acidity of the aqueous extract not higher than pH = 8.5. For a preliminary study of the physical and mechanical characteristics of the obtained environmentally safe granules, tests recommended by national and interstate standards for natural and man-made soils were carried out.

Acceptable quantities of the test material were obtained from a pilot plant designed and tested for the disposal of up to 200 liters of the sulfur-alkali solution per shift. The general view of the light technogenic soil is shown in Figure 1.

Granules were prepared by mixing trepel powder and the sulfur-alkali solution, 400 g of the sulfur-alkali solution was added to 1000 g of trepel and the granules were pelletized in a disk granulator. The silicate material obtained from trepel and sulfur-alkali wastes consists of strong granules. A photo of such a pellet, heat-treated at 700°C, is presented in Figure 1.

Some areas with remnants of diatomite microorganisms can be traced in the structure of the material, but in general, it has a high porosity and homogeneity. To analyze the hazard of the initial waste and the resulting product, standard techniques were used.

The proposed technological scheme was implemented as follows. The initial sulfur-alkali solution of waste is mixed with trepel powder in a disk granulator in the ratio of 400 ml of the sulfur-alkali solution per 1000 g of trepel powder (Figure 2).

The obtained raw pellets are fired in a drum furnace at 700°C with a calculated residence time in the firing zone of 25 minutes. The organosulfur compounds in the form of water vapor, carbon

monoxide (IV) and sulfur monoxide (IV) are removed from the raw pellets, and the obtained pellets form a strong glassy silicate material. The proposed technology was implemented in practice on a pilot scale. Figure 2 shows the external view of the firing furnace.

Figure 1. Light technogenic soil: left – general view; right - micrograph of a chipped silicate pellet obtained by utilizing a sulfur-alkali solution through interaction with trepel.

The technology of sulfur-alkali waste recycling makes it possible to receive an environmentally safe material from the alkaline component of sulfur-alkali waste and to transform highly toxic sulfur-organic compounds into sulfur oxide (IV) of a low hazard class. In this connection, the physical and mechanical properties of the material were investigated for the possibility of its application as a technogenic soil.

2 GEOTECHICAL INVESTIGATIONS OF OBTAINED TECHNOGENIC SOIL

2.1 *Physical properties of light soil*

2.1.1 *Granulometric composition*

The granulometric composition of the material was determined according to GOST 12536-2014 by the sieve method with water washing. Samples weighing 100 g in an air-dry condition were taken. At the first stage, the sample was placed on a sieve with a hole diameter of 0.1 mm

and washed under a stream of water until the water flowing out of the sieve became clear. The particles remaining on the sieve were dried in a desiccator and sifted through 10, 5, 2, 1, 0.5, and 0.25 mm diameter sieves. The results of partial determination of the particle size distribution are shown in Table 1.

Based on the sieve analysis it was concluded that, in accordance with GOST 25100-2020 "Soils. Classification", the obtained material corresponds to the dusty sand by particle size distribution (the content of particles with a diameter of more than 0.1 mm is less than 75%).

Table 1. Particle size distribution.

Size of fractions, mm	Share of total mass, %
>10	0
5-10	0
2-5	0.11
1-2	3.72
0.5-1	14.02
0.25-0.5	11.96
0.1-0.25	14.19
<0.1	56.0

2.1.2 *Density of solids*

Next, an attempt was made to determine the density of solid particles of the material using the pycnometric method according to GOST 5180-2015. The test involves boiling a soil sample with distilled water in a sand bath to remove the absorbed air. When testing the man-made soil, the boiling reaction was very violent, so the water was replaced by a neutral liquid - acetone, which does not contradict GOST. As a result, a preliminary value of the particle density of the technogenic soil was obtained, which was 1.83 g/cm^3. Thus, it can be concluded that the density of the technogenic soil particles is about 30% lower than the density of natural soil.

2.1.3 *Compaction ability*

The next test of the product was a preliminary study of its ability to compact and finding the maximum density by the method of standard compaction according to GOST 22733-2016. The method consists in determining the dependence of the dry soil density on its moisture content during compaction. For the test, we used a device for mechanized compaction of soil by a falling load from a constant height and samples of man-made soil, the moisture content of which was sequentially increased.

The maximum density of the dry soil according to the preliminary tests of standard compaction was ρ_d = 0.98 g/cm^3 at moisture content w = 56%. At these parameters, the natural density of soil is ρ = 1.53 g/cm^3. Thus, one can make a preliminary conclusion that the density of man-made soil is about 25% lower than the density of natural soil, and the optimum humidity, at which maximum density is reached, is higher compared with the optimum humidity of natural sandy and clayey soils approximately by 4.5 and 2.5 times respectively. In this case, the nature of the compaction process is similar to natural soils.

It should be noted that the resulting product does not have the plasticity characteristic of clay soils, that is, the man-made soil does not have the ability to deform under external pressures without disturbing the continuity and does not retain the given shape after the removal of the load.

2.1.4 *Filtration ability*

To assess the ability of man-made soil to pass water, we determined the filtration coefficient k according to GOST 25584-2016. A filtration device for determining the filtration coefficient of sandy soils at a variable head gradient was used for the test. A sample of the material with a density ρ = 1.48 g/cm^3 and moisture content w = 62%, which corresponds to the compaction factor = 0.93, was placed in the device. As a result of the test, the material filtration coefficient

k = 0.013 m/day was obtained. In accordance with GOST 25100-2020 “Soils. Classification”, the technogenic soil can be preliminarily classified as “low permeable”. In terms of the permeability characteristic, the obtained product is close to dense loams and sandy loams.

2.1.5 *Degree of heaving*

To assess the degree of material heaving, tests were carried out to determine the relative deformation of frost heaving on the device UPG-MG4 “Soil” according to GOST 28622-2012. A sample of the material was prepared in the device casing using layer-by-layer tamping. Density was $\rho = 1.38$ g/cm^3 with moisture content w = 62%, which corresponds to the compaction factor = 0.87. As a result of the test, the relative deformation of swelling was $\varepsilon_{fh} = 0.1$, according to which the man-made soil can be tentatively classified according to GOST 25100-2020 “Soils. Classification” as “strongly heaving soil”. By the degree of heaving the obtained product is close to clayey soils.

2.2 *Mechanical properties of light soil*

2.2.1 *Results of compression tests*

The deformability characteristics were obtained from the preliminary compression tests. A sample of the material with density $\rho = 1.51$ g/cm^3 and humidity w = 56%, which corresponds to the compaction factor = 0.99, was placed in the device,. The load on the samples was transferred in stages equal to 25, 50, 100, 200 kPa. Transition to every next stage was realized when the conditional stabilization of soil was achieved, the criterion for which was strain increment not exceeding 0.05 % in 6 hours.

The compression curve shows that the nature of deformation of the technogenic soil is similar to that of the natural soil. The compression tests gave the normative value of the odometric deformation modulus in the interval of construction pressures of 0.1-0.2 MPa $E_{oed} = 5.8$ MPa. In order to switch from the odometric modulus to the strain modulus, which is used in calculating strains of soil masses, according to SP 22.13330.2016 “Foundations of buildings and structures” we need an empirical factor m_{oed}, which depends on the type of soil and is taken, based on the physical state of soils, equal to 1.0-3.0. Since the test material is not a natural soil, further research, including large-scale one, is required for a full assessment of its deformation characteristics. Another deformation characteristic by which the deformability of the material can be estimated is the compressibility factor m_0. In the pressure range of 0.1-0.2 MPa, the average compressibility factor of the tested samples was $m_0 = 0.34$ MPa^{-1}, which allows us to classify the soil as “highly compressible”.

2.2.2 *Strength characteristics of light soil*

The strength characteristics of the technogenic soil were obtained by the method of single-plane unconsolidated shearing, which allows obtaining the values of the angle of internal friction and cohesion in the unstabilized state. Samples for the shear test were prepared with a density $\rho = 1.44$ g/cm^3 at moisture content w=59%, which corresponds to the compaction factor = 0.92.The shear test was conducted in a kinematic mode with a given shear rate of 0.5 mm/min. Samples were tested at normal pressure values of 100, 200 and 300 kPa.

As a result of single-plane shear tests we obtained the normative values of strength characteristics of the material: the angle of internal friction $\varphi = 18°$ and cohesion c = 79 kPa. Thus, we can make a preliminary conclusion that the obtained material has a high shear resistance, and the resulting strength parameters are close to the normative values of semi-solid clays according to SP 22.13330.2016 “Foundations of buildings and structures”.

3 CONCLUSIONS

Based on the preliminary tests, we can conclude that the resulting material has the characteristics of both cohesive and non-cohesive soil. The granulometric composition of the product is close to silty sands. It is also united with the non-cohesive soil by the lack of plasticity. At the

same time, the technogenic soil has high strength and low water permeability, typical for cohesive soils. The material is highly compressible as per the compressibility coefficient, and as per the degree of heaving - highly heaving, which is also close to cohesive soils. The density of the material is about 25% lower than that of natural soil.

When studying the properties of the technogenic soil, attention was also paid to the density of solids, which was on average 30% lower than that of natural soils. It should be noted that the soil is characterized by the properties of both non-cohesive and cohesive soils. The strength characteristics of this soil obtained in conditions of unconsolidated shear tests are of certain interest: the angle of internal friction $\varphi = 18°$ and the cohesion $c_u = 79$ kPa.

The initial void ratio at the compaction coefficient of 0.99 was 0.9, which corresponds to 47% porosity. The optimum moisture content was 56%, which exceeds the average values of this indicator for natural sandy and clayey soils by about 4.5 and 2.5 times, respectively.

Thus, the conducted research has established in principle the possibility of recycling sulfur-alkali wastes of gas purification into a safe silicate material. The obtained material has the characteristics of light technogenic soil and can be placed in the environment without restrictions. According to the preliminary studies, the most important feature of the resulting technogenic soil was found to be its lower density, which was on average 30% less than that of natural soil, thus making it possible to build earth structures on weak soils without additional improving measures and to substantially reduce the impact on the environment. The significant strength characteristics of the obtained product in comparison with natural soils also attract attention. Increased strength properties allow us to construct embankments with steeper slopes from such soil, which in turn reduces the area occupied by the earthworks on the ground surface.

The study was conducted with the financial support of the Ministry of Education and Science of Russia as part of the program of the world-class Scientific and Educational Center "Rational Subsoil Use".

Use of the enzyme-induced carbonate precipitation method for containing the sulfate

J. Kim & T.S. Yun
Yonsei University, Seodaemun-gu, Seoul, Republic of Korea

ABSTRACT: The high concentration of sulfate (SO_4^{2-}), involved in wastewater and leachate, damages the environmental condition and human health when it leaks. This study aims to contain SO_4^{2-} into the ground by applying chemical precipitation with calcium ions. The enzyme-induced carbonate precipitation (EICP) was proposed to get Ca^{2+} which remained after the reaction and the effect of SO_4^{2-} was observed in terms of stiffness. The results showed SO_4^{2-} solution decreased the shear wave velocity a little, which means it is negligible, and the SEM image proved SO_4^{2-} was precipitated on the sand particle surface.

1 INTRODUCTION

Sulfate (SO_4^{2-}) is a common contaminant in industrial wastewater like effluent from mining, fertilizer production, and landfill leachate (Tait et al., 2009). Exposure to SO_4^{2-} has little effect since SO_4^{2-} is chemically inert and non-toxic. However, the high concentration of SO_4^{2-} causes many problems, such as damage to the natural sulfur cycle, pipe corrosion, water mineralization, and diarrhea. Among the management of SO_4^{2-} concentration, chemical precipitation is the most widely used method due to its cost-effectiveness and simplicity. The calcium ion (Ca^{2+}) has been used to precipitate SO_4^{2-} as forming gypsum in typical conditions, which is non-toxic and reusable although the solubility is higher than the barium sulfate (Benatti et al., 2009).

In a synthetic solution, the gypsum crystallization reaches equilibrium in 1 ~ 2 hours, while takes more time in wastewater, because of the inhibition of crystal nucleation by impurities (Tait et al., 2009). Geldenhuys et al. (2003) and Tait et al, (2009) demonstrated the increase of crystallization rate and decrease of the SO_4^{2-} concentration by adding the seed crystal to wastewater.

In this study, SO_4^{2-} removal proceeded using Ca^{2+} remained after enzyme-induced carbonate precipitation (EICP) reaction. In order to exist adequate Ca^{2+} to react with SO_4^{2-} in EICP, the concentration of urea, calcium chloride, and urease was calculated, where the raw soybean powder was used as urease in this study because the purified urease is expensive. Also, the effect of the seed gypsum crystal on SO_4^{2-} removal in the EICP solution was investigated because cells and tissue of soybean in the EICP solution, except for urease, can act as an impurity. The effect of SO_4^{2-} on EICP-treated sand was analyzed by measuring the shear wave velocity using the bender element test.

2 MATERIAL AND METHOD

2.1 *Urease activity*

Raw soybean used in this study was stored in a refrigerator at 2°C before experiments and the target amount of powder was added to distilled water. The mixture was mixed until homogeneous and was centrifuged at 3000 rpm for 15 min. After then, clear supernatant including crude urease was used for the urease solution.

DOI: 10.1201/9781003299127-289

The crude urease activity was measured using the electrical conductivity (EC) method. In general, the urease decomposes the urea to ammonium and carbonate, called urea hydrolysis, and the EC increases due to increase ions. In standard conditions (1 M urea at 20℃ and pH = 7), the increasing rate of 1 mS/cm/min of EC means 11 mmol/L/min of urea hydrolyzing rate, which corresponded to activity. The 3 ml of crude urease and 27 ml of urea (1.11 M) were prepared, and the EC proceeded for 15 min. Since only 3 ml of crude urease was used in 30 ml of total volume, the actual activity should consider a 10-times dilution factor.

2.2 *Optimal recipe of EICP for removing* SO_4^{2-}

The molar ratio of urea-calcium chloride ($CaCl_2$) was an important factor to decide the amount of calcium carbonate ($CaCO_3$). Song et al, 2020 measured the amount of $CaCO_3$ by changing the molar ratio of urea-$CaCl_2$ in a certain urease concentration. The result shows the 1.5 molar ratio of urea-$CaCl_2$ had the highest efficiency regardless of the concentration of $CaCl_2$. Also, the maximum concentration of SO_4^{2-} in this study based on the leachate from Korean landfill cooperation was 0.1 M. Therefore, 1.5 M urea and 1 M $CaCl_2$ were used, and the crude urease solutions with 5 – 55 g/L were prepared to calculate the reaction efficiency where reaction efficiency was calculated by dividing the amount of produced $CaCO_3$ by the amount of theoretically producible $CaCO_3$. The reaction was allowed for 3 days, after then, the 3 ml of supernatant was mixed with an equal volume of 0.1 M SO_4^{2-}.

As shown the Figure 1, the reaction efficiency increased as the urease concentration increased and reached 100 % at 50 g/L. 100 % reaction efficiency indicates all Ca^{2+} is so exhausted in the EICP supernatant that the gypsum is not formed when SO_4^{2-} is added. To remain the excessive Ca^{2+} and produce as much $CaCO_3$ as possible, 15 g/L was used, and the reaction with SO_4^{2-} reduced by about 20 ~ 30 % SO_4^{2-}. To increase the SO_4^{2-} reduction, the seed gypsum above mentioned was produced, and more details are provided in the next section.

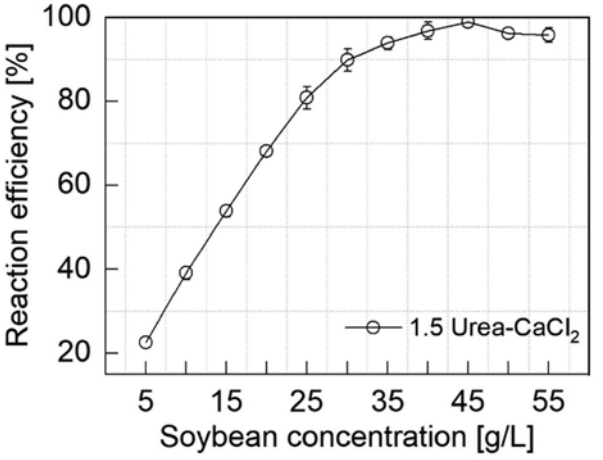

Figure 1. Reaction efficiency as a function of soybean concentration under 1.5 molar ratio of urea-$CaCl_2$.

2.3 *Seed gypsum crystal*

The equimolar concentrations of calcium chloride and sodium sulfate were mixed for preparing the synthetic seed gypsum. Figure 2 (a) shows the reaction was constant after 8 hours of reaction. The mixed solution composed of analytical reagent chemicals was stored at room temperature (25 ± 2℃) for 24 hours. After the reaction, the crystals were filtered and rinsed with distilled water to remove the chloride and sodium ions because the ions may inhibit the reaction SO_4^{2-} with Ca^{2+} in EICP supernatant. And then, the absolute ethanol was added to

the filtered crystals and the filtering process was repeated to get the pure crystal seed. After completing the course, the crystals were dried in the oven for a day at 45℃, and the detailed features of the crystal were shown in Figure 2 (b) through SEM image and EDS analysis.

To observe the change of produced $CaCO_3$ and SO_4^{2-} concentration according to the addition of seed gypsum, EICP samples were made with different amounts from 4 g/L to 10 g/L in increments of 2 g/L. After 3 days of reaction, SO_4^{2-} was mixed with the EICP solution, and SO_4^{2-} concentration was measured at 1-day intervals for 3 days considering the reaction time of gypsum.

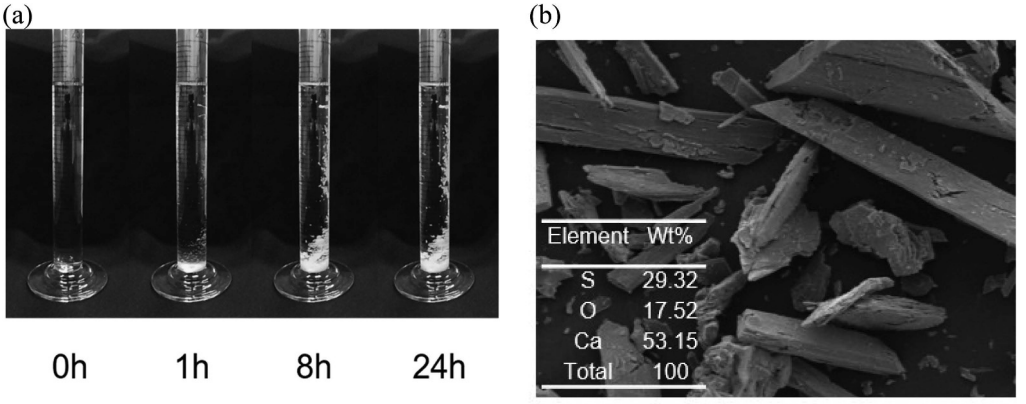

Figure 2. (a) The proceeding of gypsum formation and (b) SEM and EDS of seed gypsum crystal.

2.4 *The shear wave velocity*

The shear wave velocity (V_s) has been utilized to observe the contact level between soil particles, and bender element tests are a method to measure V_s in a laboratory as well as simple and have low cost. This study used this method to confirm the effect of SO_4^{2-} solution on the connection of EICP-treated soil particles. A pair of bender elements were embedded on the top and bottom cap of the oedometric cell and a 50Hz square wave was propagated from bottom to top. The arrival signal was filtered by a filer-amplifier (Krohn-hite 3944, low-pass filter: 1 MHz, high-pass: filter 100 Hz). The 1 pore volume (PV) of EICP was poured on the jumunjin standard sand (D_{50} = 0.542 mm, e_{max} = 0.897, and e_{min} = 0.6) with 70 % of relative density, and the reaction was allowed for 2 days. After finishing the EICP reaction, the 0.1 M sulfate solution made by adding Na_2SO_4 (403008, Sigma Aldrich) into distilled water was circulated using JIHPUMP 253Yx. 12 ml/min of flow rate was applied to minimize the effect of flow on particle arrangement and the circulation proceeded until the sum of circulated solution volume reached 2 PV. After the circulation, V_s was measured at 2-hour intervals for 8 hours.

3 RESULTS

3.1 *Urease activity and optimal recipe*

The activity of crude urease increases linearly as the concentration of soybean powder increases and ranged from 1.02 to 9.26 mM/min (Figure 3). Many researchers have evaluated the activities of bacteria or urease for ground improvement fell in the range of 0.5 to 10 mM/min (Whiffin et al., 2007, Chu et al., 2013, Jiang et al., 2017). These results indicate the soybean powder in this study can be used sufficiently for soil treatment.

Figure 4 (a) shows the SO_4^{2-} removal efficiency according to the added seed gypsum and curing time under 15 g/L urease concentration. The removal efficiency increased from 30 % to 62 % by adding the seed gypsum, and there was no significant difference in the SO_4^{2-} removal on the 2nd and 3rd days of the reaction, although the 2nd day has higher efficiency than the

1st day. Also, the removal efficiency and the reaction efficiency were similar in all seed gypsum. The reaction efficiency was 50 % and may decrease by the change of Ca^{2+} in the EICP solution due to the solubility of gypsum (Figure 4 (b)).

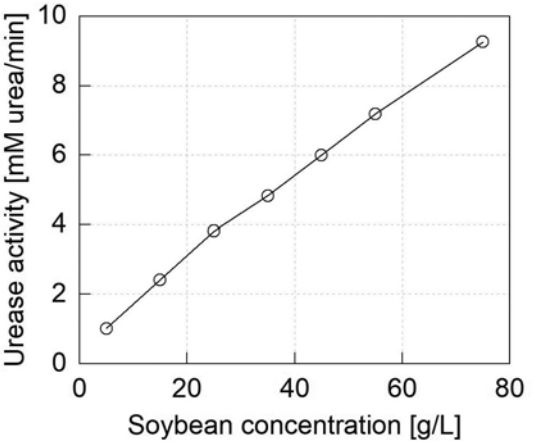

Figure 3. The activity of crude urease as a function of soybean concentration.

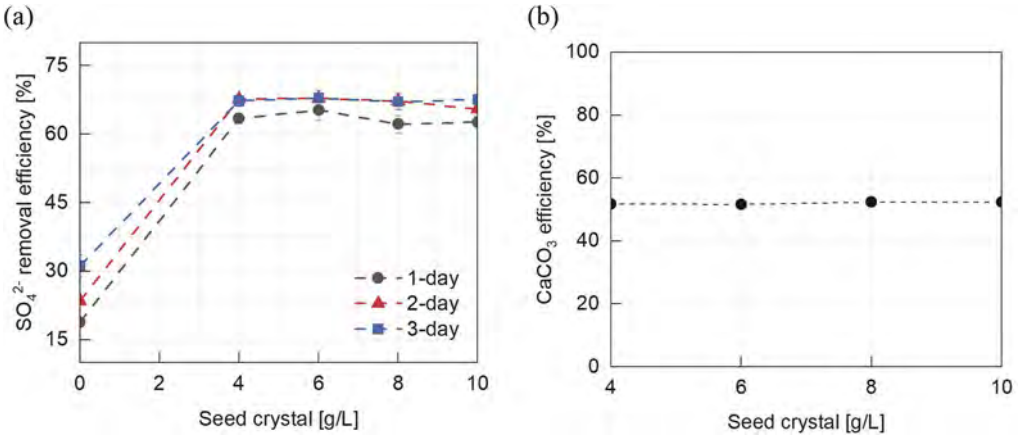

Figure 4. (a) The SO_4^{2-} removal efficiency and (b) $CaCO_3$ efficiency as a function of the added seed gypsum crystal.

3.2 *The effect of SO_4^{2-} in V_s*

V_s during the EICP reaction and SO_4^{2-} circulation is presented in Figure 5. Initial V_s increased sharply from 229 m/s to 858 m/s within 24 hours and 973 m/s at 48 hours, increasing shear stiffness by 18 times. In general, shear stiffness depends on the bonding between particles, and many researchers have studied the improvement of soil stiffness by the EICP treatment using purified urease. Song et al, 2020 showed an almost 31 times increase under 12 kPa sitting pressure, and Nafisi et al., 2019 proved 9 times increase through the triaxial test. Such comparative results mean that the crude urease used in this study has an ability for soil treatment. V_s after 48 hours reaction indicate the effect on SO_4^{2-} in soil structure. After SO_4^{2-} circulation, V_s initially decreased a little from 973 m/s to 951 m/s and increased as time goes by. It may be the result that the precipitated gypsum increased the bonding of particles.

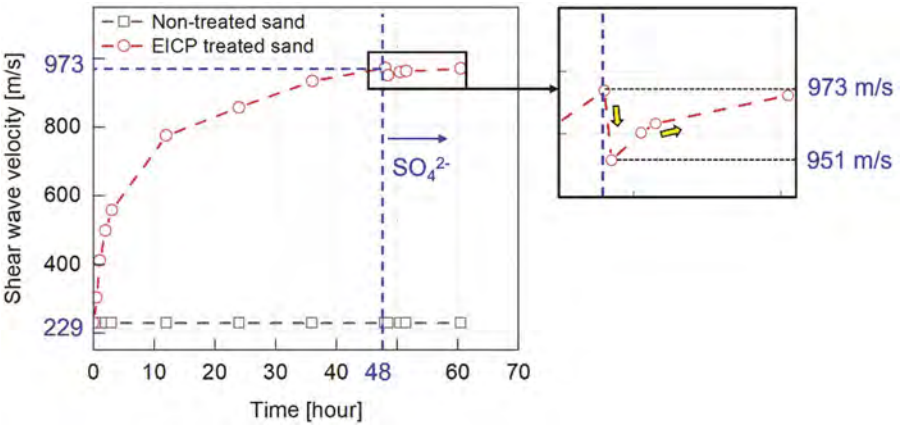

Figure 5. V_s evolution of EICP treated and SO_4^{2-} circulated specimen.

4 CONCLUSIONS

This study evaluated the SO_4^{2-} removal efficiency using remained Ca^{2+} in the EICP solution, and V_s was measured to observe the effect of SO_4^{2-} on the bonding between particles. The crude urease was used in this study to replace the purified enzyme, which had enough activity that can be utilized for ground improvement. To increase the SO_4^{2-} removal from the reaction with the EICP supernatant, the seed gypsum was used, and it increased the removal efficiency from 30 % to 62 %. So, the 1.5 M urea, 1 M $CaCl_2$, 15 g/L crude urease, and 10 g/L seed gypsum were determined as the optimal recipe.

V_s was measured using the bender element test, and the jumunjin sand was treated with 1 pore volume of the optimal solution. 0.1 M SO_4^{2-} solution was circulated to the specimen after 2 days of EICP reaction using a peristaltic pump, and V_s was measured during the gypsum was precipitated. The shear stiffness increased about 18 times by EICP reaction and SO_4^{2-} did not significantly affect the shear stiffness.

ABSTRACT: Non-destructive techniques (NDT) for on-site analysis of various structures such as historic buildings and monuments are gaining traction due to inherent limitations of conventional invasive methods requiring sample collection for often off-site assessment. This work will investigate current trends in non-invasive assessment of built structures of historic and/or cultural significance, which include methods such as infrared thermography (IRT), ultrasonic pulse tomography (UPT), ground (surface) penetrating radar (GPR), and others. It will also explore whether NDTs available today can replace traditional destructive analysis methods in physical assessment.

1 INTRODUCTION

Preservation of cultural and historic heritage, which includes physical structures such as monuments and buildings as well as construction methods among other things, is essential to society's identity and sense of belonging. Preservation activities may involve exploration, health monitoring, and, if necessary, restoration processes, all of which require appropriate tools for the assessment of the structure's physical conditions (Goncalves, Rodrigues & Gaspar 2018).

The conventional procedure for an assessment of structures with historic and/or cultural significance (often referred to as heritage) consists of several stages. It starts with determining objectives of the investigation, i.e. clarifying if the final goal is conservation of the structure, scientific exploration or some other objective. It is usually followed by preliminary investigation of the structure including steps such as analyzing available information on the structure's building materials and previously performed construction and restoration works (Hughes & Callebaut n.d., Wong 2019). Then, based on the scope of the investigation and the preliminary inspection results, the methods for a further detailed analysis can be selected. Common analytical techniques are invasive in their nature and require sampling for off-site laboratory analyses (Goncalves, Rodrigues & Gaspar 2018).

However, this poses significant challenges in terms of both heritage conservation and validity of the obtained results, as the stakeholders involved in the structure's assessment try to minimize interventions while striving for greater accuracy. The significance of the studied objects accompanied by difficult physical and political circumstances impose restraints on the

*Corresponding author: aiganymkumisbek@gmail.com

DOI: 10.1201/9781003299127-290

assessment process enforcing additional caution during sample extraction and handling stages. Moreover, conservation philosophy encourages minimal alterations to the original form of the structure leading to small or non-representative sample quantities, which can possibly cause doubts in the validity of assessment results (Hughes & Callebaut n.d.).

This work will investigate current trends in non-invasive assessment of built structures of historic and/or cultural significance, which include methods such as infrared thermography (IRT), ultrasonic pulse tomography (UPT), ground (surface) penetrating radar (GPR), and others. It will also explore whether NDTs available today can replace traditional destructive analysis methods in physical assessment.

2 REVIEW OF SELECTED NON-DESTRUCTIVE METHODS FOR HERITAGE ASSESSMENT

The primary difference between destructive and non-destructive testing is the fact that the former destroys the sample during the analysis. Non-destructive testing (NDT), on the other hand, allows repeatable testing as well as preservation of the sample material.

2.1 *Infrared thermography (IRT)*

IRT is a technique based on measured discrepancies in heat flow rate of surfaces due to various features such as subsurface voids, delamination, poor bonding, moisture retention, deteriorated surface, different building materials, materials of varying porosity or thermal heat transmission, and air leakages. The method does not need a direct contact with the structure's elements (Tavukcuoglu 2018) and has been successfully applied to study hidden structural elements, undocumented transformations as well as consequences of restoration activities (Goncalves, Rodrigues & Gaspar 2018).

Since the method relies heavily on thermal conductivity, it can be challenging to apply it in tropical climates due to low temperature variation during the day. This is often negated by performing IRT during sunrise and sunset hours or before and after the rainfall to achieve maximum possible temperature difference. Another workaround involves spraying the analyzed surface with water or heating it (common approach applied in the active IRT method) provided that the structure will not be damaged as a result (Chaban, Deiana & Tornari 2020).

In addition, the IR results are affected by distance and angle and the assessment can be impeded by wind, shade, blockage by trees, and recessed corners. This is why the IRT imaging assessment is often coupled with tactile and supplementary inspection.

2.2 *Ultrasonic pulse tomography (UPT)*

UPT is an acoustic method based on measuring travel time of ultrasonic waves sent through a solid material between the instrument's transmitter and receiver (Tavukcuoglu 2018). Due to this, the method is naturally better at studying structures made of homogeneous materials such as concrete (for detecting cracks) and timber (for studying rot and termite attack), but struggles with masonry due to resultant echo (Wong 2019).

Ultrasonic pulse velocity measured in the structure is correlated with physical and mechanical properties of the materials, state of structure deterioration, moisture content, presence and size of various discontinuities (e.g. invisible cracks). This makes UPT suitable for identifying used materials, their dimensions, and various embedded members, as well as determining the state-of-deterioration of buildings by assessing visible and invisible defects and failures such as deep or surface cracks and detachments (Tavukcuoglu 2018). The analytical technique can also be useful in detecting failures in functional systems of historic structures, such as water supply and drainage systems. Finally, it can be utilized for in-situ monitoring of the existing conditions before and after applied treatments to determine their efficiency.

2.3 *Ground penetrating radar (GPR)*

GPR is an electromagnetic pulse reflection method based on physical principles similar to those of seismic reflection, which emits very short electromagnetic pulses in a specific frequency band and measures their propagation through the studied material (Goncalves, Rodrigues & Gaspar 2018). It is usually used for shallow investigations requiring high resolution and can be performed to achieve three-dimensional visualization. GPR can be utilized for the following purposes: identifying hidden elements, detection of cracks, estimation of wall thickness, detection of moisture in structural elements, detection of reinforcing steel bars, subsoil investigation, and more. Goncalves, Rodrigues & Gaspar (2018) list several cases where GPR was successfully applied, including studies on a medieval church, a stone masonry bridge, and a masonry house.

GPR offers a rapid and relatively simple way to acquire data, but requires direct contact between the instrument's antenna and the analyzed surface, which adds to an already challenging heritage assessment (Chaban, Deiana & Tornari 2020). The selected center frequency affects the resolution, where the standard range is between 200 MHz and 1 GHz, but high frequencies of 1-2 GHz can yield detailed low-depth imaging (Wong 2019). One of the profound challenges of this method is the complexity of result interpretation and the subsequent need for highly-skilled specialists (Goncalves, Rodrigues & Gaspar 2018). In addition, its results have to be often verified using other methods.

2.4 *Concerns related to use of NDTs*

There are numerous concerns with using NDTs in the assessment of historic and cultural heritage. NDTs have considerable limitations in their accuracy and analytical depth, most of them being performed only for surface analyses. They also often require extensive work with interferences such as echoes due to the composite nature of building materials utilized in construction and restoration of the heritage objects (Wong 2019). The inherent difficulty of interpretation and quantification of these methods leads to the need for highly trained personnel (Fais et al. 2018, Tavukcuoglu 2018). Another common limitation of non-destructive methods is an inability to provide data on the chemical composition as well as some physical and mechanical properties (Wong 2019). All of these contribute to the need to conduct destructive analysis to verify the results of and/or fill in the gaps left by NDTs.

Although, NDTs can supply data necessary to reduce the quantity of samples needed for invasive assessment by aiding in selecting strategic sampling points and highlighting areas requiring further investigation (Wong 2019). There are some cases, when a combined use of two or more NDTs enhanced their performance and enabled quantification (Fais et al. 2018, Tavukcuoglu 2018).

3 CONCLUSIONS

Non-destructive testing (NDT) methods today offer a non-invasive way to investigate various physical properties of the object of interest. This is crucial to exploration and conservation of structures with historical and cultural significance, as utilization of NDTs can become a common practice when preservation of the object's materials is imperative. Since the use of NDTs such as infrared thermography (IRT), ultrasonic pulse tomography (UPT), and ground penetrating radar (GPR) entails certain challenges, especially the need in an additional testing to investigate chemistry of the studied materials, it is commonly advised to pair NDTs with conventional invasive methods. NDTs can form the basis of preliminary analyses and become complementary analytical techniques informing strategic invasive assessment as well as aid in monitoring of structures' health and restoration processes.

Surface morphology of stone chamber using less destructive thermoplastic resin impression

Mai Sawada
Tokyo Institute of Technology, Tokyo, Japan

Mamoru Mimura
Kyoto University, Kyoto, Japan

ABSTRACT: The development of less destructive methods for estimating the shear strength of stone joints is necessary to improve the stability assessment of historical monuments. This study proposes a novel impression method using thermoplastic resin to examine the surface morphology of stone joints, which significantly influences the shear strength, and its application in the stone chamber of a burial mound. The three-dimensional coordinates of the impressions were obtained using an optical profiler, and roughness was determined using a statistical coefficient. This case study shows that the proposed impression method can be successfully applied to field surveys and is valuable for quantifying the geometric characteristics of stones. The polished and rough faces were quantitatively distinguished. Furthermore, the roughness of the polished faces of the granite ceiling and tuff sidewalls was slightly different owing to the difference in the ease of processing between the granite and tuff.

1 INTRODUCTION

Accurate stability assessment and the development of countermeasures are critical for conserving historical monuments, such as masonry buildings, petroglyphs, and rock caves. The shear strength of stone joints significantly influences the stability of historical monuments. However, investigations are limited to the application of less invasive techniques, and the shear strength contribution from the surface morphology of stone joints is challenging to estimate. Some noncontact methods such as laser profilers, optical scanners, and photogrammetry have been developed for examining the surface morphology of stone joints. However, the requirements for obtaining highly accurate stone surface morphology using these methods in field surveys are difficult to satisfy.

Thus, the authors developed a less destructive impression method for obtaining the surface morphology of stone joints, which is beneficial for use in historical monuments (Sawada & Mimura, 2022). The method uses a thermoplastic resin solid in the air but becomes soft and clay-like at temperatures higher than 70 °C. Impressions are rapidly stabilized and can be smoothly detached from the stone joints within approximately 10 s. Thermoplastic resins can be applied to floors, walls, and ceilings owing to their low fluidity and short curing times. This impression method has been proven to yield sufficient geometric accuracy while having other advantages. The geometric accuracy of the replicas produced using impressions is comparable to that of the replicas used in previous studies.

The aim of this study was to quantify the surface morphology of the stone chamber of a burial mound using the impression method as a case study for application in field surveys. The acquisition of the surface morphology enables shear strength estimation using empirical models, such as the JRC–JCS model (Burton, 1973), or practical/computational shear tests on the stone joints, which is particularly useful for accurate seismic analysis of burial mounds because the stone joint shear strength is a critical factor influencing seismic damage to burial

DOI: 10.1201/9781003299127-291

mounds (Sawada et al., 2022). Twenty-three impressions were obtained on cut stones from a stone chamber, and the surface geometry was acquired using an optical profiler. The geometric characteristics of the stones were analyzed by quantifying the roughness of the impressions using a statistical coefficient.

2 METHOD

Figure 1 shows the impression process using thermoplastic resin (K-500, Muto Trading Inc.) in a field. The stone surface was wiped with a wet cloth before accurately obtaining the surface morphology. The thermoplastic resin (20 g) was warmed in boiling water for several minutes before being rolled into a ball, as shown in Figure 1(b). The resin ball was carefully placed on the stone surface and pressed slowly using a trowel to prevent air-trapping between the stone surface and the resin (Figure 1(c)). After pressing for 10 s, the impression was detached from the stone and cooled to an ambient temperature of approximately 10 °C for 5 min (Figure 1 (d)). The pressing force was controlled to produce an impression with a diameter of 70 mm and a height of 5 mm. The impression cannot provide representative stone surface morphology when the impression area is tiny. The appropriate representative area can be estimated from the specimen length used for the direct shear tests; a length of at least 10 times the maximum asperity height is recommended (Muralha et al., 2014). Impression height influences surface geometry measurements using an optical profiler. The optical profiler can be applied to semitransparent objects; however, incorrect surface recognition can occur for thin impressions with a high degree of transparency.

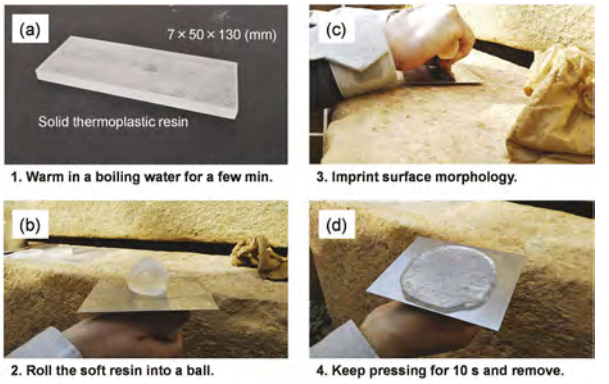

Figure 1. Impression process using thermoplastic resin in field.

The impressions were shaped into disks using a cutter ring with a diameter of 60 mm. The three-dimensional (3D) coordinates of the shaped impressions were measured using an optical profiler (VR-3200; Keyence Co., Ltd.). The measurement accuracy values were ±5 and ±3 μm (the width and height, respectively), and the measurement repeatability values were 1 and 0.5 μm (the width and height, respectively). The apparatus provided 3D coordinates at intervals of approximately 25 μm in the x- and y-axes by default. In this study, the interval was modified to approximately 0.25 mm by extracting every 10 data points from the raw data because roughness coefficients and their correlations with the shear strength of rock joints are mainly established based on the joint surface geometry measured at intervals larger than 0.25 mm (Yu & Vayssade, 1991).

3 CASE STUDY

The impression of the resin was applied to the stone chamber of the Nakaoyama Tumulus in Nara, Japan, which was constructed at the beginning of the eighth century. Figure 2 shows a cross-section of the burial mound and photographs captured in the arrow directions. The

stone chamber with inner dimensions of 90 cm × 90 cm × 90 cm consisted of stone plates hewn out from three different rocks: granite (ceiling), tuff (sidewalls), and granodiorite (floor). The inner faces of the stone chamber were polished, except for the floor, whereas the outside and joint faces were rough. Impressions were obtained at 23 points (A–W) on the ceiling (A–G, 7 points), sidewalls (H–S, 12 points), and floor (T–W, 4 points) in February 2021 when the earth mound was excavated for archeological investigations. Six (H–M) out of 12 points on the sidewalls were placed on the upper and lower joint faces, and the remaining points were placed on the inner faces.

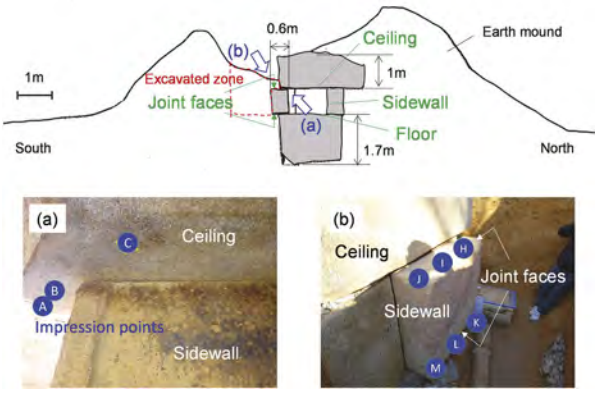

Figure 2. Cross-section of burial mound and impression points.

Figure 3 shows contour maps of the impressions obtained at representative points. The legend shows the distance from the highest point in each impression. The concave and convex portions of the impressions are inverse to those on the original stone surface. The contour maps show that the floor was rough compared to other faces.

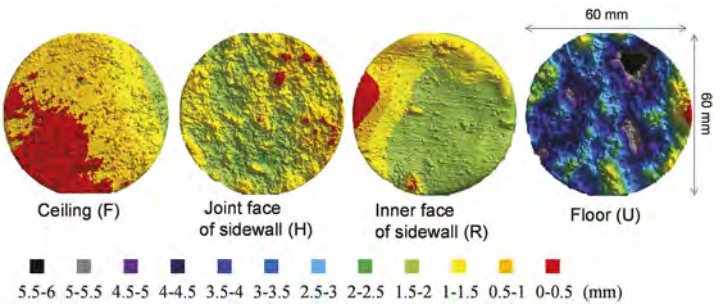

Figure 3. Contour maps at impression point F, H, R, and U.

The scan data of a square area of 40 mm × 40 mm in the center of the impression were extracted from the entire dataset to quantify the roughness. In this study, a statistical roughness coefficient, called the root-mean-square first-derivation, Z_2 (Myers, 1962), was used. Z_2 is widely used for predicting the joint roughness coefficient (JRC) used in Burton's empirical shear-strength estimation model (Burton, 1973) because it significantly correlates with the JRC. Z_2 is defined as follows:

$$Z_2 = \sqrt{\frac{1}{M-1}\sum_{i=1}^{M-1}\left(\frac{\Delta z}{\Delta x}\right)_i^2} \quad (1)$$

where M is the number of data points along the profile line, Δz is the elevation difference between two adjacent data points, and Δx is the interval between data points (0.25 mm). The modified scan data were used to calculate Z_2 to minimize the effect of the slope of the specimen surface. The scan data were modified by rotating the x- and y-axes based on the angle of the regression plane of the surface obtained using Microsoft Excel. Z_2 was calculated for 160 profile lines in the x- and y-axes on the square. The calculated Z_2 values of the impressions are presented in Figure 4. The mean values of Z_2 in the x- and y-axes of each impression on the polished faces are equivalent, whereas the roughness anisotropy on the non-polished joint faces and floor is significant. This indicates that the inner faces of the ceiling and sidewalls were thoroughly polished, but the sidewalls were slightly smoother than the ceiling. This difference in roughness could be attributed to the differences in rock type; that is, the granite used for the ceiling might have been difficult to polish because it was stiffer than the tuff used for the sidewalls.

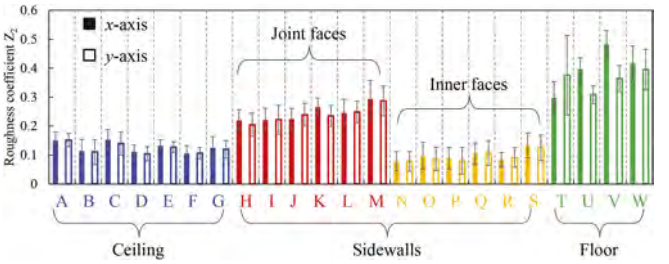

Figure 4. Roughness coefficients at different impression points.

4 CONCLUSIONS

In this study, a less destructive impression method that offers advantages for use in historical monuments was developed and applied to a stone chamber of a burial mound to evaluate the characteristics of stones by quantifying the surface morphology. The results showed that the polished and rough faces were quantitatively distinguished based on the roughness coefficients of the impressions. Furthermore, the roughness of the polished faces of the granite ceiling and tuff sidewalls was slightly different, which can be attributed to the difference in the ease of processing between the granite and the tuff. This case study shows that the proposed impression method can be successfully applied to field surveys and is useful for quantifying the geometric characteristics of stones. Establishing a shear strength estimation of stone joints using geometric data obtained with the impression method is required in future studies.

Proactive conservation of the foundation of the Main Tower, Bayon, Angkor Thom

Y. Iwasaki
Geo Research Institute, Osaka, Japan

M. Fukuda
Taisei Geotech, Kurume, Japan

M. Ishizuka & R. McCarthy
JASA Conservation Office, Siem Reap, Cambodia

T. Nakagawa
Waseda University, Tokyo, Japan

ABSTRACT: The main tower of Bayon temple, Angkor Thom stands upon a platform foundation of thick manmade sandy fill by a shallow direct sandstone and laterite foundation. The sandfill consists of very densely compacted fill of SPT, N value of 100 to 200 with the special feature of collapsing under a submerged condition. In the projected coming climate change, long and heavy rain is anticipated in Cambodia and every heritage site should be prepared to protect against the change of water conditions. The present situation at Bayon was evaluated by monitoring the change of water contents during rain. In case of squall type rain, heavy but short duration, water does not penetrate deeply in the ground. However, in long and heavy rain conditions, the situation is quite different. This paper discusses how to protect the main tower of Bayon temple based upon the basic principles of conservation based on 1. minimum intervention, 2. incremental approach, and 3. removable measures.

1 FOUNDATION OF BAYON TEMPLE

1.1 *Bayon temple, Angkor Thom*

Bayon, as shown in Figure 1, is the central temple of Angkor Thom constructed around in the late twelfth to early thirteenth century. Figure 2 shows section and plan view of the Bayon temple. Japanese Government Team Safeguarding Angkor (JSA) performed an archaeological trenching study at the northeastern corner as a "long trench" as shown in Figure 2.

1.2 *Trenched foundation*

The result of the long trench has revealed the following facts as shown in Figure 3.

1. The surface of the first terrace was covered with sandstone and laterite blocks, beneath which densely compacted sandy filled layer was identified.
2. Compacted sandy filled layer continued with and additional laterite block layer to the level of the original ground surface.
3. It was identified that the compacted sandy filled layer continues from the original ground level to 2–3 m in thickness.
4. The compacted sandy filled layer below the original surface was found to continue horizontally to about 10 m outside of the outer gallery plinth.

DOI: 10.1201/9781003299127-292

Figure 1. Bayon temple, Angkor Thom.

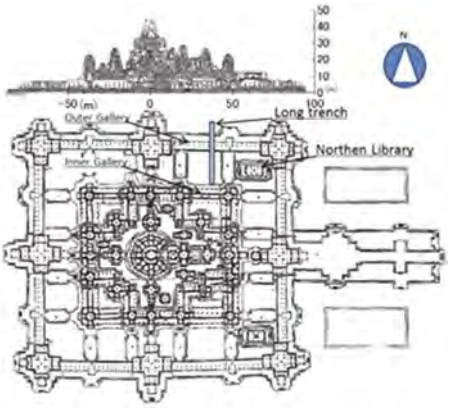

Figure 2. Section and plan view of Bayon Temple.

The archaeological study suggests that the foundation work for the Bayon is "trenched foundation" and was systematically constructed by excavating the original ground 2–3 m vertically as well as about 10 m outside of the temple boundary of the outer gallery as shown in Figure 2. The stone masonry structures were constructed upon terraces with three different levels of 2.95, 6.95, and 12.40 m.

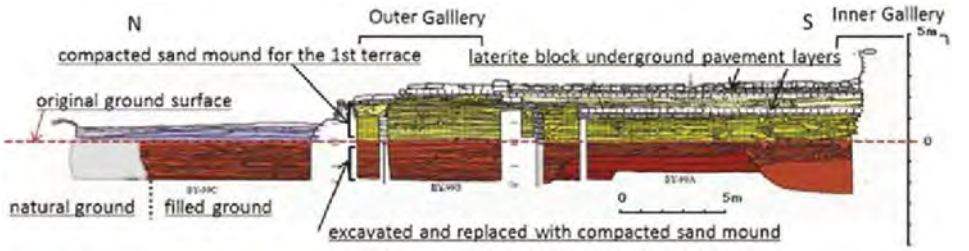

Figure 3. Long trench of archaeological study (Narita).

1.3 *Platform foundation of main tower of Bayon temple in Angkor Thom*

At the center of the base of the main tower of Bayon, a vertical shaft was excavated in 1933 by the French mission as shown in Figure 4. The stone masonry main tower of 31 m in height stands upon the platform of manmade fill of 14 m in thickness by direct shallow base stone as shown in Figure 4. It is amazing that the tower has been standing for 800 years since the late twelfth early thirteenth century upon the manmade fill (Iwasaki).

Several borings were carried out to study the platform foundation. The results of two borings are shown in Figure 5 BYV-2009 at the vertical shaft and BYV-2010 at the edge of the foundation of the tower on the third terrace. Boring BYV-2009 at the vertical shaft shows very loose sand layer of SPT, $N < 4$, which shows no compaction efforts were initiated by the French conservator. Boring BYV-2010 shows laterite block of 6 m in thickness beneath the pavement stone followed by densely compacted sandy fill.

The manmade filled layer showed very large SPT, N-values larger than 100–250 as shown in Figure 5 with water contents.

Based upon several borings, a ring-shaped laterite structure has been identified in the filled mound as shown in Figure 6.

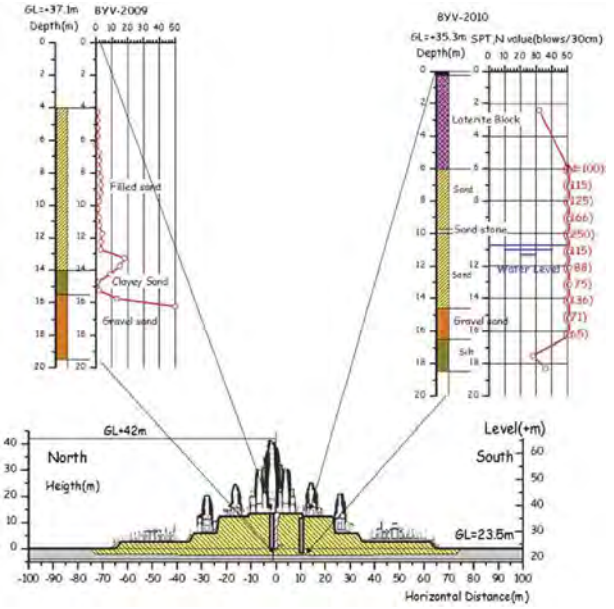

Figure 4. Boring results at the platform foundation.

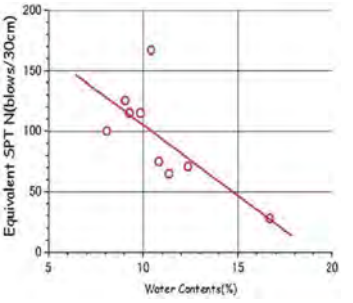

Figure 5. SPT N-value and water contents.

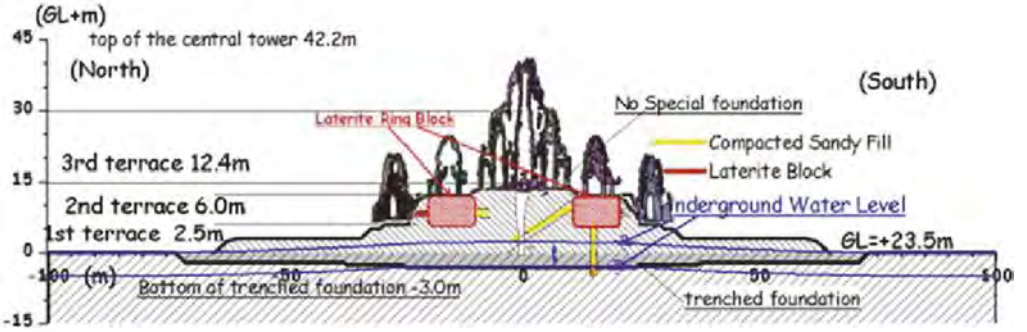

Figure 6. Trenched foundation and ring shaped laterite blocks.

2 CHARACTRISTICS OF FILLED SOILS IN BAYON TEMPLE

2.1 *Response to water*

The sampled soil, when dry, is the equivalent of soft rock rather than sand. A sample of the sandy fill was put into water as shown in Figure 7. The stiff unsupported sandy fill collapsed in the water within 10 min (Iwasaki).

2.2 *Grain size distribution*

Grain size distributions of the samples of filled soil by the vertical boring within the platform foundation are plotted in Figure 8 including additional horizontal boring in the platform, Northern and Southern Libraries, N1 Prasat Suor Prat and Baphuon Temple. Surprisingly, two kinds of clayey and sandy fills are clearly separately grouped with uniformity.

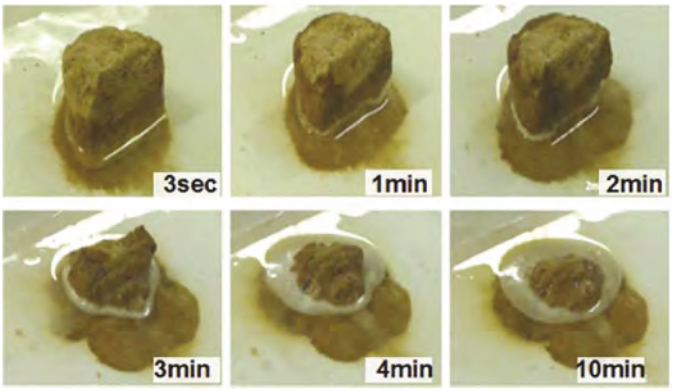

Figure 7. Collapse of stiff sandy filled soil in water.

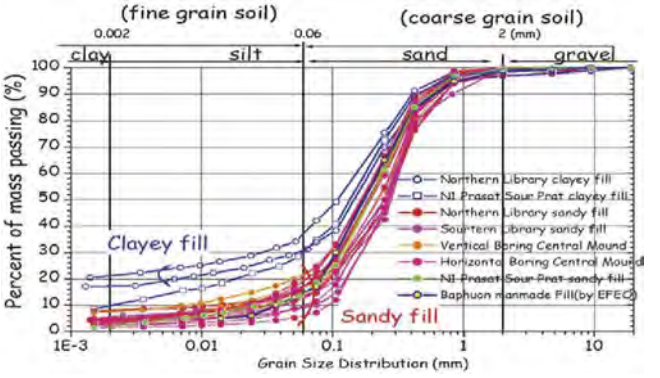

Figure 8. Grain size distribution.

2.3 *X-ray diffraction analysis*

X-ray diffraction analysis was performed to study the mineral components of the filled soil. Figure 9 shows the results of X-ray diffraction analysis. The major mineral is quartz with the clay mineral halloysite of the kaolin group.

The micrograph sample of the sandy fill is also shown in Figure 10. The rounded particles of sand of quartz are gathered filled with kaolin clay.

3 PROACTIVE COUNTERMEASURES AGAINST FAILURE OF THE MAIN TOWER

3.1 *Failure of filled mound by heavy rain*

In the history of Angkor, heavy rains had caused failures of filled mound monuments and embankments. One of the examples of such failure was the failure of northern east slope of Baphuon Temple (Figures 11 and 12), constructed in 1060, near Bayon in the same Angkor Thom site during a heavy rain in June 1943 as shown in Figure 12.

The characteristic of grain size distribution of the mound of Baphuon is shown in Figure 8, which shows the distribution shape is the same as those of Bayon Temple. This implies the original mound of the Baphuon had very high strength and had been stable for 900 years. The stability of high mound of 40 m in height with the steep angle of 45° of the manmade filled structure (shown in Figure 12) is never realized by the present common knowledge of the geo-technical engineering.

In 1960, EFEO (Ecole Francaise d'Extreme-Orient), French governmental organization had tried to reconstruct the failed mound by the compaction of the original soil. However, the fill

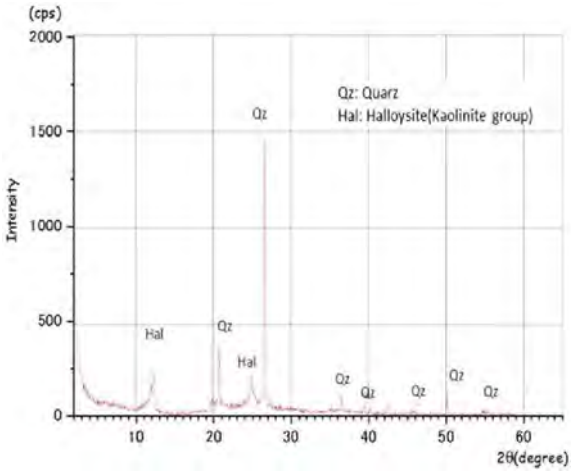

Figure 9. X-ray diffraction analysis.

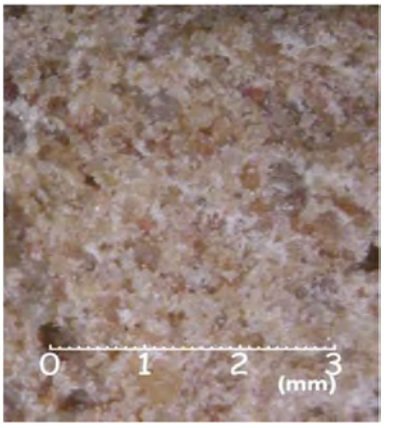

Figure 10. Micrograph of sandy fill.

height reached at 5 m in height, and the filled mound failed three times. The clear mechanism of stability of the high mounds for several hundred years from tenth -thirteenth century to twenty-first century for such high mound structures as the Bayon temple and Angkor Wat in Angkor are not known. The secret was the very large strength of the sandy soil in a dry condition.

Figure 11. Baphuon temple in Angkor Thom.

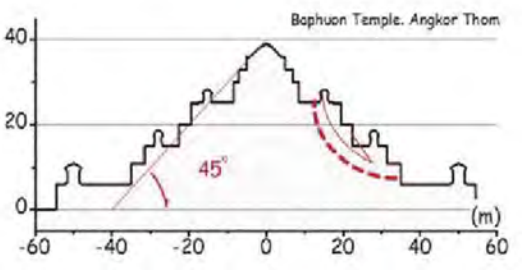

Figure 12. Vertical section of Baphuon (east side).

3.2 *Safety mechanism of filled mound of Bayon for 700 years*

The effects of rainfall to the sandy filled mound were evaluated by monitoring the moisture change within mound. Moisture sensors were installed from the top third terrace to several depths as shown in Figure 13.

An example of monitored results during May 27 to 28 in 2017 is shown in Figure 14. The rainfall intensity was about 10–15 mm/10 min for about one and half hours of 80 mm in total. The rain was a very heavy intensity, but rather in short duration of a few hours with squall conditions in a monsoon area.

As shown in Figure 14, the water content at GL-2.0 m has increased with some delay time, but returned to a dry condition due to stopping the supply of rainwater from the surface.

In the projected coming climate change, the duration time of precipitation is anticipated to become much longer, and the supply of rainwater will result in high water content to cause the damage to the platform foundation leading to the failure of the Main Tower of Bayon.

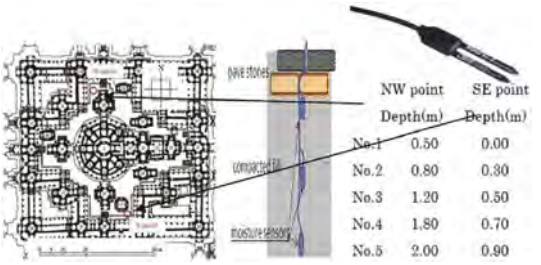

Figure 13. Installation moisture sensors.

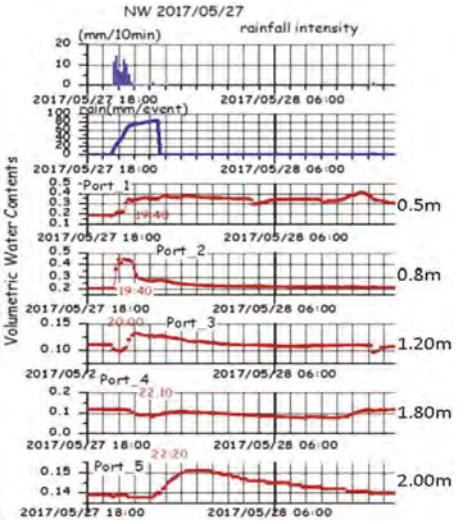

Figure 14. Monitored results of water contents.

3.3 *Proactive countermeasures against projected climate change*

In the projected coming climate change, the present rain of squall type is anticipated to change to a heavy and long duration. To avoid water seepage into foundation soil, the following countermeasures are being prepared based upon the basic three principles of countermeasures for conservation of cultural heritage of 1. minimum intervention, 2. incremental approach, and 3. removable measures.

There are three routes for rainwater to penetrate into the foundation of the main tower of Bayon as follows,

1. Open space at the top of the main and sub towers
2. Gaps between stone pavement on the mound surface
3. Gaps between step stones of the surface of side steps of the platform foundation

As proactive countermeasures for the above objectives, A. To cover the open spaces of the top of the central and sub towers by some cover, and B. To fill the gap between surface and step stones to prevent the rainwater from penetrating into the inside of the towers as well as to seepage into the foundation mound as shown in Figure 15.

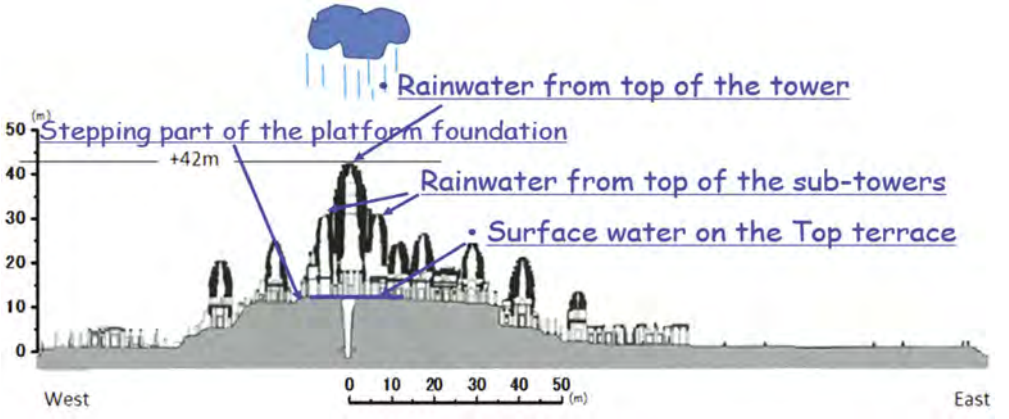

Figure 15. Proactive measures to prevent rainwater into the foundation soil.

It is also being prepared to install sensors under the ground to obtain moisture changes of the ground under the platform surface to confirm the effectiveness of the countermeasures.

4 CONCLUSIONS

The foundation was identified to consist of densely compacted sand fill with large strength in dry, but collapsible in submerged conditions. The projected coming climate change is expected to result in heavy rain for a long duration. To prevent the rainwater from penetrating the foundation, the simple and yet effective counter measures are being prepared to prevent the failure of the Main Tower of Bayon temple in Angkor Thom.

Architectural and design features of the brick buildings of petropavlovsk city XIX-XX centuries

R.U. Chekaeva, M.G. Chekaev, F.M. Chekaev, A.Z. Issina, Ye.N. Khvan & Ye.D. Sarsembayeva
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: This paper discusses the stone, brick architecture of Petropavlovsk at the end of the 19th century and the beginning of the 20th century. The paper analyzes the architectural planning solution and the style of objects. At the end of the XIXth century, in the era of the industrial revolution, it was necessary to create new types of buildings - industrial workshops, railway stations, covered markets, trading houses, gymnasiums, and apartment houses. Turning into the main customer of construction work, the merchants introduced traditions, criteria, and views of their own cultural environment. The meaning of the activities of the merchants in this area is reduced to one thing - to make obvious the cultural and historical roots of the merchants, to show its connection with the folk culture (Voloshinov et al. 2011).

1 INTRODUCTION

Compositional techniques and artistic norms of the classicism style that prevailed before in the architecture were not always able to meet the requirements of the new time, therefore, it became a natural departure from them. Eclectic architectural style appeared in response to the needs of life itself (Ageeva et al. 2011). Well-preserved to our time buildings, the expressiveness of which was built on the brickwork and aesthetic properties of the brick. The red-brick style is called non-plastered eclecticism. Such buildings were relatively inexpensive and more "unpretentious" in the conditions of the harsh Siberian climate, so they quickly gained popularity in the province. One of the most expressive architectural and constructive elements are the crowning eaves of buildings. (Figure 1) Giving the building a finished look, at the same time, they perform an important function of protecting the walls of the house from moisture. Under the brick cornices are often brackets that complement the architectural decor, facilitate the laying, support the cornices and allow them to increase the removal from the wall. Above the windows and doors, too, arrange small cornices topped with gables - sandriks. From the point of view of engineering mechanics, curtain elements reinforce the load-bearing walls, correctly distributing the load.

In the late nineties of the XIX century, a new stage of development of trade and the entire economic life of the city of Petropavlovsk began, which was associated with the completion of the construction of the Siberian Railway. During this period, merchant houses, trading houses, shops, banks, offices with intricate brickwork, transforming the view of the city, are being built (Morozov 1981). A large number of houses and shops of Petropavlovsk merchants were located along Voznesensky Prospekt (Kazakhstan Constitution Street) and many of which are preserved today.

The merchants financed gymnasiums, madrasas, a merchant club, on the basis of which the local drama theater grew. They owned enterprises for processing livestock raw materials, mills, warehouses, factories equipped with the most modern equipment (Makhmutov 2015).

Most of the architectural monuments of Petropavlovsk are merchant houses and shops. Having emerged in 1752 as a military fortress, the city soon lost its military destination,

DOI: 10.1201/9781003299127-293

becoming the center of commerce. The favorable geographical position made Petropavlovsk one of the major trading centers. Archival documents say that "in 1777 in the fortress of Sts. Petra (Petropavlovsk) exchanged steppe goods more than in Ust-Kamenogorsk, Semipalatinsk, Yamyshevsk and Omsk fortresses together." Merchants made a significant contribution to the architectural appearance of Petropavlovsk (Poluyanova 2014).

Houses and shops still adorn the streets of the city, they are located mainly on the streets of the Constitution of Kazakhstan. The surviving merchant houses and buildings gave Petropavlovsk a unique architectural appearance. At the end of the XIXth century, the architects of Russia and Siberia used the techniques of such styles as Baroque and Classicism, and also reproduced forms of ancient Russian architecture - Old Russian romanticism. It was the so-called pseudo-Russian style or red-brick architecture. The expressiveness of the red-brick style is based on the use of shaped brickwork (Ponomarenko 2008).

Well-preserved to our time buildings, the expressiveness of which was built on the brickwork and the aesthetic properties of the brick. The red-brick style is called plastered eclecticism. Such buildings were relatively inexpensive and more "unpretentious" in the conditions of the harsh Siberian climate, so they quickly gained popularity in the province. Thus, the brick style represents the rationalization of eclecticism for mass and utilitarian construction (Gumenyuk 2009).

Beautiful examples of the red-brick style in the architecture of Petropavlovsk are: House and Shop of the Merchant Strelov, House of the Merchant Arkel (Complex of the Museum of Regional History); House and Shop of Merchant Ismailov (Restaurant; private enterprises); House of merchant Shamsutdinov (Shops, private enterprises); The house of the merchant Mukhamedyarov and many others. Architectural and structural elements of historic buildings determine the belonging of a building to a specific architectural style, and also combine in themselves a decorative and functional purpose. One of the most expressive architectural and structural elements is the crowning eaves of buildings (Figure 1).

Figure 1. Crowned cornices with ribbon toothed brick brackets.

Giving the building a finished look, at the same time, they perform an important function of protecting the walls of the house from moisture. Under the brick cornices are often brackets that complement the architectural decor, facilitate the laying, support the cornices and allow them to increase the removal from the wall. Above the windows and doors, too, arrange small cornices topped with gables - sandriks. From the point of view of engineering mechanics, curtain elements reinforce the load-bearing walls, correctly distributing the load. (Figure 2).

Figure 2. Figured Sandrik above the windows.

2 MAIN PART

Constitution Street is a pedestrian street, a kind of local "Arbat". Before the revolution, the street was called Voznesensky Prospekt and had a narrow wooden pavement. In Soviet times, it was called the standard for such streets - Lenin Street.

Figure 3 presents a vivid example of decorative towers, attic and dormer windows, as well as the rich complex red-brick architecture of the facades of the house and merchant Shakirzhan Shafeev's shop.

The eclecticism of these buildings combines elements of red-brick style, baroque and classicism. The facades of many merchant buildings erected in the eclectic style are decorated with embossed masonry and pilasters, which have a considerable amount of brick columns and turrets on the roof. This is the house and shop of the merchant Shafeev. Figured parapet columns and walls connected by an openwork metal fence give buildings special expressiveness and completeness.

Figure 3. Architectural decor of the facade of the House of Merchant Shafeev.

The next object is "Trading house of the merchant of the first guild of Blumenthal" in Petropavlovsk (Figure 4). Before the revolution, a merchant family of Jewish origin, Blumenthal, lived in Petropavlovsk. In 1909, a stationery shop and the printing house of the merchant of

the 1st guild Alexander Lazarevich Blumenthal was in place of the present TSUM. Alexander Blumenthal was a great expert in hides leather. At that time there were three or four such experts in this business as he, to the whole of Russia. Taking the item, Blumenthal sorted it at the same time. He did not enter into any contracts, everything was built on trust, no one was deceiving anyone or cheating. A few years later, the owners sold the building for the construction of the Siberian Trade Bank. In 1915, a rubble foundation was laid for the bank, walls were erected, but the revolution of 1917 prevented the final construction of the bank.

Figure 4. Trading house of the merchant of the first guild A. Blumenthal.

The Bolshevik government seized the unfinished building, and the next mention of it dates back to 1926. In the same year, the building was finally completed and the People's Commissar of the Kazakh SSR was located there, which was later renamed the North Kazakhstan regional executive committee. At present, the building houses the "Tsum" trade house by all recognizable residents of Petropavlovsk (Figure 5).

Figure 5. Modern view of trading house of the merchant A. Blumenthal.

The merchant Blumenthal's family, who lived in Petropavlovsk before the revolution, left a legacy to contemporaries in the form of a series of postcards with views of the city of the publishing house Blumenthal Alexander Lazarevich and Lydia Isaevna. In 1912, Blumenthal and his family left Petropavlovsk forever, where they lived for 12 years.

3 CONCLUSION

For the construction of houses at the end of the XIXth century, burnt bricks were used and they were built in eclectic style in the Petropavlovsk city. We need to preserve these unique architectural monuments, which, being in the center of the city, without detracting from its appearance, still fascinate with their exterior. As each of these houses conceals the history of its roommates and their greatness.

In the process of studying, studying historical and architectural monuments, an understanding of the relationship of the artistic image of each building, its design features, and the mechanics of its parts is taking place. Each element is multifunctional, as it adorns the building, and strengthens it, at the same time, giving it originality.

The buildings are a sample of the historical planning of a provincial merchant city, characteristic of the XIXth - early XXth century, expressed in the planned integrated building of brick buildings of a hotel and shopping destination and are the architectural heritage of the city.

Solution of geotechnical problems in operational basement floors construction process during restoration

M.A. Stepanov & Ya.A. Pronozin
Industrial University of Tyumen, Tyumen, Russia

ABSTRACT: Restoration of cultural heritage sites and their adaptation in the modern urban environment as dominant objects is one of the most important issues in the development of historical cities.This paper presents the results of computational modeling with regard to step-by-step work to increase the volume of restoration building by basement floor construction: arrangement of bored injection piles, step-by-step soil excavation, construction of insitu reinforced concrete caisson and foundation plate. According to monitoring data, this method of basement floors construction excluded critical additional deformation of the structure and can be applied in similar conditions.

1 INTRODUCTION

A restoration of cultural heritage sites and their adaptation in a modern urban environment as dominant objects is one of the most important issues in a development of historical cities.

Appearance of Tyumen, the first Russian city in Siberia, is largely determined by the historical center and individual historical districts, such as, for example, a complex of buildings with a park on Daudelnaya Street.

One of buildings in this complex is the City Hospital ("Tekutievo hospital"), which built in 1902–1904 by A.I. Tekutiev, Tyumen mayor, merchant of the first guild, honorary citizen of Tyumen (Kozlova-Afanasyeva, 2008). A historical value of this building is in the fact that S.I. Karnatsevich, N.I. Russkikh, A.S. Gasilov worked in the "Tekutievo hospital" in first decades of twentieth century. They are well-known famous Tyumen doctors. In the summer of 1914, Grigori Rasputin was treated in the hospital after a severe wound.

Before 2019 the object of cultural heritage of regional significance is not in operation and was closed because of critical conditions (Figure 1).

Figure 1. "Tekutievo hospital" before restoration (2011).

DOI: 10.1201/9781003299127-294

"Tekutievo hospital" is a two-storey building without underground floors, which has a complex configuration in plan and made in a classical red-brick style with elements of eclecticism (Figure 1). The structural layout is frameless with lateral load-bearing walls, which consist of clay brick and lime mortar. External load-bearing walls have a thickness of 640 mm, internal - 570 mm, foundations of the building are shallow, strip type. The bottom of foundations is approximately 1.2 m from the level of ground surface.

As preliminary work, depreciation analysis and inspection of the building load-bearing structures were made. It was established, that the building was out-of-commission and thus, it was necessary to renew roof construction and floor decks, partially to replace brick layout, repair cracks and reconstruct fronts of the building. The foundations being walls' broadening and didn't have waterproof finish, but there were not any other construction defects.

The main engineering issue during restoration work was to increase the volume of the building by constructing a full-functional underground floor and entering it into united space. For this reason, works were done to deepen of the basement below the existing foundation footing.

Geomorphologically, the site of building is confined to the high right-bank terrace above flood-plain of Tura River. The soil of the ground bed was composed of loams of various densities ranging from firm-stiff to soft-firm (consistency index I_c classification, ISO 14688). Physical-mechanical properties of soil base are presented in Table 1.

Table 1. Physical-mechanical properties of the soil base.

№ of engineering-geological element	1	2	3
Unit weight γ, kN/м^3	19.1	19.2	18.5
Water content w, %	20.3	19.5	30.5
Liquidity index I_L	0.29	0.49	0.69
Void ratio e	0.67	0.9	0.87
Angle of internal friction φ, °	17	19	19
Cohesion c, kPa	22	26	24
Elastic modulus E_{oed}, MPa	10	12	6

The groundwater level was found at depth of 2.7 m from the ground level, which is 1.3 m higher than the level of the foundation footing.

Floor loading increasing during basement floor construction below the existing foundation footing was difficult geotechnical task in conditions of high groundwater level and high sandiness of loams. It was necessary to ensure the reliability and stability of the foundations of the building, as well as limiting deformations (technological settlements), during execution of work. Otherwise, the building could have been subjected to structural failure (Mangushev 2015, Mangushev&Osokin 2020, Ilyichev&Mangushev 2016, Shashkin et al. 2019, Ulitskiy et al. 2012).

2 METHODS

During restoration of "Tekutievo hospital", its painterly architectural look, agreeable with the time of construction, was recreated (Figure 2).

Underground floor construction was carried out by using low impact construction technology (Pronozin et al. 2013), embracing:

1. Drilling a perforation at an angle into the brick foundations for the bored-injection piles.
2. Installation of the bored-injection piles of "Atlant" type with a diameter of 200 mm and a length of 5 m (Ibragimov & Semkin 2012, Mangushev 2013, Pronozin et al. 2014, Salnyi et al. 2021, Pronozin & Samokhvalov 2018).
3. Implementation of dewatering measures.
4. Installation of tie girder for the underground floor.

Figure 2. «Tekutievo hospital» design view after restoration.

5. Ground excavation to the depth of the underground floor with the installation of a barrier to ensure there is no soil dumping out of the base of the existing foundation.
6. Laying the base of crushed stone, the base of concrete preparations and an installation of the waterproofing membrane. Installation of the caisson slab with protruding reinforcement.
7. Installation of welded meshes of the caisson wall, fixing them with protruding reinforcements and reinforcement passing through the existing foundation.
8. Concreting of the caisson walls with monolithic underground floor beams.
9. Installation of the underground floor slab.

In the bored injection process, cement mortar displaces drill cuttings and ensures the bearing capacity of piles. It is injected through a chisel located at the bottom of the piles.

The bored-injection piles depth was accepted using the results of calculating the required bearing capacity of piles and the Plaxis program numerical modeling (Pronozin et al. 2013, Strokova 2010, Ulitskiy et al. 2014). Stabilization of the foundation and soil base was considered. Mohr-Coulomb model was accepted by the standard engineering geology prospecting data in spite of the ground unloading modeling disadvantages. Excavation depth was about 3 m.

Pile diameter, pile length and caisson thickness (stiffness of the structure) were designed by computational modeling. Figure 3 presents one of calculation schemes.

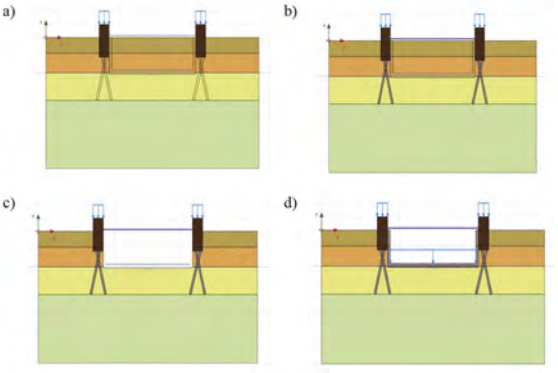

Figure 3. Calculation scheme with taking into account the sequence of work: a - before basement floor construction; b - installation of piles and tie girder; c - soil excavation to the depth of the basement; d - after basement floor construction.

As a result of the numerical simulation it was established:

1. Caisson usage minimizes irregular settlements, because of foundation and walls combined action. Stiffness of the substructure increases. Caisson wall thickness is equal to 200mm, thickness of caisson slab is equal to 400 mm.
2. Minimal pile depth is 5000 mm for the settlement uniformity condition and uncritical advance of plastic strain zone in the basement. Pile diameter is 200 mm (Figure 4).
3. Because of Mohr-Coulomb model disadvantages, soil behavior doesn't correspond to the real situation. According to numerical modeling, soil surface raises in 20 mm after design basement excavation of 2600 mm (assuming that the deformation modules are equal at the stages of loading and unloading (Ulitskiy et al. 2014, Shashkin & Shashkin 2005, Stepanov et al. 2017).
4. Caisson usage balances the settlements of the whole building (Figure 4). Additional design settlement from the application of all operational loads was 20 mm. But there are some areas with more than 20mm settlements under the caisson. It happens because in Mohr-Coulomb model stress-strain relationship develops linearly up to a point of yielding (Ulitskiy et al. 2014, Shashkin & Shashkin 2005, Stepanov et al. 2017).

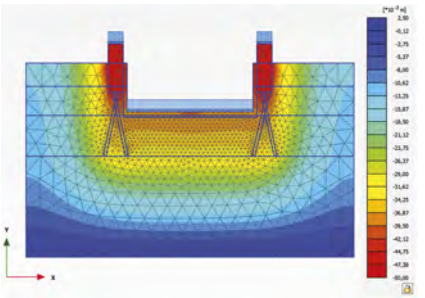

Figure 4. Isolines of vertical displacements.

To clarify the applied bored-injection piles bearing capacity, two test piles were made on the site of the restored object. The tests were carried out with a static load in steps of 1-tonne force (Figure 5). Each step was maintained until the stabilization of soil displacements (velocity of pile settlement at the loading step does not exceed 0.1 mm over the last 2 hours of observations) in accordance with the requirements (GOST 5686-2020). After experimental data processing, the bored-injection piles bearing capacity was 90 kN with a settlement of 12 mm (maximum allowable settlement for this object) and 120 kN with a settlement of 30 mm.

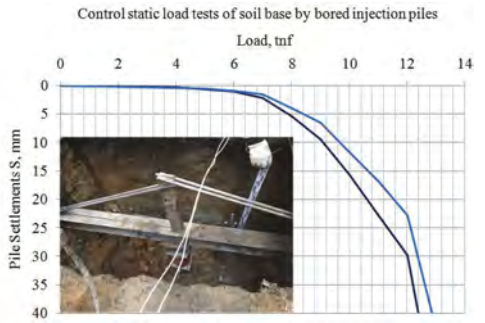

Figure 5. Graph «load – settlements» of test static load tests of piles.

3 RESULTS AND DISCUSSION

In June 2016 restoration work of "Tekutievo hospital" started. The authors monitored construction technology of underground floor building such as injection pile installation, soil excavation, erection of insitu reinforced concrete caisson (Figure 6).

Figure 6. Work process: installation of tie girder for the basement floor; excavation of the soil to the depth of the underground floor.

Geotechnical monitoring showed the following:

- the chosen method of underground floor construction did not cause the development of ultimate stresses and deformations in the building structures;
- the maximum technological settlement was 9 mm, even taking into account gross violations of work rules, widespread soil dumping from beneath the foundations and regular problems with dewatering;
- factual injection pile shape was different from pile shape used in computational modeling; the diameter of the piles along the length is not constant, from 200 to 230mm.

This method of basement floor construction excluded ultimate additional deformation of the structure, cracks in bearing constructions and can be applied in similar conditions. In 2019 restoration work of "Tekutievo hospital" was finished. Figure 7 presents the exterior of "Tekutievo hospital" after restoration.

Figure 7. "Tekutievo hospital" after restoration.

4 CONCLUSION

1. Field tests of bored injection piles ("Atlant" type, 5 m long) confirmed the results of numerical modeling pile bearing capacity, which was 90 kN.
2. According to numerical modeling, the additional calculated settlement from the application of all operational loads was 20mm. The restoration work with increasing the volume of underground space was completed, and according to the results of geotechnical monitoring, the maximum technological settlement was 9mm.
3. The accepted method of the basement floor construction did not cause ultimate additional deformations of the building, overstresses and cracks in the load-bearing structures in conditions of a high level of groundwater, interbedding of sandy and silty-clay weak soils. Thus, the method can be recommended for use in similar conditions.

ABSTRACT: The study of urban wooden, brick and stone-wooden architecture is of undoubted historical and cultural value and is perceived as evidence of an important stage in the history of architecture and urban planning of cities in Kazakhstan. The preserved residential buildings of the XIX and early XX centuries are a valuable representative in the urban structure, which creates an interesting color in combination with other buildings. As a result of studying, for the first time, the development of urban planning and architecture of the cities of Northern Kazakhstan in the XIX-XXI centuries are considered and studied comprehensively and in detail. For the first time, regional specificities of the architecture of residential, public, religious buildings and facilities, their architectural and planning solutions are identified. The stylistic and compositional characteristics of the architectural monuments of the region and objects of modern architecture are considered, the systematization and classification of buildings and structures is carried out, the chronological description of the development of urban planning in Northern Kazakhstan up to the XXI century is restored, the genesis of architectural forms of facilities and the main historical stages of the architecture development of the period under consideration are determined. In this paper we consider brick residential architecture.

Keywords: brick houses, residential buildings, analysis, architectural style

1 INTRODUCTION

From the mid-90-s of the 19th century began intensive resettlement of the population from Russia to Siberia and Kazakhstan. The development of industry and domestic trade was largely contributed by the construction of railway lines connecting Kazakhstan with Siberia and other regions of the Russian Empire [1]. One of the conductors of the agricultural policy of the autocracy was the Siberian Railway Committee. The issue of the construction of Trans-Siberian Railway arose at the end of the 19th century. Projects of its construction were compiled and discussed for many years. Finally, in 1891, a Royal Decree was issued on its construction. For the general management of the construction of the road, on October 10, 1892, the "Special Committee of the Siberian Railway" was established which existed until December 15, 1905, that is, until the end of its construction [2]. The Trans-Siberian Railway, which construction began in 1891, was supposed to pass through Northern Kazakhstan. The "Special Committee of the Siberian Railway" allocated 24489,31 km^2 of land in the three

DOI: 10.1201/9781003299127-295

Aqmola regions for resettlement of 160 thousand of peasants. From the mid-90-s of the 19th century began intensive resettlement of the population to Siberia and Kazakhstan [3].

During the last decade of the 19th century, 514 km of rail lines were built in Kazakhstan [4]. In general, the local industry was predominated by enterprises processing agricultural raw materials: tanneries, fat-making factory, soap-making factory, distilleries, oil mills, and others. Wool and fleece factories, meat cannerie, milling and cereal industry have received its wide development in Semirechensk, Aqmola and Semipalatinsk regions, in which the military department showed their special interest [5].

Intensive migration of the population since the 90s of the 19th century from Russia to Siberia and Kazakhstan served and led to the development of industry and domestic trade. This was facilitated by the construction of railway lines connecting Kazakhstan with Siberia and other parts of the Russian Empire [6]. As a result of implementing «temporary rules» with settlers to Kazakhstan came the traditional wooden and stone architecture. The settlers brought the original architecture of their regions, which has undergone changes in the layout, due to the climatic conditions of Northern Kazakhstan [7]. Urban housing in the 19th and early 20th centuries is a striking feature of the historic city, shaping its environment and preserving its national and regional flavor.

Historic wooden, stone (of burnt bricks) and mixed development of the period studied have until recently retained its urban planning significance as an essential component of architectural ensembles in a number of city districts (mostly in historical centers). However, active urban planning transformations of the last decade in the cities of Northern Kazakhstan (Petropavl, Kostanay, Pavlodar, Kokshetau) has entailed the mass destruction of entire blocks and streets with wooden and stone buildings. In addition, many buildings has changed in the process of repairs or reconstruction.

Due to insufficient scientific substantiation of the value of the wooden, stone, stone-wood architecture of the historic city, this heritage is often negatively assessed for its short lifespan, the lack of modern comfort levels and its poor condition, which requires repair and restoration. Urban planners do not take their significance and value into account when designing master plans of cities.

Based on archival material, historical sources and field surveys, it is safe to say that the architectural shaping, volume-spatial composition, planning features of stone buildings in the cities of Northern Kazakhstan at the end of 19th - beginning of 20th century emphasize consistent approaches to formation of building styles (Art Nouveau, eclectic, brick and wooden architecture), which accentuates the relevance in the study of this issue.

The purpose of this study was to identify understudied buildings and structures that are important for determining the process of evolution in urban architecture in Northern Kazakhstan. The study of the cities of Northern Kazakhstan in the 19th and early 20th centuries contains a comprehensive systematic analysis of features of brick, stone and wooden architecture, which helped to fill the lack of scientific data on historical and architectural, urban planning, artistic and aesthetic significance, and determine the relevance of this work.

As a result, the objectives of the study were defined:

– to analyze the identified factual material;
– to conduct field surveys of the architecture of the cities of Northern Kazakhstan (Petropavl, Kostanay, Pavlodar, Kokshetau) of the 19th and early 20th centuries;
– to systematize and determine the classification of brick buildings and structures.

Work has been carried out to determine architectural planning and compositional solutions of residential buildings (brick buildings and stone-brick, with the first storage being made of stone-wood, and the second of wood); 2-storey, urban multi-bedroom residential buildings in «brick», «Art Nouveau» and «Eclectic» styles.

2 MATERIALS AND METHODS

The method of research is based on a systematic analysis of the objects of study, a compositional and graphic analysis of urban planning, with the use of graphic measurements and scientific generalizations.

The work was built on a holistic coverage of the extensive factual material collected by the authors as a result of the study of the state archive materials, analytical review of the scientific literature, as well as information collected during field research (measurement work) and inspection of historical sites.

3 RESULTS AND DISCUSSION

In the study of general patterns and regional peculiarities of the development of residential buildings architecture during the XIXth and early XXth centuries, the following houses were identified: wooden, brick and stone-and-wooden type. The study of wooden, brick and stone-wood urban architecture is currently of undoubted historical and cultural value and is perceived as evidence of an important stage in the history of architecture and urban development of the cities of Northern Kazakhstan. In order to trace the dynamics of the architecture of residential buildings in a historical retrospective in the stated period, consider examples of residential buildings.

3.1 *One-story brick houses of rectangular or square shape with a corridor system*

For example - house of merchant Kolmogorov, which was built in 1906 in Pavlodar, located on Lenin Street, 155. (Figures 1 and 2).

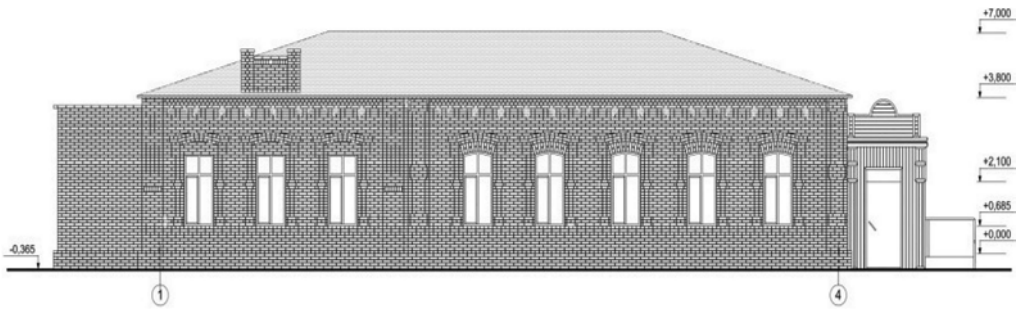

Figure 1. Kolmogorov Merchant's House, graphic work, measurement of the building in 2016.

Figure 2. The house of merchant Kolmogorov, color scheme, measurement of the building in 2016.

The house has wooden entrance part (hallway). Apparently, the original volume was close to a square in plan, had 5 windows on the facade. Subsequently, an additional volume was

added to the northern end. Decorative masonry with high skill applied to all elements of the facade, enriching, emphasizing and artistic expressiveness of the whole. Skillfully drawn plinth, visually ending with a wide part, uniting all the window openings.

Developed plinth, elongated window frames and rich cornice visually increase the height of the building. The floors are wooden with joists. Foundation and walls are made of fired brick. Windows, double doors. Interior finish: plastering with cement mortar, whitewashing. The outer part of the walls has decorative elements [8].

The residential building of the private entrepreneur Turlapov was built in 1900. There was a small sheepskin coat factory in the yard. The building is one-storey, rectangular in plan, measuring 19x10 m, made of brick, with external walls of 710 mm thick, and it's installed on a brick foundation. The overlap and roof structures are wooden. Roofing is made of galvanized roofing steel. The facade of the building is decorated with elements of brickwork. Window openings are completed by the segmental form of masonry. Elements of the uncovered cornice, as well as the platbands on the windows, are executed in the distinctive old Russian style. The shape of the parapet is closer to the baroque style, with elements of the Art Nouveau. The stylistic direction of the monument is characteristic of the eclecticism, which was widespread at the beginning of the 20th century. The building is an example of historical layout of a merchant small-town, typical for the early 20th century and is an architectural heritage of the Pavlodar city.

The next brick house was built in 1907 for the merchant family of the city head I.L.Osipov, who owned salt mines. Located in Pavlodar, Dzerzhinskiy str., 160. One-storey brick-building, with complex masonry on a high basement, built in the traditional style of merchant architecture (Figures 3 and 4).

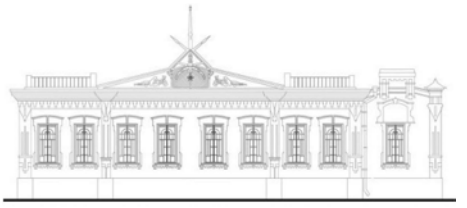

Figure 3. Merchant's house of the city head I.L. Osipov. Graphic work, measurement of the building, 2015.

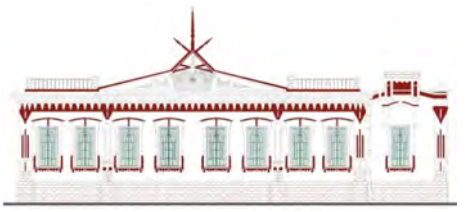

Figure 4. Merchant's house of the mayor I.L. Osipov. Color scheme, measurement of the building, 2015.

The building has a central gable with a spire. The windows are high and elongated, protruding from the plane of the walls due to their design . The corners are finished with semi-column walls with intricate ornamentation. The last ones have drainpipes. The roof of the building is made of iron. The average height of the premises is 3.45m. The total useful space - 316,7 sq.m. Exterior and interior walls are made of brick, double-casement windows, without shutters. The doors are paneled. Finishing: plaster, whitewash. In 1976-77 in the building conducted restoration work (interior repairs, whitewashing the facade). Now it is in private hands, which oversees the state of the house (Figure 5).

3.2 *2-story "brick" style urban multi-room apartment houses*

The merchant Senokosov's house, which was built at the end of the XIX century - beginning of the XX century, is a good example of a "brick" style two-storey city multi-room apartment building (Figures 6 and 7).

The residential building is located on Gogol Street - former Altynsarina, 70, Kostanay [9]. The house belonged to famous Kostanay merchant Turlapov and sold to Senokosov. It is a rectangular building with a brick addition on the north-eastern side of the front yard (Figures 8 and 9).

Figure 5. The house now, a photo taken in 2015.

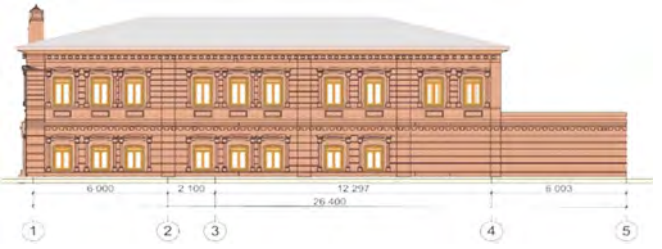

Figure 6. Merchant Senokosov's House, facade in axes 1-5, measurement of the building, 2016.

Figure 7. House of Merchant Senokosov, facade in the D-A axes, color scheme.

The internal structure is a set of rooms, almost not communicating with each other, with two corridors and a hallway with stairs. The building is made of brick, not plastered, is set on a cobble foundation.

The house stands at the intersection of two streets and the solution of its street facades makes it stand out actively compared to surrounding buildings. The brick 2-storey building has a clearly defined integral volume, despite its varied decor solutions (Figure 6).

The main facade is 26.5 meters long and faces Pushkin Street. The facades are decorated with typical Russian folk architecture techniques of the late 19th and early 20th centuries. All

Figure 8. Merchant Senokosov's House. Plan of the 1st floor, measurement of the building, 2016.

Figure 9. Merchant Senokosov's House. Plan of the 2nd floor, measurement of the building, 2016.

kinds of masonry laid on the surface of the wall create a sort of 2nd cladding of the building with a lot of protruding and receding elements. The corner of the building (at the intersection of the streets) is distinguished by a two-story rectangular-shaped tower (belvedere), which is an organic continuation of the shallow risalit.

The lower floor has a doorway flanked by half-columns made of brick and they resemble balusters. The 1st and 2nd floors have slightly different solutions. On the first floor, the wide windows have segmental arches, accentuated by a wedge arch, supported by semi-columns. Between the windows are blades with vertically elongated perspective panels. The blades at the level of the upper boundary of the windows have shallow perspective pediments, above which are capitals-consoles, a ribbon of entablature, lined with masonry, separating the floors (Figures 6 and 7).

2-story multi-bedroom, Art Nouveau residential buildings. The former house of merchant Kiyatkin (1911). The building is located in Kostanay, Tolstoy Street 40, on the corner of 5th April Street, now it's the town planning and construction department of akimat. The building is one of the unique monuments of residential architecture of the early 20th century (Figure 10).

Figure 10. House of merchant Kiyatkin (1911), a photo taken in 2015.

It is one of the few surviving examples of so-called pure Art Nouveau in Kazakhstan. It is a one-storey, angular, two-faced brick house with risalit and an iron, multileveled roof. The towers of the parapet are connected by a decorative metal lattice. The windows are high with double glazing. Apart from pilasters, other decorative elements of the façade are rectangular niches above and below window apertures and in the basement on a strip foundation of natural stone. There is a wooden house adjoining the building on the northeast side. There is a corridor floor planning. Its measurements are 22 m x 17 m. The height of the building is 6 m (Figure 11).

Figure 11. Merchant Kiyatkin's apartment building. Facade in axes 1-5, measurement of the building in 2015.

The fate of the owner of this house - one of the founders and most prominent industrialists of the city, Fyodor Petrovich Kiyatkin - is remarkable. Coming from a family of Mordovian peasants - immigrants, hardworking and enterprising Fyodor Kiyatkin graduated only from a parochial school, but in his youth he decided to become rich. Beginning with the construction of a windmill, he proved himself as a talented financier and entrepreneur. F.P. Kiyatkin owned the largest highly mechanized steam mill in the city. By the way, the Kiyatkin family owned three of the city's five steam mills. Later, F.P. Kiyatkin took part in financing the construction of the first railroad between Troitsk and Kostanay, was chairman of the Kostanay branch of the Russian-Asian commercial and industrial bank, and a member of the city council. In 1916 he sold his businesses, saying he wanted to retire from business but "remain useful to society by lending to industry". After the revolution, Fyodor Petrovich thought it's best for him to leave Kostanay. Until 1928, he had never been a stranger to any kind of work, he used to work modestly as a carpenter. Then he returned to the city and got a job as a janitor and guard at the local Collective Farmers' House, which, by a curious coincidence, used to be the former and long ago nationalized house of F.P. Kiyatkin. The townspeople were firmly convinced that the former rich man was working here for a reason and was probably going to secretly dig up his hidden treasures. But the treasure remained one of the city's legends, and Fyodor Petrovich Kiyatkin, who experienced ups and downs in his life, died peacefully in the summer of 1941, leaving a good memory of himself and his house, which even now remains one of the most interesting monuments of Kostanay architecture.

3.3 *One-storey, mixed - enfilade and corridor - systems of planning are made in the style of eclectic*

The following eclectic buildings are worth attention: Strelov's and Arkel's houses that currently make up a complex of buildings of Regional Museum (1891, Lenin St. 44, 46, 48 and Kirov St. 145). Strelov's house of 1891 consists of 2 volumes with a "passage" between them and is L-shaped. The facade facing Lenin Street on the right side, apears to look like a detached composition, there is an entrance 2-winged panelled door [10].

The remaining three sections claim symmetry - the middle one, is the main one, topped by a 2-stepped attic with a triangular gable at the end. The tympanum of the gable has two semicircular arched niches "covered" by a suspended superimposed arch; the side parts of the attic have a panelled decorative design. Overhead multilobed archeswith "sagging" segments, that are supported by pilasters with shaped imposts in the upper, middle and lower parts of the building, have two rectangular panels. The panels in turn frame the windows of the 2nd floor. The balcony with openwork metal railings uniting all 3 windows of the central part gives the building a distinct splendor and functional singularity. The asymmetry of the facade, with the balcony and the attic, can obviously be explained by the introduction of a section with an entrance opening: in this way the architect consciously "deforms" the usual classic 3-part scheme (Figure 12).

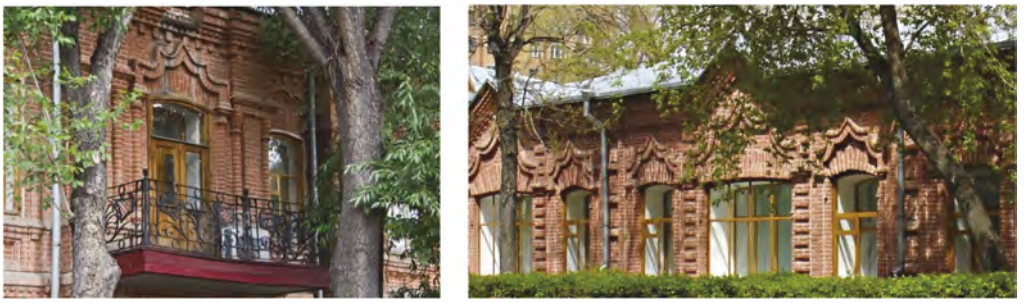

Figure 12. House of the merchant Strelov - was built at the end of the XIX century, 1891.

The structure of the L-shaped plan of the 2-storey house is designed so that only the front rooms face the city street and the secondary rooms face the courtyard part (Figure 13). The mixed - enfilade and corridor - system of layout, widespread at that period, was used. At present, the Strelov House, in a complex with neighboring buildings, the Arkel House, is part of the spatial exhibition of the ancient history of the region and includes part of the administrative premises of the museum.

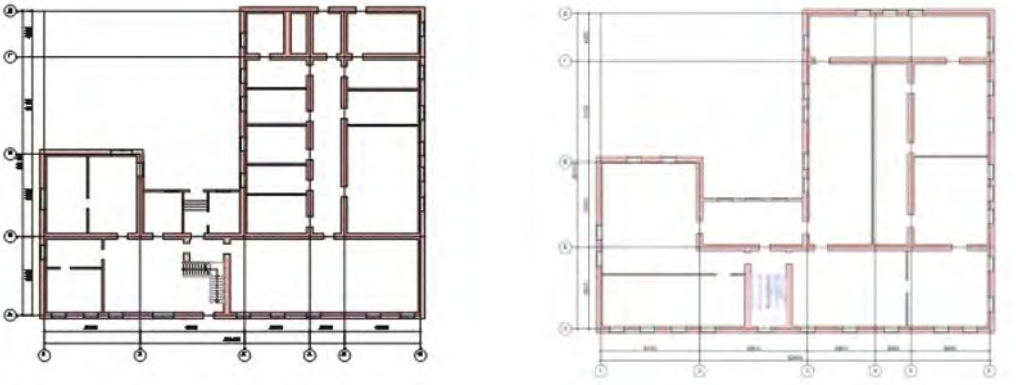

Figure 13. Arkel House, 1891. Plans of the 1st and 2nd floors, measurement of the building in 2016.

Arkel House is one of the largest and most magnificent residential buildings not only in Petropavl, but also in all of Northern Kazakhstan. Its architecture had a noticeable influence on the formation of both the planning structure and the appearance of urban dwellings of the period under consideration. Arkel House, 1891, is located at Constitution Street 48, Kazakhstan (corner of Park Street). Arkel House is a two-storey building, L-shaped in plan (Figure 14).

Built of burnt brick, with external walls710 mmthick. Facade of the building is decorated with decorative elements of masonry. The building has two outward balconies, with openwork wrought iron lattices, located on the main facade . On the first floor, the window openings are completed with segmental form of masonry. On the second floor the window openings are decorated with architectural elements (Figure 15). The architectural appearance of the building is characteristic of the widespread in the late 19th - early 20th century style - eclecticism.

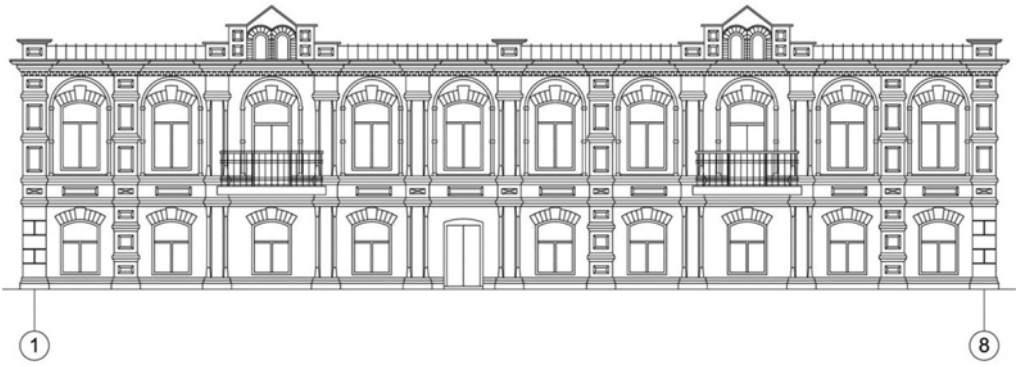

Figure 14. Arkel House, graphic work, measurement 2016. Facade in axes 1-8.

4 CONCLUSIONS

On the basis of field research and the study of archival materials, an analysis of the development of the planning structure of stone and stone-wood dwellings was carried out, it allowed to determine the following features:

- In the first half of the 19th century, the predominant type of house was the one, in which the first floor, divided by stone walls into large rooms - kitchen and utility rooms - was used mainly for household. The second floor with living rooms had an enfilade layout. The layout was compact as a rule. The entrance was made through a wooden enclosure attached to the side or courtyard facade.
- The second half of the 19th century saw the development of the stone and stone-wood dwelling house type with separate apartments on each floor. Entrance to the building was made from the street through the half-stone (less often wooden) volume with staircase along the side facade (the second additional ladder was located on the side of the yard in the same or a separate volume); there is the formation of an internal structure with a distribution space in the form of a corridor, an example is the residential house of the merchant Davletkadiev.

In the first half of the 19th century, when classicism and early eclecticism prevailed, the stylistic and morphological unity of the system of brick and wooden decoration parts was achieved due to the fact that the wooden decor largely copied the architecture of stone buildings.

The second half of the 19th century saw the development of mature and late eclecticism and an increase in the range of stylistic currents characteristic of stone architecture. There is a variety of forms of stone decor with the inclusion of stucco elements; as well of forms of wooden decor, corresponding in general to the classicist tradition of shaping, which are often enriched with motifs from folk architecture.

Early 20th century - the final stage of late eclecticism; variations on the theme of art nouveau and neo-Russian style; the "brick style" in stone decor is prominent(The wooden part of the buildings was the most stylistically expressive, the stone floor was often a volume with little or no decoration).

Architectural and planning solution of these buildings, in accordance with the requests and tastes of the customers, imitated the various currents of Russian architecture in the second half of 19th early 20th centuries.:

The survey revealed the main types of volumetric-spatial composition of stone and stone-and-wooden houses, typical for different stages of the 19th - early 20th centuries.

In the first half of the 20th century, the following type of stone buildings was identified:

Type 1 - stone, 1-2-storey house in the form of a horizontally extended parallelepiped;

type 2 - stone, 1-2 storey house of compact parallelepiped with symmetrical-axial main facade.

And mixed type, i.e. wood on stone half-storey houses:

Type 1 - a wooden house on a stone half-storey in the form of a compact parallelepiped with a symmetrical-axial main facade;

type 2 - wooden house on a stone half-storey in the form of a horizontally extended parallelepiped.

At the end of the 19th and beginning of the 20th centuries there were these types of masonry houses influenced by the architecture of late eclectic and art nouveau mansions:

- Type 1 - a stone house in the form of a horizontally extended parallelepiped with a protruding accent element (a bay window with a hipped roof or a tower);
- Type 2 - stone dwelling house with a stone archway.

The analysis of buildings reflects the basic concept of stylistic preferences in architecture during the late 19th - early 20th centuries in the cities of Northern Kazakhstan, with adjustments and adaptations for regional features, which largely depended on socio-economic aspects. This confirms the formation of the typological foundations and characteristics of the buildings and structures that were built in the North Kazakhstan region during the period under study.

Solution of the problem. The problem of preservation and use of buildings and structures can be solved by creating compositional units, grouping in an ensemble of residential, public, religious buildings, shopping malls of the early 20th century, as well as modern buildings, which determine the silhouette and panorama of the city. Allocate architectural accents so as to harmonize the space of the urban environment as much as possible. Speaking of the artistic and aesthetic aspects, it is necessary to use the contrast in form and materials between existing historical and new objects, to accentuate squares and intersections, to form an environment of scale for the perception of the viewer, as it improves the visualization of the city space.

The determining factors in this case are the folk traditions and ornamental art of local peoples - Kazakhs, Russians, Tatars and decorative design style architecture - Art Nouveau, "brick style", eclectic [12].

The above expected results will allow to systematize the educational process, to achieve the training of architects and improve the level of scientific and pedagogical staff, in accordance with the requirements of industrial-innovative development of the country and achieve a world-class quality and performance of scientific research on the basis of updating the material and technical base and the stimulation of research activities.

Thus, the evolutionary path of development of the architecture of Northern Kazakhstan from the end of the 19th to the beginning of the 20th centuries was traced, while the continuity and formation of new properties of architecture were also revealed.

Ecology and architecture of Kazakhstan cities in the 21st century

O.N. Semenyuk, B. Ozganbayeva, N. Lutsenko & D. Sadykbekov
Gumilyov Eurasian National University, Kazakhstan

ABSTRACT: On the base of general theory on bio ecological territorial systems, the article analyzed urban planning, resource, infrastructural and environmental problems cities, on the example of development modern Nur-Sultan and other cities of Kazakhstan. It known that the greening of the entire socio-economic system of any state is the basis for successfully solving environmental problems and preventing environmental disasters. Environmental security, as an integral part of national security, is a prerequisite for sustainable development and serves as the basis for preserving natural systems and maintaining the appropriate quality of the environment. The environmental consequences of industrial development of cities are air pollution, chemical contamination of soils, surface fresh water and fish stocks in reservoirs, and an increase in the level of morbidity of the population.

1 INTRODUCTION

For the first time, the term "sustainable development of the city" defined in the report of the UN Commission on Environment and Development in 1992. It implies programs to stabilize the population and industrial production, to develop an economy that does not destroy the nature of the Earth. In the concept of sustainable development, the concept of urban habitat is not limited to the ecological aspects of the interaction between man and nature. The city considered as a holistic anthropogenic complex, where society must provide and preserve for descendants optimal living conditions. Not to the detriment of the environmental component, the attractiveness of the urban environment has strengthened due to the streamlining of economic and economic activities and the expansion of various types of services.

Sustainable urban development defined as a much broader concept than environmental protection. This concept has socio-economic, cultural, and environmental characteristics. The problem of sustainable urban development includes the problems experienced within cities, the problems caused or created by cities, as well as potential solutions that can found and represented by cities.

The influx of population into cities related to their attraction, which is that large settlements are centers of work. Multi-functional cities provide a variety of livelihoods and job choices, while offering a wide range of cultural and social services. The unification of various places of employment and the satisfaction of social and everyday needs are very important for a person of the 21st century. A habitat that fully possesses such properties recognized as optimal, but only if protection provided against the negative effects caused by the concentration of people in small areas.

However, according to the UN, most modern cities have negative properties, the main of which are:

- Intensive pollution of the environment by products of economic activity concentrated in one place;
- Disequilibrium in the use of indigenous labor resources, changes in the properties of the "ecological niche" occupied by Aboriginal people;

DOI: 10.1201/9781003299127-296

– Insufficient housing, health and hygiene services due to overcrowding and overcrowding;
– Expansion of urban areas, which entails the removal of the population from each other's points of attraction and the consequent deterioration of transport services, unless the problems of intensification and organization of traffic are resolved;
– Insufficient water and energy supply, drainage and disposal of solid waste.

2 MATERIALS AND METHODS

Urban design, like architecture, is an exercise in analysis and synthesis enhanced by intuition. But uniting a building with its immediate hinterland, creating a community of buildings, or recreating a part of a city provides greater opportunities for beneficial environmental design and allows us to address the wider aspects of sustainability. Whereas a master plan often ends up as a conceptual model of physical infrastructure buildings and landscape, it is the design of the life support systems that link them that lies at the heart of holistic environmental design. Flows of heat, light and energy, air and water, material and waste and most importantly the movement of people are all issues that need to considered, mapped and modeled.

The study analyses the state of modern cities in Kazakhstan from the standpoint of urban planning ecology. Urban planning, resource, infrastructural and environmental problems of the cities of Kazakhstan and the capital of Nur-Sultan are analyzed based on the general theory of bioecological territorial systems. The purpose of the study is to identify existing problems and form ways to improve the environmental situation in the urbanized environment of cities. Numerous environmental problems of cities, mainly the largest of them, are associated with the excessive concentration of population, transport and industrial enterprises in relatively small areas, with the formation of anthropogenic landscapes, which are very far from the state of ecological balance. On the one hand, urbanization improves the living conditions of the population. On the other hand, it leads to environmental pollution, an increase in the chemical, physical and mental load on the human body.

Kazakhstan has a very vulnerable natural environment. The territory of the republic is mainly composed of steppes, semi-deserts and deserts. There are unique inland seas and lakes, such as the Caspian, Aral, Balkhash, Zaysan, Alakol. As result of anthropogenic loads in almost the entire territory of Kazakhstan, the natural ability of the natural environment to ensure the future economic and social development of the country has violated. In the cities of Kazakhstan, the main contribution to air pollution made by road transport. The poor quality of the fuel used and the lack of filters for cleaning exhaust gases, the poor condition of the rolling stock of motor farms, the increase in the number of cars in cities, leads to the release of huge amounts of carbon monoxide, lead into the atmosphere. Urban air pollution is increasing during the heating season. (Figure 1).

Fifteen cities of the republic have increased the level of atmospheric air pollution by harmful emissions. Among these cities are Zyryanovsk, Aktau, Temirtau, Taraz, Petropavlovsk, Shimkent, and Almaty. The high level of air pollution in cities is the result of outdated production technologies, inefficient treatment facilities, and poor quality of fuel used. The main pollutants are dust, sulfur dioxide, nitrogen dioxide, hydrocarbons, phenol, lead, hydrogen sulfide, hydrogen chloride, ammonia, etc. Each of these substances negatively affects health in its own way.

Dust, for example, causes diseases of respiratory substances, liver, blood. The dustiest cities of Kazakhstan are Aktau, Atyrau, Zhezkazgan, Semipalatinsk, and Ust-Kamenogorsk. Disorders of the nervous system can caused by an increased content of carbon monoxide in the air. At the same time, headaches occur, memory decreases, sleep gets upset. High carbon monoxide content observed in cities such as Almaty, Aktobe, Karaganda, Kostanay, Petropavlovsk, Pavlodar, Semipalatinsk and some others. If there are several types of pollutants in the air, which usually happens, the negative effect even more enhanced. This affects the immune system, which often leads to cancer [1].

Figure 2. General plan of Nur-Sultan by the architect Kisho Kurakawa. Adjustment general plan until 2030.

3 RESULTS

3.1 *Impact of urban planning systems on the environment*

Cities are the largest consumers of all types of natural resources - territorial, energy, food, and are the main source of environmental pollution. The pressure on the natural environment is increasing dramatically not only in the cities themselves, but also beyond their borders. The ecological impact of a large city on the environment is 50 times its own radius. Urban planning ecology deals with the problems of the impact of urban planning systems on the environment. In urban planning ecology, there are three degrees of ecological balance: complete, conditional, relative. Ecological balance in urban planning defined as the state of the natural anthropogenic environment, which ensures its long-term stability.

As in the rest of the world, in large cities of Northern Kazakhstan and in Nur-Sultan, it is also possible to predict a violation of the ecological balance of the environment of urban spaces associated with a sharp increase in the population, if measures not taken to eliminate the negative impact of factors of urban pollution and environmental problems. The rapidly developing capital of Kazakhstan, the city of Nur-Sultan, is at high risk of environmental degradation in the near future. The rate of demographic growth of the population in the capital has surpassed all projected indicators. Back in the first half of 2003, the forecast indicator, which was the basis for the development of the general plan of Nur-Sultan by the architect Kisho Kurakawa, was significantly overlapped, which provided for an increase in the city's population to 800 thousand inhabitants in 2030 (Figure 2).

Currently, there are more than a million people in Nur-Sultan; over the past year, the population of the capital of Kazakhstan has grown significantly. With the current population growth, rate of Nur-Sultan the population of the capital will reach 3-4 million inhabitants in 2030 [2]. A large city changes almost all components of the natural environment - atmosphere, vegetation, soil, relief, hydrographic network, groundwater, soil and even climate.

The fundamental concept is also comfort, defined as the most favorable conditions for the life of people, a set of amenities, livability and environmental safety. The very rapid pace of urban development in the modern world has revealed a number of problems associated with maintaining a stable ecological situation. A number of major environmental problems can identified. These include the following problems: - urban planning; - infrastructural; - resource; - environmental protection. Let is consider these problems in sequence, deciphering each of them. Urban planning problems:

– Unbalanced transport framework of the city, inability to accommodate increased traffic flows, resulting in increased air pollution;
– Excessive building density, because of which there is a violation of urban planning norms for insolation and aeration of territories;
– A significant shortage of green areas, a discrepancy between the area of greenery and the number of residents in cities;
– Lack of a developed recreational infrastructure.

Road transport is one of the main sources of air pollution in cities. This is due to a number of reasons:

– Narrow streets;
– High building density;
– Insufficient level of landscaping.

Ultra-dense residential buildings reduce wind speed, and stagnant air contributes to the concentration of highly toxic traffic pollutants. According to environmental monitoring data in recent years, over large cities, the atmosphere will contain 10 times more aerosols and 25 times more gases. At the same time, 60-70% of gas pollution provided by road transport. The low level of greening of urban areas leads to a lack of fresh air, oxygen, pollution and gas pollution of the air environment. The cities of Northern Kazakhstan have a sharply continental climate with a low amount of natural precipitation, as well as swampy and saline soils, and this does not contribute to the rapid growth of plants. Therefore, there is a problem of greening urban areas. In particular, in the capital Nur-Sultan, trees have to plant several times in the same areas, as they do not take root well. At present, a program for landscaping the territories of Nur-Sultan has developed, which defines the stages of planting new trees in the city. Selected tree species that can survive in harsh climatic conditions [3]. A green ring created around the city to protect the city from strong steppe winds. There is a need to develop program of the following points in order to solve the environmental problems of Nur-Sultan and other large cities:

– Creation of a regional environmental doctrine;
– Determination of the ecological potential of the environment;
– Development of the urban ecological framework of Nur-Sultan (calculation of the area of compensatory zones, calculation of the ecological load on the environment);
– Carrying out urban ecological zoning of the city territory;
– Carrying out a clear normative regulation of urban development of the territory;
– Optimization of the city's transport framework, the introduction of new types of transport, such as the monorail;
– Substantiation and design of the city's recreational system;
– Compliance with the optimal ratio of building and landscaping. The implementation of this program will improve the ecological state of the capital of Kazakhstan, as well as program and control the ecological situation in the city.

It should note that during period there were violations of urban planning norms and rules during the development of the old part of cities in Northern Kazakhstan. The houses are on the red line close to the road, there are no protective green stripes. As a result, residents of older residential areas not protected from noise and pollution. One of the important urban-ecological problems that have a significant negative impact on the existing natural landscape is the lack of a developed recreational infrastructure. For example, in Nur-Sultan, the available 500 meters of sandy beach in the park on the banks of the Esil River do not solve the problem of recreation for the citizens of the millionth city. Therefore, many residents of the capital rush out of the city, using the banks of the river outside the city park for recreation. The consequences of spontaneous rest are the most negative. The coastal zone of the river outside the city limits for kilometers polluted with household waste: broken glass, bottles, plastic bags, food leftovers. Rubbish also dumped into the water, and piles of rubbish block the already narrow riverbed. The solution to this problem lies in the purposeful creation of a scientifically grounded system of recreational areas with organized parking, swimming places. These zones are not concentrated in one place, but distributed along the riverbed to reduce the environmental load on the recreational area. Urban development of the banks of the Esil River in the capital is a complex environmental problem. For many years, construction carried out close to the banks of the river. Esil, flowing through the steppe landscape, receives water replenishment only during the period of snow melting. Slight precipitation does not affect the water level in the river. The construction of multistore buildings along the banks of the river requires the digging of foundation pits for the installation of pile foundations, which leads to artificial drainage and outflow of water from the river.

The southern capital of Kazakhstan, the city of Almaty is located in the southeastern part of Kazakhstan in the north of the mountain spurs of Tien Shan at the foot of the slope of the Zailiysky Alatau at an altitude of 600-900 meters above sea level, in the valleys of the Big and Little Almaty rivers. The territory adjacent to the city and lying at 600 meters above sea level is fertile, abundantly overgrown with forest and shrubs. Like any big city of Almaty, it faces great environmental problems, which will discussed below. Almaty is the largest city in Kazakhstan, on the territory of which there are large enterprises, thermal power plants and the private housing sector, which, along with vehicles, are intensive sources of environmental pollution. The catchment area of the rivers of Almaty flowing into Ili characterized by a high degree of pollution, including heavy metals. The Big Almaty, Little Almaty, Esentai rivers flow through the territory of Almaty, into which sewage pipes of a number of enterprises discharged. The Yesentai River flows into Big Almaty further into the Kaskelen River and into Ili, the Little Almaty River flows into the Kapchagai Reservoir. The multifaceted distribution of contaminated waters, self-treatment and conversion of contaminants in water bodies has led to the fact that the problem of forming water quality in rivers and reservoirs with anthropogenic effects has not solved sufficiently. In addition, unorganized and untreated waters of the private residential sector and numerous car washes, catering points and other small business facilities discharged into the waters of these rivers; these discharges are not actually controlled.

Today, freshwater pollution has become so significant that it takes on the nature of a disaster and is alarming in many countries of the world. The Republic of Kazakhstan is relatively poor in water resources compared to European countries, but richer than other States in the Central Asian region. According to its sources, Kazakhstan's water resources divided into surface, underground, glacial and artificial reservoirs. The southern capital of the Republic of Kazakhstan is unique in its physical, geographical and natural-climatic characteristics. The city of Almaty is located in the north of the mountain spurs of the Tien Shan mountain system, at the northern foot of the Zaili Alatau, on the cones of the Ulken (Big) - Almaty and Kishi (Little) Almaty interfluve. In Almaty, the natural zones of the harsh north and the sultry south are crossed. Complex terrain, climatic features create unfavorable conditions for dispersing impurities from low sources of emissions, as result of which harmful substances accumulate at high concentrations, which then take part in the formation of smog phenomena. Pollution of the city's atmospheric air is one of the serious factors of water and soil pollution, since due to poor storm sewage, pollutants are washed away into water bodies with meltwater and storm water. The most polluted is the atmospheric air of Almaty, according to

the estimates of the Environmental Monitoring Center. The main source of air pollution in Almaty is motor transport. As a result, the atmospheric air of the city has an increased content of formaldehyde, nitrogen dioxide, phenols, carbon monoxide. The most disadvantaged areas of the city are the TETs-1 areas, the highway along Rayimbek Avenue, the area of the Fruit Canning Plant (Figure 3).

Figure 3. Air gas content in Almaty city.

The ecological state of rivers, taking into account the state of the catchment basin, water protection zones, strips and water quality, estimated according to the data of the Research Institute of Environmental Problems as follows: Big Almaty River - more satisfactory; Yesentai River - less satisfactory; Little Almaty River - extremely unsatisfactory; - other watercourses are extremely unsatisfactory.

The vegetation of Almaty performs a certain positive function in normalizing and supporting the ecological situation of Almaty. According to the official statistics of Almaty, green spaces of public use occupy 3% of the city, which in translation per resident is about 7.0 m of green spaces. Parks, squares, green streets are, for various reasons, in unsatisfactory condition. The largest environmental problem for Almaty is the problem of accumulation and storage of solid industrial waste. About 24 hectares of city land contaminated with household waste. Of which the city garbage reloading station and spontaneous landfills in various areas of the city occupies 10 hectares. The ecological state of any region, city, and settlement known to be a factor characterizing their demographic situation. According to the Almaty City Statistical Office, over the past 10 years, almost all indicators of the demographic situation in Almaty have worsened. Thus, the birth rate (per 1000 people) since 1990 has decreased from 15.8 to 10-11 with an average republican value of 14.7. There currently only six posts that monitor atmospheric air. 10-20 points are required for the city, in accordance with regulatory requirements. Being one of the most beautiful cities in the country, Almaty remains one of the most environmentally disadvantaged. To improve the situation, "Rules for the protection of the plant fund of public use in Almaty," a program for the reconstruction and restoration of green spaces in the city, have developed [4].

3.2 *Threats to environmental safety*

Threats to Kazakhstan's environmental security environmental problems, depending on the importance and level of their solution, divided into global, national and local. Global environmental issues included climate change, the state of the ozone layer, and conservation of biodiversity, opus and land degradation. Kazakhstan ratified the UN Framework Convention on

Climate Change in 1995, for the implementation of which it is necessary to achieve stabilization of the concentration of greenhouse gases in the atmosphere at a level that does not allow dangerous anthropogenic impact on the natural climate system. In 1999, Kazakhstan signed the Kyoto Protocol to this Convention, according to which commitments have made to reduce greenhouse gas emissions, which opens up great prospects for our country to attract international investment. Over the next few decades, anthropogenic activity projected to determine the change in the state of the ozone layer, suppressing natural factors, including the impact of solar activity cycles. Observations since 1973 show that the thickness of the ozone layer over Kazakhstan has decreased by 5-7%. The control measures adopted under the Vienna Convention for the Protection of the Ozone Layer and the Montreal Protocol on Substances that Deplete the Ozone Layer have contributed to an 85 per cent reduction in the production of ozone-depleting substances from 1986 levels. Kazakhstan had ratified those instruments in 1998 and had begun implementing commitments to reduce the use of ozone-depleting substances and to remove them from circulation. One of the most important global environmental challenges is the conservation of biodiversity. The ecosystems of Kazakhstan distinguished by the uniqueness of biological diversity in the ecosystems of Central Asia and the continent as a whole. Under the influence of anthropogenic factors in Kazakhstan, the number of many species of animals began to decline and their habitat began to decrease [5].

The main areas of conservation of biological diversity:

- Assessment and inventory of objects of biological diversity at different levels of its structural organization (species, population, landscape and regional);
- Development of a network of specially protected natural areas and the maintenance of natural populations of rare species through their artificial reproduction;
- Restoration of biological diversity in disturbed areas, taking into account modern natural and anthropogenic-stimulated processes.

Desertification and land degradation are a serious problem. In Kazakhstan, significant areas (66% of the territory) are subject to desertification and degradation to varying degrees, which leads to the withdrawal of land from agricultural circulation [6]. This is due to extensive agriculture, pollution of mining areas, hydrocarbon transportation and processing areas, including oil products and radioactive compounds. To prevent these processes, it is necessary:

- Restoration of degraded land and soil fertility;
- Improving public administration of land use;
- Introduction of economic mechanisms for environmentally sustainable land management.

In addition to the listed global environmental problems, the Republic of Kazakhstan has identified national environmental problems. There are zones of environmental disaster (Aral and Semipalatinsk regions). In these zones, due to the unfavorable environmental situation, significant damage to the health of the population and the destruction of natural ecological systems, degradation of flora and fauna occurred.

The main directions of solving problems:

- Comprehensive analysis of the socio-economic and environmental conditions of the population in environmental disaster zones;
- Development of rehabilitation and rehabilitation measures taking into account the environmental assessment of the territories of the Aral Sea region and the Semipalatinsk region;
- The consequences of nuclear explosions and other factors on public health and the environment;
- Development of programmers for internal population migration and economic use of ecological disaster zones.

The widespread development of hydrocarbon resources by the Caspian Sea basin States increases the scale of negative impacts on marine and coastal ecosystems. In accordance with the State Development Program of the Kazakh sector of the Caspian Sea, special studies envisaged to determine the maximum possible level of oil production without damaging marine ecosystems, eliminate orphan wells and other historical pollution and take measures to

stop the burning of associated gas on flares. Work is currently under way at the international level to adopt the draft Framework Convention for the Protection of the Marine Environment of the Caspian Sea. The decision of the regional Strategy of Priority Actions adopted, which identified the main directions for the use of the resources of the Caspian Sea, and measures for the protection of the Caspian ecosystem. The environment also affects public health. It has found that many types of human diseases are associated with negative changes in the environment. However, the issues of determining the causal relationship of the incidence of the population with environmental factors remain insufficiently studied. In this regard, it is necessary to expand work in the field of medical ecology with medical assessment and monitoring of geographical studies in cities. One of the important issues is the impact of the military-space complex landfills. Currently, there are four military test sites and the Baikonur complex in the country. Fragments of rockets, spills of highly toxic fuel and other factors that have a negative impact on the environment pose a particular danger to the environment. In this regard, it is necessary to organize work on monitoring the environmental condition of landfill territories with the development of a set of measures to eliminate the consequences of their activities.

The solution of local environmental problems has an important role in the policy of Kazakhstan. These include:

- Pollution of the air basin (emissions from non-ferrous metallurgy, thermal power engineering, ferrous metallurgy, oil and gas complex);
- Depletion and pollution of water resources (heavy pollution by mining, metallurgical and chemical industries, urban utilities);
- Radioactive contamination (the presence of large uranium-bearing geological provinces, many small deposits and uranium mining, which lead to an increased level of natural radioactivity);
- Accumulation of industrial and domestic waste; natural and fabricated emergencies.

3.3 *Implementation of the concept of sustainable development in the Kazakhstan cities*

The concept of sustainable development on the international agenda emerged in the second half of the 20th century when environmental and societal problems have become an obvious obstacle stable economic development. Social and environmental problems - inequality, poverty, resource depletion, climate change - continued to worsen and began to affect not only the negative impact on the environment and society, but as a result, on economic development in the long term.

Sustainable development takes into account social and environmental factors and aims to achieve economic growth through social well-being and preservation of the environment. That is why the concept often presented in the form of trinity economy, society and nature.

All three aspects are equal and balanced. Environmental dimension addresses status issues environment, resource consumption, air pollution, water and energy use, etc. The social dimension concerns quality of life issues people and their well-being, economic – condition the economy, its opportunities and development.

At present, sustainable development is becoming increasingly relevant.

Kazakhstan's cities take necessary measures to achieve sustainable development based on economic, social and environmental interaction. The State, the financial sector and business are the driving forces of an economy that depends entirely on society and the environment. Society and the environment provide the necessary resources for the development of the economy, which turn into goods and services, private capital, waste and emissions. If resources entering the economy not properly regulated or adversely affected and depleted, the entire process of economic development jeopardized.

Environmentally oriented urban infrastructure should aim to preserve and restore the environment, reduce air pollution and greenhouse gas emissions, minimize and properly manage waste, take into account the development of the territory and preserve biodiversity. It is

resistant to the effects of climate change, for example, emergencies (fires, floods, etc.). Transport infrastructure development enables developing countries to become involved in international trade, and the growing share of rail transport increases transport energy efficiency and reduces emissions to the atmosphere.

Sustainable development is necessary to achieve the goals of the Development Strategy of Kazakhstan until 2030. The principle of sustainable development is also the basis of Kazakhstan's strategy to become one of the fifty most competitive countries in the world [7].

This Concept for the transition of the Republic of Kazakhstan to sustainable development for 2007-2024 defines the vision of principles, goals, objectives and basic mechanisms for achieving sustainability in all spheres of the country's life. To this end, it is necessary that the economic, environmental, social and political factors of development integrated and considered as a single process aimed at improving the quality of life of the population of Kazakhstan.

The Republic of Kazakhstan, as a full member of the world community, has undertaken to fulfil the objectives set out in Agenda 21 (Rio de Janeiro, 1992) and the declarations of the Millennium Summit (New York, 2000) and the World Summit on Sustainable Development (Johannesburg, 2002). Kazakhstan is a member and active participant of the UN Commission on Sustainable Development, the processes "Environment for Europe" and "Environment and Sustainable Development for Asia," the regional Eurasian network of the World Council of Entrepreneurs for Sustainable Development. The Development Strategy of Kazakhstan until 2030 has adopted. The Republic of Kazakhstan plays a special role in ensuring the ecological stability of the Eurasian continent. As a political, cultural and economic bridge between Europe and Asia, Kazakhstan performs a similar connecting function in the development of landscape and ecological systems on the continent. The size of the territory of Kazakhstan, the variety of climatic conditions, the peculiarities of the water balance of the region entail a significant dependence of the ecological situation throughout Eurasia on its stability in Kazakhstan. The goal of the Concept is to achieve a balance of economic, social, environmental and political aspects of the development of the Republic of Kazakhstan as the basis for improving the quality of life and ensuring the competitiveness of the country in the long term.

There is a significant gap in the economic and social situation of the regions of Kazakhstan. Problems remain in the demographic and health situation of the country's population, while there is still an insufficient level of its legal, economic and environmental literacy. Overcoming these barriers should be a major milestone in Kazakhstan's transition to sustainable development.

The main principles of the transition to sustainable development in the Republic of Kazakhstan are:

- The involvement of society as a whole in the achievement of sustainable development;
- creating a policy framework for sustainable development;
- Inter-agency integration, a systematic approach to state management, improving the efficiency of forecasting, planning and regulating key development indicators;
- Economic progress because of the active introduction of high technologies into the country's economy, improving the efficiency of resource use;
- ensuring the competitiveness of science and education;
- Improving the health of the population and demographic situation because of the introduction of the paradigm of a healthy society;
- Improving environmental protection;
- Territorial development based on a trans-regional ecosystem approach.

The priorities for the transition to sustainable development are:
The introduction of sustainable production and consumption patterns;

- The use of new and environmentally sound technologies;
- The development of sustainable transport systems;
- Energy efficiency and energy conservation;
- Regional sustainable development issues;
- Improving the social security of the population;
- Combating poverty from an environmental and gender perspective;

– Further development of science and education for sustainable development;
– Preservation of historical and cultural heritage;
– Prevention and reduction of environmental threats to public health;
– Combating desertification;
– Conservation of biological diversity;
– Reducing emissions, including greenhouse gases and ozone-depleting substances;
– Access to quality drinking water;
– Addressing transboundary environmental problems;
– Radiation and biochemical safety;
– Waste management;
– Formation of environmental status indicator systems;
– Environmental zoning;
– Development of solutions to local environmental problems;
– Creation of new resource-saving, low-waste, environmentally efficient technologies [8].

4 DISCUSSIONS

For the sustainable development of cities, projects in the field of urban planning aimed at:

1) Reconstruction of old residential areas;
2) Revitalization of former industrial sites by creating social infrastructure and residential and commercial real estate facilities on them;
3) Formation of architectural uniqueness of the city (including creation of symbolic structures);
4) Creation of recreational zones, including parks.

Specialized strategies:

1) Development of the tourism industry;
2) Attracting the headquarters of large corporations and developing business tourism [9].

Environmental initiatives can developed with the goals:

1) Environmental policy to improve the environmental situation in the city;
2) Regulation of enterprises from the environmental point of view;
3) Combining environmental and social policies (recreational areas for city residents and tourists).

The management of sustainable development of the modern city based on the following factors [10]:

1) In the field of technology;
   a) Replacement of non-renewable resources with renewable ones;
   b) Phasing out particularly environmentally hazardous technologies;
   c) Reuse of extracted substance and waste disposal;
2) In the demand structure:
   a) Shift towards reduction of material and energy intensity consumption of products;
   b) Development of services;
   c) Emphasis on the production of durable goods;

Abandoning expensive needs;

3) During production:
   a) Orientation to the production of biodegradable products;
   b) Shift towards reduction of material and energy intensity production;
   c) Production of products of improved quality;
   d) Reduction of the quantity of products produced;

4) In the field of production organization:
   a) Zoning of the territory;
   b) Increasing the diversity of natural and cultural landscapes;
   c) Deepening of specialization between regions.

Strategies for the sustainable development of modern agglomerations in Kazakhstan - is an objective process to better utilize the concentration of human, material and financial resources, as well as to obtain synergies from resource management not only territory as a spatial resource, but also production urban infrastructure, engineering and technical support networks, knowledge and technology.

Development of sustainable development strategies for Russian cities opens up new opportunities for rational and efficient use all types of resources, striking a balance of interests between social, environmental and economic factors of development, between the authorities, business and society. Potential targeted design of sustainable cities with a centrally oriented approach to agglomerations in directions corresponding to patterns of spatial development, deployment of productive forces in the territory of cities and their surroundings.

If we build logical relationships between agglomerations and cities, suburbs and other settlements, then we can to count in the medium term on synergistic and multiplicative effects in the country's economy [11].

Indicators and indicators of environmentally sustainable development in the regional context perform a number of functions:

1) Defining goals in the formulation of long-term and medium-term regional development strategies;
2) Forecasting the effect of sustainable environmental management policies;
3) Monitoring the achievement of goals and objectives and evaluation of results;
4) Evaluation of the effectiveness of programs, strategies;
5) Holding interregional comparisons;
6) Attracting investments and forming programs.

5 CONCLUSIONS

In this regard, the key challenges of sustainable urban development can identified. One of them is long-term planning of economic and production and economic activities. There is a need to develop a city-forming base with the creation of various places of employment. This is important for residents, since there are wide opportunities for choosing jobs. When determining the composition of production, one should take into account the stereotypes prevailing among the population. Use human resources in production and agriculture in accordance with their demographics and qualifications.

Another problem of forming an urban planning base related to the ecological safety of the habitat. It is necessary to introduce resource-saving, low-cost and waste-free technologies into all production. It is necessary to improve and build facilities for the treatment and disposal of solid and liquid waste.

Another problem is the rational development of the city's engineering life support infrastructures. The purpose of their development is to meet the needs of the population for resources such as clean water, electricity and other energy.

The systems of engineering infrastructure include transport. It is necessary constantly improve transport services for citizens by reconstructing the existing road network, improving the organization of urban traffic and communication with external transport.

Social policy recommended aimed at increasing the palette of cultural services. It is rational to expand the system of objects of culture, recreation and trade. Due to the need for religious and religious buildings to restore them and build new ones.

In cities, the problem of preserving landscapes is very acute. Land resources should use sparingly to prevent their degradation. It is optimal to combine the development of new

territories with the compaction of existing buildings. Consider that the expansion of cities, among other consequences, entails the problem of long-distance transport.

Sustainable and environmentally optimal urban habitat can created only with a rational combination of economic activities and environmental measures. Therefore, the strategy and tactics of maintaining and developing cities should base on the principles of an integrated approach to the space-planning organization of territories. Such an organization is the subject of urban planning. Therefore, urban planning inextricably linked with the organization of optimal habitat, environmentally friendly and necessarily stable over time.

Sound economic policies play a key role in the area of environmental security of States and sustainable urban development. Moreover, every State today faces environmental problems that it cannot solve alone. There is therefore a need to integrate the efforts of all countries. Sources of ecological disadvantage: accumulations of ash dumps, spontaneous landfills and the absence of citywide treatment facilities; poor condition of sewage networks and filtration fields located near cities; large volumes of dumps of mining enterprises; emissions of pollutants from numerous solid fuel boiler houses. Sustainable development is the ideology of Kazakhstan's development strategy. The future of Kazakhstan connected with unity, balance of all aspects of the development of society. Kazakhstan seen as a country that achieves sustainable urban development, economic growth, well-being, health and a favorable environment for all its citizens. The sustainable development of the country is a set of conditions, factors, tools that ensure the growth of social wealth, natural capital, cultural heritage and the standard of living of society. The countries of the world in the 21st century are in constant interaction, cooperation and competition with each other. In relation to the nature of the Earth, urban entities act as elements of the global environmental system. Due to population growth, globalization processes are increasing, and competition between countries of the world for spheres of influence and resources. Sustainable urban development inextricably linked to a country's competitiveness. The Republic of Kazakhstan plays a special role in ensuring the ecological stability of the Eurasian continent. As a political, cultural and economic bridge between Europe and Asia, Kazakhstan performs a similar connecting function for landscape and ecological systems on the continent. The size of the territory of Kazakhstan, the variety of climatic conditions, the peculiarities of the water balance of the region entail a significant dependence of the situation throughout Eurasia on environmental stability in Kazakhstan.

Development of residential architecture in Astana

O.N. Semenyuk & U.D. Dyisebayev
Gumilyov Eurasian National University, Kazakhstan

ABSTRACT: New socio-economic conditions of Kazakhstan in recent years, as well as increased requirements for the most efficient use of the territory of Astana and the cities of Northern Kazakhstan, have led to new design directions, where intensive construction of a large number of new residential buildings has begun. A prestigious home appeared in terms of comfort and location. The capital city develops in its own way, different from other cities of the country. Construction trends and characteristic architectural and typological features of residential buildings of the last decade considered on the example of Astana architecture. In the urban environment, the formation of a new aesthetics of residential buildings traced. Improving the quality level became possible due to competition in the housing construction market, with the beginning of the modernization of industrial technologies and the use of new building materials. Under these conditions, the typology changes. The changes affect both the functional and planning structure of the dwelling and the appearance of residential buildings. Identification and analysis of the process of changing the economic, typological, functional and artistic content of the dwelling allows us to draw certain conclusions and predict further trends in its evolution.

1 INTRODUCTION

The construction of residential buildings is one of the complex problems of architecture, synthesizing the achievements of construction art, modern technology and architectural craftsmanship. The compositional significance of such buildings in the development of the city determines the high requirements for their architecture. It is residential buildings that are designed to create the individual face of the city's districts, to be the most expressive.

The analysis of architectural compositions of residential buildings and their conditioning on functional, hygienic, economic and technical requirements is of practical interest, despite the relatively small amount of their construction.

Leading experts in modern architecture consider residential development as the main task of modern urban planning. With their works and project proposals, they proved that economic and demographic conditions and changes in the way of life of people lead to the emergence of such problems of a large city that cannot solved without the development of residential development.

The modern architectural practice of housing design and construction represents a great variety - this is associated with the formation of a typology in the aspect of time. The process of improving the home in accordance with changing needs is noted. Currently, in Astana, commercial residential buildings for citizens with medium and high-income levels of the sectional type of medium and variable storeys are the most common, while, for the most part, these houses are single piece objects, and individual houses of the cottage type are also common.

The previously developed typology of residential buildings, unified for the whole country, with the nomenclature of apartments intended for an average consumer, in modern conditions does not meet the requirements of the emerging new socio-economic structure of the urban population and does not always correspond to the multivariability of the lifestyle of specific

DOI: 10.1201/9781003299127-297

families. The recommendations of outdated norms and rules do not fully comply with the requirements for modern housing by various categories of the population.

Currently, there are not enough scientific studies analyzing all the factors that collectively affect the formation of housing in the city. A comprehensive study of space planning and composition features and development trends of residential buildings in Astana and North Kazakhstan not carried out. All this, along with the constantly changing requirements of people for the comfort of living, testifies to the relevance of the topic of this study and the need for a theoretical solution to the problem.

2 HISTORY OF URBAN DEVELOPMENT

History of North Kazakhstan's urban development in XX century's 50-60-s have especial importance. The development of virgin lands and strong growth of productive forces between 1954 -1964 in the north regions of Kazakhstan served as a powerful stimulus for the development of the city. Sharply rising of agricultural production in the region was issues of industrial, social and cultural development of the city with particular urgency. Only in the first three years of development of virgin lands between 1954 -1957 made Akmola actively building and developing city. Despite the presence of newly build large buildings, in the beginning of 1950, overwhelming majority of town remained single-story, mainly with wooden and adobe houses. Progress of construction volumes during this period led to the transition to standard projects and a series of residential buildings. One of beginning projects in the republic was residential buildings of the series 207. Town's in 1954 planning terms completely preserved the existing quarterly building and consisted of the city itself and the settlement village, which developed along the railway in the north-west direction. Streets, thoroughfares, squares, which exceeded regulatory requirements by more than 3 times, occupied the predominant part of urban areas (41.3%). Wide streets (40 m.) In the city formed tiny quarters of 0.6 to 2 m.

Construction of housing did not satisfied at all demands of growing urban population. According housing department of the city council's information, whereas needed rate of living area at a rate of nine square meters per city dweller the town has only approximately 3.6 square meters per city dweller. The existing housing stock of the city had a large percentage of depreciation, in the first place were housing municipal public utilities. Statistics represents that 88,000 square meters the living area of the city worn out by 20-40%, 71,000 square meters by 40-60%, 73,000 square meters by 60%. Repairing the housing of the municipal fund was broke systematically from year to year. For example, in 1957 only two houses repaired in the whole city. The Almaty «Gorselstroyproektom» developed first master plan of the city in 1957. Reflecting the building principles of the time, the plan considered formation of a residential area of the city from quarters of 6-10 hectares. In addition, there were trend of growth from one to five storied buildings with the corresponding zoning of the territory by the number of storied in the buildings. It was also planned distinguish a zone of individual building. Town's development and construction under this master plan were until 1961-1962. At this time, there were build 2, 3 and 4 storied buildings in Monina street, half of Mira street and numerous quarters in the eastern part of the city.

By order of the Kazakh Railways Administration, the contractor, construction management in the construction of the Stalin-Magnitogorsk highway, built completed architectural ensemble on Monina Street and a complex of large-panel houses along Mira Street. Rapid growth of urban construction, both in quantitative and in qualitative parameters, occurs in the early 60-ies, about which the witness the following figures. If the input of living space in 1959 was 23 thousand square meters, in 1961 it increased to 62 thousand square meters. In late 1950s, which had about 57 thousand square meters, more than half of the built-up public housing stock were low-rise houses that have poor house-improvements like courtyard. Since 1961, all of housing stock, which gets into exploitation, consists of 4-5-storeyed large-panel and stone houses, in which all the elements of apartment improvements as courtyard were present. Only in one 1962 were built about 200 residential houses and commissioned in the city.

Despite the well develop housing construction; it was not easy to solve the housing problem. In 1962, repairs needed around 70% of the city's residential area consisted of old dilapidated houses. The commission period of objects into exploitation were annually broken. Construction works extremely disorganized, existing mechanisms are often idle, and the quality of work was poor, observed gross violations of technical conditions.

In the construction of the existing part of the town, there were problems. For the reason that mass housing construction carried out by typical 4-5story houses, were created type of different-story buildings, which was difficult to improve with the methods of volumetric-spatial composition. Moreover, the construction of the territory carried out without the presence of project with detailed planning (PDP). The construction carried out according to the projects developed for individual quarters, parts of quarters, and sometimes made the binding of single residential objects to already existing arrays. The planning and composition organization of the building and cultural-consumer services of the population did not correspond to the present achievements of urban planning. Developed in 1953 – 1957 years Akmola's master plan did not meet the prospects of development of the city as the administrative center of Tselinograd region, according to several parameters:

- Forecasts on the population for 1965-1975;
- Changes in the provision of residential area of citizens;
- The location in the city of a number of large administrative and public buildings, which were to become priority, objects of construction;
- Not matching the economy of the current stage of urban development with more than half of the housing stock: 57% were low-rise buildings, 4-story houses – 43%, 2-3-story –31%, single-story – 26%.

Single-story buildings were 52% of the total volume of urban housing commissioned in 1957 – 1960. The desire for "light square meters" led to an irrational expansion of the urban area, an increase in the scope of works for improvement, the extension of communications of engineering equipment, a rise in the cost of housing construction. However, it did not take into account that the cost of one square meter of area in a 4-storey house is 9–10% less than in a one-story house. Akmola Regional Committee subsequently adopted a decision to ban in a single-story building along the state building and transition to a massive 3-4-story building construction based on cooperation means developers.

Starting 1960 until 1980 in the residential part of the Tselinograd based on the availability of living space per one person determined: 1965 –7 sq. m., 1970 9 sq. m., 1980 – 15 square meters. m. New housing construction for the period from 1962 to 1980. Was 5140 thousand square meters. Including in 1962–1965. – 560 thousand square meters. m., in the years 1965–1970. – 1180 thousand square meters, in the 1970–1980's. – 3400 thousand square meters.

The abolition of the Tselinograd region in 1964 and the decline in the status of the city of Tselinograd to the regional administrative center and, as a consequence, the reduction of budget funding, could not affect the city development plans and the volume of construction work. At the same time, the city continued to grow quite dynamically, consistently and systematically improving and developing its planning structure and architectural appearance of the building.

The construction of the city was conducted mainly 4–5 story houses, mainly with the construction of large-panel construction. The houses planned taking into account the best orientation on the sides of the world, in relation to the prevailing winds, taking into account the terrain and the features of the relief. House united in residential groups, made closed courtyard spaces to neutralize constantly blowing winds. Residential houses of a tower type, 9-story houses, as high-storied the buildings, were located in different parts of the districts, on sites with good prospects. They were supposed to bring excitement and flavor to the building [1].

The architecture of residential complexes and individual residential houses of recent years favorably differs from previously erected by professional elaboration and imagery of architectural solutions. Sharply increased the number of stories of residential development. The first five-story houses appeared in the city in 1960, nine-story houses - in 1970, twelve-story - in 1980. By percentage of total number of buildings on 1.01.1989 in the city was 9–12 floors – 4%; 5 floors – 53%; 2 floors –14.5% and one floor – 28.5% [2].

Housing construction 70-80 is different from housing construction in early 1960 with a higher professional study of design solutions, improved layout of apartments and some imaginative expressiveness of the buildings. Changing and silhouette characteristics of the city.

In 1960, the first five-story houses appeared in the city, which occurs the leveling of the building at this level. In the 1970–1980ies built 9-12-story houses, used to highlight urban sites as high-rise dominants [3].

In 1970, the first 9-storey residential building commissioned at the intersection of Monina and Mira streets, according to the typical project 1-447s-41. The dwelling house consisted of one section and had 36 apartments with a total area of 1374 sq. m. The next multi-story residential building commissioned in 1973. Further multi-story housing built every year, therefore the volume of housing construction of small and medium-storied buildings started decrease.

In the 1970s, similar multi-story residential buildings with inexpressive architecture built, but already at this time, architects began to build in and attach various kinds of people serving the population. In those years, it dominated by the type series 9-storey residential buildings 1p-447s-25m. In total, the 70-ies of nine 9-storey residential buildings built.

In the early 1980s built a complex of apartment buildings, located on both sides of the avenue consisted of two pairs of 12-storey and 9-storey single-section residential homes on an individual project. At that time, the complex was differed from the same type of urban development, as the number of floors, and architecture. At mid-1980s put into operation similar houses on the "students" avenue (today Al Farabi Avenue) in the monument district, dedicated to the victims in Afghanistan. It should note that the 80-ies multi-story housing construction is gaining momentum. Fifty-one multi-story apartment house built in the years, mostly 9-storey, in some cases 10-12-storey building. The prevailing model series were 86 and 83 series [4].

3 DEVELOPMENT OF MODERN ARCHITECTURE

With Kazakhstan's independence in 1991, marked the construction of multi-story housing slump, it lasted until the transfer of the capital in 1997 from Almaty to Astana. As a result, there have been dramatic changes in the development of high-rise housing in Astana. The city begins to develop as a capital. Mainly being build individual multi-story residential buildings, the first of them are two 26-storey residential buildings along Bogembai Prospekt, and the people called buildings - "Candles".

In 2000–2001, the development of the planning structure has defined and development of the city in accordance with the General Plan developed by a group of "Saudi Bin Laden" and approved by the Government. The program of this stage included the beginning of work on the formation of a new planning structure of the city, the active demolition of existing dilapidated buildings and the construction of new facilities in their place, corresponding to the metropolitan standards and requirements. Along with domestic construction companies and organizations in the construction of Astana, foreign construction companies began to take an ever more active part.

Significant contribution to the development of Astana, in the formation of its architectural appearance of the building made of Switzerland, Great Britain, the Czech Republic, Turkey and Other De countries. From the beginning Kazakhstan independent, the construction of the new capital of Kazakhstan were active participation of Turkish construction firms: for example, the Turkish construction company «Ahsel Ins. Investment "on-site wetland at the beginning of Republic Avenue in 1999 built a new residential district" Samal "on the 718 apartments.

In order to create a favorable investment climate and attract funds from domestic and foreign companies, in January 2002, the President of the country signed a decree "On Introduction of the Regulations of the Free Economic Zone -" Astana - New City ". As a result, the number of domestic and foreign companies that want to invest in the construction of the new capital of Kazakhstan has sharply increased and take an active part in the construction of modern residential complexes, facilities for maintenance, trade and entertainment. Almost all the construction in Astana, with the exception of social and city facilities, as well as the transport and engineering infrastructure of the city, began financed by private investors. In this regard, it

should be noted these domestic and international investors, property developers, as "Basis-A", "Kuat", "of Bi GROUP», «HIGHVILL», « Ceylan", "Sembol","Okan" and "Axel" that investing considerable funds for the construction of ultra-modern residential complexes and unique buildings and structures, made a great contribution to the formation of an expressive architectural appearance of the new capital of Kazakhstan. However, the President set the task to the designers and builders not just to build a typical, a beautiful city, but the city corresponding to the level of achievements of modern architectural and town-planning ideas, the city XXI century. To the architectural appearance of Astana meet the following requirements - model city XXI century, it was necessary to raise sharply the level of the art-planning solutions to the level of creative search for new directions in the development of architecture. To this end, the outstanding architects of the present began to be involved in the design of the most significant facilities built in Astana on the instructions of the President of the Republic of Kazakhstan. The then President of the International Union of Architects Vasilisa Sgutasa and president of the International Academy of Architecture Georgi Stoilov exerted all possible assistance to the city akimat. Due to their help, a number of world-famous architects took part in international competitions for the development of projects of the most significant facilities in Astana. It has become the practice of the system construction of large projects with urban importance in shaping the architectural appearance of the main streets and squares, only for projects selected in the competition [5].

With the approval of the Government of the Republic of Kazakhstan Astana Master Plan, developed by the research group led by Dr. K. Kurokawa, with the official presentation of the new General Plan as a project embodying the philosophy and theory of urban development postulates XXI century, large-scale work on their active implementation, the formation of a new planning structure and architectural appearance of the city. The main part of construction work was moved to the left side of river Yesil.

In 2004, the Corporation "Basis-A" has commissioned houses "Nurly -Dala" and "Zhan Saya." At the same time, large-scale works developed to reconstruct the old part of the city.

In 2001, commissioned 231 thousand square meters. Meters of housing, and in 2005 – 1 million 67 thousand square meters. The capital housing stock of the capital increased from 4 million 768 thousand square meters in 2000 to 7 million 204 thousand square meters in 2005. In the old part of large-scale demolition of dilapidated housing and construction of modern residential complexes started in the areas of Soldier and Cossack suburb, Central Market, Valikhanov, Potanin Tlendiev and others streets. They began actively build up high-rise residential complexes areas south of the Water-Green Boulevard. Within the framework of the state program "Affordable housing" designed by architects, "Astanagenplan" project organization turned the construction of urban complexes.

In 2006, the corporation "Basis-A" has started construction of a super contemporary multi-functional residential complexes of the original architecture "Emerald Quarter", "Northern Lights" and "Triumph of Astana".

In 2006–2007, there were incompatibility on real of population growth rates and predictions, which led new conditions and opportunities created by the dynamics of the country's economic and social progress. Situation in the city put before the architects and city planners of the capital a number of problematic tasks related to the adjustment of the current master plan and beyond with the corresponding changes in the urban development policy of the city development. Taking into account the analysis of the results of town-planning activities for of the Master Plan, bans made to unreasonably high-density of buildings in of the old part of the city. Due to the growing number of citizens made mandatory as part of the residential complexes and parking buildings including parking at the rate of not less than one parking space per apartment. Also were established strict requirements for compliance with the regulatory density of buildings and insolation of residential apartments and territories.

In order to create conditions that would make buildings mutual and holistic as complex, it was decided to move from the method of "dotted" development of local plots to the method of integrated development of the block or its most part by one investor-developer. An example of such an integrated apartment complexes, "HighVill" and "Grand Astana", erected with all the objects of social and cultural-leisure purpose, necessary for serving the inhabitants of the microdistrict. In 2007, "Astana genplan" in conjunction with the "Kazgor" based on the

study and understanding of international experience developed updated standards of urban planning, designed for the conditions of Astana. In the future, an adjustment of the Master Plan of Astana using urban-regulating documents will carried out only based on these standards, relevant international standards and local conditions.

For the consideration of projects of large objects and the most individual problems, and to develop the most effective strategy was established by President of Kazakhstan urban development of Astana in 2007. The Council, along with well-known architects of Kazakhstan involves the most respected masters of world architecture. All these measures, approaches and principles were the basis for urban development policies pursued by the akimat of the city and the Department of Architecture at the new stage of development of the capital. However, not only the organizational and technical measures and activities influenced architectural appearance of the buildings in this period.

Middle and late of 2010's of XXI century, characterized by the appearance of new factors that raise the architectural appearance of the capital to a new level. Such factor was the active participation of architects around the world to design unique objects of Astana. Currently, the various stages of implementation are objects constructed in a project of outstanding masters of world architecture. Momyshuly prospect were construction it high-rise modern apartment complex. New residential areas with original architecture grows in the southern and western parts of the city.

4 CONCLUSIONS

Capital of Kazakhstan strongly and greatly growing upwards and outwards, causing widespread astonishment and delight. So on based of close cooperation and competition of Kazakh architects with bests of world architecture, powerful innovation, making the necessary adjustments and changes to the adopted programs and plans of construction the Astana – became city of the future, the city of XXI century.

Regional features influence the architecture of residential buildings in the city of Astana and the cities of Northern Kazakhstan: natural and climatic, socio-economic, national, architectural and artistic factors. Recently, much attention has been paid to energy saving and environmental qualities of individual residential buildings.

Housing is an important part of the architectural environment of the city, which reflects the structure of the structure of society, culture and social ties. The global changes of recent decades that have taken place in Kazakhstan require a serious revision of the concept of the formation of an urban, in particular, residential environment.

The option to solve the design problem lies in the field of environmental design of residential buildings. This approach can be justified based on regional features: climatic conditions, local construction conditions and increased use of local materials with a long life. Taking into account all modern trends, a new regional quality should developed based on this principle. Only taking into account regional differences can a cost-effective, individual nature of a residential structure created.

Vibration characteristics of lightweight embankments converted from bridges on soft ground using polyurethane filling

A. Koyama, D. Suetsugu & Y. Fukubayashi
University of Miyazaki, Miyazaki, Japan

ABSTRACT: A method of filling the lower space of a bridge with rigid polyurethane foam (RPU foam) to reduce the traffic load along with seismic reinforcement is often applied to extend the life of bridges in Japan. The purpose of this study was to evaluate the reinforcement effect and change in the vibration characteristics of a bridge that was converted into a lightweight embankment using RPU foam filling. A truck was driven before and after filling an actual bridge with RPU foam and monitored the embankment behavior. RPU foam was observed to reduce the vibration and strain of the slab at the center of the span. The predominant frequency inside the RPU foam when a traffic load was applied was approximately 5 Hz, and long-period vibration was confirmed compared to the slab.

1 INTRODUCTION

The maintenance and management of aging bridges has become a worldwide problem in recent years. In Japan, to extend the life of bridges and prevent them from falling, a rare method of filling lightweight embankment materials such as rigid polyurethane foam (RPU foam) and air mortar in the space under the bridge girders is adopted. In this case, as inspecting a bridge is impossible, it is maintained as a lightweight embankment. There is no need for traffic control when compared with seismic reinforcement and the replacement of bridge members. However, the reinforcing effect of bridge members and changes in earthquake resistance owing to the filling of lightweight materials have not been investigated. Among the lightweight materials used in existing construction cases, RPU foam was selected in this study. This is because RPU foam is extremely lightweight (approximately $1/50^{th}$ of the soil weight), and after filling under the girder, it yields a top-heavy structure. Polyurethane foam is a polymer material that is foamable, lightweight, and waterproof (Buzzi et al. 2008). A lightweight embankment method using RPU foam has been independently developed for approximately 30 years in Japan (Koyama et al. 2022). However, in recent years, many unpredictable earthquakes have occurred, including long-period ground and direct earthquake motions. As top-heavy structures are susceptible to long periodic oscillations, it is necessary to elucidate the vibration characteristics of a composite lightweight embankment consisting of bridges and RPU foam. To reduce the earth pressure on the back of the abutment and underground structures, an expanded polystyrene (EPS) geofoam polymer material is installed in the ground (Bartlett et al. 2015). However, the target structure used in this study has bridge members buried in lightweight materials, and the structure itself is very different from that of the previous study.

In this study, to elucidate the structural performance and vibration characteristics of lightweight embankments converted from bridges, trucks were driven before and after filling the

DOI: 10.1201/9781003299127-298

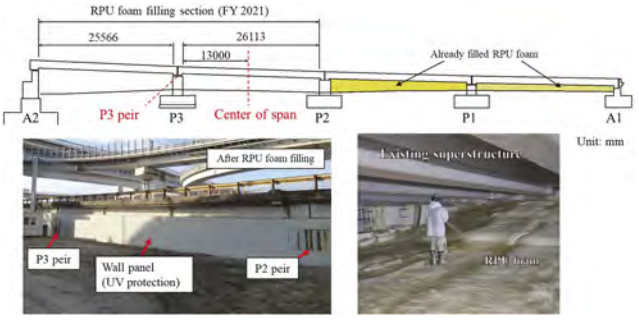

Figure 1. Monitoring target bridges and RPU foam filling process.

bridge on soft ground with RPU foam, and each member was monitored. The load and acceleration generated by slabs, piers, and RPU foam were measured, and the load and vibration reduction effects of the RPU foam were examined.

2 OVERVIEW OF TARGET BRIDGES AND MONITORING METHOD

The bridge to be monitored was an elevated expressway. Figure 1 shows a cross-sectional view of the bridge and the RPU foam filling process. The subdermal space between piers A2 and P2 was filled with RPU foam and reinforced in 2021. We monitored the bridge before and after filling the RPU foam in the section from A2 abutment to P2 pier. Measuring instruments were installed in the center of the span in the section between piers P2 and P3 and near pier P3. This study reports the measurement results at the center of the span. To satisfy the seismic performance of this bridge during a large-scale earthquake, it was necessary to add collapse-prevention devices and seismic reinforcement to large-scale piers. Furthermore, because the foundation ground was soft with a layer thickness of approximately 40 m (N = 4), there was a concern regarding high construction costs. Therefore, despite the reduction in the bearing capacity of the bridge due to disasters or deterioration over time, the substructure was filled with RPU foam to ensure that it could be restored while maintaining traffic capacity. Two-component RPU foam was used in this study. This RPU foam was used in an actual lightweight embankment with a weight of 0.35 kN/m^3. It is assumed that the structural functions of the bridge will be utilized until the superstructure and bearing functions of the existing bridge are lost. Finally, the deadweight is supported only by RPU foam.

Figure 2 shows the installation position of the instrument. The bridge has two lanes on each side, and the driving lane of the down line was monitored. An earth pressure gauge, accelerometer, and strain gauge were installed in series below the slab. To measure the compressive stress at the center of the RPU foam, a steel plate was fixed to the scaffolding at the bottom, and the earth pressure gauge Pu1 was attached to it. The accelerometer Au1 was embedded inside the RPU foam 300 mm above the scaffold. The heat-insulating property of the RPU foam was confirmed using a thermocouple, but the results are omitted in this paper. A 10t truck loaded with iron plates (23.8t in total) was used as the monitoring vehicle. At a speed of 80 km/h, the tire on the right side of the truck passed directly above the instrument. A low-pass filter of 150 Hz was applied for data sampling, and the frequency was set to 1000 Hz.

3 MONITORING RESULTS AND DISCUSSION

This section describes the changes over time of each instrument and the results of the spectral analysis of the acceleration waveform. The change in the sampling data over time is obtained by extracting the data for 5 s before and after the rear wheel of the truck passes through the center of the span, and the running data of the 5th week is shown as a representative.

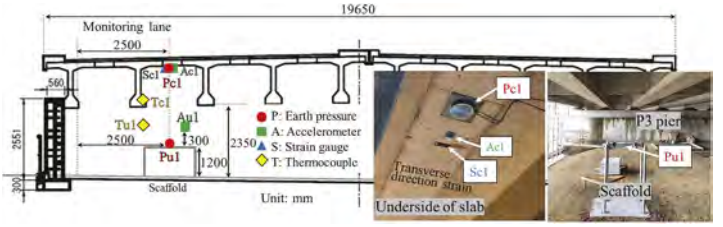

Figure 2. Instrument installation position.

3.1 *Behavior of strain and earth pressure*

Figure 3 shows the changes over time in each strain gauge and earth pressure gauge. From the behavior of the strain gauge in Figure 3 (a), the strain decreased in Sc1 after RPU foam filling. In particular, the strain when the rear wheels passed through the gauge, was reduced by 35%. In addition, Sb1 installed on the slab directly above P3 pier had no change in the strain behavior regardless of the presence or absence of RPU foam because the bearings supported the superstructure. Figure 3 (b) shows the results of the earth pressure gauge. In this study, the earth pressure before running the truck was set to the initial value (zero). It was installed such that a positive value could be obtained when a compressive force acted on the earth pressure gauge. Because an earth pressure of up to 1.2 kPa is generated in Pc1 in the center of the span, the RPU foam supports the superstructure and suppresses deflection. A positive earth pressure of 0.15 kPa was generated in Pu1 when the front wheels passed through Sc1, after which a slight but temporary negative earth pressure was generated when the rear wheels passed through Sc1 and Sb1. Based on this behavior, it is considered that the RPU foam was compressed by the load of the truck in the center of the span, and then deformed to repel when it was unloaded. Moreover, the value of Pu1 was much smaller than that of Pc1, and the load was supported near the surface layer of the RPU foam.

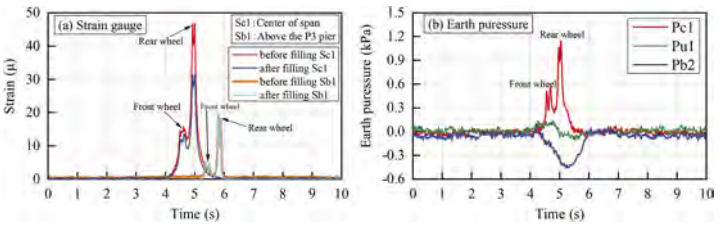

Figure 3. Variation of strain and earth pressure with time.

3.2 *Acceleration waveform and spectrum analysis*

Figure 4 (a) shows the time course of accelerometer Ac1 on the slab in the central part of the span. The accelerometer was installed such that its output were positive and negative values in the vertically upward and downward directions, respectively. The figure shows the time required for a truck to pass through each strain gauge. The positive acceleration shows the maximum value regardless of the presence or absence of RPU foam when the rear wheels pass through Sc1. In addition, the acceleration of Ac1 was reduced to approximately half by the RPU foam in 4 to 6 s, as shown in Figure 4 (a). It is considered that the deflection of the superstructure was reduced and the vibration was suppressed. Figure 4 (b) shows the behavior of Au1 embedded inside the RPU foam. A long-period acceleration waveform was confirmed for Au1. Figure 5 shows the Fourier amplitude spectrum of the acceleration waveform shown in Figure 4, which was subjected to waveform processing by FFT transformation. For Ac1 in Figure 5 (a), multiple dominant frequencies were confirmed between 4 and 35 Hz before filling. After RPU foam filling, the amplitude was particularly reduced to below 5 Hz from–15–20 Hz. The frequency at which the amplitude is the highest before filling is 16.5 Hz, but after filling, it decreases slightly to 14.6 Hz. It is assumed that the flexibility of the RPU foam affects the frequency. In Au1, as shown in Figure 8(b), the components of low-frequency

waves of 1–6 Hz are more prominent than those of Ac1 after filling. These results indicate that the natural frequency of the RPU foam dominates the embankment behavior for vibrations in which long-period components are pre dominates.

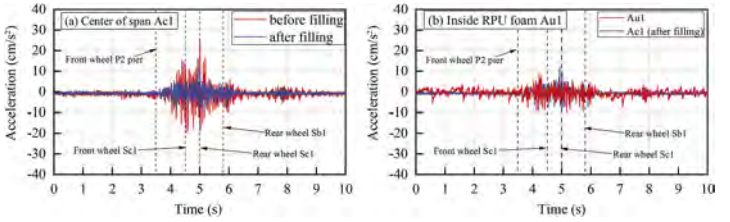

Figure 4. Acceleration waveforms of the slab and inside RPU foam in the center of the span.

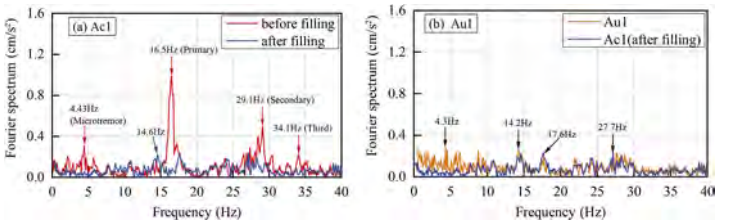

Figure 5. Fourier spectra of Ac1 and Au1.

4 CONCLUSION

The key findings of the present study can be summarized as follows:

1) After filling of RPU foam, the deflection of the slab at the center of the span decreased. However, because the supporting function of the bearing was maintained, the deflection near the bearing did not change regardless of the presence or absence of the RPU foam.
2) The acceleration of the slab after RPU foam filling decreased by approximately half compared with that before filling.
3) Multiple predominant frequencies of the slab were observed at frequencies of 10 Hz and higher. The predominant frequency at the maximum amplitude of the slab decreased slightly because the space under the girder was filled with flexible material. By contrast, low frequencies of 1–6 Hz were predominant inside the RPU foam.

In a future study, we will analyze the monitoring results using FEM analysis and investigate the behavior of the embankment during earthquakes with respect to long-period ground motion.

ABSTRACT: During the 2016 Kumamoto earthquake, which caused two seismic intensities of seven for two days, numerous severely damaged infrastructures were constructed in the vicinity of active faults. Most of these structures have now been reconstructed and are currently in service. In such areas, it is necessary to consider the minimization of the damage as much as possible in the event of future seismic motion or ground surface displacement. In addition, if the deformed structure can avoid collapse, it is necessary to evaluate its integrity for its use. In this study, surveys were conducted on two types of structures: a steel strip reinforced soil wall and an expanded polystyrene lightweight embankment located near active faults that was damaged during the Kumamoto earthquake. The methods were used to evaluate the integrity of the structures and the policies and methods of reconstruction.

1 INTRODUCTION

In April 2016, two severe earthquakes occurred in two days, M6.5 and M7.3, with seismic intensities of seven, centered in Kumamoto. The earthquakes caused extensive damage to numerous soil structures in a wide area of Kumamoto Prefecture. The structures near the active faults were subjected to earthquake motion and ground displacement. This study investigated the methods of integrity evaluation and restoration for two types of soil structures: a steel strip reinforced soil wall and an EDO-EPS (by EPS Development Organization, hereinafter referred to as EPS) lightweight embankment located near active faults damaged during the Kumamoto earthquake, as shown in Figure 1.

2 DAMAGE AND RESTORATION OF REINFORCED SOIL WALL

2.1 *Damage of a reinforced soil wall immediately after the earthquake*

The partially collapsed reinforced soil wall with steel strip reinforcements was constructed along the Nigori River on Prefectural Road No. 149, and numerous earthquake-induced damages and

DOI: 10.1201/9781003299127-299

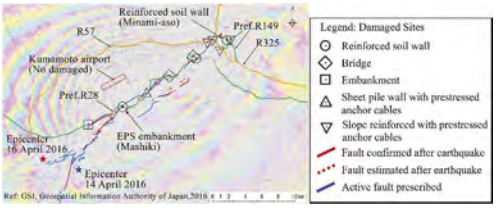

Figure 1. Damaged structures along the active fault shown on an InSAR analyzed map by Geospatial Information Authority of Japan.

ground deformations occurred around the site. As shown in Figure 2, the reinforced soil wall had a mixture of collapsed and remaining sections within the same wall alignment. The characteristics of the wall are as follows: (i) River flows in front of the wall, and gravity concrete trestles are used as the foundation. (ii) The plane alignment of the wall is a folded line and the collapsed wall is at the protraction zone. (iii) The section of the collapsed zone had two overburden layers, whereas the remaining area had one overburden layer. (iv) The adjacent wall of the completely collapsed wall retained an unstable self-supporting condition. Although approximately 20 years have passed since construction, no significant deterioration was observed in the reinforcements and facings.

Figure 2. Condition of remaining and collapsed reinforced soil wall and plane alignment of wall.

2.2 *Evaluation of integrity by close visual inspection*

The visual inspection points of the reinforced soil walls include the road pavement condition, embankment deformation above the wall, wall-facing deformation, embankment material leakage between wall-facings, and foundation ground stability. After close visual inspection of the reinforced soil wall, an emergency damage assessment was performed to evaluate the current condition on a 6-level risk scale. The collapsed and severely deformed sections of the reinforced soil wall in this study correspond to the VI level of damage. However, the remaining sections correspond to sections I (no damage) to II (partial damage). Therefore, it is necessary to verify the difference in the condition of the remaining sections compared to the collapsed and severely deformed sections and to evaluate the integrity of the remaining sections before putting them into service in the future.

2.3 *In situ pull-out test with core extraction*

It is difficult to ascertain the internal conditions of the reinforced soil wall. However, it is possible to confirm the internal stability of the wall by pulling out the reinforcement directly through the concrete facing a drilled hole that is in turn facing the remaining wall, as shown in Photo 2. Because the original design documents could not be found from the field pull-out tests of the two sites, structural stability calculations were performed based on the site conditions to estimate the density and length of the installed reinforcement. The results of the pull-out resisting force at the first site were 60 kN at the site (>54 kN at the design site), and at the second site, 45 kN at the site (>33 kN at the design site) confirmed that the pull-out resistances were greater than the assumed design pull-out load. From the in situ pull-out tests, the steel-strip-reinforced soil wall was confirmed to be internally stable.

2.4 *Measuring wall displacement with a laser rangefinder*

Because each wall facing the reinforcement is stacked without rigid connections, reinforced soil walls are flexible and allow a certain degree of deformation. The degree of deformation was within 3% of the wall height and 30 cm between the top and foot of the wall. To confirm the wall condition, the displacement of the wall was measured using a laser rangefinder.

Figure 3. In situ pull-out test and displacement measurement of wall facings by laser rangefinder.

The measurement locations and results are shown in Figure 3. The maximum difference between the displacement and area near the foundation occurred at a medium wall height and reached more than 3% of the wall height. The integrity of the large deformation area was not secured, and the wall was removed and reconstructed.

2.5 *Status of restoration and future issues*

The reconstructed section, compared with the collapsed and remaining sections, and the completion of the wall are shown in Figure 4. The collapsed section was removed, and the large deformed section was reconstructed by removing staircase-like wall material. In this study, the existence of a fracture zone was revealed by a γ-ray survey (Sahara, K., et al., 2019). Future issues include how to conduct a collapse investigation at the time of planning and how to utilize the results for restoration design.

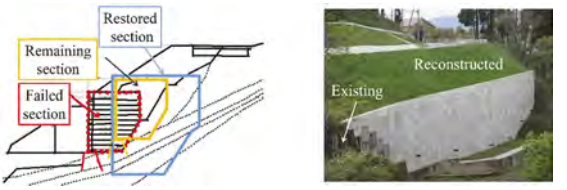

Figure 4. Comparison of sections between collapsed, remained, and reconstruction as a photo.

3 DAMAGE AND RESTORATION OF EPS EMBANKMENT

3.1 *Damage of EPS embankment immediately after the earthquake*

The damaged EPS embankment on the prefectural road along the Kumamoto Takamori line was located directly above an active fault (Futagawa-Hinaku fault zone), as shown in Figure 5 (Taneichi, K., et al., 2018). As shown in the figures, the road surface had an 80 cm wide crack, a 50 cm differential settlement, and a 30 cm horizontal displacement. In addition, the foundation of the EPS embankment subsided locally by approximately 90 cm, and the wall-facings in the heavily subsided section fell off.

An 18 m wide surface slide occurred on the slope just behind the damaged EPS embankment.

Figure 5. Damage of EPS embankment affected by active fault.

3.2 *Methods of reconstruction*

The EPS embankment and the slope behind it collapsed owing to the earthquake and subsequent heavy rainfall. Therefore, countermeasures were taken for the surrounding areas, including the EPS embankments. The slope above the ground anchors was protected by surface protection. The collapsed lightweight embankment was designed in accordance with the "EDO-EPS Method of Design and Construction Standards (Draft)". The EPS embankment had $H/B = 0.76 \leq 0.8$ and $H = 5.8$ m ≤ 6 m. Generally, seismic design can be omitted for embankments; however, because this line has already been severely damaged by an earthquake, seismic design was applied. Based on the ground investigation, stability was examined using the standard value of the design horizontal seismic coefficient for ground type III ($k_{h0} = 0.15$) and the design horizontal seismic coefficient ($k_h = 0.13$) based on the regional correction factor $C_Z = 0.85$.

The stability did not satisfy the bearing capacity under normal conditions and stability against sliding under seismic conditions. Therefore, root piles were used as the foundation to satisfy the bearing capacity under normal conditions, and horizontal force deterrents due to nailings were used to integrate the upper slab with the background to prevent sliding during the earthquakes. Figure 6 shows the designed cross section and front view of the reconstructed EPS embankment.

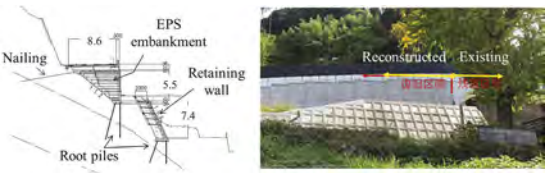

Figure 6. Designed cross section and front view of restoration of EPS embankment.

4 CONCLUSION

This paper introduced a case study on the restoration of two heavily damaged soil structures located near the active faults caused by the Kumamoto earthquake. The integrity of the reinforced soil wall was evaluated based on on-site tests for the remaining wall, and the wall was reconstructed using a seismic design. A new seismic design was applied to an EPS lightweight embankment. It is necessary to verify the earthquake resistance of structures that have been improved and reconstructed when they are subjected to seismic ground motion and ground displacement. Furthermore, we believe that the analysis of reconstruction measures for structures damaged by earthquakes will be useful for quick reconstruction from similar earthquake damage in the future.

ACKNOWLEDGMENTS

This study was part of the research conducted by the Research Committee of JGS-Kyushu. For this research, we received convenience from the Kyushu Regional Bureau of the Ministry of Land, Infrastructure, Transport and Tourism, and Kumamoto Prefectural Government. We also received financial support from the Kyushu Kensetsugijutsu Kanrikyokai. The authors hereby express their sincere gratitude.

Case study of slope failure and early warning system of landslides induced by heavy rainfall in Tajikistan, Central Asia

Avzalshoev. Zafar
Ph.D. candidate, Geotechnical and Geosphere Research Group: GREG, Saitama University, Saitama Japan

Taro. Uchimura
Professor, Geotechnical and Geosphere Research Group: GREG, Saitama University, Saitama, Japan

ABSTRACT: In the current paper, the author would like to present the most common annual natural hazard hitting Tajikistan: landslides. Although Tajikistan is landlocked, it is prone to many natural hazards such as earthquakes, liquefaction, rockfall, avalanches, and mudflow. Previous researchers investigated landslides induced by earthquakes. However, in this paper author would like to focus on landslides and mudflow caused by heavy rainfall. Especially now, due to climate change and global warming, glaciers melt, and the intensity of rains eventually increases the frequency of landslides. Per the Tajik Glavgelogy, annually 50, 000 landslides have been reported all over the republic, including both seismic and non-seismic. Thus, this paper analyzes the case study from a geotechnical perspective and suggests early warning systems to prevent such threats in the future.

1 INTRODUCTION

The current paper aims to define the reasons and possible mitigation measurements for the most common natural disaster-landslides occurring annually in Tajikistan. In particular, section 6 of Obigarm – Nurabad road. Tajikistan is prone to many natural hazards, such as earthquakes, liquefaction, rockfall, avalanches, and mudflow. Previous researchers investigated landslides induced by earthquakes. However, in this paper author would like to focus on landslides caused by heavy rainfall.

It has been recorded by Tajik Glavgelogy that annually 50, 000 landslides have been reported all over the republic, including both seismic and non-seismic.

Although landslide hazard analysis has a long history in Central Asia, mainly the earlier publications were in Russian Fedorenko (1988), eventually stuck around, and were either never published or buried. In addition to that, a large amount of data was stored and never shown due to security requirements. Even if it was published somewhere, most figures were presented without identification, making them almost useless for further studies Havenith (2013).

Table 1. List of prominent landslides in the last 50 years technical background of the site.

Date	Disaster type	Total death	Total affected
13.05.1992	Landslide	243	24100
07.05.1993.	Landslide	5	75357
19.11.1997	Landslide	40	not available
13.04.2003	Landslide	1	6000
03.02.2005	Landslide	16	1853
26.01.2006	Landslide	21	728
03.04.2015	Landslide	10	not available

DOI: 10.1201/9781003299127-300

Table 1 shows all types of landslides, seismic and non-seismic, that have occurred in Tajikistan in the last 50 years Emergency and Disaster Reports (2018).

1.1 *Background*

This paper presents attributes of investigated area based on geological and metrological aspects. Due to the new road construction crossing the studied area, it is essential to propose mitigation and early warning systems to prevent landslides after construction.

1.2 *Geological background*

The current section of the road is a landslide-prone massif. The length of the area is about 315 m. There is no precise orientation of the cracks; they are located randomly. The soils are stable in a dry state; they become subsiding and easily eroded when moistened. Landslide processes are strongly developed on the section of the route; during periods of rain, they are activated.

The slope is flooded, as evidenced by small springs. The springs are located on the upper slope of the road.

Figure 1 illustrates the location of the investigated site and its geological condition. In the current area, the predominant type of soil is loam.

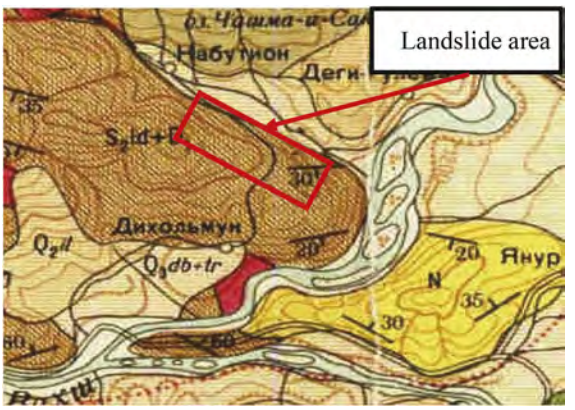

Figure 1. Geological map of the investigated area.

The following rock complexes are distinguished: a. Cover loose deposits of sandy-loamy soils with the inclusion of coarse-grained material, b. rocky soils, limestones, conglomerates, siltstones.

Figure 2(a) demonstrates the field condition and slope failure during the investigation. Figure 2(b) shows water infiltration through the slope induced by rainfall and springs.

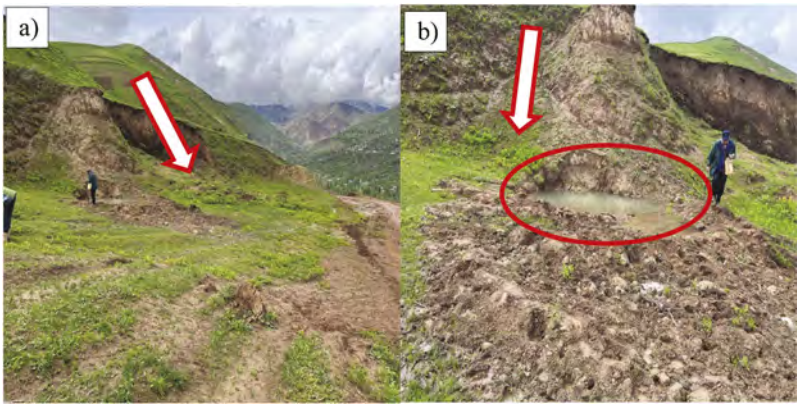

Figure 2. Field photos of the investigated area, a) slope failure, b) infiltration of the water.

1.3 *Hydrological background*

Underground waters are opened at depths from 0.5 m to 6.5 m. Groundwater is of a porous type and occurs sporadically in loose Quaternary formations and comes to the surface in the form of springs of seasonal manifestation.

The rock formations that make up the area are characterized by dip angles of up to 30° and large fractures, which is why no aquifers are sustained over the place. The formation and accumulation of groundwater in this area are associated with precipitation in the form of rain and snow.

2 EARLY WARNING SYSTEM

2.1 *Current condition*

A landslide is a mass of rock, debris, or soil moving down a slope under gravity Cruden, (1991). Not only in Central Asian countries but worldwide, landslides cause significant damage and casualties annually. Brabb (1993) persevered that 90% of landslide damage can be avoided if the risk is recognized before the landslide event. The first successful prediction by Saito (1965) used a model where the time to failure in the tertiary creep phase was inversely proportional to the current strain rate. Further, based on Saito's model, Fukuzono (1985) introduced an extended model expressed as the displacement's inverse velocity.

2.2 *Monitoring system*

Monitoring slope failure is considered one of the best options for predicting slope failure. Monitoring rainfall intensity is widely used as a warning system. There have been proposed lot of applications based on real-time rainfall records. The Japan Meteorological Agency has developed a Soil Moisture Index (SMI) as a more appropriate index to represent the virtual moisture content in slope grounds Uchimura (2015). It is calculated by assuming a three-tank model for the infiltration and drainage process of rainwater Ishihara & Kobatake (1979), Okada (2001). However, monitoring only the rainfall intensity is not enough. Monitoring each slope's characteristics along with the rainfall is more reliable. Displacement or deformation of the slope is the most commonly observed property Uchimura (2015). At the moment, extensometers shown in Figure 3(a) are the most widely used equipment for monitoring the displacement of the slope surface. Although this type of sensor is less costly than the construction of retaining walls or other structures, there are still some disadvantages.

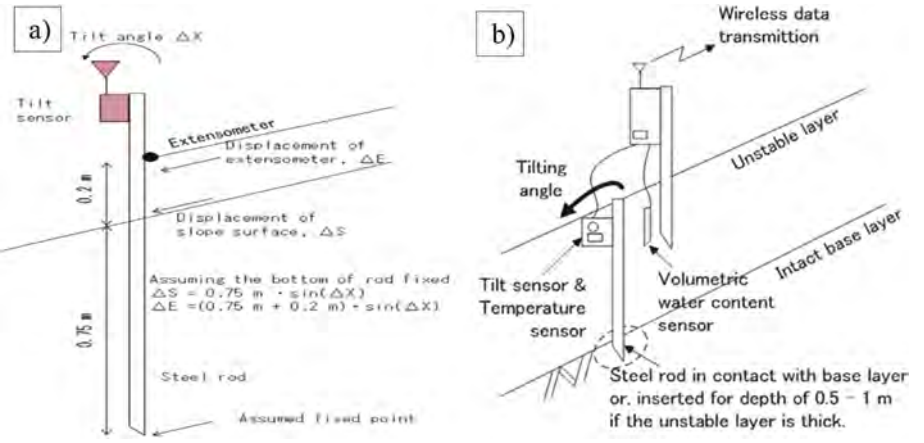

Figure 3. Slope monitoring equipment a) extensometer, b) tilt sensor, Micro Electro Mechanical Systems (MEMS), Uchimura (2015).

Considering new development techniques and previous experiences, Uchimra (2015) proposed a simple monitoring system with Micro Electro Mechanical Systems (MEMS), shown

in Figure 3(b) technology, that can measure the tilt angles (rotations) in the unstable surface layer of slopes. The proposed system is primarily suitable for detecting the pre-failure stages of surface failures with shallow slip surfaces. Based on the obtained results, Uchimura (2015) suggests that a precaution be issued at a tilting rate of 0.011 per hour and that a warning be issued at a tilting rate of 0.11 per hour to be on the conservative side.

3 CONCLUSION

From the case study presented in the current paper author would like to highlight the following findings:

I. The landslide length in a current case study is 300m – 315m. Landslide due to heavy rainfall occurs annually in Tajikistan. In most cases, an unstable layer is affected by the continuous rain that infiltrates through the top layer. On the bottom layer effect of the capillary barrier may occur that triggers the displacement of the unstable layer.
II. It has been recorded that there are springs inside the ground, affecting the slope stability jointly with seasonal rainfall. Consequently, it triggers the failure of the slope, which is the main reason for the collapse in such a hilly area of the country.

In most cases, individual slope failure is not studied well in Tajikistan. Typically, typical stabilization methods are promoted and applied for most slopes; however, from a geotechnical perspective, it is incorrect. Therefore, the author would like to suggest implementing the monitoring system and strengthening activities.

The author would like to focus on a monitoring system of slope displacement that should be implemented through the current case study.

ACKNOWLEDGMENTS

All the field studies were done by GUP "IPTS," to whom the author would like to express his gratitude. In addition, the author would like to thank Professor Taro Uchimura for his continued support and advice.

ABSTRACT: Tengiz oilfield was selected as a study area for the present research because of its historically reported continuous subsidence and limited studies for this area during recent years. This study focused on the quantitative assessment of the vertical displacement velocities retrieved using Sentinel-1 and Cosmo-SkyMed synthetic aperture radar images for the Tengiz oilfield. The small baseline subset time-series technique was used for the interferometric processing of radar images acquired for the period of 2018–2020. The geospatial and statistical analyses allowed to determine the existing hotspots of the subsidence processes induced by oil extraction in the study area. Ground deformation measurements derived from the Sentinel-1 and COSMO-SkyMed satellite missions showed that the Tengiz oilfield continuously subsided during 2018–2020 with the maximum annual vertical displacement velocity around −77.4 mm/y and −71.5 mm/y, respectively. The vertical displacement velocities derived from the Sentinel-1 and the COSMO-SkyMed images showed a good statistical relationship with $R^2 \geq 0.73$ and RMSE ≤3.68 mm. The cumulative vertical displacement derived from both satellites for the most subsiding location also showed a good statistical relationship with R^2 equal to 0.97 and RMSE = ± 4.69. The observed relative differences of measurements by both satellites were acceptable to determine the ongoing vertical surface displacement processes in the study area. These studies demonstrated a practical novelty for the petroleum industry in terms of the comparative assessment of surface displacement measurements using time-series of medium-resolution Sentinel-1 and high-resolution COSMO-SkyMed radar images.

1 INTRODUCTION

Tengiz oilfield is located at the coast of the Caspian Sea with low-lying wetlands. The recent successful studies by (Bayramov et al. 2021; Grebby et al. 2019 and Orynbassarova 2019) proved that the Tengiz oilfield was under the impact of ground deformation processes induced by the petroleum and gas operational activities.

DOI: 10.1201/9781003299127-301

Nowadays, industry significantly benefits from the ground deformation mapping as one of the important advancements for the surveillance programs of onshore oil and gas reservoirs. It is well known that the interferometric technologies were verified as effective for the measurement of the sensor-to-target line of sight projection of the ground deformation mapping of large onshore reservoirs rather than traditional in-situ measurements using geodetic tools (Zhou et al. 2006; Mirzaii et al. 2019). The studies by Grebby et al. (2019) and Orynbassarova (2019) clearly indicated the vertical displacements caused by oil and gas exploitation in the Tengiz oilfield during 2004-2009 and 2016-2017, by using Envisat and Sentinel-1 radar images, correspondingly. The investigations by Grebby et al. (2019) and Orynbassarova (2019) applied the Intermittent Small Baseline Subset (ISBAS) method from Sowter et al. 2013 which contributed to the determination of the continuously increasing cumulative vertical displacement (maximum of -79.3 mm/year) in the Tengiz oilfield during 2016–2017.

To the extent of our awareness, there have been few publically accessible studies on the multi-satellite monitoring of vertical displacements in the Tengiz oilfield, in particular with the focus on the comparative assessment of vertical displacements derived from multiple Sentinel-1 and Cosmo-SkyMed Synthetic Aperture Radar (SAR) imagery.

Our research specifically focused on the assessment of vertical displacements derived from COSMO-SkyMed and Sentinel-1 SAR imagery using SBAS multi-temporal interferometric technique and geostatistical interpolation techniques followed by the cosine corrections to derive vertical movements from LOS measurements. The primary advantage of the present research is to quantitatively examine the differences in vertical displacement measurements using C-band Sentinel-1 and X-band Cosmo-SkyMed SAR imagery since in-situ geodetic measurements were not accessible for the present research. The detailed goals of the present research are as follows:

1) SBAS-based detection of vertical displacement hotspots using COSMO-SkyMed and Sentinel-1 imagery acquired during 2018–2020
2) Quantitative analyses of the vertical displacement velocities and cumulative vertical displacement derived from Sentinel-1 and COSMO-SkyMed satellite images
3) Determination of spatial relationships between the detected patterns and the hotspots of vertical displacements, wells and faults

2 DATA PROCESSING

2.1 *Research area*

Tengiz oilfield is one of the largest in the world and it is located at the coast of the Caspian Sea with an area of 2,500 km2 (Figure 1a and b). The climate in the study area is semi-arid with temperature range −30 °C - 40° in summer and winter, respectively. The average annual precipitation is in the range of 100–200 mm (Klein et al., 2012). Tengiz field is located in the seismically active region of Kazakhstan. The seismic faults derived from (Anissimov et al. 2000) are indicated in Figure 1. According to (Grebby et al. 2019), the reservoir is estimated to be around 25 billion barrels of oil and is located at the depth of 3885–5117 m. High pressure with large proportion of gas was observed in the oil coming out of wells. The production is estimated to be 720,000 barrels per day. Sour gas injection enhanced oil recovery method is used in the Tengiz oilfield (Bealessio et al. 2020).

2.2 *Quantitative assessment of vertical displacement in the Tengiz Oilfeld using SBAS processing of Sentinel-1 and Cosmo-SkyMed images*

Sentinel-1 A/B TOPS with C-band (5.6 cm wavelength and 5.4 GHz) images from the European Space Agency (ESA) and COSMO-SkyMed (CSK) with X-band (3.1 cm wavelength and 9.6 GHz) from the Italian Space Agency were used for the present study to assess the vertical displacement velocities and cumulative vertical displacement in the Tengiz oilfield. The extents of the Sentinel-1 and COSMO-SkyMed imagery are presented in Figure 1b. 96 Sentinel-1 images were acquired on descending Path 35, Frame 441, Absolute Orbit 30,557 in the TOPSAR Interferometric Wide Swath (IW) mode, with VV + VH Polarization between 1 January 2018 and 31 December 2020

Figure 1. (a) Tengiz oilfield with the representation of wells and faults; (b) Extents, count and acquisition period of Sentinel-1 and COSMO-SkyMed imagery.

(Figure 1b). VV polarization band of Sentinel-1 was used because of a higher coherence (Imamoglu et al. 2019). Sentinel-1images in wide-swath mode provide a wide coverage of about 250 km with a range resolution of 5 m and an azimuth resolution of 20 m (Yang et al. 2019).

87 COSMO-SkyMed images were acquired on descending Frame 2, Absolute Orbit 39,000 in the interferometric StripMap HIMAGE mode with HH polarization between 1 January 2018 and 31 December 2020. HH polarization band of COSMO-SkyMed that was only available had been used for the present research. COSMO-SkyMed images in StripMap Himage mode provide coverage of about 40 km with a range resolution of 3 m and an azimuth resolution of 3 m (Tapete and Cigna 2019) (Figure 1b). Descending tracks of Sentinel-1 and COSMO-SkyMed satellite images provided a complete coverage of the Tengiz oilfield.

SBAS - based interferometric processing technique was used for the assessment of the vertical displacement. SBAS workflow is presented in Figure 2 with the following processing steps: creation of a connection graph, definition of AOI, generation of interferograms, refinement and reflattening, first inversion, second inversion and geocoding (Loesch and Sagan 2018; Sarmap 2021).

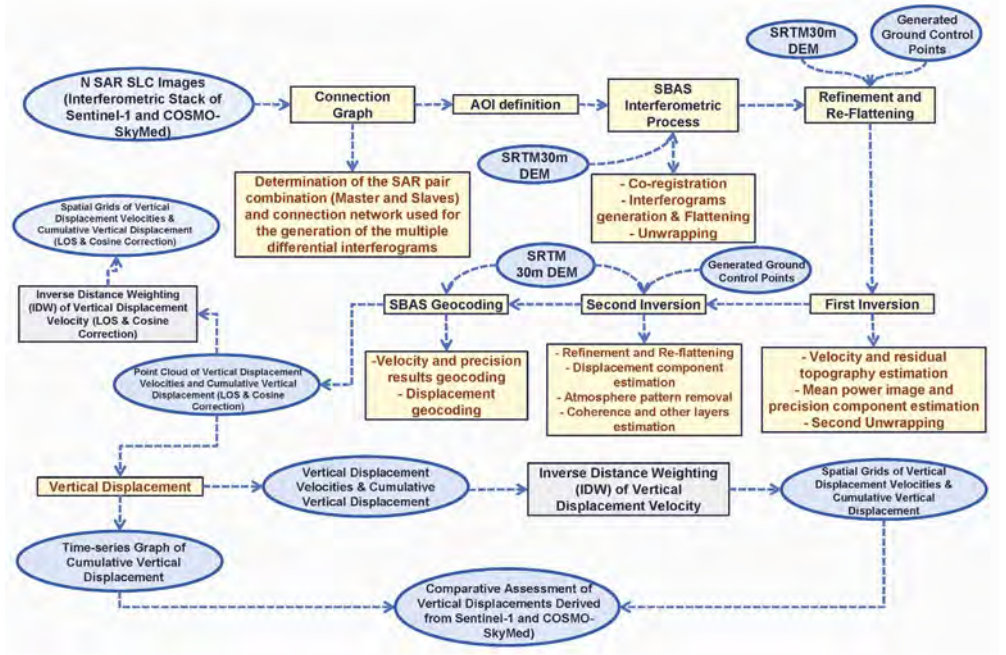

Figure 2. Workflow of SBAS interferometric processing followed by the cosine correction for the assessment of vertical displacements and spatial interpolations.

3 RESULTS

LOS displacement velocity derived from the Sentinel-1 radar satellite images was observed to be in the range of − 58.9 - 22.7 mm/y (Figure 3a). The vertical displacement velocity derived through the division of the LOS displacement rates by the cosine of the radar incidence angle is presented in Figure 3b with the range of −77.4 - 29.4 mm/y. The spatial distribution histogram of the measured LOS and vertical displacement velocities derived from the cosine corrections are presented in Figure 3c. It is possible to clearly observe the prevailing number of pixels with negative values which confirms the ongoing subsidence in the Tengiz oilfield.

The hotspot of significant subsidence can be observed at the crossing of profile lines in Figure 4a. The same location was observed to be as the most subsiding. As it is possible to observe in Figure 4b, the maximum annual subsidence velocity along the profiles reaches about −70 mm/y. The cumulative vertical displacement is shown in Figure 5a with the range of −243.7 - 79.9 mm. The maximum cumulative vertical displacement along the profiles on 23 December 2020 reaches − 235 mm (Figure 5b).

Unfortunately, because of no accessibility to the historical in-situ high-precision geodetic measurements in the present research, it was not possible to validate the reliability and accuracy of the SBAS measurements derived from the Sentinel-1 images. Therefore, it was considered to use the COSMO-SkyMed images for the cross-validation of measurements from both satellites. The processed area of the COSMO-SkyMed images was limited to the subsiding hotspots derived from the processing of the Sentinel-1 images. The spatially interpolated vertical displacement velocity derived from the COSMO-SkyMed images is presented in Figure 6a. Figure 6b presents the spatial distribution of SBAS measured points derived from the COSMO-SkyMed and the Sentinel-1 images. These points with measured vertical velocities were used in the interpolation of spatial grids used in the comparative analysis (Figure 6a). The enhanced view of the vertical displacement velocity derived from the COSMO-SkyMed images and profile lines are presented in Figure 6c. The histogram of negative vertical displacement velocities derived from the COSMO-SkyMed images is presented in Figure 6d. This implies that the SBAS analyses using the COSMO-SkyMed images also showed the subsidence processes in the same hotspot detected by the processing of the Sentinel-1 images.

The profiles of the vertical displacement velocities derived from the Sentinel-1 and the COSMO-SkyMed images are presented in Figure 6c and Figures 7a–d. As it is possible to observe, the vertical displacement velocities derived from the Sentinel-1 and the COSMO-SkyMed images for the Profile 1 showed a good statistical relationship with R^2 equal to 0.93, p-value < 0.05, RMSE equal to ±2.86 (Figures 7a and b). Good statistical relationship was also observed for the Profile 2 with R^2 equal to 0.73, p-value < 0.05, RMSE equal to ±3.68 (Figures 7c and d). The standard deviation of the phase calculated over the profiles 1 and 2 was observed to be 8.9 for profile 1 and 7.9 for the profile 2 (Figures 7a and c).

The location for the maximum subsidence derived from the Sentinel-1 images is presented in Figure 8a. The cumulative vertical displacement derived from the Sentinel-1 and the COSMO-SkyMed images for the most subsiding location are presented in Figure 8b. The cumulative vertical displacement in the most subsiding location reaches around 245 mm on 23 December 2020 (Figure 8b). The regression analysis between the cumulative vertical displacements derived from the Sentinel-1 and COSMO-SkyMed images for the most subsiding location showed a strong statistical relationship with R^2 equal to 0.97. This was also reflected in RMSE = ± 4.69 and p-value < 0.05. This allows to conclude that SBAS produced identical results from the Sentinel-1 and the COSMO-SkyMed images. It is obvious that the ground deformation measurements from the COSMO-SkyMed images are more detailed because of the higher spatial resolution of images.

Since the hotspot of the most subsiding areas is not anyhow spatially related to the concentration of wells, it is possible to assume that the primary factors controlling the vertical displacements in the Tengiz oilfield are the oil and gas extraction industrial processes and natural subsurface tectonics. However, it is possible to observe that a number of wells are located within the detected hotspot of the subsidence in Figure 8a. The oil terminal is located outside of the subsidence hotspot (Figure 1a; Figure 8a) and it is obviously less vulnerable to the potential geohazards.

Besides these areas are crossed by faults which might be subject to the potential reactivation (Figure 8a). Hence, some of the wells located within the detected subsidence hotspot should always be prioritized for the regular geotechnical and geohazard risk assessment.

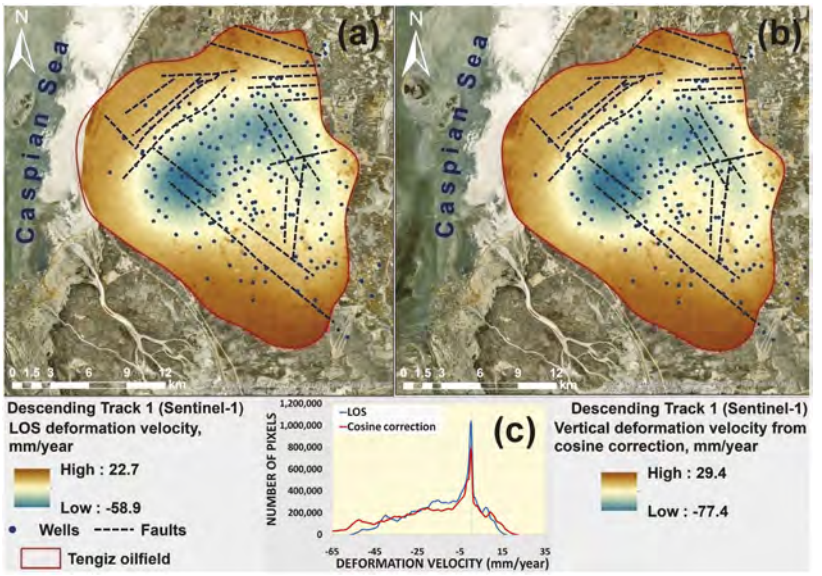

Figure 3. (a) LOS and (b) vertical displacement velocity from cosine correction of the Tengiz oilfield; (c) Histogram of LOS and vertical displacement velocity.

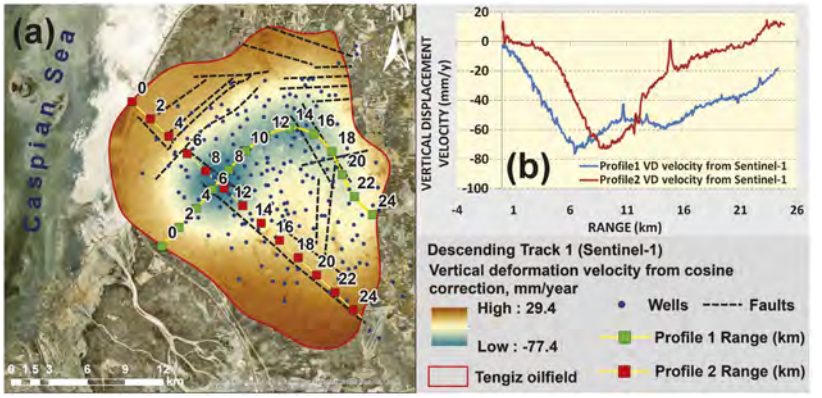

Figure 4. (a) Map of vertical displacement velocity derived from the Sentinel-1 images with the indication of profile lines; (b) profile lines of vertical displacement velocities.

4 DISCUSSION

The assessment of the vertical displacement velocities and cumulative vertical displacement derived from the Sentinel-1 and the COSMO-SkyMed images showed a good statistical relationship. This allows to assume that the measurements by both satellites are reliable. The present research results also exhibit shortcomings related to the non-accessibility to the historical in-situ geodetic measurements to verify the accuracy of the measurements. Therefore this study used both Sentinel-1 and COSMO-SkyMed images to cross-validate the achieved results from both satellites. The qualitative judgment for the verification of the present research

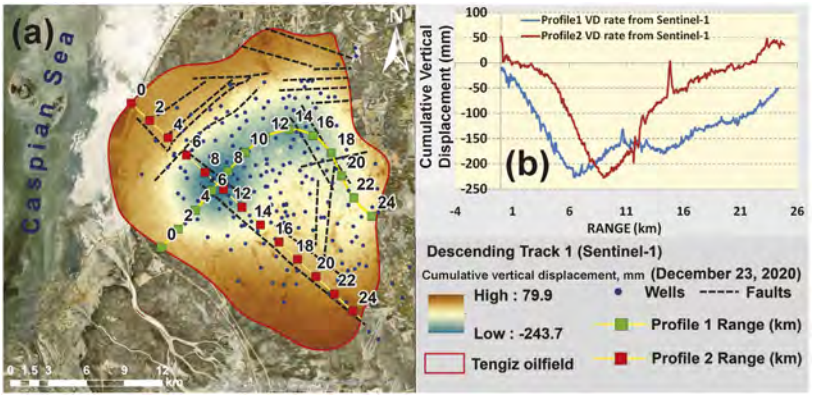

Figure 5. (a) Map of cumulative vertical displacement derived from the Sentinel-1 images with the indication of profile lines; (b) profile lines of cumulative vertical displacement.

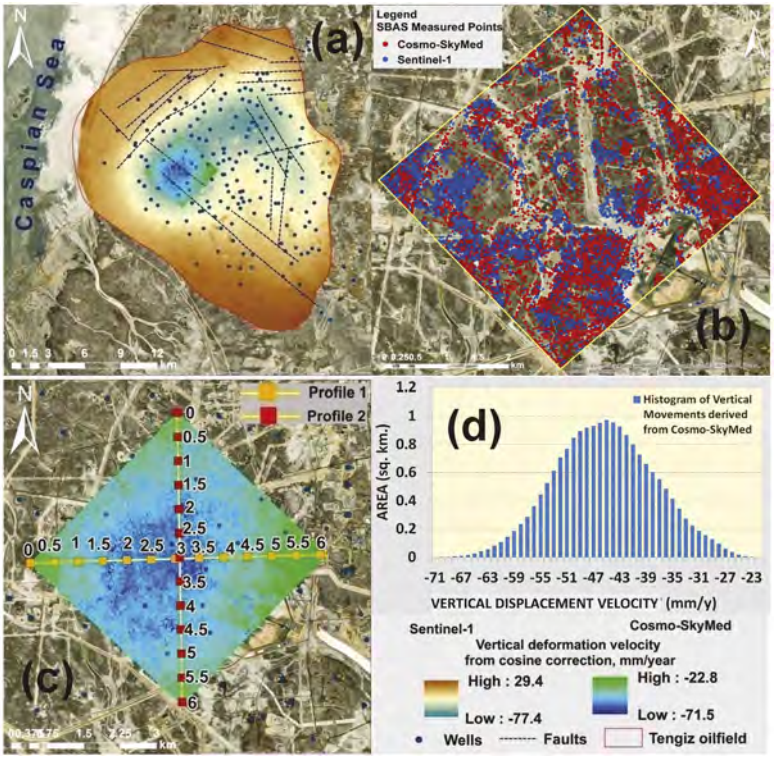

Figure 6. (a) Map of the spatially interpolated vertical displacement velocity derived from the Sentinel-1 and COSMO-SkyMed satellite images; (B) SBAS measured points from the Sentinel-1 and COSMO-SkyMed satellite images used for the spatial interpolation; (C) profile lines of vertical displacement velocity derived from the COSMO-SkyMed images; (D) histogram of vertical displacement velocities derived from the COSMO-SkyMed satellite images.

results was also based on the previously published studies which also observed and detected continuous subsidence processes in the Tengiz oilfield (Del Conte et al. 2013; Comola et al. 2016; Grebby et al. 2019; Orynbassarova 2019; Bayramov et al. 2021). The identical spatial deformation patterns and trends with a maximum subsidence rate rising up-to −79.3 mm/year were observed in the previous studies by Grebby et al. 2019 and Orynbassarova 2019.

Vertical displacement velocity derived from the Sentinel-1 and COSMO-SkyMed satellite images for: (a) profile 1 VD, (b) regression analysis between vertical displacement velocities derived from the Sentinel-1 and COSMO-SkyMed satellite images for profile 1; (c) profile 2 VD, (d) regression analysis between vertical displacement velocities derived from the Sentinel-1 and COSMO-SkyMed satellite images for profile 2.

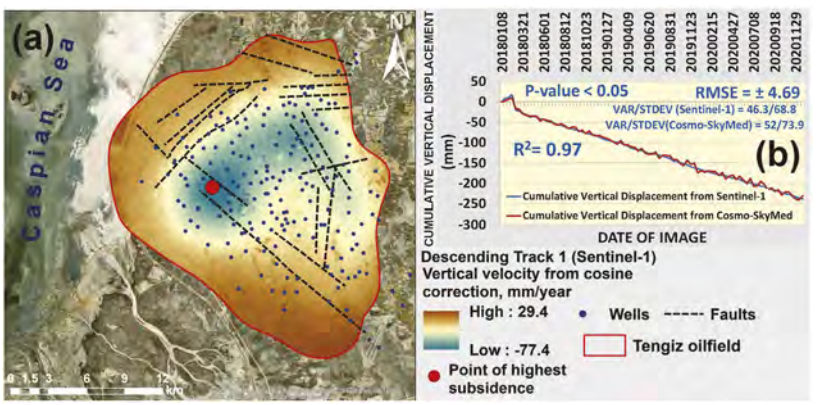

Figure 8. (a) Location of the most subsiding location based on the cumulative vertical displacement derived from the Sentinel-1 images; (b) regression analysis between the cumulative vertical displacements derived from the Sentinel-1 and COSMO-SkyMed satellite images for the most subsiding location.

It is quite difficult to judge about the criticality level of the ongoing and increasing vertical displacement velocities and cumulative vertical displacement of the Tengiz oilfield subsidence in the relationship to the petroleum and gas industry standards for the effective risk management.

However the previous studies by (Mahajan et al. 2018) indicated that the reservoir compaction cases in Oman resulted in the well damages, well integrity, and subsidence damage to the facilities of surface tremors because of fault reactivation. As it was possible to observe in the present studies, around 15 wells of the Tengiz oilfield are located in the detected subsidence hotspot from two satellites. Besides, it is necessary to emphasize the fact of the increasing subsidence velocity that was also well spotted by the present research and previous studies of (Grebby et al. 2019). The application of Sentinel-1 or COSMO-SkyMed images should be selected depending on the scale of analysis, required density and precision of measurements.

5 CONCLUSION

The present research compared the vertical displacements derived from the Sentinel-1 and COSMO-SkyMed radar images collected during 2018-2020 for the Tengiz oilfield.

- The vertical displacement velocities and cumulative vertical displacement derived from the Sentinel-1 and COSMO-SkyMed images showed good agreement. The vertical displacement velocities derived from the Sentinel-1 and COSMO-SkyMed images showed a good statistical relationship with R^2 equal to 0.93, P-value < 0.05 and RMSE equal to ±2.86 for the Profile one and R^2 equal to 0.73, P-value < 0.05 and RMSE equal to ±3.68 for Profile 2. The cumulative vertical displacement derived from the Sentinel-1 and COSMO-SkyMed images for the most subsiding location showed a good statistical relationship with R^2 equal to 0.97, P-value < 0.05 and RMSE = ± 4.69. This allowed to assume that the SBAS measurements from both satellites are reliable and also confirmed the ongoing subsidence processes in the Tengiz oilfield.
- Vertical displacement velocities and cumulative vertical displacement derived from the COSMO-SkyMed images were observed to be more dispersed than from the Sentinel-1 images. This was reflected in the higher sample variance and standard deviation of the vertical displacement values derived from the COSMO-SkyMed mages.
- Ground deformations derived from the Sentinel-1 and COSMO-SkyMed images showed that the Tengiz oilfield subsided during 2018-2020 with the maximum annual vertical displacement velocity around −77.4 mm/y and −71.5 mm/y, respectively. - The detected hotspot of the most subsiding areas was not anyhow spatially related to the concentration of wells. Therefore, it is possible to assume that primary factors controlling the vertical displacements in the Tengiz oilfield are the oil and gas extraction industrial processes and also natural subsurface tectonics.
- The selection among the Sentinel-1 or COSMO-SkyMed images should be decided depending on the scale of analysis, required density and precision of measurements.

FUNDING

This research was funded by the Nazarbayev University through the Social Policy Grant and Faculty-development Competitive Research Grant (FDCRGP) - Funder Project Reference: 080420FD1917.

Issues and challenges in geotechnical investigations – Case studies from Cochin, India

Akhil Anil
Junior Engineer, Geostructurals Pvt Ltd, Cochin, India

Anil Joseph
Managing Director, Geostructurals Pvt Ltd, Cochin, India

ABSTRACT: Heightened development activity occurring throughout the world leaves us with more challenging or marginal land for future developments. Soil related issues and challenges, are often poorly or conservatively evaluated thus inviting risk or additional costs to the project. This paper shares the case studies of challenges encountered for value engineering with respect to geotechnical investigation for a 40 Storied Twin towers in Smart City, Cochin and the problems encountered with the bulk movement of very soft clay during the construction of foundation for a Mall at Maradu, Cochin. In terms of controlling the risks of over-expenditure on a project, a good soil investigation can save a client considerable amount in the project foundation cost even up to 100%. It is worthwhile to spent up to 2% of the project cost in geotechnical investigation as a safety against financial risk involved due to inadequate data.

1 INTRODUCTION

Construction in soft soil is a great challenge in the field of geotechnical engineering. Ground engineering issues such as slope instability, bearing capacity failure or excessive settlement could occur either during or after the construction phase due to low shear strength and high compressibility of this soil (Mohamad et al 2015). The most important aspect of every civil engineering project is acquiring reliable information on the ground on which the project will be constructed (Hussain et al 2022). Preliminary geophysical investigation of subsurface strata is important prior to tendering or execution of project and preparation of project plan of any construction which help in proper planning, cost estimation, and time-bound project execution (Anbazhagan 2018). During the planning of subsurface investigation, the Engineer shall always remember majority of the unforeseen costs associated with construction on soft clay are geotechnical. Additional costs are often attributed to inadequate planning of subsurface investigation and improper interpretation of the results of field and laboratory tests (Gue et al 2000). Given the wide range of topics covered by site investigations, the geotechnical consultant should bring the required adjustments for each unique project. The need of "value engineering" should be made clear to those who are procuring site investigations in order to make sure that site investigations are integrated into project planning as early as feasible and not as a last-minute "necessary evil." Along with providing advice on site investigation requirements, a skilled geotechnical consultant should also emphasize the importance of using a staged strategy for practically any size of study. The concept of a single phase ground investigation should be firmly resisted by any geotechnical practitioner, as only once the investigation proceeds can one assess the need or otherwise, for further probing (SAICE, 2010). Geotechnical investigations are an essential component of a successful geotechnical engineering analysis and foundation recommendation report. These investigations allow geotechnical engineers and geologists to characterize subsurface conditions and make engineering judgments about how the earth will behave when subjected to structure and embankment loads (MnDOT Geotechnical Manual, 2017).

DOI: 10.1201/9781003299127-302

2 COCHIN MARINE CLAYS

Port City of Cochin in India has been witnessing large scale construction activities due to the rapid industrialization of the area. Most of the "Greater Cochin" area consists of extremely soft marine clays, posing numerous problems for foundation engineers (Jose et al 1988). Therefore, the need for accurate and reliable geotechnical investigation methods and proper site characterization is becoming vital. The marine clays of Cochin have very low undrained shear strength and possess moderate sensitivity. Pandian et al 1991 indicated the change in the index and engineering properties of Cochin Marine Clay on air drying and that the test results of standard procedures which recommend air drying could be misleading. Physico-chemical and mineralogical studies on Cochin marine clays indicate that these marine soil samples have high water content and high void ratio. The natural moisture contents are very close to the liquid limit. These soils are classified as organic and active in view of their high colloidal activity (Rajasekaran et al 1994). The smear zone radius of Cochin marine clays was estimated to be about 130 to 150mm, which was five to six times the radius of the central drain. The horizontal permeability within the smear zone is about 25 to 30% less than in the undisturbed zone (Anil et al 2015). This paper deals with two case studies of challenges encountered for value engineering with respect to geotechnical investigation for a 40 Storied Twin towers in Smart City, Cochin and the problems encountered with the bulk movement of very soft clay during the construction of foundation for a Mall at Maradu, Cochin.

3 CASE STUDY I: 40 STORIED I.T. TWIN TOWERS PROJECT AT SMART CITY, COCHIN, INDIA

3.1 *About the project*

The project consists of 40 Storied IT Twin Towers with a total plinth area of more than 45 lakh square feet, located in Cochin, India. The project contains a robotic parking garage that can hold roughly 4500 parking spaces. The tender for an end bearing pile foundation sitting on rocks was called after the initial soil research studies and preliminary drawings. The project was referred to the authors for value engineering and peer review. The project's projected cost for piling was 7 Million USD, and the total number of piles anticipated according to the original design was 4500 numbers. Figure 1 displays the site plan and building elevations.

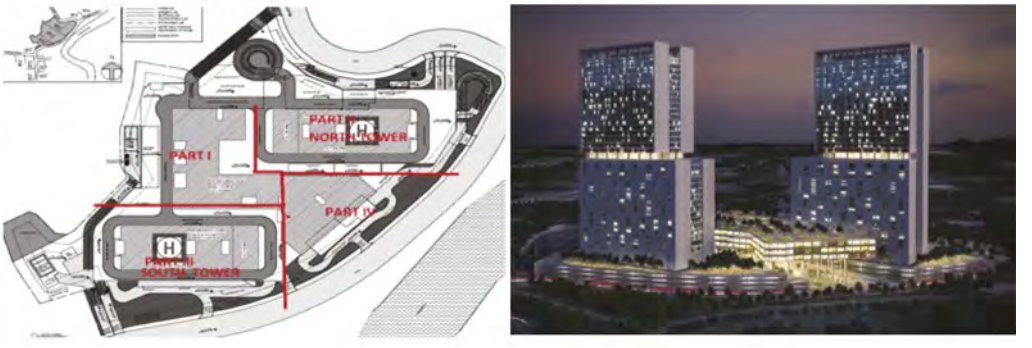

Figure 1. Layout and elevation of the proposed project.

3.2 *Soil profile*

Rotary drilling was used to drill six bore holes a maximum of 17.1m deep. Standard Penetration Tests were carried out at regular vertical intervals, and laboratory testing was done on

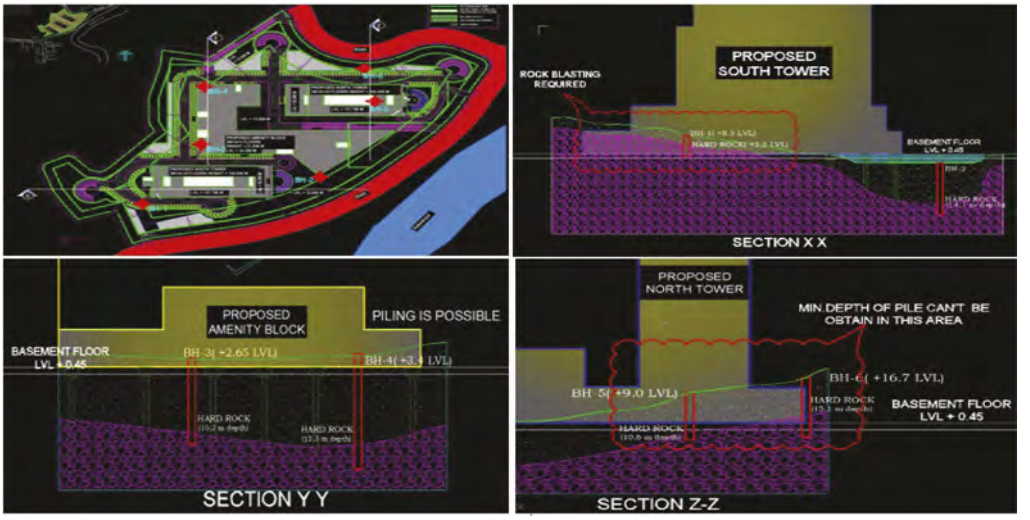

Figure 2. Layout of boreholes and sections through the towers.

the samples collected throughout the study. The analysis of boreholes revealed that the soil profile exhibits unpredictable fluctuation. The plot has a level difference of about 18m, and the founding strata are composed of very hard volcanic rock in some places, hard lateritic formation in others, and thick deposits of very soft organic clay with S.P.T. values ranging from 0 to 1 that extend to a depth of 8m. Figure 2. depicts the location of the boreholes as well as the cross section along the towers.

3.3 *The problem*

According to the drill investigation, some sites would require rock blasting at the foundation level and the first concept of the piling is not feasible throughout the entire region. The minimum pile depth won't be available in some other places, and in some places, deep piles resting on hard rock will need to be provided together with suitable anchorage. For a complete study of the foundation needs and to determine an estimate of cost, the data from the available geotechnical investigation is insufficient. Additional boreholes are therefore necessary.

3.4 *The solution – Value engineering*

Additional 21 bore holes were drilled at the site as part of the decision to conduct a thorough study, as indicated in Figure 3(a). In order to determine the depth of encounter of rock strata and guarantee the minimal length of pile in the piled raft region, bore holes were taken in every 10m grid in the transition zones in the south tower and north tower areas where rock strata suddenly dips and soft weak layer shows up. Additionally, rock bottom profiling was done, and the results are shown in Figure 3(b). Based on the newly acquired geotechnical information, the foundation system was modified to include deep piles end bearing in hard rock with sufficient anchorage for soft clay areas, footings resting on hard rocks or on piles end bearing in hard rock for amenity blocks, rafts for towers beginning from the hard rock layers, and piled raft systems for lateritic areas. The total number of piles on redesign was decreased to 1356, lowering the cost of piling to 1.9 million USD, and resulting in a 5.1 million USD reduction in budget for piling. The case study emphasizes the significance of thorough geotechnical investigation to determine an accurate project estimate. The construction of the foundation work and current stage of the project are displayed in Figure 4(a) and (b).

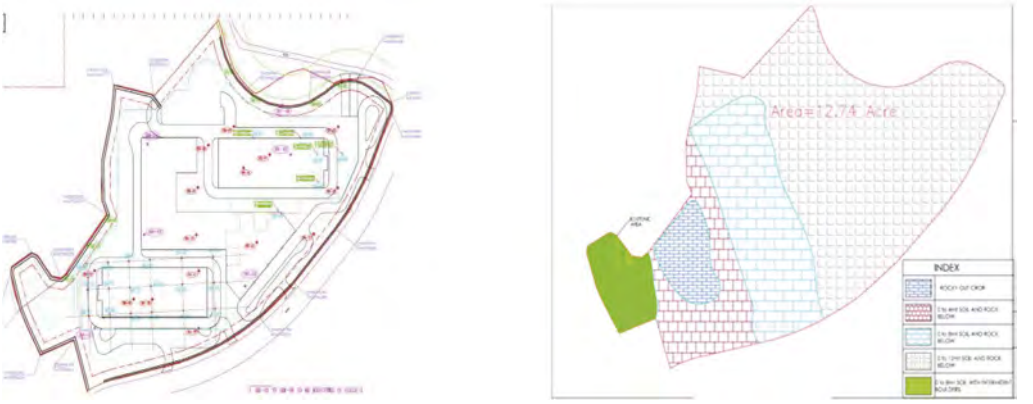

Figure 3. Work of superstructure in progress (a) Layout of additional bore holes (b) Rock bottom profiling.

Figure 4. (a). Foundation work in progress (b). Current status of the project.

4 CASE STUDY II: MALL AND RESIDENTIAL TOWERS AT MARADU, COCHIN

4.1 *About the project*

Project comprises of a Shopping Mall of about 10 lakhs square feet consisting of Hyper market, restaurant, retail shops, multi-level car parking, Multiplexes and swimming pool and two residential towers of 20 floors, having an approximate area of 5 lakh square feet. The site location and 3D view of the project is shown in Figure 5. The soil investigation conducted at site reveals the presence of very soft marine clay extending up to a depth of 24m. The Towers and Mall building is designed as resting on D.M.C. Piles end bearing in the very dense sand strata noted from a depth of about 47 to 56m. The compound wall and the ramp area piles were terminated at a depth of 36 to 40m in the medium dense sand strata.

4.2 *The problem*

Building has two basements catering to car parking and services, and the depth of excavation required from the existing ground level was 7m. As the cost of Diaphragm wall and touch piles was too high, where ever sufficient set back were present the contractors decided to go for stage excavation with ordinary sheet piling. During the progress of excavation, the entire system failed and due to the bulk movement of the soft marine clay, the D.M.C. piles

Figure 5. Site location and 3D View of the project.

Figure 6. Failure of stage excavation.

moved laterally and shearing failure was noted in many piles. Figure 6. shows the failure of stage excavation.

4.3 *The solution - Value engineering*

The project was referred to authors for working out a safe and optimum solution for retaining system. After carrying out detailed investigation of failure, additional data regarding soils were collected at specified intervals. The plan indicating the phases of construction and retaining requirement for excavation is shown in Figure 7. The corrective piles were executed in place of the damaged piles. After carrying out the analysis for different retaining

system it was decided to go for profiled high strength interlocking sheet piles extending up to 12m depth with back anchorage systems where ever sufficient set back is available. Where ever set backs are less it was decided to go for touch piles with propping system to optimize the design. During the course of construction, it was noted that due to the bulk movement of the soil happening the stress formation on the supporting system on the interlock piles was much higher than envisaged, and the system moved to the verge of collapse as shown in Figure 8.

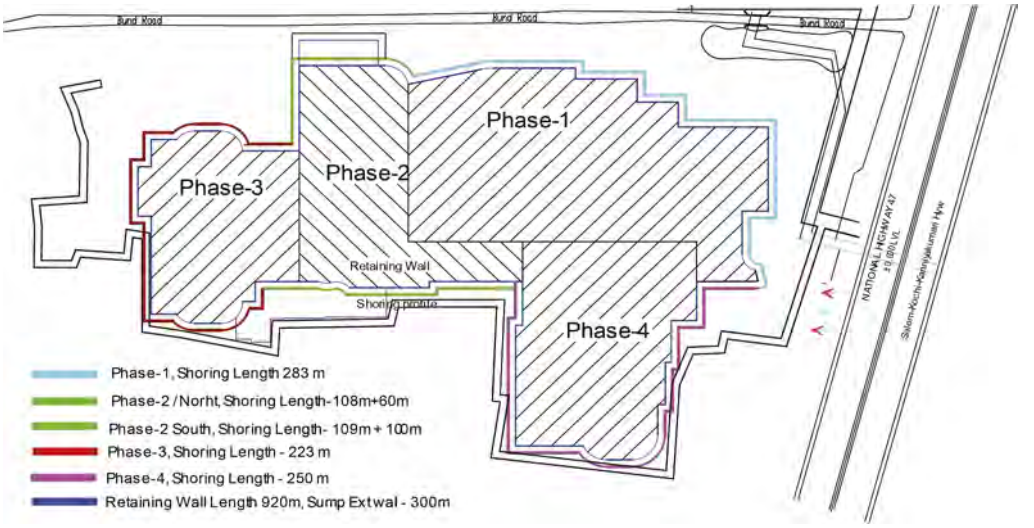

Figure 7. Plan indicating phases of construction and retaining requirement for excavation.

Figure 8. Huge stress on sheet piling system due to block movement of the soft clay.

Additional propping was provided from the bottom to prevent the collapse. In order to prevent the bulk movement of soft marine clays and to have better factor of safety, in the remaining phases for the areas where sufficient set backs are available it was decided to improve the ground by providing a combination of preloaded compacted lime fly ash columnar intrusions and Multiple Driven Fibre Reinforced Columnar intrusion as indicated in Figure 9. Figures 10(a) and (b) shows the photographs of the project during construction and current stage.

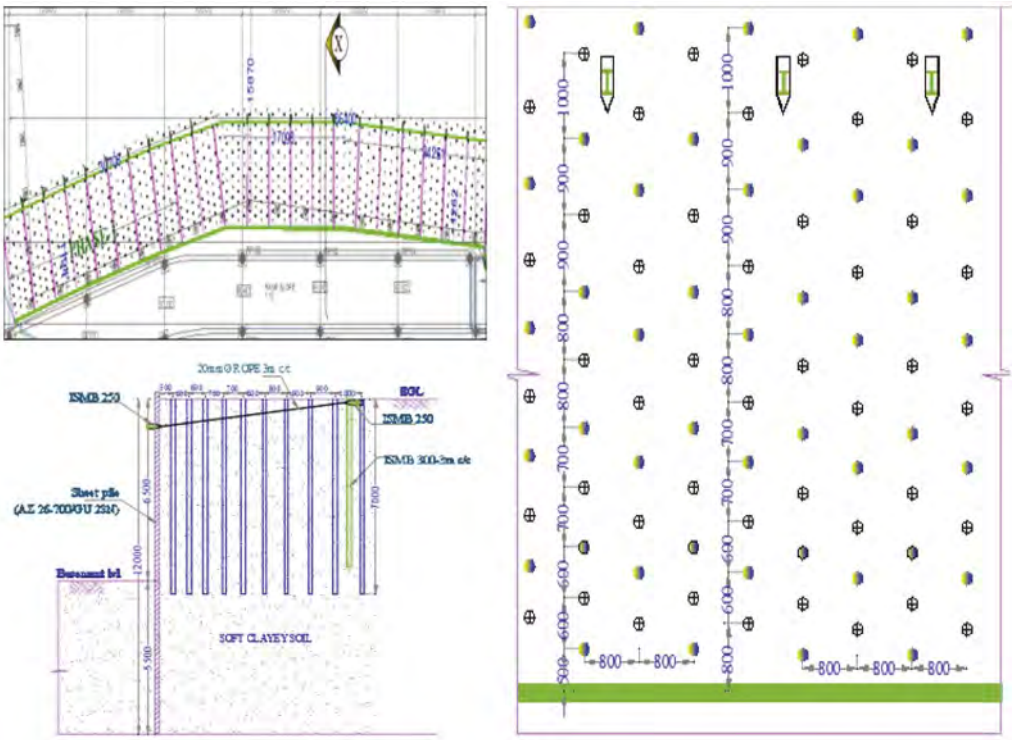

Figure 9. Ground improvement system by providing a combination of preloaded compacted lime fly ash columnar intrusions and Multiple Driven Fibre Reinforced Columnar intrusion for preventing bulk movement.

Figure 10. (a) Project during construction (b) Current status of the project.

5 CONCLUSION

A good geotechnical consultant apart from giving guidance on site investigation requirements has to highlight the phased investigation approach that is essential to almost any size of investigation. The case study for the 40 storied I.T. Twins Towers project emphasizes the significance of thorough geotechnical investigation to determine an accurate project estimate. The total number of piles on redesign was decreased to 1356 from 4500, lowering the cost of piling to 1.9 million USD from 7 million USD, resulting in a 5.1 million USD reduction in budget for piling. From the case study of the mall and residential towers, it is noted that the block movement of soft marine clays can cause catastrophic effects - shearing concrete piles and exerting huge pressure on the sheet pile/ touch pile retaining wall systems. Providing a combination of preloaded compacted lime fly ash columnar intrusions and multiple driven fibre reinforced columnar intrusion for ground improvement in soft marine clays can prevent the bulk movement and thereby leading to optimization of design of retaining walls and improving the safety of the projects. It is worthwhile to spent up to 2% of the project cost in geotechnical investigation as a safety against financial risk involved due to inadequate data.

Restoration works of dry dock of Sveaborg

K.C. Avellan
KAREG Consulting Engineers, Helsinki, Finland

ABSTRACT: Sveaborg (Suomenlinna) is an UNESCO sea fortress. The dry dock is built under Swedish, Russian and Finnish rule. Most of the concrete structures are made after Finnish independence (1917). The masonry debris of the wall face is concrete covered. The northern corner of the basin is supporting the floating gate. The corner restoration started in 2012 by grouted steel pipes. Anchors were drilled though the existing structure. A drainage system and reinforcement were installed, and concrete was poured. Instability of the damaged structures made the projects challenging and safety precautions had to be implemented at all work stages. By close monitoring, and the ability to resolve problems of the flowing water, the project's first phase was successfully completed. The design water pressure is 95 kN/m². The second phase was undertaken in 2018 by repairing the drainage channels around the dock and repairing the wall faces and the floor.

1 INTRODUCTION

Suomenlinna (Sveaborg) is a sea fortress which was built on a group of islands at the entrance to Helsinki harbor. It was originally built for defending Sweden against Russia (1748-1809). After the Crimean war (1853-1856) the fortress was strongly strengthened structurally and by heavy artillery due the defense problems against English and French fleet. The reason was that time to defend ST. Petersburg. The Russian empire continued to strengthen the fortress until the October revolution (1917). The independent Finland started to use the fortress and deepened the bottom of the yard by blasting and pouring concrete up to WW2.

In 1991, the fortress was added to the UNESCO World Heritage List as a unique monument of military architecture.

Figure 1. Dry dock of Suomenlinna and strengthened corner of the floating door.

DOI: 10.1201/9781003299127-303

2 MANDATE AND SCOPE OF WORKS

The first scope was strengthening of supporting corner of floating door and the old quay wall 2011-2012 (Figures 1–2).

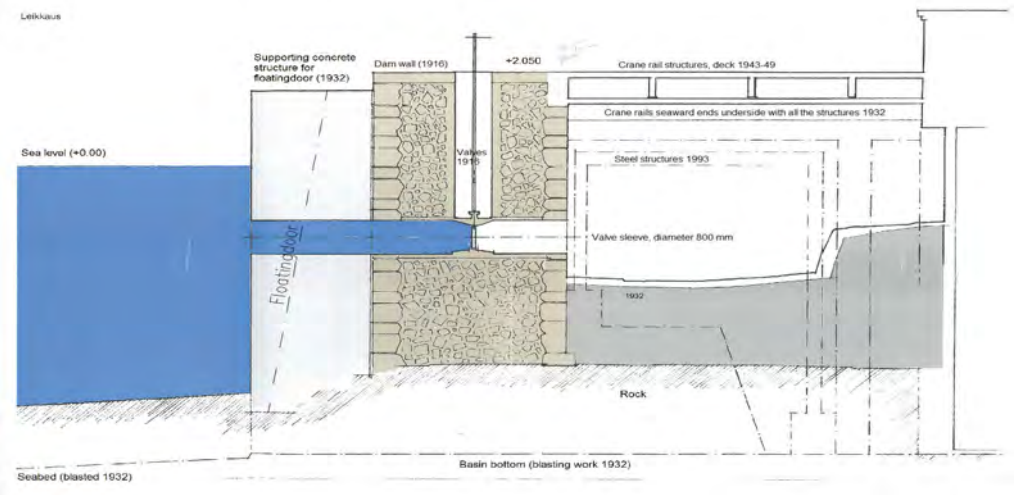

Figure 2. Supporting corner of the floating door. Section. Construction phases and periods.

The second scope was renovation of the bottom slabs (2 x 2 x 0.1 m^3) of concrete and dewatering channels of the bottom. The channels are situated near the rand of the walls having occasionally wipeholes. The environmental problems were based on having the dock after WW2 mainly as repairing dock for ships. The sandblasting of the ships caused environmental problems due to toxic paint.

3 STABILIZATION OF SUPPORTING CORNER OF THE FLOATING DOOR

The supporting corner of the floating door at the dry dock was made in 1932. Over the years, a section of approximately 4 m (width) by 11 m (height) of the corner of the concrete basin wall supporting the floating door had deteriorated from exposure to seawater and frost damage and was in a poor state of repair. Further damage and disintegration of the structure was caused by water leakage through the wall at an increasing rate despite an attempt to recondition it in 2009.

The process of restoration of temporary stabilization of the damaged gravity wall was initiated using two vertical grouting steel pipes (114.3 x 5 mm) with 120 holes per meter, ϕ = 10 mm, driven 2.0 m deep into bedrock, drilled and installed on the level 2.05 m. Having had the old corner stabilized, and water from the basin pumped out, the structure could be then tieback anchored. In order to cease and prevent supplementary water leakage from the structure, the old, traditional method of timber wedges was employed (Figure 3).

The Tieback anchors, Titan 40/16 Combi-coat, were drilled through the existing structure to the depth of 3 m into the bedrock using rock crown drill bit of ϕ =90 mm with centralizing spaces 88 mm. The reason for the large crown drill bit was that the denoted location of the bedrock was based on expert assessment using available data, therefore there was a slight, but potential probability that the anchors could have been as well bonded in the old, underwater structure (Figure 3).

Figure 3. The corner before rebuilding. Timber wedges.

4 REPAIRING THE BOTTOM COCRETE SLAB AND THE WALLS

During the years after WW2 some of the concrete slabs 2 x 2 x 0.10 m^3 were broken to pieces. The slabs were slightly reinforced, and the quality of concrete was poor (Figures 4–5).

A practical but important problem was to make the contract documents so understandable that the builders can estimate the lumpsum. For that reason KAREG took a lot of photos and made an overview drawing with the situations of the photos. The bill of quantities was one part of the contact documents. The contractor could then estimate the workmanship and equipment for the work (Figures 4–5).

The contaminated material paid by weights (tn) had to be lifted by crane to trucks and then delivered first by vessels to Helsinki and then by trucks to waste treatment facility. The wet contaminated material was first packed in big bags with holes for having the material without extra water but still wet (w ≤ 10 %).

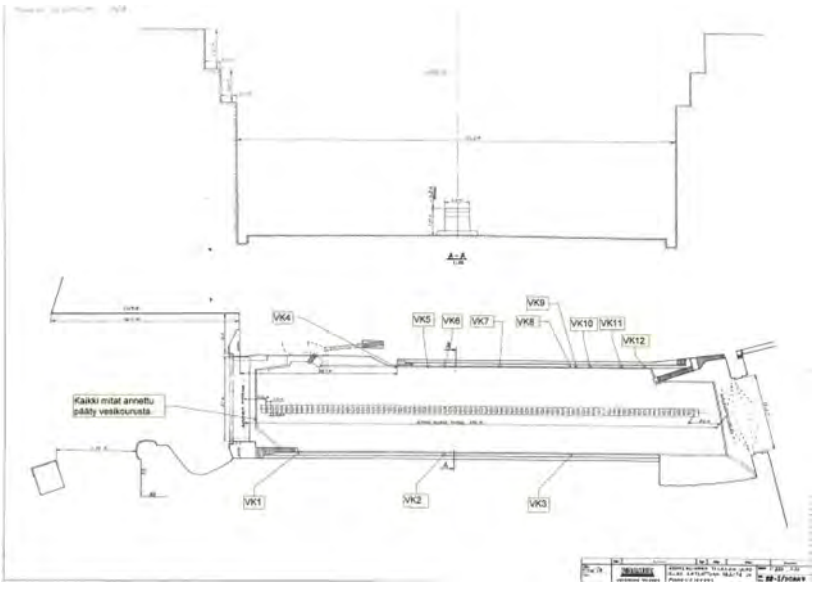

Figure 4. Section and overview. Bottom. Photos for the bill of quantitative.

Figure 5. Bottom. Section. Quantity surveying by photos.

5 CONCLUSSIONS

5.1 *Strengthening the supporting corner of the floating door*

The strengthening scheme presented is an economic and aesthetic solution to the refurbishment, restoration and preservation of understrength and unstable wall of the dry dock of Suomenlinna.

The use of the selected strengthening option and technique for structural intervention of the wall of the dry dock was found to be an appropriate technique to achieve the desired objective and at the same time being minimal invasive, quick and discreet when compared to conventional strengthening techniques. In addition, the selected method has proven effective in keeping the wall in as close to its original condition as possible for many years to come.

5.2 *Repairing the bottom*

The quantity of rebuilt dewatering channels (meters) and wipeholes (pieces) could be surveyed as exactly as possible and to be listed in the bill of quantifies. The amount of broken slabs were predicted for the bill of quantities in a practical and understandable way by photos.

To have the wet contaminated material first packed in big bags with holes and having then the moisture content $w \leq 10\ \%$ saved a lot of money.

Analytical and numerical methods for determining the stress-strain state of a soil massif for solving a planar problem

V.M. Polunin, I.S. Kolyukayev & M.R. Gorkina
SPbGASU, Saint-Petersburg, Russia

ABSTRACT: In this work, an own calculation module, written in Python and based on a numerical method for processing elements, which solves the issues of plane deformation within the framework of a linear elastic soil model. The right-hand side vector and the local stiffness matrix construction algorithms are provided. The Dirichlet and Neumann boundary conditions are taken into account using various methods that are described. The analytical solutions to the elastic problem of the stress-strain half-space and the Plaxis software are compared with the calculation results obtained by solving the problem with the calculation module. The results obtained by the developed numerical solution converge with the analytical solutions and with the results obtained in the Plaxis software package.

Keywords: boundary conditions, finite element method, linear elastic soil model, plane strain, stiffness matrix of elements

1 INTRODUCTION

Finite element method was chosen because it allows for the numerical calculation to take into account the interactions between foundation soil and structures, the interactions between materials with linear and nonlinear properties, and the intricate stratification of soils. A set of soil models that are each applicable for solving the corresponding problem are included in modern computational complexes, as well as an easy-to-use interface for developing a computational scheme and dividing the finite element mesh. However, in such calculation systems, due to their commercial nature, the program code is closed to users, which makes it impossible to add custom or make changes to existing soil models. Regarding view of this, it is necessary to develop open-source numerical calculation module that can be altered to account for unique and non-standard conditions applied to the problems of soil mechanics and geotechnics.

2 LIERATURE REVIEW

The numerical finite element method is the primary method used in geotechnical practice to calculate soil foundations [1, 2, 3, 4, 5]. Despite the popularity of computational computing complexes such as Plaxis, Midas, there are still difficulties in setting certain parameters of soil models that cannot be adjusted. Especially, in order to be able to take into account the specific conditions characteristic of weak soils of St. Petersburg [6, 7] or temperature problems [8].

The plane strain problem, which assumes that there is no deformation along an axis perpendicular to the considered plane, is used to solve an elastic problem in a plane formulation. For more information on the plane strain problem, see [9, 10, 11].

DOI: 10.1201/9781003299127-304

The following dependencies of the theory of elasticity hold true within the context of the elastic problem of plane deformation:

$$\begin{cases} \sigma_x = \frac{E}{(1-2\nu)(1+\nu)} \cdot \left(\varepsilon_x(1-\nu) + \varepsilon_y\nu\right) \\ \sigma_y = \frac{E}{(1-2\nu)(1+\nu)} \cdot \left(\varepsilon_y(1-\nu) + \varepsilon_x\nu\right) \\ \tau_{xy} = \tau_{yx} = \frac{E}{2(1+\nu)} \cdot \gamma_{xy} \end{cases} \quad (1)$$

where σ_x, σ_y = stresses along the *x, y* axes, kN/m^2; τ_{xy} = shear stresses, kN/m^2; ε_x, ε_y = relative strains along the *x, y* axes; γ_{yx} = shear deformations, *rad*; E = deformation modulus, kN/m^2; v = the lateral expansion coefficient.

The strain and stress elements in (1) can be represented as vectors in a matrix [9]:

$$\{\sigma\} = \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}, \ \{\varepsilon\} = \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} \quad (2)$$

After translating the stress vectors (2) from system (1) into matrix form, we arrive at Hooke's law:

$$\{\sigma\} = [D]\{\varepsilon\}$$
$$\downarrow$$
$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix} = \frac{E}{(1-2\nu)(1+\nu)} \cdot \begin{Bmatrix} 1-\nu & \nu & 0 \\ \nu & 1-\nu & 0 \\ 0 & 0 & \frac{1-2\nu}{2} \end{Bmatrix} \cdot \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} \quad (3)$$

where $[D]$ = element properties matrix:

$$[D] = \frac{E}{(1-2\nu)(1+\nu)} \cdot \begin{Bmatrix} 1-\nu & \nu & 0 \\ \nu & 1-\nu & 0 \\ 0 & 0 & \frac{1-2\nu}{2} \end{Bmatrix} \quad (4)$$

The purpose of the finite element method (FEM) is to find an unknown parameter, which is described by a surface function. The *x, y* coordinates, a fundamental physical principle (in our case, Hooke's law), and boundary conditions (bonds, loads, [12, 13, 14, 15]) all affect how this surface will look.

3 METHODS

In general terms, to solve the problem using the FEM, a system of linear equations is compiled, which contains the desired values of the unknown parameter, the boundary conditions of displacements and loads, body forces and fundamental laws that characterize the linear and nonlinear properties of the material. All of the aforementioned initial data are contained in three main matrices that make up the matrix analogue of such a system [16, 17, 18, 19, 20]:

$$\{s\} = [K]^{-1}\{R\} \quad (5)$$

where $\{s\}$ = the vector of values of the function of the desired parameter in nodes (in our case, the desired parameter is displacement); $[K]^{-1}$ = global stiffness matrix of elements, containing basic functions [9], FE material properties (in our case, elastic properties) and boundary conditions for displacement. Consists of local stiffness matrices determined for each FE; $\{R\}$ = the vector of the right-hand side or the vector of known values, containing the boundary

conditions of loads and displacements, as well as body forces (in our case, the own weight of the soil). Consists of local vectors of the right-hand side determined for each FE.

The displacements u and v along the x, y coordinates, respectively, are needed parameters in the plane strain elasticity problem. The values of the desired parameters within each element are presented as functions of linear polynomials of the first degree after discretizing the computational domain into a three-node FE [9]:

$$\begin{aligned} u(x,y) &= a_1 + a_2 x + a_3 y \\ v(x,y) &= a_4 + a_5 x + a_6 y \end{aligned} \tag{6}$$

where $u(x,y)$, $v(x,y)$ = displacement functions within one FE along the x, y axes, respectively (hereinafter referred to as u, v); $a_1 \ldots a_6$ = constants. Each of the functions (6) has three components for each node. In sum, these components form a local displacement vector $\{\delta\}$, which is part of the global vector (5).

The result of the matrix transformation of functions (6) [9] is the determination of relative deformations:

$$\{\varepsilon\} = [B]\{\delta\} \tag{7}$$

where $[B]$ = matrix of derivatives of shape functions (a detailed derivation of this matrix is presented in [9]).

The matrix of the form's derivative functions takes the following shape:

$$[B] = \begin{bmatrix} y_j - y_k & y_k - y_i & y_i - y_j & 0 & 0 & 0 \\ 0 & 0 & 0 & x_k - x_j & x_i - x_k & x_j - x_i \\ x_k - x_j & x_i - x_k & x_j - x_i & y_j - y_k & y_k - y_i & y_i - y_j \end{bmatrix} \tag{8}$$

According to (5), the global stiffness matrix and the global vector of the right-hand side, which are composed of the corresponding local matrices and vectors, must be known in order to identify the components of the displacement vector.

The local stiffness matrix is determined from the condition of equality of the work of the external force and the work of internal stresses at small displacements and contains a matrix that includes the fundamental law of material behavior under load, as well as a matrix of derivatives of shape functions:

$$[K] = \int_S [B]^T [D][B] dS = \Delta [B]^T [D][B] \tag{9}$$

where S = FE integration area.

Each component of the matrix [K] is an integral over the area of the element according to the area integration sign in equation (18). Integration over the area of the element can be replaced by multiplying the integrand by the area of the FE Δ [9].

The right-hand side's local vector is made up of loads and boundary conditions. It includes internal processes that take place right inside the boundaries of the finite elements; these processes are also referred to as body forces and include the self-weight of the soil. However, in problems solved in a plane setting, the body force is distributed over the area of the structure in the considered plane and along one linear meter in the direction perpendicular to the considered plane.

The body forces must be distributed equally among the nodes in each FE in order to be taken into account in the local vector of the right-hand side for the forces acting uniformly throughout the FE's entire volume. By turning the body force into a concentrated force, multiplying by the FE area, and then dividing the resulting force by the quantity of FE nodes, it is possible to distribute the force over the FE nodes.

The load value applied to the chosen design scheme boundaries is determined by the Neumann boundary conditions. Only the components of the vector on the right-hand side–the nodes of those FE—whose boundary is subject to the Neumann condition are taken into consideration. The load that is dispersed along the FE boundary is recalculated into a concentrated force and distributed evenly among its nodes by multiplying by the length of the FE boundary.

The Dirichlet conditions are taken into account in the elements of the local stiffness matrix and the local vector of the right-hand side, which correspond to the FE nodes that fall on these boundaries according to the following rule: the elements of the main diagonal of the stiffness matrix are assigned one, and the rows corresponding to the main diagonal are reset; for the vector of the right-hand side of the displacement according to the Dirichlet condition is assigned to the corresponding element of the vector according to the boundary condition. As applied to our problem, the displacement along the Dirichlet boundary along the side boundaries of the computational scheme is equal to zero in the direction of the x axis and zero in the direction of both axes along the lower boundary.

The local stiffness matrix and the local vector of the right-hand side take into account stiffness parameters and boundary conditions for each FE separately. However, the calculation of the unknown displacement vector is performed for the entire computational domain, which includes many FEs, so it is necessary to ensure their joint interaction. Since the FEs are connected at the nodes, the neighboring FEs will have nodes with a common number in the global reference frame. Accounting for the interaction of FE with each other is provided by summing the elements of the corresponding blocks of the local stiffness matrix and the local vector of the right-hand side according to the corresponding numbers of nodes in the global system.

The components of the stress and relative strain vectors (2) act over the entire area of the FE. The stress vector for each FE is determined according to Hooke's law (3) through local displacement vectors $\{\delta\}$, determined by the results of finding the general displacement vector (5), the matrix of element properties [D] and the matrix of derivative functions of the form [B]:

$$\{\sigma\} = [D]\{\varepsilon\} = [D][B]\{\delta\} \tag{10}$$

The authors have created a calculation module that implements the definition of the stress-strain state of the soil mass for an elastic problem in a flat formulation in accordance with the aforementioned algorithm. Further, the results of calculations of the stress-strain state of the soil mass from the application of a strip load are given and a comparison is made with analytical solutions and solutions in the Plaxis software package. The design scheme is shown in Figure 1.

Basic formulas for calculating stresses through rigorous analytical solutions [6]:

1. Normal vertical stresses from the application of a strip load σ_{zp}:

$$\sigma_{zp}(x,z) = \frac{-p}{\pi}\left(\operatorname{atan}\left(\frac{0,5b-x}{z}\right) + \operatorname{atan}\left(\frac{0,5b+x}{z}\right)\right) - \frac{-b\cdot p}{\pi}\cdot\frac{z\cdot\left(x^2-z^2-0,25b^2\right)}{\left(x^2+z^2-0,25b^2\right)^2+z^2b^2} \tag{11}$$

where p = band load; b = band load application width; z = depth;

2. The value of relative deformations:

$$\varepsilon = \frac{-\sigma_{zp}(x,z)\cdot\beta}{E(z)} \tag{12}$$

where β = coefficient taking into account the transverse expansion of the soil;

3. Base settlement:

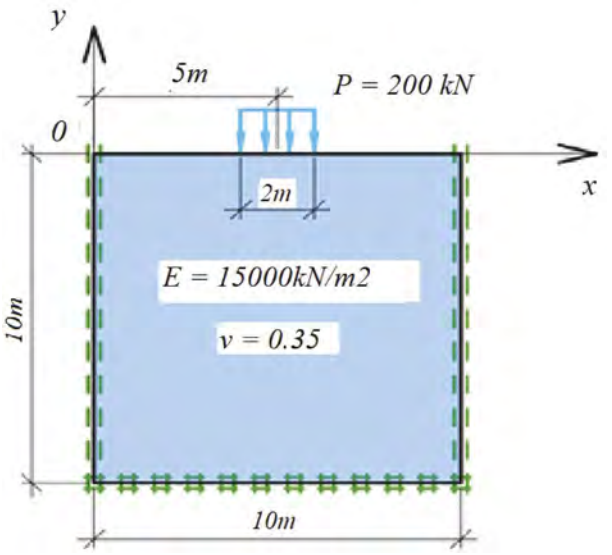

Figure 1. Calculation scheme.

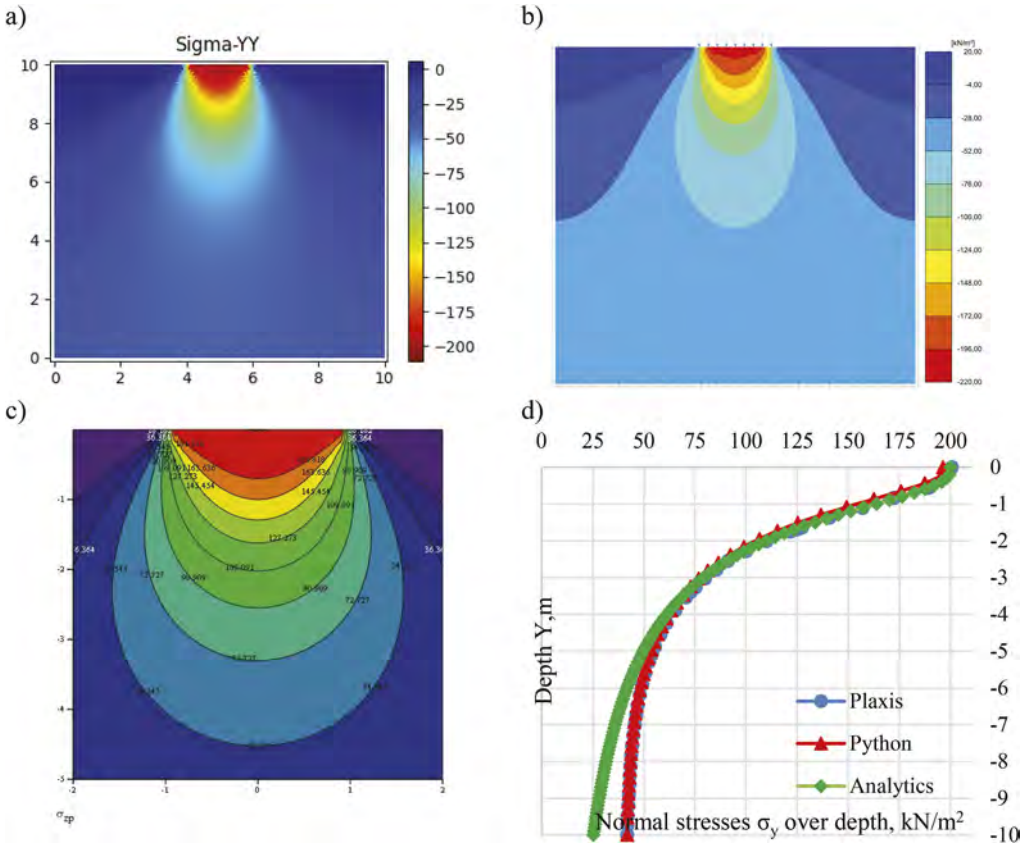

Figure 2. Calculation results of normal stresses σy from the applied strip load.

$$s = \int_0^{Hc} \varepsilon dH \tag{13}$$

where H_c = depth of compressible thickness equal to 10m.

Figure 2 shows calculation results of normal stresses σy from the applied strip load a – stress isofields obtained by means of the calculation module written by the authors; b – stress isofields obtained in the Plaxis software; c – stress iso-fields obtained by rigorous analytical solutions in Mathcad; d – comparative graph of the results obtained in the center of application of the load in depth: blue line - results “a”; red line - results “b”; green line - results “c”.

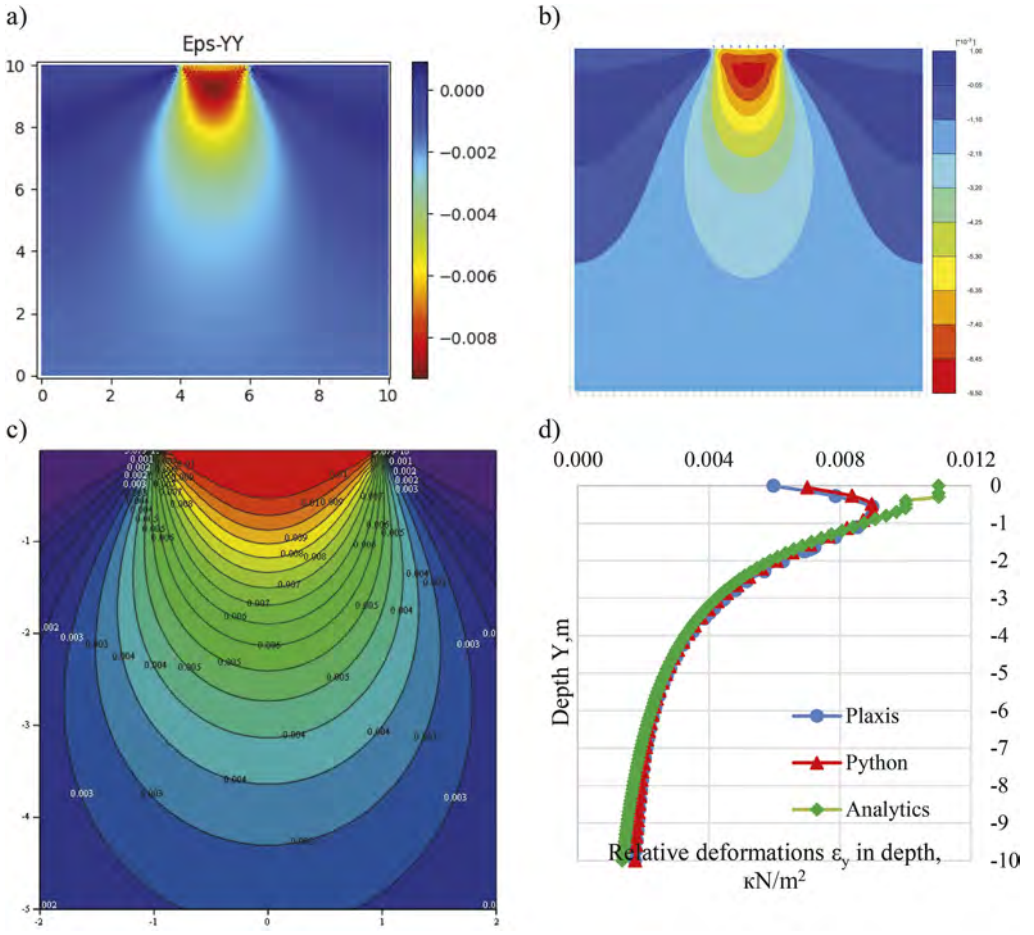

Figure 4. Results of calculation of relative deformations εy from the applied strip load.

4 CONCLUSIONS

1. The stresses and displacement isofields that were calculated using the three methods mentioned above have a general distribution.
2. Plaxis and Python charts built on the basis of the calculation results have the highest convergence compared to the Analytics chart.
3. In contrast to the computational module created by the authors, which uses 3-node FE with first-degree interpolation polynomials and a structured FE mesh, Plaxis software employs 15-node FE with fourth-degree interpolation polynomials and an unstructured FE mesh. The Plaxis program can generate highly accurate calculations thanks to a significant amount of interpolation and an unstructured grid. However, both calculations showed

a convergence of over 95% despite the disparity in how the interpolation accuracy was implemented between Plaxis and the Python calculation module within the context of a flat elastic problem of determining the stress-strain state in a soil mass.

4. The algorithm described can be used as a foundation for calculations of nonlinear problems where the distribution of stresses in finite elements is crucial.

ABSTRACT: An anisotropic constitutive model (BBM) has been implemented in a finite difference-based computer program to simulate the geo-mechanical behavior of unsaturated soils subjected to continuous wetting and drying. In this view, the Barcelona Basic Model (BBM) has been implemented into the finite difference-based computer program to clarify the mechanical behavior of fine-grained partially saturated soils during the wetting process. This numerical modeling was verified based on available data in the literature review. The application of the code was investigated for modeling a slope considering the suction-induced process. The research also determined the effect of the over-consolidation ratio in partially saturated or unsaturated soils, especially stress paths, as a modification to yield relation. In this regard, a soil structure system and its capability for checking the instant and consolidated settlements in different stress paths have been evaluated. Based on the results, finite difference methods with BBM and modified BBM efficiently demonstrate the actual behavior of unsaturated or partially saturated fine grained soils. Moreover, OCR criterion has been added to BBM fundamental relations to improve its application in wetting-Induced processes. In this way, more rational results have been gained by this modification.

Keywords: Continuum mechanics, Barcelona Basic Model, unsaturated soil, Bending failure, improvement systems, finite difference analysis, fine grained soils

1 INTRODUCTION

A geo-mechanical constitutive model for considering the elastoplastic behavior of partially saturated soils is known as Barcelona Basic. This model was developed and presented in the earlier 1990s by extending the Modified Cam-Clay (MCC) model for unsaturated soil conditions (Alonso et al. 1990). The model has to describe specific aspects of unsaturated-soil behavior, including wetting-induced swelling or collapse strains, depending on the magnitude of applied stress, as well as the boosting in shear strength and apparent pre-consolidation stress through suction (Gens et al.,2006; Sadeghabadi et al. 2021). A key factor in the design procedures of soil stabilization systems is studying the mechanical behavior of clays in the porous medium, especially expansive soils. An appropriate model for this type of soil is required for numerical simulations. Alonso et al. (1987, 1990) presented the (BBM) describing the low activity stress-strain behavior of partially saturated soils. Figure 1 represents the 3D

*Corresponding author: a_noorzad@sbu.ac.ir

DOI: 10.1201/9781003299127-305

yield surface in $\bar{p} - q - s$ space, where $\bar{p}$ is the net mean stress (i.e., total stress minus air phase pressure), q is the shear stress, and s is matric suction. In this paper, the the BBM into a coupled multiphase fluid flow has been implemented in FLAC.

In Figure 1 the 3-Dimensional yield criteria in $p - q - s$ space has been represented, in which p'q and s are the net mean stress, shear stress and suction, respectively. As shown, both saturated and unsaturated status has been depicted. In two-phase zone, the first variable is air pressure, which is greater than water pressure (vanapalli and Oh 2014). Therefore, for saturated and unsaturated cases, the behavior of soil model is related in these stress variables. The first one is net mean stress and the next is suction, identified in Eq. (1) and (2).

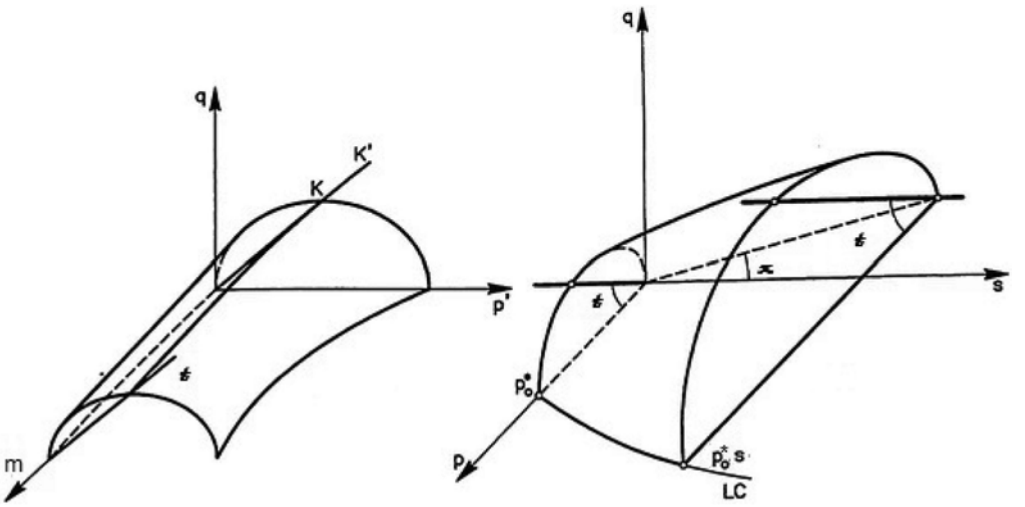

Figure 1. The yield surface in 3-D space for BBM (after Alonso et al. 1990).

A well-known sample for a single stress measured for unsaturated soils refer to Bishop's proposal for a general effective stress σ' to un-saturated states (Bishop, 1959) who identified an averaging parameter χ, being a function of the water pressure u_w:

$$\sigma' = \sigma - (1 + \chi)u_a - \chi u_w \tag{1}$$

Fine-grained soils in earthen structures such as slopes are usually under unsaturated conditions. In this study, an applicable model from Zheng and Lytton (2012) has been considered to demonstrate a compacted soil fill structure's suction response to estimate model displacements. In these structures, the wetting-induced proceedings occur while rising the water table. Volumetric and linear strain change behavior has been investigated in disparate confining stresses toward loading collapse (LC).

Stress paths have been produced for two instances, one for BBM and the other for BBM, considering the over-consolidation ratio, which has been carried out by describing an algorithm in Finite Difference formulation, then comparing them with experimental results of Alonso's research. Finally, immediate and consolidation settlements and vertical displacements of the soils are presented.

2 VERIFYING THE MODEL BY FINITE DIFFERENCE METHOD

FISH is a program with a Finite Difference Method (FDM) base linked with FLAC. This language program provides opportunities for users to introduce new variables and functions. Also, servo-control could be used to simplify numerical modelings (Ho and Hesieh 2018). The

wetting and drying-induced paths due to suction changes have been depicted by decrement from an identified value to the minimum. This analyzing method can simulate the reduction changes in suction relatively simply. Volumetric deformation related to the wetting-induced problem (After Gens et al. 2006) has been depicted in Figure 2, which has produced a stress path in the SI part of the yield surface. In this moving chart, the elastic zone is along with the route ABFH inducing a bit of swelling.

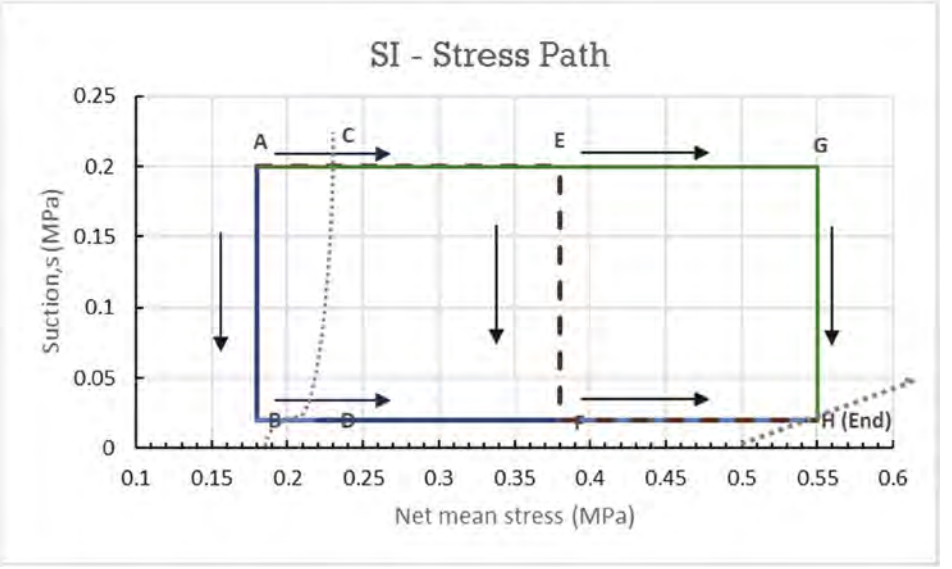

Figure 2. Stress paths in this study (Gens et. al 2006).

In Gens's research, the specimen had been compressed to a specific value for net mean stress in the path AEFH. For smaller stresses, the soil experienced a little swelling. A comparison of the results indicates an acceptable agreement between the experienced (Alonso et al. 1990) and numerical analysis obtained using FDM (Figure 3).

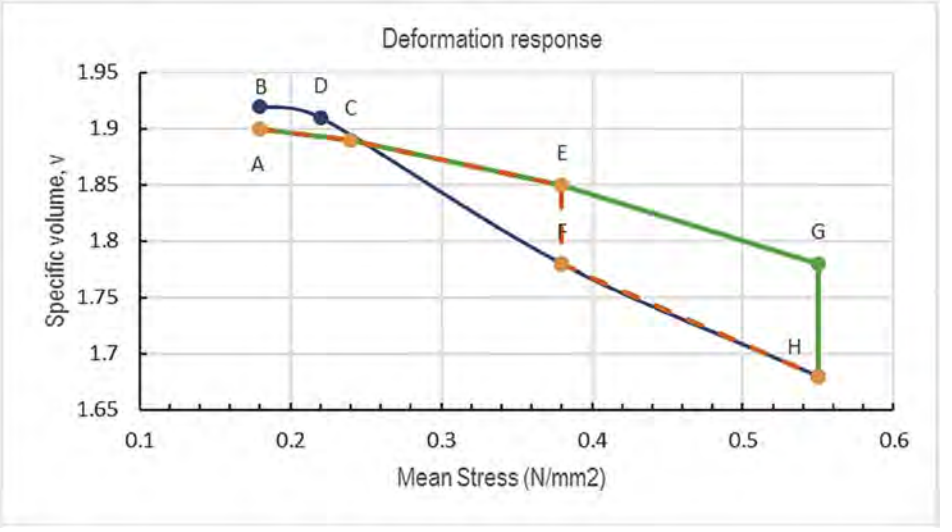

Figure 3. Numerical analysis prediction and experimental model analytical results comparison in the stress paths.

This approach causes wetting process shorten leading to suction reduction.

2.1 *Modeling of a soil structure in an unsaturated approach*

A soil slope structure has been considered to evaluate modeling application in design criteria in different stages of construction and matric suction contents. Table 1. indicates unsaturated soil parameters related to BBM, which have been utilized for the present model. These parameters were reported by Josa et al. in 1987.

Table 1. BBM parameters from Josa et al. (1987).

	Stress Phase				Matric Suction Phase						Reference stress parameters	
Soil type	λo	K	β $(MPa)^{-1}$	r	P^c MPa	λs	κs	G MPa	M	a	Pp_o	S_o MPa
CK	0.14	0.015	16.4	0.20	0.04	0.05	0.001	3.0	1.0	0.8	0.06	0.03

CK Compacted Kaolin

In this part, the Compacted Kaoline (CK) from Josa et al. 1987 with definite unsaturated model parameters have been categorized as the model properties. On the other side, the stress paths are generally utilized to characterize parameters captured from isotopically triaxial tests presented by Alonso et al. (1990). The soil slope structure has been demonstrated by numerical modeling in Figure 4. This centrifuge model was constructed in research executed by Zhang and Lytton (2009a).

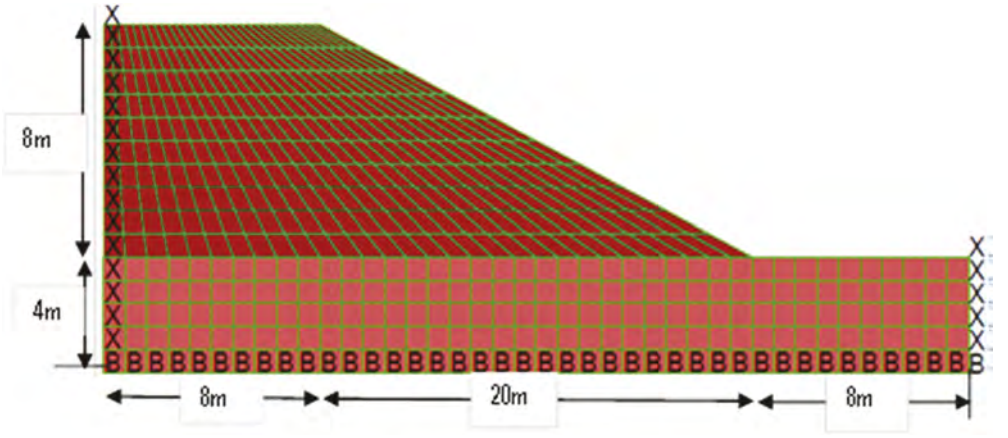

Figure 4. Numerical model of the soil slope structure (after Zheng and Lytton).

The partially saturated zone (Body) and the saturated zone (Foundation) of the slope have been modeled with BBM and Mohr-Coulomb (MC), respectively. Boundaries at the bottom have been fixed in the X and Y directions and lateral sides in the X direction. BBM codes have been implemented for analysis of unsaturated to partially saturated parts with the initial value of 150 kPa for matric suction. In the centrifuge model, the soil structure has been constructed in 8 continuous parts. While the suction value changes from the amount of 150 kPa to zero, the whole slope has been subjected to transient equilibrium.

In this way, natural situation in real construction process could have been better demonstrated.

2.2 *Discussion on implemented model*

The BBM codes programming by FISH were utilized to make analytical solutions and to be compared with those in the same conditions in the experimental research. In the first step, by calculating displacements in the Y-direction, the values of 63 mm and 144 mm have been reached, respectively, which are in good agreement with the same in the literature. Therefore, numerical analyses are applied for evaluating settlements and displacements in the lateral direction in various conditions.

With providing partially saturated to fully saturated zone in numerical modeling, settlements of the slope base in various distance from the centerline are measured. Figure 5 illustrates settlements in comparative charts gained from the current research and former experimental studies. In this figure, by following the fully saturation, the settlement of the slope surface is about two times larger than that at the initial situation. In current study, vertical displacements has reached 205 mm and while the value of 196 mm had been recorded in the literature.

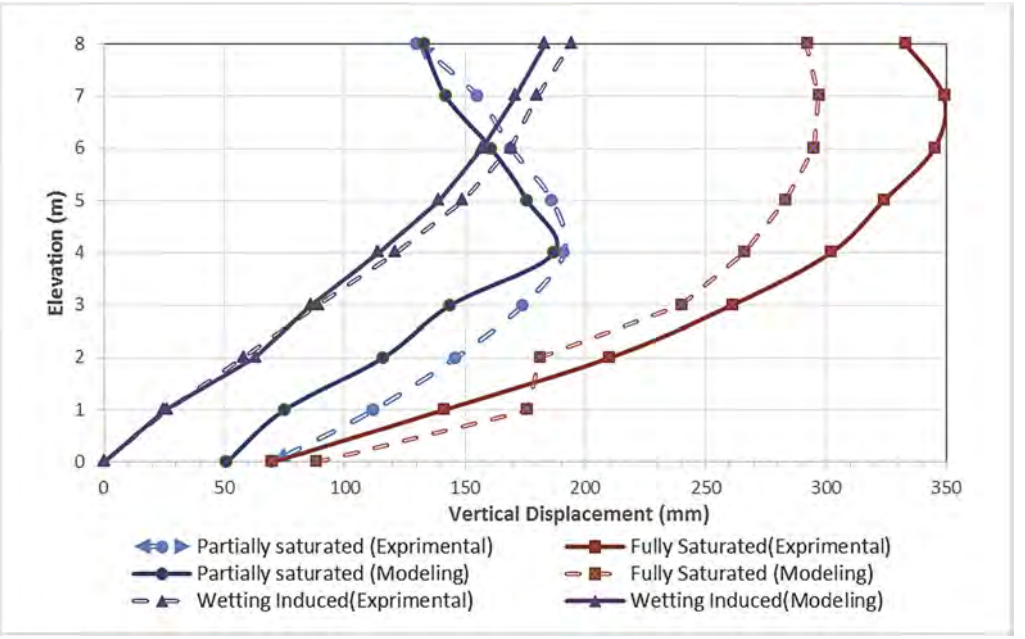

Figure 5. Comparative charts for vertical displacements in partially and fully saturated, and wetting-induced process.

Vertical displacements of the slope at a different elevation have been presented in Figure 6 including he maximum settlement related to Zhang and Lytton experiments and also present study, have taken place at the upper third-height of the soil structure. Cause the slope has been constructed in stages, the accumulative displacements have been resulted since the placement of each level. Also, the modeling results are in fine agreement with the same comparative values extracted from literature.

3 EVALUATION OF WETTING AND OVER CONSOLIDATION IN UNSATURATED MEDIA

According to the previous studies on unsaturated soils the most researchers had focused on studies related on the mechanical behavior of partially saturated soils. Relevant constitutive models have been developed to predict the stress-strain behavior of normally or over-consolidated unsaturated soils (Mojezi et. al 2018; Sadeghabadi et al. 2022).

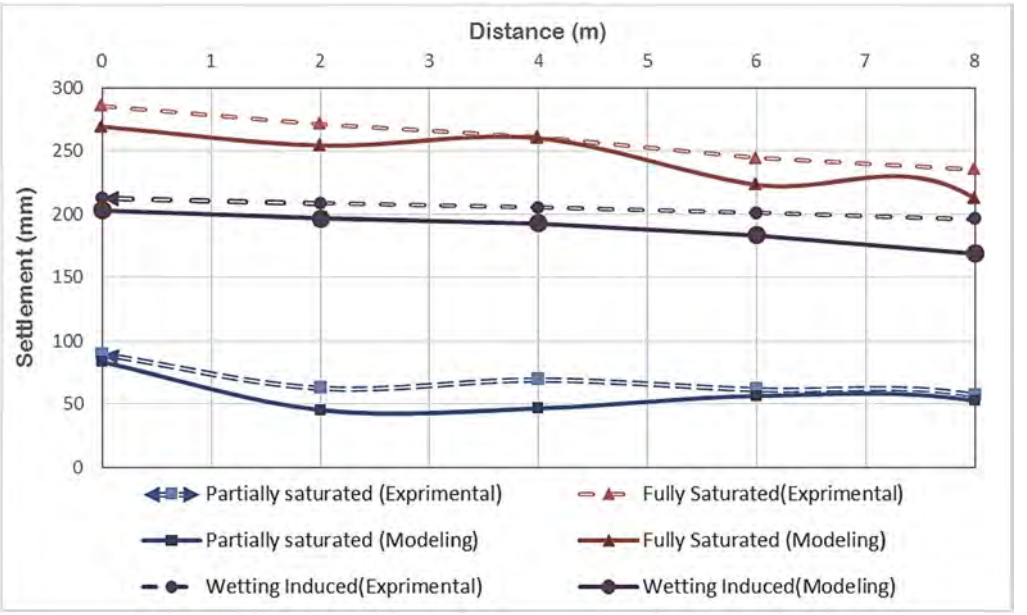

Figure 6. Comparative charts for settlements in different stages in partially and fully saturated, and wetting-induced process.

Since the initial principles of soil mechanics have been from the study on fully saturated soil behavior, some remarkable progresses in comprehension of unsaturated soil behavior have been observed in the last decades, both in experimental and in theoretical analysis (Alonso et al. 1990; Cui and Delage 1996; Fredlund et al. 1996; Wheeler 1996). However, by the recent studies, unsaturated soil mechanics problems are still in an initial stages and involved in a number of unsolved problems.

The critical state in stress spaces and Hvorslev state surfaces have been studied for an over-consolidated unsaturated fine grained soil through a complex of suction -controlled laboratory researches. For silty compacted soils, the history of applied stress can also be reflected by the different densities nearly, and the effect of density on the geo-mechanical behavior of these types of unsaturated soils has been studied.

Figure 7 has demonstrated the volume change behavior in unsaturated specimens in initial matric suction 300 kPa. As can be seen from the figure, in normally consolidated conditions, the curves has been dilated however in over-consolidated ones contractions are observed. (Zhu et al. 2018).

On the other side, as demonstrated in Figure 8. the compression curve decreases while suction value is being increased in a fine grained unsaturated soil. As can be seen, the slope of the unloading curve hasn't been changed (Alonso et al.1990). On the presumption that the values of plastic volume strain at points X and Y are equal, the equation for function of the yield curve (Loading-Collapse) can be gained as following relation:

$$\frac{Po}{p^c} = \left(\frac{p_o^*}{p^c}\right)^{\left(\frac{\lambda(o)-\kappa}{\lambda(s)-\kappa}\right)} \tag{2}$$

In this equation p_0^* and p_0 are pre-consolidation pressures for saturated and unsaturated fine grained soils, κ is the slope of unloading line for unsaturated states; $\lambda(0)$ and λ (s) are the slopes of the compression curves for saturated condition; and p^c is the pre-consolidation stress under saturated conditions ($s = 0$).

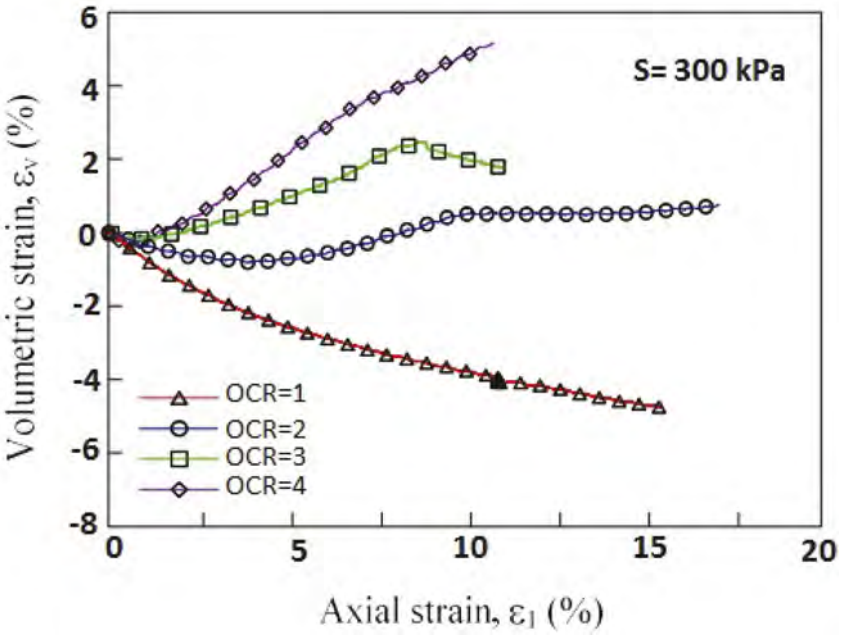

Figure 7. Volumetric strain changes in different over-consolidation ratios for a definite value of matric suction (Zhou et. al 2018).

By Alonso's experimental studies, as categorized in Figure 2 there are stress paths named BDFH, ACEGH, and ACEFH. In the present study, the path BDFH has been investigated using an over-consolidation phenomenon in unsaturated model (BBM). In Figure 9 comparative charts have been identified as the results of Alonso's experimental studies, Numerical Modeling prediction, and BBM with OCR consideration. The curves produced in Figure 9 mention that applying over-consolidation as a modification in (LC) yield relation, causes more acceptable results that match the experiment compared with normally consolidation states.

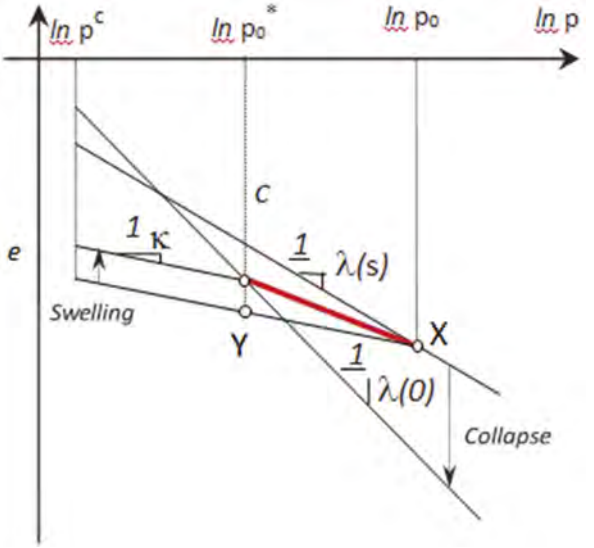

Figure 8. The relationship between p_0^* and p_0 (Alonso et al. 1990).

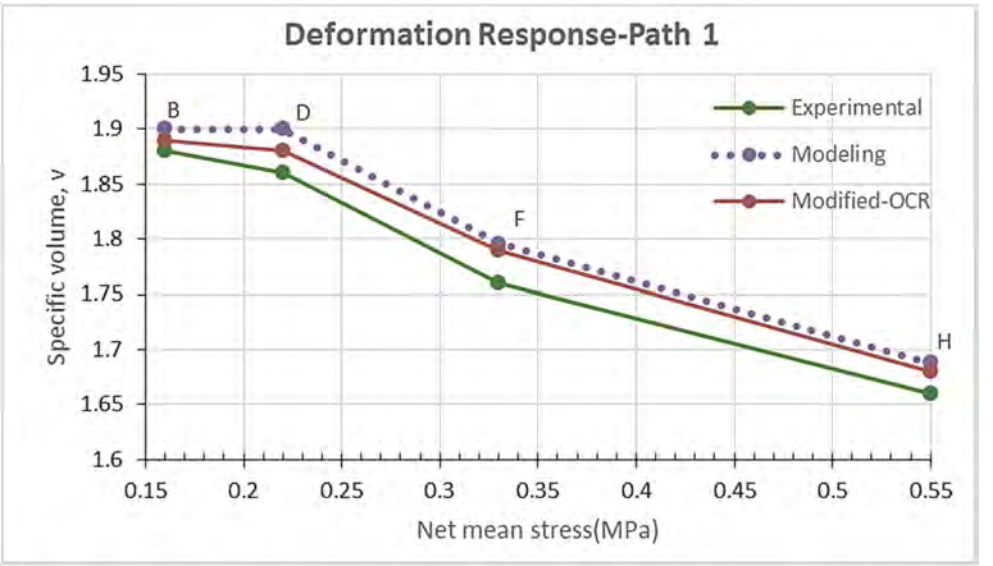

Figure 9. Comparative curves of numerical modeling, Alonso's experimental results, and modeling with OCR modification for stress path BDFH.

By investigation on the current soil structure, it's concluded that considering over-consolidation phenomenon has a positive effect on an optimized design of soil slope in partially saturated or unsaturated media with minimum settlement approach. As demonstrated in Figure 10, three cases of numerical modeling, Alonso's experimental results, and modeling with OCR Modification for stress path BDFH, for calculating vertical displacement of upper crust of the soil structure have been presented in which the path based on the OCR consideration has a better situation compared to the real circumstances.

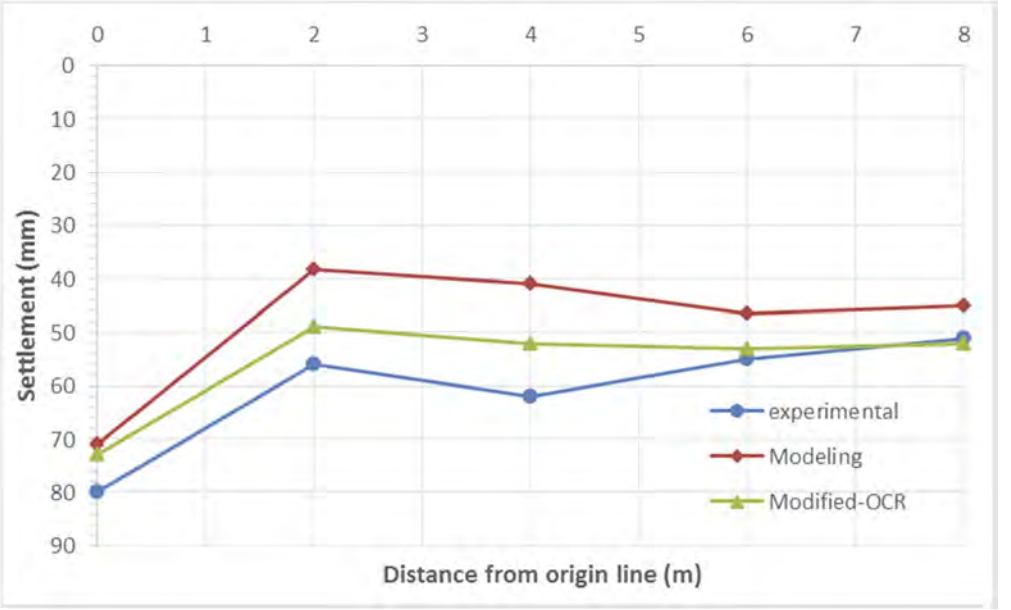

Figure 10. Vertical displacement of crust of the surface at different cases along the path BDFH.

4 CONCLUSIONS

The current study has been directed to achieve innovated methods for slope design and foundations in soil construction subjected to wetting in partially saturated or unsaturated medium. To achieve this subject, numerical modeling in Finite Difference approach was applied to investigate on a definite constitutive model based on the Alonso's former study. The initial target was checking geo-mechanical behavior of unsaturated soils. The current model was examined utilizing different case studies. On the other side, analytical computations were performed to test and optimize the finite difference program (FISH).

The study clarified that considering over-consolidation in an unsaturated constitutive model leads to preferable results comparing with the original model in stress path approach. Moreover, stress paths in BBM yield surfaces (i.e., LC and SI) are the most effective segment to simulate behavior of unsaturated soils, wetting-induced process, and volumetric strain variations. In this way, demonstrations of stress paths in BBM with the Characterized algorithm in FISH program indicate fine agreement with Alonso's experimental research. The checked model depicts a rational compliance to check practical engineering programs such as the response of a slope structure subjected to wetting and drying processes. Moreover, in wetting induced duration, OCR as a modification in BBM matches better with stress paths in the based model. The results indicate that the slope structure has a significant effect on settlements throughout the wetting and drying. The relative vertical displacements can be decreased significantly at higher value of matric suction when role of over-consolidation in LC yield function in BBM, is considered. As an example in S_i=150 kPa, the after fully saturation, the surface settlement in the slope has been approximately 65 mm larger than that for S_i=100 kPa. while, this difference in settlements for the modified model is less than 44 mm. It can be also derived from modified BBM that considering OCR in BBM formulation results a lower value of settlements. Vertical and lateral displacement analysis of the model with this modification have no more difference about 5% from to experimental results. Furthermore, investigation on differential displacements of the slope surface through a definite stress path has come to similar conclusion with unsaturated approach.

In unsaturated media, matric suction variations are in such a close relationship with over-consolidation conditions that considering this parameter into unsaturated models has a remarkable effect on both stress paths and consolidation's displacements. The current study conclusions can be applied for more optimize design of soil structures, slopes, and pavements related to loading-unloading cases on partially saturated or unsaturated over-consolidated soils.

Introduction of geotechnical modelling and seismic disaster prediction in the case of Utsunomiya City, Tochigi Prefecture, Japan

T. Seiki
Utsunomiya University, Utsunomiya, Japan

K. Soramoto
Kanto Regional Development Bureau, MLIT, Mito, Japan

ABSTRACT: The authors have tried to propose the geotechnical model of Utsunomiya City, Tochigi Prefecture, Japan based on borehole data from the local governments of Tochigi prefecture, Japan by the Three-dimensional grid model method. Its grid has 250m in each side. This method includes averaged geological feature around boreholes by geostatistical concept. At first the authors had assembled the borehole data from the local government. Actually, even though it is difficult to get sufficient numbers of borehole data, it has done someway. The authors discussed the geological and topological characteristics in this area. Finally, the authors carried out seismic stability analysis to consider in the area. Based on the results, we considered the seismic intensity of the area on the geotechnical model. As local government also has opened hazard map on the website, we compared those results and discussed the seismic response in this area.

1 INTROUCTION

1.1 *Background*

Geological and geotechnical information on the subsurface structure is a public asset, which can be used not only for earthquake disaster prevention but also for various other fields. In the past, a large number of subsurface structural investigations have been carried out for various purposes in Japan, but these data have not been fully utilised except for limited purposes, and some of them have been in danger of being lost. On the other hand, recently concept of digital transformation is focused on applying and utilising that geotechnical information actively to prevention for natural disaster.

1.2 *Objectivity*

In Utsunomiya City, which is a capital city in Tochigi Prefecture, Japan, a hazard map that assumes damage from floods and landslides that may occur as a result of large-scale natural disasters, and a map that indicates the index of shaking susceptibility, have been prepared. Hazard maps that not only show where buildings will shake in an earthquake, but also take into account building collapse, ground cracks and so on, are required (Utsunomiya City Hall, 2020). It is desirable to identify and visualise the possibility of earthquakes from viewpoints other than floods and landslides, so that citizens can know where exactly they should evacuate to in the case of an earthquake. As a first step towards the disaster prevention, this study analyses geotechnical information models using earthquake ground motions.

2 GEOLOGICAL MODEL FOR UTSUNOMIYA CITY

2.1 *Geotechnical model for Utsunomiya City*

In this study, a three-dimensional grid model (hereafter 3D grid model) was created using its construction programme (Kimura, et. al, 2011), which was created as a means of linking

DOI: 10.1201/9781003299127-306

geotechnical information from a nationwide perspective, as was the objective of the National Geotechnical Information Map Creation Support System. The elevation ranges from about 100 m to 160 m, decreasing from north to south. There is relatively little difference in elevation between the east and west, and the terrain is gentle. In addition, the distribution of the strata is dominated by gravelly soil, with sandy soil, clayey soil and volcanic ash clay. A 3D grid model of Utsunomiya City is created using its construction programme. The number of borehole data used to create the 3D grid model in this study is 953. The borehole data were provided by Tochigi Prefectural Government and Utsunomiya City Hall. Although there are relatively more borehole data in Utsunomiya City than in other cities in Tochigi Prefecture, the distribution range of the data is very uneven. If more accurate modelling is to be aimed at, it is necessary to narrow down the range. Therefore, in this study, it was decided to model the central area of Utsunomiya City, where many borehole data were distributed (blue dots in Figure 1).

2.2 *Example of cross section in 3D grid model*

The starting latitude and longitude of the central section is Lat. 36.56 degree North and Long. 139.83 degree East, and the ending latitude and longitude are Lat. 36.56 degree North and 139.94 degree East. The elevation of the central part of Utsunomiya City is not so high, which is around 110 m to 120 m, but the elevation differs between the east and west sides of the city, with the central part of the model as the boundary. The soil types in this area consist of clay, sandy soil, gravelly soil, Kanto loam and topsoil, with the central part also mostly gravelly soil. The surface layer is mainly Kanto loam in the western part, with topsoil in the other parts. In terms of stratigraphy, the surface has been covered by vegetation and only fragments can be observed, and the strata themselves have been deformed by folding, faulting and other fragmentation, or have been partially lost due to erosion (Yoshikawa et.al, 2010). The terrace deposits, alluvium and terrace deposits are separated from the west, so there is a difference in elevation at the centre of the terrace. The area on the left-hand side or west side of the figure, where the elevation drops sharply, is fed by a river. The borehole data are also reasonably well represented in this area.

3 SEISIMIC STABILITY OF MODELS

3.1 *Seismic response analysis using earthquake ground motions*

In this section, the earthquake records of relatively small magnitude less than M6.0 at each location, which is hereafter referred to as small earthquakes, are the 3.2 magnitude earthquake centred in southern Ibaraki Prefecture on 27 November 2018 and the 2011 off the Pacific coast of Tohoku Earthquake, which is hereafter referred to as 3.11 earthquake and is the largest earthquake that has occurred around Tochigi Prefecture in recent years and caused much damage within the prefecture. In this paper, the authors mentioned the results from small earthquakes. The East-West and North-South components of the acceleration of the seismic wave system were applied to individual grid of the 3D grid model corresponding to each axis. From the observed acceleration data at KiK-net TCG007, sections with relatively large acceleration were extracted, and the seismic waveforms were prepared and input to the analysis model for approximately 120 s, which is the S-wave part of the seismic wave where large changes in acceleration were observed.

3.2 *Seismic analysis of geotechnical models*

In this section, representative geotechnical models were selected from the northern, central and southern cross-sections of Utsunomiya City as section 1, section 2 and section 3(Figure 1) for seismic response analysis by the equivalent linearization method by DYNEQ. In order to make the seismic response analysis more accurate and to reproduce realistic phenomena, and to confirm the differences in seismic response due to differences in geological structure, the geotechnical models were selected on the basis that they contain as much borehole data as possible and have the topographical and geological characteristics of each region. This paper mentioned the results om section 1(Figure 2). The selection assumed that the model should contain as much borehole data as possible and have the geomorphological and geological

characteristics of the regions. The N-value and S-wave velocity models for the regions from section 1 to section 3 created during the construction of the 3D grid model. The N-values show the distribution resulting from quadratic interpolation, and the conversion to the S-wave velocity model uses equations of Ohta and Goto (Ohta, Y. and Goto N., 1978). In consideration of the conversion to S-wave velocity (m/s), the upper limit of the N- value was set to 50. The S-wave velocity model clearly shows a gradual increase in S-wave velocity in the direction of depth, reaching 50 m/s at the top and more than 550 m/s at the deepest part. This S-wave velocity model can be used for seismic response analysis.

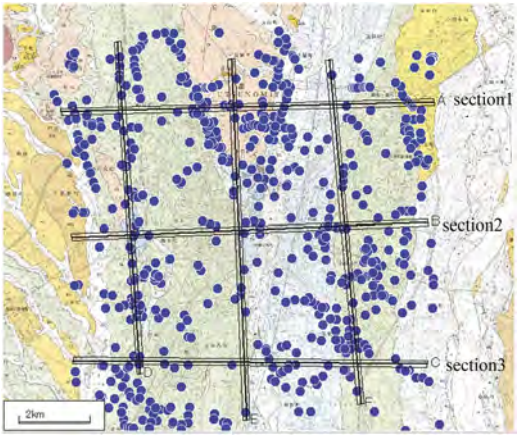

Figure 1. Geology map and borehole data location of Utsunomiya City, blue dots show the borehole location, solid lines are location of cross section.

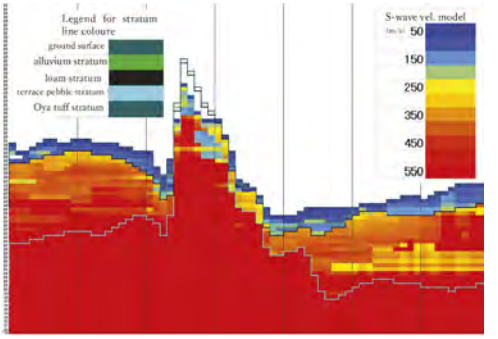

Figure 2. North cross section of S-wave velocity on the 3D grid model (section 1).

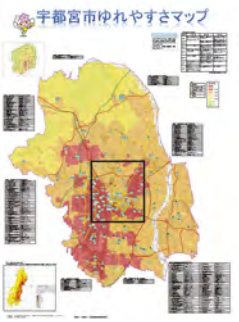

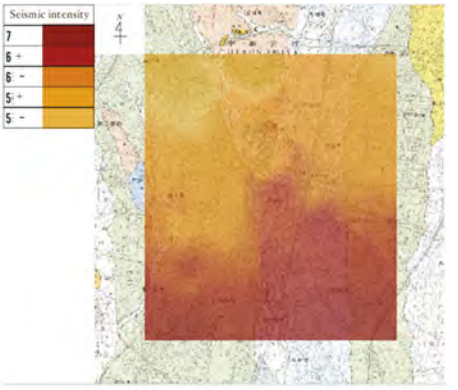

Figure 3. Utsunomiya City Shakeability Map (in Japanese, left hand side) and the seismic intensity distribution on 3D grid model by 3.11 earthquake (right hand side). Solid rectangle on the left figure is the area for 3D grid model on the right figure.

3.3 *Using seismic data for disaster prevention against earthquakes*

The acceleration of the seismic waveform calculated is transformed according to the method specified by Japan Meteorological Agency, JMA, and the measured seismic intensity is calculated. This result is compared with the measured seismic intensity actually observed, and the seismic behaviour of the ground under consideration is discussed. The measured seismic intensities obtained from the seismic data observed in Utsunomiya City at Kik-net TCG007 and those occurring near the ground surface of the analytical model took similar values. Hazard maps in Utsunomiya City provide

information on evacuation and preparation in the event of an increase in the risk of large-scale flooding or landslides due to typhoons, torrential rains or earthquakes, with the aim of predicting the areas where damage may occur and the extent of damage, evacuating citizens to a safe place quickly and minimising the damage. The information on evacuation and preparedness is compiled for the purpose of minimising damage. The shaking susceptibility map shows the location of evacuation centres (left hand side of Figure 3). The seismic intensity-converted values obtained by analysing the input seismic waves of 3.11 earthquake uniformly to the geotechnical model are shown as areal distributions in QGIS software (right hand side of Figure 3). The seismic values obtained from the seismic intensity conversion of the 3D grid model are visualised by the different colours. The conditions are divided into 69 grids in the east-west direction and 81 grids in the north-south direction, and the seismic intensity is converted for each of them. The seismic intensity map shows the distribution of seismic intensity when an earthquake of magnitude 6.9 occurs, with the epicentre as the City Hall (main office). The similarity between these maps is that the southern part of Utsunomiya tends to be more vulnerable to shaking in the flat areas. The Utsunomiya hillside area is at risk of landslides and is subject to evacuation. The difference is that the seismic intensity map of Utsunomiya City has a coarser stepwise distribution of seismic intensity in the southern part of the city. If the grid can be divided more finely, as in this study, detailed information on shaking susceptibility can be obtained.

4 SUMMARY

In this study, an attempt to update and compare the 3D grid model was made in Utsunomiya City, the prefectural capital of Tochigi Prefecture, Japan using borehole data provided by the city hall and prefectural government. The validity of the 3D grid model and the geological characteristics of each area were confirmed and examined for use in disaster prevention through seismic response analysis using one-dimensional seismic response analysis by DYNEQ. The characteristics of the models created were discussed by comparing them with the columnar maps and geological history illustrated for each cross section. The results of seismic response analysis are discussed. Section 1, section 2 and section 3 are divided into three analytical sections. This paper has mentioned section 1 only. The S-wave velocity model clearly shows a stepwise increase in the S-wave velocity model in the direction of depth. The input seismic waves were strong earthquake and a small earthquake. The three patterns in this analysis showed a similar tendency in terms of shaking susceptibility. Finally, the seismic intensity distribution based on the seismic intensity conversion of the 3.11 main shock and small earthquakes is shown for use in disaster prevention against earthquakes. Regarding evacuation centres, it was stated that evacuation centres are expected to be set up in the northwestern part of Utsunomiya City, which is a flat area with low seismic intensity. The seismic analysis in this study differs in some respects from the method of geotechnical modelling and the consideration of seismic models in the government's evaluation of strong ground motions, but the seismic analysis using the 3D grid model was connected to the seismic intensity distribution to create the basis for the hazard map. Comparing the created hazard map with the shaking susceptibility of Utsunomiya City, the similarity is that the southern flat area of Utsunomiya shows a tendency to shake easily and is a dangerous area. In addition, parts of the Utsunomiya hills are at risk of landslides and are subject to evacuation. The difference is that the seismic intensity map of Utsunomiya City has a coarser gradient distribution in the southern part of the city.

ABSTRACT: Clay with different moisture contents has very different mechanical properties, which are vital for the stability of geotechnical structures. When desiccation cracks start to develop, the failure of soil structure might happen. Traditional image processing methods have been extensively applied to analyze the development of desiccation cracks in clay. However, these image analysis methods usually rely on the interval image shooting technique, which lacks continuity and might miss some critical moments during cracking process. This study proposes a deep learning-based video instance segmentation algorithm to locate, identify and segment soil cracks in real-time video stream. The training loss was found less than 0.1. The algorithm could record the cracks' locations and numbers simultaneously. Besides, the crack ratio of clay could be calculated by crack pixels divided by total clay pixels among the entire soil cracking process. The proposed video instance segmentation method monitored the soil crack reached a number of 25 and the crack ration was about 8.5% at the experiment end, which has demonstrated the potential application for crack monitoring of geotechnical infrastructures via surveillance cameras.

1 INTRODUCTION

The generation and propagation of the desiccation crack network within clayey soil is a complex phenomenon controlled by the coupling of soil hydraulic and mechanical characteristics.The propagation of the desiccation crack network could deteriorate the engineering performance of clayey soil, and change the hydraulic properties of soils. Therefore, it is crucial to characterize the patterns of desiccation cracks in clayey soil as they have practical solid implications in geotechnical and geoenvironmental engineering (Lakshmikantha et al., 2009; Taboada et al., 2008).

Traditionally, the inspection and acquisition of soil desiccation crack patterns require in-situ manual measurements (Dasog & Shashidhara, 1993), which take a lot of effort and resources to complete. Also, labor-dependent work lacks automation. Therefore, researchers have sought more intelligent and automated ways to characterize soil cracks. With the rapid developments in computer vision and image processing techniques, many image process techniques (IPTs) have been utilized for crack detection and segmentation in concrete structures, steel structures, and asphalt surfaces (Spencer et al., 2019). To achieve a higher accuracy of

DOI: 10.1201/9781003299127-307

crack segmentation, Otsu's method has been applied in threshold selection to transfer an RGB image into a binary image (Lu et al., 2016; Otsu, 1979). Yamaguchi & Hashimoto, (2010) proposed a percolation-based image processing technique to accelerate the crack detection speed in large-resolution images.

With the development of computer science and information technology, an innovative network was developed by imitating human neuron function, which was named as the artificial neural network (ANN). Inspired by the human visual cortex, a convolutional neural network (CNN) was designed for feature extraction based on ANN (Fukushima & Miyake, 1982; LeCun et al., 1989). He et al., (2017)proposed the mask region conventional neural network (Mask R-CNN) based on Faster R-CNN (Ren et al., 2015)by attaching a binary mask to the detected object, which could help highlight each target from the background with masks in varying colors. Due to its outstanding performance in instance segmentation, the three-fold-function Mask R-CNN soon got the attention of the civil engineering community. So far, Mask R-CNN has been applied for automated crack characterization in various scenarios, such as concrete crack detection (Xu et al., 2022), road crack characterization (Singh & Shekhar, 2018), tunneling crack, and water leakage detection (Zhao et al., 2020), defects detection (concrete crack and spalling) in structure health monitoring (Kim & Cho, 2019), and cable-stayed bridge inspection (Hou et al., 2020). However, few studies have reported video instance segmentation of desiccation cracks in clay.

This study adopted a deep learning approach based on the state-of-the-art Mask R-CNN algorithm for clayey soil desiccation crack characterization. A soil crack dataset consisting of multi-source crack images was prepared and annotated for the Mask R-CNN training, validation, and testing.

2 MATERIALS AND METHODS

2.1 *Soil parameters*

To ensure the repeatability of the experiment, a commercial bentonite was obtained, and a series of soil classification tests were finished. The results of the physical and mechanical properties are listed in Table 1. The soil was oven dried thoroughly before mixing with water and reaching a water content of 120%.

Table 1. The physical and mechanical properties of the bentonite.

Soil parameters	Value
Soil classification (ASTM D2487)	MH
Liquid limit (LL)	95.4%
Plastic limit (PL)	58.2%
Plasticity index (PI)	37.2
Specific gravity (G_s)	2.464
Water content in soil misture(%)	120%

2.2 *Video capture device*

Once the soil mixture was stirred into a uniform paste, it was poured into a transparent petri dish. The petri dish was carefully transferred to a mini photo studio with LED lights. Due to the desiccation process usually taking more than 40 hours, mass storage will be required for the video write-in. An interval image shooting method was obtained using a Nikon D7000 digital camera. The camera will automatically take images of the petri dish every 2 minutes, and later these images can be compressed into a video for further instance segmentation.

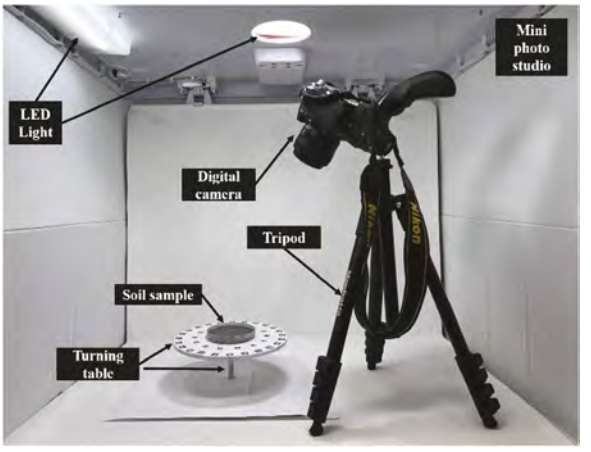

Figure 1. Video recording setup.

2.3 *Mask R-CNN architecture*

Mask R-CNN adopts a two-stage framework to accomplish the detection, locating, and segmentation with sufficient accuracy. Crack images are fed into the backbone network (Resnet-50) and unique feature maps are produced at the first stage. Based on a feature map, a region proposal network (RPN) could generate a series of pre-designed bounding boxes that possibly contain targets (i.e., cracks in this study). These bounding boxes are also known as regions of interest (RoI). Taking Figure 2 as an example, it could be found that more proposed bounding boxes are shown on the right side since the crack appears on the right side of the image. Then, the RoIAlign properly aligns the proposed bounding boxes on the feature map with a more accurate location, which results in a higher detection precision (He et al., 2017). At the second stage, the fully connected (FC) layers passed the fixed feature map to a normalized exponential function (SoftMax) and a bounding box regression layer parallelly, giving the classification and object detection results, respectively. Parallelly, a full convolution network (FCN) is utilized to generate a binary mask, which could segment the detected objects from the background.

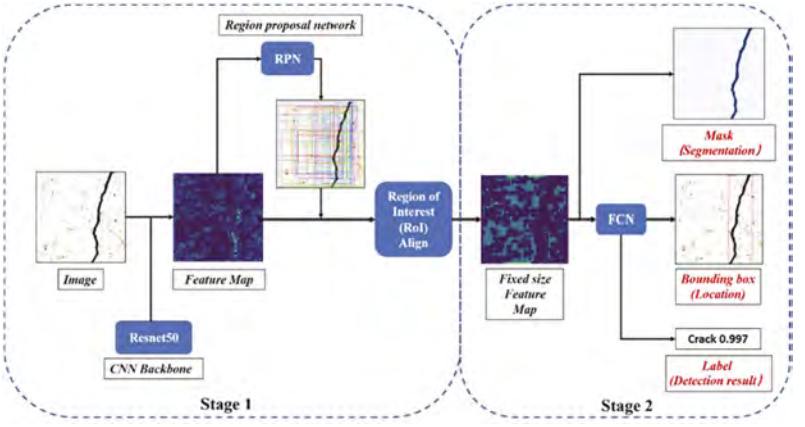

Figure 2. Mask R-CNN algorithm structure diagram.

2.4 *Dataset preparation*

The clayey soil crack images were obtained from Google Images, Instagram, and laboratory-captured images to prepare the dataset. Therefore, the diversity of the dataset could be assured and the high generalization ability of the proposed algorithm could be achieved. After all raw images were downloaded or captured, these images were cut into a series of small patches with a uniform resolution of 256×256 pixels through a Python program (Han et al., 2022). This way, a balance between keeping image details and lowering computational demands can be sustained. In total, 1200 crack images were selected and shuffled randomly to eliminate the bias from the same image. Within these chosen crack images, images originating from Google Images, Instagram and laboratory accounted for 60%, 20%, and 20%, respectively.

In the current study, the images were annotated using the VGG Image Annotator (Dutta & Zisserman, 2019). All cracks in the images were carefully annotated along their boundaries using the polygon region shapes. All annotation information, including file name, category name, coordinates of the polygon, etc., were saved into a json file and ready for the training process. Then the total dataset was further divided into the training set, validation set and test set, as shown in Table 2.

Table 2. Image details in the soil crack dataset.

Dataset name		Amount	Resolution
Calibration set (90%)	Training set (80%)	864	256×256
	Validation set (20%)	216	256×256
Test set (10%)		120	256×256
Total		1200	256×256

3 RESULTS AND DISCUSSIONS

3.1 *Model training and validation*

The online platform Google Colaboratory (Colab) was used for the Mask R-CNN model training and fine-tuning. The platform offers a Tesla P100 GPU (16 GB graphic memory) for online model training.

To balance the calculation efficiency and hardware capacity, the batch size of the training dataset was set as 8, and the synchronous stochastic gradient descent (SGD) was used to train the model with the weight decay and momentum set as 0.0001 and 0.9, respectively. A stage-wise training strategy was adopted here to help the model converge earlier and avoid gradient explosion in the early training phase. To begin with, the head part of the whole network composed of the bounding box generator and mask generator was trained for 10 epochs at an initial learning rate of 0.001. Then, for the subsequent 40 epochs, the learning rate was reduced by 10 times and the first three stages of the Resnet-50 were activated to continue the training process. After that, the learning rate was decreased by 10 times again and all five stages of the Resnet-50 were activated to train another 100 epochs. Finally, the learning rate was decreased by another 10 times until the last 50 epochs were finished. The entire training process took less than 6 hours to complete.

The loss curves during the training and validation process in the current study are shown in Figure 3. The training loss curves demonstrate a sharp decline at the initial 10 epochs, which indicates the algorithm parameters and dataset size were reasonable. Then the loss curve showed a smooth and slow declination from about 0.6 to less than 0.1. Thus no overfitting was observed during the training and validation period (Hou et al., 2020).

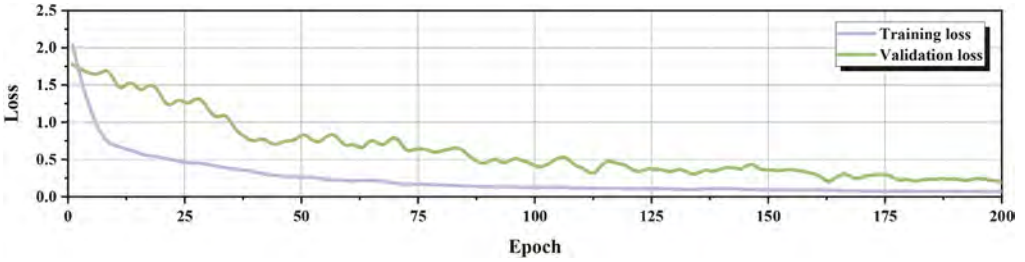

Figure 3. Curves of the loss function during model training and validation process.

3.2 *Soil crack characterization via images*

Before the Mask R-CNN is applied to video instance segmentation, the algorithm is executed on the test dataset. The inference results of the instance segmentation and crack characterization are shown in Figure 4. The raw images containing various crack patterns are shown in Figure 4(a)-(d), and the crack characterization results are exhibited in Figure 4(e)-(h). The green bounding box reveals the crack locations within the image. The crack number, crack pixel area, and crack ratio(total crack area in pixels/total soil area in pixels) are shown on the left corner of each detected crack. For example, three soil cracks are detected, located, and segmented in Figure 4(f). The most significant crack in Figure 4(f) is crack No.2, with a crack area of 894 pixels, which accounts for 1.36% of the total soil area in the image. The test dataset has proved the accuracy and efficiency of the Mask R-CNN algorithm. Xu et al., (2022) achieved soil crack recognition using a semantic segmentation algorithm (U-Net)(Ronneberger et al., 2015). The method could calculate the crack ratio but fail to distinguish every crack. The defects of the semantic segmentation algorithm make it hard to extract useful information like single object dimension and object amount. However, the semantic segmentation algorithm usually requires less dataset and training efforts. A detailed evaluation shall be made before adopting these algorithms with different focuses.

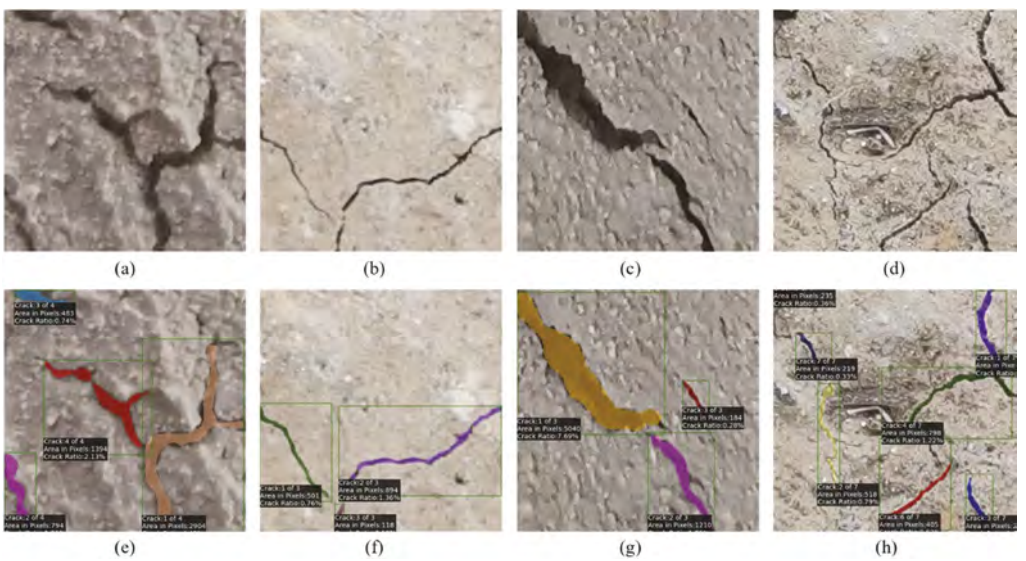

Figure 4. Instance segmentation results of the desiccation crack in clay:(a)-(d) raw images from the test dataset;(e)-(h)characterization results from the Maks R-CNN algorithm.

3.3 *Soil crack characterization via videos*

3.3.1 *Instance segmentation results*

During the whole desiccation process of the clay, 1500 images are captured through the camera at an interval of 2 mins. These images are transferred into a 50 seconds video with a resolution of 3840×2160 pixels. The video has a frame ratio of 30 FPS (frame per second). The video will later be fed into the Mask R-CNN algorithm to implement the instance segmentation and crack characterization tasks.

In order to demonstrate the results from the abovementioned tasks, four sample frames are extracted from the video and displayed in Figure 5. Figure 5(a)-(d) shows the raw images of the desiccation crack. With the speckle pattern, it is not easy to spot the thin cracks at the initial stage of the desiccation process. Besides, the crack pattern and number are more complex and less significant than the cracks shown in Figure 4. However, the algorithm could successfully detect, locate and segment these cracks, as shown in Figure 5(e)-(h), which proves an excellent generalization capability of the model. These cracks have been highlighted with different colors. Thus, the shapes can be observed with less effort.

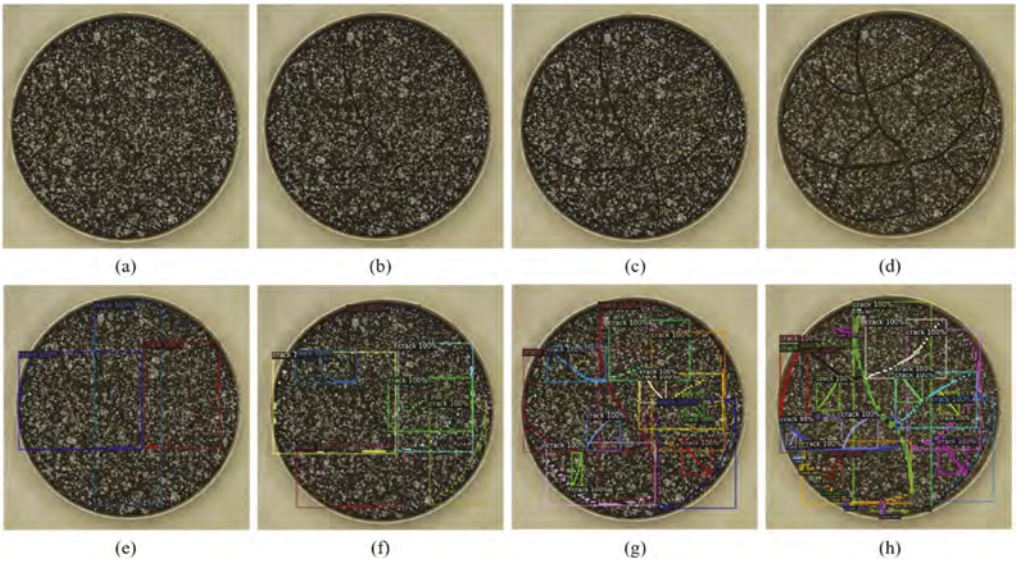

Figure 5. Instance segmentation results of the desiccation crack in the clay.

3.3.2 *Crack characterization results*

During the clay desiccation process, the crack network develops from a single thin crack into a crack backbone structure that covers the top, bottom, left, and right sides of the petri dish. After that, more minor cracks begin to expand along the branches. Finally, these cracks develop into a crack network. There are 3, 7, 13, and 27 cracks detected in Figure 6(a)-(d). The pixel area and the crack ratio of each crack are also listed in the image.

After the algorithm processes the entire video, the crack number and crack ratio of each frame are calculated automatically by the algorithm. The results are demonstrated in Figure 7. It can be seen from Figure 7 that the first crack is generated around 1870 minutes after the experiment starts. When the experiment lasts 2100 minutes, the crack number reaches the first plateau (15 cracks). The plateau phenomenon was also reported by Zeng et al., (2019), where crack segments number reached a plateau at about 3000 minutes. However, only one plateau was reported in their study and the image sampling frequency was not provided.

When it comes to the crack ratio, the crack ratio keeps increasing from 5% to 6.5% until it reaches its plateau at 2190 minutes. The delay of the crack ratio indicates that once 15 cracks are generated, these cracks keep growing longer or thicker to cover more area of the clay. The

same pattern can be seen from 2700 minutes when the crack number peaks at 27. Nevertheless, the crack ratio increased slowly from around 8.2% to 8.5%. Yang et al., (2021) utilized the traditional image processing (IPT) method (binarization method) to monitor the soil crack ratio. The desiccation crack ratio at the end varies from 6% to 11%. The image sampling interval was not reported either.

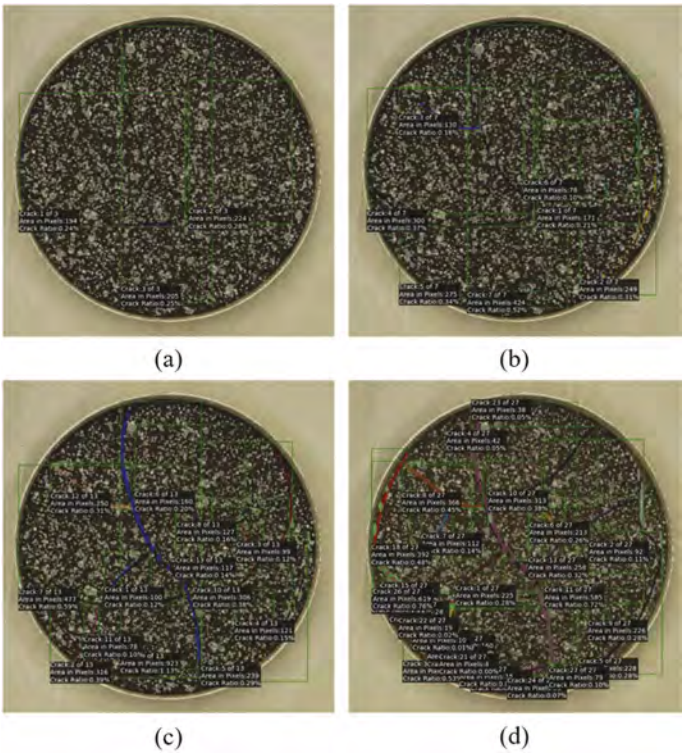

Figure 6. Video instance segmentation results in desiccation cracks in clay.

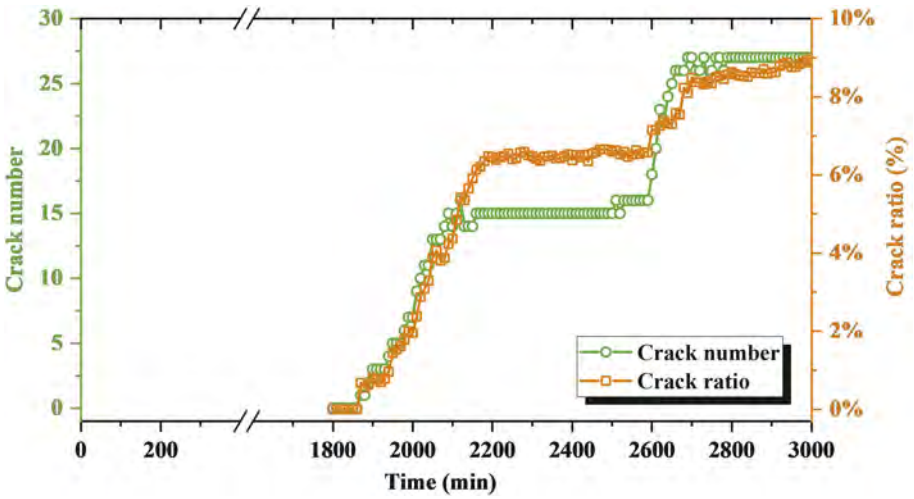

Figure 7. Characterization results of desiccation cracks in clay via video instance segmentation.

4 CONCLUSION

In the current study, a state-of-the-art deep-learning algorithm Mask R-CNN was introduced for clayey soil desiccation crack characterization via video instance segmentation. The Mask R-CNN could automatically detect, locate and segment soil desiccation cracks with sufficient accuracy and efficiency. The following conclusions could be obtained: (1) A mixing dataset containing images from multi-sources can be used for Mask R-CNN algorithm training and validation. The trained model can be applied for desiccation crack characterization in clay. The model has proved the generalization capacity of the algorithm. (2) The algorithm can be applied to the instance segmentation of images and videoes. Essential information like crack location, area, and shape can be displayed. (3) The algorithm captured the final crack number to be 25 and the crack ratio of 8.5%. Besides, the delay phenomenon of the crack ratio and the crack number would be an interesting topic for future research. (4) The algorithm demonstrates its potential to characterize soil desiccation cracks automatically, which can improve crack monitoring accuracy and efficiency.

ACKNOWLEDGEMENTS

This study was financially supported by the Natural Science Foundation of China (No. 42007246) and the Hawaii Department of Transportation (No. 2020-4R-SUPP). We would also like to thank Google Colab for offering online computation resources to all deep learning users.

Challenges associated with the use of earth pressure cells in field tests

Dinesh Bishnoi, Vikas Patil & S.M. Dasaka
Civil Engineering Department, Indian Institute of Technology, Bombay, India

ABSTRACT: Earth pressure cells (EPCs) are the most common part of any geotechnical instrumentation project. These are used on the structures or within the soil to monitor soil pressures or to verify the adopted design methodology. The selection of EPC type varies depending on the project requirement. In present paper, a brief idea is given to the new EPC users about the parameters that needed to be considered while selecting EPC for field studies. The challenges associated with EPC installation, EPC output reliability and other miscellaneous factors are discussed by mentioning the issues faced by authors during field testing. Proper EPC selection, calibration and installation is very essential for obtaining reliable data from the EPCs.

1 INTRODUCTION

In geotechnical engineering, field studies are essential to verify the results obtained by small-scale physical model tests or through numerical simulation. Instrumentation is an important component of field studies and the measurement of earth pressure is a common parameter in various structures such as retaining structures, buried pipelines, tunnels, etc. There are several types of Earth Pressure Cells (EPCs) available for the measurement of earth pressure. Keykhosropour et al. (2018) mentioned briefly the types of EPCs available. Extensive work is carried out by the researchers such as Selig (1980), Weiler & Kulhawy (1982), Hanon & Jackura (1985), Take & Valsangkar (2001), Kootahi & Leung (2022), etc., to understand the parameters that affect the performance of EPCs. It can be found that there are multiple parameters that can affect the response of EPC such as soil properties, properties of contact material, if different from soil, EPC properties, installation methods, temperature, etc.

An understanding of the EPC from literature is necessary before procurement but the aim of the present study is to give an idea to EPC users about the factors that need to be considered when selecting EPCs for field tests, which are seldom mentioned in the literature. The authors of the present study constructed a retaining wall of 6 m height to perform large-scale tests for understanding the behavior of Expanded polystyrene (EPS) as an inclusion material and EPCs were a major part of the instrumentation of the field study. Thus, the challenges faced during the field tests such as EPC selection, EPC installation, and reliability of measurement are mentioned briefly in the present paper.

2 PARAMETERS FOR SELECTION OF SUITABLE EPC

The EPC selection is dependent on several parameters such as expected pressure, measurement type, project type, budget, etc. Some of the parameters are discussed below which were considered before purchasing EPCs for the field project carried out to assess the suitability of EPS as an inclusion material.

DOI: 10.1201/9781003299127-308

2.1 *EPC capacity and accuracy*

The expected pressures in the field are calculated by using the traditional earth pressure theories and the EPC capacity required should be determined accordingly. The EPC capacity should be taken 1.5-2 times the calculated pressure to take into account the uncertainties associated with the field studies such as compaction stresses, environmental changes, temperature effects, etc., and more importantly, the uncertainties associated with the transformation model used to estimate the earth pressures.

The EPCs are available in various ranges such as 200 kPa, 350 kPa, 500 kPa, etc. and generally, there is no difference in cost due to the EPC range for same model types but the accuracy or least count of the EPC is dependent on the range of the EPC. The least pressure that can be measured by the EPC is some percentage of the EPC capacity or Rated Output (RO). For an EPC if it is 0.05% of RO then for 200 kPa, it is 0.1 kPa but for 500 kPa it increases to 0.25 kPa. Thus, the EPC should be selected by considering the expected pressures as well as the accuracy of pressure required for the tests.

2.2 *Type of EPC*

There are numerous types of EPCs available that work on different principles such as strain-gauge based, vibrating-wire based, tactile pressure sensors, null pressure based sensors, etc. The selection of EPC type depends on whether the measurements are static or dynamic and the monitoring period i.e., short-term or long-term monitoring. Strain gauge-based EPCs are able to measure dynamic variations but they undergo drift with time. The vibrating wire EPCs are found to be more suitable for long-term monitoring but for dynamic measurements, the EPC cost increases significantly.

2.3 *Calibration of EPC*

The EPC manufacturer generally provides a calibration chart for each EPC, generated by correlating the EPC response to the applied pressure. Usually, the manufacturer calibration is carried out in a fluid medium due to its simplicity but for soil, the calibration values may be different from the fluid. Thus, it is recommended that the EPC is calibrated for both fluid and soil conditions. The fluid calibration can be carried out in the modified triaxial calibration device suggested by Dave & Dasaka (2013) or the Pneumatic calibration chamber (PCC) by Gade & Dasaka (2018). Set-up similar to the universal calibration chamber developed by Theroux et al. (2001) can be used for soil calibration.

3 CHALLENGES WITH EPC IN THE FIELD

3.1 *EPC Installation*

The EPC sensing surface should be flushed with the interface of the structure during installation to minimize the deviation of measurements from the absolute values (Lazebnik & Tsinker 1998). The EPC can be installed during the construction of the structure or suitable openings should be provided if the EPCs are not available during the construction.

The procedure followed for the installation of dual diaphragm EPC used in the field study is shown in Figure 1. Apart from the flushing of the EPC with the surface, the base prepared for EPC (refer to Figure 1c) should be strong and uniform so that EPC gets a proper reaction. Depending on the type of EPC, the installation process will vary but two key points mentioned above should be taken care of properly.

3.2 *Contact material with EPC*

It is not necessary that the material in contact with the earth pressure cells will always be soil as the use of various materials such as geosynthetics, waste rubber tyres, fly ash, etc. is rapidly

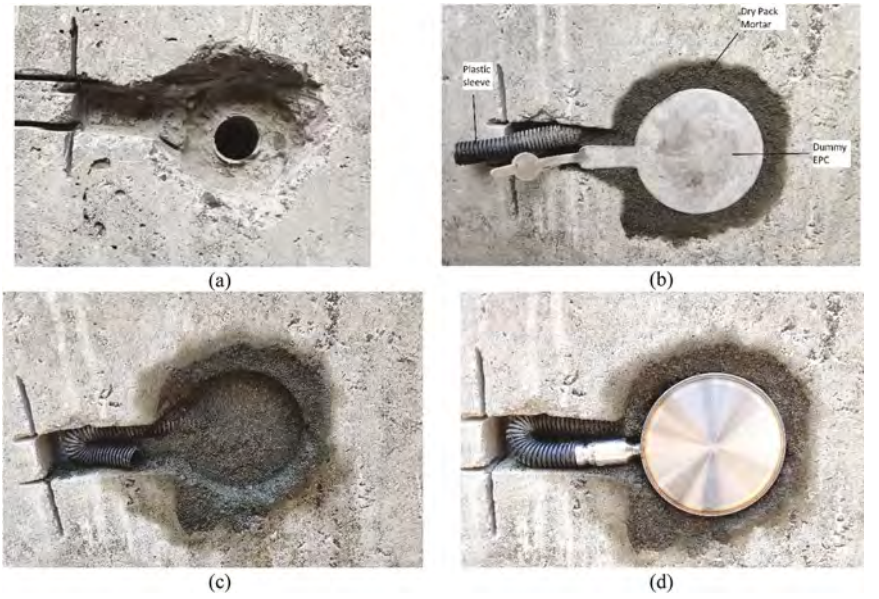

Figure 1. EPC installation process a) the groove made during construction, b) the filling of groove with mortar using a dummy EPC, c) the slot made in the wall for EPC after proper curing and, d) the final installation of EPC.

increasing. Gade & Dasaka (2019) mentioned that the response of EPC changes when the contact material changes. Calibration tests with three different contact materials are performed with diaphragm type EPC and the result is shown in Figure 2. The slope of the equation shown in Figure 2 represents the calibration value for that particular case. Thus, it can be observed that the calibration factor provided by the manufacturer gives higher pressures compared to the actual pressure which can be obtained by using soil calibration factor. It can be seen from Figure 2 that even if the material is sand, there is difference in calibration value. Thus, the EPC should be calibrated with the contact material expected in the field prior to installation and to the likely densities to be achieved during the actual backfilling.

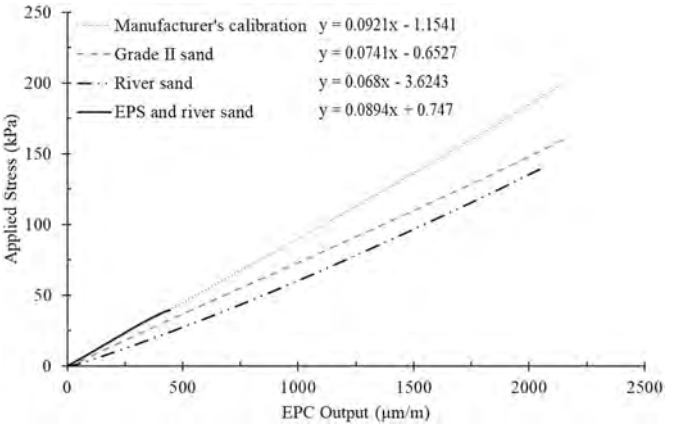

Figure 2. Calibration result of dual diaphragm EPC with Grade II sand, river sand and Expanded polystyrene (EPS) - sand as contact material.

3.3 *Reliability of EPC data*

The EPC calibration along with proper installation are important for field studies but the data obtained by the EPCs should be sensible and user should analyse the data properly. For example, Figure 3 shows the lateral earth pressure measured by 4 nos. of EPCs at same height on a cantilever concrete retaining wall constructed to study suitability of EPS as inclusion material as mentioned earlier.

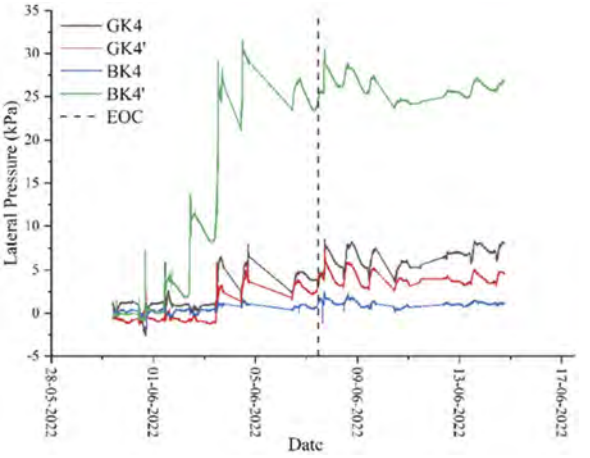

Figure 3. Earth pressure recorded by EPCs in control case (GK4 & GK4') and EPS inclusion case (BK4 & BK4').

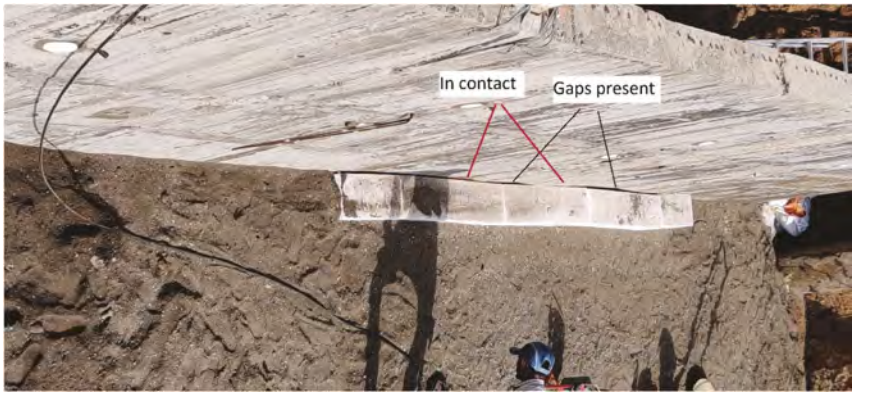

Figure 4. Inadequate contact between EPS and pressure sensor causing earth pressure measurement errors.

Two EPCs are placed on control side (i.e., no EPS inclusion) viz. GK4 & GK4' and two EPCs are placed with EPS as contact material viz. BK4 and BK4' in Figure 3. The EPCs in control case showed sensible results but in EPS inclusion case, the EPCs are giving either extremely high (BK4') or extremely low pressures (BK4) compared to control case. By carrying out some site investigation it was found that at the EPS locations, the EPS blocks are not in contact with the wall uniformly, as shown in Figure 4, which led to error in pressure measurements. Thus, as suggested by Hanon & Jackura (1985), apart from EPCs some other alternatives should also be used to back up the data obtained by EPCs regarding soil stress conditions.

3.4 *Miscellaneous*

There are other miscellaneous factors also which can affect the performance of the EPCs in field studies such as corrosion, water proofing, damage by compaction etc. It is necessary that the EPCs are properly protected against the corrosion before installation and the zone at the cable-sensor connection should be covered by waterproof material. The EPCs may get damaged during compaction by the compaction equipment, thus at least a layer of manually compacted sand should be provided above EPC or the manual of EPC should be referred to avoid damage of the sensors.

4 CONCLUSIONS

The selection of suitable EPC for field tests is important to get reliable results. The capacity of EPC and its type should be determined by calculating the expected earth pressures and project requirement respectively. It is necessary to calibrate these EPCs with the actual contact material expected in the field prior to installation as the calibration factor of EPC changes with contact material. There are numerous unknown factors in the field that can affect the response of EPC output and use of alternative methods along with EPC will provide confidence in EPC measured data.

Application of soil moisture sensor with submersion detection to slope

K. Omine
Nagasaki University, Nagasaki, Japan

ABSTRACT: The author developed a cheap and simple sensor for measurement of soil moisture using a voltage control element transistor (MOSFET). The soil moisture sensor consists of multi-MOSFETs, carbon electrodes, plastic rod, PVC pipe, and cloth for cover. The moisture sensor can be installed into a hole made by portable cone rod in arbitrary depth of the slope. Voltage of the sensor is measured and the value is converted to soil moisture. One of MOSFET detects a submerged condition of the soil. The moisture sensor is applied at a site of the slope and its applicability is discussed based on the field observation. From the result, it is indicated that the simple sensor using MOSFET are useful for not only the measurement of soil moisture but also detection of submerged condition of the ground.

1 INTRODUCTION

Due to the effects of torrential rains and typhoons caused by climate change, river floods and sediment-related disasters occur frequently. Many countries are facing the deterioration of social capital, and it is required to control the maintenance cost of soil structures and reduce the damage in the event of a disaster. Therefore, it is expected to develop a low-cost, power-saving, long-distance communication system that can observe, detect, and communicate ground moisture condition in real time .The cause of the collapse of slopes on steep slopes is a rise in groundwater level due to heavy rain. Although it is difficult to identify the location of the slope failure, it is important to grasp the risk of collapse in advance by observing the rise in groundwater level and the submerged ground condition in real time.

This paper introduces a soil moisture sensor with submersion detection that can detect various states of the ground using a voltage control element. In addition, The author will describe the concept of a ground water detection system by combining wireless communication and simple sensors, and discuss on the results by field observation on steep slope.

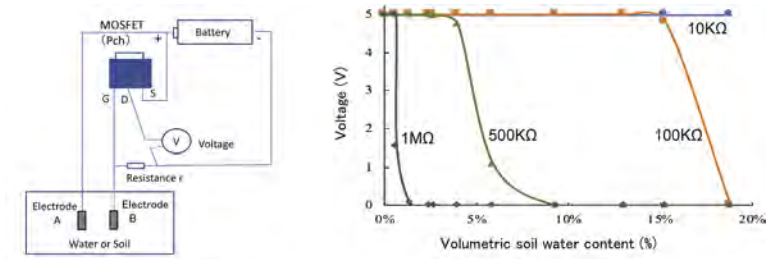
2 SOIL MOISTURE SENSOR USING VOLTAGE CONTROL ELEMENT

MOSFET is a type of transistor, and there are two types, N-channel type and P-channel type. Basically, a 3-terminal electrode (gate, drain, source) is used, and when a voltage is applied to the gate of the P channel used in this study, the drain is turned off. For the P-ch MOSFET, the voltage of the drain is turned on before the electrodes A and B are submerged in water, and is turned off when the electrodes A and B are submerged in water. In this circuit, the voltage changes according to the magnitude of the resistance attached to the gate of the MOSFET and the amount of soil moisture. Taking advantage of this feature, the author will make a simple soil moisture sensor.

Figure 1 shows the results of investigating the relationship between resistance and voltage by inserting electrodes A and B into sand with different soil moisture content. The larger the resistance, the more sensitive the voltage changes to a slight change in volume moisture content. The smaller the resistance, the larger the volume moisture content at which the voltage drops. Although the voltage does not change with a smaller resistance (10 kΩ), it is possible to measure the difference in the volumetric water content of the soil by changing the resistance

DOI: 10.1201/9781003299127-309

within a certain range. However, this relationship changes depending on the type of soil and the salinity in the soil, it is therefore calibration is required. Using this feature, the author will try to construct a soil moisture sensor and a soil submersion detection sensor.



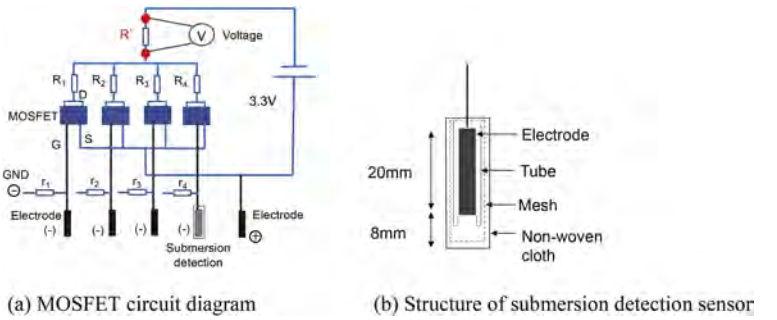
(a) MOSFET circuit diagram (b) Measurement of voltage

Figure 1. Relationship between voltage and volumetric soil moisture content at different resistances.

3 APPLICATION OF THE SOIL MOISTURE SENSOR FOR SLOPE MONITORING

3.1 *Overview of soil moisture sensor with submersion detection*

Figure 2 (a) shows the circuit diagram of the soil moisture sensor. Here, four pieces of MOSFET are used to detect four different water contents. Different resistances ri reacting to each soil moisture are connected from the gate of the MOSFET circuit to the minus (GND). The larger the resistance value, the smaller the soil water content, and the smaller the resistance value, the higher the soil water content. If the resistance R attached to the drain of the MOSFET is connected in parallel, it is possible to know a number of reacting MOSFETs by measuring the voltage value of the resistance R'. In addition, a change of R' enables to arrange by setting resistance Ri to an appropriate value. In this study, R_1 = 100kΩ, R_2 = 150kΩ, R_3 = 180kΩ, and R_4 = 220Ω are used. For example, if the number of responding sensors is 0 (low water content), the voltage of the resistance R' becomes the maximum value, and if all the sensors (high water content) react, the resistance R' becomes 0V. Furthermore, the structure of submersion detection sensor is shown in Figure 2 (b). The submersion detection sensor has a structure of an electrode in 20 mm length, tube, mesh, and non-woven fabric, and the total length is about 30 mm. The submersion detection sensor reacts by wrapping a non-woven fabric and when excess water touches a carbon rod. In addition, since the water attached to the non-woven fabric may not separate from the carbon rod, a mesh is wrapped between the non-woven fabric and the carbon rod. The apparatus consists of three soil moisture sensors and one submersion detection sensor, and when the submersion detection sensor reacts, the voltage becomes 0V. Therefore, from the voltage value of the resistance R', the author can confirm not only the soil moisture level but also whether it has saturated and submerged.



(a) MOSFET circuit diagram (b) Structure of submersion detection sensor

Figure 2. Circuit of soil moisture sensor with submersion detection.

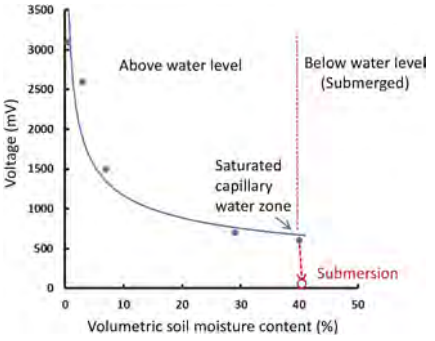


Figure 3. A change of voltage value of the soil moisture sensor with submersion detection.

Figure 3 shows the relationship between the volumetric soil moisture content and the voltage value by the submersion detection sensor. It was confirmed that the voltage was 1000mV or less in the saturated capillary water zone on the groundwater table, all three resistances (r_1, r_2, r_3) of the soil moisture sensor reacted, and the submersion detection sensor did not react. In addition, the voltage became zero below the groundwater level, indicating that the submersion detection sensor can respond correctly to the submerged state.

3.2 *Verification by field observation of slope*

The soil moisture sensor is connected with wireless communication device (TWELITE DIP) and microcomputer (Arduino Mini Pro 3.3V). The wireless communication device can send and receive data between the slave unit and the master unit. Corrosion does not occur even if a voltage is applied to the carbon rod for a long period of time, however it was found that the resistance on the surface of electrode has changed. It is therefore that an instantaneous voltage is applied to the soil moisture sensor using Arduino. As a result, stable measurement can be performed over a long period of time, and an arbitrary time interval can be set. The data from the soil moisture sensor is wirelessly communicated from the slave unit to the master unit, the data is saved in the cloud from the ESP8266 connected to the master unit, and the measurement results can be viewed on an external terminal. The power supply is a dry battery (3.3V) for the soil moisture sensor on the slave unit side, and a solar panel and battery for the ESP8266 on the master unit side. The master unit can always receive radio waves from the slave unit. The soil moisture sensor was installed on the slope in Nagasaki City, Japan. This site is designated as a steep slope in Nagasaki City, and is where sand control dam construction is being carried out. The soil moisture sensor is installed at a depth of 0.2m, 0.4m, and 0.6m from the ground surface. For a detection of the different soil moistures, the resistance values of r_1 = 1MΩ, r_2 = 200KΩ, r_3 = 100KΩ, and r_4 = 1MΩ (submersion) are used. The reason for using high resistance of r_4 is to ensure that the sensor is turned on when water comes into contact with it, regardless of the soil. For comparison, two EC-5 sensors are also installed at 0.2m and 0.4m from the ground surface. Using Arduino, a voltage is applied to the soil moisture sensor and the slave unit at 30-minute intervals, and the voltage value at that time is wirelessly transmitted to the master unit about 100 m away from the slave unit. The slave unit was powered by Arduino using 3.3V battery. The data of the master unit is transmitted to the cloud at 30-minute intervals by ESP. A rain gauge was also installed.

Figure 4 (a) shows the change of the volumetric soil moisture content converted from the voltage value of EC-5 and the hourly precipitation. Figure 4 (b) shows the change of the volumetric soil moisture content converted from the voltage value of the soil moisture sensor which was obtained by the cloud service (Ambient). From this relationship, the volumetric soil moisture content tended to increase after rainfall. After rainfall, the volumetric soil moisture content increases from the side closer to the ground surface, and then the value increases in the depth direction. At a depth of 0.6 m, the volumetric soil moisture content rises to about 40% after rainfall, confirming that the value is close to saturation. Figure 5 shows the volumetric soil moisture contents measured by the soil moisture sensor and EC-5 before and after rainfall.

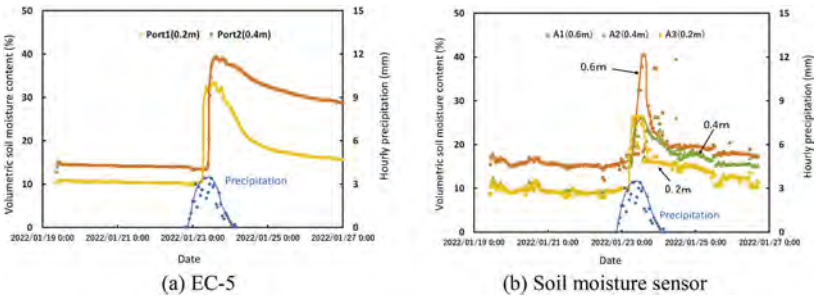

Figure 4. Change of the volumetric soil water content and the hourly precipitation.

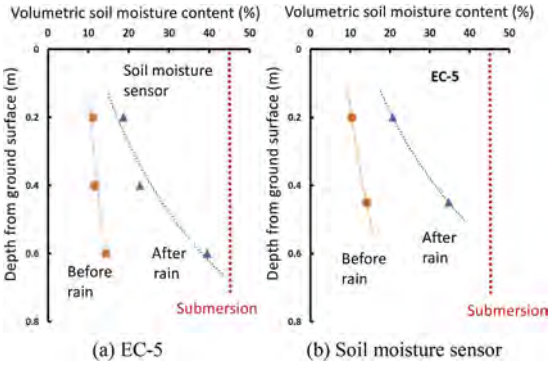

Figure 5. Volumetric soil moisture contents before and after rainfall.

Before rainfall, it can be confirmed that there is no difference in volumetric soil moisture content in both sensors in the depth direction. However, after rainfall, the deeper the ground surface, the larger the volumetric soil moisture content, and it is considered that rainwater has penetrated into the ground. From the measurement results, it is considered that the ground at a depth of 0.6 m was almost saturated after rainfall.

4 CONCLUSIONS

A ground water detection system was made by a simple moisture sensor using wireless communication equipment, a microcomputer, and a voltage control element. It is possible to receive data from the slave unit and the master unit by using a wireless communication device even in forests and slopes where the communication environment is harsh. It was clarified that the soil moisture sensor with submersion detection can measure the submerged state below the groundwater level. The soil moisture sensor was applied at a site of the slope for the field observation. From the monitoring result, after rainfall, it was possible to confirm the change in volumetric soil moisture content by the soil moisture sensor equivalent to that of the conventional soil moisture meter. For disaster prevention and mitigation, it is expected to be used as a low-cost sensor for observing, detecting, and communicating ground moisture condition in real time.

Building Design Department, Nagoya Branch Office, Takenaka Corporation, Nagoya, Japan

ABSTRACT: This paper offers long-term monitoring and design of piled raft foundation supporting a 162 m high isolated residential tower. The average contact pressure over raft is 600 kPa. The foundation consists of thirty-six 50 m long cast-in-place concrete piles which diameter are from 1.5 m to 1.9 m and compression strength is 48 N/mm^2. To confirm the validity of the foundation design, long-term field monitoring was performed in the settlement of the foundation and ground, axial loads and bending moments on the piles, contact earth pressure and pore-water pressure beneath the raft from the beginning of construction to over thirteen years after the end of construction. In addition, the piles' bending moments due to differential settlements between center and corner of the raft can be well measured, however those are sufficiently small comparing to design values during earthquake. These values were almost stable after the end of construction.

1 INTRODUCTION

Recently, piled raft foundations were applied for the foundation of super high-rise buildings, e. g., the world's tallest building of 828 m in height, Burj Khalifa in UAE (Poulos & Bunce, 2008), and the tallest building in Japan with 300 m in height (Hamada et al, 2016).

This paper presents performance and design of a piled raft with end-bearing cast-in-place high strength concrete piles supporting a 162 m high isolated residential tower. To confirm the validity of the foundation design, long-term field monitoring was performed on the foundation settlement, loads of the selected piles and contact pressures between raft and soil as well as pore-water pressure beneath the raft. A part of the measured results from the beginning of construction to seventeen months after the end of construction have been reported (Yamashita et al, 2011). In this paper, the measured data to thirteen years and five months after the end of construction are added and axial/ bending strains on monitored piles also discussed.

2 BUILDING AND SOIL CONDITIONS

The 48-story (47th and 48th floors for machine rooms) residential tower of 162 m in height above the ground surface and measures 50 m by 34 m in plan is located in Nagoya, Japan. Figure 1 shows a schematic view of the building and foundation with soil profile. The building is a reinforced concrete structure with base isolation system of laminated rubber bearings. The soil profile down to a depth of 4 m from the ground surface consists of fill and alluvial silt. Below the depth of 4 m, there lie Pleistocene medium-to-dense sand-and-gravel and sand with SPT N-values of 20 to 30 with some thin layers of silt to a depth of 17 m, underlain by medium silt. Between depths of 27 m to 43 m, there lie dense sand, very dense sand-and-gravel and medium-to-dense sand with SPT N-values 20 to 60 or higher. Below a depth of 43 m, there lies medium silt. Below a depth of 53 m, there lies very dense sand-and-gravel. The groundwater table appears

DOI: 10.1201/9781003299127-310

approximately 2.5 m below the ground surface. The shear wave velocity derived from P-S logging was from 180 m/s at the foundation level and 510 m/s in the sand-and-gravel below a depth of 53 m.

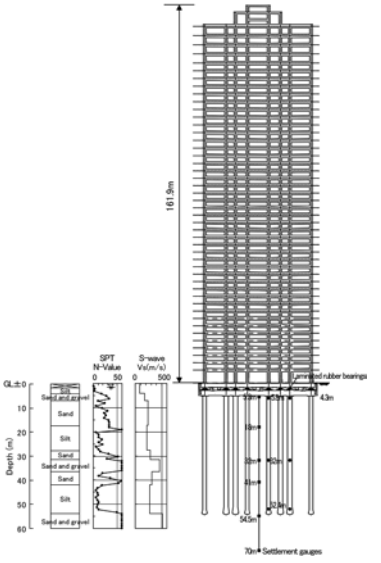

Figure 1. Schematic view of the building and foundation with soil profile.

3 FOUNDATION DESIGN

Because the building has a base isolation system, differential settlement of the foundation is rigorously restricted. The average contact pressure over the raft is 600 kPa. The reinforced concrete raft located 4.3 m below the ground surface is founded on the medium-to-dense sand-and-gravel. In order to reduce the differential settlement, a piled raft foundation consisting of thirty-six 50-m long cast-in-place concrete piles was proposed, where the piles were embedded in the very dense sand-and-gravel layer below a depth of 53 m. The ratio of the load carried by the piles to the total load was assumed to be 0.8 to 0.9 in the design, based on the values of 0.74 to 0.84 derived from the numerical analysis.

The piles have a diameter varying from 1.5 to 1.9 m and a 1.8 to 2.2 m enlarged bell at pile bottom. The nominal compressive strength of concrete is 48 MPa. The lateral loads and incremental axial loads on piles in the seismic design are relatively small due to the use of a base isolation system which can reduce the inertial force and overturning moment of superstructure. Thus piled rafts are compatible foundation system especially for isolated high-rise buildings. If a conventional pile foundation was adopted, the diameters of piles would be larger

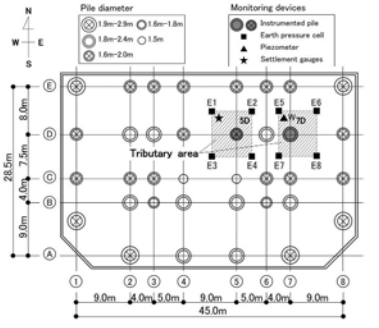

Figure 2. Layout of piles with locations of monitoring devices.

than these values, e.g., 2.0 to 2.5 m at shaft and 2.5 to 3.0 m at bottom. Figure 2 shows the foundation plan with a layout of the piles.

4 INSTRUMENTATION

The locations of the monitoring devices are shown in Figure 2. The two piles, 5D and 7D, were provided with a couple of LVDT-type strain gauges at depths of 5.8 m (at pile head), 32.0 m (at intermediate depth) and 52.4 m (at pile toe). Surrounding the instrumented piles, eight earth pressure cells E1 to E8 and one piezometer were installed beneath the raft. The vertical ground displacements below the raft were measured using differential settlement gauges. LVDT-type transducers were installed below the raft at depths of 5.3, 18.0, 32.0, 41.0 and 54.5 m to measure the relative displacements to the reference point at a depth of 70 m from the ground surface as shown in Figure 1.

The measurements on the strains of the piles, the contact pressures between raft and piles and pore-water pressure beneath the raft started just after casting of the 0.5 m thick foundation slab. The measurement of vertical ground displacements below the raft began just before the beginning of the excavation for the foundation construction in December 2006.

5 OBSERVATIONS

Figure 3 shows the measured vertical ground displacements at depths of 5.3 m, 18.0 m, 32.0 m, 41.0 m and 54.5 m relative to the reference point at a depth of 70 m where the initial values of the displacements were taken right before casting the foundation slab. The broken lines after 2013 January are assumed values no differential displacements have occurred because the settlement gauges at depth of 54.5 m, 32.0 m and 18.0 m had broken. The ground displacement measured at a depth of 5.3 m is approximately equal to the foundation settlement. The measured ground displacement increased with construction progress and reached 23.4 mm at the end of construction. Thereafter the displacement increased very slightly and reached 26.6 mm at thirteen years and five months after the end of construction. The differential settlement of Pleistocene medium silt layer between a depth of 54.5 m and 41.0 m was 12.4 mm at E.O.C. which was relatively larger than other layers.

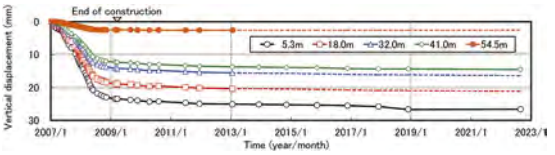

Figure 3. Measured vertical ground displacements.

Figure 4 shows the development of the strains measured on the pile 5D (diameter of 1.6 m). The negative value means compression. The average compression strains reached about -400 m at both pile head and intermediate depth, whereas the strain at pile toe was relatively small. (The strains at a depth of 32 m and 52.4 m have not measured since 2013.) The average strain of -400 m correspond to axial load of 25.5 MN (Axial stiffness, EA = 63700 MN). Figure 5 shows those on the pile 7D (diameter of 1.8 m). The average compression strains were about -350 m at both pile head and intermediate depth, whereas the strain at pile toe was relatively small similar to pile 5D. The average strain of -350 m correspond to axial load of 28.2 MN (axial stiffness, EA = 80600 MN). The measured pile-head loads were almost stable for both piles. Focusing on difference of strains at pile head, the strains at South direction (1S) were considerably larger than those at North direction (1N) for both the piles 5D and 7D. The difference of a couple of strains, 250 and 300 m were shown at piles 5D and 7D, respectively. These values correspond to bending moment of 1.71 and 2.88 MNm (bending stiffness, EI = 9590 and 15400 MNm^2, respectively). The bending moments on the piles may have occurred due to the differential settlements between center and corner of the raft, however those are sufficiently small

comparing to design values during earthquake. Figure 6 shows the settlement profile measured by the optical level of street 7 at the end of construction and sketch of possible deformation of the piles.

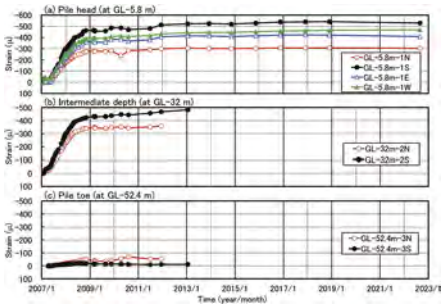

Figure 4. Measured axial loads of the piles 5D.

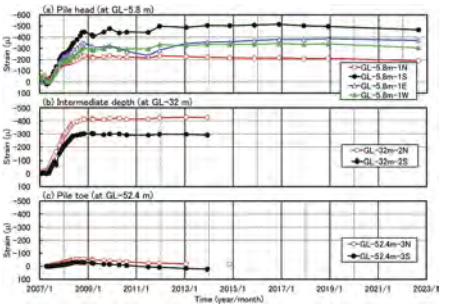

Figure 5. Measured axial loads of the piles 7D.

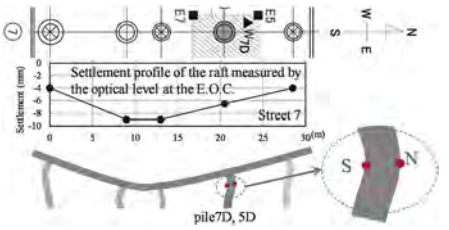

Figure 6. Measured settlement profile and sketch of possible deformation of piles.

Figure 7 shows the development of the measured contact pressures between raft and soil and pore-water pressure beneath the raft. The measured contact pressures differ considerably and the values were 28-98 kPa from the earth pressure cells E1-E4 near the pile 5D and 63-137 kPa from the earth pressure cells E5-E8 near the pile 7D at the end of construction. The measured pore-water pressure was approximately 20 kPa that is consistent with the ground water table from the soil investigation. Thereafter the measured contact pressures were almost stable except E2 and E8. The earth pressure cell of E8 would have been broken since circa 2011.

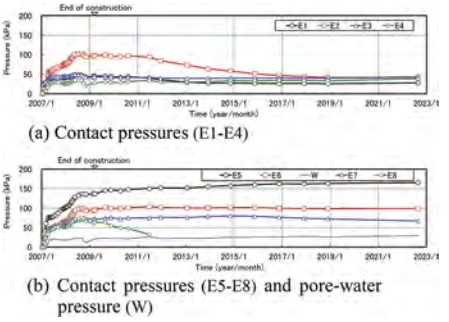

Figure 7. Measured contact pressures and pore-water pressure.

Figure 8 shows the time-dependent load sharing among the piles, soil and the groundwater buoyancy on the tributary areas of the columns 5D and 7D shown in Figure 2. At thirteen years and five months after the end of construction, the sum of the measured pile-head load and raft load on the tributary area is 29.3 MN and 32.4 MN on the columns 5D and 7D, respectively.

The raft load was obtained based on the mean value of the contact pressures near the columns. The design vertical loads of the columns 5D and 7D, which correspond to the sum of dead load and live load, are 26.3 MN and 35.6 MN, respectively. Therefore, the sum of the measured pile-head load and raft load on the tributary area is consistent with the design loads of both columns.

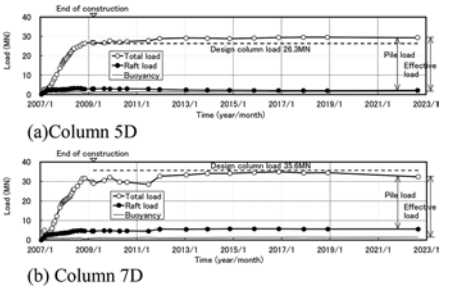

Figure 8. Time-dependent load sharing between raft and piles on the tributary area.

The ratio of the load carried by the pile to the effective loads (total load minus buoyancy) in the tributary area of columns 5D and 7D were estimated to be 0.93 and 0.87, respectively, at the end of the construction and 0.98 and 0.87, respectively, at thirteen years and five months after the end of construction.

The above observations are simulated and validated by three-dimensional finite element analysis. The results will be shown at another chance for want of space.

6 CONCLUSIONS

Performance and Design of piled raft foundation supporting a 162 m high isolated residential tower were described. Long-term monitoring was performed on settlement and load sharing of the piled raft foundation from the beginning of construction. The measured ground displacement was 23.4 mm at the end of construction, thereafter the displacement increased very slightly and reached 26.6 mm at thirteen years and five months after the end of construction. The ratio of the load carried by the pile to the effective loads were also stable from 0.87 to 0.98 at thirteen years and five months after the end of construction.

ACKNOWLEDGEMENTS

The authors are grateful to Messrs. Y. Soga and T. Yokonami of Takenaka Corporation for their contribution to the structural design and field measurements of the piled raft foundation.

ABSTRACT: Destructuring settlements due to frost heave during the structures' exploitation are often not taken into account at the designing stage, although they are indirectly related to the bearing capacity of the soils. The objective of this research was analyzing the effect of the number of freezing–thawing cycles on the strength characteristics of soils. Tests of the clay loams with void ratio $e = 0.55$ and with various initial parameters (initial moisture content, and the number of freezing–thawing cycles) was carried out. According to the experimental results, the cohesion largely depends on the above parameters which might lead to its decrease by up to 5 or 6 times. The internal friction angle demonstrated an indefinite behavior during the freeze-thaw cycles, which is confirmed by a literature review. Changes in strength parameters of the soil during freezing–thawing cycles can lead to significantly decreasing of the soil bearing capacity. A program based on the least-squares method was used to calculate the approximation coefficients of the dependence describing the changes in strength characteristics from the abovementioned parameters. Changes in strength characteristics must be taken into account when designing structures, as they can lead to additional settlement or even subsidence of the foundations.

1 INTRODUCTION

Many scientists around the world have observed changes in soil moisture and density during freeze–thaw cycles and, accordingly, a change in bearing capacity, directly related to engineering characteristics (Wang et al. 2010, Sarsembayeva & Zhussupbekov 2021, Qi et al. 2008). Options for addressing these impacts were investigated by (Yarbaşı et al. 2007, Kalkan 2009, Ghazavi & Roustaie 2010). Russian scientists from the Soviet era, including M.N. Goldstein, A.M. Pchelintsev, E.P. Shusherina, and N.A. Tsytovich (Goldstein 1948,

DOI: 10.1201/9781003299127-311

Pchelintsev 1964, Tsytovich 1973, Shusherina et al. 1970), have studied the influence of the number of freezing–thawing cycles on the mechanical properties of soils and contributed to the development of methods for strengthening base soils subject to freezing (Medvedev 2007, Kiselev 1985).

A significant part of the conducted experiment deals with road construction in areas with seasonally frozen soils, as well as problems associated with freezing–thawing of the roadway and its subgrade, such as settlement, frost heaving, and slope sliding (Ling et al., 2009; Li et al., 2016; Tebaldi et al., 2016).

Destructuring settlement and heave settlement during the exploitation of buildings and structures are not taken into account in most construction design standards, although they are indirectly related to the strength characteristics of the soil. According to (Magushev et al. 2011), the vertical deformation of foundations on a natural base is determined as the sum of four components (Equation 1): calculated settlement, elastic settlement, destructuring settlement, and heave settlement.

$$\boldsymbol{S} = \boldsymbol{S_{comp}} + \boldsymbol{S_{elast}} + \boldsymbol{S_{destr}} + \boldsymbol{S_{heave}}, \tag{1}$$

where $\boldsymbol{S_{comp}}$ is the calculated value of the final settlement, according to regulations, which is a consequence of repacking of particles under a load, leading to soil compaction, within the compressible thickness.

$\boldsymbol{S_{elast}}$ is settlement associated with the unloading of the excavation and the subsequent construction of the foundation and backfilling with soil.

$\boldsymbol{S_{destr}}$ is settlement associated with destructuring of soil, for example, under the influence of heavy machinery, frost exposure, water saturation, unfavorable weather conditions, etc.

$\boldsymbol{S_{heave}}$ is heave settlement associated with the accumulation of shear strains in the soil leading to the squeezing out of the soil from under the base of the foundation.

Destructuring settlement S_{destr} and heave settlement S_{heave} are not taken into account by domestic standards (SP 22.13330.2016) and are indirectly related to the strength characteristics of soil. The change to these characteristics caused by freezing–thawing is studied in this paper.

Many geotechnical scientists have paid great attention to studying the changes caused by freezing in the cohesion and the angle of internal friction of the soil as these are the main strength characteristics. It is generally accepted that with an increase in the number of freezing–thawing cycles, cohesion decreases, but the stabilized value of cohesion after several freezing–thawing cycles remains controversial (Chang et al. 2014, Wang et al. 2005, Wang et al. 2018, Yu 2007, Liu et al. 2016, Zhang et al. 2015). However, some results show that cohesion increases or defies the obvious law when exposed to freezing–thawing (Fang et al. 2012). Studies of changes in the angle of internal friction of soil are rather contradictory: according to some studies (Wang et al. 2010, Wang et al. 2005, Yu 2007, Fang 2012), the angle of internal friction increases; according to other studies (Chang et al. 2014), it decreases or remains constant (Zhang 2015, Su et al. 2008, Dong et al. 2010). Some studies note the inconsistent nature of the change in the angle of internal friction during freezing–thawing (Wang et al. 2005, Lui et al. 2016, Wang 2012). One way or another, the obtained scientific results are difficult to apply in engineering practice unambiguously. In 2018, Wang et al. were the first to propose a mathematical equation using correction factors for calculating the shear strength of soil during freezing–thawing, which had never been considered before (Wang et al. 2018). However, the dependence is only for clays with a moisture content of 18.5%.

The purpose of this research is to analyze and to study the mathematical dependence of changes in the strength characteristics of clayey soils with different void ratios and initial moisture content due to freezing–thawing cycles.

2 MATERIALS AND METHODS

The southern area of the Tyumen region of the Russian Federation contains -clayey soils which are considered as frost-susceptible soils, resulting in severe frost heave during the winter time.

Remolded clay loam samples with the particle density 2.70 g/cm3 were compacted in accordance with the Russian State Standard GOST 30416–2012 "Soils. Laboratory testing. General" (GOST 30416-2012). The samples were compacted in four layers, with the required density and moisture content. The specimens were prepared as cylinders in metal rings of 71.5 mm in diameter and 35 mm in height. Physical characteristics of the soils are presented in Table 1.

Table 1. Physical characteristics of the soil.

No.	Designation	Indicator	Unit	Value
1	ρ_s	Density of soil particles	g/cm3	2.70
2	w_P	Plastic limit	-	0.15
3	w_L	Liquid limit	-	0.27
4	I_p	Plasticity index	-	12.1
5	e	Soil void ratio	-	0.55
6	W	Initial moisture content	%	16.5/19.5

In the experiment, two paired samples were considered for testing with varied initial settings (Table 1). Tests were conducted on loam with void ratio e = 0.55 and two different initial moisture contents (W = 16.5% and W =19.5%).

The samples were frozen at a temperature of −20 °C and thawed at 20 °C, with the freezing time and thawing time each being 12 h. The specimens were covered with sleeves during the freeze–thaw cycling to prevent the evaporation of water. The all-round freezing method with constant temperature was applied for the freeze–thaw cycle test in a closed system without a water supply. The samples were placed in metal rings without normal stress. The samples experienced different numbers of freeze-thaw cycles of 0, 1, 3, 5, 10 (Table 2).

The experiment set matrix is presented in Table 2.

Table 2. Experiment set.

Experiment No.	Void ratio, e	Moisture content W, %	Number of freeze-thaw cycles, Nc
1	0.55	16.5	0
2	0.55	16.5	1
3	0.55	16.5	3
4	0.55	16.5	5

The engineering properties of soil samples after freeze–thaw cycles were determined using a direct shear apparatus, according to GOST 12248–2010 "Soils. Laboratory methods for determining the strength and strain characteristics" (GOST 12248-2010). Four shear tests were conducted with normal stresses 100, 150, 200, and 300 kPa. After conducting experiments under each set of conditions and processing the results of the direct shear test, the data were analyzed to determine the influence of each of the studied factors (Lawson & Erjavec 2017).

3 RESULTS AND DISCUSSIONS

The results of the direct shear test for each experimental sample set are presented in Table 3.

Figure 1 shows that the angle of internal friction increases dramatically up to two times during the first freeze-thaw cycle. Further freezing-thawing up to three cycles can lead to a decrease in the angle of internal friction to the initial value or lower. In general, the character of the freeze-thaw curve is not constant. After ten freeze-thaw cycles, the characteristic either remains equal to the initial value (W=16.5%) or exceeds it by 1.5 times (W=19.5%).

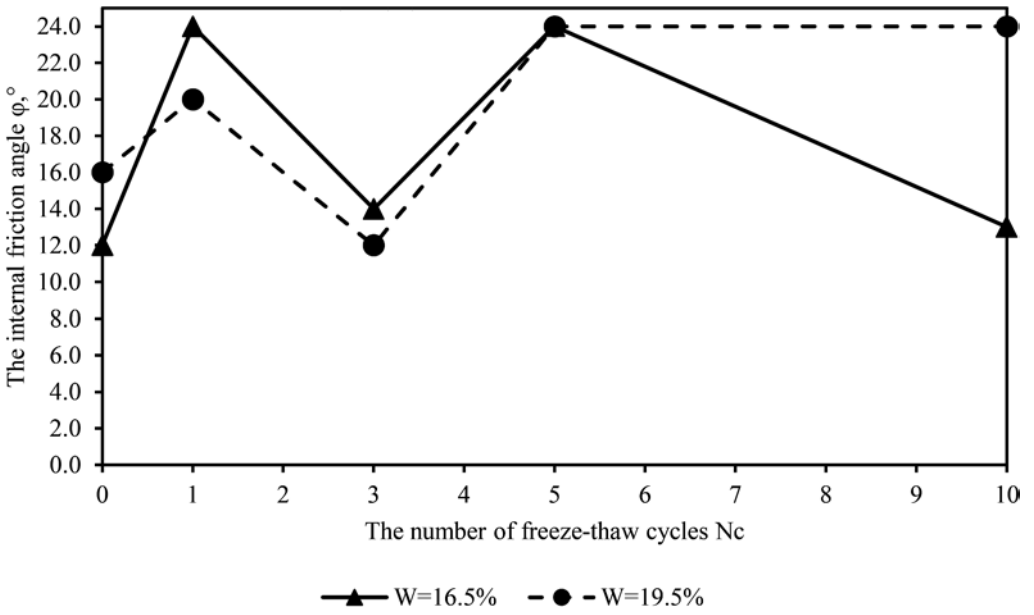

Figure 1. Dependence of the internal friction angle of the soil with e=0.55 from the number of freeze-thaw cycles.

Table 3. Direct shear test results.

Experiment No.	Void ratio, e	Moisture content W, %	Number of freeze-thaw cycles, N_c	Internal friction angle φ,°	Cohesion, kPa
1	0.55	16.5	0	12	39
2	0.55	16.5	1	24	22
3	0.55	16.5	3	14	41
4	0.55	16.5	5	24	6
5	0.55	16.5	10	13	28
6	0.55	19.5	0	12	39
7	0.55	19.5	1	24	22

9	0.55	19.5	5	24	6
10	0.55	19.5	10	13	28

The study have shown that the first freeze-thaw cycle leads to a decrease in the cohesion up to 44% (Figure 2). Further freezing-thawing leads to restoration of the initial value of the cohesion. However, the cohesion decreases up to 6 times after five or ten cycles of freezing-thawing.

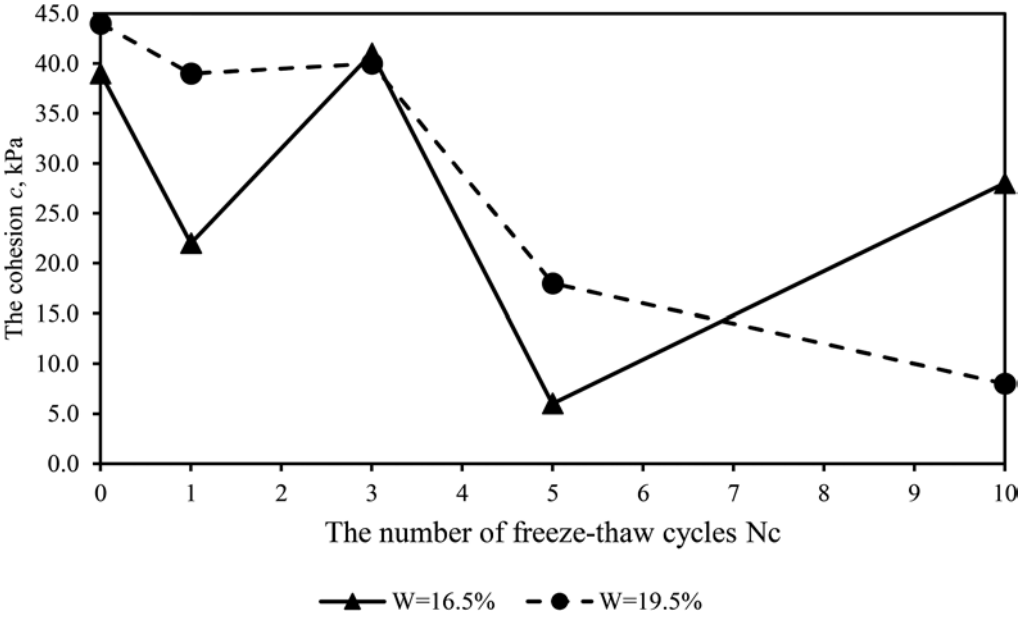

Figure 2. Dependence of the cohesion of the soil with e=0.55 from the number of freeze-thaw cycles.

4 CONCLUSIONS

In this work, a paired experiments were conducted in order to analyze the influence of the number of freezing–thawing cycles on the engineering characteristics of soil, such as angle of internal friction and cohesion. According to the results of the study, the following outcomes were highlighted:

The angle of internal friction increases dramatically up to two times during the first freeze-thaw cycle. Further freezing-thawing up to three cycles can lead to a decrease in the angle of internal friction to the initial value or lower. In general, the character of the freeze-thaw curve is not constant. After ten freeze-thaw cycles, the characteristic either remains equal to the initial value (W=16.5%) or exceeds it by 1.5 times (W=19.5%).

The first freeze-thaw cycle leads to a decrease in the cohesion up to 44%. Further freezing-thawing leads to restoration of the initial value of the cohesion. However, the cohesion decreases up to 6 times after five or ten cycles of freezing-thawing.

Moisture sensing technology for assessment of rainfall-induced slope failure

A.N. Amantay, A. Satyanaga, S.-W. Moon & J. Kim
Nazarbayev University, Astana, Kazakhstan

ABSTRACT: The frequency and duration of rainfall are two examples of the climatic conditions that have changed as a result of global warming. According to earlier research, slope failures are more likely to happen after a protracted period of drought followed by a strong rainfall or after a long period of light rains followed by a heavy rainfall. This occurrence demonstrates the significance of slope susceptibility or hazard maps in identifying high-risk areas during periods of excessive precipitation. The stability of high-risk slopes can then be sustained before failures by designing the proper slope preventive actions. This study reviewed various moisture sensing technologies for real-time evaluation of slope collapses brought on by rainfall. A thorough analysis of various literatures revealed that capacitance moisture sensors offer the best compromise for affordable and effective early warning systems, particularly in a tropical environment.

1 INTRODUCTION

As industry and human activity has increased, so have greenhouse gas emissions, which has significantly accelerated global warming. According to the most recent conclusions from the Intergovernmental Panel on Climate Change (IPCC, 2021), any forecasted emission scenarios will result in an inescapable rise in temperature over this century. Temperatures and humidity have risen throughout numerous regions, while rainfall patterns have altered. Numerous geotechnical structural issues involving road building, foundation design, slope stability, municipal waste storage, and nuclear waste disposal are frequently caused by climate variations, and these issues call for a fundamental understanding of unsaturated soil mechanics. Rainfall-induced slope failures are one of the most frequent physical dangers in the globe (Kristo et al., 2017; 2019; Rahardjo et al., 2007). Long and severe episodes of rainfall, which are anticipated to occur more frequently as a result of climate change, are what cause the majority of these slope failures. In example, steep and high slope with deep groundwater table frequently experience rainfall-induced slope failures (Chua et al., 2022; Rahardjo et al., 2007). According to research, shallow slip surfaces are typically involved in rainfall-induced slope failures in Asia, as seen in Kazakhstan (Satyanaga et al., 2022), Hong Kong (Brand, 1993), Singapore (Chan et al., 2020; Rahardjo et al., 2020a), Sri Lanka (Nawagamuwa and Dayarathne, 2014), and Malaysia (Saadatkha et al., 2015).

The main contributing variables to unsaturated soil mechanics have been identified as changes in soil suction and volumetric water contents. In addition, reductions in soil suction and shear strength can result in slope failures brought on by rainfall (Fredlund et al., 2012; McCartney and Khosravi, 2013). Numerous studies on landslides are carried out to promote the development of in-situ real-time monitoring employing field equipment (piezometers, tensiometers, and moisture sensors) to measure the water and suctions contents of the soil (Alonso et al., 2003; Greco et al., 2013; Rahardjo et al., 2014; Leung and Ng, 2016; Kim et al., 2017).

In order to measure soil suction in the slope, conventional water-based tensiometers are frequently employed. However, there were numerous restrictions on soil suction measurements, particularly in relation to concerns with maintenance and durability (Guan and Fredlund, 1997;

DOI: 10.1201/9781003299127-312

Tarantino and Tombolato, 2005; Rahardjo and Satyanaga, 2019; Satyanaga and Rahardjo, 2020). Therefore, considerable work has been put into developing a soil moisture measurement system with increased measurement capacity and reliable performance. The goal of this work was to offer acceptable soil moisture sensors for real-time assessment of rainfall-induced slope failures by analyzing the various types of moisture sensing devices.

2 MOISTURE SENSING TECHNOLOGY

Early Warning Slope Stability Monitoring (EWSSM) systems are becoming more and more popular, but their widespread deployment has been stymied (Oguz et al., 2019) by the expensive sensors, complexity, and lack of automation of the techniques, as well as the need for regular maintenance. To predict rainfall-induced slope failures, scientists from all over the world are searching for an effective EWSSM solution (Pajali et al., 2021). Unpredictable behavior of landslides leads to serious outcomes like human casualties and financial damage. One of the key elements in keeping track of the slope instability brought on by rainfall is the soil-water dynamics. Regular measurements of the soil moisture are required for excellent simulation accuracy (Rodriguez-Iturbe, 2003).

For a variety of purposes, including agriculture, oil and gas, studies of climate change, slope stability evaluation and monitoring, numerous companies and researchers have researched soil moisture sensing systems in the recent years. The system should have appropriate response time for an early warning system built in, be low cost, simple to maintain, and suitable for real-time monitoring before a slope fails.

The many methods for detecting soil moisture that are currently available each have their own benefits and drawbacks. To choose the best one to use, some work is needed. Figure 1 depicts common methods for assessing soil moisture. Typically, two methods can be used to measure soil moisture: Soil Water Potential (SWP) and Volumetric Water Content (VWC). The most popular key parameter for assessing slope stability is SWP. SWP can be measured using tensiometers and resistance blocks (gypsum blocks), which are pricey and require extensive maintenance (WMO, 2018). Additionally, salinity has a significant impact on the readings of Gypsum blocks, and sensors have a limited lifespan in a salty environment.

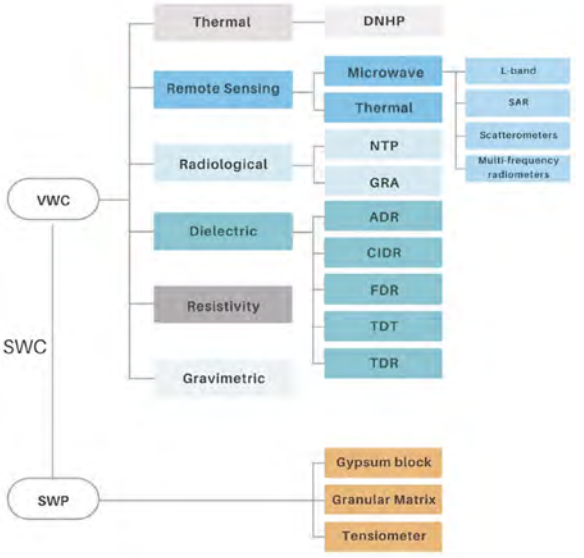

Figure 1. Prevalent soil water content (SWC) measuring techniques.

VWC is a crucial measure to quantify the effect of rainfall on the stability of the slope, according to studies by Greco et al. (2010) and Rahardjo et al. (2020a). Additionally, Greco et al. (2010) determined that VWC should be prioritized over SWP when developing a successful EWSSM system since VWC varies gradually whereas SWP may experience abrupt changes that are challenging to interpret. To increase the precision, accuracy, optimization, and cost effectiveness of moisture sensing technology, a variety of businesses and research institutes have looked at a number of approaches to measure and monitor VWC. Only a few of the widely used VWC approaches that are practical for slope stability monitoring can fulfill specific project needs when taking into account the advantages and disadvantages of each technology. Low cost, which includes the price of the sensor system, installation, and maintenance, was one of the key factors in the decision. Cost-cutting, though, shouldn't come at the expense of accuracy. At the same time, the technology must be reliable, straightforward to use, and energy-efficient. The sensor system should also be able to gather measurements from various depths in one place. This will enable the creation of a hydrological profile of slopes and improve the usability and accuracy of monitoring.

2.1 *Thermogravimetric technique*

The thermogravimetric method measures gravimetric water content (GWC) directly and uses oven drying to ascertain the real water content of soil samples. VWC can be calculated from GWC using the bulk density of the soil. The strategy is not practical for the EWSSM system due to its destructive nature and lack of logging capacity (Little et al., 1998). Before installing them on the actual slopes, it can be used to calibrate some water content sensors (such capacitors) for the soil.

A reliable methodology for carrying out automated VWC measurements with high temporal and spatial precision in the field is the Dual Needle Heat Pulse technique (DNHP) (Oschner et al., 2003). The DNHP sensor consists of two tiny (a few millimeters) needles, one of which acts as a heater and the other of which records temperature changes. Heat capacity is calculated and converted into VWC. Since the probe needles are so sensitive, any physical variation can cause measurements to be inaccurate. The technique precisely measures temperature changes just a few millimeters from the needle. To reduce the fluctuation of the DNHP sensor accuracy, Liu (2011) developed a thermo-Time Domain Reflectometry technique (TDR) sensor based on the combination of two techniques: heat-pulse and time-domain reflectometry. Thermo-TDR sensor might offer precise field estimations of VWC.

2.2 *Remote sensing*

The soil thermal characteristics measured by remote sensing can be used to estimate the moisture of the topsoil (top 5 to 10 cm) on a global scale (Mohanty et al., 2017; Lakhankar et al., 2009). To remotely monitor soil moisture over wide areas, radiometers and radars are fitted to satellites (Muoz-Carpena, 2012). The two main categories of remote sensing technologies are thermal infrared and microwave remote sensing. By analyzing interactions between the ground and electromagnetic (EM) waves, microwave techniques can estimate the soil's dielectric characteristics, allowing for the determination of the landcover's VWC (WMO, 2018). On the basis of the variations in the thermal characteristics of soil and water, thermal infrared remote sensing can be used to determine VWC (WMO, 2018). The strong contrast between the dielectric and thermal characteristics of wet and dry soil is used to determine the soil moisture (Lakhankar et al., 2009). In most cases, space-based remote sensing techniques offer measurements of moisture with time intervals of one to three days (passive radars) (WMO, 2018) or a few months (active radars) (Mohanty et al., 2017).

The Soil Moisture Near Real-Time Processor (SM-NRT-OP) was introduced in a new version of Soil Moisture and Ocean Salinity (SMOS) released by the European Space Agency in May 2021. With the fastest data retrieval possible, it promises to give soil moisture readings based on a neural network approach within three hours of sensing (European Space Agency, 2021). The spatial resolution of the measurements ranges from ten meters (synthetic aperture radar) (Moran et al., 2004) to tens of kilometers (passive radiometer) (Mohanty et al., 2017) depending on the remote sensing technique. Through the application of averaging parameters,

the use of satellite-based technology to retrieve soil moisture data for vast areas appears promising. However, because of the relatively high cost, complexity of implementation, and highly fluctuating soil moisture across both time and location, this technology is not yet ready to be employed for the EWSSM system in small metropolitan islands (such as Singapore). The technique's ability to accurately predict rainfall-induced slope failures is constrained by the fact that it can only determine the soil moisture content within the top 10 cm of the surface and at a time-frequency of 3 hours at best.

2.3 *Radiological technique*

A reliable way for obtaining precise VWC profiles at any depth up to the length of the logging line is radiological technology. Currently, the soil water content (SWC) can be measured using either the neutron thermalization probe (NTP) or the gamma ray attenuation method (GRA). According to Muoz-Carpena (2012) and WMO (2018), the NTP approach is based on the interaction of high-energy (fast) neutrons with hydrogen atom nuclei. A wetter soil is represented by a slower neutron flow. Gamma ray attenuation as it travels through soil pores is measured using the GRA method (Muoz-Carpena, 2012).

2.4 *Resistivity and dielectric technique*

By measuring electrical resistivity between two electrodes, the Resistivity method (Res) is used to determine the relative moisture content. Due to its extremely low precision, the resistance probe is not appropriate for effective warning systems (Fares et al., 2011). Salinity of the soil has a considerable impact on it, necessitating frequent calibration (Tremsin, 2017). Additionally, sensors lose their effectiveness quickly. According to Muoz-Carpena (2012), the soil-probe impedance can be utilized to determine the soil water content using the amplitude domain reflectometry technique (ADR). An electro-magnetic field that is propagating between the rods is created by an oscillator. The measured impedance is a function of the soil dielectric constant. There are numerous more soil factors that affect the VWC as evaluated by the ADR approach (e.g., density, temperature, and salinity). The usefulness and viability of the ADR approach for slope stability monitoring were proven by Shimobe and Ujihira (2009). Rod contact with stones, air spaces, or water channels has a significant negative impact on the accuracy of ADR measurements. The cost of deployment is impacted by how sophisticated the system is set up. Additionally, there aren't enough field studies and publications to draw firm conclusions about its applicability for the larger EWSSM system.

Based on measured dielectric permittivity (real and apparent), the soil moisture is estimated using the Coaxial Impedance Dielectric Reflectometry technique (CIDR). The electromagnetic signal (EM) produced by an oscillator travels through the metal tines and goes into the soil (Ojo et al., 2015). The sensor determines the strength of the incident and reflected signals. After determining impedance, the raw voltage ratio is used to determine dielectric permittivity. Although the CIDR sensor's creators assert that soil-specific calibrations are not necessary, the results of an independent research revealed that doing so improves the accuracy of the sensors (Ojo et al., 2015). In order to minimize ongoing dependencies, it is not recommended to use the sensor for large-scale applications because CIDR is a patented technology.

Based on apparent dielectric permittivity, the Frequency Domain Reflectometry technique (FDR) is used to measure SWC (Ferrarezi et al., 2020). An oscillator creates an electromagnetic signal (EM signal) that travels through metal electrodes. The interference waves that are produced are then monitored at continuous frequencies (Brahma and Goswami, 2017). For reliable results, a soil-specific calibration is needed for the FDR sensor (Muoz-Carpena, 2012). Additionally, the accuracy of sensors is greatly dependent on the probes making excellent contact with the soil, and soil temperature might have an impact (Brahma and Goswami, 2017). However, this sensor is able to produce measurements at various depths at the same spot and can be used in high salinity environments. This method is also thought to be too sophisticated and expensive to be used with the EWSSM system.

The Time Domain Reflectometry (TDR) method is a well-liked method for obtaining precise measurements of VWC (Nobrio, 2001; Ferrarezi et al., 2020; Askarinejad et al., 2018). The usage of TDR technology in the field is supported by a considerable number of publications. The sensors can detect the presence of water in many types of soil, but only at a single depth and one location (Campbell, 2017). The generator transmits an EM pulse through the sensor rods, which is the fundamental idea behind TDR. The pulse moves to the rod's end and reflects there. The soil's dielectric permittivity, which can be translated into water content, determines how long it takes for the pulse to go down and then return up (Topp, 2003).

A more advanced substitute for the TDR is the Time Domain Transmissometry technique (TDT). The TDT method only calculates the length of time needed for an EM pulse to travel to the rod's end. Consequently, the transmission line must have an electrical connection at both ends (Will et al., 2012). It is possible to estimate the water content by using the relationship between the pulse's travel time and the dielectric constant. TDT, like TDR, is a sophisticated and pricey technology that does not meet the specifications of the EWSSM system.

2.5 *Capacitance technique*

The dielectric permittivity of the soil is determined using the capacitance technique (Cap), which is influenced by the soil's water content (Atkins et al., 1998). The ability of a medium to store charges is measured using two electrodes (metal probes). The charge time in the soil is measured using an oscillating voltage, which links the dielectric permittivity to the volumetric water content. Capacitance sensors have undergone a revolution in electronics recently, including their accuracy. Capacitors are out of date due to their inaccuracy and overestimation of moisture in saline environments. The effects of salinity are minimized by using the high-frequency technique (Fares et al., 2011) in the construction of contemporary sensors. Capacitance sensors are a common low-cost option for large sensing networks nowadays since they are very precise (Campbell, 2017). Additionally, this sensor's setup, upkeep, and data administration are the most straightforward of all the soil moisture measurement options. Because cap sensors use less energy and are environmentally beneficial, they could be used for many years (Campbell, 2017). Additionally, Cap sensors that have been modified with a unique circuit architecture may detect incredibly minute changes in VWC. These customized sensors have been used by NASA to investigate whether there is water on Mars (Campbell, 2017). Thus, Cap can be seen as a very alluring technology that may be used in effective and affordable EWSSM systems.

3 CONCLUSION

A thorough analysis of several moisture sensing technologies revealed that capacitance moisture sensors offer the best compromise for affordable and effective early warning systems, particularly in a tropical environment. With less expense, precision, and little maintenance requirements, capacitance sensors enable smooth water content measurement for critical slopes of interest.

Sensing technology for measurement of thermal properties of frozen soil

Bakytkul Serikbek, Alfrendo Satyanaga, Sung-Woo Moon & Jong Kim
Department of Civil and Environmental Engineering, Nazarbayev University, Kazakhstan

ABSTRACT: Soil is one of the most widely used materials in the civil engineering sphere. Different types of soil can be broadly used in its natural or compacted form in the construction of roads, dams, canals, and railways. Due to the differences in moisture content and temperature, soil can be in various states; saturated and unsaturated, frozen or thawed. Advances in the development of laboratory testing equipment for unsaturated soil properties along with the ability to measure soil suction have prepared the way for the implementation of unsaturated soil mechanics. It is now possible to measure most unsaturated soil properties, and these achievements help for unsaturated soil property characterization that best describe the actual unsaturated soil properties. However, the static and dynamic responses of frozen soils have been found to be distinctly different from those of unfrozen soils. The behavior of frozen soils is expected to depend on the inter-particle friction and particle interlocking, the unfrozen water content, pressure melting, and the ice/water phase change. Therefore, unsaturated frozen soil properties should be measured and investigated separately from unsaturated unfrozen soil. The objective of this study is to investigate the appropriate sensors for the measurement of thermal properties of unsaturated frozen soil.

1 INTRODUCTION

Extreme weather conditions, such as lengthy periods of drought, rain or frost significantly impact building foundations. The level of soil moisture is a critical factor in potential detrimental influence. During rainy seasons, the soil absorbs large amounts of water, combined with freezing and further thawing, threatening urban infrastructure (Azmatch et al., 2012). Such activities can severely damage the foundation and load-bearing structures of houses, buildings, and facilities. During frosts, unfrozen water remains in the soil's pores, and the processes of freezing and thawing strongly influence it. These processes significantly affect the physical and mechanical properties of the soil. Therefore, studying the relationship between the amount of unfrozen water and sub-zero temperatures is an important aspect, and it is defined as the soil freezing characteristic curve (SFCC) (Malaya and Sreedeep, 2012). During the freezing period, the pore model changes, and a water film forms around the ice, which is located between the soil particles (Wang et al., 2017). According to the studied information, soil freezing begins with ice formation in the pore with the largest radius (Watanabe and Mizoguchi, 2002).

The freezing and thawing and drying and moistening cycles have similar characteristics. Water with a low matrix potential remains in the soil during the drying process, and the pores filled with water are gradually filled with air. A similar process occurs during the process of freezing, water takes on a solid form. Adsorption and capillary forces affect changes in the matrix potential of water in the soil. The decrease in the matrix index is considered to be the same for both processes, due to the fact that during freezing, water is absorbed by the soil pores in the form of a thin film and the presence of water or air and considered insignificant

DOI: 10.1201/9781003299127-313

(Spaans and Baker, 1996). For capillary strength, there is a difference in the values of the matrix index, since the surface energy of particles is different for soils in the cycles of freezing and drying (Spaans, 1994).

Figure 1 describes the process of soil freezing. The following conclusions emerge from it. The upper part of the soil undergoes freezing, while the lower layers remain unfrozen. There is a partially unfrozen layer which leads to negative pore pressure, which causes water to move into the frozen ground and ice lenses formation (Ren, 2018). The formation of ice lenses and their uneven distribution leads to the appearance of cracks, which can be a problem for infrastructure system in cold regions.

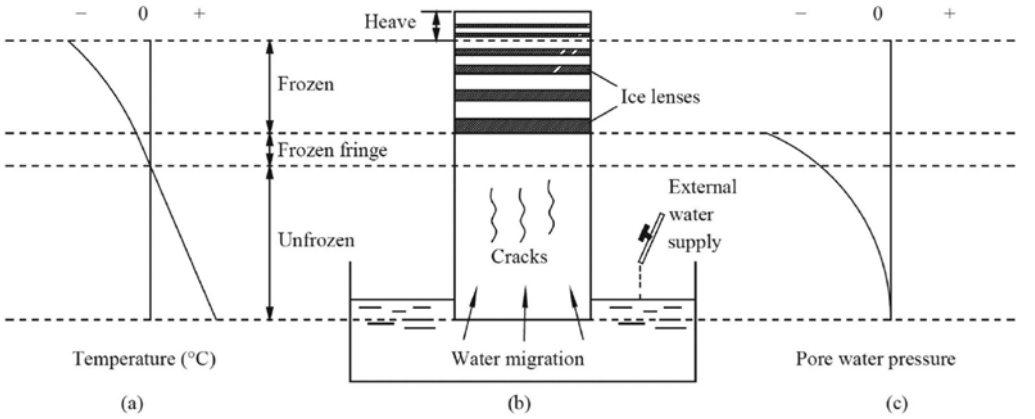

Figure 1. Soil freezing process (Ren et al., 2018).

The inter-particle friction and particle interlocking, the amount of non-frozen water, pressure melting, and the ice/water phase change are all expected to affect the behavior of frozen soils (Xiantiang et al., 2018). These distinctive features are primarily caused by the ice lens and the ice solidifying between soil particles. For instance, the presence of ice in the soil pores for frozen soils result in a decrease in hydraulic conductivity (Fredlund et al., 2012). Due to the distinct behavior of frozen soils, using existing well-established knowledge of mechanical behavior and modeling frameworks for non-frozen soil is not recommended for frozen soils without firstly performing a thorough analysis and examination. Therefore, unsaturated frozen soil properties should be measured and investigated separately from unsaturated non-frozen soil, so that a concept of unsaturated soil properties in frozen soil can be implemented in engineering practice. The objective of this research is to review the sensing technology for the measurement of thermal properties in unsaturated frozen soils.

2 THE HP METHOD FOR MEASUREMENT OF FROZEN SOIL PROPERTIES

Precision measurements of soil thermal and hydraulic parameters are required for environmental sciences and engineering applications and steady-state methods are impractical in determination of these parameters. In lab and field settings, the heat pulse (HP) method is a rapid way to detect soil thermal parameters and a range of other physical features (He et al., 2018).

Single-probe HP (SPHP) and dual-probe HP (DPHP), shown in Figure 2, are the two categories into which HP probes fall. Since SPHP can be either short or long, there are several available sampling volumes. In addition, SPHP is sturdy which provides the reduction in

inaccuracy caused by needle deflection (He et al., 2018). Unfortunately, single-probe HP can only be used to test soil thermal conductivity. In order to improve SPHP to assess other parameters such as heat capacity and soil water content, a deeper understanding of the thermal contact conductance between the soil and the probe is required (He et al., 2018).

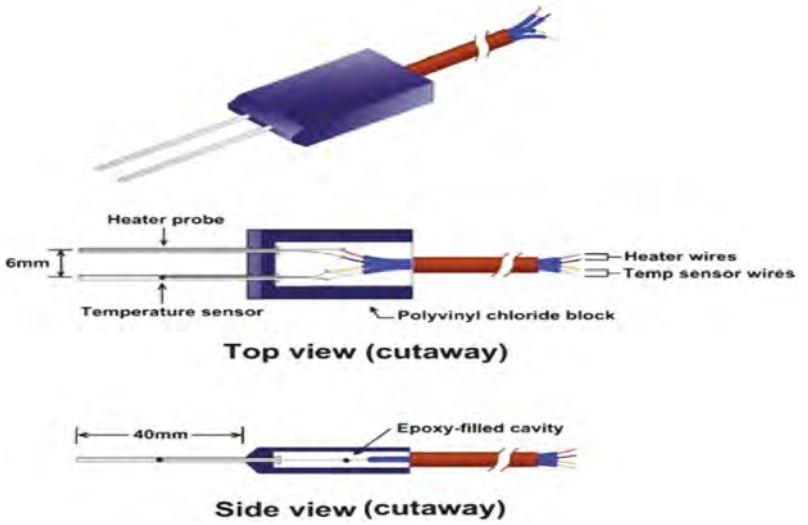

Figure 2. Example picture of dual-probe HP probe (He et al., 2018).

Heat and water flow in non-frozen soils have been measured extensively using the HP technique. However, heat causes soil ice to melt and then refreeze, complicating the use of the HP approach in partially frozen soils (He et al, 2018). When ice melts and subsequently refreezes, a considerable part of the energy in the heat pulse is concentrated on phase shifts rather than conduction heat transfer (He et al, 2018). Thermal properties of the system, such as thermal conductivity and thermal diffusivity, vary in conjunction with phase transitions, such as when water crystallizes or ice melts (Zhang et al., 2015). The measurement of soil thermal properties during such a process can be extremely useful in understanding and forecasting heat transport in such material systems.

Melting ice increases the volumetric heat capacity anticipated by HP and reduces the thermal diffusivity of the soil because partially frozen soils do not fulfill the general assumptions of the HP approach, namely no phase change and temperature invariant thermal characteristics. In accordance to the findings of Ochsner and Baker (2008), dual-probe HP sensors overestimated λ and C values in partially frozen soils (Kojima et al., 2018). Overestimation of λ was most common between 2 °C and 0 °C, whereas Putkonen (2003) discovered that C was overestimated between 10 °C and 0 °C (Kojima et al., 2018). C readings from dual-probe HP sensors were utilized in certain studies to determine the quantity of soil ice. Zhang et al. (2011) observed that the ice content of sand based on C measured with DPHP sensors was incorrect at temperatures ranging from 2 °C to 0 °C (Kojima et al., 2018). Furthermore, in partially frozen soils, as compared to non-frozen soils, C and κ (thermal diffusivity) have a distinct dependence on ambient soil temperature (Ochsner & Baker, 2008). For example, when the soil ambient temperature is very low (below 20 to 2 °C depending on the soil type), the HP melts less ice and the thermal values obtained by the HP are more accurate (He et al, 2018).

The heat conduction Equation (1) shows how heat flows from the heater to the sensors by using the radial coordinate system and refers to the phase shift in partially frozen soils.

$$C_v \frac{\partial T}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(r\lambda \frac{\partial T}{\partial r}\right) + L_f \rho_I \frac{\partial \theta_I}{\partial t} \quad (1)$$

There is no analytical alternative to equation (1) for practical soil conditions and using HP technology in frozen soils is difficult by the melting and refreezing of ice induced by the heat pulse. There are three ways in the literature for applying the heat pulse to experiments on partially frozen soil (He et al, 2018):

- By utilizing the analytical procedure applied in non-frozen soil and assuming the absence of phase change.
- By limiting ice melting through optimal heat application. Nevertheless, the only temperature range where ice melting induced by HP could be stopped was between -2 and 20 degrees Celsius, and ice melting was substantial at low temperatures, particularly around 0 °C.
- By considering how the melting of the ice changes the thermal parameters that were measured. Ochsner and Baker (2008) included the effects of melting ice into apparent thermal properties to quantify lumped conduction and latent heat components. Once the HP-induced temperature change and the change in λ with temperature are both low, λ can be removed from the partial derivatives in equation (1) and and the equation simplified as in Equation (2).

$$C_{\mathrm{a}} \frac{\partial T}{\partial t} = \lambda_{\mathrm{a}}\left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{\mathrm{r}}\frac{\partial \mathrm{T}}{\partial \mathrm{r}}\right) \quad (2)$$

The apparent heat capacity is defined as the amount of energy required to raise the temperature of a unit volume of partially frozen soil by one degree whereas the phase shift between water and ice occurs as a result of the temperature change caused by the HP. The technique employed by Ochsner and Baker (2008) did not try to monitor ice melting or calculate real thermal soil values. He et al. (2015) evaluated the Time Domain Reflectometry (TDR) method's capacity to quantify ice melting and improve the chance of getting exact thermal properties of frozen soil. For non-frozen liquid water and ice content, they combined Ochsner and Baker's (2008) technique with composite dielectric mixing models (He et al., 2018). C might be determined before to adding HP using the liquid water and ice content observed by TDR using Equation (3). The amount of ice melt may be calculated by comparing the computed C to the Ca estimated using the HP technique, which is influenced by ice melting (He et al., 2018).

$$C_v = \theta_v \rho_I c_I + \rho_g c_g f + (1 - \phi)\rho_{\mathrm{s}} c_{\mathrm{s}} \quad (3)$$

He et al. (2015) applied this approach to a sandy soil and observed that ice melting of 0.5% and 2% had a major influence on the soil thermal characteristics as determined by the heat pulse method. This investigation proved that the HP technique without extra modifications was useless for measuring thermal properties of frozen soil at temperatures ranging from 5 to 0 °C (Putkonen, 2003). The soil freezing characteristics, freezing and thawing curves, and heat capacity estimations from TDR and HP all exhibit hysteretic behavior (He et al., 2018). At temperatures ranging from 5 to 0 ° C., determining both λ and C simultaneously remains problematic.

3 CONCLUSION

This paper described the applications of heat pulse (HP) method and HP sensors to determine the thermal properties of frozen and partially frozen soils. In frozen soils when the ambient temperature is between 20 and 2 ° C, HP sensors gave more accurate thermal values. However,

at 5 to 0 ° C, HP method without developments can not be applied to measure the frozen soils parameters. Therefore, it is needed to conduct further research on modification of HP technique and HP sensors to identify frozen and partially frozen soil properties under variable low temperature conditions.

Potential applications of maturity sensors for monitoring geotechnical structures and their setup methods

A. Aniskin
University North, Varaždin, Croatia

Sh. Zharassov
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: Recent years demonstrated the widespread use of maturity sensors for monitoring structural elements of monolithic building frame resulting in the development of many instructions on their application, which does not apply to the monitoring of geotechnical structures. This paper presents potential use cases and setup methods of embedded maturity sensors. Proposed instructions can be used as a method statement for the real-time strength control of concrete foundations and underground walls.

1 INTRODUCTION

Concrete is one of the basic and widely used materials on the construction site. Many processes have to wait for this building material to reach its strength, which can lead to postponement under negative circumstances. For this reason, the goal of timely achievement of strength or design strength after 28 days plays a very important role in reducing the time of construction. It is worth noting that the priority in the accumulation of strength has massive structures, lying below the net floor level of the first floor, taken as 0.000 m. Solid and strip foundations, deep and shallow foundations, retaining walls, crossbeams, etc. are considered massive constructions. The processes inside the concrete and measures such as summer watering and winter heating (concrete care) to maintain favorable conditions are therefore given close attention(Christiaan 2019).

The process of concrete strength gain is a set of physical and chemical processes at the time of hardening. For example, concrete curing is accompanied by an exothermic reaction and its persistence for 1, 3, 7, 14,and 28 days with a rise at the beginning and a subsequent decrease in temperature at the end. The temperature graph arising from the exothermic reaction is the standard, approved by the destructive method of quality control of cubic specimens at the achievement of indicators for 28 days, and any discrepancy suggests a deviation from the mixing technology of concrete or the subsequent care of him(Jung 2009; Rudeli 2015).

In connection with the above, some regularities apply to new methods of monitoring and controlling concrete curing. In turn, the new monitoring methods involve the use of high-precision sensors and sensors that track various indicators during the curing process. In the information environment, such electronic devices are called temperature sensors or sensors of concrete maturity. The second name is rather more scientific than the first because it is derived from a method (ASTM 1998)and describes the nature of the method by reference to the temperature-time factor (TTF). (ASTM 1998)regulates two fundamental formulas in the basis of the method for calculating the temperature-time index known as Nurse-Saul (Formula 1) and Arrhenius (Formula 2). It is worth noting that the maturity method Nurse-Saul is widespread in the market of electronic devices (Jung 2009). The advantage of this method is the obvious relationship between concrete strength and the hydration temperature of the cementitious paste.

DOI: 10.1201/9781003299127-314

$$M(t) = \sum_{0}^{t} (T_a - T_0)\Delta t \tag{1}$$

where M(t)= temperature-time factor, ºC-days or ºC-hours; Δt = time interval, days or hours; T_a = average concrete temperature, ºC, during the time interval, Δt; and T_O = datum temperature, ºC.

$$t_e = \sum e^{\frac{-E_a}{R}\left(\frac{-E_a}{T_a} + \frac{-E_a}{T_s}\right)\Delta t} \tag{2}$$

where t_e= equivalent age at a specified temperature, T_s, days or hours;

E_a= activation energy, J/mol; R = gas constant, 8.31 J/(K*mol);T_a= average temperature of concrete during the time interval, Δ*t*, K; T_s= specified temperature, K; and Δ*t* = time interval, days, or hours.

The current market for electronic devices offers various variants of maturity sensors, both foreign and domestic, and assemblies (Figure 1).

Figure 1. Examples of existing concrete maturity sensors.

Several parametersare considered when choosing a maturity sensor, such as the presence of a wireless or wired network, the measurement of various indicators, the minimum and maximum temperature range, the accuracy of the error and measurement interval, as well as the data transmission range and battery life(Utepov 2022).

During the existence of maturity sensors, the development of the electronic component has gone far beyond the technical regulations and regulatory and technical documentation for their installation and operation. Based on the analysis of existing literature sources, it can be concluded that the works (Christiaan 2019; Jung 2009; Rudeli 2015), where concrete maturity sensors were used, mainly refer to the building framework, that is, columns and floor slabs lying above zero level of the first floor.During the existence of maturity sensors, the development of the electronic component has gone far beyond the technical regulations and regulatory and technical documentation for their installation and operation. Going back to what was said before, the priority in strength gain is given to massive structures lying below the level of the clear floor of the first floor; the problem that emerges in this article is the following. Concrete maturity sensors should be installed in the areas withthe slowest strength gain and the most stressed areas(Nurakov 2020).In this connection, as the main attention is paid to the typical floors above the 0.000 m elevation, the moment of installation of concrete maturity sensors and operation, in the form of instructions, not to mention technological charts has been missed, which forms the purpose of this article. The authors offer effective methods of installation and operation of concrete maturity sensors in the construction of geotechnical structures (foundations, retaining walls, etc.) (Awwad 2019; Zhussupbekov 2019).

2 USE CASES

Long-term durability is very often discussed in the construction of reinforced concrete structures. Various sensors and devices for monitoring the condition of reinforced concrete structures are used for this purpose. Thus, in the example of tunnel construction, the focus is on concrete life-cycle monitoring sensors. Depending on the environment in which the structure is operated,

the installation of sensors plays a very important role. The importance of technology compliance and subsequent monitoring is described in (Feng-Hui 2000), where an example of the collapse of parts of tunnel interior walls is given. The colossal damage to public property and the threat to ordinary citizens is the result of an untimely inspection of the structure. The authors decide to use a robotic automatic tunnel inspection system compatible with sensors in the concrete, but the question of their design when the sensors are immersed in the body of the concrete remains open. The behavior of sensors during construction of the tunnel is considered in (Bursi 2016), where the performance of built-in and externally installed sensors are compared. It is worth noting that the difference in readings was 50%. To give an example of other constructions, we can highlight works related to massive foundations (Utepov 2022).Another important factor deals with the monitoring of deformation and temperature of reinforced concrete pile foundations, namely, the careful installation of sensors for obtaining correct data. Attention is paid to such secondary, but not unimportant factors as the transportation of sensors and the protection of sensors during the process of concreting foundation wells. Some works (Qin 2014) mention the use of several sensors to monitor the condition of reinforced concrete structures. An interesting point when conducting experiments of this type is the compatibility of electronic devices or their location relative to each other. The construction of massive structures or large volumes of concrete has always had its nuances. This problem is discussed in (Chang 2012), where a temperature difference exceeding the permissible limit is considered. This phenomenon is fraught with cracking, which leads to the subsequent penetration of moisture and further corrosion of the reinforcement (Lukpanov 2021; Lukpanov 2021).The prerequisites for determining the location of temperature sensors are given in (Ye Utepov 2019). This method can be applied to temperature sensors (Utepov, Tolkynbayev 2022; Utepov, Tulebekova 2022), which may not be applicable in other cases, but the validity of this methodology can form the basis for instructions or process maps for installation and operation of temperature sensors. Thus, when examining the sources currently available, it can be concluded that the given examples of using sensors to monitor phenomena occurring in concrete contain information for theoretical analysis, while attention to the features of installation in practice, especially on geotechnical structures and structures, is not adequately paid.

3 MATURITY SENSORS SETUP METHODS

The installation process for any sensor on a construction site begins with a secure attachment to the structure. Before installation begins, the depth of the sensor or its components, such as a cable with a sensor at the end, must be determined. Here is an example of fixing a concrete maturity sensor to working rebar (Figure 2).

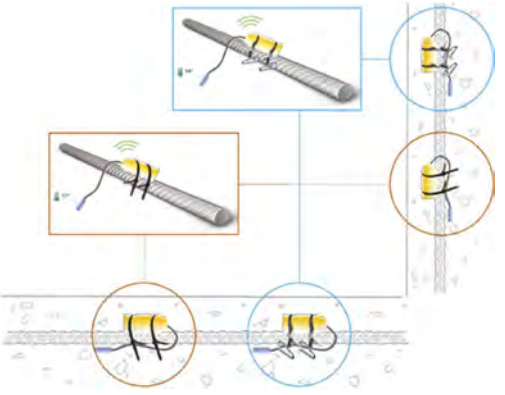

Figure 2. Example of mounting and fixing the concrete maturity sensor on horizontal and vertical reinforcement.

According to the figure above, the sensors are installed according to a certain scheme on the longitudinal (working) and transverse (distribution) fittings. Fixing in the field is done with

a wire or a clamp. Depending on the strength of the signal transmission at the construction site, the sensor is immersed to a greater depth than the protective layer of concrete. This distance from the surface of the housing to the paved mixture must be strictly maintained, as required by the technology of the concrete mix. If the casing is leaking or the signal transmission is poor, only the cable with the sensor at the end is immersed, while the main part of the cable is placed on the surface. The contact of the sensor with other surfaces, except for the concrete mixture, is excluded, as it may lead to distorted data. It is worth noting that when pouring and compacting the concrete mixture, you must be careful because the vibrating machine can damage the sensor. The transmission of measured data goes locally within the range of the sensor and does not apply to the entire structure. In this regard, the pitch and depth of the sensors are very important. The logic of the schematic location of the sensors on the example of a strip foundation on pour piles, a foundation slab, and a retaining wall is given in the sections below.

In the case of a cast-in-place pile, the sensors are installed at the initial stage when the frame is tied in because access to the sensor is restricted after the frame has been sunk into the borehole. Depending on the depth of the pile, the required number of sensors is selected. Due to the location of sensors under the soil layer the signal transmission power can significantly decrease, in this regard it is reasonable to sink only the cable with the sensor into the concrete body and fix the body itself on the armature outlet above the ground (Figure 3). When assembling the strip foundation formwork, the sensor housing can be both in and out of the concrete body. In this case, it is advisable to install the sensors on the transverse reinforcement, so that the cable with the sensor at the end is located in the center of the structure (Figure 3).

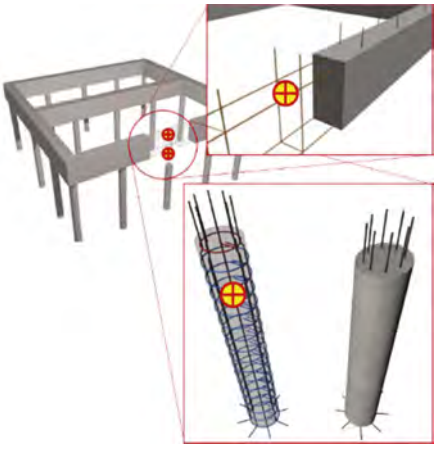

Figure 3. Location of sensors inside the strip foundation on pour piles.

The foundation slab is the most massive structure when installing sensors for monitoring. At this scale, it is necessary to install sensors at several heights (Figure 4).

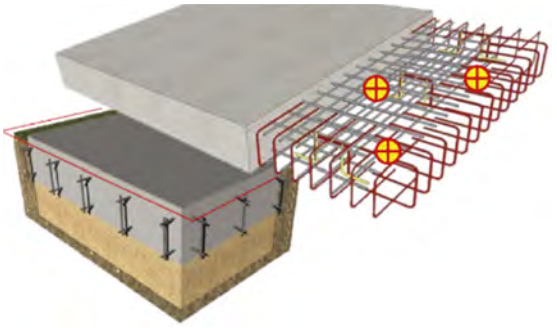

Figure 4. Sensor location inside the foundation plate.

In the case of installation of sensors in structures at height, it is necessary to install scaffolding, decking, and scaffolding with enclosing structures. An obvious example of installing sensors at height is retaining walls, which come in different heights and thicknesses. Alternatively, sensors are installed as in the case of pouring piles at the initial stage of tying the reinforcement cage, and then the finished cage is connected to the outlet of the reinforcement at the bottom of the foundation (Figure 5).

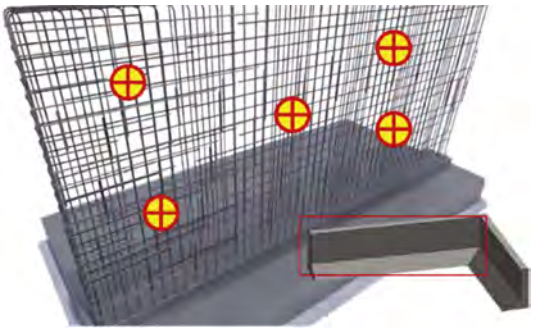

Figure 5. Sensor location inside the retaining wall.

4 CONCLUSIONS AND RECOMMENDATIONS

Based on various examples, based on the existing sensors on the market for concrete monitoring, the following generalized conclusions and recommendations have been formulated, which apply to the installation of any sensor, regardless of its purpose:

1. Subsequent monitoring of the design may be accompanied by the following hazardous and harmful factors:
- increased or decreased temperature of the air in the working area;
- increased air humidity, noise and vibration level;
- location of working place at a considerable height relative to the surface of the ground (floor, overlapping);
- insufficient illumination of the working places;
- physical overloading.

2. To ensure the reliability of the results obtained, you should pay attention to the following points in the operation of the sensors:
- completeness and reliability of attachment of parts;
- serviceability of the sensor components, protective sheathing, and presence of mechanical damages;
- the integrity of insulating parts of the sensor housing;
- serviceability of the sensor activator (free switching on and off before the beginning of work);
- serviceability and connection of the data acquisition station, if any, to the socket with voltage (change of light indicators);
- location of the data collection station in a hard-to-reach and low-traffic location for safety and uninterrupted operation.

The results are reflected in the technological schemes (Figures 2–5), which show the proposed locations for the installation of sensors. The number, pitch, and depth of installation may vary depending on the size, massiveness of the structure, and the peculiarities of the geotechnical construction. It is worth noting that the issue of using different sensors to monitor one structure remains open, which makes it possible to continue the development of technological schemes and maps when several sensors work in one working field.

Swedish weight sounding test: Site investigation for a solar power facility in the Philippines

M.J.P. Armario, M.P.V. Follosco, J.M.B. Gargullo, P.A.R. Lu & R.A.C. Luna
AMH Philippines, Inc.,University of the Philippines, Diliman, Quezon City, Philippines

ABSTRACT: Swedish Weight Sounding Test (SWST) is one of the common in-situ penetration testing techniques. This is often utilized as a part of the geotechnical investigation for foundation, liquefaction, and landslide assessments. In the Philippines, this is typically conducted as a supplement to Standard Penetration Test (SPT), which is the most used in-situ test in the country. Empirical correlations between the SPT N-values and the number of half-turns (N_{SW}) from SWST are developed from the data gathered on several soil exploration sites. Considering the portability of the equipment and the cost of the test, this offers a good supplement and/or alternative to SPT.

A case study of a solar power plant located in the Central Luzon Region is presented. A total of fifty-four (54) test points are located strategically for the subsurface investigation for the expansion of the said solar power plant. The correlation was found to be applicable to fine-grained or clayey soils, with conservative inherence. The verification and development of correlations based on the local/Philippine setting are needed to provide more accurate and consistent results.

1 INTRODUCTION

At the end of the 19th century, the SWST was first used in Scandinavia by the Swedish State Railways as a survey of bad roadbed conditions. The commission was called State Railways Geotechnical Commission, which developed and standardized a penetrometer test, later to become known as the Swedish Weight Sounding Test. The main purpose of the test is to obtain estimates of the shear strength of SPT-Numbers of soil deposits (Tsukamoto et. al., 2004). The SWST has also been used in reconnaissance and surveys of landslides and earthquake-disaster-stricken sites (Towhata et. al., 2004).

The SWST is composed of 1-meter-long steel rods with a 19 mm diameter, with the first rod being 800 mm long with a 200 mm long twisted screw point. It is common in Scandinavian countries but also became popular in Japan for assessing the liquefaction susceptibility of soil and determining its bearing capacity.

It was in 1954 that this testing method was first introduced in Japan for field inspections on river embankments. Since then, it has become a popular technique for soil surveys for the construction of subgrade and base of pavements and port facilities. In 1976, it was standardized by the Japanese Industrial Standards (JIS), and by the International Society for Soil Mechanics and Foundation Engineering (ISSMFE) in 1989.

2 BACKGROUND OF SWST

The Swedish Weight Sounding Test (SWST) was popularized and is widely used in Japan and some European countries. It is an in-situ type of static penetration test commonly used in loose to medium dense sand and silt, clay, peat, and organic soils.

DOI: 10.1201/9781003299127-315

The SWST equipment consists of a 200 mm screw-shaped point, steel plates weighing a total of 100kg (0.98kN), 22mm Ø steel extension rods (standardized by ENV 1997:3-2000), and a handle for rotating the equipment. Measurement of soil resistance can be recorded as N_{SW}, which is the number of half turns the device is rotated for every 1 meter penetration. The typical depth that the SWST can penetrate is 6 meters up to 9 meters, the data gathered from this depth is sufficient for light structures, typicall1 1 to 2-storey residences. The SWST presumes that the project site is on a flat semi-infinite ground, similar to a standard penetration test.

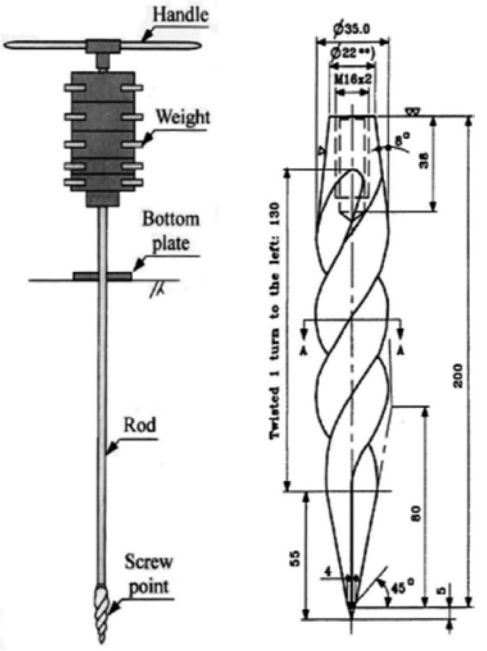

Figure 1. (a) Schematic view of SWST (Tsukamoto et. al., 2004) (b) SWST Screw (ENV 1997:3-2000).

3 METHODOLOGY

The SWST equipment is assembled by connecting the rods, connecting the screw at one end of the rods, and placing the dead weights equal to 100kg (0.98kN), W_{SW}, as shown previously in Figure 1-a. For soft soils, penetration may occur even without rotation, the depth penetrated is then recorded. If there is no more self-penetration, the handle is then rotated. The number of half turns (180 degrees) for every 1 meter is then recorded and is called N_{SW}. The higher the N_{SW}, the harder the soil.

Testing should be terminated when a certain penetration resistance or certain depth is reached. Testing could be terminated if the screw point does not penetrate anymore when rotated or when driven by at least 10 blows of a 3.0 kg sledgehammer. Another criterion is when two adjacent 25 cm thick layers are encountered with increasing penetration resistance exceeding 50 half turns per 25 cm, or penetration is less than 1 cm per blow after 5 blows of the sledgehammer.

4 CORRELATIONS

There are several correlations developed between the SWST and SPT results (e.g., Inada, 1960; JGS, 19995; Tsukamoto et. al., 2004). The great advantage of using Japanese correlations is that it uses a small variation of SPT Energy Ration (ER) in Japanese practice. An average value of 72% can be considered as the average value of ER in Japan (Ishihara, 1993).

The equivalent SPT N-value may be obtained using the empirical formula developed by M. Inada (1960).

For Sandy Soils,

$$N = 0.02 W_{SW} \tag{1}$$

$$N = 2 + 0.067 N_{SW} \tag{2}$$

For Clayey Soils,

$$N = 0.03 W_{SW} \tag{3}$$

$$N = 3 + 0.05 N_{SW} \tag{4}$$

Inada suggests a factor of safety of ±1.5 to 4 for sandy soils and 3 for cohesive materials due to the various types of soil and other factors. The empirical equation for the unconfined compression strength of the soil is as follows:

$$q_u = 0.045 W_{SW} + 0.75 N_{SW} \tag{5}$$

On the other hand, Tsukamoto (2004) proposed an empirical formula to estimate the SPT-N values and the relative density, D_r by using the void ratios and the effective overburden pressure. The empirical equation for the SPT N-value and relative density are as follows:

$$N = \frac{\sqrt{e_{max} - e_{min}}}{10} (N_{SW} + 40) \tag{6}$$

$$D_r = \sqrt{\frac{(N_{SW} + 40)(e_{max} - e_{min})^{2.2}}{90} \sqrt{\frac{98}{\sigma'_v}}} \tag{7}$$

where σ'_v is the effective overburden stress in kPa, and the values of maximum and minimum void ratios, e_{max} and e_{min}, are evaluated based on the testing method by the Japanese Geotechnical Society (2009). This method is usually employed for fine sands containing fines less than 5%, though it is not limited to silty sands.

5 ADVANTAGES AND LIMITATIONS

One of the advantages of the SWST is that it can easily detect weak thin strata, but it is not suitable for soil sampling at a specific depth and for monitoring the groundwater depth accurately.

Like other sounding methods, the primary advantage of SWST is that a nearly continuous profile of penetration resistance is developed for stratigraphic interpretations. It allows detailed definitions of soil layers and detection of thin layers of seams. The manual type of SWST has the optimal performance/accuracy in the soils with rotational resistance between 2 to 40 half turns per 0.20 meter of penetration (Habibi, 2007). SWST, as compared with other soundings is simpler, faster, has lighter reaction weight, and better cost-efficiency. SWST can be classified as a "low-cost in-situ test". However, it has low accuracy on soil classification, and the rod friction included in the test result makes the ability lower.

As mentioned, SWST is optimal for soil resistance of 2 to 40 half-turns for every 0.20 meter. Below this limit, the accuracy of SWST measurements decreases due to the discontinuous measurement of resistance. Also, in high resistances (N_{SW} > 100 half turns/0.20 meter) the repeatability of the results is not clear (Habibi, 2006).

The effect of friction along the rods should be taken into consideration also (ENV 1997:3-2000, JIS A 1221-2002). This effect is considerably high, particularly when there are fill material or peat layers on-site (Broms and Flodin, 1998; Habibi, 2006). Using SWST in these cases should be accompanied with caution.

Other factors considered to have direct impacts on the results of the SWST are the location of maximum rotation diameter from the screw point, screw point abrasion, and different shapes of screw points. The variation in these factors leads to differences in cutting mechanisms. Specifically, this can lead to a considerable impact on self-weight penetration (Fujii et al, 2003).

6 CASE STUDY

6.1 *Project location*

The study area is in Mt. Sta. Rita in Subic, Zambales. It has generally mountainous terrain which makes soil investigation difficult. As such, SWST was performed in conjunction with the SPT to cover as much area as possible.

The study area can be accessed through Binictican Drive, then passes through Pamulaklakin Trail. It is approximately 7.67 kilometers from Subic Bay Freeport Zone and 10.10 kilometers from the City of Olongapo.

6.2 *Results*

The empirical equation proposed by M. Inada gives a very low equivalent N-value. With this, we have come up with a new empirical equation to derive N-values which is closer to the N-value from SPT.

For Sandy Soils,

$$N = 2 + 0.54N_{SW} \tag{8}$$

For Clayey Soils,

$$N = 3 + 0.40N_{SW} \tag{9}$$

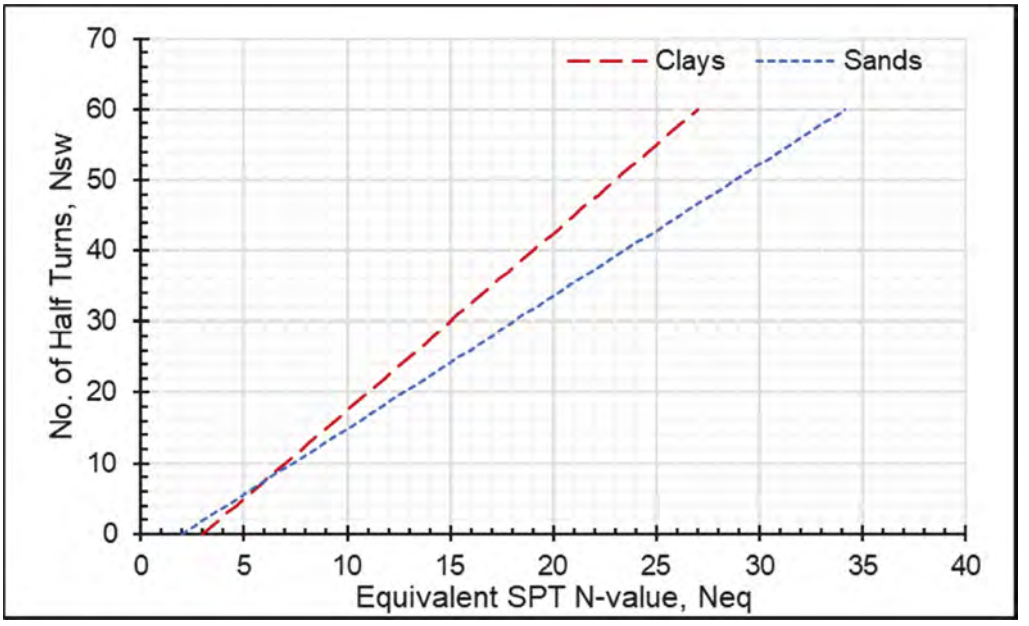

Figure 2. Corresponding N-value from the results of the SWST.

The following chart presents the result of 54 SWS tests conducted in the study area. Due to uncertainties at the test points, the equivalent N-values for sands and clays are presented to give the range of the possible actual N-value.

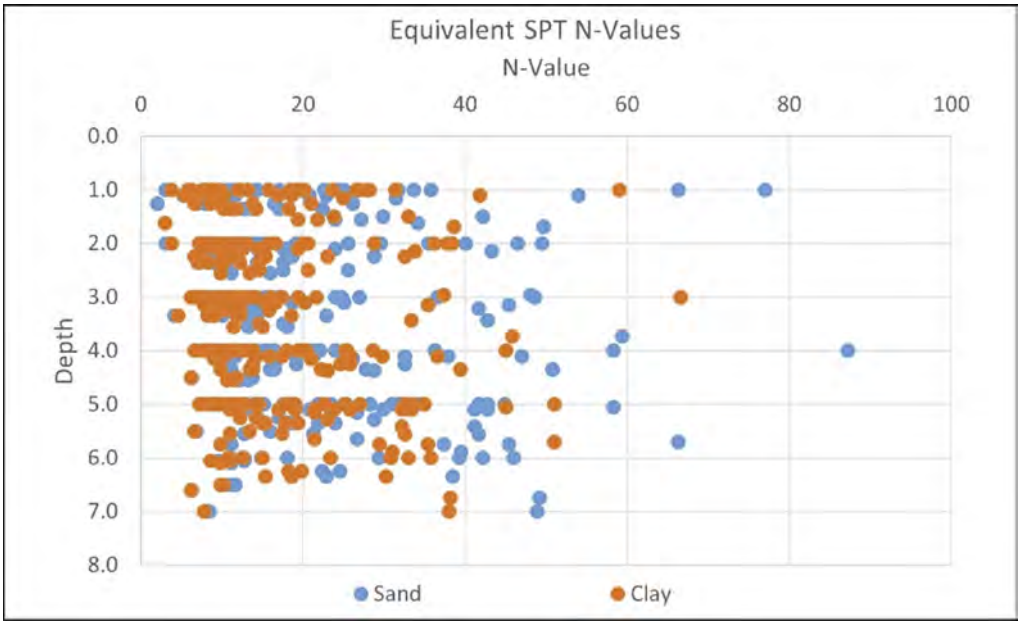

Figure 3. Equivalent SPT N-values from the results of the SWST.

6.3 *Comparison with SPT*

The data obtained from the site with the SWST need to be verified. As such, an SWST was conducted immediately adjacent to one of the SPT (MV-10). Based on the laboratory tests conducted on the soil samples of MV-10, the soil is classified as clay. Thus, Equation (4) proposed by M. Inada will be used.

The following table presents the SPT N-value from the SPT conducted on MV-10 and the equivalent N-value from the SWST conducted immediately adjacent to the SPT using Equations (4) and (9). It could be observed from the table that the N-value from the SWST is generally conservative compared to the values obtained from the SPT.

Table 1. SPT N-Value of MV-10 and Equivalent N-Value from SWST.

Depth	Soil Classification	Soil Penetration Test N-Value	N_{SW}	Equivalent N-Value (Equation 4)	Equivalent N-Value (Equation 9)
0.00 – 1.50	ML	39	30	4	15
1.50 – 3.00	MH	16	39	5	19
3.00 – 4.50	Sandy Clays	13	21	4	11
4.50 – 5.00	Sandy Clays	11	19	4	11
5.00 – 5.50	Sandy Clays	13	15	3	9

6.4 *Findings and recommendations*

The test results of the SWST conducted immediately adjacent to the SPT at MV-10 show that the equivalent N-value from the SWST is generally consistent with the recorded N-values from SPT for fine-grained or clayey soils. The calculated equivalent N-values are also

consistently relatively more conservative, which in turn, results in the use of more conservative soil strength and deformation properties for use in the analysis and design of foundations.

Furthermore, it is recommended to always conduct an additional SWST immediately adjacent to an SPT for correlation purposes since the proposed empirical equation by M. Inada will need further verification for other types of soil. Some modifications to the said correlation equations may be essential to better suit local soil conditions.

The results of the investigation were based on the SWST conducted by AMH on the project site which is composed of 54 SWST points. The investigation aims to provide a practical alternative to the SPT by providing the equivalent N-value of the soil at these test points. The verification is deemed limited at this time and recommended to be supplemented in future opportunities in the potential expansion areas of the project site.

7 CONCLUSIONS AND WAY FORWARD

The SWST was utilized for the subsurface investigation of a study area in Subic, Zambales. The SWST data were correlated using the empirical equations by M. Inada (1960) to an equivalent SPT N-value for the individual subsurface layers. The correlation was found to be applicable to fine-grained or clayey soils, with conservative inherence. The verification and development of correlations based on the local/Philippine setting are needed to provide more accurate and consistent results, which may allow SWST as an alternative to SPT in certain project conditions.

Further use of the SWST adjacent to borehole sites with SPT is highly encouraged to further develop an empirical relationship of SWST data to SPT N-values in the Philippine setting.

Comprehensive recognition of soil and water conditions in the area of critical infrastructure - case study

P. Popielski, Ł. Kaczmarek, A. Dąbska & B. Bednarz
Faculty of Building Services, Hydro and Environmental Engineering, Warsaw University of Technology, Warsaw, Poland

R. Mieszkowski
Faculty of Geology, University of Warsaw, Warsaw, Poland

ABSTRACT: The article presents selected advantages of a wide range of applied soil testing methods in the field used to evaluate undesirable changes in soil and water conditions at the site of critical infrastructure represented by a drinking water pipeline. The pipeline is located in the flood zone of a large lowland river. Various testing methods were applied due to the diverse geological structure characterised by the high dynamics of geomorphology evolution. Drilling, two penetration methods (Cone Penetration Test with pore water pressure measurement - CPTu, Dynamic Probing Super Heavy - DPSH), piezometric observation, three geophysical methods (Electrical Resistivity Tomography - ERT, Seismic Refraction Tomography - SRT, Multichannel Analysis of Surface Waves - MASW), and laboratory tests were done. Hence, it was possible to identify the exact locations of soils susceptible to deformations inducted by seepage zones. The paper briefly synthesises the selected results of the realized field and laboratory tests.

1 INTRODUCTION

The value of critical infrastructure induces that the soil and water conditions studies program has to be comprehensive and customised to each individual case. Therefore, there is a necessity to face various types of challenges (research, methodological and organisational), such as:

1. The need to determine the full range of boundary conditions to eliminate the slowly progressing unfavourable processes. Here, it is essential to point out the integration of the study's results previously carried out, as well as from neighbouring areas. A large amount of data enables a description of soils with naturally possible large variations through statistical tools. Dealing with such a task is very difficult due to the usually time-limited research schedule. In this context, various geotechnical and geological-engineering databases are invaluable (e.g. Zhussupbekov et al. 2021);
2. The reliability of determining soil parameters (referred to the previously mentioned statistical analysis). Thus, the need to consider the specifics of different testing methods - in some cases, despite obtaining the same parameters, their values are different (e.g. determination of shear strength parameters: field vis laboratory tests). A particular solution is to use a "preserving" approach, no less, it often results in the emergence of very high reinforcement costs;
3. Related to the issue of reliable determination of soil parameter values is the knowledge of the soil characteristics modification (e.g. geomechanical) as a result of various processes (e.g. soil creep phenomenon - Kaczmarek et al. 2021; cyclic freezing and thawing - Bragar et al. 2022);
4. Limited possibilities of conducting invasive testing methods such as repeated drilling of a small study site. It can lead to soil and water conditions degradation. Also, critical infrastructure sites may be legal protection areas limiting further the locations of testing as well

DOI: 10.1201/9781003299127-316

as the range of methods to be employed. Moreover, next to the critical infrastructure, there is often a significantly developed accompanying underground and aboveground infrastructure (e.g. high voltage lines), causing the lack of possibility of entering heavy and high equipment. The described situation can translate into the reliability of the obtained data (it is worth mentioning the need for subsequent application of test results extrapolation);
5. The lack of possibility to turn off such infrastructure for conducting a study, especially *in situ* reference studies in the case of already existing facilities.

The aforementioned exemplary challenges underline the value of practical papers on study programs for critical infrastructure areas, as well as the presentation of their results.

The study was done with the perspective of analysing the development of soil deformation (inducting geomechanically parameters changes) caused by water flowing through the soil (examples of such relations: Chang & Zhang 2013; Ke & Takahashi 2014). Such processes can be crucial for the safety of critical infrastructure in the flood zone of a large lowland river. Deformations due to seepage, like different types of suffusion, can lead to serious failures and disable the water supply (in the case of a water supply line), which can be destructive, especially during hydrological drought. In order to define zones of soil susceptible to suffusion, diversified field and laboratory tests have to be done.

2 RESEARCH AREA

The analysed area is located at the right embankment of the river, situated within a large city. Morphologically, the area is on the floodplain terrace. Nearby areas are mainly green areas; they are not industrially developed. The ground elevations vary (Figure 1), related to river activity and anthropogenic changes. Denivelations within the study area amount to several meters. The dominant slopes in the analysis area range from 5% to 12%.

3 INFRASTRUCTURE

The critical underground infrastructure at the research site states a pipeline supplying drinking water for the city. This pipeline, about 310 m in length and 5 m in height is founded ca. 6 m below ground level before the embankment and about ca. 8.5 m below ground level within the embankment area.

4 METHODS

The following field and laboratory works were carried out in order to recognise the soil and water conditions in the vicinity of the pipeline (a description of the research methods can be found in, i.e. Head 2006 and Tarnawski et al. 2020):

1. Geophysical surveys - Electrical Resistivity Tomography (ERT), Seismic Refraction Tomography (SRT), Multichannel Analysis of Surface Waves (MASW);
2. Exploratory drillings with sampling for further testing;
3. CPTu static penetration tests and DPSH dynamic penetration tests;
4. Laboratory tests covering physical parameters (water content, grain size distribution, minimum and maximum density of the soil skeleton) as well as shear strength properties (where during numerous triaxial compression tests also the liquefaction has been observed);
5. Piezometers installation with groundwater monitoring, including the measurements of the groundwater table, water temperature and electrical conductivity at various depths.

Investigations were performed at two longitudinal cross sections and four cross sections perpendicular to the pipeline (at eight test nodes). The location of the research nodes (boreholes, piezometers, static and dynamic penetration tests) is shown in Figure 1.

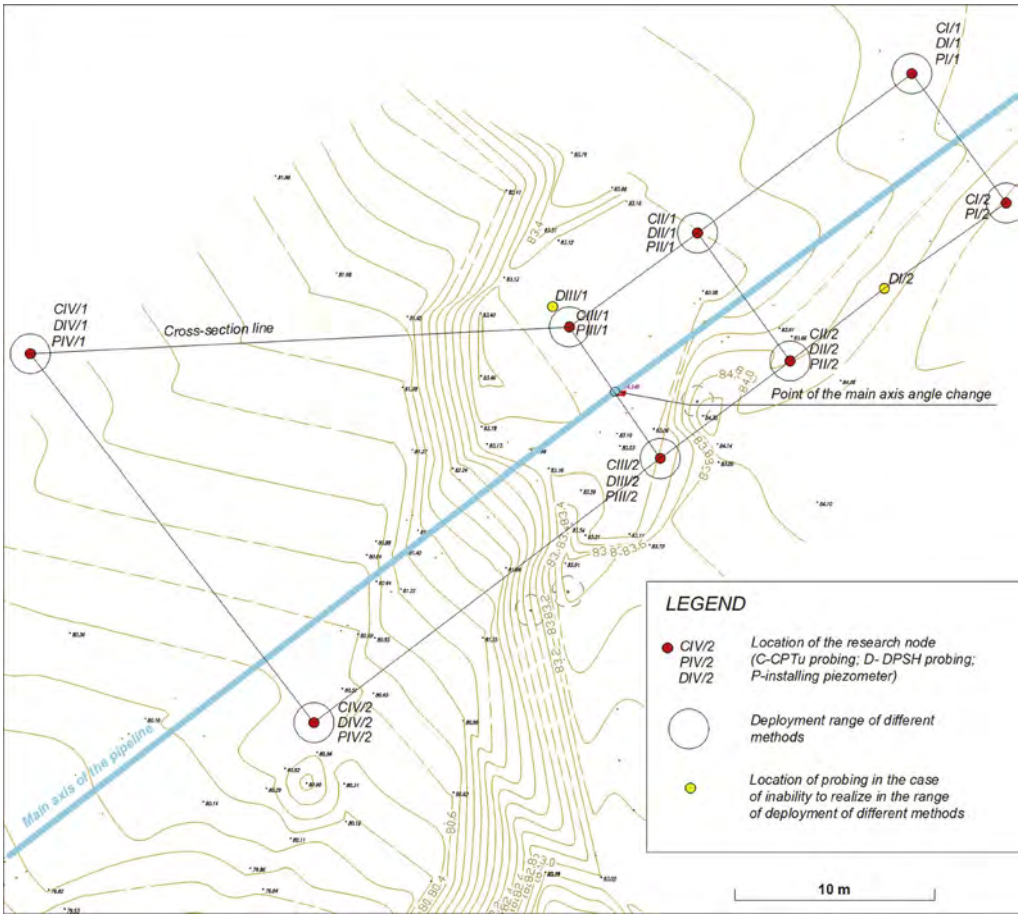

Figure 1. The geomorphology of the research site and the location of individual field tests were realised as part of the filtration deformation analysis.

5 RESULTS

Two types of *in situ* penetration test - dynamic (DPSH) and static (CPTu) - were carried out at all testing nodes to identify loose soil zones. Furthermore, the outcome of the MASW geophysical prospecting, led through the testing nodes, provided the data converted to a generalised density index cross-section (Figure 2). A compilation of the results (there were cases, where different methods suggested various places of loose soils) indicates that there are loose sands at various elevations in most of the research nodes (Figure 3). Loose soils were also found in the contact zones between the underground infrastructure and the soil. Each testing method revealed loose soils in PIII/1 at 74-76 m a.s.l., PIII/1 at 76-78 m a.s.l. and PIII/2 at 78-80 m a.s.l. It confirmed that these soils are especially susceptible to the occurrence of deformations due to seepage. Most probably, local zones of loose soils are already a result of the deformations induced by seepage. In order to obtain clear documentary material, monitoring is continued to cover extreme *boundary conditions*.

One of the elementary factors affecting the subsoil is infiltrating water. The direction of groundwater flow (Figure 4) is related to the piezometric head and the water level in the river (the documented groundwater flow paths corresponding to the direction of flow into the adjacent river). Piezometric observations show varying filtration conditions along the pipeline below the ground surface. Deformation caused by seepage (Dąbska & Popielski 2019) is

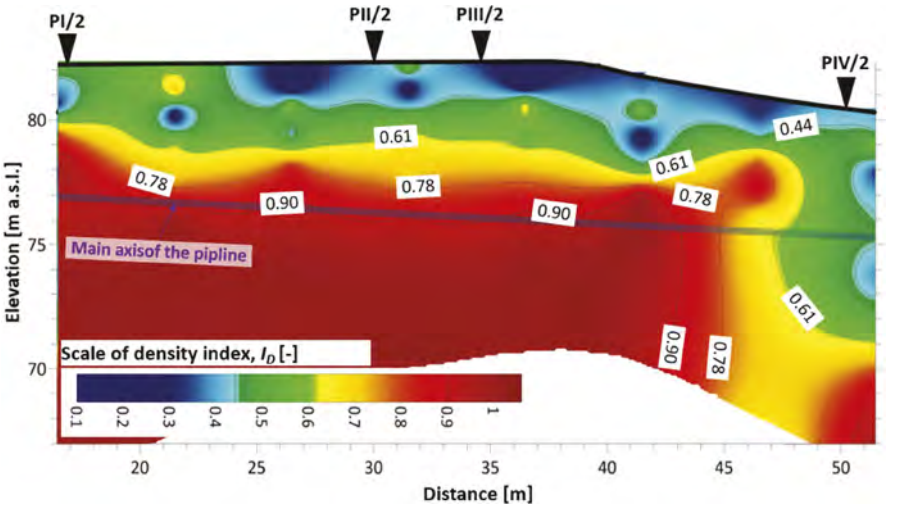

Figure 2. Results of seismic prospecting (converted to a density index) in the cross-section from the PI/2 to PIV/2 testing node.

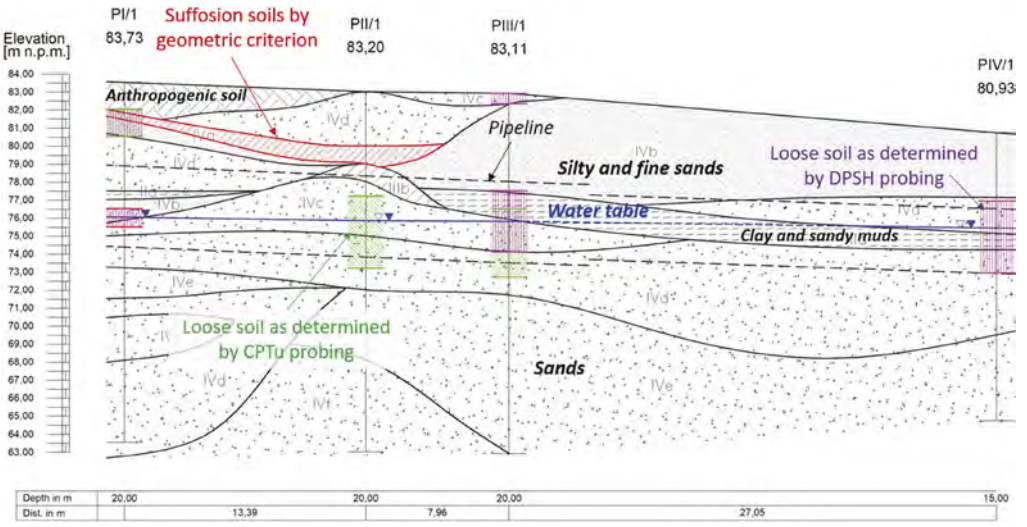

Figure 3. Locations of loos zones against the background of the observed soil and water conditions in cross-section PI/1-PIV/1.

a phenomenon determined by the current value of the hydraulic gradient and the granulometric characteristics of the soil, characterised by high dynamics and variability over time. No critical hydraulic gradient exceedances were registered in the analysed soil and water conditions from 29.04.2022 to 2.09.2022. However, exceedances must have occurred in the past, as evidenced by specific soil loose zones.

The occurrence of intensive filtration (caused by seepage) will lead to further development of deformations. It should be underlined that the lack of an appropriate safety margin of soil bearing capacity was documented during the recognition of the soil and water conditions. Therefore, it is necessary to permanently monitor water levels in the installed piezometers along with river water level monitoring. It will provide a range of filtration directions and flow velocities in relation to critical hydraulic gradients and zones prone to deformation. If the filtration velocity increases or there are unfavourable changes in soil structure at the

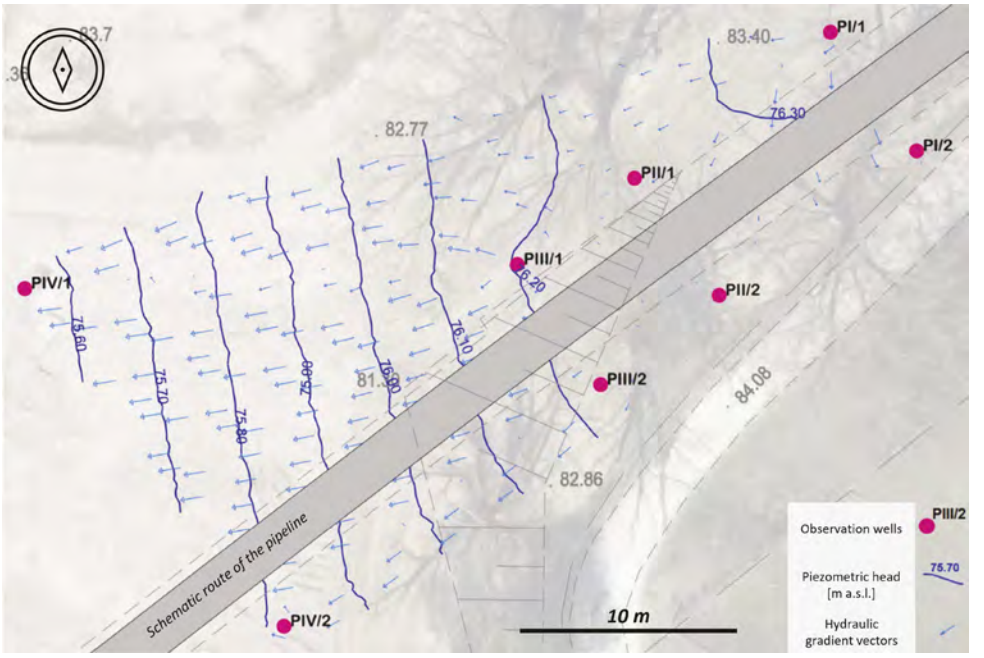

Figure 4. Groundwater flow in the research site on 2.09.2022.

filtration path, soil modification should be performed (low-pressure injections or subsoil compaction).

Comparative geophysical surveys can be applied to monitor the development of deformation caused by seepage in addition to piezometric measurements. Surface geophysical surveys have documented the current subsoil state as the reference point in the research site. It is reasonable to perform analogous cyclic geophysical surveys at the same locations (e.g. every 3 months - in the first survey period and after a cycle of 4 surveys, the frequency can be adjusted).

6 SUMMARY

The comprehensive research program provides a reference overview of soil and water conditions. Effects of deformation induced by seepage have been revealed in the pipeline area at the research site. One of the most crucial elements is the presence of loose zones of non-cohesive soils. The further development of deformations must be monitored, and emergency response needs to be taken in case their increase. Otherwise, large settlements, pipeline damage, and soil liquefaction with loss of embankment equilibrium may happen. Thus, it is particularly essential to monitor the groundwater table and the neighbouring river to cover the extremes. It will enable the identification of places where (permanently or temporarily) an increased hydraulic gradient and intensive filtration is present.

ABSTRACT: Basic results of geotechnical monitoring at construction of skyscraper "Lakhta-Center" are presented. Pit fencing displacements while constructing under-ground part of building are considered, effectiveness of excavating pit of regular shape in plan is shown: operations in open pit. Measurements of building settlements are given based on extensometer system witnessing possibility of minimum settlements of high-rise building at pile driving to Venda deposits which opens prospective of high-rise construction in geotechnical conditions of Saint-Petersburg. Pore pressure gauge measurement results show no excessive pore pressure in subsoil, expectedly, due to solid consistency of pre-quaternary clayey soils. Gauges are reported to record water head within permeable fractured-block structure of Venda clays and overlaying soils. Measurements by system of sensors located in piled raft stated that pressure is not transferred to soil via piled raft base, i.e. pile-raft foundation effect is not manifested in unevenly compressible subsoil – all load it applied to piles.

1 INTRODUCTION

Monitoring of structures at operation is a direct requirement of the existing Russian legislation, which is especially relevant for technically difficult structures including high-rise buildings. It is important not only for providing mechanical safety at operation of a structure but also as a tool of back analysis of actual strain-stress behavior of soil and structures corresponding to a calculation prediction implemented at design, that finally should facilitate development of construction theory and practice (Katzenbach 2005). The purpose of the research work was to make an efficient system of monitoring at construction and operation of the unique high-rise building constructed on a thick soil bulk of sedimentary origin. The methods of organization of the monitoring system as well as the measurement results are significant.

2 THE MAIN REQUIREMENTS TO THE SYSTEM OF MONITORING AT OPERATION

Monitoring systems should be based on the principles of interactive monitoring, i.e. they must include a possibility of comparison of monitoring data and a prediction, back analysis of monitoring results using computer models of an object, an opportunity to adjust the prediction or make necessary managerial decisions based on the conducted analysis.

The main features of an efficient monitoring system include (Shashkin 2018): (1) an ability to respond to possible hazardous processes; (2) adequate assessment of a danger degree, timely

DOI: 10.1201/9781003299127-317

identification of dangerous processes to give experts an opportunity to analyze a situation and take necessary measures; (3) existence of a formalized managerial decision-making subsystem.

The efficient monitoring system should contain at least an intermediate state between the "normal" and "failure" states. The "alarm" signal (like the yellow of the traffic lights) should timely emerge when dangerous trends occur and leave a sufficient time period for a required response – beginning from the analysis of causes of the signal emergence to taking measures on structure reinforcement (if necessary).

In order to create an efficient monitoring system, the criteria of a state of structures should not be set only based on limit states of these elements according to the standards, it is necessary to introduce the notion "a predicted value of a parameter". A significant deviation of measurement results from a predicted parameter is to be considered as an alarming signal.

Contrary to calculations at design which are always conducted with a "safety factor", calculations for defining predicted parameters should reflect the most probable state of a calculated structure, if possible, computer models should completely reflect actual structural behavior.

The system of setting ultimate values of parameters is advisable to be generalized using relative distances to limit values for groups of physically interlinked parameters. In this approach, for a control subsystem a state of groups of any number of parameters is described by a minimum set of two numbers – a relative distance to the limit value and a value of the "alarm" signal.

3 THE THEORETICAL BASIS FOR GETTING CRITERIA OF "ALARM" AND "FAILURE" STATES

For a single measured parameter X the system of criteria should include a limit value (which in most of cases is defined according to the requirements of the existing standards) and a predicted value (or several predicted values as per different combinations of loads) of the parameter. A predicted value is calculated as the most probable value of the parameter in certain conditions (without tolerances towards "a safety factor", with account of actually applied loads etc.) As a result of a series of calculations for different combinations of loads we obtain a suite of possible results of the calculation $X_1 \ldots X_n$. Then one should define the most probable average value$\bar{X}$ based on either general consideration (for example, a calculation without wind impacts), or on the arithmetic mean of the obtained calculation results.

Let a monitoring system observe some value of the parameter X. We indicate a difference between a predicted average value and an observed value as $r = |X - \bar{X}|$ $r_{\lim}$ is a distance to the limit value, we sort out of two limits in the numerical axis, they limit in the same direction, in which X deviates from$\bar{X}$. Mathematically it can be written down as:

$$r_{lim} = |X_{lim} - \bar{X}| \text{ ПрИ } (X - \bar{X})(X_{lim} - \bar{X}) > 0. \tag{1}$$

It is not expedient to overload the system of control representation of the results with difficult values in different measurement units. Therefore, in order to facilitate let introduce the notion of a relative distance to the limit value:

$$\varepsilon = \frac{r}{r_{lim}} \tag{2}$$

In this case the limit state corresponds to $\varepsilon = 1$. A location of the "alarming" boundary is obtained according to the results of a series of prediction calculations $X_1 \ldots X_n$. For each of these calculations we compute a distance from the mean value $r_i = |X_i - \bar{X}|$ and a distance to the limit value in the corresponding direction $r_{\lim i}$. Then the area of admissible values of the parameter can be limited by a relative value:

$$\varepsilon_a = \gamma \cdot max\left(\frac{r_1}{r_{\lim_1}} \ldots \frac{r_n}{r_{\lim_n}}\right) \tag{3}$$

where γ – a factor, which takes into account prediction inaccuracy and it is accepted, for example, as 1.1…1.2.

For the system of interlinked data this approach can be generalized, in this case X represents not a single value, but a suite of values, instead of the limit values of parameters one should consider surfaces, which limit the areas of their admissible values.

Let consider building a system of restrictions for a set of parameters on the example of observation of a column cross-section. A set of strain gauges should be installed in a column cross-section to record not only longitudinal forces but also the moments. According to the log of these gauges least square method defines a longitudinal strain and angles of section rotation (with account of the hypothesis of flat sections which is conventional for frame systems). Based on the obtained values of deformations, with account of the known material properties, forces are defined: a longitudinal force N and a moment in two directions My and Mz. The acting forces can be manifested as a point in the space N, My and Mz. One can depict with a point the predicted values of forces in the same space.

Then, according to the requirements of the standards, for example, as per non-linear strain model of reinforced concrete a limit surface is built in the space of coordinates N, My and Mz. The boundary of admissible values at monitoring is computed according to formula (3) around the area of predicted values of forces.

The described mathematic transformations result in unification of operation with any groups of interlinked data. In any case, for the control system a group state is described by one number – a relative distance to the failure boundary ε. If this value exceeds 1, the "failure" signal sounds. An admissible value ε_a is computed for timely response to development of a process for each group of parameters in the monitoring system. If $\varepsilon > \varepsilon_a$ the system gives the "alarm" signal.

It is noteworthy that as the complex multidimensional system of limitations is actually reduced to one number ε_a, this value is not stationary. When gauge logs change, not only a value, but a direction of black and white vectors shown in Figure 1 change. Therefore, both values ε and ε_a should be recalculated.

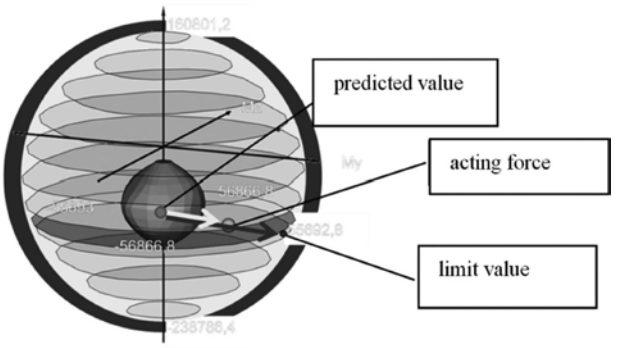

Figure 1. An example of the system of limitations for strain gauges in a column: the white vector shows the distance from the predicted values to the observed ones, the black vector shows the distance to the limit values (the "failure" boundary); the relative distance to the limit values ε equals the ratio of the length of the white and black vectors; the boundary of admissible values (beyond which the "alarm" signal occurs) is shown in the center.

4 THE COMPONENTS OF INTERACTIVE MONITORING

In an efficient monitoring system for a building or a structure, which meets the requirements of mechanical safety, in practice the "failure" system should not emerge at all. The whole operation of the monitoring system is to be made after receiving the "alarm" signal without allowing the system to reach the limit state (the "failure" signal).

An approximate sequence of possible measures on the analysis of work of a structure and fixing possible negative trends after receiving the "alarm" signal can be represented as follows (Figure 2).

In order to provide serviceability of the monitoring system it should include the following main components:

1. The system of gauges in structural elements and subsoil.
2. The system of collecting and archiving the logs from gauges.
3. The system of control observation of logs of groups of gauges, which track emergence of the "alarm" and "failure" signals and generate signals to inform people in charge.
4. The system of managerial decision making.
5. The interactive calculation models for assigning the "alarm" and "failure" criteria with a possibility of recalculation and adjustment of predicted values during monitoring.

Let consider determining the "alarm" and "failure" criteria on the example of a high-rise building in St. Petersburg.

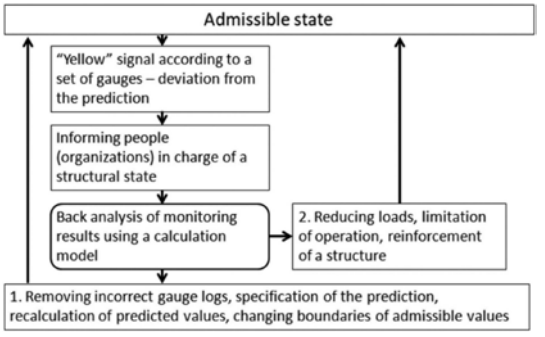

Figure 2. The facilitated algorithm of managerial decision making.

5 A BRIEF CHARACTERISTICS OF THE HIGH-RISE BUILDING

The construction of the tallest building in Europe – "Lakhta center" tower in St. Petersburg was completed in 2019. Considering a high degree of responsibility of the building, a part of information is closed but the authors think that open information is interesting for experts.

The structural section of the design was developed by the companies "Inforsproekt" and "Gorproekt" under the supervision of V.I. Travush and A.I. Shakhvorostov (Travush 2015, 2018), the design solution of the underground part was elaborated under the supervision of O.A.Shulyaev (Shulyaev 2016). The main dominant of the multi-functional complex "Lakhta Center" reaches 462 m, it consists of 86 floors and 3 underground levels (Figure 3a, b).

The high-rise building has a frame-and-stem structural scheme. Its rigidity and stability are provided due to joint operation of the central RC core and 10 streel-reinforced concrete columns along the perimeter interconnected with outriggers, which are located at several levels. To decrease spans in the building there were implemented other 5 streel-reinforced concrete columns up to the level of the 47^{th} floor.

The underground part of the high-rise building has the shape of an equilateral pentagon in plan, the side length is 57.5 m. It forms a box foundation, which consists of a lower 3.6-m-thick slab, located at the depth 17.65 m from the ground surface, an upper 2.0-m-thick slab, the central rigidity core of 28.5 m diameter and 10 vertical rigidity diagram walls. The box footing is supported by 264 piles of 2 m diameter. The piles are 65-m-long (84 m from the surface) within the contour of the high-rise building and 55-m-long (74 m from the surface) beyond it.

The engineering-geological profile of the high-rise building consists of quaternary deposits of different genesis and Upper Proterozoic Kotlin solid clays (Venda deposits; their roof lies at the depths of about 25 m from the ground surface), which serve the subsoil for pile foundations of the structure (Figure 4).

As regards headed aquifers within the area under consideration, Venda aquifer suite is of special importance, it is connected with interlayers of sandstones in the lower part of Venda

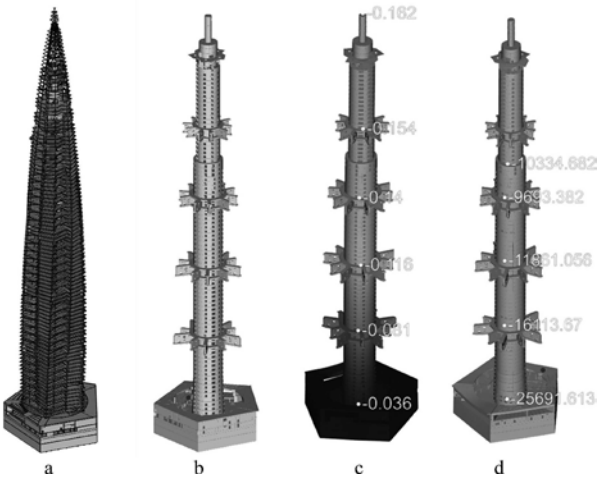

Figure 3. The general view of the calculation model (*a*) and its fragment made of volumetric finite elements for organizing monitoring at operation (b); vertical displacements of the core, m (*c*) and stresses in the core concrete, kPa (*d*).

deposits, with the head at 90 m of the absolute elevation – minus 12 m BS. Moraine deposits underlain by dislocated Venda clays lie directly under the base of the piled raft.

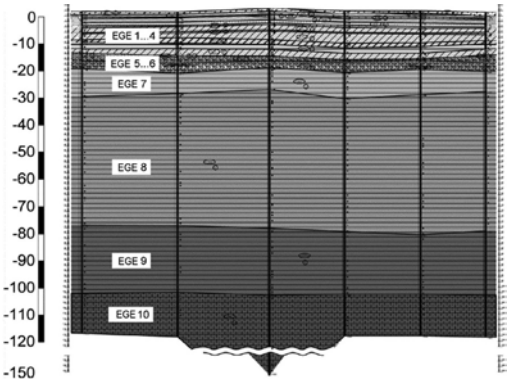

Figure 4. Engineering-geological profile in the area of the high-rise building. Notes: EGE (engineering-geological element) -1. . .4 – Quaternary deposits, EGE-5, 6 – glassier deposits; EGE-7. . .10 – Upper Proterozoic Kotlin deposits.

6 THE CONTROLLED PARAMETERS OF THE MONITORING SYSTEM

The controlled parameters of the monitoring system of technical condition of the building's bearing structures include:

- movements of the upper point of the tower;
- a tilt of the foundation;
- a tilt of the building;
- natural frequencies and maximum amplitudes and fluctuation curves of the walls of the tower core;
- frequencies of mutual fluctuations of parts of the tower;
- strains in RC cross arms;
- strains in RC walls of the superstructure;
- strains in metal columns;
- strains in outrigger beams.

Movements of the upper point of the tower are defined automatically via processing results of measurements by a high-precise GPS-system.

A tilt of the foundation and structures of the building is controlled with a help of automatic inclinometers installed in the foundation and structures of the building.

Frequencies, amplitudes and fluctuation curves are defined via processing the results of measurements of 3D vibro-sensors-accelerometers.

Strains in the tower structures are controlled by strain gauges installed in slabs and walls of the box foundation, walls of the core and columns of the building. Strain gauges were installed to obtain data on a relative longitudinal deformation of the box foundation, a relative longitudinal deformation of composite columns, core walls and outrigger frames during construction of the building and at the stage of its operation.

Reading of gauge logs is implemented with a help of the automated system of data collection.

The sensors of geotechnical monitoring, namely strain gauges controlling deformations in piles, pore pressure gauges, pressure gauges along the base of the piled raft slabs are also connected with the monitoring system.

The monitoring system at operation was developed by the Institute "Georeconstruction" together with "Telros" company. Geotechnical monitoring at construction of the building was implemented by the Institute "Georeconstruction".

7 THE NUMERICAL MODEL AND PREDICTED VALUES OF THE CONTROLLED PARAMETERS

A mathematical model of the building implemented in the software complex FEMmodels-IEECloud, which was developed by the Institute "Georeconstruction" and allows making soil-structure interaction calculations taking into account non-linear properties of structural materials and soils (Ulitsky 2014), is the key element of the monitoring system, it represents a kind of an analytical center. The layout of the geometrical position as well as assigning parameters of the tower structures in the calculation model were made via conversion of an analytical model of a scheme built in "Revit", issued as initial data in the environment of "FEMmodels-IEECloud". The model consists of volumetric, plate and rod finite elements. The mathematical model considers joint behavior of the building structures, piles and subsoil.

The respective standard piecewise linear, bilinear and trilinear diagrams of deformation of steel and concrete were used as deformation curves. The results of the model calculation with account of non-linear strain model of RC structures include not only more adequate consideration of their rigidity but also a possibility of building sought-after strength surfaces, which define "the red boundary" (a surface of the "failure" signal). Therefore, "the red boundary" for each point of strain gauge installation is defined by a strength surface in axes N, My and Mz, obtained according to the results of the numerical calculation of the analytical model of the building for a certain section of an element of the bearing structure where a gauge is installed. Based on this limit strength surface, limit strain surfaces in each point of installing strain gauges and ultimate values for each strain gauge are defined.

The value of the "red level" of strain-stress behavior of the walls of the tower core is suffice to be limited by a standard value of limit strain due to their predominantly compressive operation.

As regards the "yellow level" (surfaces of the "alarm" signal), it is more justified to take an area near the predicted (based on the calculation results) forces (in the case under consideration deviation from the area of the predicted values of more than 10% is accepted as the yellow border). Exceeding the "yellow level" means that a structure operates not in compliance with the prediction, that requires additional examinations and identification of causes of deviation from the assumed strain-stress state.

It is noteworthy that making a calculation model implies multiple simplifications at assigning models of material behavior, boundary conditions, loads, which in line with various violations and drawbacks in the course of construction work implementation often lead to inconsistency of a calculation model with an actual operation of a structure. Therefore, during in situ measurements at the site monitoring initial parameters of a calculation model of the building should be specified, then it is necessary to make recalculation of the changed model. As a result of several

iterations the calculation model of operation of the structural system under consideration will start to be consistent with its actual behavior. It is this iteration method which allowed bringing the mathematical model of the tower of "Lakhta Center" in consistency with the in situ measurement results.

The figures below give the results of building-structure calculation. According to the results of the calculation for each group of installed gauges (ranges), predicted values of changeable parameters have been defined. The predicted values are taken directly from the calculation model as per a coordinate of location of a group of gauges (Figure 3c, d, 5).

Foundations of the tower structure have different tilts from the vertical axis due to applying horizontal forces (wind loads) at different heights in different time moments.

According to the design assessments, deviation of the tower top from the vertical line due to applying wind loads is 301 mm from the average wind load and 161 mm from pulsing loads (the total displacement of the top of the building is 462 mm). According to the results of monitoring, measuring a wind speed, there has been identified a period of time when the wind speed approached to the maximum calculated one.

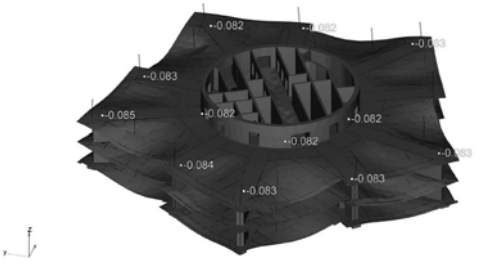

Figure 5. Vertical displacement of outrigger levels L17-L18, m, the scope of strains has been increased 100 times.

According to the analysis, in this case the maximum value of deviation is in a good agreement with the calculated one (Figure 6a). According to the results of the analysis of the maximum angles of tilt there were accepted borders as per inclinometers which change depending on a level of a gauge location (Figure 6b).

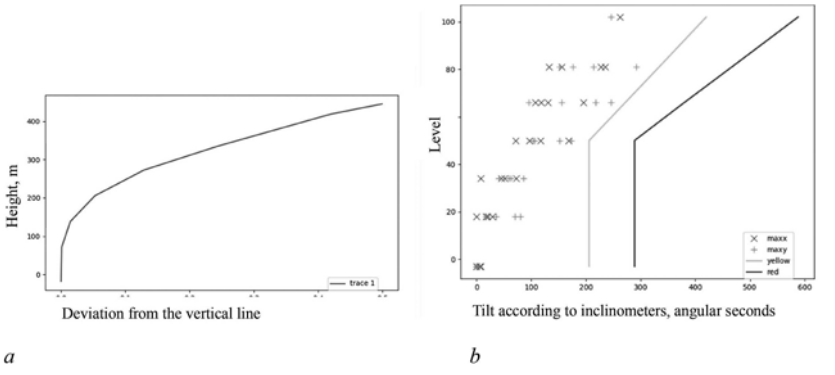

Figure 6. Evaluation of a shape of deviation from the vertical line of the building tower at wind loads, which are close to the maximum calculated ones, m (*a*), maximum values of tilts in directions x and y (*b*) according to the results of measurements at wind loads, which are close to the calculated ones; the location of the "yellow" and "red" boundaries depends on a number of a level relating to the building height.

8 THE CRITERIA FOR DEFINING FREQUENCIES OF SELF-INDUCED OSCILLATIONS

A reduction of a frequency of oscillations witnesses a decrease of the building rigidity or an increase of weights, it characterizes changes in the scheme of operation of bearing structures.

An increase of a frequency of oscillations of the building is highly unlikely, and it does not witness worsening of operation of structures.

According to the calculation results made by the authors of the design, the first self-induced frequency of oscillation was 0.12 Hz. The first actual measured frequency of vibrations after termination of the construction (March 2019) was 0.178 Hz. In the course of constructing floors, partitions in the tower, increasing useful loads and changing glaze ice loads a weight of the building changed along with reduction of the oscillation frequency. In June 2019 the first frequency ranged from 0.161 to 0.167 Hz, the second frequency – from 0.570 to 0.610 Hz; the third frequency – from 0.744 to 0.771 Hz.

It is possible to make an approximate evaluation of the predicted frequency of oscillations depending on a share of loads from floors, partitions, useful and glaze ice loads applied to the building, without account of tolerances for quick creeping, and considering the dynamic RC modulus according to the following formula:

$$\nu = \nu' \cdot \sqrt{\frac{M_1}{M_1 - (M_2 \cdot (1-\kappa))} \cdot \frac{1}{\phi_b} \cdot \frac{1}{\phi_0}} = 0.160 \text{ Hz}, \quad (4)$$

where $\nu' = 0.122$ Hz – the calculated frequency of oscillations, $\phi_b = 0.85$- the factor of quick creeping, $\phi_0 = 0.83$ – the ratio between the initial and dynamic RC modulus (at very small deformations), M_1=509392 t – the designed weight of the building, M_2=134206 t – floors, partitions, useful and glaze ice loads, k = 0.3 – the approximate factor of account of loads of floors, partitions, useful and glaze ice loads.

Therefore, the changed frequencies are quite in a good agreement with the calculated ones.

As the limit values of oscillation frequencies are not regulated by the existing documents, the condition of reduction of the frequency of tower oscillations by 10% of the actual one is taken as the "yellow" boundary of accelerometer logs, the "red" boundary implies reduction of the recorded frequencies of oscillations by 30% of the measured value.

9 THE RESULTS OF THE GEOTECHNICAL MONITORING AT CONSTRUCTION

Creating the efficient monitoring system at operation is possible as continuation of the efficient monitoring system at construction. Therefore, it is important to pay attention to the results of the geotechnical monitoring.

In the framework of geotechnical monitoring before digging the pit a system of inclinometers was installed around the pit fence; pore pressure gauges and extensometers were installed in the subsoil; in the course of constructing the structures of the underground part of the building strain gauges were installed under the base of the piled raft.

The measurement results demonstrate that, opposite to the cylindrical shape of the underground part, the underground structure, which is pentagonal in plan with the fence in the form of diaphragm wall with strut rings, does not allow reaching the same horizontal displacements of the pit fence as expected. In more rigid corner areas displacements are almost twice as small as in the middle of each side of the pentagon (Figure 7). The maximum total displacement was observed at inclinometer I-11 at the depth 14 m, it was 46.4 mm, that did not exceed the maximum calculated values (76 mm). However, the correct shape of the underground structure in plan still allows using the effect of "a barrel with hoops inside", which works for external pressure, and thereby carrying out works in an almost open pit with a minimum working area under cover of contour strut "hoops".

Observations of layer by layer settlements of the subsoil were made according to extensometers down to the depth 97 m (see Figure 8). As the lower elevation of an extensometer is only 12 m lower than the toes of piles of the central part of the high-rise building compound and it can settle itself, location of the upper elevation was controlled using geodetic methods.

The settlements of the high-rise building developed along an increasing curve and came to an end by the moment of termination of the construction in 2018 – 32 mm in the area under the core. In the edge zones the settlements were twice as small. Almost the same settlements were recorded

by geodetic methods connected with foundation benchmarks. Therefore, one can state that quite a limited layer of soil under pile toes has settlements. The compressed bulk below the pile toe is about 15 m. This conclusion is rather expected as the thickness of the bulk of solid Venda clays under the pile toe is 20 m, they are underlain by sandstones, which have higher rigidity and lower flexibility.

The effect of compression of piles and soil in the inter-pile area also made a contribution to the development of settlements (its share is almost 2/3 of the accumulated settlements). Based on the simplest calculations, elastic compression of the shaft of the pile of 2.0 m diameter and 65 m length under the load 3000 t is approximately 2 cm, that is in full agreement with the measured value of settlement due to self-compression of a "default foundation".

The measured values of settlements correlate with the results of the conducted calculation of long-term settlements of the building on non-linear visco-plastic soil (with account of possible development of long-term creeping) (Shashkin 2014). According to the calculation results the maximum long-term settlement of the building will reach 8 cm at a relatively small differential settlement. About 1/3 of settlements occur during construction, i.e. about 3 cm, that is in a good agreement with the observation results.

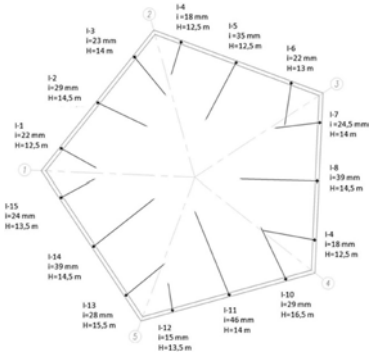

Figure 7. The scheme of layout of inclinometers and vectors of maximum total displacements of inclinometers with indication of a depth of the maximum displacement (28.08.2013 – 05.04.2015).

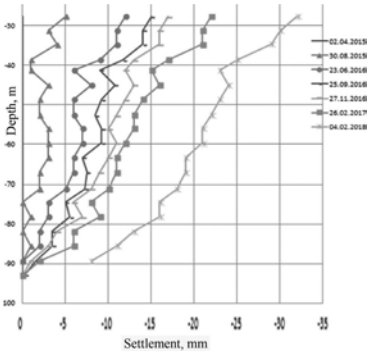

Figure 8. Strain curves of the soil bulk as per extensometer #1.

The gauges installed under the base of the piled raft demonstrated that contact pressures of soil are small (they do not exceed the pressure of the dead load of the slab of the piled raft). Therefore, the slab of the piled raft does not participate in operation of the pile foundation, it witnesses that the idea of a pile-raft foundation works only for a homogenous soil (Ulitsky 2014). If soil under the slab of the piled raft is more flexible than under piles, the raft is excluded from operation. Identical logs, which almost correspond to the water head pressure with zero elevation at rest approximately at the level of the Gulf of Finland, were recorded at all borehole piezometers (Figure 9). In the period of construction of the underground part of the building gauge logs drop (07.08.2013- 07.04.2014) precisely by the value of the water head released at the pit excavation (15–16 m). Then, in the course of building construction there was observed a slow growth of the gauge readings.

The gauge logs demonstrate permeability of Venda clays due to their intrinsic fracturing-block structure (Dashko 2000, 2011), earlier they used to be considered almost impermeable (it is noteworthy that chemical composition of water samples taken at the level of the slab of the piled raft showed their origin from Venda aquifer, i.e. from the depth 90 m). As expected, no excessive pore pressure was observed: it cannot occur in solid clays where pore water is in cohesive state.

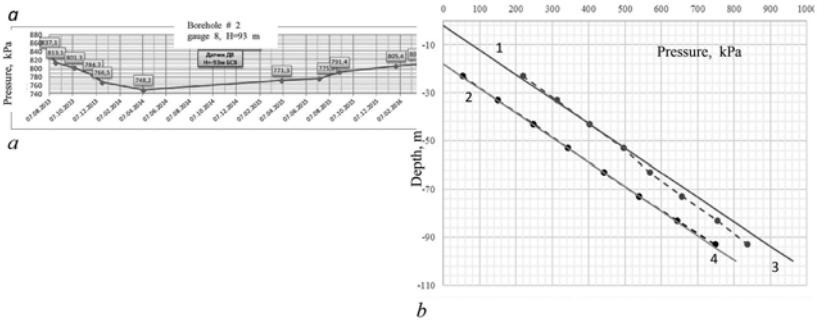

Figure 9. The logs of pore pressure gauges installed in borehole #2: *a* – measurement of pore pressure in time; *b* – graphs of pore pressure development as per the depth (1 – hydrostatic pressure before excavation and 2 – after excavation of an 18-m-deep pit; 3, 4 – logs of pore pressure gauges before and after excavation of the pit, respectively).

10 CONCLUSIONS

The practical implementation of the system of interactive monitoring at the site of "Lakhta Center" has demonstrated efficiency of using the soil-structure interaction calculation model at the analysis of the monitoring results and definition of the boundary values of the parameters for the "alarm" signal.

The calculation model for monitoring purposes which reflects the most probable state of a site without tolerances and safety factor simplifications considerably differs from the calculation models applied at design.

Assigning parameters of the "alarm" signal at the boundary of predicted parameters of the most probable state of the system ensures sensitivity of the system to negative changes, which appear possible to be identified at an early stage of their development, it provides timely analysis of a situation and taking adequate measures.

Assessment of deformation modulus of dispersive soils by multichannel analysis of surface waves

V.G. Ofrikhter & V.V. Antipov
Perm National Research Polytechnic University, Perm, Russian Federation

ABSTRACT: Nondestructive techniques of wave analysis can be applied for the express preliminary geotechnical soil assessment. One of these techniques is Multichannel Analysis of Surface Waves (MASW) which allows obtaining velocities profile of shear waves and the initial shear modulus for the upper section promptly and at minimal labor costs. The soil deformation properties assessment requires the deformation modulus that is obtained by the direct technique of plate load test (PLT). The purpose of the study is to assess the correlation between the PLT deformation modulus and the initial shear modulus determined with MASW.

Plate load tests (PLT) were carried out for various plates and moduli of deformation were calculated. Deformation modulus adjustment factors were applied to bring values of different size plates to the 5000 cm^2 plate one in order to perform a comparative analysis. Wave analysis was carried out by the active method of MASW.

During the comparative analysis a correlation coefficient was evaluated for the deformation modulus determined strictly according to the Russian State Standard (GOST 20276-2012). In this case "correlation coefficient - unit weight" indicative dependence was observed. The regression equation is presented.

Correlation between the two types of tests was established by in-situ tests. The proposed empirical regression equation allows us to obtain the deformation modulus on the basis of MASW data and to perform an express soil foundation geotechnical assessment for the future construction.

Preliminary assessment of the geotechnical situation on the site enables carrying out a technical and economic analysis of the object of reconstruction or new construction. Preliminary geotechnical evaluation includes: determination of the geotechnical category of the object of construction or reconstruction, analysis of nearby structures, assignment of the survey work scope, and determination of arrangement options for the underground part of the object and their economic comparison. To correctly choose the variants of constructive solution of the future construction underground part, it is necessary to know the existing layering of soils on the construction site, their physical and mechanical characteristics, and the presence of anomalous inclusions (mines, pipeline cavity, other underground structures, etc.) that will allow performing the feasibility study as correctly as possible. Modern non-destructive research methods enable rapid and cost-effective construction of ground layer sections and estimation of physical and mechanical characteristics of soils. One of such methods is MASW.

The MASW technique was first introduced in (Park et al. 1999) and continues to develop and improve up to now (Park & Carnevale 2010). The authors of this study also conducted a number of natural and numerical experiments to determine the possibility of using the wave analysis for geotechnical calculations (Ofrikhter & Ofrikhter 2015, Antipov & Ofrikhter 2019). The MASW technique is applied to measure the surface wave velocities in layered soil thicknesses. From the received velocities it is possible to pass to the initial shear modulus at small deformations by the known dependence (Foti et al. 2015). For practical purposes, it is very useful to establish the relationship between the surface wave velocity, the initial shear modulus, and the soil deformation modulus from the plate tests. The purpose of the researches is to establish the correlation between the initial shear modulus determined with MASW and the soil deformation modulus determined with PLTs.

1 MATERIALS AND METHOD (ANTIPOV & OFRIKHTER 2019)

1.1 *Description of the sites*

PLT and MASW surveys were performed at five sites with different soil conditions:

1. Site No. 1. Soil under the foundation slab:

a. Sand fill of fine homogeneous dense low moisture sand;

2. Site No. 2. Highway. Site beside a pillar of bridge crossing:

b. Medium strength loose fractured saturated argillite-like clay with pockets of low and medium strength sand rock;

c. Fine-grained loose fractured saturated sand rock of low and medium strength;

3. Site No. 3. Site of the former factory that is free from construction:

d. Tough and medium-hard clay;

4. Site No. 4. Base of the foundation plate for a residential building:

e. Gray-brown areneceous fluid clayey sand with veins and pockets of 3–5 cm fine gray saturated sand and very soft brown clayey sand;

f. Dark-grey heavy silty very soft sandy clay with up to 15% inclusions of well-decomposed black organic matter;

5. Site No. 5. A test site of the Department of Construction Operations and Geotechnics of PNRPU that is free from construction:

g. Brown fine-grained sand.

Physical properties of the soils determined in the laboratory are presented in Table 1.

Table 1. Physical properties of the soils at testing sites.

Site No	Soil type	w	w_L	w_p	γ, kN/m^3	γ_s, kN/m^3
1	a	0.068	–	–	17.84	25.68
2	b	0.170	0.34	0.14	19.99	25.68
	c	0.170	–	–	20.09	26.07
3	d	0.129	0.33	0.07	20.78	26.46
4	e	0.296	0.24	0.18	19.80	26.46

5	g	0.099	–	–	15.97	24.60

w is water content; w_L is liquid limit; w_P is plastic limit; γ is unit weight of soil; γ_s is unit weight of soil particles

1.2 *PLTs*

PLTs were performed in accordance with the standard procedure set out in the Russian State Standard (GOST 20276-2012). The true value of the deformation modulus is assumed as the modulus E5000 obtained for a plate of 5000 cm^2 (Kashirsky 2014, Kalugina et al. 2017). Deformation modulus determined for the 600 cm^2 plate was transformed to the modulus E5000 using formula (1) (Lushnikov 2014):

$$E_{5000} = E_{600} \cdot m \tag{1}$$

where E_{600} is the deformation modulus for the 600 cm^2 plate; m is the conversion factor depending on the void ratio e according to Table 3 of (Lushnikov 2014).

According to (Lushnikov 2014), for the plates of other areas the coefficient m in equation (1) can be calculated by the expression (D.3) from Annex D of (SP 23.13330.2018):

$$m = (A_{5000}/A_i)^{n/2} \tag{2}$$

where A_{5000} is the 5000 cm^2 plate; A_i is the i cm^2 plate area; n is the reduction argument according to Annex D of (SP 23.13330.2018), for silt-loam soil n = 0.15–0.3, for sandy soil n = 0.25–0.5, minimum or maximum value from the conditions $\sigma_{z,p} = 0.5\sigma_{z,g}$ or $\sigma_{z,p} = 0.2\sigma_{z,g}$ respectively (p. 11.6.2 of SP 23.13330.2018).

1.3 *MASW*

MASW is an express inexpensive non-invasive in-situ technique of wave analysis of the low velocity zone in the upper part of the soil profile. The procedure of the in-situ survey and further data processing used by the authors is described in detail in (Park et al. 1999). A telemetric 24-channel seismic exploration system TELSS-3 was applied for the MASW technique. The system consists of: seismic wire interface for communication with a laptop; vibration seismic receivers – 24 vertical 10 Hz geophones; 7 seismic streamers for 4 geophones; telemetric modules for signal transmission from receivers to the interface; a 4.5 kg (10 lbs) sledgehammer with a metal base plate used as a wave source. The trigger was implemented by closing the sledgehammer and the plate. The signal from the trigger at the beginning of recording was transmitted to the interface via a connecting cable. A streamer test and a full seismic station test were made at each shot before recording.

MASW tests were performed with an active flank observation system ZZ with an offset of 10 m. Two layouts of the surveillance system were used: a 46 m receiving line with a 2 m receiver spacing, and a 11.5 m receiving line with a 0.5 m receiver spacing. As an example, Figure 1 shows the scheme of the second layout type on the site No. 4 at the location of the e soil type and it also illustrates the actual in-situ testing. The receiving line length corresponds to the maximum measured wavelength, and the receiver step corresponds to the minimum wavelength. The centers of the receiving lines were located as close to the points of the PLT tests as possible.

Figure 1. Surveying system on the site No. 4 at the location of the e soil type: left – layout of the site; right – image of the site.

Optimum parameters were taken according to (Ofrikhter & Ofrikhter 2015, Ofrikhter et al. 2018). The number of repeats at each point was 3 (two main and one reconnaissance). Noise interference and distortions were eliminated by repeating the record 5–8 times in each measurement at each point. The accepted MASW parameters are shown in Table 2.

Experimental data were processed with RadexPro 2014 Starter software package in a semi-automatic mode. The obtained average values of the S-wave velocities in the tested soil layers were used to calculate initial shear moduli from the expression (Mayne 2001):

$$G_0 = \rho \cdot V_s^2 \tag{3}$$

where ρ is soil density determined in laboratory tests, kg/m^3; V_s is soil layer shear wave velocity, m/s.

It is worth noting that expression (4) proposed in (Mayne 2001) allows calculation of the soil unit weight with values of S-wave velocities and depth:

$$\gamma = 8.32 \cdot \log V_s - 1.61 \cdot \log z \tag{4}$$

where γ is the unit weight of the soil layer, kN/m^3; z is the layer base depth, m.

Table 2. MASW testing parameters.

Site No	Soil type	D,m	X,m	dx,m	dt,ms	tn	N
1	a	11.5	2.5	0.5	0.5	2048	5–8
2	b	46.0	10.0	2.0	0.5	2048	5–8

2 EXPERIMENTAL DATA (ANTIPOV & OFRIKHTER 2019)

As an example, the MASW result for No. 4 site at the location of the e soil type and PLT results for the same soil are given in Figure 2.

The summarized MASW results are presented in Table 3 together with the soil unit weight calculations. Unit weights determined in the laboratory are provided for comparison. Calculated deformation moduli and initial shear moduli according to PLT and wave analysis are given in Table 4. Deformation modulus E was estimated according to the standard procedure recommended by the Russian State Standard (GOST 20276-2012) using the well-known Schleicher's equation for the first four points of the load-settlement curve counting from the initial pressure under plate.

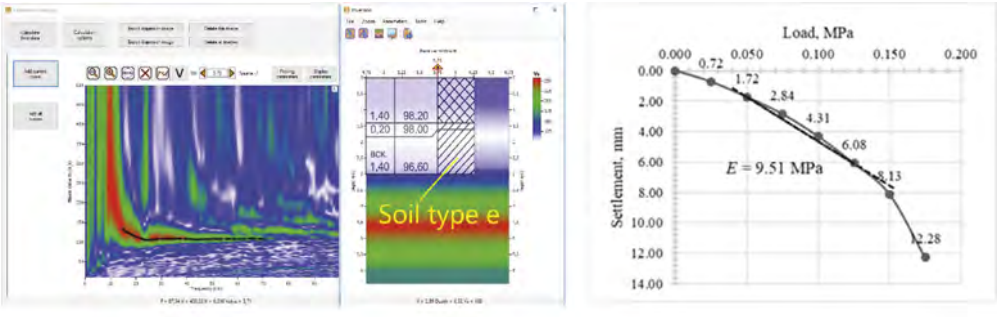

Figure 2. Experimental results for the site No. 4: left – the MASW survey; right – PLT.

Figure 3 and Table 5 present correlation coefficients between the deformation modulus and the initial shear modulus. The correlation coefficient was calculated by the formula: $k = E_{5000} / G_0$, and next the dependency was obtained:

$$k = -0.003321\gamma^3 + 0.206374\gamma^2 - 4.281230\gamma + 29.789383 \quad (5)$$

3 DISCUSSION OF THE RESULTS

In the course of the experiments, a simple mathematical dependence (6) was obtained between the deformation modulus, comparable with the results of the plate test, and the initial shear modulus. The transition coefficient k in the formula depends only on the specific gravity of the soil. Taking into account that the magnitude of the initial shear modulus depends only on the speed of surface waves and the soil specific gravity, and that the specific gravity is directly related to the speed of surface waves in accordance with formula (6), the obtained dependences make it possible to estimate the soil deformation modulus in the shortest time both by the velocity of surface waves and by the soil unit weight. The soil unit weight can be determined by the standard engineering and geological surveys or can be calculated using formula (4) in case of a site without geological survey data. The proposed approach seems to be very convenient for the specialists in assessing the geotechnical situation at the site.

4 CONCLUSION

The article presents the results of soil plate load testing and wave analysis by the MASW method at the sites of Perm and Perm Region, Russian Federation, for different soils and their comparative analysis. Based on field researches, regularity was established and the relationship between the initial shear modulus G_0 according to wave surveys and the soil deformation modulus E according to standard plate load tests was determined. The correlation coefficient k between the soil deformation modulus E and the initial shear modulus G_0 varies within 0.142–0.525 according to the explicit regularity presented in Figure 5, and it decreases as the soil unit weight increases. A simple empirical formula (6) is proposed, which allows one to perform express evaluation of the soil deformation modulus by MASW and make a preliminary geotechnical assessment of the proposed construction site of the future facility.

The authors thank the research support services of Perm National Research Polytechnic University for providing the equipment for field and laboratory testing.

Sand-plate interaction experimental investigations

S.O. Shulyat'ev
NIC Stroitelstvo, NIIOSP N.M. Gersevanova

ABSTRACT: The article presents stress distribution analysis in sand soil, loaded with a square reinforced concrete foundation with dimensions 2*2*0,2 m. Vertical and horizontal stresses, as well as layer-by-layer deformations in sand with increasing load, were obtained. Comparison of experimental data with the results of analytical and numerical data made it possible to draw important conclusions regarding bases calculations.

1 INTRODUCTION

Investigations were made in tray with dimensions 5*15 m and depth 4 m (Figure 1). To increase thickness of sand layer, embankment 2 m high was arranged on top of the tray. Medium size sand with density 18,9 kN/m^2 used as tray filler. Load was transferred through two special made reinforced concrete plate with dimensions 2*2*0,2 m, made by B35 and B60 concrete. There were three tests in two stages. At the first stage, two plates were tested at the same time with 6 m distance between edges. At the second stage, one slab was tested, located in central part of the tray (Figure 1). During the experiments, tray was covered with a tent with constant temperature ±5C°.

1 – test plate №1 (stage №1), 2 – test plate №2 (stage №1), 3 – test plate №1 (stage №2), 4 – reflector, 5 – displacement sensor, 6 – pressure sensor, 7 – settlements sensor, 8 – vertical and

horizontal stress sensors (blue – plate №1, stage №1, pink – plate №1 stage №2), 9 – reference beam, 10 – force beam, 11 – loading system, 11A – load sensor, 11B – jack, 11D – concrete reinforced cube 0,2 m, 12 – automated level, 13 – sand embankment, 14 – experimental tray 15*5 m, 15 – tray steel pile wall, 16 – anchor pile.

2 EQUIPMENT

Base was equipped with 76 sensors operating simultaneously in automated mode. Displacements of each plate were measured using 10 potentiometric sensors located along one of its sides. Layered deformations were also measured using potentiometric sensors at 10 points, set with step of 0,5 m with base depth for each slab (Figure 2). All vertical movements were fixed relative to reference beam, hinged at one end. Reference beam position was controlled using automated level, position of which was monitored using three reference points (Figures 1 and 2). Horizontal and vertical stresses in soil were measured using strain gauge pressure transducers PMD-70/II (force cell). Force cells were located in depth increments of 0,25, 0,5 and 1 m to depth of 4 m. (Figure 2). More details about tests in (Travush & Shulyat'ev 2022).

3 TEST PROCEDURE

Loading of each plate was made in two stages, at first stage plate loaded up to 0,4 MN, after which controlled unloading was carried out. At second stage plates were loaded up to 1,5 MN, followed by controlled unloading. Loading step was 0,1 MN, unloading was 0,2 MN. Next loading step was applied when settlements velocity were less than 0,1 mm per 1 h. Loading was applied using jack equipped with tow pressure gauges. Load on plate was transferred through reinforced concrete cube with a side of 0,2 m. Measurements were made in automated mode with a frequency once every five minutes.

4 MEASUREMENT ANALYSIS

Lets compare measurement results with stresses obtained by solving problem of stress distribution in elastic half-space base. Solutions prepared by G.V. Kolosov for flat task with

uniformly distributed load (Tshitovich 1963), J. Boussinesq for three-dimensional task for vertical concentrated force applied to elastic half-space bace (Boussinesq 1885), A. Lyav (Lyav 1935) and V.G. Korotkin (Korotkin 1938) for conditions three dimensional stress-state by load distributed over square area.

J. Boussinesq's solution for upper base part isn't considered due to peculiarity that arise when concentrated force is applied to half-space. As depth increases, vertical normal stress most closely match with analytical three dimensional case. Distribution of vertical normal stresses obtained by plane stress solution is significantly higher than real, which indicates limited use of plane stress models. Under the load of 1,5 MN, thickness of base, on which additional stresses are half of natural reaches 3,7 m, which corresponds to the depth of compressible thickness, equal to 4 m and determined according to Russian codes (Figure 3).

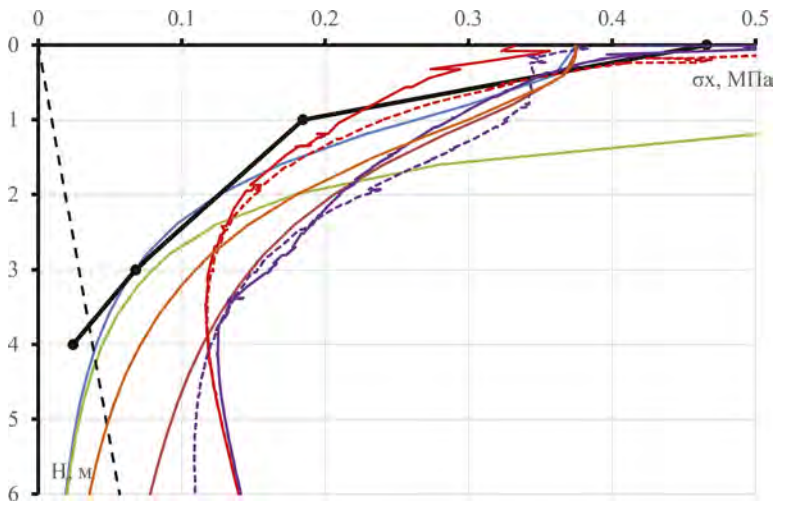

Figure 3. Vertical stress distribution along dept, under 0,375 MPa.

Analytical solutions: Blue – A. Lyav, gray - J. Boussinesq's, orange - G.V. Kolosov, green - V.G. Korotkin, black – monitoring data, dotted black line – half of natural stress, Numerical solutions: Elastic model FE 250 mm (100 mm) – red (dotted red), Mohr-Coulomb (Hardening soil) – violet (dotted violet).

Deformation measurements shows that settlement developed at certain depth linearly depends on average pressure value. Distribution of layer-by-layer deformations with depth correlates with general ideas about deformation of layer and is shown in Figure 4. Limitation of compressible thickness adopted in Russian codes as half of natural stresses for dispersed non-weak soil makes it possible to determine settlement with an accuracy of 10%, which acceptable for engineering purposes. Measurement results and comparison made possibility of using theory of elasticity and continuum space for geotechnical problems.

Lets perform numerical simulation using various soil models, such as elastic model, ideal elastic-plastic model with Mohr-Coulomb strength criterion and Hardening soil model. As can be seen from Figure 3, changing the size of finite element by two times leads to differences in vertical stresses of up to 40% at top of base. Comparing upper parts in different models, results of numerical and analytical calculations are quite close to each other. With increasing depth, vertical stress distribution largely depends on chosen foundation model, however, for any model, stress distribution in general does not coincide with results obtained analytically from monitoring date. This is consequence of influence of artificial stress concentration when boundary conditions are introduced, selection of which should be given special attention. Choice of soil model should be approached taking into account problem under consideration, type of soil and level of stresses.

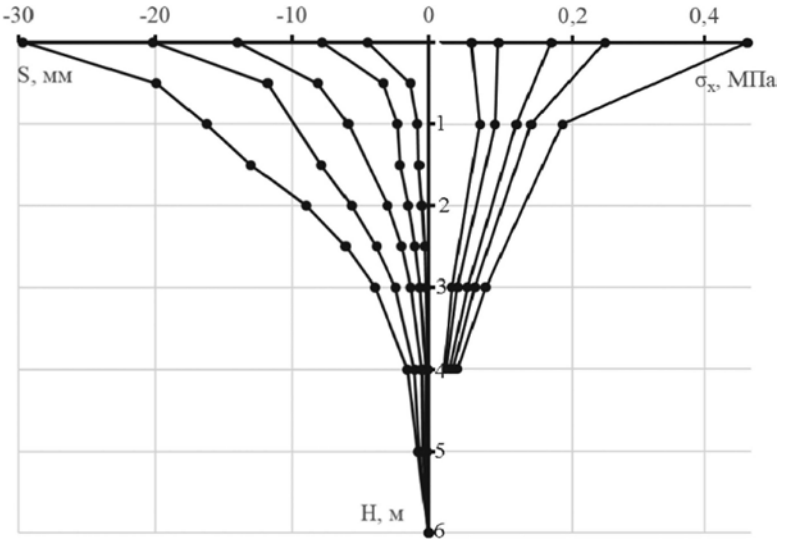

Figure 4. Combined graph of settlements distribution and vertical stresses along depth of foundation at average pressures 0,375 MPa, 0,3 MPa, 0,25 MPa, 0,175 MPa, 0,125 MPa.

5 CONCLUSIONS

Unique investigations of interaction of reinforced concrete slab with sandy soil were carried out, 76 sensors were involved in testing process, measuring stresses under base of slab, vertical and horizontal stress in soil, layer-by-layer settlement of soil. In general, investigations results confirm possibility of using theory of elasticity and continuum space for geotechnical calculations. Present research confirm Russian code approach to determining depth of compressible soil. Contribution of additional settlement from soil under compressible thickness does not exceed 10%. Choice of size of finite element, accepted boundary conditions, as well as soil model significantly depends on magnitude of vertical stresses in soil, as well as their distribution in depth. Investigations of influence of parameters of finite element model should be given special attention and require additional research.

ABSTRACT: An effective way to strengthen shallow foundations is contour reinforcement - the execution of vertical elements in the soil base along the edges of the foundation. The introduction of reinforcement elements that perform the function of a "compression wall" leads to a noticeable decrease in deformations and an increase in the bearing capacity of the soil at the base of the reinforced foundations. As reinforcing elements, various structures and materials with strength properties that exceed the corresponding properties of the soil can be used.

To determine the rational parameters of the contour reinforcement with injection bodies, a set of numerical experiments was performed to calculate the stress-strain state of the soil foundation for different reinforcement schemes in the MIDAS GTS NX 2019 software package. The calculations were carried out in a 3D formulation, taking into account the nonlinear nature of the soil operation.

Based on the results of the calculation, the most effective schemes for the location of reinforcement elements were determined when strengthening shallow foundations with contour reinforcement with injection bodies, and the technology for consistent reinforcement work with a gradual increase in the number of reinforcement elements was substantiated.

1 INTRODUCTION

An efficient way of strengthening shallow foundations is contour reinforcement, i.e. applying a number of vertical elements in the soil body along foundation sides. Application of reinforcing elements, functioning as "compression wall", leads to a significant reduction of deformations and increase in the bearing capacity of reinforced foundation base [1-5]. Various structures and materials with strength properties exceeding the corresponding soil properties can be used as reinforcing elements [6–10, 18–20].

A method of forming reinforcing elements by means of high-pressure pack injection grouting has proved itself. The essence of the method consists in simultaneous supply of cement and sand mortar through several pressurized sources, arranged in series and exceeding the structural strength of soil, and further formation of flat grouting bodies of a conditionally rectangular shape in the soil body [11–14]. A major issue in contour reinforcement is defining optimal parameters of injection grouting, i.e. the number and grid of the grouting bodies both in plan and depth, that can lead to an essential reduction of complexity and cost of works of the reinforcement [15, 16].

DOI: 10.1201/9781003299127-320

2 METHODS AND PROBLEM STATEMENT

In order to define rational parameters of contour reinforcement of shallow foundations by grouting bodies a complex of numerical experiments to calculate stress-strain state of the foundation soil with different strengthening schemes was performed. Numerical modeling was realized in software package MIDAS GTS NX 2019. Calculations were performed in 3D with account of nonlinear character of soil behavior.

Shallow foundation of the existing building that had suffered significant deformations was considered as an example. Foundation bottom size in plan – 2.4×2.4 m, bottom pressure P = 210 kPa. Foundation soil to a depth of 10 m consisted of loam that was light, pulverescent, very soft, non-subsiding, nonsaline: $\rho = 1.95$ g/cm^3, $\varphi = 14°$, C = 15 kPa, E = 4.5 MPa. Settlement of foundation during building construction achieved 156 mm that is significantly higher than the limit value of 10 cm recommended by Rules SP 22.13330.2016.

The calculation was performed for the reinforcing elements of a rectangular shape and size of 0.5×0.2 m, height 0.7 m; distance to foundation sides – 25 cm; gap between the elements in depth – 50 mm and 75 mm in plan; stress-strain properties: $\gamma = 20$ kN/m^3, $\nu = 0.2$, E = 100 MPa. Foundation material – heavy concrete.

Options with uninterrupted and interrupted contour reinforcement along the entire perimeter and at the opposite sides of the foundation were considered. For each option cases of 5-, 4-, 3-, 2- and 1-level reinforcement to the depth of 1.5b, 1.2b, 0.9b, 0.6b, 0.3b, respectively, were calculated (Picture 1).

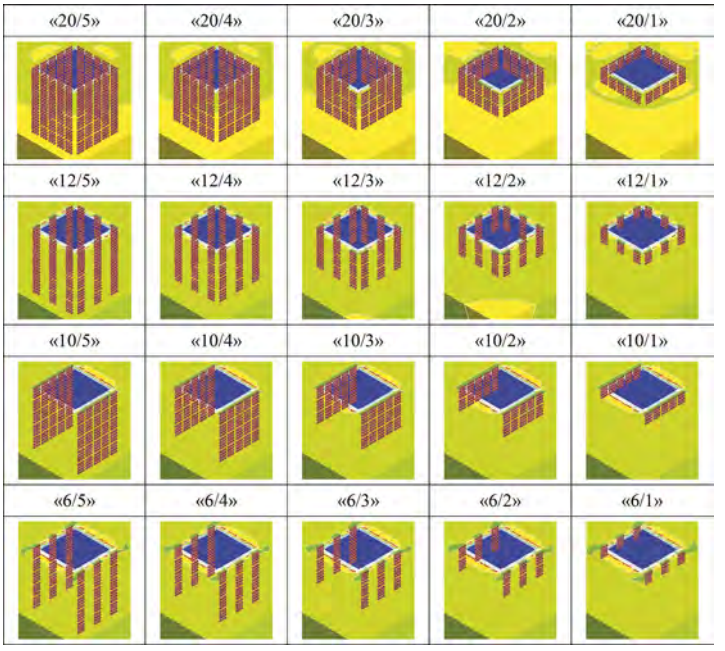

Figure 1. Arrangement schemes of reinforcement elements when strengthening shallow foundation with contour reinforcement.

Note to Picture 1. Symbols in schemes: first figure – number of columns, second figure – number of levels of reinforcing elements in depth.

The structural model in MIDAS consisted of a grid of hexahedral and tetrahedral elements, including 26,070 finite elements and 13,908 nodes with 42,231 degrees of freedom. Overall dimensions of the computational domain were 13.5×13.5×15 m.

The calculations of the foundation reinforced by means of contour reinforcement were performed consecutively in three stages: calculation of stress-strain state of the foundation due to

soil's own weight; after foundation construction and implementation of reinforcing elements; calculation of reinforced foundation after load application.

3 CALCULATIONS RESULTS AND ANALYSIS

The settlement value of foundation with natural (not reinforced) basis calculated in MIDAS, using elastic-plastic Mohr-Coulomb model, comprised 144 mm that is close to the value of real foundation settlement.

The calculation results of the foundation on a reinforced basis are given in Table 1, the contours of vertical movements of foundation soil strengthened according to characteristic schemes are given in Picture 2.

Table 1. Results of Calculating Shallow Foundations Strengthened by Contour Reinforcement With Reinforcing Elements Arrangement According to Different Schemes.

«20/5»	«20/4»	«20/3»	«20/2»	«20/1»
S = 110 мм ΔS = 34 мм V = 7,00 м^3 $К_{ПРМ}$ = 2,06	S = 112 мм ΔS = 32 мм V = 5,60 м^3 $К_{ПРМ}$ = 1,75	S = 114 мм ΔS = 30 мм V = 4,20 м^3 $К_{ПРМ}$ = 1,40	S = 116 мм ΔS = 28 мм V = 2,80 м^3 $К_{ПРМ}$ = 1,00	S = 122 мм ΔS = 22 мм V = 1,40 м^3 $К_{ПРМ}$ = 0,64
«12/5»	«12/4»	«12/3»	«12/2»	«12/1»
S = 121 мм ΔS = 23 мм V = 4,20 м^3 $К_{ПРМ}$ = 1,83	S = 123 мм ΔS = 21 мм V = 3,36 м^3 $К_{ПРМ}$ = 1,60	S = 123 мм ΔS = 21 мм V = 2,52 м^3 $К_{ПРМ}$ = 1,20	S = 124 мм ΔS = 20 мм V = 1,68 м^3 $К_{ПРМ}$ = 0,84	S = 128 мм ΔS = 16 мм V = 0,84 м^3 $К_{ПРМ}$ = 0,53
«10/5»	«10/4»	«10/3»	«10/2»	«10/1»
S = 126 мм ΔS = 18 мм V = 3,50 м^3 $К_{ПРМ}$ = 1,94	S = 127 мм ΔS = 17 мм V = 2,80 м^3 $К_{ПРМ}$ = 1,65	S = 128 мм ΔS = 16 мм V = 2,10 м^3 $К_{ПРМ}$ = 1,31	S = 129 мм ΔS = 15 мм V = 1,40 м^3 $К_{ПРМ}$ = 0,93	S = 132 мм ΔS = 12 мм V = 0,70 м^3 $К_{ПРМ}$ = 0,58
«6/5»	«6/4»	«6/3»	«6/2»	«6/1»
S = 133 мм ΔS = 11 мм V = 2,10 м^3 $К_{ПРМ}$ = 1,91	S = 134 мм ΔS = 10 мм V = 1,68 м^3 $К_{ПРМ}$ = 1,68	S = 134 мм ΔS = 10 мм V = 1,26 м^3 $К_{ПРМ}$ = 1,26	S = 134 мм ΔS = 10 мм V = 0,84 м^3 $К_{ПРМ}$ = 0,84	S = 136 мм ΔS = 8 мм V = 0,42 м^3 $К_{ПРМ}$ = 0,53

Note to Table 1. S – settlement of foundation on a reinforced basis, ΔS – difference between settlements of foundations on natural and reinforced bases, V – volume of reinforcing elements, $К_{ПРМ}$ – coefficient of given material consumption equal to the ratio of volume (V) of reinforcing elements to the difference of settlements (ΔS).

The efficiency of various strengthening schemes is clearly shown by the coefficient of given material consumption $К_{ПРМ}$ (Table 1), equal to the ratio of the reinforcing elements volume to the difference of settlements of foundation on a natural basis and that after reinforcement and numerically identical to the volume of reinforcing elements in m3 necessary for the settlement reduction by 1 cm.

Thus, for instance, as might be expected, the minimum value of foundation settlement is achieved by maximum reinforcement (uninterrupted 5-level to the depth of 20/5) – S = 110 mm that is by 34 mm or 24% lower than the settlement of foundation on a natural basis. However, interrupted reinforcement along two opposite sides of the foundation, one-level to the depth (6/1), allows to reduce the settlement by 8 mm, i.e. by 6%, at the same time the volume of the reinforcing elements used differs 17-fold – 0.42 m^3 against 7.00 m^3 in the first case. When strengthened according to 20/5 scheme the coefficient of given material

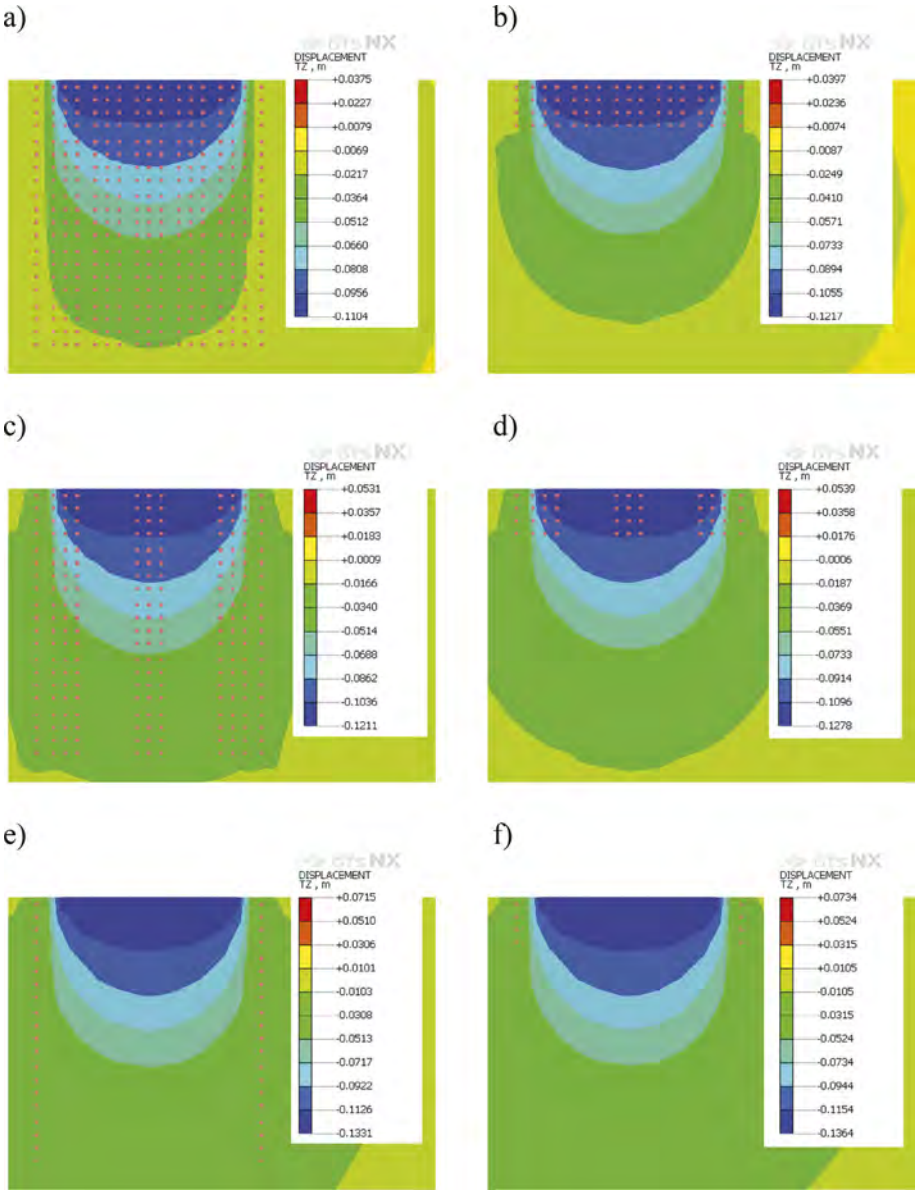

Figure 2. Isolines of vertical displacements of the foundation soil base when reinforced with contour reinforcement: (a, b) – solid 5-level («20/5») and one-level; (c, d) intermittent 5-level («12/5») and one-level («12/1»); discontinuous, along two opposite sides of the foundation: (e, f) – 5-level («6/5») and one-level («6/1»).

consumption $K_{ПРМ}$ = 2.06, when done so according to scheme 6/1 – $K_{ПРМ}$ = 0.53, that is to say specific efficiency of strengthening at maximum reinforcement is 4 times lower.

Interrupted contour reinforcement is more cost effective than uninterrupted one. The coefficient of given material consumption $K_{ПРМ}$ for interrupted 5-level contour reinforcement along the entire foundation perimeter (12/5) comprises 1.83 and for one-level (12/1) – $K_{ПРМ}$ = 0.53. When uninterrupted 5-level reinforcement is applied, the coefficient of given material consumption $K_{ПРМ}$ = 2.06 and when uninterrupted one-level reinforcement is applied, $K_{ПРМ}$ = 0.64. Uninterrupted reinforcement along two opposite sides also has higher specific efficiency

in comparison with uninterrupted reinforcement along the entire perimeter of the foundation – $K_{ПРМ}$ = 1.94 and $K_{ПРМ}$ = 0.58, respectively.

By analyzing the values of coefficient $K_{ПРМ}$, it is fair to say that in all cases the increase in the number of columns of reinforcing elements, as well as in the levels to depth, leads to the reduction of foundation soil deformations, but at the same time the reduction of settlement from minimum to maximum reinforcement schemes is not proportionate to the volume growth of reinforcing elements used, i.e. specific efficiency of strengthening decreases.

The comparison of deformations of soil foundation strengthened by reinforcement according to schemes with similar number of levels allows to make a conclusion about almost direct dependence of the settlement value on the number of reinforcing elements in plan at approximately equal values of $K_{ПРМ}$. For example, when 5-level reinforcement is applied the difference of settlements

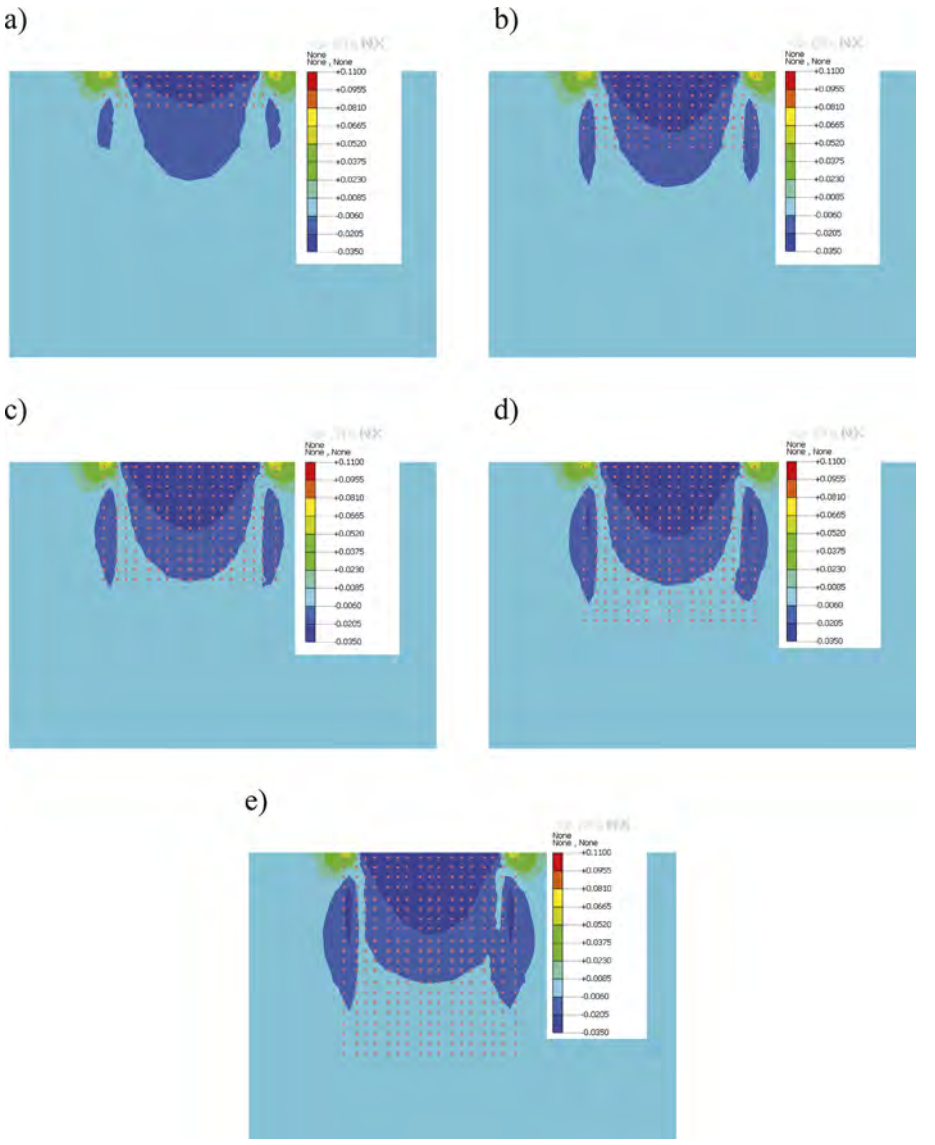

Figure 3. Isolines of differences in soil base deformations before and after reinforcement: (a) – with a single («20/1»), (b) – two («20/2»), (c) – three («20/3»), (d) – four («20/4») and e – five-level («20/5») solid reinforcement.

of foundations on a natural basis and on the basis strengthened by interrupted contour reinforcement at two opposite sides (6/5) is 11 mm, by uninterrupted contour reinforcement at two opposite sides (10/5) – 18 mm, by interrupted reinforcement at four sides (12/5) – 23 mm, and by uninterrupted contour reinforcement at four foundation sides (20/5) – 34 mm. The value of $K_{ПРМ}$ in such a case lies within 1.83 and 2.06, and at that point the minimum value of $K_{ПРМ}$ equal to 1.83 corresponds to the scheme of interrupted contour reinforcement at four foundation sides (12/5). The latter is also true for options with 4-, 3-, 2- and one-level reinforcement.

As the implementation of additional levels of reinforcing elements from the top down is extremely difficult while strengthening real foundations [17], it is necessary to assign the reinforcement depth at the stage of design.

To define effective depth of contour reinforcement the comparison of deformation contours of soil foundation without strengthening and after it was made. The calculation was performed for all schemes. Differences of deformations of soil foundation before and after strengthening by uninterrupted contour reinforcement along the entire perimeter for options with different levels in depth are represented in Picture 3 as an example.

Picture 3 shows that contour reinforcement leads to a substantial change of the strain state of the soil body – the difference area of deformations of the foundation before and after strengthening is wedged-shaped and extends to the depth of 0.81b, 0.86b, 0.90b, 0.91b and 0.97b at 1-, 2-, 3-, 4- and 5-level reinforcement, respectively. When 1- or 2-level reinforcement is applied, the area border is located below (0.3b and 0.60b), with 3-level reinforcement – it practically coincides (0.9b), with 4-level reinforcement – it is above (1.2b), and with 5-level reinforcement – it is significantly higher than the reinforcement depth (1.5b). At 2-, 3- and 4-level reinforcement the reduction of lateral deformations within and beyond the reinforcement contour is clearly observed. Elements of the 5^{th} level provide certain increase mainly in the side areas of a soil body transformed state, however, at the same time, they do not expand below the elements of the 4^{th} level. Therefore, the schemes with 3- and 4-level reinforcement that correspond to the depth of 0.9b…1.2b from the foundation bottom are the most effective. This statement is true for all schemes of reinforcing elements arrangement in plan, when applying contour reinforcement to shallow foundations.

4 CONCLUSION AND DISCUSSION

On the basis of numerical modeling on the forecast of stress-strain state of soil foundation with various strengthening schemes performed by the authors in software package MIDAS GTS NX 2019, the following conclusions can be made:

1. Strengthening of shallow foundations by contour reinforcement, using rigid reinforcing elements, transforms the stress-strain state of the soil body; change of the strengthening scheme together with the increase in the number of reinforcing elements reduces stress and vertical deformations. When interrupted contour reinforcement of shallow foundations is applied, the reduction of the settlement can reach 16% in relation to the settlement of the foundation that is not reinforced, in case of uninterrupted contour reinforcement the settlement can be reduced by 24%.
2. Strengthening by the maximum number of reinforcing elements leads to the maximum reduction of soil foundation deformations. However, any reinforcement scheme reduces the settlement, and in most cases the coefficient of given material consumption $K_{ПРМ}$ grows along with the increase in the volume of the reinforcing elements used.
3. Interrupted contour reinforcement is more cost effective than uninterrupted one, the coefficient of given material consumption $K_{ПРМ}$, when reinforcing the sites of the same length, is lower in the first case. Interrupted contour reinforcement along the entire perimeter of the foundations is more effective than strengthening by uninterrupted reinforcement along two opposite sides – deformations of the basis and the value of the coefficient of given material consumption $K_{ПРМ}$ are higher in the second case.
4. Based on the above, strengthening of shallow foundations by rigid reinforcing elements – grouting bodies – is advisable to be carried out in stages, increasing the number of reinforcing

elements at each stage and changing the reinforcement scheme respectively: from interrupted contour reinforcement along opposite sides to uninterrupted contour reinforcement along the entire foundation perimeter. The necessity of performing further works must be defined on the basis of results of monitoring the development dynamics of soil foundation deformations during and after each stage.

5. Optimal depth of soil foundation reinforcement for shallow foundations is 0.9b…1.2b (where b – width of the foundation bottom).

Further line of research by the authors of the article will be connected with establishing common principles of approach to strengthening foundations by high-pressure pack injection grouting based on the results of mathematical modeling.

Influence of pile foundation technology on the skin friction

O.A. Shulyatyev & S.O. Shulyatyev
NIIOSP named after N.M. Gersevanov of the JSC «Research center of construction», Moscow, Russia

ABSTRACT: The lateral bearing capacity of bored piles is determined by horizontal stresses and soil strength. The paper investigates the influence of piling technology and loading history on horizontal stresses, as well as the effect of polymer solution, which has recently been used in piling, on the strength characteristics of the ground. As a result, it is found that the horizontal stresses can vary many times depending on the bored pile technology. The horizontal stresses increase as the pile is loaded. An additional increase in horizontal stresses occurs as a result of the mutual influence of the piles. The application of polymer solution instead of bentonite increases the resistance along the side surface of the ground up to 30%.

Keywords: bored piles, tests, bearing capacity of soil, lateral surface of pile, polymer solution, mutual influence of piles, pile field

1 INTRODUCTION

Comparison of the results of experimental determination of the resistance of hard clayey soils on the lateral surface of bored piles with calculations in the construction of high-rise buildings showed that the closest results are obtained when applying the dependence based on Coulomb's law, taking into account soil over-compaction (Shulyatyev, 2020):

$$f_i = \sigma\prime_x \mathrm{tg}\varphi + \ c. \tag{1}$$

The value σ'_x depending on the vertical stresses can be determined by the formula

$$\sigma\prime_x = K_o \sigma\prime_z, \tag{2}$$

where $K_o = (1 - \sin\varphi)$;

φ and c are strength properties of the soil.

In the case of over-compacted soil, the K-factor can be determined according to the formula

$$K_o = (1 - sin\varphi)\mathrm{OCR}^{\sin\varphi}. \tag{3}$$

The main parameters influencing the calculation results are the horizontal stresses and the strength properties of the ground. The article deals with the change in horizontal stresses during pile installation and loading and the effect of the borehole drilling stability solution used on the strength properties of the soil.

2 STUDY OF THE STRESS-STRAIN STATE OF THE SOIL MASS DURING BARETTA INSTALLATION

2.1 *Analysis of experimental studies in the construction of Okhta Centre*

Until the beginning of this century, in St. Petersburg it was feared that a monolithic 'wall in soil' of the trench type would be constructed using standard technology due to the possible loss of stability of the walls of the enclosure in the ribbon loam, which has a latent flowing consistency.

DOI: 10.1201/9781003299127-321

In order to investigate this hazard, pilot works were carried out at the Okhta Centre site, which consisted of an investigation of the soil mass composed of strip loam. Five barettes were constructed with a working length of 65 m and a cross-section of 1.5 × 2.8 m (Shulyatyev, 2020). Three of the five tested barettes were subjected to a group test in which they were loaded simultaneously. The arrangement of the test burettes is shown in Figure 1.

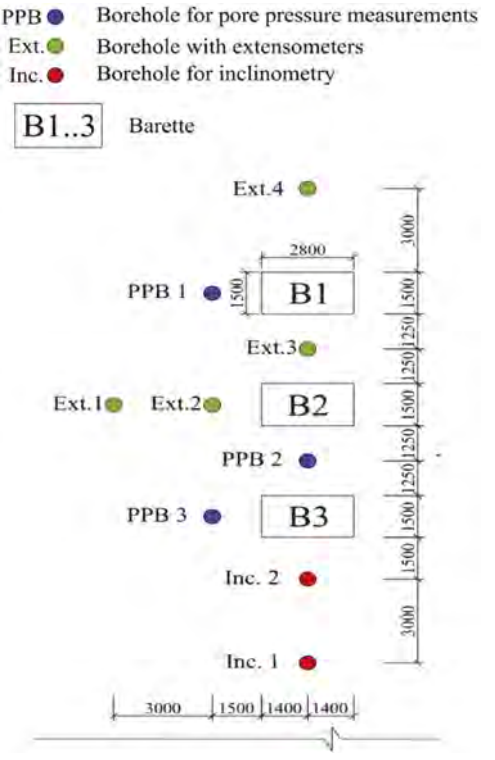

Figure 1. Baretta placement diagram for stress-strain state of the soil mass research during installation of diaphragm wall.

The engineering and geological conditions of the construction site are represented by weak water saturated soils to a depth of 30. . .35 m. Beneath them there is a layer of moraine sediments of small thickness. From 45 to 200 m there are Vendian clays, below – rocky soils. The Vendian clays are relatively firm soils and are classified as hard clay and half-rock soil at the same time.

The adjacent soil mass was equipped with monitoring sensors and instruments. A total of 9 monitoring boreholes were constructed (Figure 1), of which three (PPB 1 - 3) were for pore pressure measurements, four (Ext.1, Ext.2, Ext.3, Ext.4) were for vertical ground deformation layer-by-layer measurements and two (Inc.1, Inc.2) were for inclinometer observations.

Using the example of baretta B2, located 1.5 m away from borehole PPB 2, consider the change in pore pressure during baretta fabrication. Table 1 shows the values of natural pore pressure at various stages of the fabrication process in absolute and percentage terms compared to the natural pore pressure.

When analysing Table 1 it can be noted that the maximum change in pore pressure was observed in soils up to a depth of 20 m. The soils from the surface to this depth are weak water saturated clay soils, the application of load to which immediately causes a jump in pore pressure. The increase in pore pressure during the excavation phase is due to the fact that the clay mud used during drilling creates excessive pressure on the borehole walls from the inside. The same process, but with a greater change in pore pressure, occurs during concreting. The

Table 1. Change in pore pressure with the PPB 2 barretta.

Sensor installation depth, m	Pore water pressure before work P_{w0}*, kPa	Trenching		Installing the frame		Concreting	
		P_w*, kPa	Change, %	P_w,* kPa	Change, %	P_w*, kPa	Change, %
3	45	55	22.2	48	6.7	70	55.6
9	105	130	23.8	108	2.9	140	33.3
16	170	195	14.7	180	5.9	215	26.5
25	259	263	1.5	260	0.4	270	4.2

* P_w – pore water pressure during operation (maximum values).

reason is that the density of the concrete mix is 2.3. . .2.4 times higher than the density of the drilling mud. The maximum change of the pore pressure was fixed at the depth of 3 m and made up 55 % of the initial one. At deeper depths, the change of pore pressure in relation to natural one is not so significant, which is caused by higher density of soil at this depth. In addition, the natural pore pressure increases with depth and therefore the percentage change in pore pressure decreases.

Inclinometer measurements were taken with a Digitilt hand-held inclinometer in boreholes up to 52 m deep. Inc.1 and Inc.2 inclinometer boreholes (see Figure 1) were located 3.0 m and 1.5 m from the B3 barrette wall, respectively. The values of horizontal ground displacement towards the trench measured in Inc.2 borehole reached 29 mm during the development of trench B3 (Figure 2). At depths up to 30 m from the surface, maximum displacement values were observed. The measured horizontal displacement values are up to 5% of the barrette width and are generally in line with the expected values under the ground conditions considered. At these depths are dusty clays and loams of soft plastic and soupy consistency prone to thixotropic softening. From a depth of 30 m to the bottom of the observation well, at the depths of the more resistant semi-solid and solid loams, the movements of the soil mass surrounding the baretta are linearly attenuated with depth. Later in the concreting process, the opposite process was observed - soil movement away from the excavation was 6. . .8 mm (Figure 2).

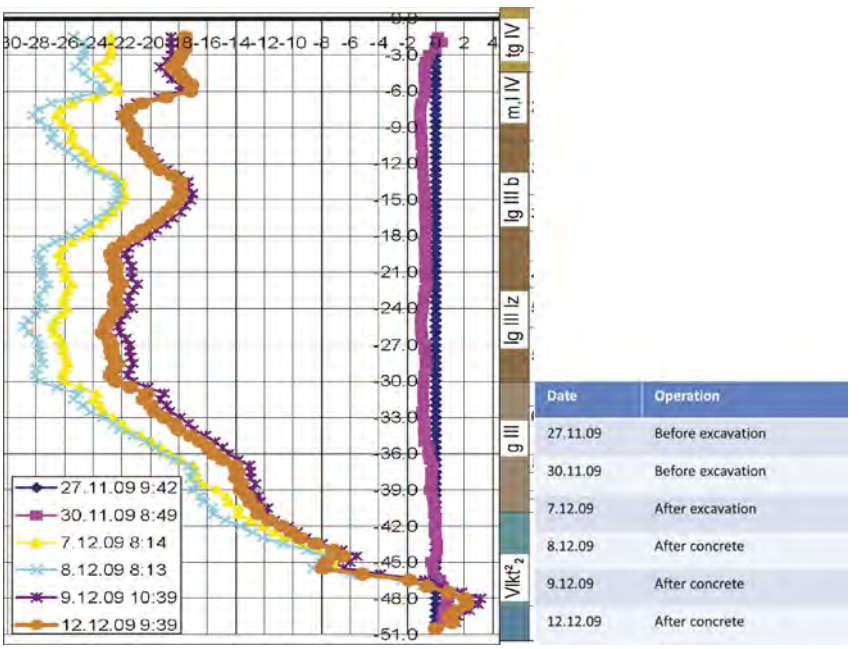

Figure 2. Horizontal movements of Inc.2 inclinometer during installation of baretta B3 for stress-strain state of the soil mass research during installation of diaphragm wall.

2.2 *Experimental studies at the Zagorskaya hydroelectric pumped storage power station*

As a result of experimental studies carried out at the Zagorskaya hydroelectric pumped storage power station construction site (Mamonov 1982, 1989), data were obtained on the actual values of radial pressures σ'_r at the contact of the bored pile with the ground. The σ'_r values were determined using pressure transducers (soil pressure cell) placed on the walls of three boreholes drilled for a 1 m diameter, 16-18 m deep pile. Immediately after placing the concrete mixture in the borehole, a radial pressure distribution σ'_r close to the hydrostatic pressure calculated for a mixture with a specific gravity of 23.3 kN/m^3 was obtained (Figure 3). Subsequently, during setting and hardening of the concrete mixture, a decrease of σ'_r pressures was observed, and after four months they were 6-16 % of the initial value.

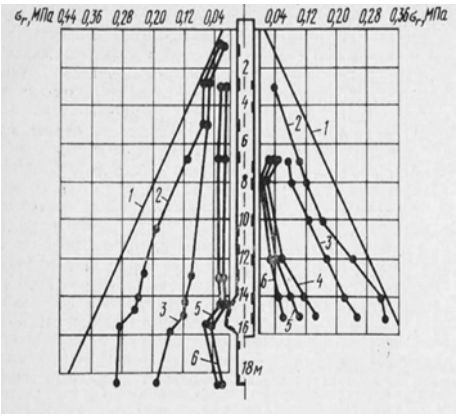

Figure 3. Radial pressure diagrams σ'_r along the length of pile No. 8 (a) and No. 3 (b) after concreting: 1 - hydrostatic pressure; 2 - after concrete filling; 3 - after 2.5 h; 4 - after 12 h; 5 - after 7 days; 6 - after 28 days.

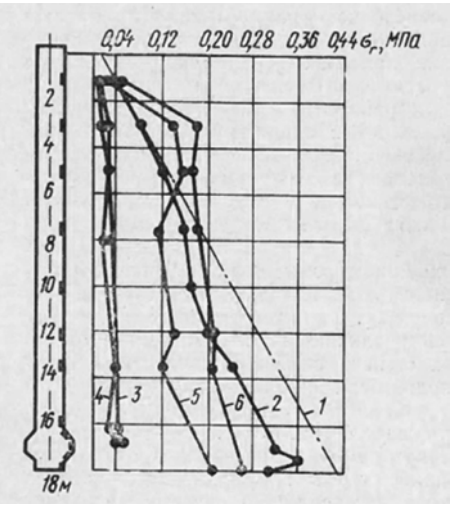

Figure 4. Radial pressure diagrams σ'_r along the length of pile No. 7 after concreting and during pile loading: 1 - hydrostatic pressure of concrete; 2 - after well filling with concrete; 3 - after 7 days; 4 - after 28 days; 5 - at 6500 kN load; 6 - at 7500 kN load.

2.3 *Calculation of concrete pressure*

Experimental data have now been obtained regarding the pressure of concrete on the borehole wall and within the concrete during the fabrication process to a greater extent barrette (Ng, 1999; Delattre, 2002; Lächler, A. 2006, 2007; Uriel, 1977; Gaba, 2017). Having processed the experimental data, Loreck (2007) obtained that the maximum pressure of the concrete mixture on the trench wall when concreting a wall grip in the ground is distributed according to a bilinear law (Figure 5). Up to a certain depth, which is conventionally called the critical depth, the concrete pressure is distributed according to the hydrostatic law. Below this depth, due to the concrete hanging on the trench walls and the onset of setting, it is assumed that the pressure of the concrete mixture on the trench walls continues to increase linearly, but with a lower intensity depending on the density of the clay solution (for each meter of depth the pressure on the trench wall increases by the value γ_{bt}×1 m):

$$\sigma_{bz} = \begin{cases} \gamma_b \times h \; at \; h \le h_{cr} \\ \gamma_{bt} \times h + (\gamma_b - \gamma_{bt}) \times h_{\text{крит}} \; at \; h > h_{cr} \end{cases} \tag{4}$$

where σ_{bz} is the pressure of fresh concrete on trench walls at depth z, kN/m^2;
γ_b is the volume weight of concrete mixture, kN/m^3;

γ_{bt} is the volume weight of the clay solution, kN/m^3;
h is the depth below the top of the wall in the ground, m;
h_{cr} is the critical depth, m.

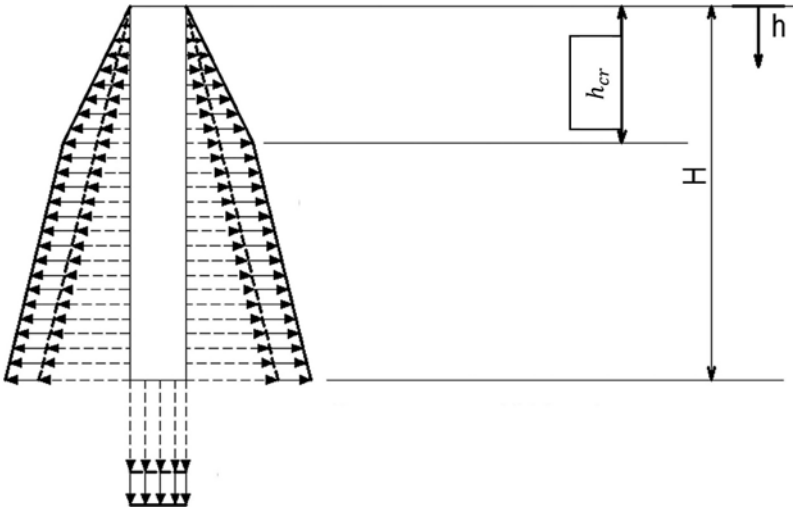

Figure 5. Diagram for determining the pressure on the trench wall during concreting.

In the publications of Lings et al. (Lings, 1991, 1994), the critical height was proposed to be defined as ⅓ of the diaphragm wall height. This approach was based on the analysis of the experimental data available at the time of publication of the paper on the three test work zones. In the publication of O.A. Shulyatyev and D.K. Minakov (Shulyatyev 2017) it was shown that the real values of critical height fluctuate within a wide range, from 0.17 to 0.57H, deviating significantly from the value of 0.33H predicted by Lings et al. (Lings, 1994), and a simple formula (5) was derived by linear approximation to determine the critical height h_{cr} depending on concreting rate:

$$h_{cr} = 0.85Vt + 1.78, \tag{5}$$

where V is the average concreting speed of the diaphragm wall, m/h; t is the time equal to 1 hour.

2.4 *Determination of pressures after stress relaxation*

After concreting is completed, stress relaxation takes place. Based on the analysis of experimental data, it was obtained that in general the value of additional effective pressures occurring in the soil at the interface with the concrete barrette at depth z ($\Delta\sigma_{gz}$) will be

$$\Delta\sigma'_{gz} = \sigma_{bz} - \sigma_w - \sigma'_{rz} = \sigma_{bz} - \sigma_{gwz} \tag{6}$$

$$\text{at } \sigma_{gwz}=\sigma_w+\sigma'_{gz}, \tag{7}$$

where σ_w is pore water pressure;
σ_{gz} is effective horizontal pressure from own weight of soil;
σ_{gwz} is total horizontal stress in the soil mass;

$$\sigma'_{gz} = K_0\gamma' z.$$

For normally compacted soil, K_0 can be determined through the transverse strain factor ν:

$$K_0 = \frac{\nu}{1-\nu}, \tag{8}$$

or by Jaky's empirical formula

$$K_0 = 1 - \sin\varphi. \tag{9}$$

For the case of over-compacted soil

$$K_0 = (1 - \sin\varphi) OCR^{\sin\varphi}. \tag{10}$$

Based on this research, a methodology for calculating the effect of bored piles and barettes on the change in horizontal pressures at the contact between the piles and the barettes and the surrounding soil is proposed (Shulyatyev, 2022).

The use of different bored pile technologies for the same soil conditions can result in a difference in the already mentioned pressures $\Delta\sigma_{gz}$ of up to 70%. The highest pressures occur when the bored piles are protected by bentonite solution and relatively lower pressures when they are protected by casing.

Due to the fact that the soil is a plastic material, the final value of the horizontal stresses is influenced by the loading history depending on the technology and the ground conditions of the site, which it is advisable to consider by applying appropriate ground models.

3 CHANGE OF HORIZONTAL STRESSES DURING LOADING

3.1 *Studies at the Zagorskaya hydroelectric pumped storage power station*

During pile testing at the Zagorskaya hydroelectric pumped storage power station (see Section 1.2, Figure 4) it was found that during loading the horizontal stresses increase to an average of 200 kPa with a pile load of 750 kN. The reason is that the soil resistance forces on the lateral surface cause an increase in the vertical stresses in the soil mass, which in turn increases the horizontal stresses.

3.2 *Study at the Okhta Centre construction site*

At the Okhta Centre construction site (see Section 1.1) three barrettes were tested together: B1, B2 and B3 (Figure 1) measuring 1.5×2.8 m, spaced 1.5 m apart from each other in the clear. The tests were performed by the O-Cell method. The barettes were equipped with sensors to measure the forces in the concrete in height (Figure 6). The tests showed that the ground resistance on the lateral surface of B2, located between B1 and B3, exceeded that of the neighbouring burettes by an average of 30% (Figure 7).

This indicates that, as a result of loading under pile field conditions, there is an additional increase in soil resistance along the lateral surface as a result of the mutual influence of neighbouring barettes.

4 EFFECT OF POLYMER AND BENTONITE SOLUTION ON SOIL RESISTANCE ON THE LATERAL SURFACE OF PILES

The bored piles can be constructed either under or without casing piles ('dry') if the borehole walls remain stable.

Figure 8 shows the results of the baretta and pile tests in the Vendian clays carried out during the construction of Okhta Centre and Lakhta Centre respectively. The burettes were installed with bentonite solution, the piles were installed 'dry'.

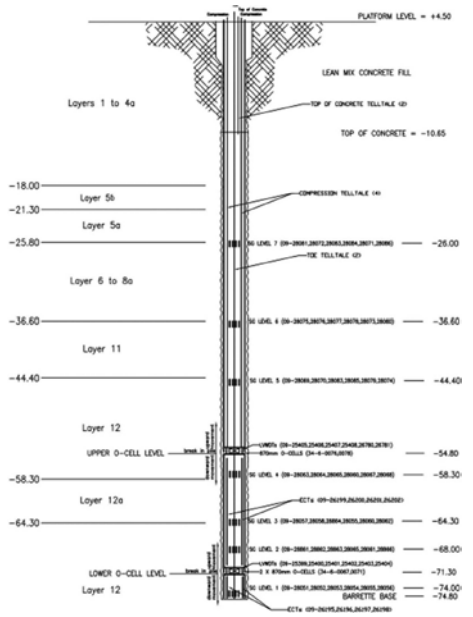

Figure 6. Layout of jacks and sensors in the baretta body.

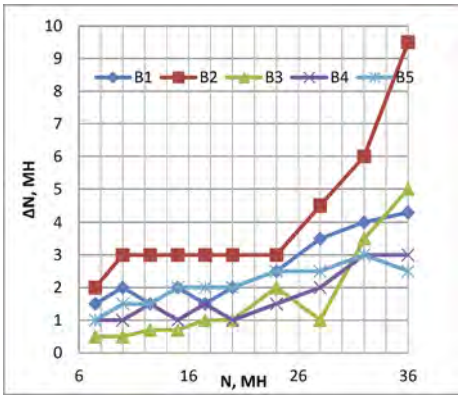

Figure 7. Change of force in the barrette body ΔN during Stage 1 loading, recorded between the Level 2 transducer and the lower O-Cell.

The tests showed that the average resistance of the soil on the lateral surface of the barettes was 240 kPa, the piles were 450 kPa at a displacement of more than 25 mm. The reason is that the burettes were made under polymer solution and the piles were made 'dry'. Thus, the use of bentonite reduces the lateral resistance of the soil by more than 30%!

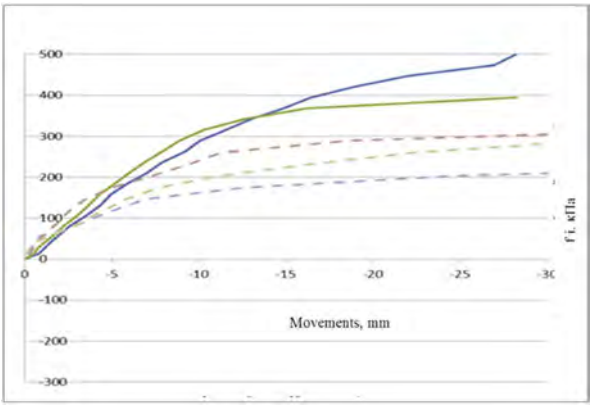

Figure 8. Dependence of skin friction (f_i) on movements: solid lines – bored piles; dashed lines – barrettes.

In recent years, in addition to bentonite solution, polymer solution has also been used for piling. Figure 8 shows the results of pile testing at the site of NIIOSP named after N.M. Gersevanov performed under bentonite and polymer solutions. The tests were carried out in sands of medium grain size, and medium density. Diameter of piles was 270 mm and working length was 1.5 m. Three types of polymer solution were tested: 1520, Bauer 703 and Bauer 709. The test results are shown in Table 2 and Figure 9.

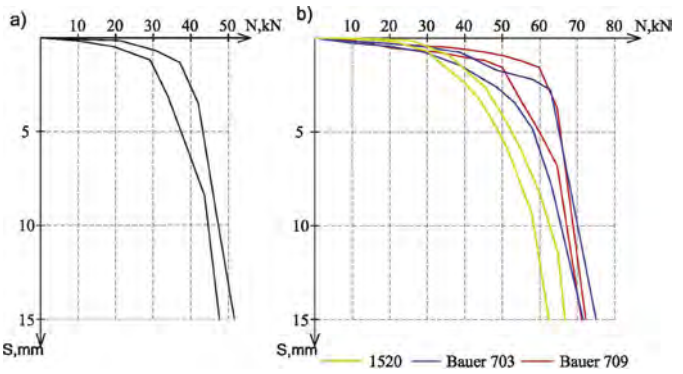

Figure 9. Test results of pilot piles: *a* – piles made under bentonite solution; *b* – piles made under polymer solution.

Table 2. Specific resistance along the side of the piles with different types of retaining solution.

No	Name of solution	Load, kN	Specific lateral resistance, kPa		Deformation value, mm
			on a pile	mean value	
1	Bentonite slurry	46.8	39.8	40.8	15.1
2		48.5	41.8		16.45
3	Polyacrilamide solution SLURRY	69.4	59.3	59.3	11.6
4	LTP 709	69.4	59.3		9.6
5	Polyacrilamide solution SLURRY	58.1	49.7	49.7	8.6
6	LTP 703	58.1	49.7		4.9
7	Polyacrilamide Polyflock 1520	56.5	47.9	48.8	15.96
8		58.1	49.9		11.3

In evaluating the test results, it should be noted that the lateral resistance of piles made under polyacrylamide solution protection is 1.2-1.46 times higher than that of piles made with bentonite solution.

CONCLUSIONS

1. In the process of piling, both pore pressure and horizontal stresses in the soil mass change.
2. Depending on the piling technology, the horizontal stresses can vary by up to 70 %.
3. Horizontal stresses increase during the loading process.
4. Additional horizontal stresses increase as a result of reciprocal influence of the piles.
5. The lateral resistance depends on the method of anchoring the borehole: the highest values occur when the borehole is dry or with casing, the lowest - when bentonite solution is used.

This article presents the results of research work carried out under the assignment of the Federal Scientific and Technical Centre for Certification in Construction of the Ministry of Construction and Housing and Communal Services of the Russian Federation:

1. Development of recommendations on calculation of the influence of the wall in the trench-type ground on the change of the stress-strain state of the surrounding soil mass and on its consideration during the design of newly erected buildings and structures in sandy soils, 2020.
2. Development of a methodology for determining technological settlements during the installation of bored-injection piles and assessment of technological settlements during the installation of the diaphragm wall of the trench type and ground injection anchors, 2015.

Subgrade assessment of unpaved roads subjected to cyclic wheel loads using dynamic cone penetration and crosshole-type dynamic cone penetrometer

Namsun Kim, Geunwoo Park, Younggeun Yoo & Jong-Sub Lee
Korea University, Seoul, Korea

Won-Taek Hong
Gachon University, Seongnam-si, Korea

ABSTRACT: For the estimation of the behaviors of unpaved roads under cyclic wheel loads, investigation of the mechanical properties with depth is required. In this study, the dynamic cone penetrometer (DCP) and crosshole-type dynamic cone penetrometer (CDP) are applied to an unpaved road to characterize both the strength and stiffness along the depth. The strength and stiffness of the unpaved road subjected to cyclic wheel loads are characterized by the penetration index (DCPI) and shear wave velocity (Vs), respectively. Experimental results clearly show the changes in strength and stiffness increase due to the wheel loads. This study demonstrates that the DCP and CDP may be effectively used for subgrade assessments of unpaved roads with depth.

1 INTRODUCTION

The assessment of the degree and uniformity of compaction according to repetitive dynamic load induced by the traffic is considered one of the most critical steps in the process of unpaved road construction (Arvidsson and Keller, 2007). For the evaluation of compacted subgrade, plate bearing test (PBT), falling weight deflectometer (FWD), and California bearing ratio (CBR) have been widely used (Roy, 2016; Rahim and George, 2003). Using heavy equipment to assess characteristics of the subgrade of unpaved roads, however, has limited by concerns about instrument cost and low accessibility. Therefore, portable devices are required to assess unpaved roads.

Dynamic cone penetration (DCP), introduced by Scala (1956), has been used to estimate THE strength properties of compacted subgrade. The DCP test is conducted by dropping a hammer from a certain height, which penetrates the penetrometer into the target depth. The test results are expressed as the dynamic cone penetration index (DCPI) which is the penetration depth per blow (mm/blow). The DCP test with its small diameter minimizes the ground disturbance and provides reliable strength characteristic profiles of subgrade along depth.

In this study, crosshole-type dynamic cone penetrometer (CDP) is adopted as a method for characterizing stiffness along the depth. The CDP test can be carried using two CDPs and penetrates in a similar way to the DCP. The hammer impact is detected by an accelerometer installed in the source CDP and the shear wave signal passing through the medium is detected by an accelerometer installed in the receiver CDP. Accordingly, the CDP test can characterize in the depth profile of the stiffness by measuring the shear wave velocity. The main objective of this study is to assess strength and stiffness along the depth of the target ground according to cyclic wheel loads using portable devices. This paper shows the experimental setup of the DCP and CDP, and the experimental results from the field tests.

DOI: 10.1201/9781003299127-322

2 DESCRIPTION OF PORTABLE DEVICES

2.1 *Dynamic Cone Penetrometer (DCP)*

The dynamic cone penetrometer (DCP) is a fast and economical method for the characterization of the subgrade strength. The device consists of a 78.5 N hammer that falls from a height of 575 mm, a cone tip with a diameter of 20 mm and a tip angle of 60°, and a driving rod with a length 1,000mm and diameter 16mm (ASTM D6951/D6951M-18, 2018), as shown in Figure 1. During the operation of the DCP, the number of blow and penetration depth are recorded. The dynamic cone penetration index (DCPI) is expressed as follows:

$$DCPI\,(mm/blow) = D_n - D_{n-1} \tag{1}$$

where D_{n+1} and D_n are the penetration depth at the blow counts of n+1 and n, respectively.

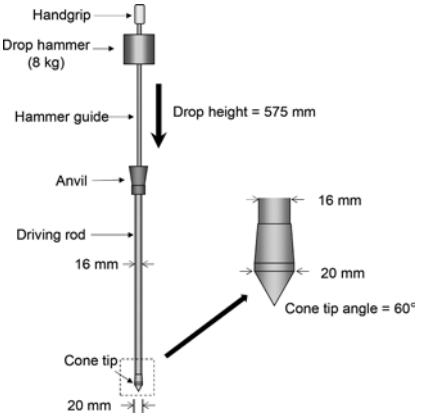

Figure 1. Dynamic cone penetrometer (DCP).

2.2 *Crosshole-type Dynamic cone Penetrometer (CDP)*

The crosshole-type dynamic cone penetrometer (CDP) introduced by Hong et al. (2017) is a portable device that was developed to characterize the strength and stiffness of the track substructure. The components of the CDP are similar to those of the DCP: a 118 N hammer that falls from a height of 575 mm, a cone tip with a diameter of 24 mm and a tip angle of 60°, and a driving rod with a length 1,000 mm and diameter 20 mm. To detect of the shear waves, a uniaxial accelerometer with a measurement range of 0–10,000g is installed on the top of the cone tip, as shown in Figure 2. The shear wave velocity (V_s) measured using an accelerometer is calculated as follows.

$$V_s\,[m/s] = \frac{L}{\Delta t} \tag{2}$$

where L is the distance and Δt is the travel time of the shear wave between the source and receiver CDPs.

3 FIELD TEST

3.1 *Experimental setup*

The DCP and CDP tests were conducted at two locations: Point-1 and Point-2. For the subgrade compaction, the test location was initially filled with 300mm of soil and then compacted to 200mm using roller compactor with a weight of 24 tons. Secondary compaction was conducted on the target ground by using a 15-ton vehicle over 200 times for Point-1 and 400 times for

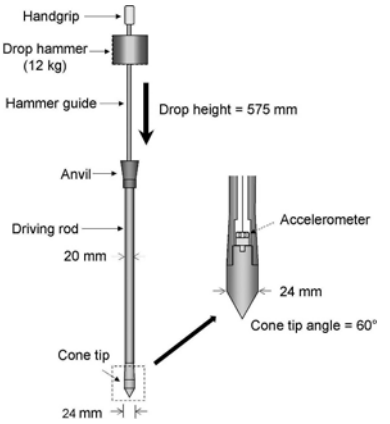

Figure 2. Crosshole type Dynamic Penetrometer (CDP).

Point-2. Note that a rut depth of 100 mm was employed as a failure criterion (AASHITO, 1993). For unifying the target depth, experiments were performed at a ground level of 100 mm.

3.2 *Experimental results*

3.2.1 *Penetration index (DCPI) measured by DCP according to cyclic wheel loads*

The DCPIs obtained from the DCP tests at Point 1-2 are plotted in Figure 3. At Point 1-2, the DCPIs of 0 cycle gradually decrease along the depth within 6–13 mm/blow at depths of 100–600 mm due to the low confining stress near the surface and effective overburden pressure. At Point 1-2, the DCPIs after 200 cycles and 400 cycles show relatively uniform results at depths of 100–400 mm with a DCPIs of 7–9 mm/blow, and show decreased results compared to 0 cycle. The range of stress applied to the subgrade by the wheel load is considered from the ground surface to a depth of 400 mm. For all DCP tests, the DCPIs gradually increase at depths larger than 600 mm.

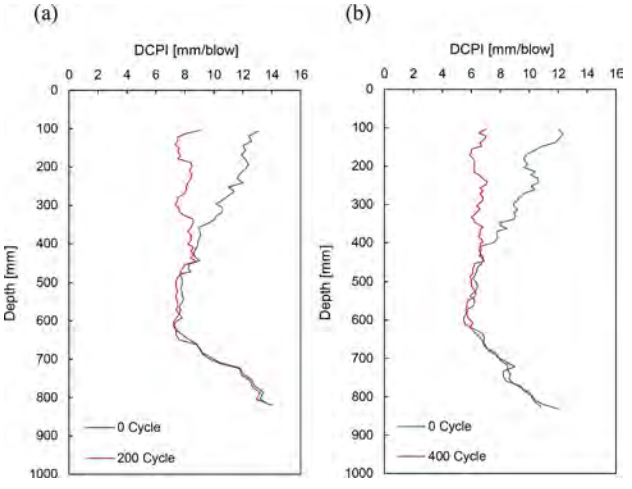

Figure 3. Experimental results of DCP tests: (a) Point-1; (b) Point-2.

3.2.2 *Shear wave velocity (V_S) measured by CDP according to cyclic wheel loads*

The shear wave velocity is obtained at the Receiver-CDP by detecting the vibration generated from the Source-CDP. The V_s values are calculated using the travel time and distance, as described in Eq. (2). The calculated V_s values are profiled at penetration depths ranging from

100 to 820 mm, as shown in Figure 4. For the 0 cycle at Point 1-2, V_s gradually increases along the depth within 110–210 m/s at depths of 180–600 mm. At Point 1-2, the V_s values after 200 and 400 cycles increase to 190 and 210 m/s, respectively, at a depth of 190–610 mm, respectively. At depths of 610–820 mm for all CDP tests, the V_s values show slightly decreased results.

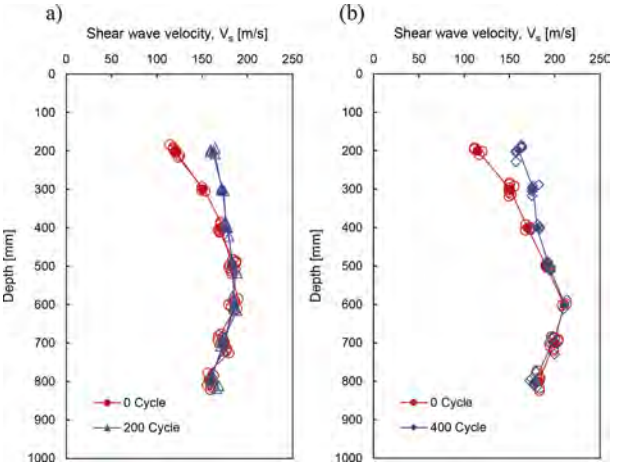

Figure 4. Experimental results of CDP tests: (a) Point-1; (b) Point-2.

4 SUMMARY AND CONCULSIONS

The objective of this study is to estimate the strength and stiffness characteristics of the unpaved roads under cyclic wheel loads using the dynamic cone penetrometer (DCP) and crosshole-type dynamic cone penetrometer (CDP). The DCP and CDP are performed at three different states including 0, 200 and 400 cycles of wheel load for two unpaved road locations named Point-1 and Point-2. Based on the experimental results, the remarkable observations are as follows:

- The dynamic cone penetration index (DCPI) and shear wave velocity (V_S) of subgrade significantly increase with the cyclic wheel loads.
- The changes of DCPI and V_S of the subgrade due to wheel load vary with depth: at the first 400mm depth, the changes are significant, and after 400mm, very little changes are observed.

ACKNOLEDGEMENT

ABSTRACT: The objective of this study is to evaluate the strength and volumetric water content of ground using an instrumented TDR dynamic cone penetrometer (ITDP). The ITDP, which is developed to simultaneously measure two parameters on a borehole, is installed by an accelerometer, strain gauges, and electrodes. ITDP tests are carried out for ground up to a depth of 700 mm under rainfall conditions, and the two parameters are measured according to time (0 h, 3 h, and 9 h). Generally, the strength of the ground decreases and its volumetric water content increases after the rainfall. The decrement of the strength and increment of the volumetric water content at 3 h are greater than those at 9 h until a depth of 150 mm, while those at 3 h are smaller than those at 9 h beyond a depth of 150 mm. Thus, ITDP may be effectively used to profile the strength and volumetric water content of ground.

1 INTRODUCTION

For prevent the natural disaster such as slope failure, landslide, and debris flow caused by heavy rainfall, characterization of ground strength and water content is very important. Most of slope grounds, where have a high possibility of failure, are hard to access. Therefore, a portable in-situ penetration testing device with high mobility is required to characterize the properties of such slope grounds.

A dynamic cone penetrometer (DCP) has been widely used to evaluate the strength properties of ground. In the DCP test, the DCP is impacted by a free-fall hammer at a constant potential energy, and penetration depth per a blow is recorded as penetration index of the DCP (DCPI). However, an inconstant potential energy caused by friction and artificial factor reduces the reliability of the DCP results. To compensate for the inconstant energy, an instrumented DCP (IDCP) was developed (Byun and Lee 2013). Transferred energies at rod head and cone tip can be calculated using accelerometers and load cells in IDCP. The strength of a slope ground can be evaluated using IDCP with high reliability.

For evaluation of volumetric water content, time domain reflectometry (TDR), which is an electromagnetic wave survey technique, has been used. A portable penetrometer incorporated with TDR probe (TDRP) was developed to profile the volumetric water content of ground (Lee et al., 2018). The IDCP and TDRP should be used to evaluate the strength and volumetric water content of the ground; however, it is not efficient to use both devices in terms of economy, convenience, and consistency. Accordingly, an instrumented TDR dynamic cone penetrometer (ITDP) was developed to simultaneously estimate the strength and volumetric water content of the ground (Park et al. 2023). The ITDP, which is IDCP incorporated with

DOI: 10.1201/9781003299127-323

TDR, is simultaneously evaluate the transferred energy and volumetric water content using accelerometers, load cells, and TDR sensors.

In this study, the ITDP test was conducted on compacted soils in an embankment for evaluation of ground strength and volumetric water content according to the time in rainfall condition. This paper provides the design and measurement system of the ITDP and calculation method for the transferred energy and dynamic resistance. In addition, the site of field test is described, and experimental results are analyzed and discussed.

2 INSTRUMENTED TDR DYNAMIC CONE PENETROMETER (ITDP)

2.1 *Design of ITDP*

The ITDP was developed by combining the IDCP and TDRP to simultaneously profile the ground strength and volumetric water content. The ITDP is composed of an ITDP probe, driving rod, energy module anvil, and hammer, as shown in Figure 1. The ITDP probe consists of cone tip energy module for evaluation of transferred energy at cone tip and a TDR probe for the estimation of the volumetric water content. Accelerometers and load cells are installed in the energy modules to obtain the dynamic responses. Shock-type accelerometers, which can measure up to 10,000 g, are used to endure the high external shock. The load cell is composed of four strain gauges configured with Wheatstone full-bridge circuit to compensate the effects of temperature and eccentricity. TDR probe is made of three electrodes in body of mono-cast nylon. The three electrodes are connected to a coaxial cable. The driving rod with 1 m length is connected to ITDP probe, and extra driving rods can be connected to estimate the ground properties at deeper depth. The hammer with 117.7 N weight is dropped at a 575 mm of height; thus, potential energy is calculated as 67.77 N·m.

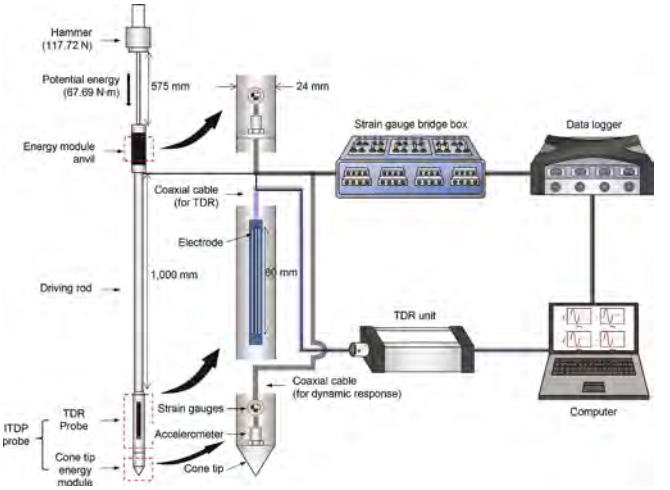

Figure 1. Design of instrumented TDR dynamic cone penetrometer (ITDP).

2.2 *Transferred energy*

The acceleration and force signals are measured using accelerometer and load cell. Velocity can be calculated by integrating the measured acceleration. Using the force measured by load cell (F_s) and velocity calculated by accelerometer (V_a), the transferred (E) can be calculated (ASTM D4633) as follows.

$$E = \int F_s \times V_a dt \tag{1}$$

The transferred energy at rod head, which is measured by energy module anvil, is used to correct the inconsistence potential energy. The transferred energy at cone tip, which is measured by cone tip energy module, considers energy loss caused by friction (Park et al., 2022).

2.3 *Volumetric water content*

In general, the survey using TDR is predominantly used to estimate the volumetric water content of ground. The generated electromagnetic wave travels through the coaxial cable and electrode. The velocity of electromagnetic wave depends on a dielectric constant of soils (Noborio et al. 1996). The travel time of electromagnetic wave is measured to obtain the dielectric constant of soils according to volumetric water content. The travel time can be calculated by apparent length and velocity of electromagnetic wave in vacuum (3×10^8 m/s). Subsequently, the dielectric constant (κ) can be expressed using apparent length (L_a) and electrode length (L) as follows.

$$\kappa = (L_a/L)^2 \tag{2}$$

Generally, dielectric constants of air, dry soils, and water are 1, 3-8, and 81, respectively. The volumetric water content is determined by dielectric constant, and Topp et al. (1980) suggested a cubic polynomial with an empirical coefficient obtained from the calibration test.

3 FIELD TEST

3.1 *Site description*

To characterize the ground strength and volumetric water content in rainfall condition, the ITDP tests were conducted on compacted soils in embankment, as shown in Figure 3. Initial ITDP test was carried out before watering; subsequently, water was sprayed on the embankment to simulate the rainfall condition. After 3 and 9 h of watering, the ITDP tests were conducted at intervals of 1 m from the borehole, where first ITDP test had been carried out. The ITDP tests were performed until a depth of 700 mm.

3.2 *Experimental results*

3.2.1 *Penetration index measured by ITDP according to the time*

The penetration index of ITDP per blow was measured as ITDPI. The ITDPI was averaged in units of 50 mm and was calculated as a representative value for the depth. The representative ITDPI was plotted with time, as shown in Figure 2. At depths of 50–150 mm, the ITDPI are greatest 3 h after watering (Figure 2a), which means that the ground strength is weakest after 3 h. The ITDPI increase as time increases at depths of 200-450 mm (Figure 2b). At depths of 500 and 550 mm, the ITDP only increases after 9 h. There is no significant change at depths of 600-700 mm (Figure 2c). Therefore, the water may be infiltrated until a depth of 450 mm after 3 h, and a depth of 550 mm after 9 h.

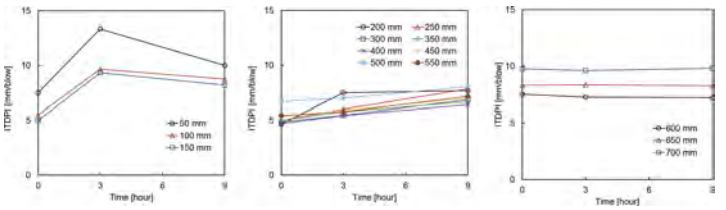

Figure 2. ITDPI with time according to depth: (a) 50-150 mm; (b) 200-550 mm; (c) 600-700 mm.

3.2.2 *Volumetric water content measured by ITDP according to the time*

The volumetric water contents were measured in unit of 50 mm and plotted with time, as shown in Figure 3. At depths of 50-150 mm, the volumetric water contents after 3 h are greater than those after 9 h due to the evaporation near the surface (Figure 3a). The volumetric water contents increase with time increases at 200-450 mm, same as ITDPI (Figure 3b). The volumetric water contents increase at depths of 500 and 550 mm after 9 h. At 600-700 mm, there is no significant change (Figure 3c). Similar to the results of ITDPI, the water may be infiltrated until a depth of 450 mm after 3 h, and a depth of 550 mm after 9 h.

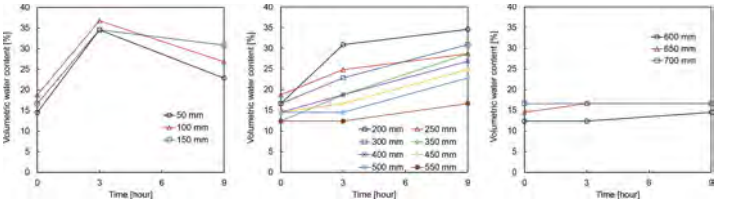

Figure 3. Volumetric water content with time according to depth: (a) 50-150 mm; (b) 200-550 mm; (c) 600-700 mm.

4 SUMMARY AND CONCULSIONS

The developed instrumented TDR dynamic penetrometer (ITDP) was applied to compacted soils in embankment to estimate the ground strength and volumetric water content, in this study. The penetration index measured by ITDP (ITDPI), and volumetric water content are generally increased according to water infiltration. Near the surface, the ITDPI and volumetric water content are greatest after 3 h due to evaporation of water. The main observations of this study are as follows:

- Near the surface, the ground strength is weakest after 3 h as the ITDPI and volumetric water content are greatest. The ground strength is about 1.77 times weaker, and the volumetric water content is more than doubled after 3 h.
- The ground strength generally weakens with time as ITDPI, and volumetric water content increased as time increases at depths of 200-550 mm.
- The characteristic of ground strength and volumetric water content can be estimated using ITDP. Thus, ITDP may be effectively used for evaluation of ground properties in rainfall condition.

Practical method for pile construction management using non-contact pile penetration movement measuring device and pile driving formulas: A case study

Seunghwan Seo, Moonkyung Chung, Ju-Hyong Kim & Changho Choi
Department of Geotechnical Engineering Research, Korea Institute of Civil Engineering and Building Technology, Goyang-si, Republic of Korea

ABSTRACT: The pile penetration movement is typically measured manually by field workers during pile driving. Manual measurement method may lead to potential risks to workers' health and safety as well as issues with measurement accuracy dependent on the operators and ground vibration. In this study, in order to address these issues, a non-contact pile penetration movement measuring device was developed and applicability was evaluated. In addition, a method to improve the reliability of the pile driving formulas was reviewed by using the values measured by the development device and the results of the dynamic load test. As a result, it is essential to accurately measure the hammer energy delivered to the pile, as well as the set value and rebound movement of pile in order to increase the reliability of the bearing capacity predicted by the pile driving formulas. Furthermore, the bearing capacity of pile obtained from the dynamic load test can be used to improve the reliability of the bearing capacity calculated by the pile driving formulas.

1 INTRODUCTION

In South Korea, precast piles, such as pretensioned spun high-strength concrete (PHC) piles, have been developed into ultra-high-strength and composite piles with the development of technology, and their utilization is increasing. However, for pile construction management only limited management regulations, such as the number of dynamic load tests or static load tests, are available and there is no clear regulation on the construction and management of all piles. Most precast pile construction sites in Korea examine the bearing capacity of 1–3% of the total number of piles by performing a dynamic load test. The final pile set value is measured and used as the management reference value. The pile set of the remaining 97–99% of the total number of piles is measured immediately after construction and compared with the management reference value. In recent years, with the increasing number of construction projects in urban areas, auger-drilled piles are increasingly being used rather than driven piles owing to noise and vibration problems. In Korea, auger-drilled piles are typically installed using the pile driving method after pre-excavation, and construction using auger-drilled piles is assessed considering the driving penetration in the final stage using a drop hammer (Lee et al. 2000; Hong et al. 1997).

During pile driving, an automatic measurement method using machines is necessary for ensuring worker safety and reliability in penetration measurement. Accordingly, various studies have been conducted to address this issue. Studies have been conducted on non-contact penetration measurement methods using optical displacement meters, laser sensors, or line scan cameras (Ha et al. 1997; Yun et al. 2005; Yeu et al. 2016; Lee et al. 2002). Previous studies focused on the measurement accuracy for driving penetration and rebound. Most methods were not applied in the field owing to inconvenient usage and procedures, such as separately

DOI: 10.1201/9781003299127-324

analyzing the data measured in the field. Methods for measuring the pile set by attaching a label to the hammer or a sensor to the drop hammer have been used recently. However, the accuracy of the pile set and rebound value calculations is limited because they measure the displacement of the hammer and casing rather than directly measuring the displacement of the pile. This study developed a device that can accurately measure the pile set and rebound values by supplementing the limitations of previous studies related to non-contact driving penetration measurement. Furthermore, a method for estimating and managing the bearing capacity of all working piles in addition to field test piles was examined using the measurement results and a dynamic bearing capacity formula.

2 NON-CONTACT DRIVING PENETRATION MEASUREMENT DEVICE

The driving penetration measurement device developed in this study (KPM, KICT Pile driving Monitor) consists of a measuring unit, hardware board, and battery. It can perform measurements without a separate analysis personal computer. The measuring unit uses an infrared light-emitting diode light source (IR-LED transmitter) as a non-contact method for detecting the light signal returned by the reflective tape attached to the observation target using a receiver. The light source concentrates the radiation angle of light as it passes through the optical lens and is designed to perform measurements within a distance of up to 70 m. Therefore, the pile displacement is measured using the speed of the light returned by the reflective tape and the measured distance according to the movement before and after pile driving. The sampling rate is 200 Hz. Figure 1 shows the overall shape of the proposed device. The exterior of the device is made of an aluminum plate and it weighs approximately 1 kg. The position of the reflective tape attached to the pile can be corrected through the device display, and it takes 1–3 min. to prepare for measurement.

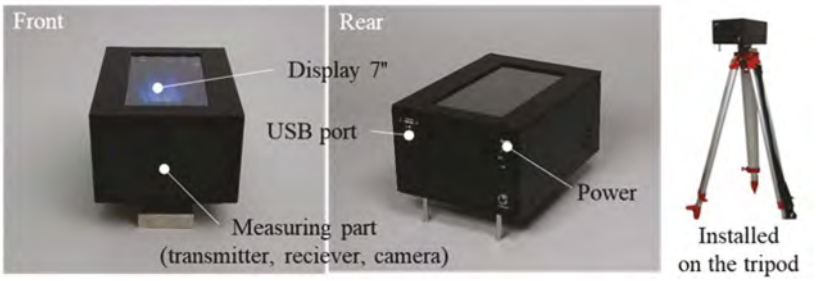

Figure 1. Device configuration and exterior.

3 EXPERIMENTAL METHOD

3.1 *Experiment overview*

The pile displacement was measured using the proposed device while a dynamic load test was performed using a pile driving analyzer (PDA) at an actual site to examine the possibility of estimating the bearing capacity of the pile using the final pile set value (Figure 2). The piles used at the site were 600 mm diameter PHC piles. They were installed through the separated doughnut auger (SDA) pre-excavation method using a 6-ton drop hammer. The piles were expected to be installed primarily in hard weathered soil or weathered rock. The soil investigation results showed that the standard penetration test (SPT) N values and construction depths were 27/30 and 13 m and 50/3 and 17 m for weathered soil and weathered rock, respectively. At the beginning of construction, a dynamic load test and measurement using the proposed device were performed simultaneously on three test piles.

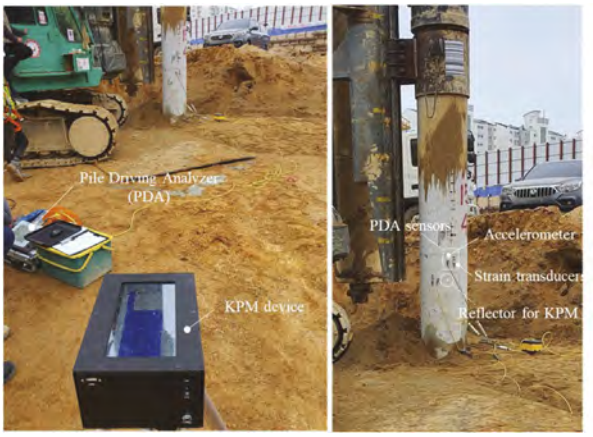

Figure 2. Experimental methods in field test.

3.2 *Dynamic bearing capacity formula*

Among various driving formulas, the Hiley formula is based on the energy balance between the driving energy of the hammer and work required for pile penetration. It is a representative calculation method that considers the pile set and rebound values. The input variables of the Hiley formula can be modified to apply the measured values of the PDA. The existing Hiley formula can be summarized as Equation 1 (Cho and Lee 2001; Denes and Kroenert 2019). In Equation 1, Ru is the total pile resistance, η is the efficiency of the hammer (energy loss allowance), W is the weight of the hammer, g is the gravitational acceleration, and h is the fall height equal to EMX, the hammer energy transmitted to the pile. S is the pile set value, and C is the rebound value, representing the temporary compressive or elastic behavior of the pile.

$$R_u = \frac{\eta Wgh}{S + C/2} = \frac{EMX}{S + C/2} \tag{1}$$

The pile set (S) and rebound (C) values were measured using the proposed penetration measurement device. The hammer weight and fall height were manually recorded. Because hammer efficiency is typically estimated and can cause an error, it must be examined using a dynamic load test equipment. Removing dynamic resistance from the Hiley formula is necessary because it contains dynamic and static resistance components. To remove the dynamic resistance component, Cho and Lee (2001) introduced a damping coefficient. The damping coefficient is related to ground and driving conditions and can be characterized for different sites. This damping coefficient is referred to as the field correction factor or dynamic reduction factor (DRF). This coefficient can be applied to the dynamic bearing capacity formula to estimate the static component from the total resistance during tests (Cho and Lee 2001; Damen and Denes 2017). The DRF is expressed as Equation 2 by comparing the control and provisioning of wireless access points (CAPWAP) static resistance of the test piles and the resistance estimated using the Hiley formula through the dynamic load test.

$$x = \frac{Hiley\ \ Resistance}{CAPWAP\ \ Resistance} \tag{2}$$

The DRF (χ) increases as the set value increases; a high pile set value indicates a high dynamic resistance component in the total resistance (Cho and Lee 2001; Denes and Kroenert 2019). Because dynamic energy is generated by the speed-dependent pile movement, the dynamic effect increases as the pile movement increases, similar to the resistance estimation

method in the dynamic load test. Therefore, the DRF can be expressed as a relationship between the pile set value obtained through the dynamic load test and measured using the proposed device. It may vary at each site and is affected by many factors, such as the hammer system, pile size, end condition, ground condition, and hammer fall height. Equation 3 shows the modified Hiley formula reflecting the field characteristics through the DRF and represents the bearing capacity of the pile at the end of initial driving (EOID).

$$R_u = \frac{EMX}{(S + C/2)x} \tag{3}$$

The long-term bearing capacity can be calculated by considering the set up factor (SUF) in Equation 3. The SUF can be obtained through the EOID and restrike tests on test piles in the field. It is calculated by dividing the restrike bearing capacity by the EOID bearing capacity (Chun and Cho 1999). In this study, the change in pile bearing capacity over time was excluded, and evaluation was performed based on the EOID test results to analyze the possibility of pile construction quality control using the final pile set value.

4 EXPERIMENTAL RESULTS

4.1 *Dynamic bearing capacity formula*

For the test piles, the driving management standard was set based on a fall height of 1.5 m for a 6-ton drop hammer. From the time when the pile began to penetrate the hard layer, the EMX value, the energy transmitted to the pile at each blow, was measured and recorded using the accelerometer and strain gauge attached to the pile. In the PDA test, the energy transmitted to the pile (EMX), maximum pile displacement (DMX), maximum pile speed (VMX), and pile bearing capacity (RMX) can be evaluated at the site for each blow. A highly reliable dynamic load test was performed at the site through rough judgment of the signal characteristics of the strain gauges and accelerometer. The EMX value measured at each blow was recorded (Figure 3). In this study, the EMX value was obtained by excluding the small values measured at the EOID and calculating the average value.

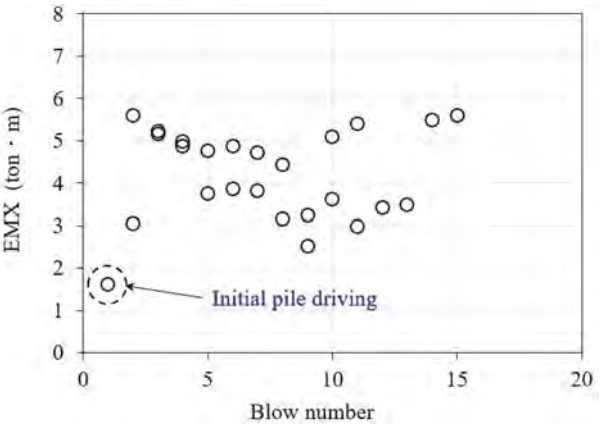

Figure 3. EMX value for each blow measured from dynamic load test.

4.2 *DRF calculation*

As shown in Figure 2, the dynamic load and penetration measurement tests using the proposed device were performed on the test piles simultaneously. The RMX value of the dynamic

load test was used for each blow to calculate the DRF (χ). The CAPWAP protocol is a standard for obtaining more accurate bearing capacity. However, the intuitively calculated RMX value was used for test convenience (Cho 2003). The results indicated that there was no significant difference between the bearing capacity calculated through an actual CAPWAP analysis and the RMX value because the end bearing capacity was primarily developed with low skin friction during the dynamic load test at the test site. The modified Hiley formula shown in Equation 3 was applied for the bearing capacity of the driving formula. The EMX value obtained from the dynamic load test was used as the numerator, and the values measured using the proposed device were used for the pile set and rebound values. Figure 4 shows the relationship between the DRF (χ) for the test piles calculated using the RMX and the pile set value. To calculate the functional relationship for various pile set values, the pile set value was measured using the dynamic load test and proposed device before calculating the final pile set value corresponding to the design bearing capacity.

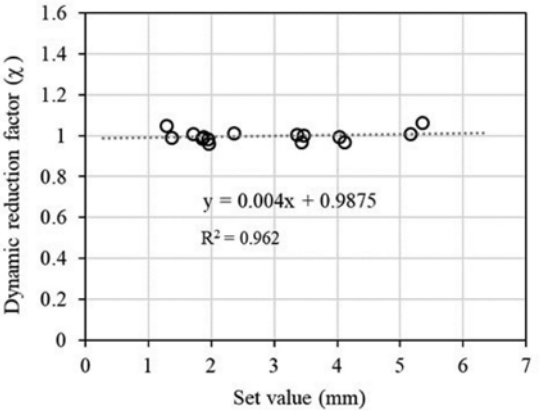

Figure 4. Dynamic reduction factor for pile set values.

4.3 *Estimation of bearing capacity using the developed device*

Based on the DRF (χ) and EMX values obtained from test pile, the bearing capacities of other test piles were estimated using the proposed device. The weight, fall height, and efficiency of the hammer or the EMX value of the PDA can be used for the EMX in Equation 3. The average hammer efficiency calculated from the dynamic load test (0.8) was applied as the hammer efficiency. In addition, the DRF for the measured penetration was applied using relationship between the DRF (χ) and pile set value in Figure 4. Figure 5 compares the bearing capacity derived using the pile set and rebound values measured using the proposed device, with the RMX obtained from the dynamic load test. Figure 11 shows a significant difference (approximately 40%) in the RMX obtained from the dynamic load test despite applying the relatively accurate EMX, pile set, and rebound values before applying the DRF. However, when the bearing capacity was corrected by applying the DRF, it was estimated with a 5–10% difference. This indicates that a highly reliable bearing capacity can be estimated using the driving formula using the EMX, pile set and rebound values by driving, and the DRF (χ) between the bearing capacity measured from the initial dynamic load test and driving formula.

5 DISCUSSIONS

In the case of measuring the set and rebound values of a pile using the non-contact pile penetration measurement device (KPM) developed in this study, there may be issues with the true

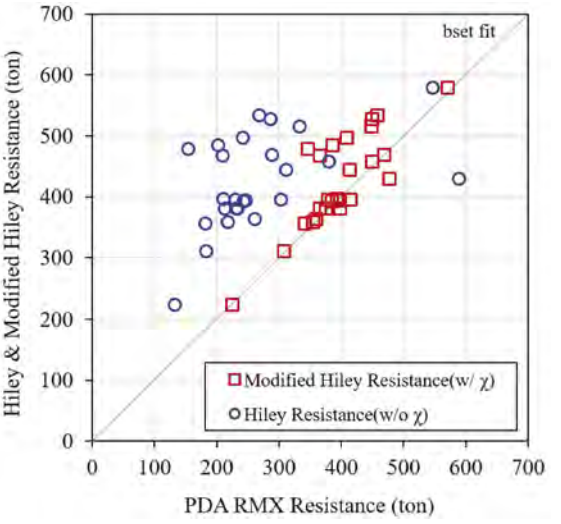

Figure 5. Comparison of the bearing capacity obtained from the dynamic load test and estimated bearing capacity using the KPM.

value in the actual field. In the case of comparing the measured values in the actual field, it will be necessary to use the maximum pile displacement (DMX) in the dynamic load test. DMX is calculated by integrating the measured velocity in dynamic load test, and since the maximum displacement occurs at one point in time, it is a highly reliable value. The theoretical maximum displacement is obtained by adding the set and rebound values measured by the penetration measurement device, so the performance of the measurement device can be checked by comparing this value with DMX. In order to reduce the estimation error for bearing capacity in the field test, it will be necessary to further improve the precision of the development device through comparison with.

In addition, in the case of prebored and precast piles, it will be necessary to calculate the set up factor through the EOID and restrike results of the dynamic load test in order to consider the time effect.

6 CONCLUSIONS

This study developed a non-contact pile penetration measurement device to secure the reliability of driving penetration measurement and work safety during pile driving. The field applicability was examined and the bearing capacity estimation method using the modified Hiley formula was analyzed using the proposed device and dynamic load test results. The primary conclusions of this study are as follows:

(1) Because the conventional manual measurement method is inaccurate and unreliable, the performance of the proposed device was evaluated through comparative measurement with a commercially available high-precision measurement device. The results of the comparative measurement performed at an actual pile construction site showed that the proposed and existing device had similar performances in terms of measurement accuracy. However, the results obtained using the proposed device showed a trend that matched the actual driving profile obtained through data processing considering the secondary recoil and hammer rise. The proposed device also has a higher field applicability owing to its low measurement preparation time requirement of 1–2 min and simplified measurement program.
(2) The proposed penetration measurement device measured the pile set and rebound values accurately. The bearing capacity calculated using the modified Hiley formula and DRF was

more reliable than that obtained from the dynamic load test (RMX). The bearing capacity obtained from the dynamic load test differed significantly with that obtained from the driving formula. Correcting the driving formula by expressing the DRF as a function of the pile penetration improved the reliability of the pile bearing capacity calculation using the driving formula.

(3) Conventionally, only piles subjected to load tests are evaluated for bearing capacity. The design bearing capacity of piles is increasing, and there are cases where pile tips are installed on hard soil rather than bedrock in areas with deep sedimentary layers or weathered soil layers. Thus, it is necessary to establish a management method estimating the bearing capacity of piles used in such conditions in addition to those of test piles. The measurement reliability using the dynamic driving formula is questionable. However, a more reliable bearing capacity estimation is possible using the proposed field correction procedure considering the dynamic load test performed at each site. Applying the corrected dynamic driving formula and proposed bearing capacity estimation procedure enables pile construction management considering the bearing capacity even for piles not subjected to dynamic load tests.

Comparative study of slope displacements using distributed fiber optic sensing technology and inclinometer

Umar Zada
Master Student, Department of Civil Engineering, National Central University, ROC

Chih-Chung Chung
Associate Professor, Department of Civil Engineering, National Central University, ROC

ABSTRACT: In order to minimize losses due to landslides, slope displacement monitoring is a vital early warning system. As a result, the internal deformation of the slope was monitored using distributed fiber optic sensing technology based on Brillouin optical time domain reflectometer (BOTDR) attached on the casing of the in-place inclinometer (IPI). Primarily, laboratory experiment was conducted followed by large scale physical slope model. The strain changes in the large-scale model were measured at regular interval of 10 minutes respectively. The finding demonstrated that the calculated displacements measured by both of the devices were closed to each other as well as a consistency was observed between them. Moreover, it was also found that the offer mentioned application can accurately locate the location of potential sliding surface and provide adequate access to the internal deformation of the slope.

1 INTRODUCTION

One of the main natural disasters is landslides, which causing loss of life and seriously harm infrastructure around the world. Approximately 2600 non-seismically generated landslides caused 30,000 casualties worldwide between 2004 and 2010 (Petley 2012). Significant efforts have been made over the past few decades to understand the underlying mechanics behind landslides (Jibson 2011). Water filtering, excavation, and erosion are among the causes that cause an increase in shear stresses and pore water pressures, which lowers the soil's overall resistance. This mechanism causes an abnormal strain field to form on the failure surface and causes segments of the slope to shift relative to one another. Then, considerable shear strains that are localized close to the failure surface start to occur. At first, they build slowly, but eventually their rate picks up speed and the stability is ultimately jeopardized. As a result, strain and displacement (both above and below ground) are acknowledged as two physical factors that are of utmost significance and more directly related to the occurrence of landslides (Zhu, Shi, and Zhang 2017).

In the past 20 years, a number of distributed fiber-optic sensors, including numerous single-point sensors that imitate conventional equipment, have been presented for the measurement of strain and displacement in landslide monitoring (LLoret et al. 2003). With a spatial resolution of a few meters, a BOTDA interrogator was used to track the St. Moritz landslide in Switzerland using a fiber cable buried in a road that crossed the slide. With enough spatial precision to distinguish the landslide limits, the fiber-equipped road functioned as a long dispersed strain meter (Iten, Puzrin, and Schmid 2008). The soil-embedded "micro-anchor" cable system was subsequently tested at the same location. Tridimensional "micro-anchors" mechanically secured to the cable at predetermined intervals were part of the system, which also included a small metal-free cable. To stop the relative slippage between the strain sensing cable and the surrounding soil, the anchors offered bearing capability in three perpendicular planes. Additionally, the anchors enabled pre-stretching of the cable during installation (Iten and Puzrin 2009). The slow-moving Ripley landslide in Ashcroft, British Columbia, Canada, was also seen by a BOTDR interrogator,

DOI: 10.1201/9781003299127-325

with the sensing cable tied to the lock-block retaining wall. Curiously, the system remained in place for three months before a black bear destroyed it, and the prolonged exposure to below-freezing conditions led the cement (an epoxy resin and caulking mixture) to disintegrate, causing the system to become detached from the retaining wall (Strong et al. 2008).

The distributed fiber optics sensor based on Brillouin scattering has been extensively studied in the field of structural safety and health monitoring (SSHM) for aircraft, bridges, tunnels, highways, and railways due to its high measurement accuracy, high spatial resolution, and real-time fully distributed measurement characteristics (Pang et al. 2021; Dakin 1993; Ding et al. 2018). Brillouin optical time domain reflectometry with coherently probed (BOTDR), A single-ended device with a basic construction that can continue to function even if the fiber breaks uses frequency-shifted local heterodyne sensing to increase signal-to-noise ratio (SNR). Several methods, including the Raman amplification technique, have been developed to enhance the functionality of BOTDR sensing systems (Ding et al. 2018; Li et al. 2018). Additionally, several unique fibers, such as those with a large effective area, photonic crystal fiber, few-mode fiber, and multicore fiber, among others, have been thoroughly explored to solve the issue of temperature and strain cross-sensitivity (Li et al. 2012; Bai et al. 2019).

The OTDR and BOTDR are feasible and affordable alternatives to slope monitoring among the point-based approaches. The fibers used to implement OTDR in slope research are cheap and offer long-term, remote monitoring of slope movement. Measurements only take a few seconds, which is far faster than the traditional, labor-intensive "cable pull" method of inclinometer probing (Sargand, Sargent, and Farrington 2004). The advantages of optical fiber and fiber grating technologies, including their low optical signal loss, 80 km maximum measuring range, and ability to pinpoint defects, have made them very popular in the field of civil and geotechnical engineering. (Zhang et al. 2006; Chai et al. 2004).

2 WORKING PRINCIPLE

BOTDR technique can be employed with Brillouin optical time domain reflectometry; the wavelength of Brillouin scattering depends on the temperature and strain of the optical fiber sensor. The way it functions is by injecting a beam of light with a specified frequency into the fiber, which then interacts with the elastic sound waves to create Brillouin backscattered light. The fiber's changes in temperature and stress have an impact on the wavelength of Brillouin scattering. Brillouin frequency shift can be measured, and its relationship to strain and temperature can be used to determine how external variables affect the fiber (Bai et al. 2019; Lee 2003).

There is a linear relationship between the temperature and strain of the optical fiber and the frequency shift of Brillouin scattered light; the strain and temperature of the object can be measured using BOTDR technology. The relationship between Brillouin frequency shift with strain and temperature is given by equation (1) (Dan, Bin, and Hongzhong 2004; Horiguchi et al. 1995; Hong et al. 2017).

$$\Delta Vb(\Delta T, \Delta \in) = Vb(\in, T) - Vb(0, To) = \mathrm{CT}\ (\mathrm{T} - \mathrm{To}) + \mathrm{C} \in (\in - \in 0) \tag{1}$$

Equation (1) demonstrates that distributed real-time monitoring of the measured object can be used to determine the strain and temperature induced by external forces (Zhang et al. 2018).

3 MATERIALS AND METHODOLOGY

3.1 *Laboratory set-up*

Initially laboratory experiments were performed to check the applicability of the distributed fiber optic sensing technology based on brillouin optical time domain reflectometry. Strain and temperature calibration were executed to find the calibration coefficient for the large-scale application of the DFOS. Moreover, the laboratory experiment was also conducted to investigate the relationship between frequency shift, strain and horizontal displacement of the fiber optic cable. Figure 1 illustrate the laboratory experimental set-up of the DFOS technology.

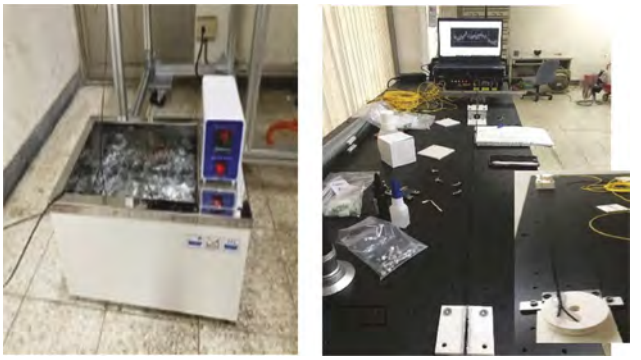

Figure 1. Strain and temperature calibration set-up.

3.2 *Field application*

After the conduction of laboratory experiments, large scale physical model was conducted. Two PVC tubes were installed in the slope model with Fiber optical cable pasted on four sides of the PVC pipe and then connected with the brillouin optical time domain reflectometer. Similarly, Inclinometer was also installed in the same tube. Two experiments were performed at time interval of 10 minutes just to check the applicability and accuracy of the fiber optic sensing technology based on BOTDR with inclinometer.

4 RESULTS

4.1 *Strain and temperature calibration*

The purpose of the calibration is to determine the relationship between Brillouin frequency shift with strain and temperature. The calibration was carried out with a 50 m span fiber cable that was clamped at lengths ranging of 1m. A combination of displacement and temperature influences the fiber at the same time, with the temperature adjusted to 50 degrees Celsius. The results of the calibration is shown in Figure 2.

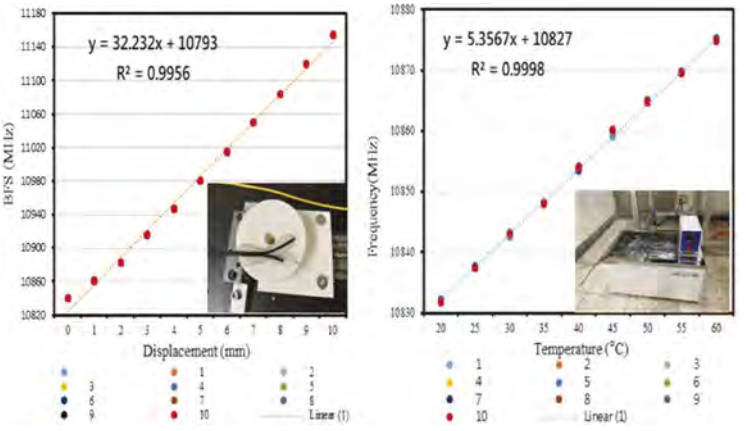

Figure 2. Calibration results.

4.2 *Field displacements measurement*

Displacements were measured by using distributed fiber optic sensing (DFOS) based Brillouin optical time domain reflectometry and in place inclinometer. DFOS recorded Frequency shifts

with the help of BOTDR and then frequency shifts was converted to displacements. The frequency shifts is actually due to the external stresses on the cable which change the internal configuration of the cable due to which the light waves bounced back and the spectrum was analyzed using BOTDR device. Similarly, the displacement was measured using inclinometer at the same time. The results of the displacements is shown in Figure 3. Moreover, the data was recorded at a regular time interval of 10 minutes and at this stage only two values have been reported just to confirm and encourage the implementation of the distributed fiber optic sensing technology for the large scale physical model test.

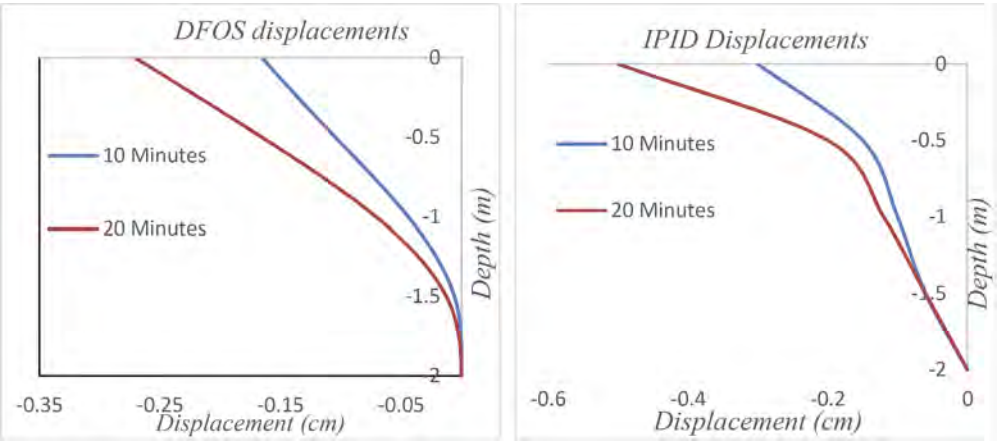

Figure 3. Displacements.

5 CONCLUSION

Based on the laboratory and field experimental observations it was concluded that both of the displacements results were closed and consistent. As a results the distributed fiber optic sensing technology based on BOTDR can be used for the displacement measurement and can be implemented for large scale geo-hazards monitoring.

INSET, s.r.o., Prague, Czech Republic

ABSTRACT: Construction of a very steep, 6 m high embankment for the expansion of the capacity of the existing high-voltage transformer station took place nearby nuclear power plant. A complex of geotechnical control monitoring was carried out including hydrostatic levelling gauges, pore pressure gauges, geodetic stabilized points and piezometers. Main geotechnical risk was the presence of low-bearing fully-saturated sediments of the hidden river bed of the former stream, which had passed directly below the embankment. Technology of future construction is very sensitive to uneven settlement. Values obtained via long-term monitoring were continuously being compared with mathematical modelling. Subsequently, measurements were used to determine the construction speed of the embankment.

1 INTRODUCTION – BASIC INFORMATION ABOUT THE CONSTRUCTION

The aim of the project was to expand the current high-voltage transformer station. The old construction was located on the approx. 3 meters high embankment and for its expansion was necessary further land occupation. To minimize annexation of surrounding area which is always very expensive and costly (property transfers can sometimes be time consuming), a very steep embankment slope – almost perpendicular – was designed (see Figure 1).

The new embankment had a projected height of up to 6 meters. The high-voltage transformer station extension included a transformer field, one main brick building and two small service buildings. Together with the embankment a large load of the subsoil was expected. The designed building is very sensitive to uneven settlement.

2 GEOTECHNICAL CONDITIONS

Main geotechnical risk was the presence of low-bearing fully-saturated sediments of the hidden river bed of the former stream, which had passed directly below the new embankment body.

Bedrock is formed by Proterozoic gneiss in the locality of interest covered with tertiary claystone. Quaternary surface is represented by floodplain fine-grained sediments of the former river. In some places there is also peat.

During topsoil overburden and terrain work, local landslides of the old embankment occurred and in the vicinity of the relocated watercourse. Because of the presence of poor sediments of the former stream below the projected embankment a redevelopment of subsoil was designed – special geo-drains were used for subsoil of the upcoming foundation.

Dynamic penetration probes were made as control tests within the redevelopment with geo-drains (see Figure 2). These probes also served as a geological survey and were used as

DOI: 10.1201/9781003299127-326

piezometers (hydrogeological wells) as well. The field work also included installation of hydrostatic leveling gauges in the subsoil of the embankment together with pore pressure gauges installed in boreholes [1].

Figure 1. Construction of the embankment in process (high voltage transformer in the background).

3 MONITORING

The following geotechnical control devices and objects were monitored:

Geotechnical monitoring devices – hydrostatic levelling gauges, pore pressure gauges and geodetic stabilized points. System of hydrostatic leveling in individual profiles of measuring stations (HPG) served for monitoring vertical movements of the subsoil of the embankment body. The results of measurements were be used to check the expected magnitude of settlement and their development in real over time. Pore pressure gauges were used to monitor the development of pore pressures in the subsoil from the weight of the embankment body being built. Geodetic stabilized points were installed for monitoring of deformations of body surface parts.

The basic frequency of periodic control readings was realized in a 14-day interval. The measurement was used for the main geotechnical engineer of the construction, who could allow faster construction of embankments or, on the contrary, extend the intervals between sub-phases of construction. At the same time, the results of the measurements were continuously available for authorized persons on the SAHURE portal of INSET s.r.o. company: *https://inset.sahure.cz/Sahure*.

The heights of the geodetic points were determined by lateral intents from the leveling program measured by the geometric leveling method from the center. The Trimble DiNi instrument was used for measurement.

Coordinates of fixed geodetic points on the wall of the new embankment were determined by total station by measuring oblique lengths, zenith angles and horizontal directions. The

TS60 total station was used for measurement, whose accuracy is characterized by standard deviations of 0.15 mgon for zenith angle and horizontal direction and 0.6 mm and 1 ppm for inclined length.

The measuring apparatus for measuring vertical movements based on hydrostatic leveling consisted of a sensor which measured the pressure on a vibrating conductor, a hose filled with liquid wound on a portable drum, a tank with a sight glass and a signal cable with liquid hose which led from the sensor to the meter. Model 4651 Geokon was used as a measuring device. Standard range is 7 m, sensitivity ± 2 mm, accuracy ± 4 mm and temperature range of use is from -20 ºC to +80 ºC. The GK-403 is a reading unit that enables accurate measurement of vibration sensors (see Figure 3).

Figure 2. Dynamic penetration probes made during the redevelopment of subsoil with geo-drains.

Measurement of pore pressures determines the water stress in the pores in the subsoil under the foundation. The results of the measurements served as a check of the expected magnitude of the stress in the subsoil and its development over time. W9 Vibrating Wire Piezometer manufactured by Soil Instruments was installed with range from 0 to 500 kPa, accuracy classes 0.1%. The sensors were embedded in the boreholes into a pre-prepared bed of fine gravel (1.5 m above gauges), followed by a cement swab CEM 32.5 R (density 1 490 kN/m^3). Two sensors were placed in each borehole, each at a depth of 6.0 m and 1.5 m below the ground. The cables from the sensors were led to the nearest HPG site where they were led into a steel protective measuring box.

Two observation piezometers (DPV) were equipped. Immediately after the probing, a perforated casing (PVC, ø 25 mm) was embedded in the hole. Perforation of the observation piezometer equipment after its insertion into the penetration shaft begun 0.5 m above the bottom of the piezometer and ended 0.5 m below ground level (surface sealed with clay-bentonite). Steel casing with length 1.3 m and diameter 50 mm was put on perforated PVC casing to protect the probe. A standard electro-contact level meter was used to measure the ground water level in hydrogeological wells.

4 COMPARISON OF MEASURED DATA WITH MATHEMATICAL MODELLING

Estimated magnitude of deformations and their development over time were measured. At the same time, the water stress in the pores in the active zone below the foundation was documented after being loaded by the embankment and the building structure. The obtained values were compared with mathematical modelling. Numerical simulations were made in PLAXIS software using finite element method. Subsequently, measurements were used to determine the rate of the build of the embankment.

4.1 *Geodetic stabilized points and piezometers (GWL)*

Most of geodetic stabilized points the situated on the wall of the embankment showed a steady settlement (vertical drop) over the entire measurement period, while there were only small horizontal movements (changes did not exceed a total shift of 20 mm). Point installed on the north wall recorded a steady decline at the base of the wall with a maximum of 33.1 mm. Situation on the south wall was slightly different – maximal subsidence -55.1 mm was measured. The settlement process was quite fast at the first phase (the beginning of construction of the embankment), then the values stabilized.

Figure 3. Hydrostatic levelling – all measured data were continuously available on portal *https://inset.sahure.cz/Sahure*.

Declines in measured points were without significant anomalies, except in March 2019, when there was an unexpected movement at almost all points. Several control measurements were carried out, which recorded a decrease to the original values and a steady slight decrease due to the continuation of settlement of the whole embankment. The anomalous movement was attributed to the release of stress in the embankment body due to spring snow-melting without any negative consequences for the embankment body. No surface deformations or

cracks were noticed. This phenomenon was confirmed by measuring the evolution of groundwater level in hydrogeological wells (piezometers) [1].

In the last six months of monitoring, however, all geodetic points have recorded a steady settlement and their character turned from a small permanent drop into an oscillatory movement.

4.2 *Hydrostatic levelling*

The embankment settlement monitored by hydrostatic leveling did not show any uneven settlement (with the highest value of -277 mm in the HGP1 profile; see Figure 4), except for the HG2 profile.

The average decrease of the HPG2 profile was -82 mm, the maximum decrease was -586 mm (as of October 31, 2018). The measurement of the HPG2 profile was terminated prematurely on November 29, 2018 due to permanent damage of the measuring site (destroyed by construction). The speed of construction had to be slowed down in certain passages in response to the above measurements. As a result the values were stable at the end of the measurement and corresponded to the results obtained from mathematical modeling – settlement prediction [2]. Otherwise the construction would have to be interrupted.

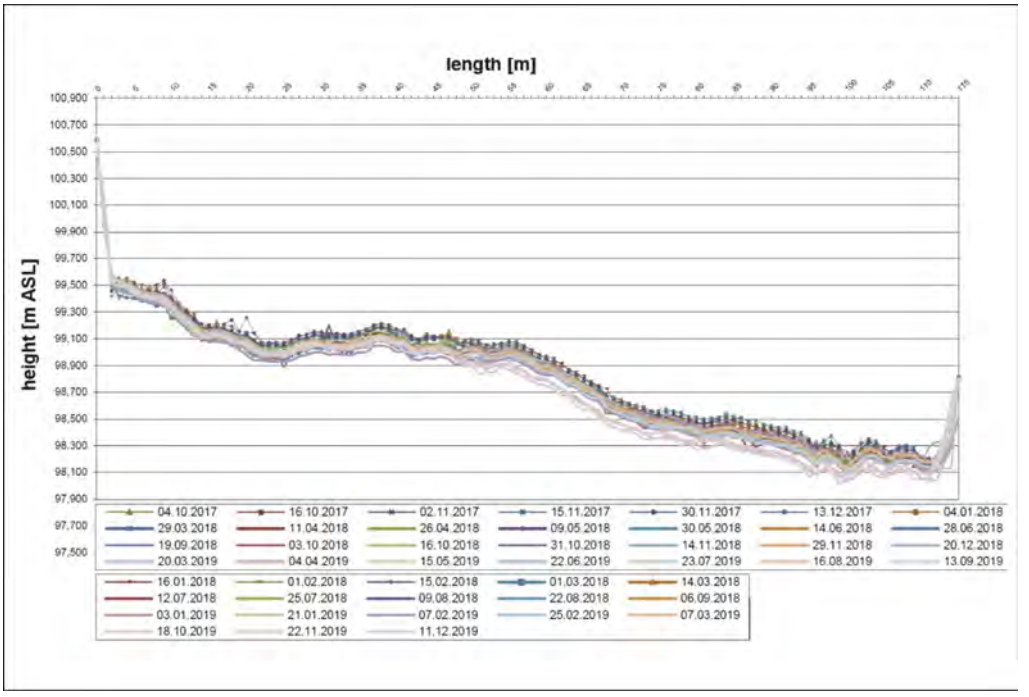

Figure 4. Results from HPG1 profile – even settlement of the embankment.

4.3 *Hydrostatic levelling*

Pore pressure sensors placed at 6 m below the foundation of the embankment body showed higher pore pressure values than gauges located 1.5 m below the surface. However, the trend in pressure development was the same for all sensor pairs.

During the whole follow-up period there was no anomaly fluctuation of the pore pressure values in any MPT, which would indicate a warning increase or decrease of soil stress in the subsoil.

The pore pressure values for sensors at a depth of 1.5 m below the ground ranged from -7 to 20 kPa, gauges at a depth of 6 m below the surface in the range of 25 to 60 kPa.

The measured values were in accordance with the numerical modelling [2].

5 CONCLUSION

A complex monitoring system was built in advance for the 6-meter high embankment to expand the high-voltage transformer station for nearby nuclear power plant.

Deformations and settlement were measured during process of construction. Obtained values were compared with mathematical modelling. The speed of construction had to be slowed down in certain parts in response to negative measurement development. As a result the values were stabilized. Finally the measured values from monitoring corresponded to the settlement prediction acquired from the mathematical modeling after all. After completion of the construction, the measured data recorded a settling of values related to the main consolidation process. The existing geotechnical control system is still functional for subsequent periodic measurements and for assessing potential risks of the monitored body.

Development of the Osaka sedimentary basin due to surface geological structure and sea level changes using boring database

N. Kitada, N. Inoue & K. Mizutani
Geo-Research Institute, Osaka, Japan

M. Mimura
Kyoto University, Kyoto, Japan

ABSTRACT: The Osaka Sedimentary Basin is surrounded by mountains and active faults. The tectonic movement causes the surrounding area to rise and the basin to subside. The basin is submerged in the sea due to sea-level changes, and the marine clay deposits. Using the boring database accumulated by KG-NET, we learn the layer thickness, bottom elevation distribution, and distribution limit of the Holocene marine clay layer. Consider the environment at the time of deposition. In particular, the Kawachi Plain on the east side of the Uemachi fault showed the environment of an inner lake, and it was clarified that a sandbank was formed around the strait when it flowed in and out due to the ebb and flow of the tide. In this area of poorly drained seawater and freshwater, sensitive clays rich in organic matter are thought to have accumulated extensively.

1 INTRODUCTION

The Osaka Plain is mainly deposited by the river flooding of the Yodo River. The north-south-trending Uemachi fault (reverse fault: footwall on the west side) and Ikoma fault (same) pass through the center and eastern edge of the plain. Since the Osaka-wan fault (mainly reverse fault: east side is the footwall side) is distributed in the western end of Osaka Bay, the sedimentary basin continues to subside gradually. The Osaka Plain is filled with sediments with a thickness of over 1000m (Figure 1.). The surface layer is alternately composed of a marine clay layer that was formed during the warm period when the sea level was high and a sand-gravel layer that was deposited mainly as river flooding during the cold period when the sea level was low. KG-NET has a database of boring logs in this area, and it is possible to understand the ground characteristics of the area (Figure 2.). About 50,000 borehole data in this area.

In this study, we discuss the potential geological risks obtained by examining using the boring database.

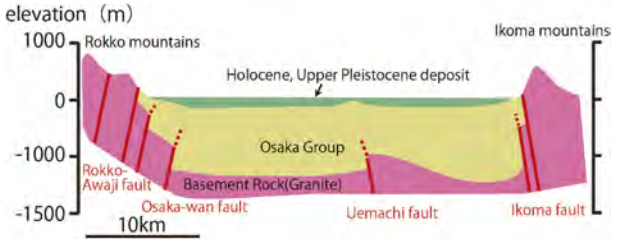

Figure 1. East-West cross section of Osaka plain[1)].

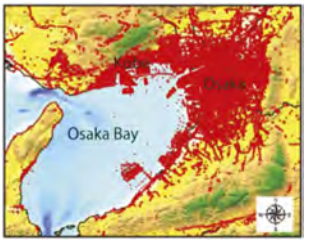

Figure 2. Distribution of boring data red cercle is location of data.

DOI: 10.1201/9781003299127-327

2 LOWER EROSION OF STRATA SEEN IN THE OLD RIVER CHANNEL

In rivers flowing through plains, since the ground level of the riverbed is lower than that of the surrounding area, downward erosion is strong, and riverbed gravel is distributed. Figure 3 shows a cross-sectional view of the former river channel of the former Yodo River. For example, if an old river channel is not assumed during shield excavation in the Ma12 layer, a gravel layer will suddenly be encountered. It is a latent geological risk that causes construction work to stagnate if a preliminary survey or geological factors are not understood.

It is important to note that the marine clay layer deposited in a calm environment has a constant layer thickness in the Osaka Plain, and that the layer thickness has been denuded to less than half by the passage of the river channel. If you don't recognize it, you will suddenly encounter a gravel layer even if you are excavating in the clay layer. Furthermore, even among the river bed gravel, if it is a large river such as the Yodo River, the diameter of the gravel is large, and depending on the location, it is as large as a human head. In addition, since there is also groundwater flow, there is a high possibility that it will become a factor such as flood accidents (Figure 4).

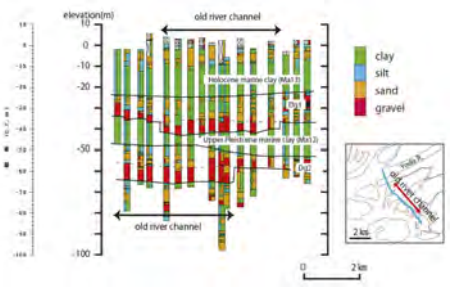

Figure 3. East-West cross section of Osaka plain[1].

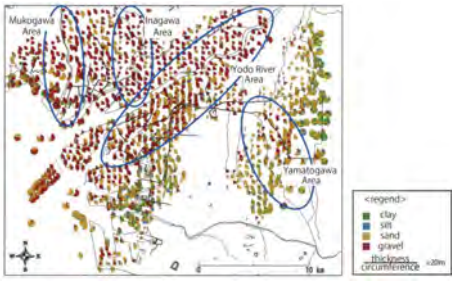

Figure 4. Distribution and grain size composition of the upper Pleistocene gravel layer[2].

3 DISTRIBUTION OF SANDBARS

During the warmest period of the Jomon period (about 6,000yr before), the Osaka Plain was almost submerged in the sea. It has been clarified from previous research that the Uemachi plateau, which is the center of Osaka, was a land at that time because it was a slightly high ground. During this period, a marine clay layer called the Ma13 layer was deposited over most of the Osaka Plain, but sand layers have been confirmed in some areas. After the boring database was completed, we examined the distribution and found that the sand layer is distributed on the

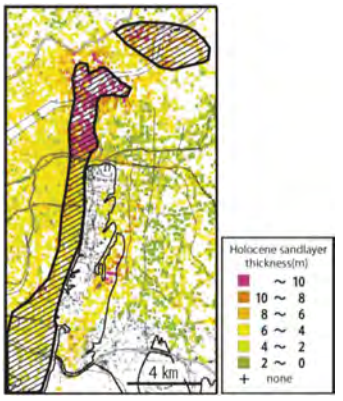

Figure 5. Distribution map of sandbars on the western side of the Uemachi plateau[2].

west side of the Uemachi Plateau and from the north to the east side of the plateau, as shown in Figure 5. A cross-section confirms that the sediments are in a relationship of simultaneous stratification (they are deposited at the same time, but the grain size is different between clay and sand) with the Ma13 layer. In addition, it was confirmed that sandy sediments (sand bank) developed due to tidal current flow due to the ebb and flow of the tide in the connecting part of the inner bay with the Kawachi Plain. Figure 5 traces the thickness of the upper alluvial sand layer distributed over the Ma13 layer. In the black shaded area, the thickness is lower and the Ma13 layer is not distributed. A cross-sectional view of this part is shown in Figure 6.

4 DEFORMED PART OF THE STRATUM ASSOCIATED WITH AN ACTIVE FAULT

It should be noted that the lateral discontinuity of the geological ground due to the passage of active faults causes large changes in groundwater flow and changes in ground strength due to large changes in strata. Furthermore, if displacement (deformation) occurs in the geological ground due to the activity of an active fault, the risk will be very high because structures will also be affected.

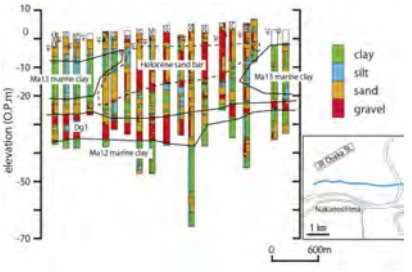

Figure 6. East-west section across the sand bar[1)].

In alluvial plains where urban areas are developed, displacement due to active faults is hidden, and flexural structures may be shown near the ground surface. In the Osaka Plain, the Uemachi fault passes through the western part of the Uemachi plateau, but the western edge of the plateau is not the point where the fault passes (Figure 7). Geomorphologically, the western edge of the plateau was previously thought to be the fault scarp, but boring data reveals that the cliff is different from the fault passage. The east-west cross section shown in Figure 8 is an area that appears particularly conspicuously. The origin of the Uemachi plateau is considered to have been formed with the activity of the Uemachi fault. As mentioned earlier (3.3), the fault scarp is thought to have receded eastward due to wave erosion during the period of high sea level. Therefore, the actual displacement and flexure of the fault are located on the west side of the fault scarp, and because the topography is flat, it is difficult to determine the exact location. In the vicinity of the fault, the stratum changes rapidly and the groundwater flow is complicated, so it is a place that requires attention during construction. In fact, even if the drilling data is used, it is not possible to judge whether the adjacent clay layers are sediments of the same period or not because the marine clay layers are greatly tilted and deformed. However, if there is a boring survey that can determine the information to some extent, it is possible to use adjacent boring data to estimate the deformation of the stratum. It becomes possible to consider bending deformation. Figure 9 is a geological cross-sectional view near the fault passage created by combining the boring data and the boring data for the geological sedimentary environment survey. The Ma12 layer in the figure is a Pleistocene sediment (deposited from about 125,000 years ago[6)]), and since it is a marine clay layer, it was deposited horizontally at the time of deposition. At present, the sediments have been significantly deformed, and the fact that a drop of about 50 m is observed at the base can be judged to be deformation associated with fault movement. Furthermore, since the upper alluvial clay

layer (Ma13 layer) has hardly deformed, the cumulative displacement of older sediments is larger than that of newer sediments (repeated displacement = periodic deformation). Such deformation structures due to active faults are latent in the underground part of the alluvial plain and cannot be fully understood from the topographical shape near the surface. Therefore, lateral contrast of strata must be carefully performed in order to make it apparent as a geological ground risk.

Figure 7. Distribution of the Uemachi fault (Left: active fault database of the geological survey of Japan, AIST[4)], right: urban active fault map published by the Geospatial Information Authority of Japan[5)].

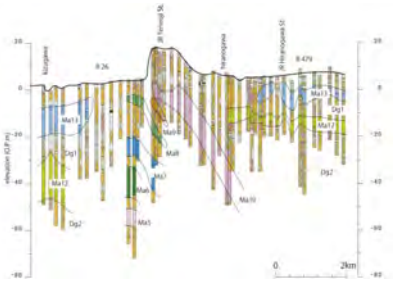

Figure 8. Relationship between the plateau topography and the Uemachi fault in an east-west cross section.

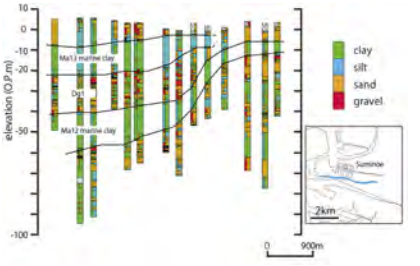

Figure 9. Flexural structure of the Ma12 layer at the suminoe flexure[7)].

5 CONCLUSIONS

When examining geological ground risk using ground information, it is necessary to read the characteristics while fully considering the geological development history of the area. The following five points are important for understanding geological ground risk.

1. It is necessary to fully understand the sedimentary structure and sedimentary environment of strata, and to fully understand the risks that lie hidden therein.

2. Even if it is the same stratum, there is no stratum that increases in the same way on the side.
3. It is necessary to have a good understanding of the geological structure and grasp the geological ground risk.
4. In particular, it is necessary to pay attention to the underlying geological ground risk in plain urban areas, which does not appear in the topography and has latent geological structures.
5. When grasping the geological ground risk, it is effective to use physical geological analysis etc. as necessary.

ABSTRACT: The issues of processing GNSS survey data, the results of observations at the points of the state geodetic network, the concepts of the quality of the result of deformation monitoring are considered.

GNSS survey data processing occupies one of the most important places in the methodology. The results of observations at GNSS points carry information both about displacements of the foundations of structures (for example, pit wall landslides) and about periodic (seasonal, annual) deformations of components caused by external factors (uneven solar heating, temperature fluctuations, wind load, snow load, icing, seismic activity, etc.). Periodic observations help to identify negative geological processes in the area where the engineering facility is located.

Changes in the position of Permanent Operating Base Stations (PBSs) installed at dynamic sites can have different values, speeds and nature. In order to determine the most accurate antenna phase centre displacement under certain conditions, different, sometimes non-standard methods of spatial information processing need to be applied. At the same time it is necessary to know exactly the expected accuracy of geodetic observations. The notion of quality of result of deformation monitoring implies high accuracy of coordinates measurement, detailed description of antenna motion, absence of influence of big errors and so on. [1].

It should also be remembered that each object of study has its own unique nature. Data processing methods may be acceptable for one type of object, but for another, seemingly identical object, such methods will not be correct. In order to accurately assess the suitability of a methodology, control or test measurements are usually carried out. This activity is experimental in nature, needed to confirm suitability by testing the same survey results, but carried out using different techniques. The method that gives the most accurate result, corresponding to the actual movement of the object, is deemed optimal and is used for further work on an ongoing basis. Such measures also help identify the influence of various mistakes that occur during surveying. One of the most widespread mistakes is signal over-reflection that occurs as a rule in urban areas with high-rise buildings. Multipathing is the cause of an error ranging from a few centimetres to a metre. Such measurements are to be rejected [2].

Geodetic monitoring of dynamic objects involves measuring the coordinates of the points in the deformation network in order to detect coordinate deviations of the points. In order to describe the coordinate deviation in detail, mathematical processing of the data obtained is necessary. This step is one of the most important, as the choice of mathematical function determines the details of the display of dynamic processes in the terrain. In practice, the most commonly used methods for mathematical processing are the moving average method, the median filter, the window function and the interval composite method. To further select the best method it is necessary to disambiguate them, in particular [3].

The moving average method is often used when it is necessary to smooth time series and remove high frequency components from the radio signal. According to the algorithm, an

DOI: 10.1201/9781003299127-328

interval of a certain length is first taken from the original data set. This is followed by finding the arithmetic mean of all signal values in this interval.

For the example, assume that signal f has N points. For each N-point there is a signal value K. The value of the moving average gi in the interval of point i will be equal to the arithmetic mean of the K previous and subsequent points, including point i. Each new value of gi will be defined as the smoothing factor in the 2K+1 interval (1).

$$g_i = \frac{1}{2K+1}\left(f_{i-k} + f_{i-K+1} + \cdots + f_i + f_{i+k}\right) \tag{1}$$

The calculation results in a new series of smoothed data consisting of arithmetic mean values (Figure 1). This method is good in that it allows fast data processing, but has a disadvantage in the accuracy of the result obtained. This is due to the fact that the averaging takes place where there may be incorrect signal values (noise, radio wave reflections, etc.). Therefore, values from the start and end points of the signal are not taken into account in the smoothing calculation. If a result with an accuracy of 1 cm is required (example: determination of the deformation of a job during operation), this method is not optimal [4].

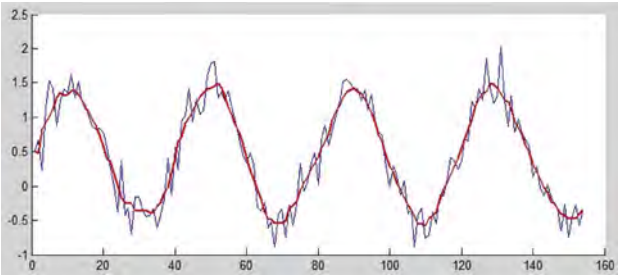

Figure 1. Result of smoothing the signal using the moving average method.

The second method is median signal filtering. This method is widely used in digital processing and can reduce impulse noise. Impulse noise is caused by electromagnetic waves or a technical failure in the signal reception system. The median filter differs from the arithmetic average filter in that it is selective in the signal window (aperture). If the values in the signal window are a monotonous sequence of numbers, the filter will leave them unchanged. With values standing out from neighbouring points, the filter performs averaging, depending on the chosen aperture. As can be seen in Figure 2, median filtering with the correct aperture is able to preserve the sharp variations in the signal while suppressing the interference in the array [5].

The median method has found its application in inertial navigation systems where fast orientation in space with an accuracy of approximately 1 meter is required. However, it is not widely used in engineering geodesy, as two-step processing first of statistical, then of impulse noises is not rational for high-precision measurements [6].

The processing methods discussed above are based on calculating the average value of a section of the signal and then averaging it further. We will now look at a new technique. This method is called the interval superposition method. The main difference from previous methods is that it applies a statistical calculation algorithm inside the signal segment. This method is basic in deformation monitoring for a structure along with the kinematics mode. The great advantage of this method is the millimetre accuracy of coordinate determination, but such a result requires strict consistency in methodology and favourable surveying conditions [7]. In static mode, the resulting data array is divided into time intervals of a certain length. Depending on the company of the equipment used (Leica, Trimble etc.) these intervals are processed in special software. The result of the processing is presented as a diagram,

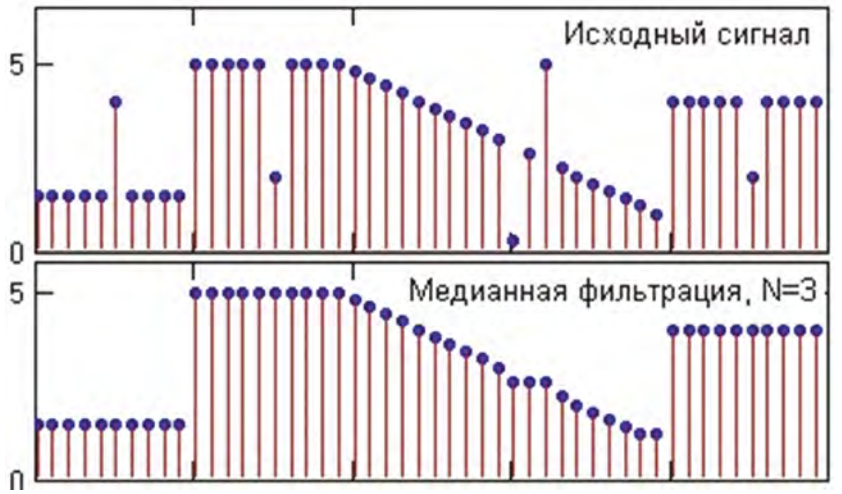

Figure 2. Comparison of signal after median filtering.

where the abscissa axis shows the offset, and the ordinate axis the time interval. Figure 3 shows an example of processing, where 1 hour was taken as the time interval.

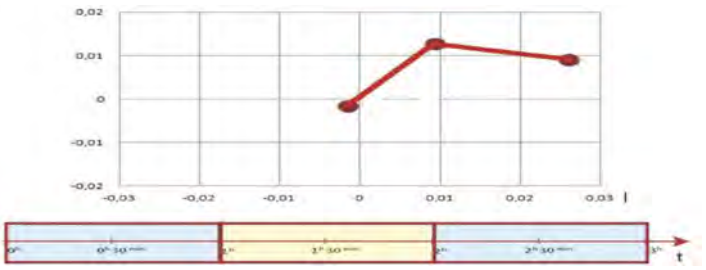

Figure 3. Processing of satellite measurements in static mode at 1-hour intervals.

Static mode requires presetting, as the quality of the result may vary depending on the shooting conditions and the task at hand. The detail can be improved by reducing the time interval, but this may lead to a decrease in the accuracy of the displacement detection. Repeated measurement of coordinates in a short period of time contributes to error accumulation. Studies have shown that 15 to 20 minute intervals are possible if there is no chance of signal re-reflection; the required number of satellites is available; and the geometric arrangement of the receiver stations is correct. But such conditions are rare. For this reason, other survey parameters must be used. The optimum is to have overlapping time slots so that observations are frequent, but not excessive. We now have four time slots of 1 hour and an overlap of 45 minutes. The observation time is three hours. As shown in Figure 4, the overlapping of intervals allows detailed tracking of the GNSS receiver antenna movements on a dynamic object. The appearance of intermediate points helps to study the trend of the object. When monitoring deformation of structures it is possible to track how stable a structure is. For geological monitoring of crustal movement, the data obtained is of great importance if the area is seismically active and suffers from destructive natural phenomena [8].

In the course of the work, the optimum mathematical variant of satellite signal processing for monitoring dynamic objects was established. The static mode proved to be one of the most

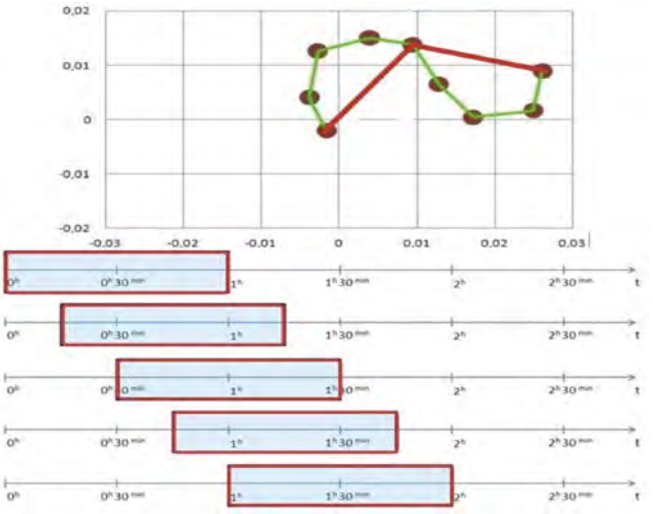

Figure 4. Processing in static mode with overlapping time slots.

feasible, as it meets most of the monitoring requirements. The resulting detail of the displacement trajectory has been realised through repeated measurements under different conditions.

Satellite observation methods have opened up new possibilities for geodetic monitoring of buildings, structures and geological processes. GNSS geodetic monitoring is actively used to study areas of high seismic hazard; for landslide monitoring of quarry sides; for geodetic monitoring of dynamic structures such as towers, bridges, etc. However, it should be noted that the development of the latest technical solutions in the field of geodesy implies the development of modern approaches to geodetic solutions [9]. In other words, when using modern geodetic equipment, it is also necessary to use modern methods of fieldwork and cameral work to replace traditional methods. Therefore, a GNSS overlay survey interval method was developed to address the processing of displacement monitoring data [10].

As is already clear from the name of the interval method, the main role here is played by the duration of those very intervals. The use of one-hour intervals is an acceptable survey parameter, but results in an averaging of the resulting structural displacement. One hour intervals may be used when monitoring targets that are not highly deformable, or when creating an overview model to show the total displacement pattern [11]. If there is a requirement to show more detailed displacement of structures, intervals of 15-20 minutes are used. And following this logic, the shorter the time interval, the more detailed changes to the object will be shown. The reason for this is that more intermediate measurements are taken in a shorter time interval. However, there is always the danger in processing satellite measurements - using short intervals may lead to a poor quality solution. As foreign experience of GNSS application shows, in absence of objects reflecting the signal, sufficient number of satellites and optimum geometric position the use of intervals of 10-15 minutes for processing of observations in static mode allows to receive the solution corresponding to the required level of accuracy of equipment. However, if conditions are different from ideal, the use of 10-minute intervals becomes risky and may affect the accuracy of the final result, so the length of the interval should be chosen, starting from external survey conditions [12]. As can be seen in Figure 5, the interval stacking method is good in that it allows the coordinates of intermediate points to be obtained.
