economical. By using this mix proportion as a reference, test construction was conducted with 90, 100 and 110 kg/m^3 of solidifier. The original soil and solidifier were mixed using a fixed-type soil improvement plant. Rolling compaction of the embankment was conducted 4, 6 and 8 times, using a 3.5-ton compound roller (cone index: 400 kN/m^2). Figure 5 shows the relationship between the rolling compaction frequency and the cone index/dry density. The degree of compaction was 90% or higher regardless of the total amount of solidifier. The cone index was 400 kN/m^2 or more, except for 70 kg/m^3. Based on these results, it was decided to construct an embankment by mixing 90 kg/m^3 of solidifier and applying compaction four times. It has been confirmed that the standard value of the elution amount of hexavalent chromium is satisfied with this mix proportion.

As the degree of compaction of the constructed embankment was 90% or higher, it was confirmed that the embankment satisfied the quality standard.

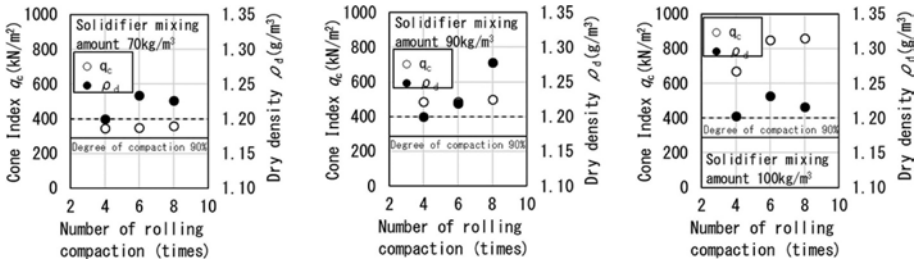

Figure 5. Results of test construction.

5 CONCLUSION

It was confirmed that crushed solidified soil has the required geotechnical properties for embankments, and that its strength development was smaller than that of solidified soil. It was successfully used for the construction of an embankment.

The technology of strengthening waterlogged foundation soil in the construction of shallow foundations

A.S. Montayeva
Korkyt Ata Kyzylorda University

S.A. Montayev & N.S. Montayeva
West Kazakhstan Agrarian Technical University

ABSTRACT: The article presents the results of scientific and experimental research on the strengthening of waterlogged soil on the foundation during the construction of shallow foundations. Efficient implementation of technological operations to strengthen soils is possible only when the moisture content of the treated soil does not exceed the optimal standard compaction, at which the soil is in a semi-solid state, capable of crumbling and compacting. However, in engineering practice, there are often cases when cohesive (clayey), fine sands, sandy loams, loams and other soils are in an overmoistened state, i.e. have moisture content above the optimum. Waterlogged soils cannot be compacted. loosen, and therefore excludes the use of binder materials such as cement, bitumen, silicate mortar and polymer components for their strengthening. Natural drying of waterlogged soils, especially clay ones, occurs very slowly. The currently used artificial methods of drying are ineffective and require large expenditures of money and time. To increase the bearing capacity and reduce the deformation of soil foundations, there are many ways to artificially fix soils. They are divided into physical - strengthening the soil mass with the help of physical fields, mechanical - placing reinforcing elements with high tensile strength in the soil, chemical - improving the properties of soils by injecting special solutions into their thickness. As a result of the analysis of research and practical work in the field of strengthening waterlogged soils, it was found that the most effective treatment of such soils with chemicals that, along with dehydration, can change the physical and chemical properties.It has been established the effectiveness of dehydration and strengthening of waterlogged soil by introducing quicklime through the use of the heat generated (T = 1000C) when interacting with water and their ability to harden due to chemical interaction with the mineral part of the soil. The patterns of change in the duration of dehydration and the state of aggregation of waterlogged soil from the amount of quicklime have been established. It has been proven that the introduction of quicklime in the amount of 20-25% into waterlogged soil radically changes the properties of these soils, enlarges the state of aggregation and creates workability for fixing by cementation, silicification and resinization.

1 INTRODUCTION

During the construction and operation of buildings and structures on weak water-saturated soils, the problem of transforming their physical and mechanical properties inevitably arises in order to increase the bearing capacity and reduce deformability. On the one hand, this is a problem, but on the other hand, it is an opportunity for innovation and modernization of existing methods for strengthening the foundation soils.

Artificial soil stabilization is the impact on the soil with the help of various structural and technological measures, which increases its bearing capacity and reduces deformations.

DOI: 10.1201/9781003299127-96

Currently, there are many methods of soil stabilization, each of which has its own advantages and disadvantages. Most often, the scope of the method is somehow limited by the type of soil.

To increase the bearing capacity and reduce the deformation of soil foundations, there are many ways to artificially fix soils.

Conventionally, they can be divided into physical - strengthening the soil mass with the help of physical fields, mechanical - placing reinforcing elements with high tensile strength into the soil, chemical - improving the properties of soils by injecting special solutions into their thickness.

The fixing method is chosen based on the soil conditions of the construction area, as well as the production capabilities of its implementation.

Thermal fixing of the soil - the transformation of structural bonds in the soil under the influence of high temperatures. It is carried out either by injection into the soil under pressure of air heated to a temperature of 600–800 ° C, or as a result of burning fuel (solar oil, fuel oil, natural gas, etc.) in hermetically sealed wells drilled for this purpose.

After fixing, the strength and water resistance of soils increase, and their subsidence properties are eliminated [1]. In accordance with the technology, it is necessary to maintain a pressure in the well from 15 to 50 kPa, which is achieved by supplying hot air to enhance the filtration of hot gases in the soil and maintain the required temperature. The diameter of the wells is assumed to be 10–20 cm, while the depth varies from 6 to 15 m or more. Depending on the loads and their distribution over the building spot, the distance between the axes of the wells is determined.

Roasting of the soil lasts from 5 to 10 days. An array of thermally fixed soil with a diameter of 1.5–3 m is formed around the well when 80–180 kg of liquid fuel is burned per 1 m of the well depth. To avoid the penetration of groundwater or water-saturated unstable soils into the mine under construction, artificial freezing of soils is used, which creates a solid fence that has a circular or rectangular shape in plan from frozen soil. To freeze soils, a refrigerant or refrigerant is usually used (most often a chilled aqueous solution of calcium chloride - brine). The main function of the brine is the ability to remain liquid at low temperatures.

The second group under consideration is the mechanical methods of fixing the foundation soils. The methods are considered the most popular, since they do not involve changes in soil properties under the action of solutions or physical fields, which is quite difficult to control. Mechanical methods involve soil reinforcement with ready-made elements from various materials with high tensile strength.

The most common method of soil compaction is tamping or layer-by-layer compaction. For compaction, hammers are used, which are mechanized and manual.

Mechanized compaction with special construction equipment significantly increases the estimated cost of construction, but for large volumes of work, the use of only manual mechanisms is impractical.

Compaction of soils with the help of hammers is carried out until the surface of the soil, with each subsequent fall, drops by the same amount, called “failure”. The size of the failure is approximately taken equal to 1–1.5 cm for dusty clay soils, and 0.5–1 cm for sandy soils.

Failure is achieved after 8–12 hits on one track. The compaction mode is set experimentally and depends on the soil conditions at the construction site.

The use of fibrous materials, namely geosynthetics, to strengthen soil foundations has now become popular. This is facilitated by their great variety, simplicity and efficiency of technology. There are several types of geosynthetic materials used to reinforce soil foundations: geotextile, geogrid, geomatrix. Depending on the manufacturing method and, as a result, the final technical characteristics, woven and non-woven geotextiles are distinguished. Nonwoven geotextile is a flat structure, which consists of synthetic fibers, fastened together by a mechanical method. Such material does not rot, plant roots do not grow through it, and the structure provides good strength and filtering properties. [2-4].

Of greatest interest is the use of geogrids, which is a honeycomb structure made of polyethylene tapes, which are interconnected by high-strength welds and have a staggered arrangement. They are used primarily for reinforcing soil foundations for the purpose of strengthening, given

their special structure, when the soil sandwiched between the cells of the geogrid cannot move from acting loads and all tensile stresses are transferred to the geogrid. One of the novelties for soil stabilization is the use of a geomatrix. Structurally, geomatrices are a box without a top cover, to the walls of which geotextile tapes are attached. Intersecting, they form rectangular cells inside the box [5–10].

When arranging the foundation and foundations of a building and construction, a certain problem exists in construction sites where the groundwater level is high. Due to the high levels of groundwater, the soil under the base of the foundation has increased water saturation. In many cases, special dewatering works are carried out to solve the problem. The essence of the method of dewatering is based on the fact that the surface of the water in the soil acquires a funnel-shaped shape with a slope towards the pumping point of groundwater that enters the well. The funnel-shaped (lowered) surface of groundwater is called the depression surface, and the depression funnel is the space between this surface and the non-lowered surface of the ground flow. The soil below the groundwater level experiences the weighing effect of water, therefore, the specific gravity of the soil decreases. In this case, artificial dewatering is used, as a result of which the soil is above the groundwater level, the specific gravity of the soil increases, and the base is compacted. The depression funnel increases as the water is pumped out. The development of the depression funnel does not occur, stabilization occurs if the pumping intensity remains constant. With the cessation of pumping, the groundwater level is restored. The main purpose of dewatering is to maintain depression funnels in a drained state during the entire period of construction of the structure.

In some cases, dewatering is used to relieve excess pressure in the underlying aquifers, separated from the bottom of the pit by a layer of water-resistant soil. When dewatering, several methods are used: using light and ejector wellpoints and the vacuum method.

Currently, of particular interest is the chemical methods of fixing soils. All chemical processes occur due to the chemical interaction of the reagents introduced into the soil, among themselves, as well as with mineral particles.

On the territory of Kazakhstan there are regions where the level of groundwater is high. These regions include Akmola, Kyzylorda, Atyrau regions. Currently, along with the construction of large civil and industrial buildings and structures, low-rise residential complexes are also being actively built up.

The use of pile foundations for these complexes is technically and economically inexpedient.

Therefore, during the construction of such complexes, the construction of shallow foundations is mainly adopted in design decisions.

Typically, the depth of the foundation in such cases is taken in the range from 1.0 -1.5 m. In these regions, the groundwater level is within these limits, which predetermines waterlogging of the soil.

Waterlogged soils cannot be compacted. Waterlogged soils cannot be loosened, and therefore, cement, bitumen, silicate mortar, polymeric and other binders cannot be used to strengthen them. Natural drying of waterlogged soils, especially clay soils, occurs very slowly, and artificial drying methods currently used are ineffective or require large expenditures of money and time.

Therefore, strengthening waterlogged soil under the foundations of shallow foundations, taking into account technological and economic feasibility, is an urgent task.

An analysis of possible ways to improve the workability of waterlogged fine sandy, sandy loam, loam and clay soils for further strengthening them with binders, including cement, silicate mortar and polymer suspensions, showed that the most effective treatment of such soils with chemicals that, along with dehydration, can change the physical - Chemical properties.

The purpose of the work is to carry out scientific and experimental work on the use of quicklime to strengthen waterlogged soils with the study of changes in their physical and mechanical properties.

1.1 *Materials and research methods*

When examining the soil, standard methods were used to determine the physical and mechanical properties of the samples.

Ground quicklime is of particular interest as the main material for solving the tasks set.

Lime is the most common material. Its main active components - CaO, when interacting with water, turns into Ca (OH) 2. The rate of hydration of these components depends on the degree of their dispersion and the temperature of limestone firing. The process of lime slaking occurs according to the reaction: CaO + H2O \u003d Ca (OH) 2 + 15.5 kcal., Where 1 kcal \u003d 4.1868 10^3 J. The lime slaking reaction proceeds rapidly, with a large release of heat - 15.5 kcal per gram-molecule or 277 kcal per 1 kg of lime. Water, penetrating into the depths of the lime grains, enters into a chemical interaction with CaO, and the heat released in this case turns the water into steam.

For scientific and experimental work, standard powdered slow-extinguishing quicklime of the 1st grade was used according to GOST 9179-2018 "Building lime. Specifications" (EN 459-1:2010, NEQ). The content of active CaO + MgO, not less than 90%.

Soil (loam) was chosen as the object of research for the construction of a residential building in Kyzylorda (Kazakhstan). At the initial stage of the research, scientific and experimental work was carried out to study the physical and mechanical properties of the soil, the results of which are given in Table 1.

Table 1. Physical and mechanical properties of soil for the construction of a residential building in Kyzylorda.

Soil name	Depth sampling, m	Density particles, Ps g/cm3	Humidity natural, W%	Plasticity number, Ip	Fluidity	Coefficient porosity, e	Coeff. water saturation, Sr
Loam	1,0	2,7	23,2	9,9	-0,52	0, 722	0,40

Samples of waterlogged loam soil had the following technical characteristics: particle specific gravity γs =26,3 kN/m^3; specific gravity before compaction γ=14,6 kN/m^3, after compaction γ′= 18,5 kN/m^3; optimal moisture content for standard seal Wo = 0,14 is between the maximum molecular moisture capacity Wm = 0,11 and rolling limit Wp = 0,15; yield strength WL = 0,25 for this type of soil. Granulometric composition, content of fractions: d > 2 mm; d = 0,1..2 mm – 34 %; d = 0,1..0,25 mm – 27 %; d = 0,05. . .0,002 mm – 14 %;loss on ignition 4,3 %; pH < 5,0 water extract.

2 RESULTS AND DISCUSSIONS

To establish the maximum temperature of the heat generated when interacting with water, laboratory studies were carried out according to the following method: quicklime in the amount of 100 g was poured into a transparent plastic dish. Then water at room temperature (t = 20-22 C) was added to the dish with quicklime in the amount of 150 g. To measure the temperature of the heat generated in the center of the plastic dish, a thermometer was installed to a depth of half the height of the poured quicklime, as shown in Figures 1 and 2.

The results of the study demonstrate that the reaction of interaction of calcium oxide with water is a transient process with a large release of heat. During the first 5 minutes, the temperature rises sharply to 100 0C, after which there is a slow decline to room temperature over 90 minutes.

At this stage of the study, it was proved that water, penetrating into the depths of lime grains, enters into a chemical interaction with CaO, and the heat released in this case turns the water into a boiling state, which leads to the release of steam. It is this effect of heat release with the release of steam that is planned to be used to drain and strengthen the waterlogged soil caused due to the high level of groundwater.

Figure 1. Temperature readings during the reaction 5 min.

Figure 2. Temperature readings during the reaction 45 min.

Table 2. Temperature readings over time.

Time (minute)		5	10	15	20	25	30	35	40	45	50	55	60
Temperature (°C)	test №1	98	96	86	82	75	70	63	61	58	55	50	48
	test №2	97	95	88	82	76	71	65	62	56	53	49	45
	test №3	98	95	87	81	75	69	64	60	57	54	52	49

For scientific and experimental work, four batches of prototypes of loamy soil with a moisture content of 20 to 40% were prepared. Figure 3.

Figure 3. The process of preparing soil with different moisture content in laboratory conditions.

After preparing the soil with different moisture content, quicklime was added to it in an amount from 5 to 25%. Quicklime was poured onto the surface of wet soil and the ongoing processes were visually observed. Figure 4.

Figure 4. The process of adding quicklime to the soil surface.

In the process of mixing the soil with quicklime, intensive adsorption of moisture contained in the soil was observed, and the process of slaking the lime with the release of heat was observed.

In addition, moisture evaporation was observed in parallel due to the heating of the mixture associated with the processes of chemical reactions. Figure 5.

At the same time, it was found that after a certain time the mixture of soil with lime acquires the ability to clot and harden.

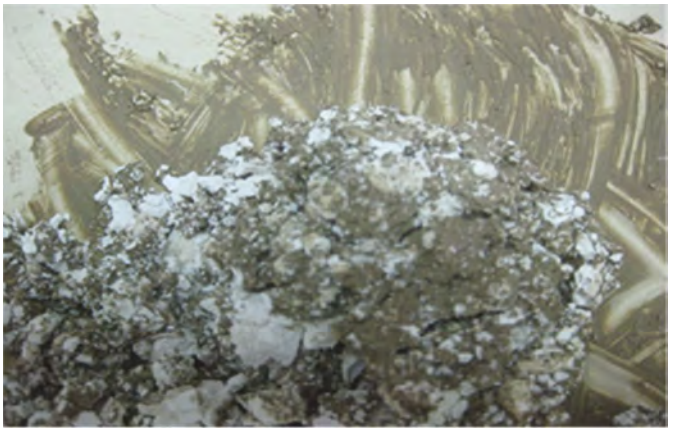

Figure 5. A mixed mixture of soil and quicklime, where the process of slaking lime takes place with the release of heat and evaporation of moisture.

The next stage of the study was the study of the duration of dehydration of wet soil from the content of quicklime. The studies were carried out until the soil moisture reached 8-10%. The results of the study are presented in Figure 6.

As the results of scientific and experimental studies show, with an increase in the content of quicklime, a decrease in the duration of soil dehydration is observed. The longest dehydration time was recorded at a soil moisture content of 20% and a quicklime content of 5%. In this case, the duration reaches up to 70 minutes. However, with an increase in the amount of quicklime from 10% to 25% (with a soil moisture content of 20%), the dehydration time is gradually reduced to 20 minutes.

It should be noted that with an increase in soil moisture, even with a minimum amount of quicklime (5%), a significant reduction in dehydration time is observed. So, with an increase in soil moisture up to 25% and with an amount of quicklime of 5%, the dehydration time is

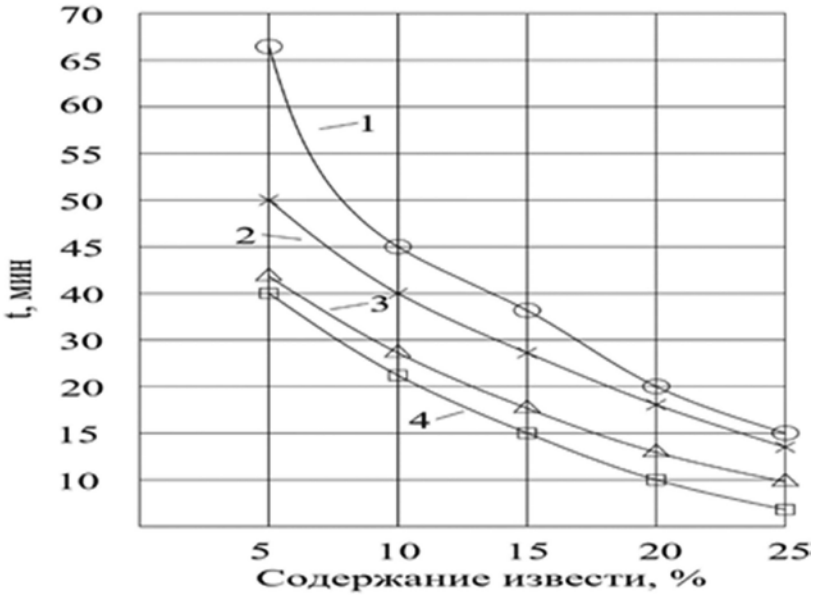

Figure 6. Dependence of the duration of soil dehydration depending on the content of quicklime. 1 - at soil moisture 20%, 2 - the same 25%, the same 30%, the same 40%.

55 minutes. The maximum reduction in the dehydration time of drying up to 15 minutes was recorded at a soil moisture content of 40% and with an amount of quicklime of 25%.

This pattern is explained by the fact that a decrease in the moisture content of waterlogged soils when lime is applied occurs as a result of the following factors:

a) in the process of lime slaking, the released heat (T=100 0C) raises the temperature of the soil, so the evaporation of moisture from the treated layer increases. In this case, the degree of activity of the quicklime quenching reaction directly depends on the amount of moisture;
b) when lime is added to the soil, part of the moisture enters into a chemical interaction with its active components and passes into a solid state due to the binding and hardening properties of quicklime.;
c) quicklime in the form of a dry powder added to the waterlogged soil increases the weight of its dry mass due to the addition of dry material and due to the weight of water chemically bound by calcium oxide.

Thus, it has been established that the addition of quicklime is capable of dehydrating waterlogged soils due to the release of heat generated as a result of chemical reactions.

The main physical properties that determine the workability of waterlogged soils are: maximum molecular moisture capacity Wm, yield strength WL, rolling limit Wp, optimum moisture content with standard compaction Wo.

The optimum moisture content of a standard seal, Wo, depends on the magnitude of the sealing load and can vary over a wide range.

After the introduction of quicklime into waterlogged soil, the physical properties of these soils change dramatically. Depending on the dosage of quicklime, two stages of change in physical properties are distinguished, such as WL, Wp, Wo and Wm.

At stage I, additions of quicklime or MgO at a dosage of 5.0 to 25% act as reagents that radically change the properties of waterlogged soil, in which the number of particles $d<0.005$ mm decreases almost to zero, the value of WL, Wp, Wo and Wm increases sharply.

At stage II, additions of quicklime from 5.0 to 25% no longer act as chemical reagents, but as mechanical components of the mixture, affecting only the increase in the strength of the mixture, since quicklime, when interacting with waterlogged soil, has the ability to harden.

The change in the properties of waterlogged soils when ground quicklime is introduced is associated with the coagulation of fine particles due to the compensation of their charges. Soil particles are charged by double electric layers of soil micelle with a negative electric charge, and these charges are compensated by cations, which, being adsorbed on the surface of negatively charged particles, reduce their charge. Ions of higher valencies cause coagulation at lower concentrations than ions of lower valences.

The amount of lime or magnesia required to change the properties of waterlogged soils depends on the composition of the soil. Therefore, for the processing of light sandy loams, loams and clayey soils with carbonate inclusions, additional scientific and experimental studies are required.

Lime pre-treatment of waterlogged soils significantly improves their workability by fixing them by cementation, silicification, claying and polymerization. At the same time, the number of dust-like particles sharply decreases and the number of aggregates with a diameter of more than 5 mm and more than 10 mm increases. Figure 7.

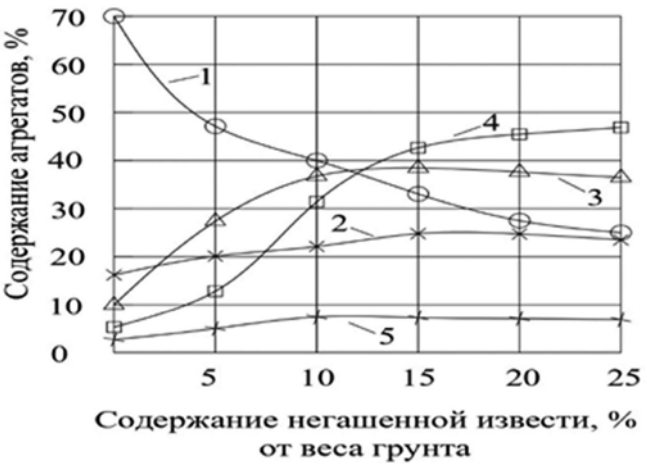

Figure 7. The influence of quicklime on the nature of the change in the content of soil aggregates from loam with the content of aggregates in size: 1 - more than 10 mm; 2 - 10-5 mm; 3 - 5-3 mm; 4 - 3-1 mm; 5 - less than 1 mm.

Influence of lime on the nature of the change in the content of soil aggregates and standard compaction for loamy soil with a specific gravity of soil γ=14.6 kN/m^3, in which, after the introduction of lime and compaction, the specific gravity became 18.5 kN/m^3, with the optimum moisture content of the standard compaction Wo= 0.14.

The influence of lime on the nature of the change in soil aggregates is carried out by thoroughly mixing them, since when lime is applied to waterlogged soil, crusts form on the surface of the soil, and lime cannot penetrate deep into. The thickness of the crust can reach 10 mm.

The optimal doses of quicklime for the waterlogged studied loam can be taken 15-20%. At these doses, the strength of waterlogged soils reaches from 0.5 to 2.0 MPa and the deformation modulus Eo - from 40 to 80 MPa.

3 CONCLUSIONS

1. As a result of the analysis of research and practical work in the field of strengthening waterlogged soils, it was found that the most effective treatment of such soils with

chemicals that, along with dehydration, can change the physical and chemical properties.

2. It has been established the efficiency of dehydration and strengthening of waterlogged soil by introducing quicklime through the use of heat generated (T = 1000C) when interacting with water and their ability to harden due to chemical interaction with the mineral part of the soil.
3. The patterns of change in the duration of dehydration and the state of aggregation of waterlogged soil from the amount of quicklime have been established.
4. It is proved that the introduction of quicklime in the amount of 20-25% into waterlogged soil radically changes the properties of these soils, enlarges the state of aggregation and creates workability for fixing by cementation, silicification and resinization.

Numerical study on stress-strain characteristics of the deep cement mixing column improved soil

M.J. Singh & S. Choudhary
Indian Institute of Technology Indore

Lalit Borana
Associate Professor, Indian Institute of Technology Indore

ABSTRACT: Infrastructural development on soft and marine soil is challenging owing to its time-dependent behaviour. Different ground improvement techniques are used to improve the naturally available soft and marine soil. Among different techniques, Deep Cement Mixing (DCM) is an efficient approach to enhance the engineering characteristics of the ground. Researchers have attempted to investigate the behaviour of the DCM-improved soil and mainly focused on the strength and stiffness characteristics of composite soil. it is noted that not much emphasis has been given to examining the time-dependent consolidation behaviour of DCM-improved clay soil. In this study, efforts are been made to investigate the time-dependent consolidation behaviour of the DCM-improved clay soil and discussed in detail through numerical simulation. Further, the distribution of the creep behaviour of the DCM column and surrounding soil with depth is also discussed in detail.

Keywords: Ground improvement techniques, Deep cement mixing, Consolidation behaviour

1 INTRODUCTION

Good-quality constructional geomaterials are becoming scarce due to limited space and continuous constructional activities, in the last few decades. Therefore, in developing countries, several infrastructural projects are being constructed on marine and soft soil (Geng 2008; Singh et al. 2022). The soft soils are characterized by their low permeability and exhibit time-dependent consolidation settlement, swelling shrinkage behaviour, and strength changes behaviour (Feng et al. 2017; Singh et al. 2021). The settlement of the soft/marine soil poses a severe threat to various engineering structures, including railways, and airport runways and damages the foundation of coastal engineering projects (Johnson Singh et al. 2022; Park and Lee 2011). Different researchers suggest several ground improvement techniques including sand drains, wick drains, stone columns, removal and replacement of soil, grouting and deep mixing of soil and many more (Andromalos et al. 2001; López-lara et al. 2017; Mitchell 2008). Among these techniques, deep cement mixing (DCM) columnar inclusion is one of the effective techniques, due to its cost-effectiveness, technologically simple, and allowing fast construction (Alhamdi and Albusoda 2021; Turner et al. 2017).

DCM method is the injection of cement additive either in powder or slurry form into soft soil and mixed together by using a mixing blade. After the completion of the curing period, this mixture converts to a soil cement column (Voottipruex et al. 2019). Bruce (Bruce and Geosystems 2000) investigated the influence of the mixing factors such as installation rate, water/cement ratio, and rate of rotation that affected the strength development of soil-cement columns. Different researchers investigated the influence of different quantities of cement content and consolidation behaviour of the soft soil with different area ratios of DCM column under different vertical stresses (Horpibulsuk et al. 2012b; Suebsuk et al. 2010). The stabilization of clayey soil with cement

DOI: 10.1201/9781003299127-97

mixing is due to the cementitious bond developed between the hydration products of the cement in aluminate and silicate form and the soil particles. Due to this interaction, the interlayer and inter-micellar swelling of the clayey soil particles reduced significantly (Fang and Yin 2007; Horpibulsuk et al. 2012a; Jamsawang et al. 2017). Horpibulsuk et al. (Horpibulsuk et al. 2010) employed finite element methods to investigate the consolidation behaviour of the composite ground and designed a practical method to predict the estimated settlement. Wijerathna et al. (Wijerathna et al. 2016) investigate the behaviour of DCM column-improved soil during the breakdown of the soil-cement structure and subsequent consolidation. The study considered the strain-softening behaviour of cement-mixed soils beyond yield. Several factors can influence the strength of the soil-cement-treated clayey soil like characteristics of soil, characteristics of the binder, curing conditions and mixing conditions (Kitazume and Terashi n.d.; Yin et al. 2022).

Few researchers have conducted several experimental and numerical analyses on DCM-improved soft soil. However, the time-dependent stress-strain characteristics of DCM-improved composite soil, especially the creep behaviour are neglected. In this study, a parametric study is conducted using finite element simulation to assess the time-dependent stress-strain behaviour of DCM-improved composite soil.

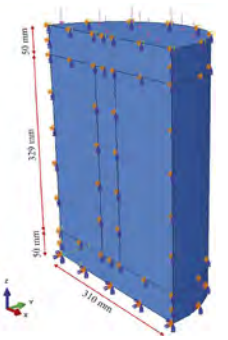

Figure 1. The boundary condition and model development.

2 MODEL DEVELOPMENT AND BOUNDARY CONDITION

In this study, the modified Drucker-Prager/Cap plasticity/creep model is used as this model is able to simulate creep in geomaterials exhibiting long-term inelastic deformation through a cohesion creep mechanism and a consolidation creep mechanism in the cap region (as suggested in ABAQUS User's Manual). A finite element model was developed in the ABAQUS/Standard to simulate the time-dependent settlement of the soil, as illustrated in Figure 1.

Table 1. Material properties and different parameters.

Parameters	Clay soil	DCM column	Sand

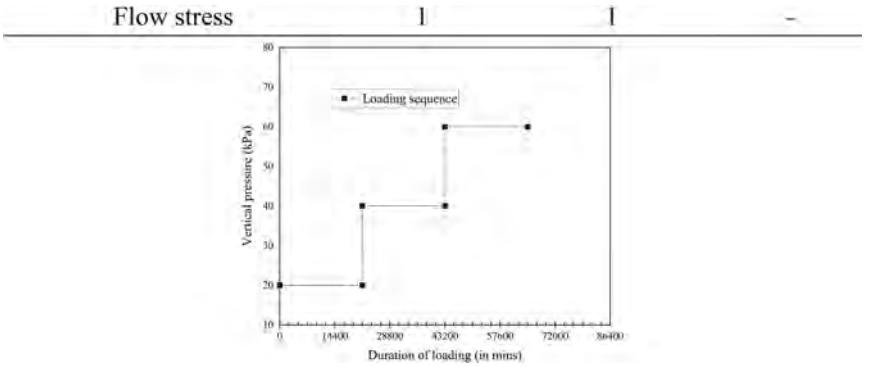

Figure 2. Loading sequences and duration of loading. (not included in theory).

Different properties of the DCM column, sand and clay soil are presented in Table 1. The parameters used in the simulation are taken from the relevant literature (Aza-Gnandji and Kalumba 2014; Gupta and Sharma 2016; Peeters 2017; Yapage et al. 2014). In this study, both the DCM column and surrounding clay soil were simulated using the Cap plasticity model, this arrangement reduces the interaction relevant problems between the soils. Drainage was allowed at the top surface of the DCM column and soft clay through the sand layers. Thus pore pressure dissipation takes place only on the upper surface of the model. To maintain the symmetry at the centre of the model, lateral displacement was restricted throughout the study. The bottom surface is constrained in both lateral and vertical displacement. The interaction between the DCM and surrounding soil is simulated using the normal behaviour and tangential behaviour with friction formulation in the penalty subsection and uses a 0.3 friction coefficient. The mesh size of the DCM column and surrounding soil sample are respectively 0.009 and 0.0095. A smaller mesh size was provided to simulate the DCM column without possible errors. There were three different stages of the loading, and each load were applied for 1296000 seconds with a magnitude of 20 kPa as illustrated in Figure 2.

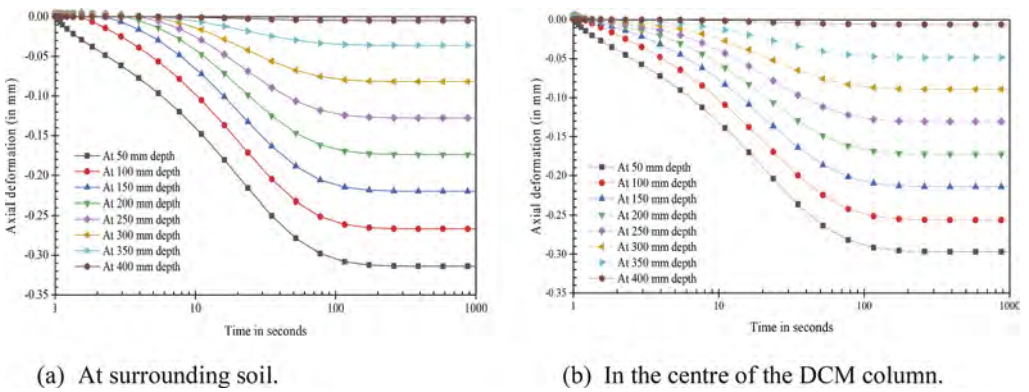

Figure 3. Axial deformation behaviour of the soil and DCM column.

3 RESULT AND DISCUSSION

The variation of axial deformation behaviour surrounding clay and the DCM column with depth during the application of 20 kPa is illustrated in Figure 3 (a) and (b). It is observed that during the application of 20 kPa effective stress the surrounding clay soil exhibits 5.69%

higher axial deformation with respect to the DCM column at 50 mm below the soil surface. Similarly, the relative settlement behaviour of the surrounding soil with depth is observed to decrease with respect to the settlement in the DCM column. A similar pattern is observed during the application of remaining effective stress. During the application of 60 kPa, the reconstituted soil exhibits a maximum settlement of 0.91 mm during the whole loading period. In this study, a small loading was applied which is below the failure of the column. The overall settlement of the DCM-improved soil is observed to be small. Different factors might be responsible and some of the probable factors may include the coefficient of consolidation, the length of the drainage path and the permeability of the soil.

Further, an attempt was made to investigate the time-dependent creep behaviour of the soil using the power law model proposed by Briaud and Garland (Briaud and Garland 1985). It considered the creep behaviour of the soil during the primary consolidation stage also. It has been extended by the author to present the time-dependent behaviour of various sources of soils on diversified data. The model is written as below:

$$\frac{s}{s_1} = \left(\frac{t}{t_1}\right)^n$$

where, s and t signify the deformation (settlement, strain, etc.) and corresponding time respectively. The s_1 is usually chosen to be the value of deformation s observed at reference time t_1. The reference time could be either 1 second, 1 minute, 1 day or onwards, and n is the viscous exponent (Bi et al. 2019; Singh et al. 2022).

Using the relationship between $\log(s/s_1)$ and $\log(t/t_1)$, the slope is used to represent the viscous time-dependent component. After the end of the primary consolidation, the slope can be regarded as a creep parameter of the soil (Bi et al. 2019). Taking the DCM-improved soil as a whole, the creep parameters are determined for every 50 mm depth from the upper soil surface. The first 50 mm which is just below the sandy layer has a creep parameter of 0.025. Similarly, the creep parameter of remaining layers 100 mm, 150 mm, 200 mm, 250 mm, 300 mm, and 350 mm are respectively 0.0259, 0.029, 0.0142, 0.0152, 0.0159 and 0.0162. For the natural clay soil, the creep coefficient is reduced with depth as reported by other researchers (Le and Fatahi 2016). But during the installation of the DCM column, it changes the drainage behaviour, soil column interaction, stress distribution and many more (Fang and Yin 2007; Turner et al. 2017). All these factors may influence the distribution of creep parameters with depth, therefore a particular trend is cannot derive. However, in this study, it is observed that the time-dependent behaviour of DCM-improved soil composite is significantly varied with the depth.

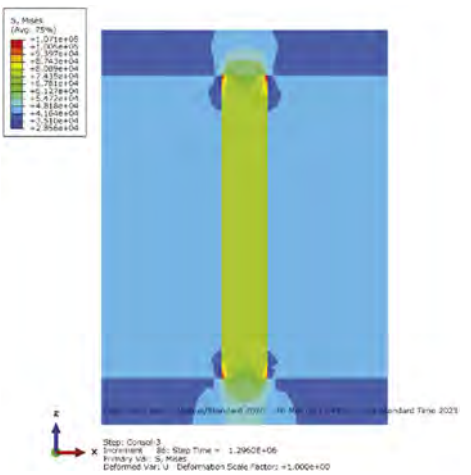

Figure 4. The stress-distribution behaviour of the DCM-installed clay soil.

The stress-distribution behaviour of the DCM-installed clay soil is illustrated in Figure 4. From this figure, it is observed that the top and bottom portion of the column carries the maximum stress compared to the other portions. Therefore, these locations may be the responsible portions for the failure of the column as maximum stress distribution takes place in these portions. The failure portion of the DCM improved soil is well agreed with the findings of other researchers (Wijerathna et al. 2016). The crushing of the soil structures is also the responsible factor for the failure of the DCM column in the laboratory (Horpibulsuk et al. 2012a). During the numerical simulation, lateral deformations are not observed in the DCM column while applying the pressure.

4 CONCLUSION

DCM columnar inclusion is a potential ground improvement technique to stabilize soft or marine soil. In this study, a numerical study is utilized to investigate the time-dependent stress-strain behaviour of DCM columns. Based on the findings, the following conclusions are drawn.

1. It is observed that the surrounding soil exhibits 5.69% higher axial deformation behaviour with respect to the DCM column at 50 mm below the soil surface. With depth, the surrounding clay exhibits higher axial deformation behaviour compared to the DCM column.
2. The distribution of the time-dependent creep parameter of composite soil is varied with depth. This might be due to changes in drainage behaviour, soil column interaction, stress distribution etc.
3. Maximum stress distribution takes place in the top and bottom edges of the DCM column play compared to the other portions. Therefore, these are the expected locations for the failure of the DCM column.

Microcapsules retention behavior in granular materials

K. Chen & Q. Rui

ABSTRACT: Due to the advantages of protection and controllable releasing of chemical materials, microcapsules have been widely used to self-heal cementitious materials. However, their applications in granular materials like soils remains to be unexplored. An initial challenge to tackle is the microcapsules retention in open porous media. From laboratory results, a distinctive demarcation between effective and ineffective gravel-microcapsules mixtures was identified in considering the washout of microcapsules. An attempt has been made to develop a design criterion in terms of the relationship of d_{85} (a representative size of microcapsules being protected) and D_{15} (a representative size of gravel), following the approach from filter design. The criterion can be adopted for both gravels and microcapsules with different particle sizes and gradations.

1 INTRODUCTION

Different functional materials can be stored and protected by polymers inside at micro-scales without reducing their functionality (Bah et al. 2020). This fabricated microcapsule is generally a sphere with its wall called a shell and the material inside termed a core. Microcapsules were initially developed for self-healing polymeric composites (White et al. 2001) and have been widely used in cementitious construction materials to self-heal cracks triggered by mechanical loadings and environmental changes (Yang et al. 2009). For cementitious materials, the size of microcapsules should be designed considering the size of cracks to achieve high level of healing (Kanellopoulos et al. 2016), otherwise microcapsules will either fail to survive the mixing process or not be ruptured when a crack forms due to inappropriate size design. Up to now, the application of microcapsules on granular materials like soils still remains unexplored. As microencapsulation method has been successfully exploited in cementitious materials, it then emerges as a potential prospect to switch and enhance the physical properties (e.g. strength and permeability) of granular materials.

Regardless of specific utilizations and encapsulation techniques, the first challenge to be solved is the microcapsules retention in voids. Generally, the particle size distribution of microcapsules (MSD) and particle size distribution of soil (PSD) should match after mixing, so that microcapsules will break and release core materials only under external stimuli such as compression, which results in decreasing void ratio of soil. The size of microcapsules should be large enough to make microcapsules retain in voids even under seepage, and meanwhile small enough to keep microcapsules from being ruptured by soil particles. These two competing design purposes coincide with the dual role of soil filters, which play a significant part in the performance of embankment dams. The PSD of filter soil (i.e. soils having a gradation designed to prevent movement of fine base soil by flowing water) is required to be sufficiently small to prevent the migration of base materials (i.e.

DOI: 10.1201/9781003299127-98

the soil adjacent to a filter through which water may pass), whilst sufficiently large to allow the seeping water to flow through the filters without the generation of pore water pressure (Terzaghi 1922).

The effectiveness of filter design, dependent on gradation of the filter and the base material, was investigated experimentally by filter-base combination tests for ascertaining washout of base soil and permeability change (Sherard et al. 1984; Indraratna et al. 1996; Lone et al. 2005). The experimental data were used to develop empirical criteria for designing suitable filters for base soils of various gradations. Most empirical relations were originated from that developed by Terzaghi (1922) and concentrated on given size ratios of base and filter, such as D_{15}/d_{85} (USBR 1987; NRCS 1994). Here, D and d represent the size of filter and base respectively, and D_a or d_a exhibits the percentage by mass the material that is finer than D_a or d_a.

In this study, similar flushing tests are conducted on microcapsules and gravel with different gradations to assess the microcapsules retention in granular materials. The effectiveness of different gravel-microcapsules combinations is validated by acceptable washout amount of microcapsules. An empirical criterion capable of describing microcapsules retention in granular materials is presented and compared with Terzaghi (1922)'s one aimed for successful filter design.

2 MATERIALS, APPARATUS AND TESTING PROGRAM

2.1 *Materials*

Calcium alginate/polydimethylsiloxane (PDMS) microcapsules were selected and synthesized. PDMS were encapsulated in calcium alginate shell by the ionic gelation method (Benavides et al. 2016). Sodium alginate and calcium alginate were utilized to form the shell. PDMS is in a liquid form and its density is 965 kg/m^3. The microcapsules were produced by the following steps: (1) sodium alginate was firstly dissolved in 100 g deionized water. (2) PDMS was added into the sodium alginate solution and emulsified with a homogenizer until a stable oil-water emulsion was formed. The mass of PDMS to water is 10%. (3) The emulsion droplets were then dripped into a calcium chloride solution through a PTFE tube by a syringe pump. (4) The microcapsules were produced and immersed in calcium chloride solution for 24 hours, then rinsed with distilled water and filtered. The microcapsules size distributions (MSDs) were characterized by a dynamic iamge analyzer (Qicpic^{TM}, Sympatec GmbH). Microcapsules range from 0.35-1.80 mm were produced, with specific gravity of approximately 0.965 (BS 1377-2:1990).

Clean granite gravel ranging in size from 2.36 mm to 11.20 mm was mixed with microcapsules for sample preparation. The wide range of size selection was aiming to have different coefficient of uniformity (i.e. C_u). The specific gravity of the granite gravel was 2.65 (BS 1377-2:1990).

2.2 *Apparatus*

The experimental set-up (Figure 1) consists of a cylinder of 180 mm in diameter and 400 mm in height to ensure the internal diameter of the cylinder is at least 12 times the maximum particle size of the soil to be tested (BS 1377-5:1990). A wire mesh (i.e. sieve) of 180 mm in diameter and 2 mm in mesh size was placed at the bottom of the cylinder to support the mixture, and separate gravel and flushed microcapsules. A flowmeter was connected between the inlet and water tank for regulating the inflow of water.

2.3 *Testing program*

Testing was conducted in well-graded and uniform gravel. Both uniform and well-graded gravel was prepared by mechanical sieving to obtain the desired coefficient of uniformity of 1.25 and 2.58-3.82, respectively. The mixtures of gravel and microcapsules were compacted in

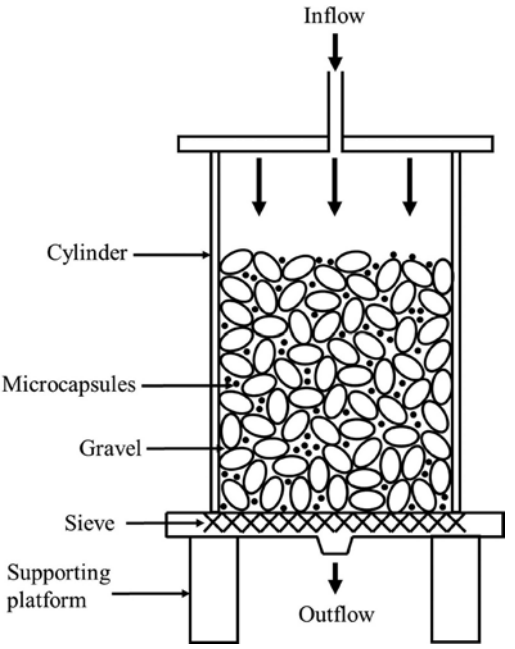

Figure 1. Schematic diagram of flushing test apparatus.

the cylinder in several light tamped layers to reach a required relative density of 50% for ease of comparison. The main gradation features of microcapsules and gravel are presented in Figure 2. As shown in Figure 2(a), only one MSD was matched with three different PSDs of well-graded gravel, in order to keep the size of microcapsules isolated while only changing the sizes of gravel. Conversely, as plotted in Figure 2(b), only one uniformly graded gravel was selected and mixed with three different microcapsules. In total, 4 groups of gravel and 4 groups of microcapsules were combined in the above-mentioned manner to form 6 experimental groups.

The ratio of mass of microcapsules to the mass of gravel was set as 2%, which provided a measurable washout amount. Average water temperature at the time of testing was 24.1°C with a density of 0.9973 g/cm^3, its average pH was 6.35 and its viscosity was approximately 1.0 mPa·s.

The tests were started by a constant downward flow of 9 L/min, with the washout of microcapsules collected at around 20-minute intervals and later weighed after air drying. The test was continued until the washout became constant with time, which usually lasted for 2 hours. After completion, the mixtures were removed and optical microscopy was used to investigate if microcapsules were cracked during sample preparation, flushing and drying. The results of all tests were classified as effective or ineffective. Effective gravel-microcapsules combinations were defined as those able to retain most of the microcapsules under downward flow for 2 hours, with washout of microcapsules less than 5% of the total weight of microcapsules mixed. Conversely, ineffective combinations were stated as those lost excessive amounts of microcapsules after flooding (larger than 5%). This specific value was determined with reference to the washout amount in filter design (Indraratna et al. 1996; Lone et al. 2005). However, it is challenging to establish a critical value of washout for microcapsules due to no previous study conducted on microcapsules retention to data, as well as no clear description of allowable washout of base materials in filters.

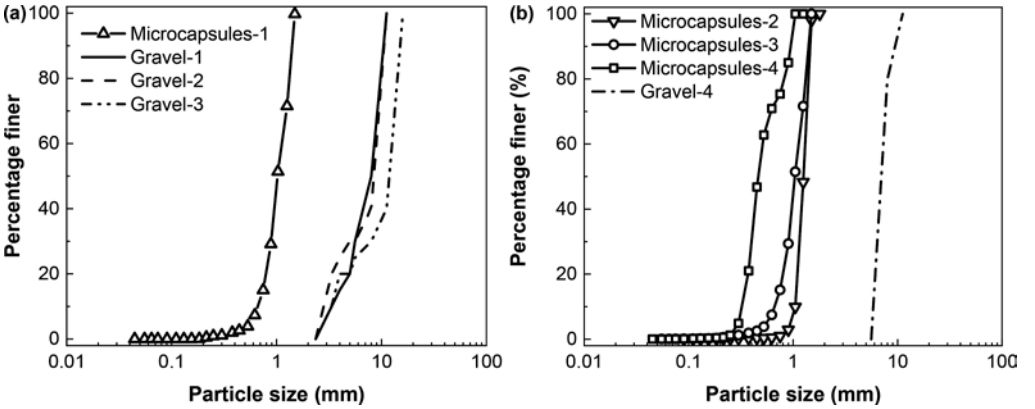

Figure 2. Particle size distributions of microcapsules and gravel for (a) different gravel gradations; (b) different microcapsules gradations.

3 RESULTS AND DISCUSSION

3.1 *Washout and time relationship*

As no obvious cracks of microcapsules were observed for all the mixtures after testing, only the loss of microcapsules was taken into consideration in this study. The relationship of microcapsules washout percentage and elapsed time is drawn in Figure 3, where *M* stands for microcapsules and *G* for gravel. The numbers (i.e. 1, 2, 3 and 4) are in accordance with those shown in Figure 2. In general, a constant washout was attained with time, which demonstrated that a stable mixture structure was established. In Figure 3(a), when the MSD was kept unchanged, gravel with larger D_{15} would result in more washouts of microcapsules, which explained why *M1G2* owned the least washout, while *M1G1* and *M1G3* would have washout larger than 5% (i.e. 5.03% and 6.93% respectively). In Figure 3(b), when the PSD of gravel was kept constant, microcapsules with smaller d_{85} would cause more washout. Also, for all the 6 experiments, the final washout percentage of microcapsules was not remarkable, with values all smaller than 11%. This may be attributed to the low specific gravity of microcapsules, making them difficult to be flushed away compared with heavier base soil in filter.

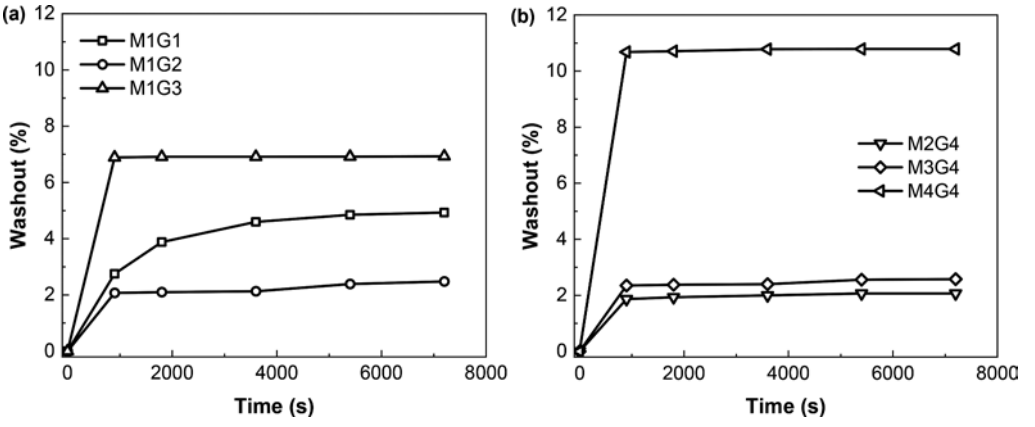

Figure 3. Percentage of washout of microcapsules against time for (a) different gravel gradations; (b) different microcapsules gradations.

3.2 *Empirical criterion*

Both effective and ineffective cases of microcapsules-gravel mixture were drawn in Figure 4 for establishing an empirical criterion to account for microcapsules retention behavior in granular media. The traditional Terzaghi's criterion (i.e. $d_{85}/D_{15} > 4$) could not fit very well with the experimental data, with two effective cases evaluated to be ineffective. If the equation was modified (i.e. $d_{85}/D_{15} > 4.3$), more effective/ineffective cases would locate on both sides of the borderline. The little inaccuracy of this criterion may be due to the judgement of effective/ ineffective cases based on this specific washout amount (i.e. 5%). It is worth mentioning that more experimental data could be conducted to more precisely validate the effectiveness of this empirical equation.

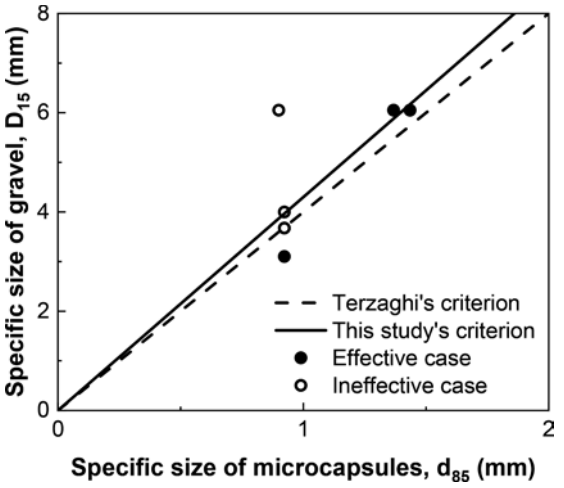

Figure 4. Application of retention criteria to distinguish between effective and ineffective filters.

4 CONCLUSION

Washout tests by changing solely the d_{85} of microcapsules and D_{15} of gravel, were conducted to experimentally investigate the microcapsules retention behavior in gravel by monitoring the loss of microcapsules during water flushing. For this microcapsules-gravel mixture, $d_{85}/D_{15} > 4.3$ is proposed to separate effective and ineffective cases, in order to make more microcapsules retain completely in pores of granular materials for further use. Note that further investigation is needed on well-graded granular materials, and microcapsules of various origins will be required to validate this design criterion.

ABSTRACT: The technology of jet grouting has been used for ground stabilization during construction of various structures for quite a long time. However, the task of developing effective methods of predicting actual geometric and physical-mechanical parameters of soil-cement columns is still urgent. Application of neural networks for assignment of ground-cement column diameters at the design stage can significantly increase the accuracy of assignment of design parameters of ground-cement columns and reduce the cost of design solutions

1 INTRODUCTION

Jet-grouting technology has been used since the 80s of the last century. The essence of the jet grouting technology is to use the energy of a high-pressure jet of cement slurry to destroy and simultaneously mix the soil with the cement slurry in the "mix-in-place" mode. A soilcrete with high strength and deformation characteristics is formed.

Jet grouting technology is widely used to strengthen soils at the base of foundations. Numerical modeling is used. A reinforced base is most often modeled homogeneous, with the given effective characteristics of the deformation modulus, the value of which is largely determined by the deformation modulus of the soil cement and the proportion of the fixed soil mass. These parameters are laid down at the design stage and determine the final constructive and economic efficiency of the selected solution (Modoni et al, 2019; Bayesteha & Sabermahani, 2020).

Figure 1 shows soilcrete columns in the base of the foundation slab at the site in Nizhny Novgorod.

Figure 1. Jet-grouting columns.

DOI: 10.1201/9781003299127-99

2 DESIGN OF JET-GROUTING COLUMNS

One of the main problems in the design of foundations reinforced by the technology of jet grouting is the problem of matching the design parameters of the fixed soil mass to the actual results The strength and diameter parameters of the soilcrete columns are assigned according to the reference tables, as well as based on the experience of the designer.

This method of assigning the design diameter of the soil-cement element has a number of significant drawbacks. The recommended diameter values have a fairly large variation within one type of soil, the effect of the strength characteristics of the soil at the construction site on the diameter of the ground concrete columns is not described. There is also a need to apply large stock coefficients, which leads to an increase in the cost of a technical solution. There is no universal method for calculating the diameter of soil-cement elements. The existing dependencies are empirical in nature and differ significantly from each other (Alexandre Pinto et al., 2016; Zuev et al., 2021).

3 NEURAL NETWORKS TO PREDICT THE DIAMETER

Neural networks can be used to predict the diameter of soil cement columns. Neural network training can be performed based on the results of work on implemented construction projects.

An artificial neural network is a subset of machine learning algorithms that arose when trying to simulate the processes occurring in the human brain during the transmission of signals between biological neurons. Each node (artificial neuron) is connected to other nodes with a certain weight and threshold value. If the output of any node exceeds the threshold value, then this node is activated and sends data to the next level of the network. Otherwise, the data is not transmitted to the next level of the network. Training data is used to train and gradually improve the accuracy of neural networks. The structure of the artificial neuron is shown in Figure 2.

Artificial neural networks consist of nodes forming layers: an input data layer, one or more hidden layers and an output data layer (Yasnitsky, 2016; Milad & Golamreza, 2018).

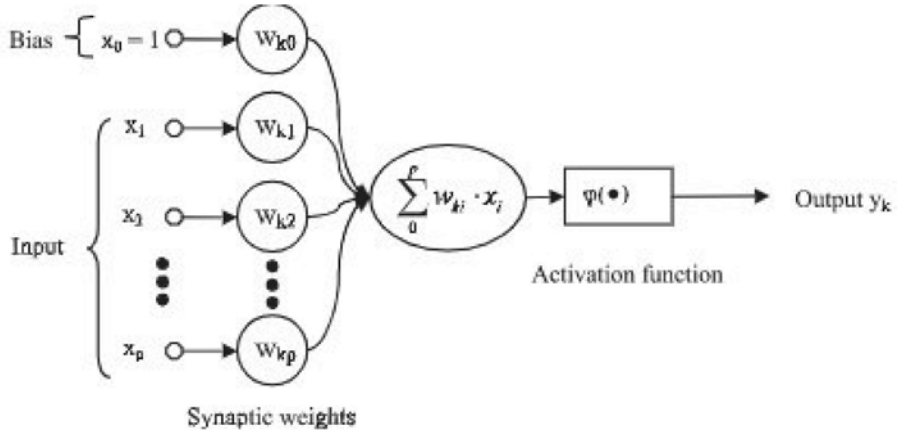

Figure 2. The structure of an artificial neuron.

In general terms, the structure of the designed artificial neural network is shown in Figure 3. We used the following as input parameters:

– Friction angle of soil at the construction site;
– Cohesion of soil at the construction site
– Specific energy of destruction of a jet of cement slurry during jet grouting Eg (MJ/m).

The diameter of the soil-cement element was chosen as the output parameter. The parameters of the physical and mechanical parameters of soils are determined based on the results of standard engineering and geological surveys. The value of the specific fracture energy can be determined by formula (1).

$$E_g = \frac{0.1PQ}{V} \tag{1}$$

where Q – solution consumption (l/min);
P – discharge pressure (Mpa);
V – monitor lifting speed (cm/min).

As part of writing this work, three neural networks were created: using EXCEL software complexes (Neural Excel) and MATLAB, as well as written in the PYTHON programming language.

Data from 38 real objects were selected for neural network training.

The structure of the neural network is shown in Figure 3

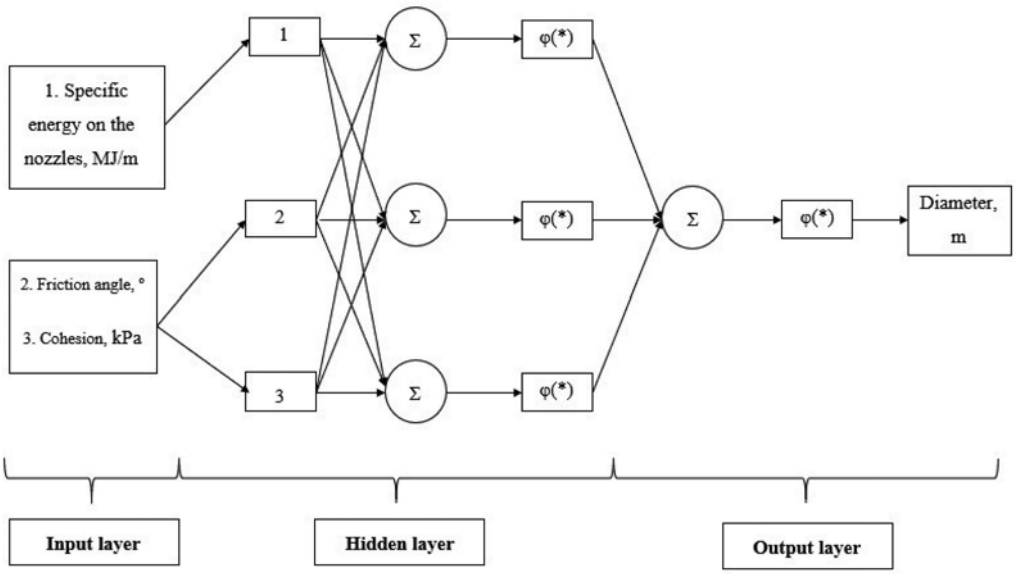

Figure 3. The structure of the designed neural network.

A fragment of the sample of the source data is presented in the Table 1.

The values were normalized in the range from 0 to 1 by interpolation methods relative to the maximum values of the output data. A fragment of the normalized learnings of the training set is presented in Table 2.

Table 1. Multitude of experimental data for neural network training.

№	Types of soil	C, kPa	ϕ, °	Specific energy of destruction, MJ/m	Measured diameter, m
1	Sandy loam plastic	10	16	59,85	2,49
2	Soft-plastic loam	13	13	47,88	1,40
37	Clay semi-hard	20	15	59,85	2,09
38	Dusty sand	1	31	59,85	2,20

Table 2. Multitude of experimental data for neural network training.

		Training set				Result		
		Input			Output			
№	Types of soil	C, kPa	ϕ, °	Specific energy of destruction, MJ/m	Measured diameter, m	EXCEL	MATLAB	PYTHON
1	Sandy loam plastic	0,4	0,52	1,0	0,87	0,88	1,00	0,91
2	Soft-plastic loam	0,52	0,42	0,80	0,49	0,55	0,65	0,61
37	Clay semi-hard	0,8	0,48	1,00	0,73	0,73	0,83	0,75
38	Dusty sand	0,04	1,00	1,00	0,77	0,78	0,90	0,79

4 DISCUSSION

The results of the forecast are shown in Figure 4.

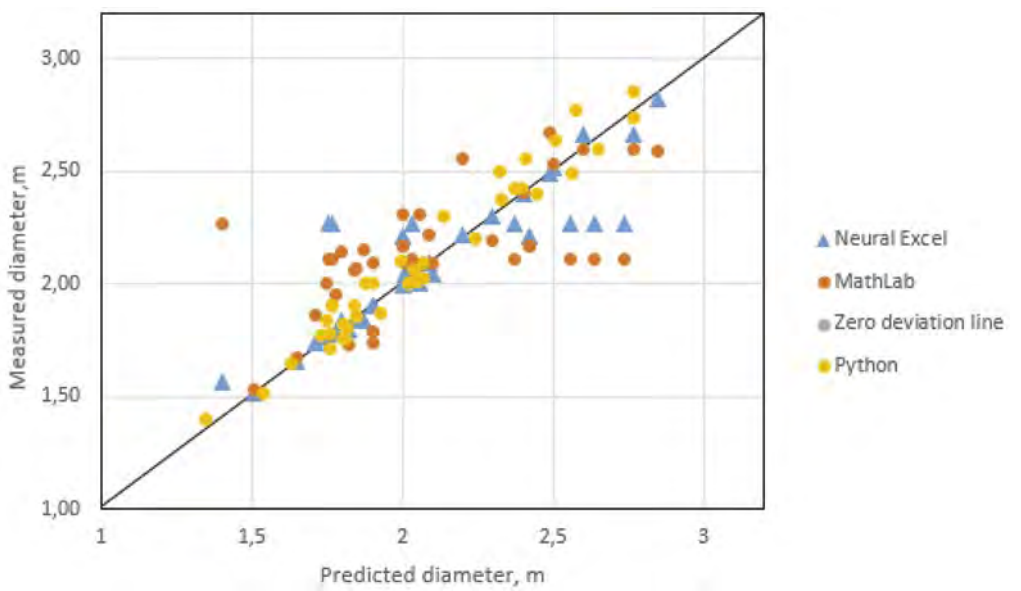

Figure 4. Obtained results.

Based on the results of the performed calculations, a comparative graph was built to evaluate and compare the results (Figure 4)

According to the results of the study, the following conclusions can be drawn

1. The average deviation when using Neural EXCEL was 0,11 m.
2. The average deviation when using MATLAB was 0,22 m.
3. The average deviation when using PYTHON was 0,07 m.

In most cases, the accuracy of the forecast is sufficient to make a project decision. Significant deviation of individual values can be caused by insufficient training of the neural network. A neural network written in Python is the most accurate among those presented.

5 CONCLUSION

Neural networks can be used to assign the diameter of soil-cement columns made by jet grouting technology in the geological conditions of the Russian Federation.

This work can be the basis for the development of new design schemes for strengthening soils using jet grouting technology.

Time-dependent settlement behaviour of clayey soil treated with deep cement mixed column

S. Choudhary, M.J. Singh & L. Borana
Indian Institute of Technology, Indore, India

ABSTRACT: In soft and clayey soils, application of deep cement mixing (DCM) columns as an effective ground improvement technique is gaining popularity in comparison to other conventional methods for several reasons such as simple methodology, cost effectiveness, rapid construction and high stiffness end products. However, past studies pertaining to DCM improved composite soil reported limited information about the time-dependent consolidation settlement behaviour. To develop a better understanding of the time-dependent settlement behaviour of the DCM improved composite soil, an experimental setup is developed in this study. From the results, it is found that the creep parameters determined during the primary and secondary stage of consolidation decrease with increase of the loading period. Further observations and results of the distribution behaviour of creep parameters before and post failure of DCM column are presented and comprehensively discussed in this study.

Keywords: Bearing capacity, consolidation settlement, creep parameters, deep cement mixing

1 INTRODUCTION

Expansive clay soils create severe problems for civil infrastructures and geotechnical structures due to the swelling and shrinkage behaviour of the minerals present in them. To mitigate or reduce the severity of the mentioned problems, various soil improvement techniques were employed by the researchers. Out of all the conventional methods, in situ soil-cement mixing has gained a lot of popularity recently and it is said to be one of the most suitable and effective techniques owing to its easy, economic, and rapid construction methodology (Kitazume and Terashi n.d., Chai et al. 2006, Fang and Yin 2007, Yin et al. 2022). The Deep Cement Mixing (DCM) technique was first employed at the Port and Harbour Research Institute (PHRI) in Japan in the 1970s. The PHRI developed the technique as a solution to improve the stability of soft soils for port and harbor facilities. DCM involves injecting cement slurry into soft soil to create columns of cement-stabilized soil. Several researchers attempted to study the behavior of strength gain and stiffness of the cement-stabilized soil columns created through DCM. These studies have examined various factors such as the curing time, the properties of the injected cement slurry, the spacing between the columns, and the effect of environmental conditions on the strength and stiffness of the soil columns (Fang et al. 2001, Jamsawang et al. 2017, Pham et al. 2017, Yin et al. 2022). However, very little emphasis was given to the time-dependent settlement behaviour of the DCM-treated clayey soil.

In this study, a small-scale physical model was developed and laboratory tests were carried out with varying vertical stresses, cement content, and area ratio to analyze the time-dependent settlement behaviour of the clayey soil treated with a DCM column installed at the centre of the model. The settlement behaviour of the composite soil and the stress distribution is recorded and monitored by using Linear Variable Differential Transformers (LVDT) installed at a specific location in the strongbox and analyzed the settlement behaviour of the composite soil using the power law proposed by (Venda Oliveira et al. 2011) Clay 1985.

DOI: 10.1201/9781003299127-100

2 LITERATURE STUDY

The DCM method comprises of mechanical mixing of soil present in the field at a natural state with cementing agents either in wet form or powder form, as per the requirement, to form a soil-cement column with high stiffness and strength qualities (Kitazume and Terashi n.d., Horpibulsuk et al. 2012b). The stabilization of clayey soil with cement mixing is due to the cementitious bond developed between the hydration products of the cement in aluminate and silicate form and the soil particles. Due to this interaction, the interlayer and inter-micellar swelling of the clayey soil particles reduced significantly (Fang and Yin 2007, Horpibulsuk et al. 2012a, Jamsawang et al. 2017). However, several factors can influence the strength of the soil-cement-treated clayey soil like characteristics of soil, characteristics of the binder, curing conditions, and mixing conditions (Kitazume and Terashi n.d., Yin et al. 2022) which directly affects the strength and stiffness properties of the DCM columns, but there has been very limited research done to understand the long-term deformation of the DCM columns and settlement of the surrounding grounds (Fang et al. 2001, Chai et al. 2006, Fan et al. 2018). Some researchers (Mesri and Choi 1987, Yang 2019) emphasized creep as a progressive and continuous deformation under constant effective stress whereas some other researchers (Yin 1999, Yin et al. 2017, Bi et al. 2019) suggested that creep phenomena occur during the entire consolidation process (including primary and secondary consolidation both). Consolidation is defined as a combined effect of both stress and time-dependent deformation, in which saturated soil exhibits a continuous volumetric reduction under static loading (Singh et al. 2020).

3 MATERIALS AND SAMPLE PREPARATION

3.1 *Soil preparation*

3.1.1 *Clayey soil*

The natural soil used in this study was procured from an excavation site in Indore which has a specific gravity of 2.6 and a liquid limit of 73.4 % respectively. Based on the Unified Soil Classification System (USCS) and AASHTO soil classification system, the soil is classified as highly expansive clay. This soil was passed through a 2 mm sieve size and oven dried for 24 hours. Water was added to this soil and mixed thoroughly to obtain a homogenous slurry consistency by adding 20.32 litres of water in 20.07 kg of oven-dry soil to make water content about 1.45 times the liquid limit.

3.1.2 *Sand for drainage purpose*

The sand was used in this study to provide drainage at the top and bottom of the experimental setup. The sand used was procured from the Narmada basin with a specific gravity of 2.45. The sand was kept saturated so that no moisture loss takes place from the clay slurry.

3.2 *DCM column preparation*

In DCM columns, dry PPC cement having a specific gravity of 3.10 is added at 20 % by weight of the dry soil and then mixed with appropriate water content to obtain slurry-type consistency. The mix design of soil cement is based on mixtures developed in previous studies (Chai et al. 2006, Horpibulsuk et al. 2010, 2012a, Fan et al. 2018, Yin et al. 2022). The prepared soil-cement slurry is poured into a cylindrical high-density polymer split mold (HDPSM) having an internal diameter of 50 mm and thickness and kept overnight to get matured and achieve appreciable strength to get de-mold further. The sample is wet-cured for 30 days in the water tanks and then it was installed in the cylindrical strongbox after the completion of the pre-consolidation period of the clay slurry.

4 METHODOLOGY

A cylindrical strongbox made of stainless steel having an internal diameter of 310 mm and height of 665 mm is used for this experimental research. 11kg of saturated sand was placed in the cylindrical strongbox up to the height of 50 mm placed in the upper and lower portion clay slurry. It acts as a uniform bed and also prevents moisture change between sand and the clay slurry during the experiment. The sand layer was lightly compacted by using a rammer and leveled with the help of a palette knife. One hollow casing of the same dimensions as the HDPSM is placed at the centre of the strongbox to create space for the installation of the DCM column in the later stage. A layer of geo-membrane filter was applied on top of the clay slurry before placing another layer of saturated sand of the same height so that there was no intermixing of sand and clay slurry. The sand layer was leveled and static loads are applied for pre-consolidation for 44 days. A rigid perforated plate is placed on the top of the soil sample for uniform distribution of load to the soil sample and soil-cement column. After the completion of the pre-consolidation period, the loads were removed and the recorded height of the clay is 329 mm. Further, the hollow casing is pulled out carefully without disturbing the surrounding soil. The DCM column was placed in the same place and covered with a sand layer. LVDT was also installed at a certain location above the upper sand layer as observed in Figure 1. Further loads are applied for 15 days, 10 days, and 15 days with an increment of 10 kPa.

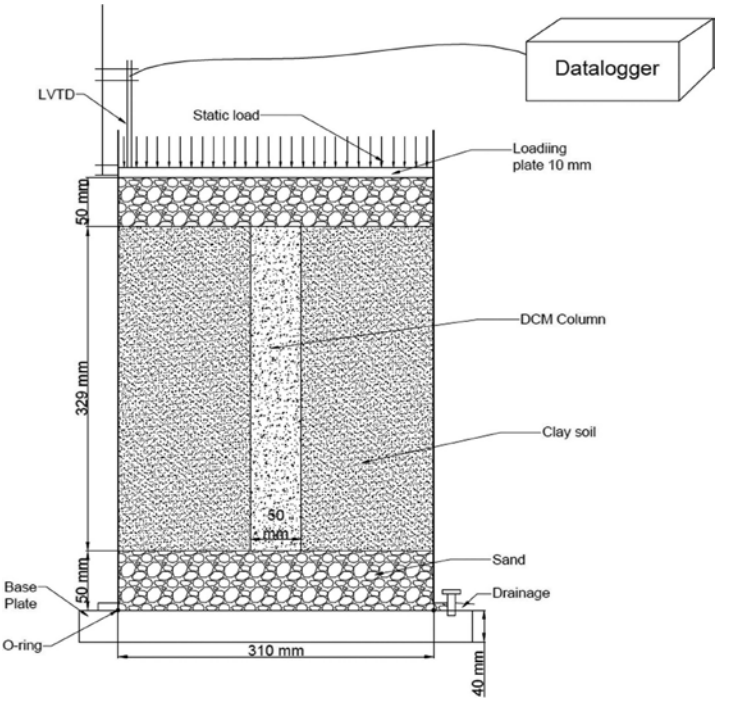

Figure 1. Physical model setup.

5 RESULT AND DISCUSSION

A power law model was proposed by Briaud and Garland (1985) to describe the rate of loading behaviour on piles of clay. It has been extended by the author to present the time-dependent behaviour of various sources of soils on diversified data. The model is written as below:

$$\frac{s}{s_1} = \left(\frac{t}{t_1}\right)^n$$

where, s and t signify the deformation (settlement, strain, etc.) and corresponding time respectively. The s_1 is the value of deformations observed at reference time t_1. The reference time could be either 1 second, 1 minute, or 1 day or any specific time, and n is the viscous exponent (Bi et al. 2019, Johnson Singh et al. 2022, Singh et al. 2022).

In the above equation, the viscous exponent can be derived from the slope of the settlement curves as illustrated in Figure 2. It is considered that after the completion of the primary consolidation, only creep settlement takes place. Therefore, the slope of the secondary line i.e., n_{cr} includes only creep and the corresponding angle can be denoted by β. However, during the primary consolidation, both creep and expulsion of excess pore water pressure take place. Therefore, the slope of the primary consolidation i.e., n_{both} includes both consolidation and creep. If the angle corresponding to n_{both} is α, the n value only including consolidation (n_{con}) during the primary consolidation will be (α − β). The n value n_{con} can be calculated by Equation 1.

$$\begin{aligned} n_{con} &= \tan(\alpha - \beta) \\ &= \frac{\tan(\alpha) - \tan(\beta)}{1 + \tan(\alpha) * \tan(\beta)} = \frac{n_{both} - n_{cr}}{1 + n_{both} * n_{cr}} \end{aligned} \tag{1}$$

Here, the parameters n_{both} and n_{cr} are small quantities and their products are quite small and negligible therefore, the above equation can be simplified as follows;

$$n_{con} = \frac{n_{both} - n_{cr}}{1 + n_{both} * n_{cr}} \approx n_{both} - n_{cr}$$

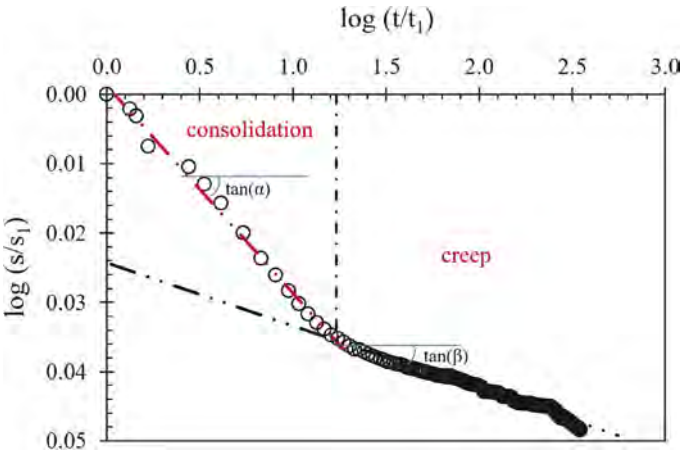

Figure 2. Different phases of settlement behaviour.

A reference time of 180 mins is assumed in this study, other reference time below 180 mins is also tried, however, a representable slope of the primary consolidation period is not obtained. During the pre-consolidation period the n_{both}, $n_{cr,}$ and n_{con} are respectively 0.0299, 0.0091, and 0.0208. After the installation of the DCM column, the n_{both}, $n_{cr,}$ and n_{con} are 0.098, 0.021, and 0.077 respectively. In the next loading period, failure of the DCM column takes place, therefore significant reduction settlement is observed. Therefore, the n_{both}, $n_{cr,}$ and n_{con} are observed to be 0.209, 0.079, and 0.130 respectively. During the last load

increment, the corresponding values of the n_{both}, $n_{cr,}$ and n_{con} are respectively 0.0083, 0.0034, and 0.00049. It is observed that after the installation of the DCM column, the creep parameters are observed to be increased and maximum values are observed during the failure period of the DCM column. After the failure of the DCM column, a significant reduction of void ratio is observed in a short period as illustrated in Figure 3. This might be due to enhanced excess pore water pressure dissipation by the DCM column (Fang and Yin 2007, Pham et al. 2017).

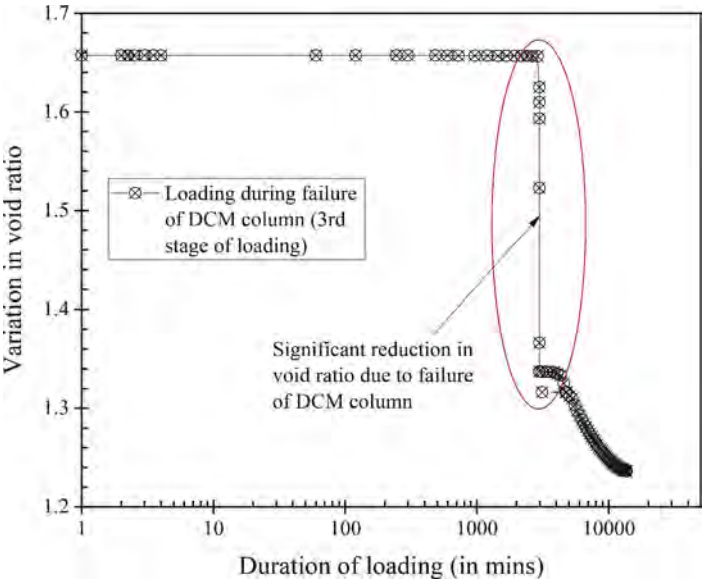

Figure 3. Significant reduction of void ratio during the third stage of loading due to DCM column breakage.

6 CONCLUSION

In this study, an indoor physical model of the DCM column installed in the clayey soil is developed to perform the experimental analysis of the time-dependent settlement behaviour at different phases for the clayey soil treated with a DCM column. Based on the experimental results achieved, the following conclusions are drawn.

1. The creep parameters determined during the primary, and secondary stages of consolidation are observed to be reduced with the increase of the loading period. However, with the failure of the DCM column, there is a sudden rise in these parameters, which might be due to the sudden transfer of load from the DCM column to the surrounding soil.
2. It can be noted that the proposed power law model can assess the creep parameters during the primary consolidation and secondary consolidation. However, the selection of proper reference time is a prerequisite for getting a representable slope of the primary consolidation period. Additionally, it can represent the concept of "creep as the rate of loading" in which the viscous exponent of the model represents the process of time-dependent settlement behaviour of soil under applied external loadings.
3. In this study, major emphasis is given to the time-dependent settlement of the composite soil. However, there are opportunities to enhance the current understanding and investigation of various parameters, such as friction, settlement behavior of column and overlying soil, the effect of rate of mixing, long-term durability, and effectiveness of soil-cement

columns. Further investigation into the suitability of the model for predicting the settlement behavior of DCM columns also needs to be investigated.

The effect of lime additives on the improvement of swelling soils in geotechnical conditions of Syrian Arab Republic

L. Awwad
Department of Geotechnical Engineering, Saint-Petersburg State University of Architecture and Civil Engineering, Russia

ABSTRACT: Clay soils are widespread in Syria. Due to their shortcomings, the need for stabilization is becoming increasingly urgent. The improvement of swelling soils is becoming very important for the archaeological sites belonging to the ancient civilizations of Syria. These buildings are mostly lightly loaded structures, consisting of domes and stone walls based on strip foundations. Therefore, expansive soils can cause significant damage to these structures. This paper presents some historical monuments in Syria with a description of their typical foundations and the main geotechnical parameters. In this paper, the effect of additives of mixtures of polypropylene fibers with lime on improving the building properties of swelling soils will be discussed. The aim of using this type of material is to improve the performance of the ground without affecting the historical mission of the building. Additives of mixtures of polypropylene fibers with lime reduce plasticity index, increases workability and shrinkage limit, reduces shrinkage cracking, eliminates almost all swelling problems, and increases the soil strength.

1 INTRODUCTION

The Syrian Arab Republic is located on the west wing of the Fertile Crescent in an important location between the East and the West. Syria has seen some of the oldest and most important civilizations as evidenced by the enormous archaeological discoveries, some of which date back to over 8,000 years BC. In Syria, there are more than 4,500 archaeological sites dated back to different periods of history. Archaeologists consider Syria the center of one of the oldest civilizations on earth, wherein was the beginning of human settlement, the first urban planning, and the development of the alphabet. In Syria were the first cities in history, such as the ancient kingdom of Ebla, from 2500 to 2400 BC, the Kingdom of Mary about 2900 BC, and Palmyra which flourished in the second half of the first century BC.

2 CONSTRUCTION AND FOUNDATION TYPES OF BUILDINGS

Most of the historic buildings and monuments in Syria are lightly loaded structures and consist mainly of domes, arches, and stone walls based on strip stone foundations that are seated directly on the soil, therefore, expansive soils are widely spread in Syria could cause considerable damage to these structures.

The main reason for soil movement is a change in soil moisture, which is occurred either artificially by construction works, or naturally because of a change in rainfall between summer and winter (Corley. J.B, Dietz. and Schürmann 2006, Ulitsky 2017, Awwad, Gruzin 2019). We will set some examples of historic buildings and monuments in Syria, and how they expose to damage because of soil movement.

DOI: 10.1201/9781003299127-101

2.1 *Al-Azem Palace*

Al-Azem Palace is located south of the Umayyad Mosque, Beside Albzoriah market, and it is one of the most important archaeological palaces in Syria. It was built by Asaad Pasha Al-Azem in 1749 when he was the ruler of the territory of Damascus and its extension in the Ottoman period.

This palace is one of the most important huge historic buildings in the old city of Damascus, and one of the best examples of early architecture for large Damascene houses where it extends over an area of 5500 square meters.

The Azem palace was divided into Haramlik (private family aria), Salamlik (business public reception area for the male head of the house and his clients or guests), Khadamlik (servants), and Hammam (baths), each with relating courtyards, fountains, and gardens. Within these spaces, the palace hosted approximately sixteen great halls, nineteen rooms on the ground floor, nine rooms on the second story, three Iwans, a basement for storage, a praying wing, Stable, and carriage parking.

Figure 1. Al-Azem Palace.

Figure 2. Waves in the soil surface under slabs.

2.1.1 *Structural description*

Al-Azem Palace walls of the interior and exterior faces were built with lime-colored stone as telescopic rows separated by basalt black stone rows which its dimension about 80 cm. The lime mortar was used to bond the stones. Roofs are made from wood and mud. Stone walls, stone arches, stone cupolas, and stone columns were used to make the palace spaces and transfer roofs loads to the foundations. Stone walls and columns are based on strip stone foundations that are seated directly on the soil. It is the only remaining palace of rulers palaces of Damascus, which is considered the oldest continuously inhabited city in history.

2.1.2 *Cracks appearance*

It was observed in the recent few years the appearance of cracks in the walls of some Al-Azem Palace halls. Engineering analysis and evaluation of this phenomenon stated that there were two kinds of cracks: vertical cracks resulted from a change in temperatures, and cracks resulted from soil movement, they are inclined and not stable in width.

The Ministry of Culture - General Directorate of heritage and Museums who is responsible for the palace implemented a project for maintenance and restoration of the Al-Azem Palace (Study of Al-Azem Palace 2010). Vertical movement of the Palace was observed during (2009-2010), there were inhomogeneous vertical movements in most of the palace parts and most of these movements are settlements with a total value of movement is between 7 mm to 2.3 mm.

2.1.3 *Maintenance and restoration*

Geotechnical situation: Al-Azem Palace was constructed of load-bearing walls based on strip stone foundations seated directly on the soil. The stone foundations are consisting of rectangular stones bond by lime mortar. Its depth is 3.25 m. Soil investigations showed that the soil in Al-Azem Palace is clayey gravel (GC) and was affected by wastewater.

Figure 3. Cracks in Al-Azem Palace.

Figure 4. Cracks in the cupolas.

It was predicted that the main reasons for the appeared cracks are both of reduction in the groundwater level in the valley of the Barada River, which is close to the Al-Azem Palace, and water or wastewater leakage from surrounding areas.

The implemented method of restoration and maintenance of foundation in Al-Azem Palace was by micro reinforced concrete piles with a diameter of 8 cm, which is connected to the foundation stone by metal bars and concrete.

Although this method of restoration and maintenance of foundations is supporting the foundation and transferring the loads to another layer of soil, which is more depth from the ground, surface and lesser exposure to the effect of water content changes. But it used modern materials (metal and concrete) which is different from the foundation materials and it could lead to detract the building's historical character (Zhussupbekov 2013, Awwad L 2016, Awwad T, Chekaeva R 2019).

3 SOIL IMPROVEMENT

3.1 *Suggested methods of soil improvement with lime (lime stabilization)*

Clay soils are widespread in Syria. Due to their shortcomings, the need for stabilization is becoming increasingly urgent. The improvement of swelling soils is becoming very important for the archaeological sites belonging to the ancient civilizations of Syria. These buildings are mostly lightly loaded structures, consisting of domes and stone walls based on strip foundations. Therefore, expansive soils can cause significant damage to these structures.

Lime is an excellent choice for short-term modification of soil, and it can modify almost all fine-grained soils, but the most dramatic improvement occurs in clay soils of moderate to high plasticity. Modification occurs because calcium cations supplied by the hydrated lime replace the cations normally present on the surface of the clay mineral, promoted by the high pH environment of the lime-water system. Thus, the clay surface mineralogy is altered, producing the following benefits: additives of mixtures of polypropylene fibers with lime reduces plasticity index, increases workability and shrinkage limit, reduces shrinkage cracking, eliminates almost all swelling problems, and increases the soil strength. The aim of using this type of material is to improve the performance of the ground without affecting the historical mission of the building.

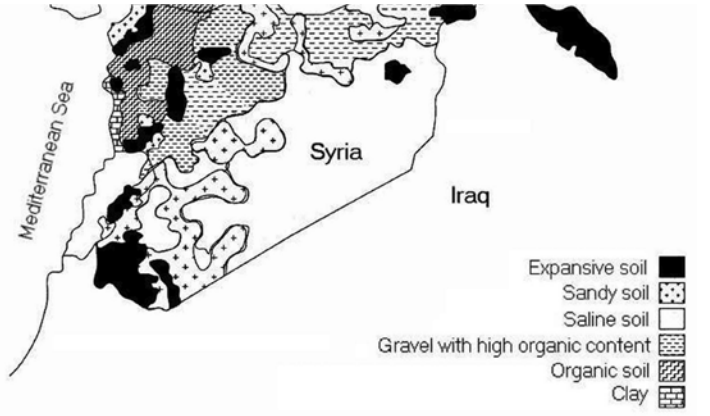

Figure 5. Location of clayey soils in Syria.

3.2 *Laboratory experiments*

A series of laboratory experiments was made on the influence of additives of mixtures of polypropylene fibers with lime on improving the building properties of swelling clay soil.

Figure 6. Laboratory experiments.

Lime was brought from the lime quarries in the province of Hama as limestone and ground with a ball mill at the Adra cement plant, and it was packed in tightly closed bags to isolate it from moisture and transported to the study site.

Table 1. Lime properties (local limestone).

Chemical analysis	
CaO	85.74 %
Ca(OH)2	13.49 %
CaCO3	0,17 %

The soil was mixed with additives in various weight ratios of both materials. Experiments on the physical and mechanical properties of the soil were made on 12 soil samples with different proportions of polypropylene fibers and lime as shown in the table.

Table 2. Laboratory experiment program.

№	1	2	3	4	5	6	7	8	9	10	11	12
lime %	2	5	8	2	5	8	2	5	8	8	0	0
Fibers %	0,05	0,05	0,05	0,15	0,15	0,15	0,25	0,25	0,25	0	0,25	0

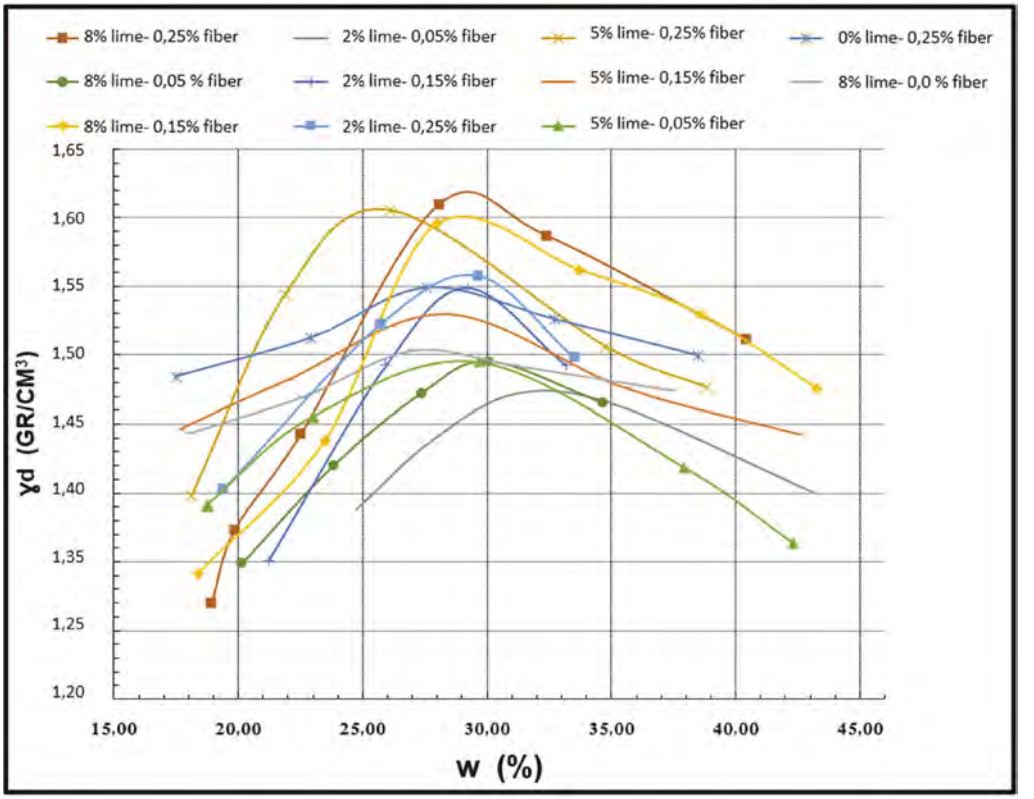

Figure 7. Maximum dry density and optimum moisture content of the soil.

4 CONCLUSIONS

Deciding the best method to improve the soil should take these following steps; a full architecture study for the building, geological and geotechnical surveys, historical study, and constant consultant support to choose the best method for restoring the building without changing its task or character. Using additives of mixtures of polypropylene fibers with lime to improve the soil considered one of the important ways to support and strengthening without harming the historical value.

Using additives of mixtures of polypropylene fibers with lime piles lead to reduce the variation of stress in soft soil after installation the materials and increase the soil strength. Besides the strength, the aspect of swelling and shrinkage improved expansive soil need to be studied in detail.

Insights into 3D printing of polypropylene geocells

Prerana Krishnaraj
Research Scholar, Indian Institute of Science, Bangalore, India

G.M. Latha
Professor, Indian Institute of Science, Bangalore, India

ABSTRACT: Geocells are three-dimensional interconnected polymeric cells filled with soil. 3D printing of geocells has several benefits including control on surface features and tensile strength of the geocells. This helps in controlled laboratory testing of scaled-down geocells and geocell reinforced soil to better quantify their performance benefits. In this study, laboratory-scale geocells of smaller dimensions and low strength were manufactured through 3D printing and ultrasonic welding and tested for their mechanical response. Polypropylene sheets were printed using Fused Deposition Modelling (FDM) based 3D printer. These polypropylene sheets were then ultrasonically welded to form geocells. A horn and table mounting apparatus were designed to facilitate the welding of the sheets. The effects of angle of printing and speed of printing on material tensile strength and geocell-sand interface properties were studied. Results showed that angle of printing is the most influencing parameter on the mechanical properties of the geocells.

1 INTRODUCTION

Geocells were initially developed by US Army of Corps in 1975 (Webster (1979)). They are the class of geosynthetics which are three-dimensional in nature. Geocells consist of interconnected cells filled with soil. The improvement in the properties of the soil due to the inclusion of the geocells can be attributed to interlocking, friction and confinement. The shear strength improvement in the soil, when reinforced with geocells, is superior to that of planar reinforcements and fibre reinforcements (Latha and Somwanshi (2009); Latha and Murthy (2007); Dash et al. (2004)). Hence, numerous experimental analyses were carried out to understand the behaviour of the geocell reinforced soil. Experimental analyses were carried out through laboratory element tests and model tests.

In conducting scaled model tests or laboratory tests of geocell reinforced geomaterial, the unavailability of geocell material of desired scaled strength properties to represent the field conditions is a major drawback. 3D printing can provide a very efficient and time saving method for obtaining geocell material of desired strength characteristics. If the sensitivity and relation of various printing parameters with respect to the strength and friction characteristics of the fabricated material are established, it can be a very useful technique to aid model testing of geosynthetic reinforced geomaterials.

3D printing is the process of manufacturing material using 3D model data one layer at a time (Campbell et al. (2011)). 3D printing involves drawing the 3D sketch of the model using any appropriate software and converting it into an STL (Stereolithography language) file (Wong and Hernendez (2012)). The printer will print one layer at a time to form the required model. The 3D printing of the polymeric components is mostly carried out using the Fused Deposition Method (FDM) based printers (Vaezi et al. (2013)). It works on extrusion principle where the extruded material is deposited on the flat base to form a 2D layer deposition one over the other to form a 3D object. In this technique, the filaments of the thermoplastics are melted and extruded through the heated nozzle.

DOI: 10.1201/9781003299127-102

2 METHODOLOGY

2.1 *3D printing*

Fused Deposition Modelling (FDM) based 3D printer was used to manufacture polymer sheets used to form the geocells. The Polypropylene filaments were used to print polypropylene sheets of the required dimensions. The polypropylene filaments were heated and were ejected through an ejector of circular shape. The printing angle, printing speed and number of layers of filament deposition could be controlled. In this study, single layer of deposition 0.2 mm was considered. Figure1 gives the schematic representation of the different angles of printing considered in this study.

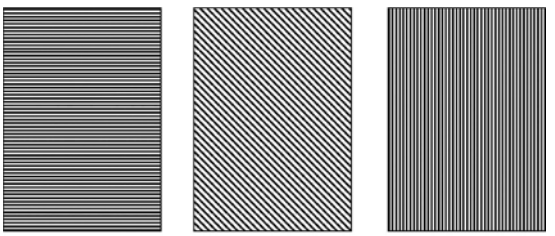

Figure 1. Orientation of printing (a) 0° (b) 45° (c) 90°.

2.2 *Ultrasonic welding*

The 3D printed polypropylene sheets were then ultrasonically welded to form geocell pockets of required dimensions. The ultrasonic welding technique was incorporated instead of stitching or glueing to better represent the actual field geocells. The seam strength could be varied by controlling the input air pressure and also welding time and hold time of the horn of the ultrasonic welding machine

2.3 *Tensile strength tests*

The tensile strength tests were conducted using the Universal Testing Machine (UTM) according to the ASTM D882-18 on the 3D printed sheets of width 0.05 m and grip length of 0.1 m. The samples were strained at a rate of 10% per minute. The tests were conducted to understand the effects of angle of printing and speed of printing on the tensile strength of sheets. The tests were conducted until the axial strain reaches 30 % or until the sample fails, whichever occurs first.

3 RESULTS

3.1 *Effects of printing parameters on tensile strength of the material*

3.1.1 *Effect of speed of printing*

The variation of the tensile strength per unit length with axial strain was plotted. Figure2 shows the variation of the tensile strength with axial strain for the sheets formed at the angle of printing of 45 degrees for different values of the printing speed. It can be seen that the peak tensile strength obtained for the speed of printing of 30 mm/s is higher as compared to that of 20 mm/s and 40 mm/s. Further, Young's modulus obtained from the graph were 378 MPa, 411 MPa and 346 MPa for printing speeds of 20 mm/s, 30 mm/s and 40 mm/s respectively. From the results, it can be seen that the speed of printing of 30 mm/s is very effective in producing polypropylene sheets of high tensile strength. Further analyses were carried out considering the speed of printing of 30 mm/s.

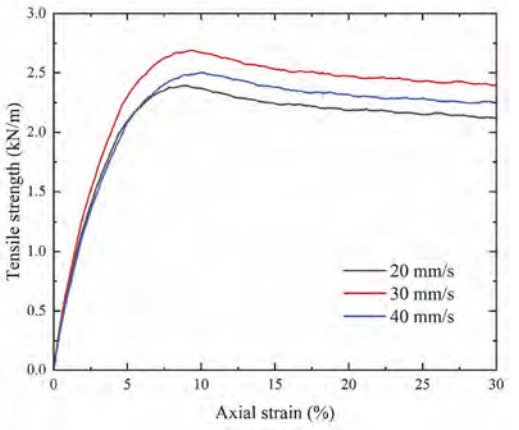

Figure 2. The variation of the tensile strength with axial strain for different printing speeds.

3.1.2 *Effect of angle of printing*

The printing angles considered in the study were 0°, 45° and 90° printed at a speed of 30 mm/s. The variation of the tensile strength with axial strain for different angles of printing is plotted in Figure3. It can be seen that the peak tensile strength is highest for the sheets obtained from the angle of printing of 45°. Young's modulus of 278 MPa, 411 MPa and 314 MPa were obtained for the angle of printing of 0°, 45° and 90° respectively.

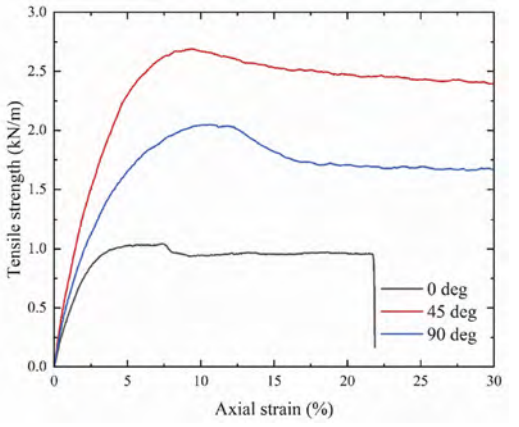

Figure 3. The variation of the tensile strength with axial strain for different printing angles.

3.2 *Interface shear tests*

Interface shear tests were conducted to understand the effects of printing parameters on the interface cohesion and interface friction properties. The polypropylene sheet is fixed to the base plate of the shearing apparatus. A movable shear box of dimensions 17 cm by 17 cm was filled with sand and placed over the 3D printed polypropylene sheet. The box was moved at a rate of 1mm/min over the polypropylene sheet. The peak shear stress for different values of the normal stresses was calculated. The variation of the peak shear stress with normal stress was plotted for three different values of the normal stress. The intercept of the plot gives the interface cohesion value, and the slope of the plot gives the value of interface friction. The interface direct shear tests were conducted on the 3D printed polymeric sheet obtained by maintaining the speed of printing of 30 mm/s as the tensile strength test results show that they

have the highest tensile strength. Table1 gives the values of the cohesion and the friction angle of the sand as well as the interface cohesion and friction angle of the sand-polypropylene sheet interface for different printing angles.

Table 1. Interface cohesion and Interface cohesion for different interfaces.

Interface	Cohesion(kPa)	Friction angle (deg.)
Sand-Sand	0.6	37.4
Sand-A0PP	1.5	25.45
Sand-A45PP	3.73	35.2
Sand-A90PP	3.32	34.04

A0PP: Printing angle 0° A45PP: Printing angle 45° A90PP: Printing angle 90°

3.3 *Peel strength of ultrasonically welded joint*

The ultrasonic welding of polypropylene sheets was carried out. The peel strength of the ultrasonically welded joints was carried out in the UTM. It was found that the peel strength of the welded joints was 90% to 95% of the ultimate tensile strength of the parent material indicating that the welding process was able to produce joints of sufficient strength.

4 CONCLUSIONS

- The effect of speed of printing on the ultimate tensile strength of the polypropylene sheets was found to be not very significant. The sheets printed at a speed of 30 mm/s displayed the highest ultimate tensile strength.
- The sheets printed at 45° angle showed higher ultimate tensile strength as compared to the ones printed at 0° and 90°. The variation in the ultimate tensile strength of the polypropylene sheet was significantly controlled by the angle of printing.
- The interface shear tests results show that the interface cohesion and friction angle between the sand and the polypropylene sheet was highest for the sheets printed at an angle of 45°
- The ultrasonically welded joints had a peel strength ranging between 90% to 95% of the ultimate tensile strength of the parent material.

Field pullout testing of geogrid embedded in pond ash at a low normal stress

B.K. Karnamprabhakara
Post-Doctoral fellow, IIT Hyderabad, Kandi, Sangareddy

U. Balunaini
Professor, IIT Hyderabad, Kandi, Sangareddy

ABSTRACT: Pullout interaction between the geogrid reinforcement and the fill material is one of the key factors in the design of Mechanically Stabilised Earth (MSE) walls. It is even more intriguing to understand the pullout interaction behavior when the fill material is a non-conventional fill material such as pond ash. The pullout resistance of the geogrid is typically defined in terms of the pullout resistance factors (F^*) and obtained from laboratory testing. Though it is uncommon to conduct field pullout testing on geogrids, it is ideal to study the pullout resistance of the geogrids in the field conditions. This case study presents field pullout testing conducted using a polyester uniaxial geogrid embedded at a depth of 0.8m (i.e., corresponding to a normal stress of ~12 kPa) in pond ash as fill material at a MSE wall construction site near Vijayawada, Andhra Pradesh, India. The field pullout resistance was found to be closer to laboratory test result under the normal stress of ~17 kPa at a normalized pullout displacement of 4%.

1 INTRODUCTION

The interaction of geogrid with the fill material varies with the orientation of geogrid connected to the facia of the reinforced retaining wall. The two commonly used facia are precast modular block facia and precast concrete panel facia. In block facia, one layer of geogrid are rolled over continuously and connected with the block facia over the fill material for the required length. In concrete panel facia, a given width of geogrids are connected through tie-hook arrangement within the facia and rolled over it to a certain length or the entire length. When geogrids are rolled over the entire length, they form an overlapping arrangement (refer to Figure 1). During the rolling over of geogrids through the hook, the width of the geogrid varies from 1B at the hook side to 2B at the other end. However, it is a common practice to conduct laboratory pullout testing on one-layer of geogrid embedded in the backfill according to ASTM D6706 (as shown in red dotted lines in Figure 1). This methodology may result in over conservatism in the estimation of pullout resistance of the geogrids used in the backfill behind the retaining walls with concrete panel facia as this procedure does not account for the overlapping effect of geogrid reinforcement (as shown in green dotted lines in the Figure 1), but simply considers the average width of the reinforcement.

There are no studies available on the effect of overlapping of geogrid reinforcement behind the concrete panel facia. On the other side, there is a significant rise in the number of mechanically stabilized structures using pond ash as a backfill material in India (Karnamprabhakara et al. 2021, Pant 2019a, b). Authors of this study have extensively worked on the feasibility of using pond ash from the same source as a backfill material, and the effect of tensile strength and aperture opening on the pullout resistance of the geogrid as per ASTM D6706 (Karnamprabhakara et al. 2021). However, the effect of overlapping of geogrids behind the concrete panel with pond ash as backfill material is yet to be explored.

DOI: 10.1201/9781003299127-103

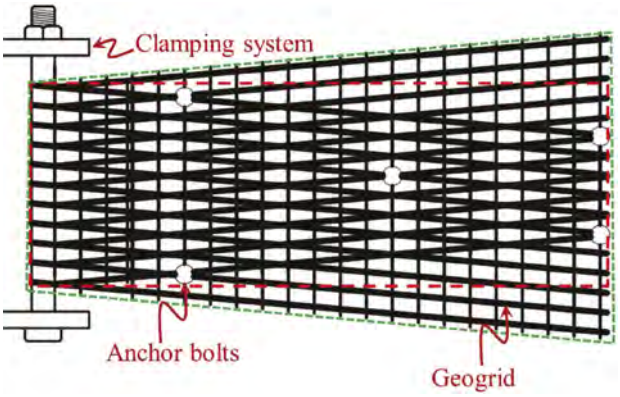

Figure 1. Schematic view of the spread geogrid behind the concrete panel.

In the present study, a field pullout testing was conducted on a uniaxial, polyester geogrid embedded in pond ash with an overlapping arrangement under an overburden stress of ~12 kPa. The variation of pullout resistance along the front-end pullout displacement was monitored and the pullout resistance factor (F^*) was determined.

2 EXPERIMENTAL DETAILS

2.1 *Materials*

2.1.1 *Pond ash*

Pond ash used in the field was collected from ash pond that belongs to Narla Thatharao Thermal Power Station (NTTPS), which is at a lead distance of 20 kms from the construction site. Preliminary studies including grain-size distribution, compaction characteristics, and the engineering properties like shear strength, permeability, and compressibility were performed and reported in Karnamprabhakara et al. (2021). Table 1 presents the properties of pond ash used in the construction site.

Table 1. Properties of pond ash used in the construction site.

Property	Value	Units
D_{10}	0.075	mm
D_{50}	0.2	mm
Soil classification	SP	-
% fines	<10	%
Optimum moisture content	30	%
Maximum dry unit weight	11.6	kN/m^3
Apparent cohesion, c	7.7	kPa
Angle of shearing resistance, φ	42	0
Secant constraint modulus, D	8.3	MPa
Hydraulic conductivity, *k*	2.3e-6	m/s

2.1.2 *Reinforcement*

Geogrids were used as a reinforcing material in the construction of MSE walls with pond ash as backfill material. Different number of geogrids with varied tensile strengths were used in the construction based on the design.

Table 2 gives the details of the geogrid used in the present study. Henceforth, the geogrid used in the study is referred as UXG. More details of the geogrid like longitudinal and transverse rib widths, thickness and so on can be found in Karnamprabhakara et al. (2021). The geogrid UXG of the present study corresponds to UXG2 in Karnamprabhakara et al. (2021).

Table 2. Manufacturer details of the geogrid (UXG) used in the study (adopted from Karnamprabhakara et al. 2021).

Detail	Value	Units
Material	Polyester (PET)	-
Tensile strength		
MD	200	kN/m
CMD	30	kN/m
Aperture size		
MD	30	mm
CMD	23	mm

2.2 *Pullout setup*

Figure 2a shows the photograph of the vibratory compactor and the panel walls used in the construction site, and Figure 2b shows the field pullout test setup with the key components. The key components of the test setup include hydraulic cylinder, hand pump, and pressure gauge. Two number of hydraulic jacks (or) cylinders of capacity 250 kN each were used in the testing. The ram diameter of the jacks was equal to 54 mm. The valves present in hand pump line helps in slow mobilization of oil flow into the cylinders.

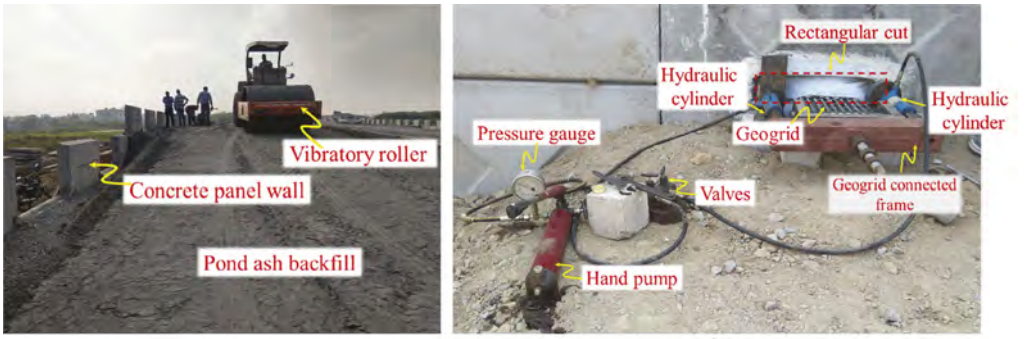

Figure 2. Construction site photographs showing (a) the vibratory roller compactor and panel walls, (b) field pullout test setup with its key components.

3 TESTING PROCEDURE

To perform a field pullout testing on the geogrid, a prefabricated concrete panel with a rectangular cut of width 600 mm and depth of 100 mm, as shown in Figure 2 was installed. Pond ash was used as the backfill material and compacted using vibrating rollers for about 0.8 m above the sacrificial geogrid. The achieved compacted bulk unit weight of the pond ash behind the precast concrete panel was equal to 14 kN/m^3. It was connected to the cylindrical-shaped rod of diameter 50 mm in the geogrid connection frame unit. The hydraulic cylinders were arranged such that the cylinders get a reaction force from the concrete panel wall when

the pistons try to pull the geogrid out from the backfill. The effective overburden stress on the sacrificial geogrid laid at a depth of 0.8m from the top was ~ 12 kPa. During the pullout testing, the loads were applied incrementally up to 50 kN. At every application of load, the geogrid was allowed to get pulled for 5-10 minutes of duration and then subsequent loads were applied. The movement of pistons in both the hydraulic cylinders was measured using a 30 cm-long steel ruler, and the average value was noted as the front-end axial pullout displacement, at every load application.

4 RESULTS AND DISCUSSION

Figure 3a shows the variation of normalized axial pullout resistance along the normalized front-end axial pullout displacement of the geogrid from the field testing. It was also compared with the normalized pullout resistance from the laboratory study (Figure 3b) (adopted from Karnamprabhakara et al. 2021). The lowest normal stress under which the pullout testing data was available corresponded to 17 kPa and the same was presented. From field testing, it could be observed that the pullout resistance of the geogrid increased continuously with the increase in the front-end pullout displacement of the geogrid. This behavior indicates that the shear stress along the reinforcement was not fully mobilized within the front-end pullout displacement of 130 mm. However, the laboratory pullout test result showed a constant pullout resistance beyond 3% of normalized pullout displacement indicates that the shear stress was mobilized along the entire geogrid. The pullout resistance corresponding to maximum front-end pullout displacement of 130 mm (i.e., normalized pullout displacement of ~4%) was considered to define the pullout resistance factor for the field pullout test. Ideally, Federal Highway Authority (FHWA) suggests considering the pullout resistance corresponding to the rear-end displacement of 15 mm for extensible reinforcements like geogrids.

FHWA (Elias et al. 2001) suggests an empirical formula to estimate the ultimate pullout resistance (P_a) of the geogrids.

$$P_a = F^*.\alpha.\sigma_n.C.B.L_e \tag{1}$$

where, F^* is the pullout resistance factor, α is the correction factor for non-linear shear stress mobilization (=0.8 for geogrids, in general), σ_n is the overburden stress on the geogrid (~16 kPa in the present study), C is the effective unit perimeter (=2 in general), B is the average width of the geogrid in the overlapping condition with 0.3 m at the hook end and 0.6 m at the other end (=0.45 m in the present study), L_e is the effective length of the reinforcement (=3.5 m).

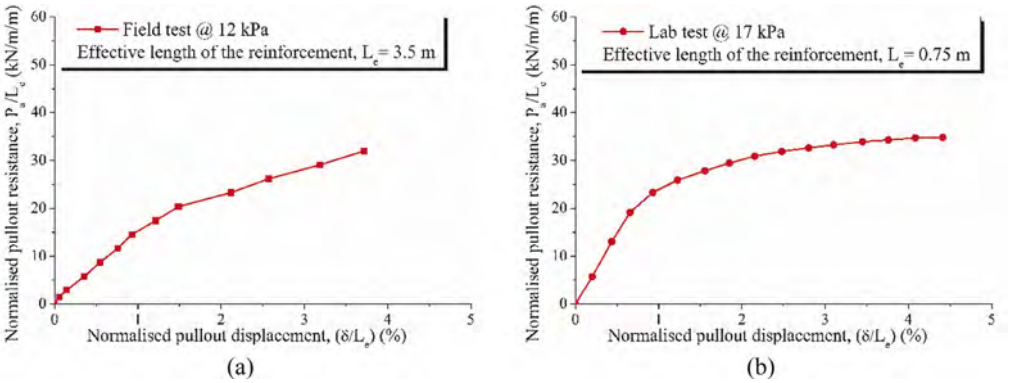

Figure 3. Variation of axial pullout resistance along the front-end pullout displacement under (a) field conditions, and (b) laboratory conditions.

The pullout resistance factor (F^*) from the field pullout test was equal to 1.11 as per Eq. 1 for the considered normalized pullout displacement of ~4%. However, it is to be noted that the effect of spread (overlapping) area of the two-layer geogrid was not considered in the analysis, but just the average width of the geogrid was used in the analysis. The calculated pullout resistance factor for the field pullout testing was closer to the reported pullout resistance factor (=1.25 corresponding to the same equivalent normalized pullout displacement of ~4%) for the same geogrid tested in the laboratory with pond ash as a fill material (Karnamprabhakara et al. 2021). However, the normal stress differs by an amount of 5 kPa between laboratory testing and field testing. This indicates a possibility of higher pullout resistance factors for field pullout testing at the same normal stress. It was expected that the high pullout resistance was anticipated in the field case owing to the increase in the frictional resistance of the geogrid and the pond ash particles and passive resistance against transverse ribs with increase in the spread area of the geogrid. In addition, the continuous increase in the pullout resistance in field testing indicates that the rear-end displacement of the geogrid is considerably lesser than 15 mm, and higher resistance can be expected.

It is inarguably acceptable that the increase in the spread area of the geogrid behind the precast concrete panel would exhibit a considerable increase in the pullout resistance. This study paves towards creating interest to study the factors in terms of increase in the pullout resistance with the increase in the spread area of the geogrid, particularly when it is embedded in non-conventional fill material like pond ash. Thus, a comprehensive study that covers the effect of overlapping (spread) area of geogrid embedded in pond ash, under different possible overburden stresses in the field and model testing for the same case in the laboratory is required to understand the realistic behavior.

5 CONCLUSIONS

Field pullout testing of geogrids behind the mechanically stabilised earth walls for the conditions discussed in the paper can provide realistic behavior of geogrid pullout and to define pullout resistance factors. The pullout resistance factor observed for the geogrid, UXG in the field pullout testing was equal to 1.11 under a normal stress of 12 kPa, which is lower to the laboratory test result (~1.25). This factor is defined at a normalized pullout displacement of ~4%. However, there is a need for a comprehensive study of field and laboratory pullout testing on geogrids in overlapping conditions, and this is suggested as the further scope of the study.

ACKNOWLEDGEMENTS

Authors would like to acknowledge SoilSol Projects, Hyderabad, for their cooperation in conducting field pullout testing in one of their projects near Vijayawada, Andhra Pradesh.

ABSTRACT: The present study aims to generate generalized equations for the determination of ultimate load-bearing capacity (*ULBC*) of geogrid reinforced foundation (*GRF*) soil using the wraparound ends technique. Firstly, the *ULBC* of the reinforced soil is investigated by employing the two-dimensional FEM tool, and then a multiple linear regression (*MLR*) analysis is performed to obtain the generalized equations for the determination of the same. A series of solutions have been generated by performing a parametric study on the geometrical configuration of the wraparound ends configuration along with the geogrid's axial elastic stiffness (*EA*). The results recommend that the generated equations are reliable as the coefficient of determination (R^2) ranges nearly 1 for *EA* up to 2000 kN/m. However, beyond certain values of stiffness parameters, some qualitative intervention is needed to interpret the *ULBC*.

1 INTRODUCTION

The use of geosynthetics to reinforce the shallow foundation is now being considered the most viable and sustainable approach for construction. In the last few decades, various studies have been performed which have proven the efficiency of geosynthetics to improve the ultimate load-bearing capacity (*ULBC*) and decrease the footing's settlement. The very first concept of soil reinforcement was put forward by (Vidal, 1969), and (Binquet & Lee, 1975) performed the first systematic study of shallow foundations resting on reinforced soil. Since then, various experimental studies have been performed to investigate the *ULBC* and settlement of the footing (Khing et al., 1993; Adams & Collin, 1997; Dash et al., 2004; Azzam & Farouk, 2010; Aria et al., 2021). The experimental test methods, such as plate load tests are time-consuming, very expensive, and require skilled labor to create the exact in-situ field condition for the test, requiring heavy machinery and tools. Researchers have conducted analytical studies to examine the *ULBC* and tried to eliminate the discrepancy in the results due to field limitations (Binquet & Lee, 1975; Chen & Abu-Farsakh, 2015; Huang & Tatsuoka, 1990). In order to eradicate the cumbersome calculations and saving in time and money, researchers have utilized the concept of finite element analysis (*FEA*) to perform the various test on the footing lying over the reinforced soil mass (Bindlish et al., 2013; Kazi et al., 2015b; Jaiswal & Chauhan, 2021a, 2021b).

Earlier, researchers had studied the improvement in the bearing capacity of soil reinforced with horizontal reinforcing layers (Adams & Collin, 1997; Shin et al., 2002; Basudhar et al., 2007)

*Corresponding author: chauhan.vinaybhushan@gmail.com

DOI: 10.1201/9781003299127-104

which requires larger space to lie geogrid beneath the footing. However, a wraparound ends technique came into the picture, which requires less space to sufficiently enhance the bearing capacity and correspondingly imparts lateral confinement to the soil strata in addition to pseudo confinement (Shukla, 2015). This technique has been researched analytically, experimentally, and numerically by various researchers in the recent past (Kazi et al., 2015; Raja & Shukla, 2020; Jaiswal et al., 2021a), and various reinforcing parameters have been recommended.

The abovementioned literatures discussed the characteristic improvement of the reinforced soil in terms of *ULBC* and settlement, yet no generalized equation for the wraparound ends technique is available for the direct estimation of the *ULBC* for varying stiffness parameters of the geogrid on the basis of the requirement of footing and soil conditions.

This study aims to develop generalized equations for the direct determination of *ULBC* of foundation soil reinforced with geogrid using the wraparound ends technique for the mentioned ground conditions. To achieve the abovementioned aim, an *FEA* has been performed using the 2D FEM tool, and a series of solutions is obtained by performing the parametric study on the geometrical parameters of the wraparound ends technique of reinforcement. Further, these solutions were utilized as input parameters for the multiple linear regression (*MLR*) analysis.

2 SCOPE OF THE PRESENT STUDY

2.1 *Problem statement*

The present study aims to perform a finite element analysis (*FEA*) of strip footing (width = *B*) resting on a *GRF* soil using the wraparound ends technique using the Optum G2 FEM tool (Krabbenhoft et al., 2020) and to develop generalized equations for the prediction of *ULBC* employing the multiple linear regression (*MLR*) analysis. The *ULBC* is dependent on the geometrical parameters of the wraparound ends technique i.e., placement of reinforcing layer near the footing (*u*), width of the geogrid (*b*), lap length (*l*), vertical distance of overlapping ends (*d*), and vertical spacing between two layers of reinforcement (*h*), which are considered as independent parameters for *MLR* analysis. A total of 405 solutions are tabulated and used for further analysis. The problem definition considered in the present study is shown in Figure 1 and the details of the study performed for deterministic study are presented in Table 1.

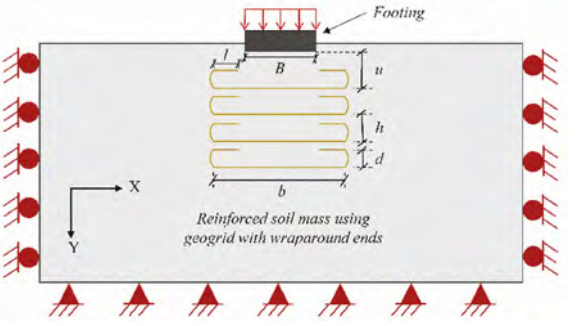

Figure 1. Problem definition.

Table 1. Details of the parametric study.

Footing Width	Width of reinforcement	Depth of first reinforcing layer	Vertical spacing between two layers of reinforcement	Vertical distance of overlapping ends	Lap length
(*B*)	(*b*)	(*u*)	(*h*)	(*d*)	(*l*)
B	3B	0.25B		0.20B	0.50B
	4B	0.30B	0.30B	0.25B	0.60B
	5B	0.35B	0.40B	0.30B	0.70B

2.2 *Methodology*

A two-dimensional finite element analysis (*FEA*) is performed for modeling a strip footing on cohesionless *GRF* soil. The material properties and modeling consideration correspond to the study of Jaiswal & Chauhan (2021a). The soil material is modeled using the Mohr-Coulomb failure criterion following the associated flow rule. The shear strength parameters are maintained invariably during the study for better comparison of the findings. The footing is considered rigid concrete material. The reinforcement is modeled using geogrid material defined in the tool having varied axial elastic stiffness, i.e., EA = 1000 kN/m, 2000 kN/m, and 5000 kN/m. A plane strain condition is considered in the present study. The interface parameters are considered in accordance with the recommendation of (Kazi et al. 2014; Srivastava et al. 2020; Jaiswal et al. 2021b). The sensitivity analysis is performed and noted that 10000 elements are enough for the considered mesh.

The multiplier elastoplastic analysis is performed in the present study and the *ULBC* is obtained by applying the double tangent method (Jaiswal & Chauhan, 2021c). The illustration of mesh deformation of unreinforced foundation and wraparound ends geogrid reinforced foundation is shown in Figure 2, which demonstrates the associated failure mechanisms during the analysis. The progressive potential failure of the *GRF* soil with wraparound ends is shown in Figure 3.

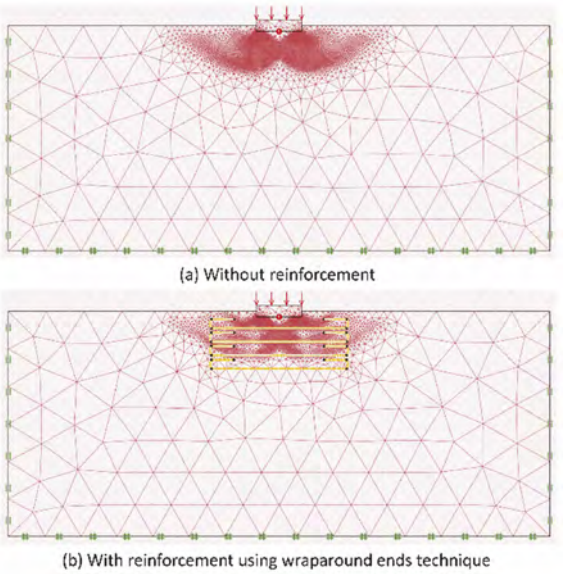

Figure 2. Deformed mesh of footing (a) without reinforcement; (b) with reinforcement using wraparound ends technique.

3 RESULTS AND DISCUSSION

3.1 *Multiple linear regression (MLR) analysis*

Empirical estimation of various significant parameters in almost all problems lying within the civil engineering discipline is a common method. Generally, for the estimation of the relationship between the dependent and independent variables, a function is assumed. An elementary model used for *MLR* analysis is postulated in Equation (1):

$$y = \alpha_1 x_1 + \alpha_2 x_2 + \alpha_3 x_3 + \ldots + \alpha_n x_n \tag{1}$$

where, y is the dependent variable, $x_1, x_2, x_3, \ldots, x_n$ are n independent variable, $\alpha_1, \alpha_2, \alpha_3, \ldots, \alpha_n$, are the unknown parameters and n is the number of independent variables.

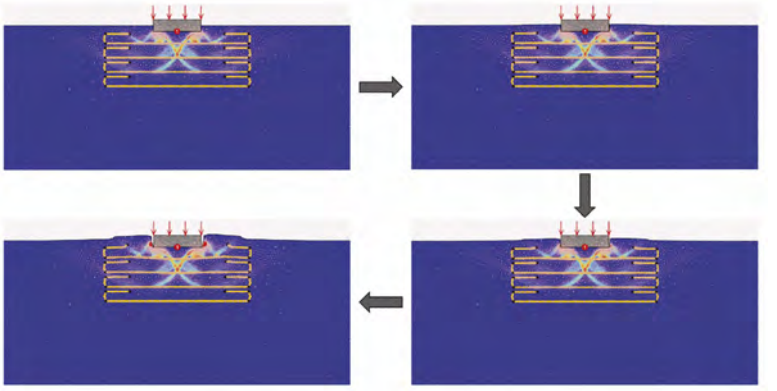

Figure 3. Progressive potential failure obtained during the FEM analysis.

Therefore, m number equations can be written in the form of Equation (1), for each observation, to study the effect of as many parameters as required. Basically, m number of equations will be solved for the n unknown parameters by using multiple linear regression. The m equations for the discussed case can be written more generally in the following way:

$$\begin{aligned} y_1 &= \alpha_1 x_{11} + \alpha_2 x_{12} + \alpha_3 x_{13} + \ldots + \alpha_n x_{1n} \\ y_2 &= \alpha_1 x_{21} + \alpha_2 x_{22} + \alpha_3 x_{23} + \ldots + \alpha_n x_{2n} \\ &\vdots \\ y_m &= \alpha_1 x_{m1} + \alpha_2 x_{m2} + \alpha_3 x_{m3} + \ldots + \alpha_n x_{mn} \end{aligned} \tag{2}$$

Equation (2) can be further generalized as:

$$y_i = \sum_{j=1}^{n} \alpha_j x_{ij}, \text{ for } i = 1 \text{ to } m \tag{3}$$

where, y_i is the i^{th} observation on y and x_{ij} is the i^{th} observation on the j^{th} independent variable.

For Equation (3) to have an intercept term, it is necessary that $x_i = 1$ for $i = 1$ to m, while α_1 becomes the intercept (Bera et al., 2005). For the development of the linear equation, it is assumed that $x_{i1} = 1$ for $i = 1$ to m. The equation thus obtained is a special case of Equation (3), and can be written in the form of:

$$y_i = \alpha_1 + \alpha_2 x_{i2} + \alpha_3 x_{i3} + \ldots + \alpha_n x_{in}, \text{ for } i = 1 \text{ to } m \tag{4}$$

Following the above procedure, an *MLR* analysis has been performed from the combination of simulations as shown in Table 1. The values of *ULBC* are determined from the present numerical study illustrated that it is not significantly affected by the l/B and the d/B ratios, although, for higher accuracy of *ULBC*, these are taken into account while performing the multiple linear regression analysis. The findings unveil that the improvement in the *ULBC* is majorly dependent on the u/B ratio, h/B ratio, and elastic stiffness (EA) of the geogrid. In line with the scope of the present study, a multiple linear regression model was developed to estimate the *ULBC* for various EA values corresponding to u/B, h/B, d/B, and l/B respectively, and represented as follows:

$$ULBC = \alpha_1 + \alpha_2 (u/B)_{i2} + \alpha_3 (h/B)_{i3} + \alpha_4 (d/lB)_{i4} + \alpha_5 (l/B)_{i5}, \text{ for } i = 1 \text{ to } m \tag{5}$$

where, α_1 = intercept; and α_2, α_3, α_4, and α_5 = partial regression coefficients.

Table 2 shows the results of the multiple linear regression analysis, in which the values of α_1, α_2, α_3, α_4, and α_5 are presented together with the coefficient of determination (R^2) corresponding to *EA* and *b*/*B*.

The results presented in Table 2 illustrate the expected change in *ULBC* for a unit change in one parameter when all the other parameters are kept constant. The numerical value of coefficients; α_1, α_2, α_3, α_4, and α_5 evaluated the sensitivity of *ULBC* to the parameters considered in Equation (5). The magnitude of the coefficient of determination (R^2) shows the significance of the generated regression model, and also depicts the variation in outcome when the value of independent variables fluctuates. For *EA* up to 2000 kN/m, R^2 ranges near 0.97, which demonstrates that the regression model (Equation 5) is more reliable. Moreover, R^2 for *EA* = 5000 kN/m ranges near 0.82 which shows that although the predicting variables are affecting the dependent variable (*ULBC*), despite some qualitative interference is required to interpret the *ULBC*.

Table 2. Constants in Equation (5) and the coefficient.of determination (R^2).

4 CONCLUSIONS

An *MLR* analysis has been performed in order to determine the ultimate load-bearing capacity (*ULBC*) of a foundation reinforced with geogrid using the wraparound ends technique based on the outcomes of *FEA* outcomes. The coefficient of determination (R^2) has been calculated for varying stiffness of the reinforcement at various geometrical parameters of the wraparound ends technique. The outcomes indicated that the equations generated during the *MLR* analysis are reliable up to the axial elastic stiffness, *EA* = 2000 kN/m. The generated equations can be directly used in the field for a similar ground condition; however, attention is required for the varying ground conditions.

Anisotropic behavior of fiber-reinforced sand in undrained triaxial compression and extension tests

J. Ganiev
Nagoya University, Nagoya, Aichi, Japan

ABSTRACT: A series of undrained triaxial experiments for compression and extension were conducted on unreinforced and fiber-reinforced. Three fiber contents of 0.0, 0.2, and 0.4% by dry weight of host soil have been utilized to investigate the trend of fiber-reinforcement. The samples were prepared in medium loose condition with approximately 40% relative density to fully reveal the effect of fibers on pore water pressure generation in a range of 20% axial strain. Experimental results showed that the fibers were more effective in compression compared to extension at a higher axial strains. However, a smaller initial stiffness in compression was observed with the increase in fiber content. A possible mechanism for such kind of behavior were proposed through the consideration of the interaction mechanism between fibers and sand particles, and the influence of fibers on the initial anisotropy of sandy soil.

1 INTRODUCTION

Reinforcing soils with tension resisting elements has raised a high interest for a long time. A lot of studies have performed both experimental and numerical investigations to comprehensively analyze the effectiveness of fiber-reinforcement (Gray & Ohashi 1983, Michalowski & Zhao 1996, Consoli et al. 2009, Diambra et al. 2013, Ganiev et al. 2022a). Despite a huge number of existing literature, there are still a lot of contentious issues and shortage of consistent data to properly describe the fiber-reinforcement mechanism.

In this study consolidated undrained triaxial compression and extension tests were performed to investigate the effect of fibers on a shear strength with simultaneous analysis of the pore water pressure (PWP) generation with the shear progress. Additionally, a mechanism of the fiber – sand particles interaction and influence of fibers on the anisotropic behavior of sand was analyzed by the comparison of the stress paths in compression and extension under several confining pressures. Compared to previous studies, where mainly the anisotropic orientation and distribution of fiber itself was considered, in this study the main attention was paid to the effect of randomly distributed fiber on the degree of anisotropy of sand specimens and the influence of fibers on the spatial distribution of sand particles.

2 MATERIALS AND METHODS

2.1 *Materials and sample preparation*

The standard sand for laboratory testing in Japan – Toyoura sand, was used for all the experiments. Grain size distribution of sand is given in Figure 1a. Its physical properties are: specific gravity G_s = 2.65; maximum and minimum void ratios e_{max} = 0.985 and e_{min} = 0.639, respectively.

As a reinforcing material polyvinyl alcohol (PVA) fibers (Figure 1b) were used with 0.2 and 0.4 percent of the dry weight of sand. The fibers with a circular cross – section have a length

DOI: 10.1201/9781003299127-105

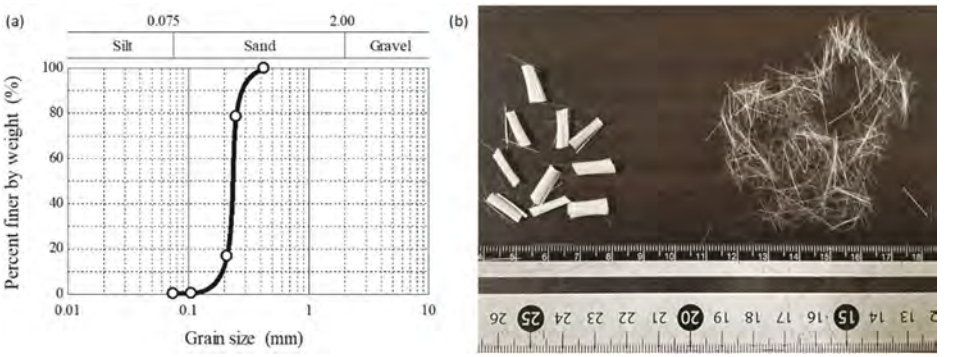

Figure 1. Grain size distribution of Toyoura sand (a) and photograph of PVA fibers (b).

of l_f = 12 mm and diameter of d = 0.04 mm; specific gravity G_f = 1.3; tensile strength 1560 MPa; and elastic modulus E_f = 41 GPa.

Reinforced samples were prepared by mixing fibers and sand with a scoop in a dry condition. All specimens, including unreinforced sand, were placed in one layer by side tapping in a dry condition. Distribution of fibers were considered to be random. The homogeneous distribution was checked by the exhumed sample analysis and the reproducibility of test results was controlled in all series of experimentations (Ganiev et al. 2022a).

2.2 *Testing conditions*

Consolidated undrained ($\overline{CU}$) triaxial compression and extension tests with the pore water pressure (PWP) measurement were performed on unreinforced, 0.2% and 0.4% fiber-reinforced sand specimens placed in a medium loose condition with a relative density of D_r = 40 %. Specimen were consolidated and sheared under p'_0 = 50, 100, 200 kPa confining pressures in compression and under p'_0 = 100, 200kPa in extension. The shearing was performed until 25 % axial strain in compression and 20% axial strain in extension with the rate of 0.5 % strain per minute.

3 TEST RESULTS AND DISCUSSIONS

3.1 *Undrained triaxial compression*

Figures 2 to 4 show the $\overline{CU}$ compression test results performed under p'_0=50, 100, 200kPa confining pressures, respectively. In q–ε_a curves, with the increase in fiber content, fiber-reinforced specimens experienced a higher deviator stress q at the end of shearing compared to unreinforced sand. However, fiber-reinforced specimens experienced smaller initial stiffness with the increase in fiber content for all confining pressures. The difference in the initial stiffness became more obvious at a higher confining pressure (Figures 2a,3a and 4a). This behavior can also be observed in stress paths curves (Figures 2b,3b and 4b), where fiber inclusions caused a higher drop of mean effective stress p'. Despite having a lower initial stiffness and a higher drop of p' until the phase transformation point, the fiber-reinforced specimens reached higher stress ratios. Furthermore, the stress ratio increased with the increase in fiber content, and even fiber-reinforced sand speci-mens, same as unreinforced sand, reached to their definite stress ratio value at the end of tests despite being sheared under different confining pressures. The higher value of initial stiffness of unreinforced sand specimens is related to the higher degree of the initial anisotropy condition with deposition method by side tapping (vibration) which created a highly anisotropic sample with more preferred orientation of sand particles. In turn, fiber inclusions prevent preferred orientation of sand particles and created

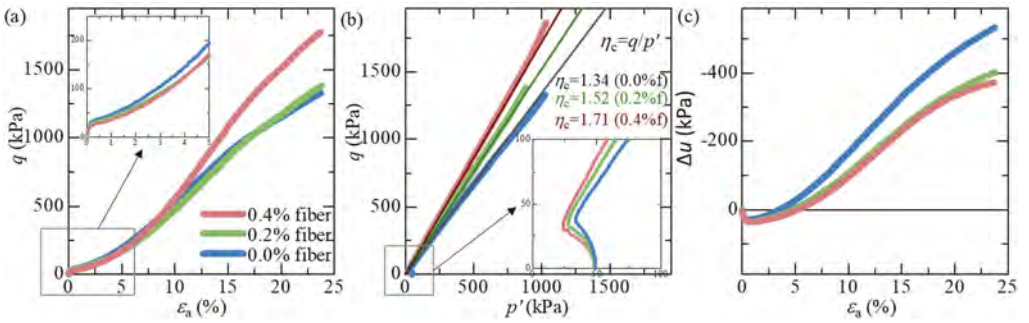

Figure 2. Undrained triaxial compression tests performed under p_0'=50kPa: (a) deviatoric stress – axial strain response, (b) stress paths and (c) excess pore water pressure – axial strain response.

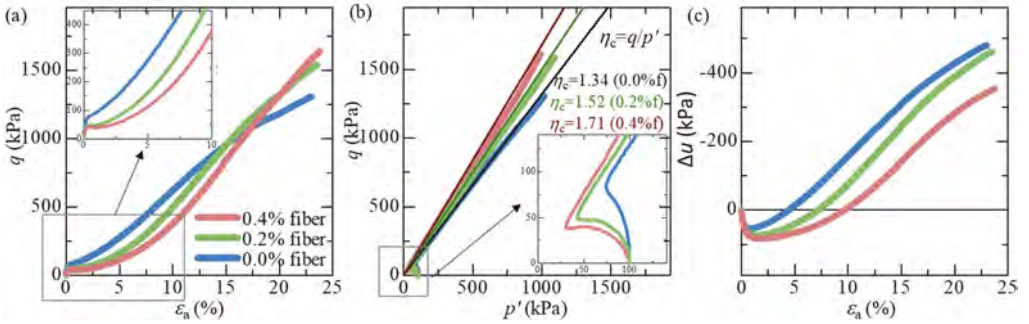

Figure 3. Undrained triaxial compression tests performed under p_0'=100kPa: (a) deviatoric stress – axial strain response, (b) stress paths and (c) excess pore water pressure – axial strain response.

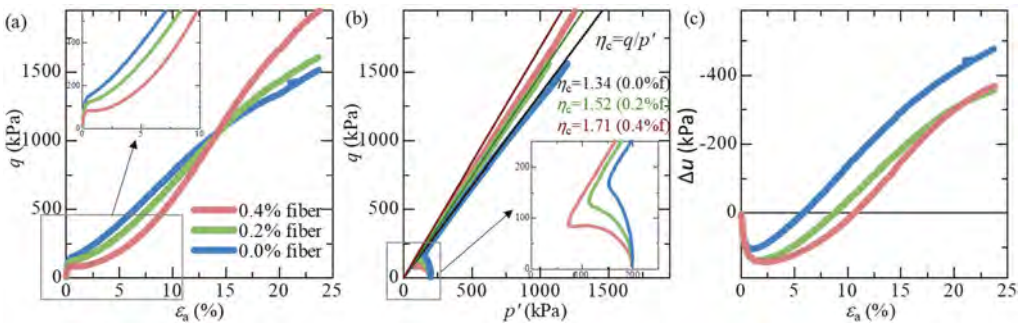

Figure 4. Undrained triaxial compression tests performed under p_0'=200kPa: (a) deviatoric stress – axial strain response, (b) stress paths and (c) excess pore water pressure – axial strain response.

less anisotropic specimens. Similar outcomes were presented in drained compressive behavior of fiber-reinforced sands (Ganiev et al. 2022b).

On the Δu–ε_a curves in Figures 2c,3c and 4c there is a clear tendency for a higher positive PWP at a lower axial strains and a less generated negative PWP at the end of shearing (hardening interval) as fiber content increased. Furthermore, a negative PWP decreased with the increase in confining pressure for all fiber contents including unreinforced sand, i.e., the higher the confining pressure the higher the initial positive PWP and the smaller the final

negative PWP. According to the results, it can be assumed that fibers act as contracting agents, positively contributing to the confining pressure by producing tensile forces in them at higher strains.

3.2 *Undrained triaxial extension*

Figures 5 and 6 show the consolidated $\overline{CU}$ extension test results performed under p'_0=100, 200kPa confining pressures, respectively. Tensile strength of fiber-reinforced sand was higher compared to unreinforced sand under both confining pressures, and fiber-reinforced specimens reached to higher residual stress ratios. In deviatoric stress-axial strain curves (Figures 5a and 6a), there was no initial stiffness decrease in fiber-reinforced specimens compared to unreinforced sand as in compression experiments. Furthermore, reduction of mean effective stresses of fiber-reinforced sand during the softening stage was smaller compared to unreinforced sand. Therefore, considering stress paths in compression and extension experiments under the same confining pressure simultaneously, it can be concluded that unreinforced specimens prepared by dry vibration resulted in a higher initial anisotropy, whereas the increase in fiber contents led to decrease of the anisotropy. Reduction of the deviator stresses q approximately at ε_a=15% was due to the shear band formation, while no explicit strain localization observed in compression.

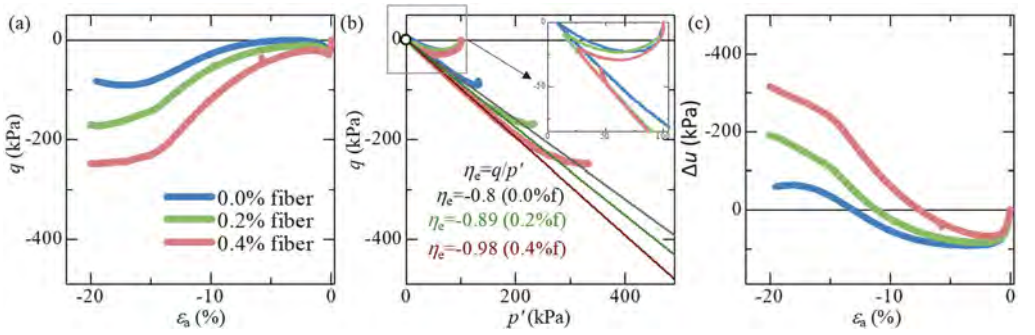

Figure 5. Undrained triaxial extension tests performed under p_0'=100kPa: (a) deviatoric stress – axial strain response, (b) stress paths and (c) excess pore water pressure – axial strain response.

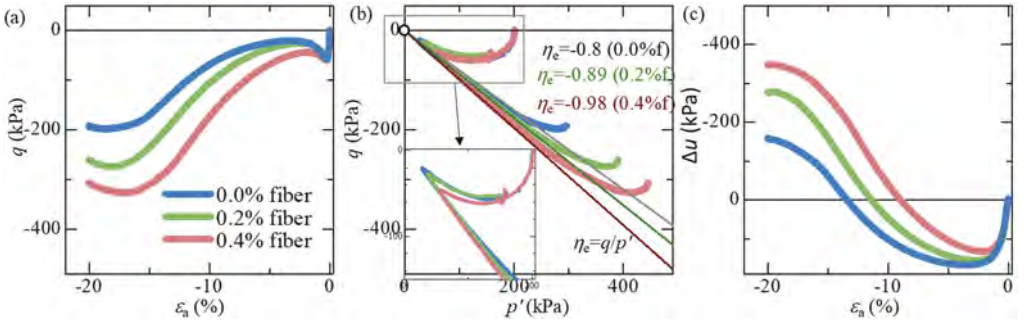

Figure 6. Undrained triaxial extension tests performed under p_0'=200kPa: (a) deviatoric stress – axial strain response, (b) stress paths and (c) excess pore water pressure – axial strain response.

4 CONCLUSION

The followings are main conclusions from the presented results and discussions:

Dry deposition of sand specimen by side tapping (vibration) created a highly anisotropic sample with more preferred orientation of sand particles. In case of fiber-reinforced sand, fiber inclusions prevented preferred orientation of sand particles and reduced the degree of initial anisotropy.

In undrained triaxial test fibers were effective in both compression and extension resulting in the increase of compressive and tensile strength with the increase in fiber contents. Also, there was a clear tendency for the increase in residual stress ratio with the increase in fiber content. Furthermore, the higher positive PWP generation at the softening stage and smaller value of negative PWP at the end of shearing clarified the contractive role of fibers.

Finally, the smaller difference in stress paths in compression and extension of fiber-reinforced sand compared to unreinforced sand might be one of the evidence that fibers reduce the initial anisotropy.

Scaled model test on cyclic response of footing on geotechnical seismic isolation layer

Dhanya JS.

Indian Institute of Technology Madras, Chennai, India

ABSTRACT: Sand-rubber mixture (SRM) is widely considered as an energy-dissipating layer for vibration mitigation in soils. The present study is focused on using the SRM as an energy dissipation layer below building foundation referred to as the Geotechnical Seismic Isolation layer (GSI) which acts as a buffer to incoming vibrations. Geosynthetic reinforcement is included in the above GSI system to accentuate the damping mechanism and prevent seismic settlements during shaking. The present study aims to experimentally evaluate the dynamic response of the geogrid reinforced SRM-GSI system through scaled model tests. Model footing resting on the geogrid reinforced SRM-GSI system was subjected to continuous cyclic loads and the results are evaluated in terms of load-settlement response for different cycles of loading. It was observed that the geogrid reinforced SRM-GSI system is crucial in reducing the seismic settlement at various loading cycles and the soil-foundation system's overall dynamic response.

1 INTRODUCTION

Geotechnical seismic isolation is a recent trend in earthquake geotechnical engineering that aims to protect buildings and structures from the detrimental effects of earthquakes using a low-stiffness isolation layer beneath the building. The basic principle behind this method is to isolate the structure from the ground, so that the vibrations of an earthquake do not transfer to the building. In conventional base isolation systems, energy dissipation is achieved through the use of isolation bearings (made of natural rubber and lead) are placed between the building structure and foundation. On the other hand, geomaterials such as rubber, geosynthetics, sand, and gravel are often used in GSI method as they provide a flexible and durable barrier between the building foundation and the ground, and they offer a cost-effective and sustainable alternative to traditional isolation systems (Tsang 2008; Pitilakis et al. 2015; Dhanya et al. 2020; Forcellini 2020). One common practice is the use of sand mixed with rubber particles from crushed recycled tires, referred to as Sand-Rubber Mixture (SRM), for seismic isolation. The SRM provides a combination of low stiffness, high flexibility, and damping that helps to dissipate the energy of seismic waves below the foundation level (Tsang 2021).

The use of rubber particles from scrap tires is becoming increasingly popular in civil engineering applications due to its environmental advantages and the large amount of scrap tires produced worldwide. Research have showed that using shredded scrap tires mixed with soil is an effective solution as a lightweight back-fill material for retaining walls, highway embankments, and as vibration absorption layers for underground structures and foundations (Kirzhner et al. 2006; Hazarika et al. 2010). The damping ratio of SRM at small strains is higher than that of pure granular soils and it increases with higher rubber fractions and larger shearing strain amplitudes making it an ideal choice for vibration mitigation studies (Senetakis et al. 2012). Studies

DOI: 10.1201/9781003299127-106

have also shown that increasing the rubber fraction in a granular sand-rubber mixture beyond 30% leads to a decrease in the mobilization peak and large-strain angle of friction of the mixture, making the mechanical response more rubber-like (Zornberg et al.2004).

In general, SRM exhibits a higher degree of compressibility compared to pure sand due to the presence of elastic and deformable rubber particles. This results in immediate settle-ment similar to that of sand during static loading. However, the settlement response under repeated loading needs to be thoroughly examined when SRM is utilized as GSI layer be-low foundations when considering building safety under seismic and other ground borne vibrations. Several researchers have conducted extensive laboratory studies to investigate the cyclic behavior of SRM and the influence of rubber content and particle size on the shear strength and deformation of the mixture (Ehsani et al. 2015; Senetakis et al. 2012). However, model studies on the response of footings resting on GSI layers under repeated loading are limited. Therefore, the current study aims to experimentally investigate the be-havior of a scale model footing on a sand-rubber mixture GSI bed under cyclic loading conditions in terms of load-settlement response.

2 SCALED MODEL STUDY

2.1 *Materials*

In this study, river sand sourced from Chennai, India that was classified as poorly graded sand (SP) per IS: 1498 (BIS 1970) was used. The scrap rubber tyre with steel reinforcements removed and fragmented into angular-shaped granulated tire particles with a size less than 4.75mm and were also classified as an equivalent of poorly graded sand (SP). Research has shown that a rubber content of 20% to 35% (gravimetric) mixed with soil is optimal for achieving maximum shear strength (Edil and Bosscher 1994; Rao and Dutta 2006). Additionally, SRM with a 30% rubber content has been found to exhibit a high damping ratio and adequate stiffness compared to higher rubber contents (Senetakis et al. 2012; Dhanya et al. 2019, 2022). Therefore, in this study, SRM with a rubber content of 30% was used. Undrained triaxial test results on the sand the SRM samples showed peak internal friction angle of 37.5° and 28.5 ° respectively.

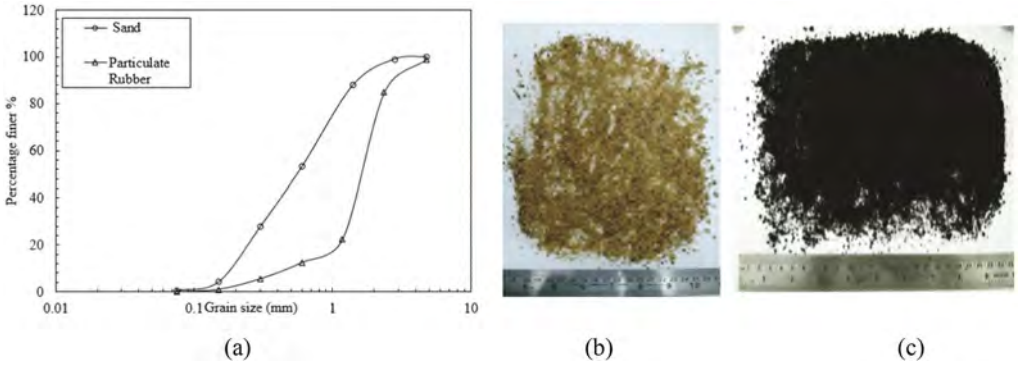

Figure 1. (a) Grain size distribution for sand and rubber (b) sand (c) rubber granules.

2.2 *Test setup and procedure*

Figure 2 presents a general overview of the laboratory test, including the testing tank and test bed. Load tests were performed on a model footing that was placed on a GBI layer made of SRM, in a laboratory setup that simulates a sand-bed tank. The test tank was made of steel and had dimensions of 1m x 1m x 1m. The model square footing was constructed using a square steel plate with a dimension of 100mm and a thickness of 10mm based on model scaling laws of similitude by Wood (2004). The steel plate was connected to pneumatic actuators

that were attached to a reaction frame composed of steel beams and columns. The loading was applied on the load plate in a displacement-control mode using a computer-controlled pneumatic actuator. The load was measured using an electronic load cell with a capacity of 20 kN and the displacement was measured by a displacement transducer (LVDT). For more detailed information on the arrangements of the testing apparatus and procedure, please refer to the work of Dhanya et al. (2019).

Initially, the load tests were conducted on a footing resting on a sand bed compacted at a relative density of 85%. The sand bed was prepared in layers of 0.1m each, using the sand pluviation/rainfall technique (Cresswell et al. 1999) where the sand was poured from a fixed height to achieve the desired density. The next series of tests were conducted on a footing placed on a GSI layer, which was prepared by excavating the required depth and size of the GSI layer in the sand bed and backfilling it with SRM. An aluminium sheet box of the plan size of the GSI bed was placed inside the sand bed to prevent caving in and control compaction during the preparation of the GSI layer. The excavated space was filled with SRM mixture and compacted in layers of 25mm to achieve a relative density of 85%. The depth of the GSI layer was varied as 0.1 B and 0.2 B, where B is the width of the footing while the width of the GSI layer was kept constant as 3B.

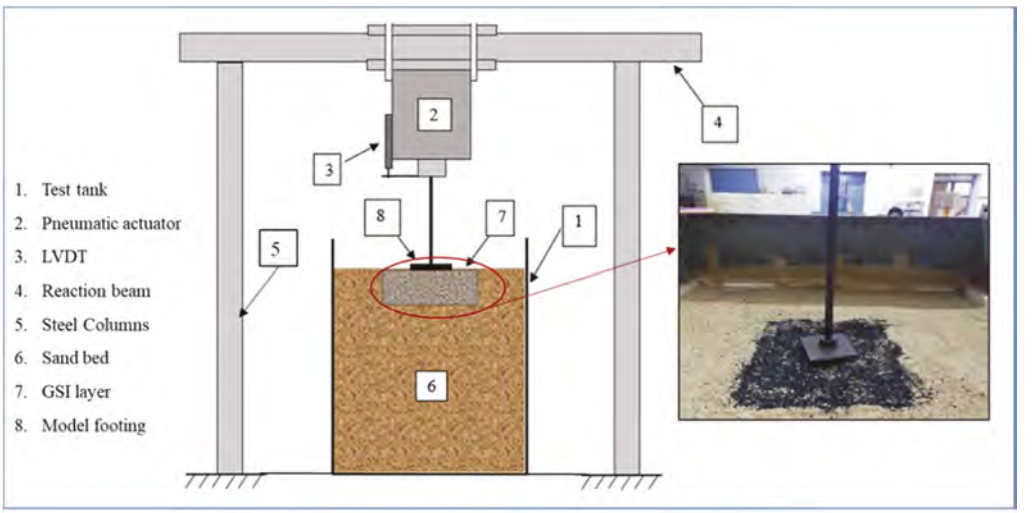

Figure 2. Experimental setup of model footing placed on GSI bed in the test tank.

During the testing phase, the following loading pattern is applied to the soil bed: first, a static load is applied at a gradual rate until it reaches 100 kPa. The static load is then maintained until no further settlement occurs or the rate of settlement is negligible. Next, a cyclic load, which is sinusoidal with a frequency of 1 Hz and is applied until the rate of settlement becomes negligible. The static load of 100 kPa was chosen as it simulates the weight of a low-rise structure, which is often the minimum factor of safety adopted in the field. The ratio of dynamic load amplitude to the static load amplitude is maintained as 0..3 as it is commonly found in seismic and machine vibration problems, as reported in Tafreshia & Dawson (2012).

3 RESULTS AND DISCUSSION

The focus of this study is to examine the settlement of a foundation specifically caused by cyclic loading. An initial monotonic loading is applied to simulate the weight of the structure and foundation, but elastic settlement from static loading is not considered. Figure 3 presents the variation of peak cyclic settlement of footing (S_c) normalized with the footing width (B)

with the number of load cycles under cyclic loading for the footing with and without GSI cases. The general characteristics of loading can be categorized into three zones: a rapid settlement in the initial cycles, a secondary slow settlement until a critical point, and a minimal rate of settlement (Zone C). It is observed that there is a significant increase in settlement in the first few cycles of loading, particularly in the GSI layers, and it is noted that the cyclic settlements are higher for GSI layers of greater depth. However, the rate of settlement decreases and becomes minimal around 1000-1500 cycles of loading. In general, it can be inferred that the stiffness of the GSI layer increases as the number of loading cycles increases, mainly due to particle reorientation and densification of the sand-SRM matrix. This is caused by the deformation of rubber particles in the SRM matrix which fill in the voids in the sand skeleton.

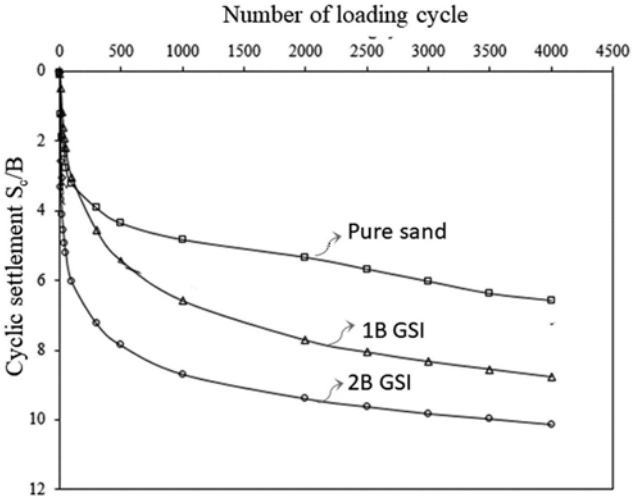

Figure 3. Variation of footing settlement (Sc/B) with number of load cycle for Sand and GSI.

Figure 4 presents the variation of load with the cyclic settlement under cyclic loading for the footing with and without GSI cases. The figure illustrates that the footing response on the sand bed demonstrated a narrow hysteresis loop, indicating hardening of the sand bed with minimal energy dissipation and no plastic deformation. On the other hand, the GSI system exhibited a broader hysteresis loop compared to the sand bed, which suggests higher energy dissipation by the GSI layer during the cyclic loading phase. Furthermore, the hysteresis loop of the GSI bed shows that the loop becomes consistent after a certain number of cycles, indicating densification of the GSI bed and a decrease in plastic deformation.

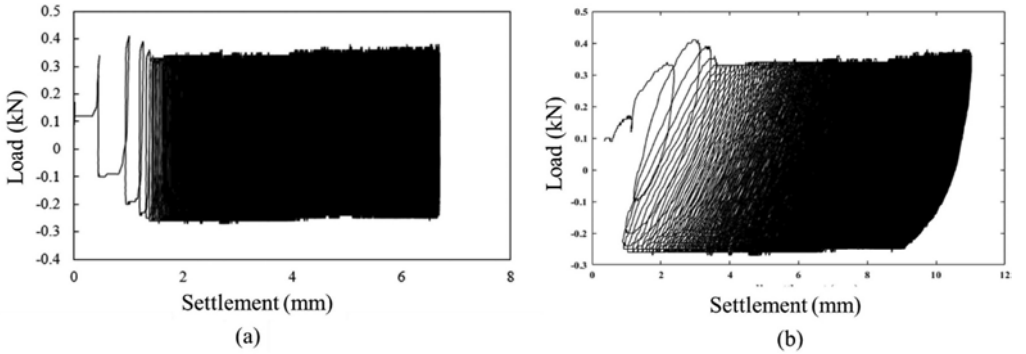

Figure 4. Load vs settlement hysteresis loop: a) Sand bed (b) GSI bed of 2B depth.

4 CONCLUSIONS

The research presented demonstrates the performance of the sand-rubber mixture (SRM) GSI system under both static and repeated loads. The results show that during the initial phase of loading, the cyclic settlement is more prevalent in the GSI system compared to the case without GSI. It is also observed that while the settlement increases with the thickness of the GSI bed, it eventually stabilizes at higher cycles of loading. The high hysteris damping mechanism of GSI that facilitates energy dissipation and vibration mitigation is evident during the cyclic loading, making it critical for vibration isolation applications. When choosing low stiffness materials for the GSI bed, such as the sand-rubber mixture layer, it is important to consider the compressibility response of the material and optimize the thickness accordingly.

The future scope of this research includes assessing the cyclic response of the SRM GSI system reinforced with geosynthetics such as geogrid and geocells which can greatly reduce cyclic settlements and enhance the applicability of SRM-GSI systems without compromising its serviceability and performance. Additional cyclic load testing on the model footing should be performed to evaluate the combined response of the geosynthetic reinforced SRM-GSI system in vibration mitigation studies in selecting appropriate parameter values for the design of footings on GSI systems.

Modeling of sub-ballast and geogrid interaction

A.F. Kolos & A.V. Petriaev
St. Petersburg State Transport University, St. Petersburg, Russia

E.V. Fedorenko
LLC NIP Informatics, St. Petersburg, Russia

ABSTRACT: The article presents the modeling results of the soil and geosynthetics interaction. To achieve this goal, a mathematical model was developed and FEM calculations were performed using the Plaxis program. The results of the calculations showed the coincidence of the soil behavior in the course of physical and mathematical modeling. The results of calculations using the Plaxis software package confirmed the influence of the angle of internal friction and the angle of dilatancy on the increase in the pulling force due to the attachment of a larger volume of soil. The influence of the geogrid ribs on the stress-strain state of the stabilized soil massif was estimated. Reducing the number of ribs leads to the concentration of shear zones along the web of the geogrid in close proximity to it, which reduces the pull-out resistance.

1 INTRODUCTION

The laying of geosynthetic materials is one of the effective stabilizing methods for sleeper bearing with minimal time for all types of track work. Previous studies have shown that the effect of using geosynthetic material is to increase the bearing capacity and reduce the deformability of the railway track (Gobel and Weisemann, 1994; Kolos et al., 2021; Brown et al., 2007; Indraratna et al., 2011; Petriaev, 2019; Esmaeili et al., 2017).

The approach to designing a foundation reinforced by geosynthetics depends on understanding the function and mechanism of mechanical stabilization of granular materials. The geosynthetics property such as stiffness, size and shape of cells, ribs shape and nodes, etc., has a great importance (Petriaev, 2020; Alagiyawanna et al., 2012). The interaction mechanisms will vary depending on the properties of the geosynthetics, as well as the properties of the stabilized aggregate, loading conditions, etc. (Hossain et al., 2012; Liu et al., 2009; Biabani and Indraratna, 2015; Fedorenko and, 2017).

The mathematical model complications leads to the need to obtain additional soil parameters during an engineering and geological survey (Petriaev, 2017; Penkov and Fedorenko, 2020). The natural variation of the foundation soils properties leads to a decrease in the reliability of the substructure behavior prediction in natural conditions. If a new model of soil behavior describes the features of its operation, which significantly affect the design calculation results, then its development can be considered justified. Numerical analysis is an alternative way to study stresses and deformations in the sub ballast, stabilized by geosynthetics.

The purpose of this study is to propose an approach to modeling a geogrid in confined by soil conditions. This is achieved in two stages. First of all the numerical model is verified by the test results, and then it is used to study the detailed behavior of the geogrid in the soil massive.

DOI: 10.1201/9781003299127-107

2 MATERIALS AND METHODS

The models presented in this study were performed by using Plaxis finite element software.

The design scheme shown in Figure 1 is presented in the form of a box with soil inside and a compressive load applied on the top.

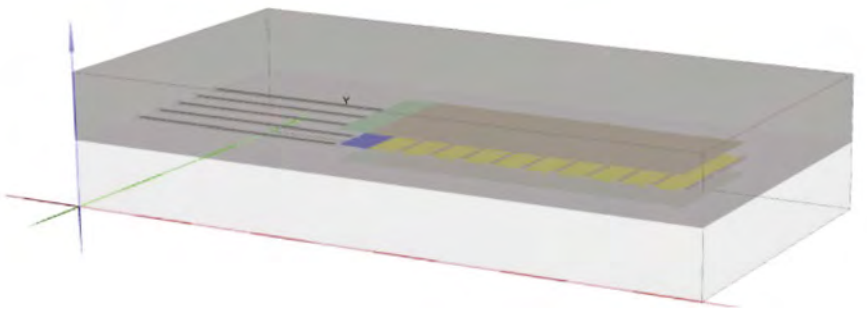

Figure 1. The scheme for study the interaction of geosynthetic material and soil during pulling.

To implement the process of pulling out, the method of fastening the geogrid element using the node-to-node anchor element is considered with the wall of the box, which in PLAXIS is a boundary condition with the prohibition of moving points horizontally (only vertical movements). The anchor as an element has only two contact points with the finite elements grid, so changing its length will have an effect only at the point at the other end, i.e. at the point of contact with the geosynthetic material. The change in the length of the anchor (compression) is set using the pre-tension function. For convenience, the pre-tension is set to 1000 kN.

The geosynthetic is attached to an inextensible plate (plate element with high rigidity and low thickness), which can be pulled by one or more rod elements (node-to-node element) due to the pre-tension set by it. The plate element allows you to transfer a uniform force from the rods to the geotextile. The ground is located on top and bottom of the geosynthetic and contact interaction is carried out due to the interface element. Moreover, zero friction is set for the interface above the plate. Such a system makes it possible to circumvent the problem of geomaterial going beyond the boundary conditions when modeling stretching. Additionally, transverse ribs of plate elements with a height of 5 cm and with distance of 10 cm are set on the web of geosynthetic material. Thus, the design considered below, will allow us to assess the reliability of such a simplification in relation to real tests and it will provide information about the geogrid elements forces and deflections, the the parameters of which are set in the traditional way for these materials and taking into account specific features. This approach is more feasible in practice, compared with the way to model a geogrid with rod elements on a grid. To model the soil, an elastic-plastic model with HardeningSoilSmall hardening was used, the yield surface of which is not fixed in the space of the main stresses and can expand due to plastic deformation (Hardin and Drnevich, 1972; Schanz et. al., 1999).

The interface element is used to simulate contact interaction. The surface contact roughness is modeled by selecting a suitable value of the strength reduction coefficient *Rinter*.

The geogrid particles friction coefficient is an important input parameter, which is the interaction between the geogrid and the ground. In numerical tests, it was adjusted iteratively until satisfactory results were obtained in comparison with the corresponding experimental data. The geogrid particles friction coefficient was found in this study to be equal to 1.0 and this parameter was used in further numerical tests. The parameters of the HSS model given in Table 1 were used for modeling.

Table 1. HSS model parameters.

E_{50}^{ref}, MPa	E_{oed}^{ref}, MPa	E_{ur}^{ref}, MPa	m	C, MPa	φ, °	ψ	$\gamma_{0,7}$	G_0^{ref}, MPa
30	30	150	0,5	0,2	30	0	$1 \cdot 10^{-4}$	70

3 RESULTS AND DISCUSSION

The boundary conditions were defined in such a way that nodes along the vertical boundaries can move freely only in the vertical direction. The nodes in the base are fixed against displacement in all directions.

The dependences of displacements on pulling forces was obtained as a result of numerical analysis and laboratory tests, which show a relatively close match for comparative purposes.

For small displacements, both numerical and experimental results were the same. However, with displacement of more than 10 mm, the results begin to diverge. The proximity of the results shows the suitability of the developed model.

The effect of the ribs placement step is considered by the example of dilatant behavior along the isofield of the porosity coefficient and is shown in Figures 2, 3. At the initial stage, e = 0.5, internal friction angle 50°, angle of dilatancy 20°. The pre-tension is set to 1000 kN. Further, only soil decompression is shown, i.e. e>0.5. Two variants of the ribs placement step are considered: 10 and 30 cm. The figures show the frontal area in front of the first edge, in which the flattening zone is formed (on the left). This zone has values of porosity coefficient less than 0.5, so it is excluded from the color display.

The maximum values of the porosity coefficient correlate with the areas of shear deformations and are concentrated above the ribs. Dilatant properties of compacted soil lead to volumetric expansion of the soil at these points, its decompression with an increase in shear deformations.

Reducing the number of ribs leads to the concentration of shear zones along the geogrid web in close proximity to it, which reduces the resistance to pulling.

The dependence of the pulling force on the ribs number is shown in Figure 4. With an increase in the number of transverse elements, the tensile forces at the loaded ends increase, which clearly shows the contribution of the transverse elements to the overall resistance to pulling.

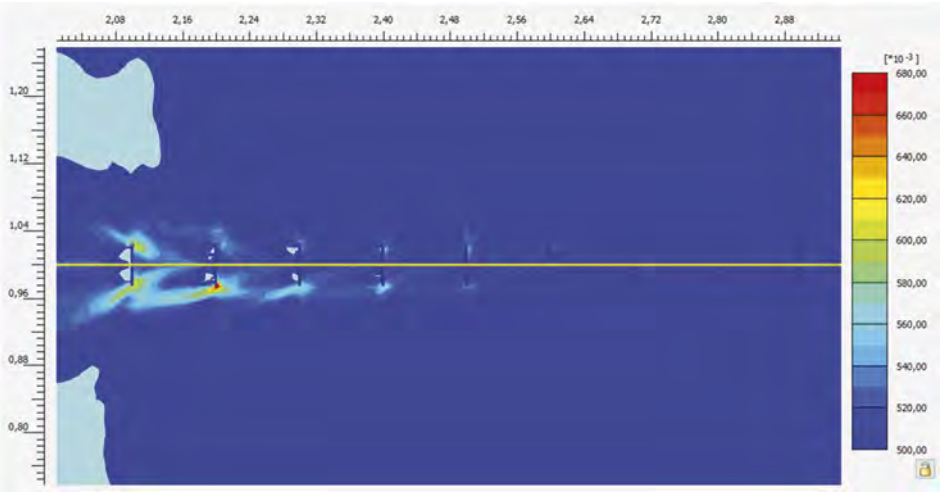

Figure 2. Distribution of porosity coefficient more than 0.5 along the geogrid for ribs step 10 cm.

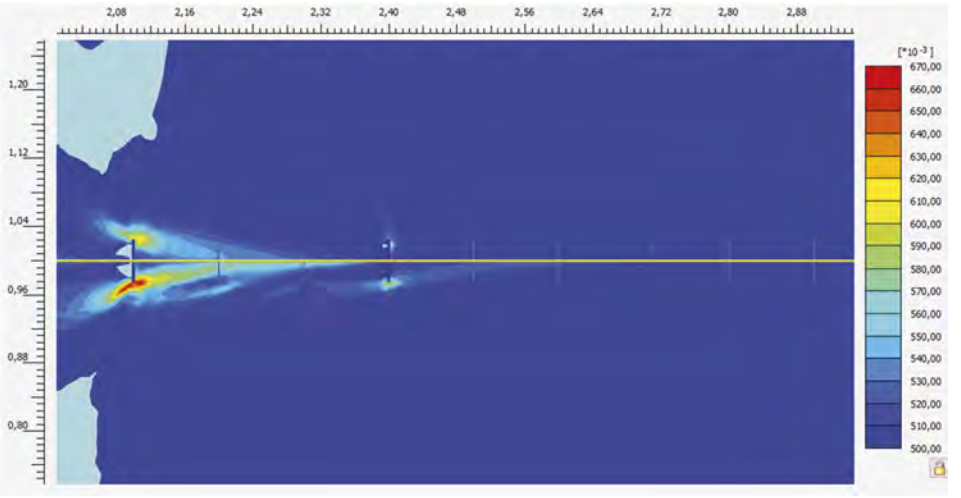

Figure 3. Distribution of porosity coefficient more than 0.5 along the geogrid for ribs step 30 cm.

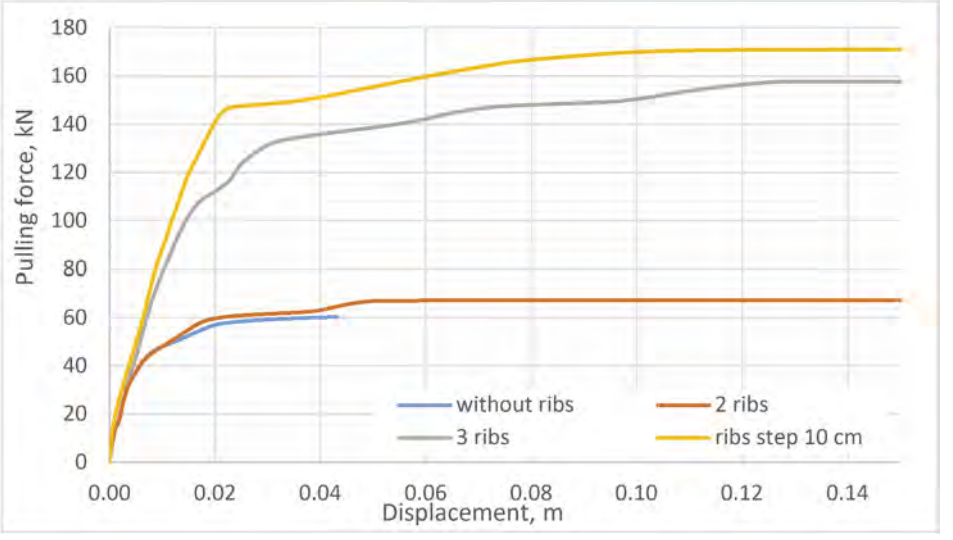

Figure 4. Shear deformations of the variant with 30 cm step.

4 CONCLUSIONS

The conducted studies have shown the possibility of using the developed model to analyze the mechanisms of interaction between the geogrid and the soil.

The results of calculations using the Plaxis software package confirmed the influence of the angle of internal friction and the angle of dilatancy on the increase in the pulling force due to the attachment of a larger volume of soil.

Reducing the number of ribs leads to the concentration of shear zones along the web of the geogrid in close proximity to it, which reduces the pull-out resistance.

ABSTRACT: Geotextile tubes are increasingly used in coastal protection structures. Typically, sand material is used as infill material in geotextile tubes as they provide good strength and stability. An alternative and sustainable solution is to use excavated soft soils to fill these geotextile tubes. Challenges to the use of soft soils are its low strength and its potential loss from the geotextile tube through the openings in the geotextile material. Thus, a small amount of flocculant or cement is needed. This paper presents the case study of a field trial where 6 geotextile tubes, infilled with lightly cemented recycled excavated soils, were installed onto the seabed using a high-capacity crane barge. Instrumentation such as strain gauges and shape array accelerometers were installed to monitor the performance of the bund during installation. Analysis of instrumentation data showed that lightly cemented recycled excavated soils is a viable infill material in geotextile tubes.

1 INTRODUCTION

Geotextile tubes are increasingly used for coastal protection structures such as breakwaters, revetments and coastal bunds. Geotextile tubes have certain advantages over conventional structures (e.g., concrete seawalls and sand bund revetments), such as the ease of construction and less environmental impact around the construction area (Siew et al., 2014; Hidayat., 2018). Typically, sand material is used as the infill material of geotextile tubes as it provides sufficient strength and stability, and is cost efficient (Lawson, 2008).

However, where sand resources are limited, excavated soft soils as an alternative infill material is explored. The use of recycled excavated soft soils presents a more sustainable construction practice. There are, however, some challenges of using soft soils as an infill material. The fine-grained particles of the soft soil may result in escaping (or piping) of infill material through the geotextile material, leading to wastage of materials and excessive settlement of geotextile tube (Leshchinsky et al., 1996) as well as contaminating the surrounding waters. Another concern with using soft soil is its low shear strength and high compressibility compared to sand material, which may affect the overall stability of the fully constructed coastal bund. One solution to the above concerns is to add a small amount of cement into the excavated soft soil to reduce piping of infill material, minimize settlement of the geotextile tube and provide sufficient overall strength.

A field trial was conducted to investigate the effectiveness of using lightly cemented excavated soft soils as an infill material for geotextile tubes. Six geotextile tubes were fully filled with lightly cemented soft soil, then lowered onto the seabed using a high-capacity crane to form into a bund. A bearing layer foundation was constructed as a bearing layer, using lightly treated excavated soft soils, prior to the lowering of geotextile tubes on top of it.

DOI: 10.1201/9781003299127-108

2 FIELD TRIAL

2.1 *Lightly cemented excavated soft soil*

The excavated soft soils used were dredged on site which contains previously dumped soil that originated from excavation activities from various land-based construction projects. The particle size distribution of the soil is shown in Figure 1. The soil consists largely of silt, with small amounts of sand and clay present.

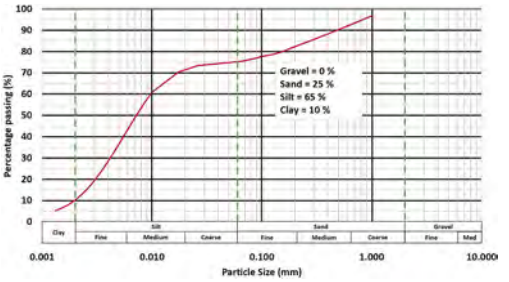

Figure 1. Particle size distribution of excavated soft soils.

To ensure stability of the bund, a target 28-day unconfined compressive strength design value of 60 kPa was determined for both the bearing layer foundation and geotextile tubes. A sufficiently high "flow" value (i.e., low viscosity value) was specified to ensure the ease of pumping. Cement content of 8% (by bulk unit weight of untreated soil) was used for the first two tubes B1 and B3, and 6% for the subsequent geotextile tubes. Cement content of 6.5% was used for the bearing layer foundation construction. The excavated soil has an initial moisture content between 175-190%, and a bulk density of 1.30 g/cm^3 before mixing with cement. After addition of Ordinary Portland Cement (OPC), the bulk density of the mixture was observed to be 1.34 - 1.36 g/cm^3.

2.2 *Construction of geotextile tube bund and bearing layer foundation*

A 30x20 m bearing layer foundation of 1 m thickness was constructed at seabed to provide a sufficiently strong foundation for the geotextile tube bund. The laying of the bearing layer foundation was done in a systematic manner to ensure a uniform and flat surface for the geotextile tube bund to rest on (Figure 2). The geotextile tubes used in the site trial were made from high tension polypropylene woven geotextile sheets with a wide width tensile strength of 200 kN/m in warp and weft direction. During the field trial, significant effort was placed on the QA/QC measures to ensure that the lightly cemented soft soil mixture was prepared properly. This mixture was then pumped into the geotextile tube via its inlet port. Geotextile tube was observed to inflate gradually. After infilling is complete, the fully filled geotextile tube was left in place for a few hours to allow for cementation and curing of infilled material to gain some initial strength. The geotextile tube was then lifted using a high-capacity crane and lowered onto the seabed. Field setup of the high-capacity crane barge is shown in Figure 3. Geotextile tube preparation process is illustrated in Figure 4 and construction sequence is illustrated in Figure 5.

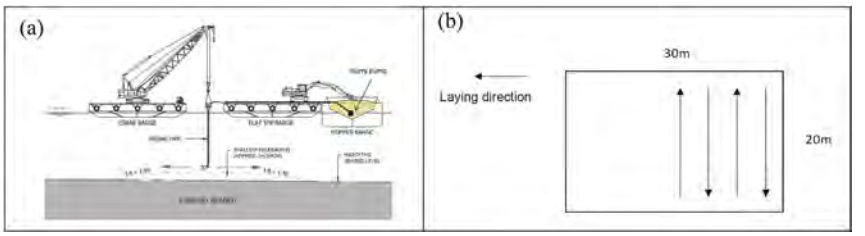

Figure 2. (a) Field setup for laying of bearing layer foundation; (b) Bearing layer foundation laying sequence.

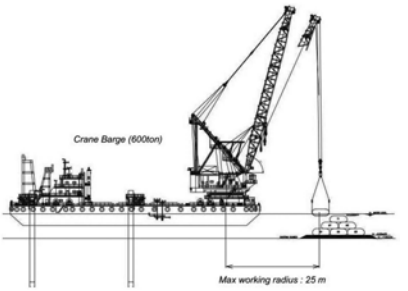

Figure 3. Field setup of high-capacity crane barge lowering geotextile tubes onto seabed.

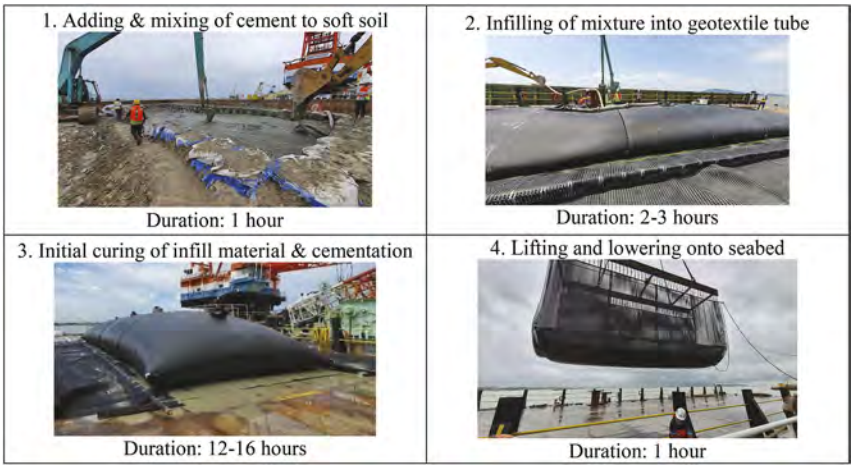

Figure 4. Preparation process of geotextile tube.

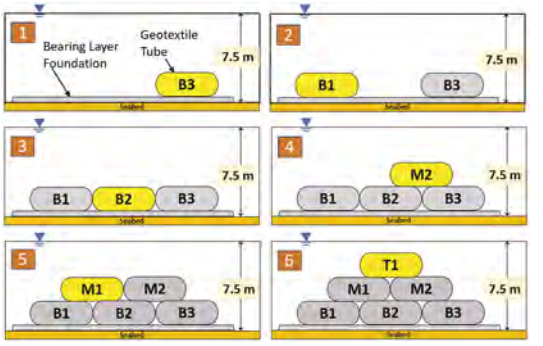

Figure 5. Construction sequence of geotextile tubes forming into a bund (Cross-Sectional View).

2.3 *Instrumentation*

Many instrumentations were installed to monitor the performance of the geotextile tube bund during the installation process. Strain gauges, Total Pressure Cells (TPC) and Pore Pressure Transducers (PPT) were installed in three (3) of the six (6) geotextile tubes. Shape Array Accelerometers (SAA) were installed at various positions to monitor the settlement of the bearing layer foundation and bottom layer geotextile tubes. The positions of the strain gauges and SAA are illustrated in Figures 6(a) and (b) respectively.

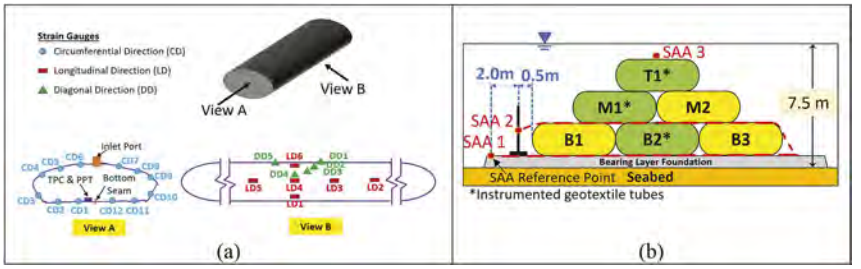

Figure 6. (a) Geotextile tube instrumentation details; (b) Positions of SAA for settlement measurement.

3 RESULTS & DISCUSSION

3.1 *Survey of bearing layer foundation and completed bund*

Bathymetry survey was conducted 14 days after the laying of the bearing layer foundation (Figure 7 (a)). The survey results show that the surface of the bearing layer foundation is relatively uniform and even. After the bund of 6 geotextile tubes were successfully installed, a bathymetry survey was conducted and showed that they were all in exact intended positions as shown in Figure 7(b).

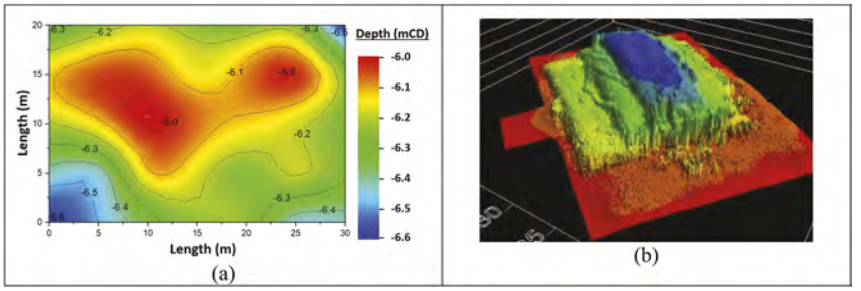

Figure 7. Bathymetry survey of the (a) Bearing layer foundation; (b) Completed geotextile tube bund.

3.2 *Strain gauge readings*

Figure 8(a) shows the strain gauge readings of geotextile tube B2 during the infilling, and 8(b) shows the strain gauge readings of tube B2 during stacking of upper layer tubes on top of it.

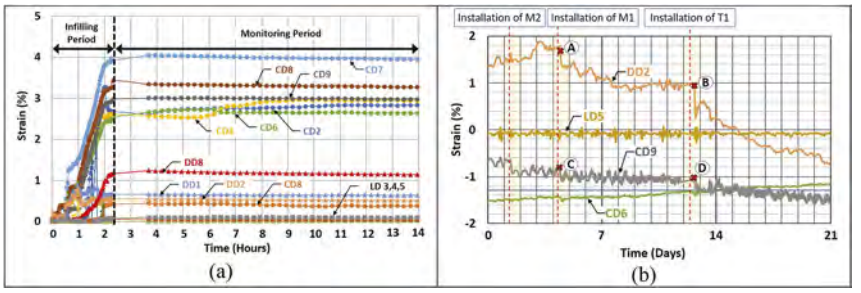

Figure 8. Strain gauge data of geotextile tube B2: (a) During infilling; (b) When upper layer tubes were stacked on it.

It was observed during infilling that the strain gauge readings increased gradually (up to ~4% in CD direction) during infilling as the geotextile tube gradually took shape and the geotextile material experienced tension. During the monitoring period, a minor decrease in strain

was registered (~0.2%) and the shape of the geotextile tube on-site was observed to remain relatively uniform and unchanged. In addition, minor piping of infilled lightly cemented excavated soft soil was observed only at the start of infilling period, and quickly stopped around 15-20 minutes. From Figure 8(b), strain gauges DD2 and CD9 experienced a reduction in tension (at A, B, C and D) while CD6 experienced increase in tension. LD5 strain readings remain relatively constant, suggesting that there was minimal deformation along the longitudinal length of tube B2. Overall, changes in strain readings were quite small, which suggests that during the loading of upper layer tubes, the shape of tube B2 remained largely uniform.

3.3 *Settlement of bearing layer foundation*

The Shape Array Accelerometer (SAA) readings from SAA 1 indicates the settlement of the bearing layer foundation as geotextile tubes were gradually lowered on top of it (Figure 9). After the installation of the bottom layer geotextile tubes was complete at day 0, the maximum settlement observed was 120 mm at the location below center of tube B2. Lightly cemented excavated soft soils (at 6% cement content) was infilled in the spaces between the three bottom layer geotextile tubes (B1, B2 & B3) in preparation for the stacking of the middle and top layers of geotextile tubes. The middle layer tubes (M1 & M2) were lowered onto the bottom layer tubes 34 days later after the completion of the bottom layer, and an almost parallel settlement of about 60 mm was observed across the whole width of the bottom layer. Eight (8) days later (i.e. 42nd day), the top layer tube was installed. An additional settlement of about 30 mm was observed at the center of the bund, directly below the geotextile tube T1. After the completion of all 6 geotextile tubes, SAA 1 readings were monitored for another 42 days and only small additional settlements of around 10-30 mm were observed during this 6-week period.

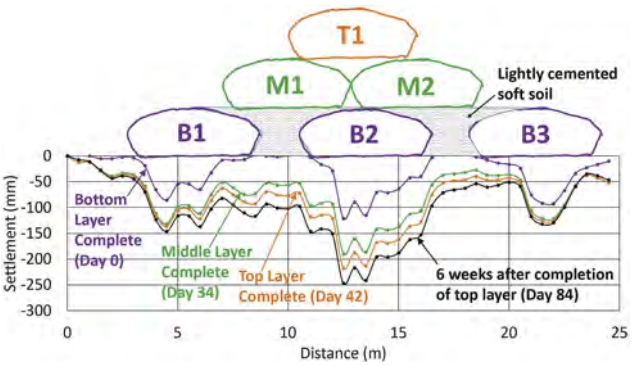

Figure 9. Settlement profile of bearing layer foundation as geotextile tubes were lowered onto it.

3.4 *Thickness of bottom layer geotextile tubes*

Using readings from SAA 1 and SAA 2, the change in the thickness of bottom layer geotextile tubes B1, B2 & B3 can be estimated, as shown in Figure 10. The thickness of bottom layer tube B2 decreases by 30 mm after stacking of the middle layer tubes M1 & M2 on top of it. There was no change in the thickness of bottom layer tube B2 after the top layer tube T1 was stacked on top of the middle layer tubes. A larger settlement of 160 mm towards the left edge and 110 mm towards the right edge of tube B2 was observed, which may be due to the tubes from the middle layer tubes (M1 & M2) deforming slightly to conform to the gap of the bottom geotextile tubes. There was also no change in the thickness of tube B2 six weeks after the completion of the bund.

These observations show that the lightly cemented soft soil infill material was able to ensure sufficient strength and stability of the bund, with only very small settlement observed in the bottom layer geotextile tubes during the stacking of geotextile tubes onto it.

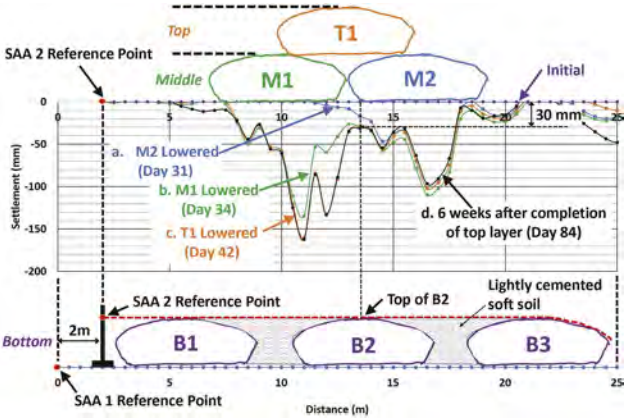

Figure 10. Thickness of bottom layer geotextile tubes as upper layer tubes were stacked onto it.

4 CONCLUSION

In this field trial, six geotextile tubes were successfully infilled with specially designed lightly cemented soft soils and were subsequently lowered onto the seabed forming a bund. Strain gauge results indicate that geotextile tube material and design is adequate in withstanding the pumping pressure and installation stress during the whole installation process. Visual observations on site also showed that only minor piping of lightly cemented soft soils was observed during a very early and brief period in the infilling stage. SAA readings showed that the bearing layer foundation only experienced minor settlement during the lowering of geotextile tubes onto it. In addition, analysis of SAA 1 and SAA 2 showed that there was only a very small settlement observed in the bottom layer geotextile tubes when the middle and top layer geotextile tubes were stacked on top of it. Thus, the results from this field trial shows that lightly cemented soft soil can be an effective alternative infill material within geotextile tubes, providing sufficient strength and stability to the geotextile tube and hence the bund.

Comparative assessment of single and double interface shear strength properties: A case study of a landfill project in the Western Cape Province, South Africa

V. Sylivery & D. Kalumba

B. Mawer
Associate, JG Afrika (Pty) Ltd., Cape Town, South Africa

ABSTRACT: Incorporation of multi-layered series of geosynthetics and geomaterials has presented new potential interfaces for shear failure of lining systems in engineered municipal solid waste (MSW) landfills. In the laboratory, interface shear strength parameters used in the design of lining systems especially side-slopes and bases are determined through single interface testing configuration according to ASTM D5321-20 and ASTM D6243-20 standards. This testing configuration, however, gives a limited understanding of shear strength transfers between the lining components when a multi-layered lining system has been proposed. Multi-interface testing configuration has been sought as an alternative by several scholars to address the above limitation. However, there is little information available as it is not stipulated in any official standard. This study was thus, conducted to ascertain the potential use of multi-interface testing methods through a case study of a proposed lining system for a new landfill cell in South Africa. It was found that single and multi-interface testing on specimens that involved geosynthetics only in the setup, similar results were observed. However, a dissimilarity in interface shear results was observed on those that involved geomaterials and geosynthetics.

1 INTRODUCTION

An engineered MSW landfill is a sensitive geo-environmental barrier system that achieves a maximum disposal capacity by increasing the side-slope gradient while limiting leachate migration to ground and surface water reserves (Rowe, 2011). The lining systems used in these structures usually constitute a multi-layered band of numerous geosynthetics and geomaterials that are project and site specific (De Brito Galvão et al., 2008). Since their inception, geosynthetics have been used extensively in different geotechnical projects fulfilling various functions including acting as pollution or contaminant barrier, reinforcement, separation, filtration, drainage and protection (Kalumba & Scheele, 1999; Mawer & Kalumba, 2014; Kiptoo et al., 2017). Thus, playing an important role in the lining system of an engineered MSW landfill. However, as several layers of geosynthetics and geomaterials are being introduced in MSW landfills' lining systems, their interaction becomes pertinent when identifying possible interfaces for shear failure mobilization (Lopes & Silvano, 2010; Zamara et al., 2012; Bacas, Cañizal & Konietzky, 2015; Feng & Lu, 2016; Cen, Wang & Sun, 2018).

To establish interface shear strength properties in the laboratory, single interface shear strength tests of soil-geosynthetic or geosynthetic-geosynthetic are typically conducted following ASTM D5321-20 and ASTM D6243-20 standards for non-cohesive materials and geosynthetic clay liners (GCLs), respectively (ASTM, 2020a,b). Previous studies on multi-interface testing found that, when similar interfaces were tested through this configuration, peak strength envelopes and

DOI: 10.1201/9781003299127-109

interface shear strength parameters were determined to be similar to those of the weakest interface under a single interface configuration (Stark, Niazi & Keuscher, 2015; Khilnani, Stark & Bahadori, 2017; Sikwanda, Kalumba & Nolutshungu, 2019). In contrast, at large displacement (LD), interface shear strength parameters obtained were very dissimilar, with the single interface configuration achieving higher values than multi-interface configuration. Observations by these scholars suggested that tests conducted under the multi-interface arrangement were still uncertain as it was difficult to pinpoint the interface facilitating failure, even though there was a certain degree of comparability to the single interface configuration. In this study, multi-interface testing was further investigated through a systematic comparison of interface shear results generated from single and multi-interface testing configurations through a case study of the proposed lining system for a new landfill cell in the Western Cape Province in South Africa.

2 METHODOLOGY

2.1 *Proposed lining system*

The proposed landfill cell was classified as a general waste landfill (classifying as a Type 2 waste stream as per South African regulations). It also had a net positive water balance during winter months due to Cape Town's seasonal rainfall pattern, therefore creating the potential to generate significant amounts of leachate at certain times of the year (Department of Water Affairs and Forestry, 1998). This landfill cell was planned to be built in a "piggyback" fashion on top of a pre-existing 7-8m thick wastefill deposit which was previously dumped on an unlined area. A multi-layered basal lining design was proposed, as shown in Figure 1.

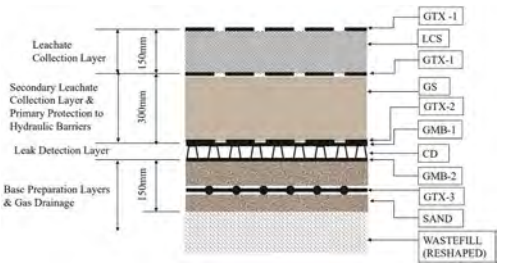

Figure 1. Proposed Basal Lining System for General Waste Landfill (Sylivery, 2022).

2.2 *Description of lining materials*

2.2.1 *Geosynthetics*

Based on the above arrangement, the two nonwoven geotextiles used were bidim® A5 (GTX-1) and bidim® A7 (GTX-2). These geotextiles were locally manufactured from 100% polyester resulting in high-performance nonwoven geotextiles whose continuous filaments were bonded by needle-punching. These geotextiles performed separation and protection functions. Furthermore, a high-strength woven geotextile-based geogrid, RockGrid®PC (GTX-3), was used in a reinforcement function thereby minimizing differential settlement within the underlying historic waste deposit.

Two smooth-sided geomembranes, i.e., 2.00mm thick HDPE geomembrane (GMB-1) and 1.5mm thick LLDPE geomembrane (GMB-2) were also proposed to form part of the lining system. These geomembranes were manufactured through a calendered flat-die extrusion process. Lastly, a durable and heat-formed multiple-cuspated synthetic drain (CD) sheet that provided a high capacity and non-restricted drainage path that was compatible with GMB-1 & GMB-2 was used. The cusps of the CD were symmetrical, thus, providing high resistance to crushing when exposed to heavy loads. Wedged between the two geomembranes the CD formed part of the primary leak detection system.

2.2.2 *Geomaterials*

This study utilized three geomaterials, namely: sand, gravelly sand (GS), and leachate collection stone (LCS). The GS and LCS were products of crushed building waste materials and were abundantly available in the old section of the landfill. The use of these geomaterials was motivated by their availability, the need to re-use building waste, and in the case of the LCS, the high permeability, allowing for easy leachate collection. The mechanical properties which were conducted in the Geotechnical Engineering Laboratory at the University of Cape Town are presented in Table 2.

2.3 *Testing procedure and program*

A total of 45 single and double interface shear tests were conducted on the lining components for the proposed landfill cell to achieve the objectives of this study. The test conditions included 60 minutes for hydration and consolidation of specimens at their respective applied normal pressures of 150, 300 and 450 kPa. The shear tests were also conducted using a shearing rate of 1mm/min as recommended by the ASTM D5321-20 standard for non-cohesive materials. Table 3 summarizes all lining components tested with their testing configurations.

2.3.1 *Single interface configuration*

In the single interface configuration, two interface setups were facilitated involving soil-geosynthetic and geosynthetic-geosynthetic interactions. In the soil-geosynthetic setup, the geosynthetic component was clamped on the lower shear box and the soil was compacted to the target density in the upper shear box. While, in the case of the geosynthetic-geosynthetic setup, the respective geosynthetic specimens were clamped on the upper and lower shear boxes.

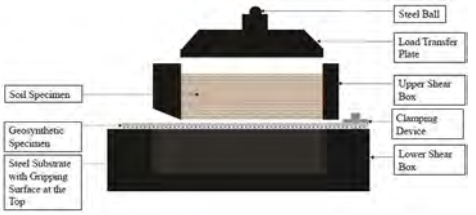

Figure 5. Soil-Geosynthetic Interface.

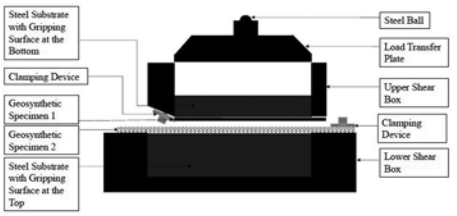

Figure 6. Geosynthetic-Geosynthetic Interface.

2.3.2 *Double interface configuration*

In the double interface configuration, testing was implemented through three setups i.e., soil-geosynthetic-soil, soil-geosynthetic-geosynthetic and geosynthetic-geosynthetic-geosynthetic interactions. The modification to the single interface configuration was an addition of a third soil/geosynthetic specimen in the setup.

In the soil-geosynthetic-soil setup, the soil was firstly compacted to the target density in the lower shear box followed by geosynthetic specimen placement on top of the lower box without any clamping mechanisms and finally, the second soil specimen was compacted on the upper shear box. A similar approach was used for the soil-geosynthetic-geosynthetic setup, except that a geosynthetic specimen was clamped on the top of the lower shear box to replace soil specimen. For a geosynthetic-geosynthetic-geosynthetic setup, two geosynthetics were clamped to the ends of the upper and lower shear boxes while one geosynthetic specimen was placed freely in the middle.

3 RESULTS & DISCUSSION

3.1 *Soil-geosynthetic-soil interactions*

Two interface test series in the double interface configuration involved soil-geosynthetic-soil interactions. The recorded interface shear strength parameters, however, were observed to vary across all sets. For instance, the shear strength parameters obtained in the single interfaces LCS |

GTX-1 and GTX-1 | GS were lower than those determined in the double interface LCS | GTX-1 | GS. Whereas the peak interface angle of friction recorded by the single interface SAND | GTX-3S2 was similar to that obtained in the double interface configuration of SAND | GTX-3 | SAND. Other strength parameters including those of SAND | GTX-3S1 were completely different. The inconsistency of this test setup was observed due to soil ploughing or soil blistering in the lower shear box attributed to the size difference with the upper shear box.

3.2 *Soil-geosynthetic-geosynthetic interactions*

There were two test series that involved soil-geosynthetic-geosynthetic interactions in the double interface configuration. The recorded interface shear strength parameters were similar to those of the weakest interfaces for the individual single interfaces. For example, in the single interfaces of GS | GTX-2 and GTX-2 | GMB-1, the weakest peak angle of friction was 11.27° with 4.30kPa apparent adhesion and these were similar to the peak parameters in the double interface configuration of GS | GTX-2 | GMB-1 which recorded 13.55° and 4.46kPa. The other set involved single interfaces CD | GMB-2 and GMB-2 | SAND with the former recording weakest interface parameters at peak of 24.04° and 9.27kPa which were similar to those observed in the double interface configuration of CD | GMB-2 | SAND of 24.51° and 0kPa. This setup suggested that the interface shear strengths of the weakest interface will prevail in the multi-interface configuration provided test conditions are the same.

3.3 *Geosynthetic-geosynthetic-geosynthetic interactions*

For the geosynthetic-geosynthetic-geosynthetic test series, the interface shear strength parameters were in between those observed in the constitutive single interfaces. For instance, the double interface configuration of GTX-2 | GMB-1 | CD recorded a peak angle of interface friction of 13.45° which was in between those recorded for single interfaces of GTX-2 | GMB-1 and GMB-1 | CD as seen in Table 4. However, the interface friction recorded at LD of 9.34° was similar to that of GTX-2 | GMB-1 and lower than that of GMB-1 | CD, partly because GTX-2 | GMB-1 was the overall weakest interface in all test series for this project. A similar trend was also observed at the peak for the double interface GMB-1 | CD | GMB-2 as seen in Table 4

Table 4. Summary of interface shear strength parameters.

		Interface shear strength parameters			
		at Peak		at Large Displacements	
Interface Configuration		δ_p [°]	$c_{\alpha\text{-}p}$ [kPa]	δ_{LD} [°]	$c_{\alpha\text{-}LD}$ [kPa]
Single-	LCS | GTX-1	17.05	65.42	10.85	29.71
	GTX-1 | GS	33.16	29.66	12.23	112.00
	GS | GTX-2	38.06	13.32	35.50	21.32
	GTX-2 | GMB-1	11.27	4.30	10.24	2.40
	GMB-1 | CD	18.45	0.00	18.45	0.00
	CD | GMB-2	24.04	9.27	23.99	8.33
	GMB-2 | SAND	29.07	0.00	22.74	0.00
	SAND | GTX-3S1	37.71	24.66	36.99	24.66
	SAND | GTX-3S2	31.21	44.99	12.95	125.00
Double-	LCS | GTX-1 | GS	42.11	30.50	41.90	24.17
	GS | GTX-2 | GMB-1	13.55	4.46	9.37	6.77

	GMB-1 | CD | GMB-2	20.30	10.00	20.54	5.13
	CD | GMB-2 | SAND	24.51	0.00	24.00	0.00
	SAND | GTX-3 | SAND	31.11	85.71	31.11	85.71

δ_p and δ_{LD} = peak and large displacement (LD) angles of interface friction
$c_{\alpha\text{-}p}$ and $c_{\alpha\text{-}LD}$ = peak and large displacement (LD) apparent adhesions

4 CONCLUSION

The following conclusions have been established from this study:

- For interfaces that involved geomaterials, i.e., soil and stone in their setups, for instance, LCS | GTX-1 | GS, GS | GTX-2 | GMB-1, CD | GMB-2 | SAND & SAND | GTX-3 | SAND; higher interface friction angles and apparent adhesion parameters were observed at peak with a decline at LD.
- For the interfaces that involved only geosynthetics in their setups, such as GTX-2 | GMB-1 | CD & GMB | CD | GMB-2 interfaces; similar interface friction angles and apparent adhesion parameters at peak and LD were generally observed. This testing configuration presents a success of multi-interface testing when compared to single interface testing.
- This study also found that some of the lining components could potentially improve shear resistances when tested concurrently in the non-standardized double interface testing configuration. For instance, due to a GS layer in the double interface configuration GS | GTX-2 | GMB-1, the shear resistances observed, were 18% higher than the constitutive single interfaces.

Finally, for both testing configurations, the critical or weakest interface involved an interaction between a smooth geomembrane (GMB-1) and nonwoven geotextile (GTX-2). This observation was noted to be similar to observations by other scholars (Buthelezi, Kalumba & James, 2016; Adeleke, Kalumba & Hardie, 2019; Adeleke, Kalumba & Oriokot, 2019).

Experiment on reducing lateral earth pressure with a biopolymer-treated layer and geogrid-reinforced sand backfill

Gi-Yun Kim & Hwijae Lee
Graduate student, Department of Civil Systems Engineering, Ajou University, Korea

Ilhan Chang*
Associate Professor, Department of Civil Systems Engineering, Ajou University, Korea

ABSTRACT: In general, the common active earth pressure theory used for retaining wall design has several limitations which render ineffective over estimation and conservative design. Recently, biopolymer-based soil treatment (BPST) is considered as a new ground improvement practice in terms of sufficient shear strength enhancement via hydrogel induced interparticle bonding. In this study, an experimental setup which allows wall rotation subjected to the bottom toe is used to monitor the lateral earth pressure variation with wall rotation. Different backfill conditions were considered to assess the BPST effect on the active lateral earth pressure behavior. Experimental results indicate that a dehydrated BPST layer embedded in the backfill reduces the active lateral earth pressure which is similar to the reinforcement effect of a geogrid layer installation.

1 INTRODUCTION

Active earth pressure theories (Coulomb 1776, Rankine 1857,) commonly used in retaining wall design have limitations which can either overestimate or underestimate the earth pressure level in practice. The magnitude of the lateral earth pressure influences the retaining wall cross-sectional dimension. Geosynthetics, lightweight materials (Arrefnia et al. 2021), compressible geofoam (Xie et al. 2020), and retaining wall relief shelves (Khan et al. 2016) are being researched to reduce earth pressure. Furthermore, in cohesive soil, the cohesive force works in the direction of sliding resistance, and friction and cohesion resistance occur along the sliding failure line, reducing active earth pressure.

Biopolymer-based soil treatment (BPST) has recently been introduced into geotechnical engineering as an ecofriendly and sustainable method for soil improvement practices. Through particle surface accumulation and interparticle bonding network formation, BPST enhances interparticle adhesion which results to overall shear strength increment (Lee et al. 2017, Chang et al. 2020). In this study, a soil tank apparatus which has a rotatable wall on the side is used to assess the lateral earth pressure of different backfill conditions with wall rotation.

2 EXPERIMENTAL SETUP AND INSTRUMENTATION

2.1 *Materials*

This study used dried Jumunjin sand to form the model ground. Basic properties of Jumunjin sand are listed in Table 1.

In this study, xanthan gum (Sigma-Aldrich, CAS No. 11138-66-2) biopolymer is used to form a BPST layer placed in the backfill behind the wall. In addition, a geogrid embedded condition was considered to compare the lateral earth pressure distributions between xanthan gum BPST layer containing backfill and typical geogrid installed backfill. Detail dimensions of the geogrid member used in this study is displayed in Figure 1. Table 2 summarizes the

2.2 *Experimental details and testing procedure*

The soil tank was fabricated with a size of 980 mm in length × 300 mm in width × 900 mm in height. A transparent acrylic plate was attached at the front.

The rotatable wall was made of acryl with a dimension of 300 mm in length × 100 mm in height × 20 mm in thickness, and consisted 7 separate plates where two load transducers and an earth pressure gauges were installed on each plate to measure the lateral earth pressure acting on the corresponding section. The vertical was corrected and a model ground was formed by installing a hinge at the bottom of the wall.

Model ground (i.e. backfill) has formed via sand pluviation. The model ground in the tank has shown a relative density of D_r = 78.2%. A xanthan gum BPST layers as well as geogrids were installed at the designated positions (Figure 2). The lateral earth pressure acting on the wall during wall rotation was continuously measured by the load transducers and earth pressure transducers. The rotation rate was set at 0.01°/min using a gear box.

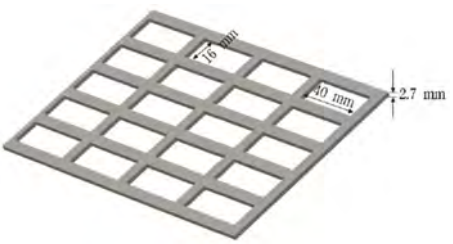

Figure 1. Geogrid detail dimension.

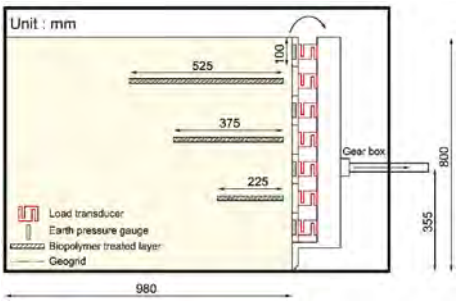

Figure 2. Soil tank.

3 EXPERIMENTAL RESULTS AND DISCUSSION

The effect of reducing earth pressure was verified by measuring lateral earth pressure according to wall rotation and installing BPST layers and geogrids in the model ground. The lateral earth pressure ratio (active earth pressure Ea/earth pressure at rest E0) and wall displacement (Δx: wall lateral displacement, h: wall height) are plotted to analyze the lateral earth pressure distribution and reduction effect by wall rotation (Figure 3). Figure 3(a) shows the total lateral earth pressure acting on the entire wall, and Figure 3(b-f) shows the lateral earth pressure acting on each measurement plate (No. 2-6). (wall number 1 from the top of the wall). In the center of walls No. 2, 4, and 6, BPST layers and geogrids were installed. An arrows indicate the effect of reducing lateral earth pressure in the dehydrated (dry) BPST condition rather than the untreated condition.

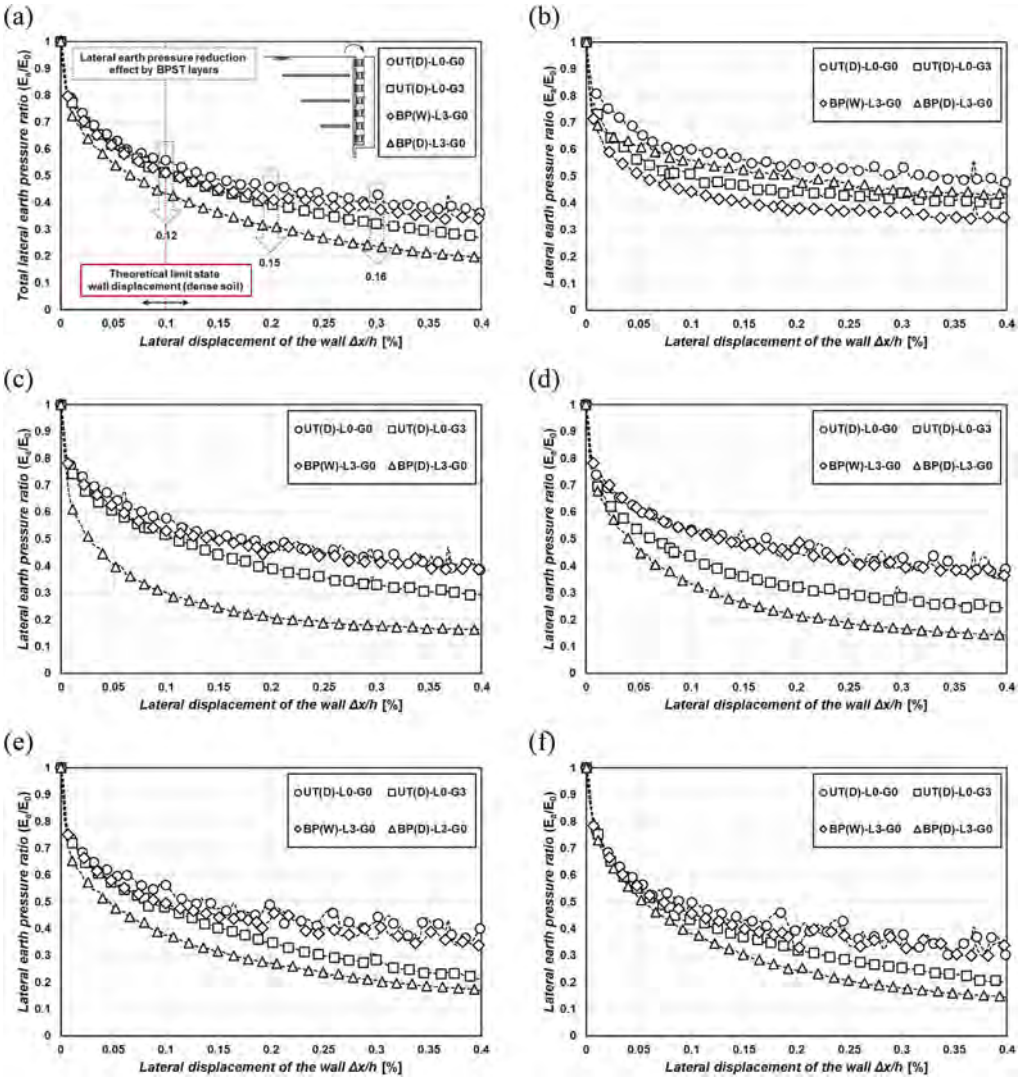

Figure 3. Lateral earth pressure ratio (E_a/E_0) according to wall rotation ((b-f) is No. 2-6 wall) .

Regardless of the backfill conditions, the lateral earth pressure reduces rapidly when the wall begins to rotate. The lateral earth pressure does not converge and decreases linearly after the active earth pressure is generated by the rotation of the wall in each condition due to wall friction and the cohesive force of the BPST layers. Shear resistance occurs when a geogrid is installed in the ground due to surface friction at the soil-soil and soil-geogrid contact surfaces. Because the geogrid was inserted into the ground without being affixed to the wall in this study, the lateral movement of the soil particles was restrained due to the surface friction of the geogrid, resulting in a slight earth pressure reduction effect. Because of the weak structure of the xanthan gum hydrogel, the initial state (wet) condition of the BPST layer (BP(W)-L3-G0) led an earth pressure reduction effect (slightly enhanced cohesion and decreased internal friction angle (Table 3)). However, as BPST layers dehydrate (drying), the strengthening effect promotes the lateral earth pressure reduction, where condensed BPST layers seem to have similar effect on lateral earth pressure reduction when compared to geogrid embedded cases. Because of the improvement in the shear parameter in the dried xanthan gum treated layer, lateral movement restraint occurs at the treated position similar to the time of geogrid installation. Furthermore, the dried xanthan gum treated layer works as a retaining wall relief shelf, reducing the lateral earth pressure under the shelf and restricting soil dis-placement. As a result, it had a little greater lateral earth pressure reduction effect than before the geogrid was installed. The effect of BPST treatment interval should also be considered in order to verify the application of BPST to retaining wall backfill. Furthermore, additional research is needed to combine the backfill of BPST with geogrid to mitigate for the BPST initial (wet) weak hydrogel structure. However, xanthan gum biopolymer has a problem in that it is difficult to dry in the ground, requiring research into materials that may overcome this.

4 CONCLUSION

In this study, a rotatable was constructed and a physical modeling test was performed to obtain the following results on the BPST influence on the backfill of the retaining wall. The lateral earth pressure rapidly decreased as the wall started to rotate. In the case of the BPST layer, the wet (initial) xanthan gum treated layers improve shear strength but does not significantly effect on lateral earth pressure behavior. However, because the BPST layers are dehydrated (dry), the improving effect of the shear strength parameter promotes lateral earth pressure reduction. This demonstrated the effect of restricting lateral movement on reducing lateral earth pressure at a position treated similar to the installation of the geogrid. Furthermore, the dried xanthan gum treated layers work as a retaining wall relief shelf, reducing lateral earth pressure under the shelf and restricting soil displacement. As a consequence, the effect of reducing lateral earth pressure was little greater than the effect of installing a geogrid.

Displacement field measurement of stacked geotextile tubes by digital image correlation

Dong-Ju Kim, Jong-Sub Lee & Jun Hyung Bae
Korea University, Seoul, Republic of Korea

Dong Geon Son, Yong-Hoon Byun & Yoon Geom Heo
Kyungpook National University, Daegu, Republic of Korea

ABSTRACT: Displacements often need to be measured to evaluate the stability of earth dams. Various instruments for measuring the displacement exist, but most contacting position sensors can measure the displacement only at a certain position. Digital image correlation is a promising technique for measuring a displacement field through a camera without any contact with the measurement points. In this study, variations in the displacement fields of stacked geotextile tubes with the water level are evaluated using digital image correlation. Experimental results show that the vertical and horizontal displacements of the bottom layers are larger than the top layers with an increased water level. The top layer mainly moves backward and then moves upward and forward. In contrast, the bottom layer consistently moves upward and forward after an initial downward and backward movement. Thus, the digital image correlation method suggested in this study may be effectively used to evaluate the behavior of a temporary dam structured with geotextile tubes.

1 INTRODUCTION

Geotextile tube has the characteristics of permeability, and the geotextile tubes can be filled with sandy soil on site. After the filling, the geotextile tubes behave as a mass-gravity unit, showing high stability (Lawson, 2008). Accordingly, geotextile tubes have been widely used for coastal protection, beach restoration, and embankments.

Geotextile tubes are often stacked in multi-layers to protect structures and slopes in various hydraulic and marine applications. Stacked geotextile tubes have various failure modes, including sliding, global slope stability, bearing capacity, settlement, and skin rupture (Zhu et al., 2014). Zhu et al. (2010) evaluated the global stability of stacked geotextile tubes using numerical analyses. However, there are few studies to characterize the behaviors of each layer of the stacked geotextile tube structure at various water levels.

Digital image correlation (DIC) is a non-contact optical measurement method based on digital image processing and numerical computation. DIC is used to investigate the displacement and strain fields of a specimen by comparing the image patterns before and after the deformation of the specimen. In the geotechnical engineering field, various studies have applied the DIC technique to observe the displacement field and failure mechanisms (Arshad et al., 2014; Wang et al., 2020; Segaline et al., 2022). However, the DIC technique has not been applied to monitor the displacement pattern of stacked geotextile tubes at various water levels.

The purpose of this study is to evaluate the displacement field of stacked geotextile tubes using the DIC technique. Geotextile tubes are filled with sandy soil for stacking. Using the DIC technique, the vertical and horizontal displacements of stacked geotextile tubes with various water levels are evaluated. Finally, the displacement patterns of the stacked geotextile tubes is discussed.

DOI: 10.1201/9781003299127-111

2 MATERIALS AND METHODS

2.1 *Materials*

The geotextile tube used in this study had a theoretical diameter of 38 mm and comprised a woven geotextile fabricated using polyester fabric. The geotextile tubes are manufactured with a length of 600 mm, and a width of 200 mm. The fill material is prepared by mixing silica sand and clay to evaluate the stability of the stacked geotextile tubes. The index properties of the sandy soils are summarized in Table 1. The mean diameter (D_{50}) of the sandy soil is 0.1.

Table 1. Index properties of sandy soil.

D_{10} [mm]	D_{30} [mm]	D_{50} [mm]	D_{60} [mm]	C_u	C_c	#200 [%]	PI [%]	LL [%]	PL [%]	G_s	USCS
0.04	0.10	0.20	0.27	6.75	0.93	20	12.5	23	10.5	2.88	SC

D_{10} = 10% cumulative passing; D_{30} = 30% cumulative passing; D_{50} = 50% cumulative passing; D_{60} = 60% cumulative passing; C_u = coefficient of uniformity; C_c = coefficient of curvature; #200 = percent passing No.200 sieve; PI = plasticity index; LL = liquid limit; PL = plastic limit; G_s = specific gravity; USCS = unified soil classification system; SC = clayey sands

2.2 *Digital image correlation system*

The DIC system consists of two industrial cameras and dual light emitting diode (LED) illumination to acquire the images. The two cameras have a 2.3 megapixel resolution. The measurement areas of the cameras range from 10×6 mm^2 to 1350×850 mm^2. A speckle pattern is applied to the specimen to obtain a high accuracy displacement field in the acquired image. Therefore, a black-on-white random speckle pattern is uniformly applied to each specimen using spray paint. The LED illuminations provide an appropriate brightness and contrast to the speckle pattern applied to the specimen. The DIC system is calibrated according to the software process. For calibration, two cameras simultaneously captured the same calibration object. The captured images were used to estimate the intrinsic (center point, lens distortion coefficients, focal length of each camera) and extrinsic parameters (translation and rotation between the two cameras) through software. The estimated intrinsic and extrinsic parameters were used to correlate the two-dimensional images captured by the cameras into three-dimensional coordinates.

2.3 *Experimental setup*

A schematic of the model test for the stacked geotextile tube is shown in Figure 1. An acrylic tank with a length of 1020 mm, a width of 420 mm, and a height of 600 mm is prepared to conduct the model test. In the acrylic tank, valves are installed on the wall on the upstream side at intervals of 30 mm in height to maintain a constant water level. A hole with a diameter of 50 mm has been installed at the bottom of the acrylic tank on the downstream side for drainage. Each geotextile tube is filled with a weight of 58.8 N of dry sandy soil. The geotextile tubes are stacked in four layers in the triangular. The voids between the stacked geotextile tubes are filled with sandy soil with the same particle size distribution as the fill material. To capture the images, the cameras are placed above the geotextile tube of the downstream side to which the speckle pattern is applied. The test program includes four different water levels. The water level on the upstream side increased from 90 mm to 240 mm. Each water level is maintained for 15 minutes. Each image is captured every 10 seconds.

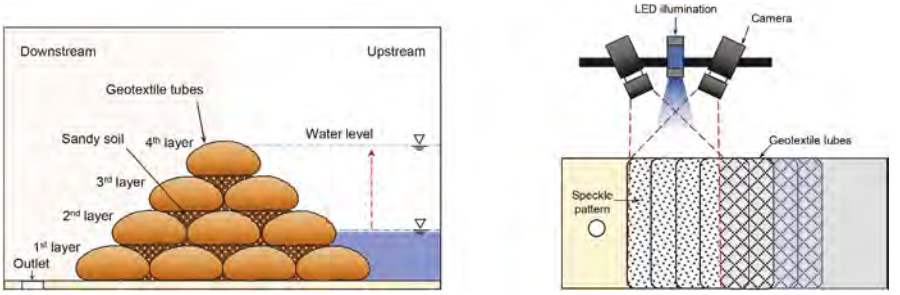

Figure 1. Schematic drawing of a model test using stacked geotextile tube.

3 EXPERIMENTAL RESULTS

3.1 *Vertical and horizontal displacement*

Vertical and horizontal displacements in each layer of the geotextile tube are evaluated from the images obtained from using the DIC technique. Figure 2 shows the vertical and horizontal displacements in each layer with elapsed time. Once the water level increases, the vertical and horizontal displacements show negative values and then converge to a constant value. Note that the negative values of vertical and horizontal displacements denote the downward and backward movements, respectively. After the first water level, the vertical displacement consistently increases up to the fourth water level, and the first and second layers of geotextile tubes show higher vertical displacements than other layers. In the horizontal displacement, all layers initially move to the upstream side in the first water level. After the second water level, the first and second layers of geotextile tubes start to move forward. After the third water level, all layers slightly move to the downstream side.

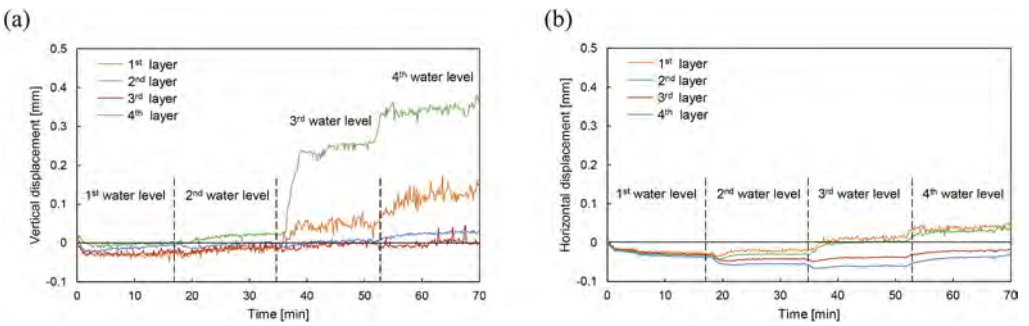

Figure 2. Evolution of displacements with water level: (a) vertical displacement; (b) horizontal displacement.

3.2 *Displacement pattern*

The displacement patterns on a two-dimensional plane estimated from measuring the vertical and horizontal displacements are shown in Figure 3. For the first and fourth layers, the final vertical and horizontal displacements in each water level are presented. In the first layer, the geotextile tubes initially move downward and backward. After the first water level, the first layer of geotextile tubes consistently moves upward and forward. In contrast, the fourth layer of geotextile tubes consistently moves backward up to the third water level and then moves upward and forward.

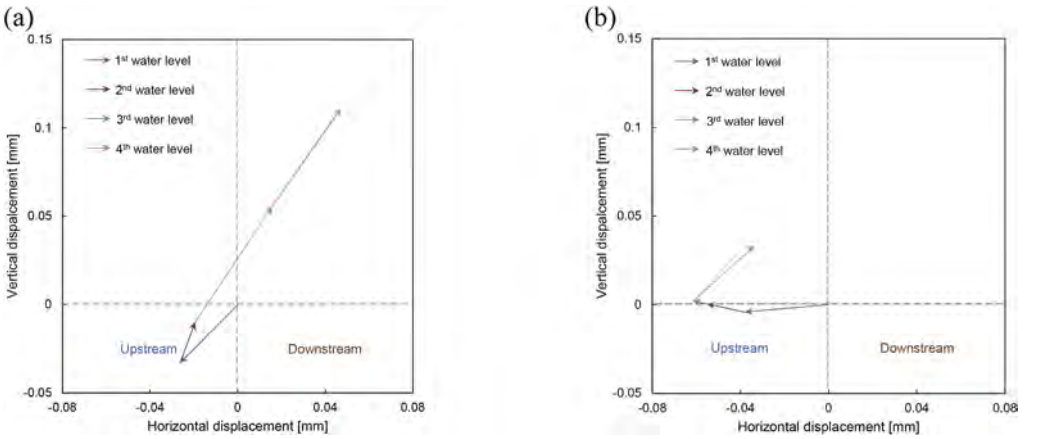

Figure 3. Evolution of displacements with water level: (a) 1st layer; (b) 4th layer.

4 CONCLUSIONS

Displacement evaluation of stacked geotextile tubes is needed for its global stability analysis. The DIC technique, a non-contact optical measurement method, was used to evaluate the displacement of stacked geotextile tubes according to the water level change. The movement of each layer of the stacked geotextile tube depended on the water level. The displacement patterns on a two-dimensional plane were obtained from the evaluated vertical and horizontal displacements. As the water level increased, the first layer of the geotextile tubes moved upward and forward more than the fourth layer. The DIC technique suggested in this study may be effectively used to evaluate the displacements of stacked geotextile tubes.

ABSTRACT: An important goal of seismological research is to predict earthquakes, but despite efforts, short-term earthquake prediction has not yet been achieved. On 9 January 2022, our upgraded Eötvös torsion balance in Budapest, Hungary, detected predictive signals 32 minutes before the earthquake in Florina, Greece, 770 km away, that were not detected by seismometers. Our measurements, in agreement with previous observations in Kazakhstan (Vol'fson et al. 2011), suggest that torsion balances can be effective in detecting earthquake precursors from a considerable distance.

1 MEASUREMENTS BY EÖTVÖS TORSION BALANCE

Our original goal was to repeat the EPF experiment in better circumstances, with at least one or two order higher precision using the original method of Eötvös. At the beginning of last century, *Loránd Eötvös* and his colleagues carried out their famous equivalence experiment by a torsion balance (known as *Eötvös-Pekár-Fekete* (EPF) measurement) for validating the equivalence of gravitational and inertial mass (Eötvös 1922). The original measurements contain tiny regular differences, so we decided to repeat the experiment under modern technical

DOI: 10.1201/9781003299127-112

conditions (Völgyesi et al. 2018). After long preparations, we started our measurements in 2019 (Tóth et al. 2019, Völgyesi et al. 2019), which are still ongoing.

The site of our experiment is the Jánossy Underground Research Laboratory (JURLab) unit of the Vesztergombi Laboratory of High Energy Physics (VLAB) at Wigner Research Center for Physics. On Figure 1 the Eötvös-Pekár torsion balance and the Güralp 3T three-axis broadband seismograph placed next to it can be seen in the laboratory corridor at a depth of 30 meters below ground. The temperature stability of this site is satisfactory, the daily change is only a few hundredths of degrees, and the amplitude of the microseismic ground vibrations is also sufficiently small. Environmental factors are continuously recorded with several temperature, pressure, humidity, infrasound sensors.

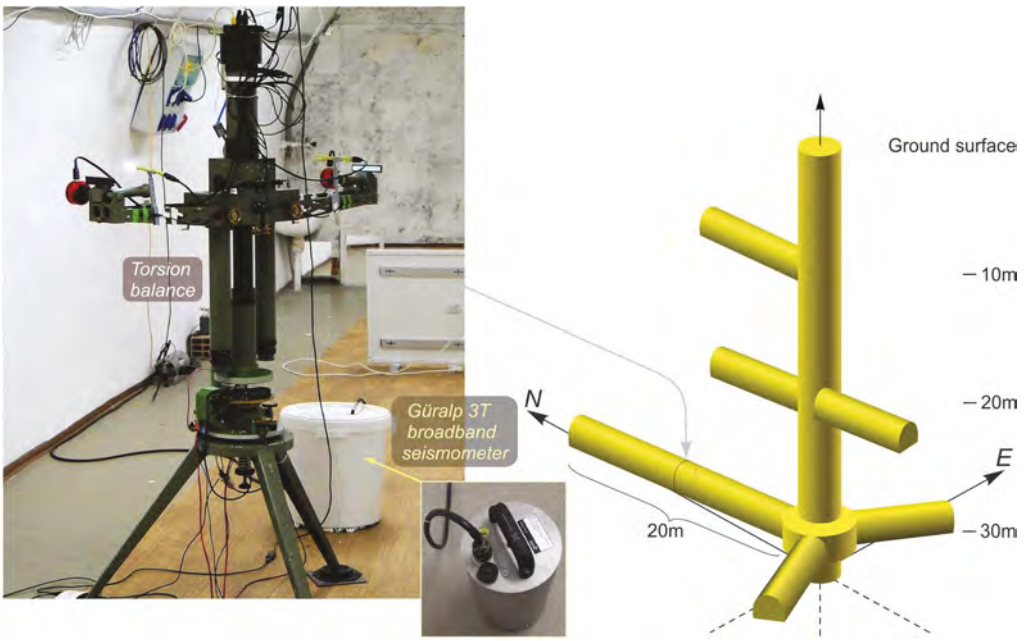

Figure 1. The location of Eötvös-Pekár torsion balance and the Güralp 3T seismometer at the Jánossy Underground Research Laboratory (JURLab).

In addition to temperature variations, measurements are most disturbed by microseismic ground vibrations. The "technogenic" noise (mainly ground vibrations caused by traffic) can be reduced, but earthquakes, free vibrations and natural sources are constantly present. In order to take these into account and to filter them out, we use a Güralp 3T seismograph, continuously recording ground vibrations and earthquakes.

2 EARTHQUAKE REGISTRATION BY TORSION BALANCE

Our torsion balance is also an excellent tool for recording earthquake waves. In the last 2 years we have recorded around 60 earthquakes of greater or lesser magnitude.

Among these earthquake records recently we have found an extremely surprising and interesting observation, namely the torsion balance registered an unusual strange vibrations approximately half hour before the internationally recognized earthquake. Furthermore, the Güralp 3T seismograph, located 1 m from the Eötvös torsion balance did not register this preactivity, it registered signal only at the official time of the earthquake.

This earthquake occurred in Greece on 9 January 2022, (the parameters: t_o = 21:43:47/UTC/, 40°43′48.0″N, 21°21′36.0″E, Richter magnitude M = 5.6, focal depth h = 9km). Several seismograms of this earthquake were registered at different seismological observatories around our measurement site. These are regular seismograms, one cannot see anything special on them.

In contrast to the usual seismograph recordings, the Eötvös torsion balance shows unusual and peculiar vibrations. The earthquake pushed the pendulum of the torsion balance out of equilibrium and then disturbance was damped and the equilibrium restored (top of the Figure 2). However,

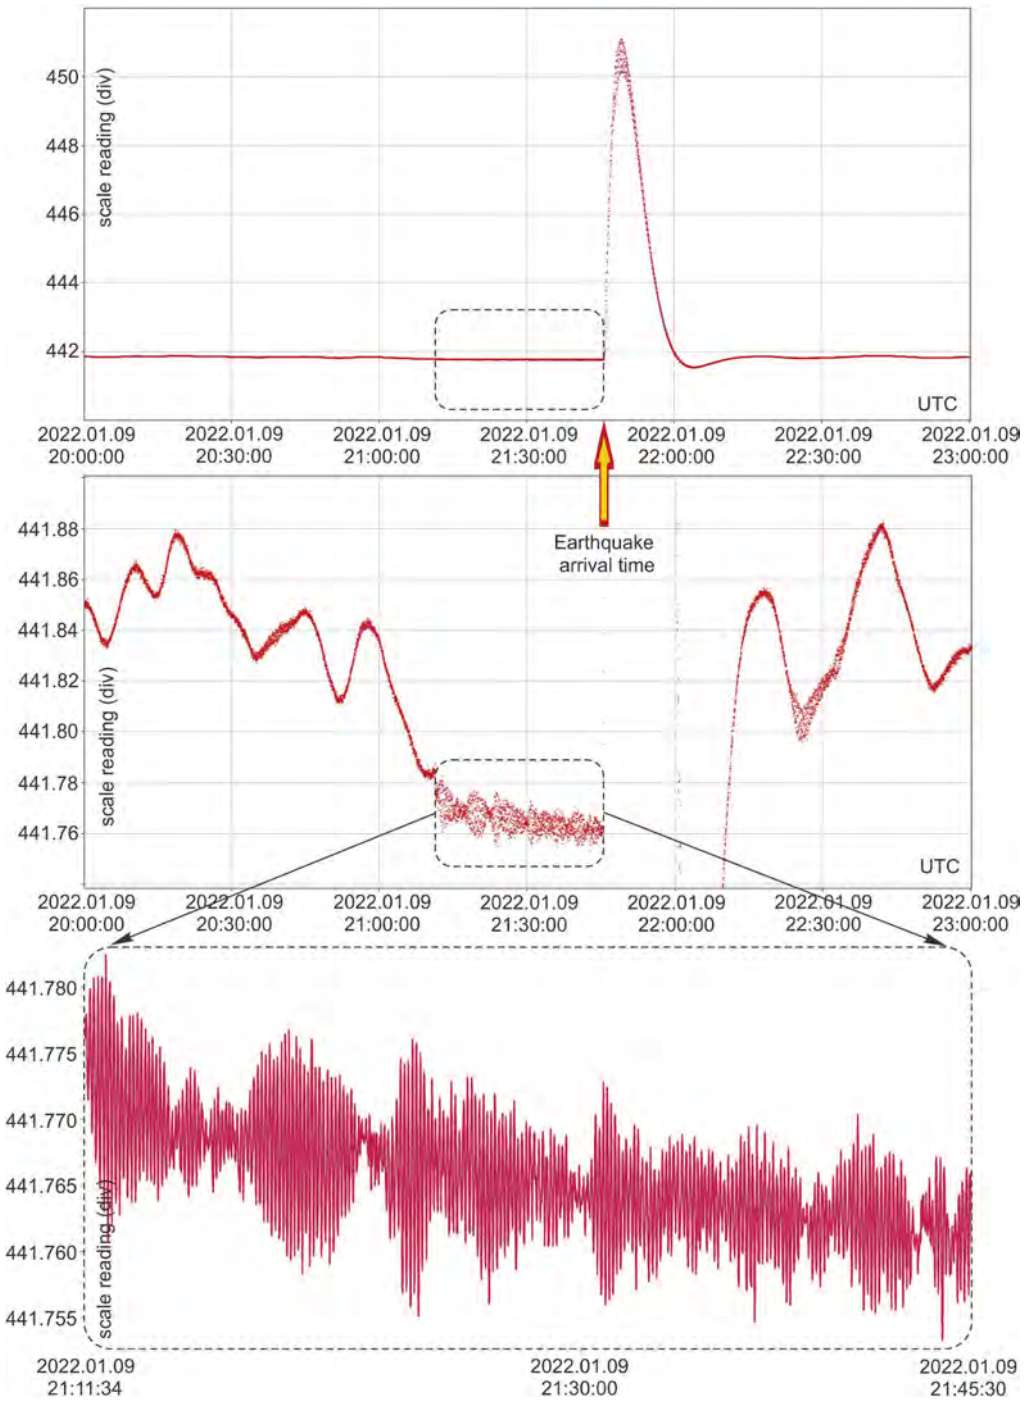

Figure 2. Earthquake in Greece on 9 January 2022, registration and enlarged images by the pendulum II of the torsion balance.

with higher resolution one can see that a characteristic signal appeared about 32 minutes before the earthquake (in the middle part of Figure 2). The lower part of Figure 2 shows a high magnification picture of the shaking of the pendulum in the half hour before the earthquake.

It is very important to note that prior to the earthquake, the Güralp 3T seismograph installed in the immediate vicinity of the Eötvös torsion balance did not indicate any unusual waves.

Further detailed investigation of the circumstances of our observation would be necessary. Neither the thermometers, barometers and the neighboring seismograph indicated any external disturbances that could be correlated to the unusual signal. The torsion balance was all the time at rest, it was not rotated.

3 DISCUSSION

Eötvös balance is a unique device that is sensitive to the force difference of its test masses with extreme sensitivity. Due to its characteristic dipole construction and the suspension system it is a sensitive frequency selective amplifier of the microseismic noise (Speake & Gillies 1987; Kalinnikov et al. 1994). This feature of the balance is available only with continuous registration of the position and high sensitivity. Similar instruments were developed in the Institute of Experimental Geophysics, Russian Federation, motivated by the possibility of earthquake prediction (Kalinnikov et al 2011, Vol'fson et al. 2010; Vol'fson et al. 2011).

Further studies are needed to clarify and understand this phenomenon. Our signal differs from the signal of the previous observations, but the structure of Eötvös balance is also different of their instruments, except the dipole construction. There are a lot of unanswered questions, a clarification requires further observations and modeling.

Our further research goal is to reproduce this observation, and also to understand the origin and the conditions of the detection. To this end we should explore the environmental, geophysical and technological factors that influence the modernized torsion balance. It is remarkable that the detection of signals, like in bottom of Figure 2 required sensitivity an order of magnitude higher than the sensitivity of the original device.

ABSTRACT: Rock formations are generally perceived as favorable and good bearing stratum. However, there are many challenges in design of earthen reservoir foundation on a rocky profile. Geological mapping coupled with comprehensive geotechnical investigation is a vital requirement for such studies. The geological mapping needs to encompass the study of active folds, faults and any other geological concerns. The geotechnical data need to be detailed covering the permeability, compressive strength, water absorption etc. which are critical in the achieving the reservoir water tightness. This paper outlines the various challenges confronted in earthen reservoir design in a rocky landscape and the solutions provided for a project case.

1 INTRODUCTION

Generally, encountering of the rock as out crops, or at shallow depths is perceived as very favourable condition for the foundation system. However, while designing foundation of earthen embankments in a rocky landscape, there are many challenges to achieve watertight and stable foundation system. Adequate factor of safety against base pressure is not the only criteria that determines the suitability of the founding stratum of earthen reservoir. It calls for exhaustive geotechnical investigation clubbed with geological mapping for arriving at the requisite data to satisfy various other stability aspects for successful design of earthen embankment. The current project is in the Cuddapah region, and earthen embankments are planned to be designed for providing impoundment for a raw water reservoir of a process plant. Rigorous design tools are to be used for checking the stability analysis, drainage arrangements, overall integrity and functioning of the raw water reservoir. The degree of water tightness of foundation strata predicts the containment of the hydraulic head for the specific time length. Further, earthen embankments can undergo breaching that is caused by internal erosion actions of undermining and seepage. *(Foster et al., 2000; Fell et al., 2003)*.

2 GEOTECHNICAL AND GEOLOGICAL ATTRIBUTES

2.1 *Geological mapping of the project site*

The site is located in Cuddapah basin which consists of sedimentary deposits that overlay gneiss and granite formations *(Sukanta Goswami et al., 2017)*, Basic geological studies of the site reveal that rocks with predominantly arenaceous and argillaceous materials form major part whereas rocks with calcareous and dolomitic materials occur as subordinate constituents.

DOI: 10.1201/9781003299127-113

Quartzite, Shale, Sandstone, Limestone, variegated shale, and dolomite are various types of rocks prevailing in the site.

2.2 *Geotechnical information*

In the raw water reservoir area, 9 boreholes and 4 field permeability tests were carried out. Sub- surface soil/rock profile indicates rock outcrops of highly weathered rock underlain by jointed/fractured medium hard rock to jointed rock. In only one borehole (BH-1) silty sand with gravel is encountered as topsoil up to 0.5m depth. The types of rock encountered are Limestone, Shaley limestone, Quartzite, weathered quartzite, and Fresh quartzite. The rock present at shallow depth possess CR (core recovery) ranging from 21% to 84%, RQD (Rock Quality Designation) ranging from 10% to 78 % and Permeability values ranging from 1.69x10-06 cm/sec to 6.39 x 10-06 cm/sec.

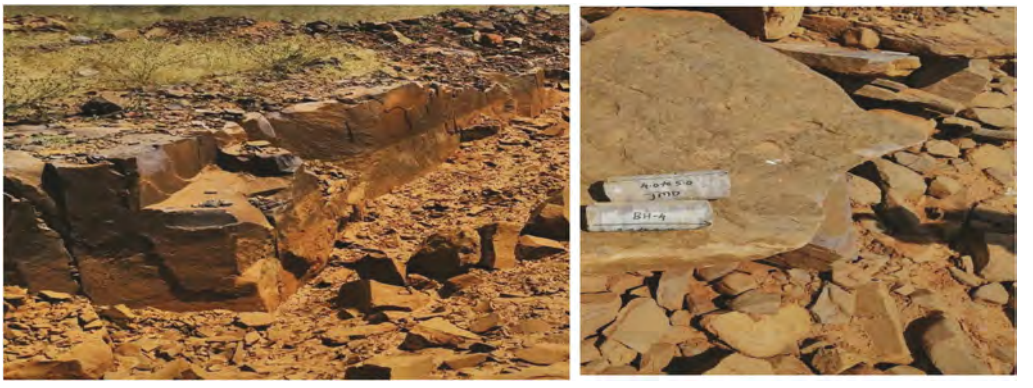

Figure 1. Rock outcrops at site.

2.3 *Topography variation*

As per the contour drawing in the Raw water reservoir area, the reduced Ground levels, are varying from RL 179 m towards the northern side and increasing to RL 203 towards the southern side. The 3D map of the entire reservoir area is hereby attached as Figure 2. As the ground topography is highly varying and site grading is not carried out in the reservoir area to avoid large earthwork volumes, the embankment top level was maintained uniformly at RL 203, this resulted in embankment heights ranging from 4 to 21m along the periphery of the reservoir.

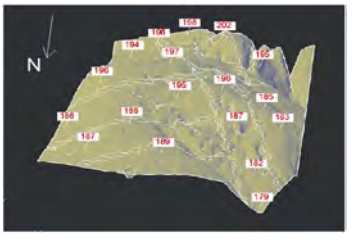

Figure 2. The 3D Topographic view of the entire reservoir area.

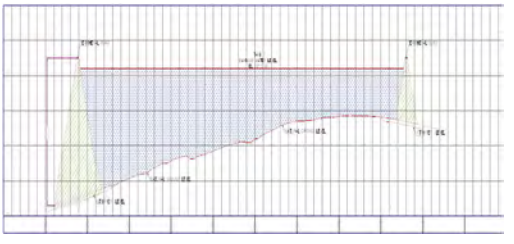

Figure 3. Profile of reservoir area.

3 COMPONENTS OF EARTHEN EMBANKMENT

The earthen embankment of symmetrical section was considered for the reservoir area. The whole area of the reservoir catchment was stripped up to 0.5m below natural ground level to exclude roots, vegetation, and other organic matter.

The design of earthen embankment for raw water reservoir was carried out with all rigorous analysis and checks for the critical aspects which can be anticipated during functionality of the design life period of the reservoir.

- Stability of earthen embankment (Slope stability and overall stability for static and seismic conditions)
- Internal and external erosion control of embankment
- Internal drainage arrangements of embankment
- Water tightness of the foundation system of embankment

The components of the Earthen embankment are categorized based on functional aspects of the reservoir and detailed as below:

3.1 *Stability of earthen embankment (Slope stability and overall stability)*

3.1.1 *Positive cut-off*

The Permeability values of the bed rock are found to be ranging from 1.69×10^{-06} cm/sec to 6.39×10^{-06} cm/sec. Hence the relatively impermeable soil of CL/ CI type soil is provided as the positive cut-off at the junction of embankment and founding strata.

3.1.2 *Core*

Core is constructed with low permeability material of 10^{-06} to 10^{-08} cm/s at center of embankment. In the considered section, central core is provided with top width 3 m and core top level fixed at 1 m above MWL (Maximum water level). Core thickness is not less than 50% of max. water head at any section and slope of 1V:0.5H is provided.

3.1.3 *Casing*

In considered section casing with slope of 1V:2H is provided on both upstream and downstream sides, using SC/SM/GC type of soil with higher permeability of 10^{-03} to 10^{-06}cm/s.

3.1.4 *Berm*

Berms are provided to provide to increase the stability of the earthen embankment. The berms of 3 m width are provided at every 5 m vertical height of the embankment in the considered section.

3.2 *Internal and external erosion control*

3.2.1 *Stone pitching*

Stone pitching is provided on upstream face over filter layer as per *IS 9429*, permeability of filter material to be $< D_{15}$ (F) and $\geq D_{15}$ with respect to base soil and not less than 0.1mm. The soil gradation used for coarse and fine filter are 40mm and 20mm down sized particles respectively. Header stones is provided extending through stone pitching by 150 mm and are spaced at 1.5 m centre to centre.

3.2.2 *Turfing*

The downstream slope is protected against the erosive action of rain and its run-off by providing wild grass turfing with provision for irrigation sprinklers.

3.2.3 *Road*

The road of 3.75m is provided on top width of the embankment for the movement of inspection vehicles.

3.3 *Internal drainage arrangements*

3.3.1 *Inclined filter*

Inclined filter made of fine sand particles passing 2mm IS sieve is provided on downstream side of core. It is provided of 1m thickness for embankment height of up to 10m and increased to 1.5m thickness for sections of embankment height 10-21m.

3.3.2 *Horizontal filter*

The Horizontal filter connecting inclined filter is made of fine sand particles passing 2mm IS sieve. It is provided of 1m thickness for bund height of up to 10m and increased to 2m thickness for sections of bund height 10-21m, with length of three times embankment height.

3.3.3 *Rock toe*

The 'rock toe or toe filter' comprises stones ranging in size from 15 to 20 cm over toe filter composed of graded cohesionless material. Toe filter generally consist of three layers of fine sand, coarse sand, and gravel. In considered section rock toe is provided at toe of downstream slope at the end of horizontal filter. Rock toe height is kept as 2.0m, above the tail/ dead water reservoir level which is 1.5m above the lowest ground elevation.

3.3.4 *Toe drain*

Toe drain of stone masonry of 0.6 m depth is provided in trapezoidal shape on all around the embankment. Toe drain connected to the rock toe to lead the rain/ surface drainage water to nearby identified nalla or water body.

3.4 *Water tightness of the foundation system*

3.4.1 *Clay bedding*

Clay bedding of low permeability of 600 mm thickness is provided on the bed of the raw water reservoir as per *IS 9451*.

3.4.2 *Curtain grouting*

The field permeability test results of the site indicate values in the range 10^{-6} to 10^{-7} cm/s respectively. The RQD (Rock Quality Designation) is found to be around 30% at these depths. The lugeon value is arrived as 0.19 and 0.39 at 2 m and 5 m respectively. Based on field permeability results as lugeon value is less than 3, curtain grouting is not envisaged.

4 SLOPE STABILITY ANALYSIS AND CHECKS

Earthen embankment is susceptible to failure due to various operational and structural reasons.

Overtopping, structural failures in foundation, and piping are the major causes for failure of earthen embankments. There may also be additional causes of failure depending on specific site conditions and embankment structures. (*Journal of Hydraulic Engg. ASCE 2011*).

The various causes leading to failure of earth embankments are listed as 1. Hydraulic Failure 2. Seepage Failure and 3. Structural Failure.

Stability analysis was performed to ensure that reservoir embankment is safe against all possible failure conditions.

In order to check the stability of reservoir against all the possible failure conditions, 3 types of analyses were performed as below:

- Seepage Analysis
- Slope Stability Analysis
- Sliding/ Overall Stability analysis

The stability analysis is carried out for the most critical section of height 21m.

4.1 *Seepage analysis*

Seepage analysis was carried out in SEEP/W module of GeoStudio 2018.

Seepage analysis is performed to check stability against following failure conditions.

- Piping through embankment body
- Piping through Foundation

4.1.1 *Critical exit gradient*

Critical hydraulic Gradient of foundation soil is calculated as $=(G-1)/(1+e)=0.95$ (1)

Figure 4 Shows pressure head variation in embankment under steady seepage condition. It can be seen that phreatic line passes below rock toe. Therefore, embankment is safe against piping through body.

Figure 5 Shows Total head variation in embankment section under steady seepage condition.

Head drop at exit (dh) = 0.25 -0 =0.25m

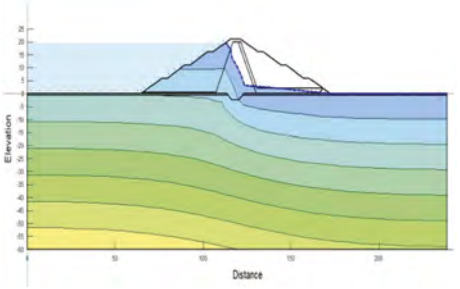

Figure 4. Phreatic line.

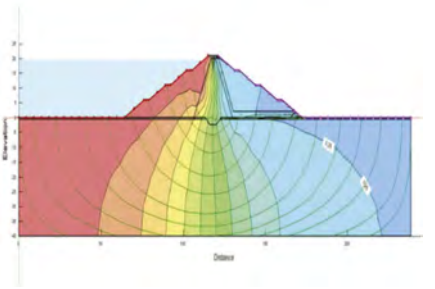

Figure 5. Total head distribution.

Average distance at between the pressure drops at exit (ds) = 5.53 m

Exit gradient = dh/ds = 0.0452

$$\text{Factor of Safety} = \text{Exit Gradient}/\text{Critical exit gradient} = 21 > 6 \text{ (as per IS 6966)} \quad (2)$$

Therefore, embankment is safe against piping through foundation

4.2 *Slope stability analysis*

The loading conditions including all likely combinations of reservoir and tailwater levels, seepage conditions, both after and during construction that could be critical for causing instability were investigated. Based on that, 3 conditions as listed below were checked.

- Immediately after Construction Condition
- The Steady Seepage Condition and
- The Rapid Drawdown Condition in the reservoir (*EJGE Vol. 18 [2013], Bund. Z 6022*)

Sliding of a large soil mass along a curved surface is the usual mode of failure of an embankment.

The stability analysis was carried out using 'GeoStudio 2018′ software by limit equilibrium method per *IS 7894* for critical conditions, which may be anticipated during the service life of the reservoir sections.

The summary of the slope stability analysis is shown by a flowchart in Figure 6. The materials considered for slope stability analysis is tabulated in Table 1.

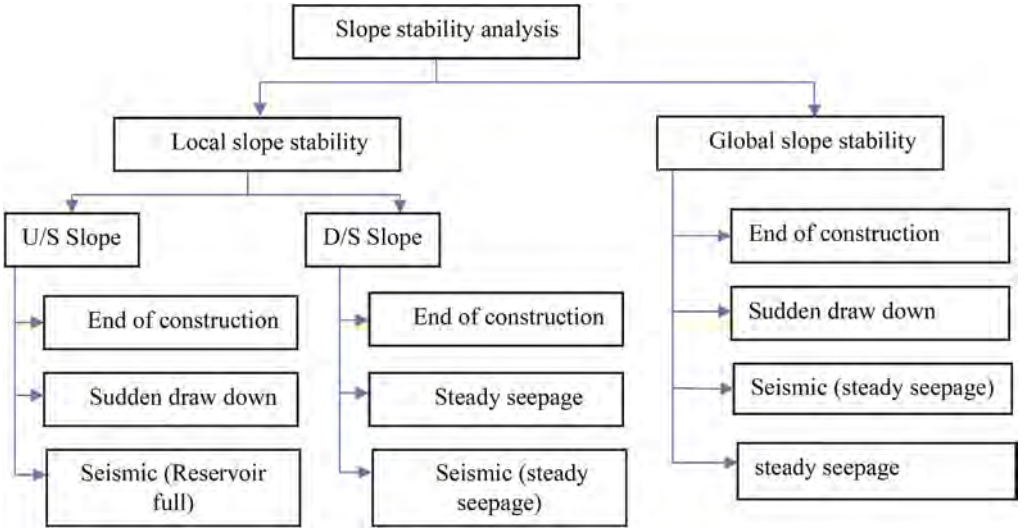

Figure 6. Flowchart for slope stability analysis.

Table 1. Material properties used for stability analysis.

SL. No.	Material	Dry density (kN/m^3)	Saturated density (kN/m^3)	Total strength		Effective strength	
				Cohesion (kpa)	Friction angle (°)	Cohesion (kpa)	Friction angle (°)
1	Casing	17.51	18.6	1.13	29	1	31.5
2	Core	16.3	19.36	37.57	23	35.94	25.67
3	Filter	18	20	0	30	0	30
4	Toe drain	18	20	0	30	0	30
5	Rock toe	20	22	0	40	0	40
6	Cutoff	16.3	19.36	37.57	23	35.94	25.67
7	Foundation soil	18	19.5	0	30	0	32
8	Foundation rock	20	22	0	40	0	40

Table 2. Calculation of seismic coefficients (IS 1893- 1984).

Location	Cuddapah
Seismic horizontal coefficient $A_h = \alpha \times I \times \beta$	0.06
Vertical seismic coefficient ($A_v = 0.5 \times A_h$)	0.03

The summary of slope stability analysis performed, and the factor of safeties obtained for local and global stability condition along with acceptable factor of safety for each condition are listed in Table 3.

From Table 3 it can be concluded that the obtained factor of safeties is within acceptable limits and the raw water reservoir embankment is safe under all critical conditions.

The input and few cases of output sketches of the stability analysis are enclosed below from Figures 7–12.

Table 3. Summary of factor of safeties obtained for various cases.

Condition	Slope	Local FOS	Global FOS	Acceptable FOS
End of construction	Upstream slope	1.53	17.23	1.0
	Downstream slope	1.53		1.0
Steady seepage	Downstream slope	1.55	5.21	1.5
Sudden drawdown	Upstream slope	1.65	18.64	1.3
Seismic (Reservoir full)	Upstream slope	1.33	3.58	1
Seismic (Steady seepage)	Downstream slope	1.44		1

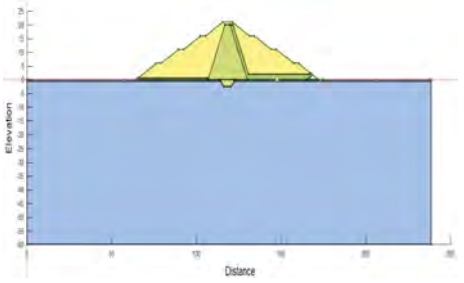

Figure 7. Input model.

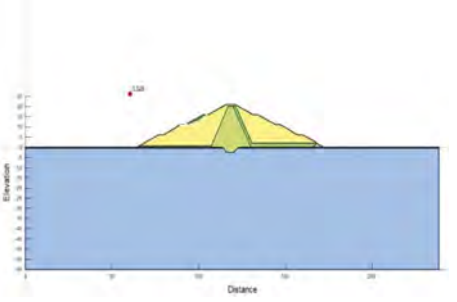

Figure 8. End of construction (upstream slope).

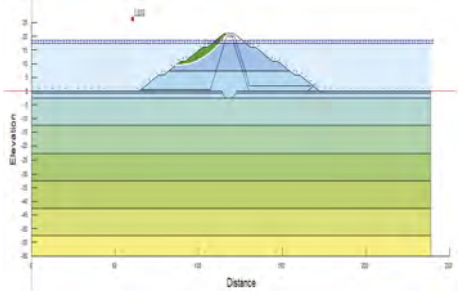

Figure 9. Sudden drawdown (upstream slope).

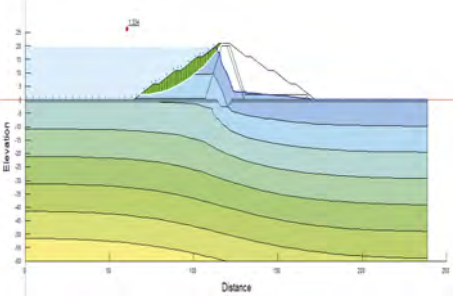

Figure 10. Seismic (Reservoir full for upstream side).

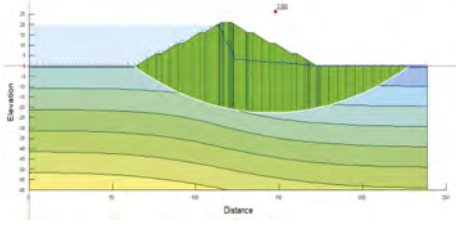

Figure 11. Seismic (Global stability).

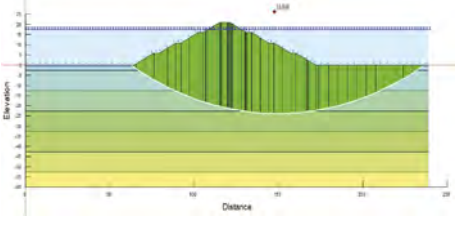

Figure 12. Sudden drawdown (Global stability).

4.3 *Sliding/ Overall stability analysis*

The soil foundations are generally weak in shear and hence the shear stresses developed should be within limits. The stability of embankment is checked against sliding failure (*Irrigation engineering and hydraulic structures by S K Garg*) for following failure conditions.

- Overall stability of embankment
- Stability of U/S slope of embankment
- Stability of D/S slope of embankment
- Stability of Foundation Soil

The acceptable FOS safety for various cases as per *IS 7894* are summarized as below:

Table 4. Summary of sliding stability.

Condition	FOS	Acceptable FOS
Embankment as a whole	1.59	1.3
Downstream Slope	2.01	2.0
Upstream Slope	5.27	2.0
Stability of foundation soil	3.01	2.0

It can be noted that the reservoir embankment is safe for the sliding stability.

4.4 *Embankment settlement criteria*

The dimensions of the embankment are base width =110m, top width = 6m and maximum section height= 21m. The average compressive stress at the base of foundation from the embankment is noted to be around 200kpa and settlement arrived was in the order 10mm. The permissible settlement is around 300-600mm for the embankments as per *IRC 75* (Indian Road Congress) code and 200mm (1-2% of dam height as settlement allowance) as per *IS 8826 (Guidelines for design of large earth and rockfill dams)*. The arrived settlement as above is within permissible limits.

5 CONSTRUCTION ASPECTS OF THE EARTHEN EMBANKMENT

The Construction materials and the aspects are very critical in achieving the requisite functionality as per design. The construction materials are categorized based on the functionality and elaborated accordingly.

5.1 *Water tightness of embankment and to ensure against piping failure*

Detailed packer permeability testing of reservoir embankment is carried out to finalize the depth of cut-off and necessity of curtain grouting.

5.1.1 *Grouting and grout holes below positive cut-off*

Curtain grouting and grout holes below positive cut off are not envisaged at the design phase based on the permeability test results.

5.1.2 *Positive Cut-off*

Borrow material from lakes of classification CI /CL and having permeability less than around 10^{-6} to 10^{-8} cm/s are considered for impervious cut-off.

5.2 *Internal stability and drainage arrangements*

5.2.1 *Core and Bed lining*

The material for core and bed lining considered of impervious material is same as that of the positive cut off.

5.2.2 *Soil in casing*

The soil conforming to classification SM/SC/GC/SC is considered from the nearby identified lakes for the casing material. The permeability of these materials ranging from 10^{-4} to 10^{-6} cm/s.

5.2.3 *Stone pitching*
Stone Pitching of 300mm thickness is laid on upstream slope by hand placing stones along the edge. Stones used for pitching are rounded or sub-angular river cobbles or rock pieces with sufficient base area to be stable. Stones should be of uniform size, not less than 15cm in any direction, sound, hard, durable and should be able to sustain weathering and water action. Stones are laid in compact manner with staggered joints starting from the bottom of the slope. The joints are matched and interlocked so that they are keyed together with a minimum of voids.

Stone pitching placed over a graded fine and coarse filter (for a course of 150mm). The graded material for stone pitching is considered from the nearby quarry. The filter materials are considered by grading of the existing topsoil available at site.

5.2.4 *Rock toe*
Hard stone 25 to 50 kg weight wrapped in geo grid Netlon C.153 or equivalent shall be used for construction of Rock toe. The geo grid shall be impaled to the soil at spacing of 5 m. Stones used are free from lamination, soft spots, cracks, and seams. The graded material for rock toe is considered from the nearby quarry.

5.3 *External drainage arrangements*

5.3.1 *Road on top of embankment*
The road section is provided in accordance with Section 400 of MORTH (Ministry of Road Transport and Highways) specification.

5.3.2 *Chute drains*
Semi-circular precast concrete pipes of 200/225 mm diameter is considered for chute drains at 90m C/C is provided on downstream face as shown in the Figure 13.

5.3.3 *Longitudinal drains*
The longitudinal drain with M15 concrete of 300 mm deep and 300mm wide with thickness of 100 mm are provided connected to the chute drains at berm level to achieve network of external drainage leading to toe drain as shown in the Figures 14 and 15.

Figure 13. Semi-circular chute drain.

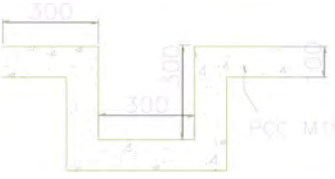

Figure 14. Longitudinal drain.

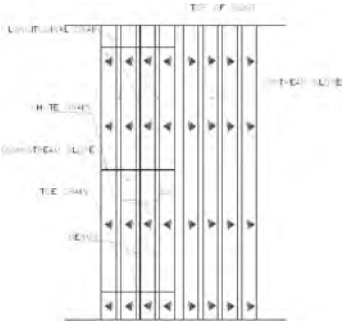

Figure 15. Drain arrangement on downstream slope.

5.4 *Compaction*

The compaction is carried out to achieve minimum 95 % maximum dry density under modified proctor conditions for clayey soil and minimum 75 % relative density for subgrade/sandy soil respectively.

The compaction is considered with a 10 to 12ton sheep foot or padfoot rollers for clayey soil and 10 to 12ton vibro roller for subgrade/sandy soil.

During compaction it is required to check that the specified layer thickness of the materials has been laid, the specified number of passes of roller of specified type and weight have been applied and there is no excessive rutting or weaving of the fill.

The embankment components core, casing, positive cut off and clay bedding are laid with layer wise compaction. Necessary sampling before and after compaction are carried out so that effectiveness checks on fill operations are maintained.

5.5 *Inspection and testing*

The scheme of field tests is considered as a part of quality control for soils used for embankment (before compaction) and on compacted layer (after compaction) is based on provision of clause 903.2.1 and 903.2.2 of MORTH.

5.6 *Construction sequence*

The embankment was proposed to be constructed as per construction sequence elaborated below

- Centre line of raw water reservoir to be marked on site as shown in Figure 16.
- The reservoir bed area was cleared including uprooting rank vegetation, grass, bushes, shrubs, sapling.

Figure 16. Plan and profile view of reservoir.

- The embankment area was stripped up to 500 mm depth to exclude the loose/soft patches, vegetation, plant root, organic material etc. and other objectionable matter.
- From centre line of reservoir, the foundation line was marked.
- Stripped surface was excavated for the construction of positive cut-off. Excavation was carried out with side slope of 1:1. The excavation in rock was carried out using hydraulic breaker etc. to avoid mechanical fracturing of rock.

- Before construction of positive cut-off, lugeon value to be checked based on the packer permeability test along with geologist's visual inspection. If the lugeon value is found to be more than 3 and considering geologist feedback too, the curtain grouting needs to be considered and grout holes to be designed accordingly.
- For construction of positive cut off the soil was laid in layers of 300 mm compacted to 95% of MDD using handheld pneumatic compactor.
- Rock toe was constructed along the toe of the reservoir. The graded filter was laid to correct profile followed by placing of the geonet filled with rocks along the toe portion.
- After construction of positive cut-off and rock toe, core was constructed up to the top level of first layer then horizontal filter, casing, clay bed lining up to the same level.
- Sheep foot roller was used for compaction of core and vibro roller was used for compaction of casing.
- The 600 mm thick clay bed lining is provided as initial layer below casing material along upstream side of embankment and compacted using sheep foot roller.

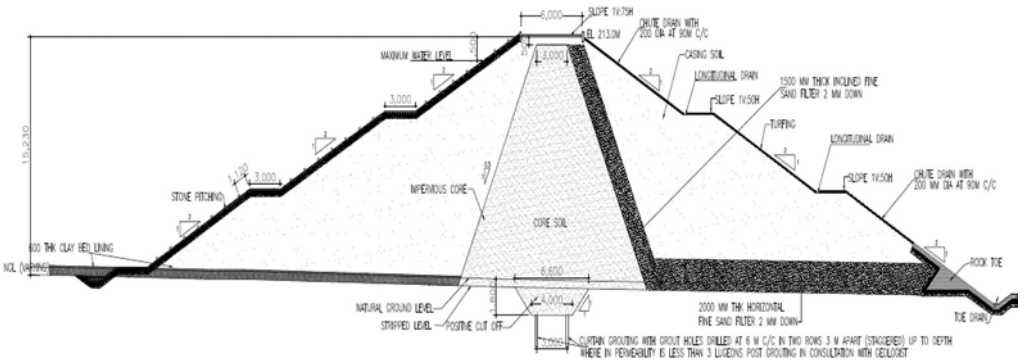

Figure 17. Cross section details.

- Inclined and horizontal filters are placed immediately downstream of the core zone within embankment. The filter layer was installed along with the adjacent core material and downstream shell in one of two ways. The first method is to lay the filter layer one lift ahead of the adjacent zones and in the second method it is laid one lift behind.
- Stone pitching was provided on upstream side of embankment and turfing was provided on downstream side of embankment.
- Toe drain was provided outside the rock toe all along the periphery of the embankment to lead the rain/ surface drainage water to nearby identified nalla or water body.

6 CHALLENGES FACED COMPARED TO EARTHEN SUB PROFILE

- Many challenges were faced due to the rocky landscape at site compared to construction on soil. The below points highlight the comparison and challenge faced in rocky profile compared to soil profile.
- As competent rock is present at shallow depth, the excavation by any machinery is not possible and blasting is the only technique which can be adopted here. Hence general concept of cut and fill could not be adopted here. Various material to be used in dam body was considered from borrow area. If rocky profile would not have encountered, excavation and use of same material for embankment construction would have been adopted, leading to reduced borrow material there by huge cost savings on the project.

- Positive cut- off is provided to increase the path of drainage and curtain grouting is done, for sealing the rock in case of low permeability and fractured rocks. This needs to be carried out to achieve water tightness of the embankment foundation. During construction packer permeability tests are carried to check the permeability of foundation rock to further assess the requirement of grouting. If the rocky profile was not encountered the need for such exhaustive tests in rock would have been avoided achieving less complex design and thereby cost savings.
- Geological mapping and geotechnical studies to carried out check permeability in case of bedding planes, rock joints, folds, and faults which are critical for safety of the embankment. The need of such rigorous foundation strata geological study is not required for foundations on soil profile. In soil profile it only calls for settlement analysis for embankment which will not be critical unless very soft strata is encountered.
- Due to limitations in excavation, higher height embankment had to be designed to achieve the same capacity. In case of soil profile, the design can be planned by using the excavated soil in embankment thereby leading to competitively lower height embankment for same capacity.
- During construction, excavation of the rock calls for rock blasting which requires careful planning. Such aspects do not arise in soil profile.
- If fractured rock with discontinuities, orientation of bedding planes in horizontal direction is encountered, the measure for overcoming the seepage problems is robust and cost effective.

7 CONCLUSIONS

a. Encountering of rock at shallow levels cannot be considered fully favorable for an earthen embankment design.
b. Comprehensive Geotechnical investigations along with geological mapping is required to completely ascertain and design structures in a undulating rocky terrain
c. In an earthen embankment, owing to the various components and materials involved, the design shall be carried out critically considering all the stability and seepage aspects.
d. The stability analysis shall be carried out considering overall embankment stability, slope stability of upstream and downstream slopes in static and seismic condition.
e. The construction materials & aspects to be in in line with the design requirement and consideration.
f. There are many challenges in design, construction and execution which leads to substantial cost increase in rock terrain compared to soil profile.

Fracture initiation and propagation in rocks with pre-existing flaws

M. Yogeshwar
Department of Civil Engineering, IIT Madras, India

G. Sivakumar
Department of Civil Engineering, IIT Jammu, India

V.B. Maji
Department of Civil Engineering, IIT Madras, India

ABSTRACT: Failure behaviour of rock mass is dependent upon the rock fracturing process and that in-turn dependent upon the crack initiation and propagation. The analysis of crack growth on a rock with pre-existing flaws is mostly carried out in open flaw configurations whereas limited study can be found for narrow flaw configurations. Unlike open flaw, narrow flaws are initially open and subsequently gets closed during loading. It also experiences friction which needed to be accounted for. Very few studies are available, to understand the effect of friction between the flaw surfaces. Additionally, the lateral confinement due to the biaxial confinement state would influence the crack initiation and their subsequent growth. In the present study, an experimental investigation is conducted to understand the crack growth behaviour of narrow flaws under uniaxial and biaxial stress environments. The tests were conducted using gypsum with a single flaw at varying orientation. The change in the behaviour of crack growth and stresses with respect to initiation and peak stress level was studied for different flaw angles. Subsequently, the numerical analysis was performed using the Extended Finite Element Method (XFEM) in conjunction with the Cohesive Zone Model (CZM). The model systematically validated with the laboratory experiments. The crack pattern was found to be influenced by various factors namely flaw angle, frictional coefficient between the flaw surface, the confinement stress level.

1 INTRODUCTION

Due to the existence of pre-existing flaws in rocks varying from micro to macro size formed by initial stage of formation of rock or due to stress induced by tectonic plates movement there pre-exist a weak point in rocks from which newly formed cracks can propagate when the stress at the flaw due to loading exceeds its material limit on microscopic level and leads to a nonlinear failure which makes it complicated to predict. But the failure can be analyzed by studying the crack pattern and the factors that cause the cracks to propagate. But the failure process gets more complicated when the flaw is narrow. Initially the narrow flaw is open but due to loading the flaw gets closed and the effect of friction between the flaw surfaces gets added. There is very little studies conducted on narrow flaws. The experimental results indicated that the crack initiation stress was higher in case of narrow flaws compared to open flaws when subjected to compressive loading. The numerical results indicate that the crack initiation stress was caused due to friction in case of narrow flaws (Steif 1984; Horri & Nemat-Naseer 1985; Ashby & Hallam 1986; Baud et al. 1996; Li et al. 2018). In order to get a deeper understanding on the behaviour of narrow flaws both experimental and numerical studies are needed. For the present study, Gypsum specimens containing narrow flaw configurations with single inclined flaw are chosen. The effect of crack initiation stress and its corresponding peak stress for uniaxially and biaxially loaded gypsum rock

DOI: 10.1201/9781003299127-114

were investigated experimentally. The specimens were investigated until the material underwent complete degradation and the crack stresses had been observed at initiation, coalescence, and peak strength. Subsequently, a numerical simulation using finite element (FE) software, ABAQUS, (version 6.14) was done with systematic validation using laboratory experiments.

2 EXPERIMENTAL STUDIES

2.1 *Preparing the specimen and its properties*

Gypsum is chosen as the specimen in both uniaxial (Sivakumar. G & V. B. Maji. 2018) and biaxial loading (Sivakumar. G & V. B. Maji 2022) because it can represent a wide range of brittle rocks and has decent similarities with respect to tensile and shear cracks development. Large number of samples can be prepared in a short amount of time and introduction of flaws is much easier. A gypsum slurry prepared with 35% water content is poured into the above-mentioned mould shown in Figure 1. After removing the sample from mould, it is further air dried for 24h and oven dried at 40°c for 4 days. The specimen is tested in 5th day to determine its properties by following the ISRM suggested methods (ISRM 1978a, b, 1979) and its properties are given in Table 1. The size of the specimen with a H/W ratio of 2 is decided in order to limit bucking effect and end friction. Due to this size of the specimen the tensile cracks growth during loading is vertical and shear cracks is horizontal. Also, the growth of cracks (both primary and secondary) from flaw tips does not get affected by these surface cracks and hence the material strength shows true behaviour. The geometric properties of the specimen are shown in Table 2

Figure 1. a) Specimen preparation mould with prepared gypsum specimen with single flaw of different angles.

Table 1. Material properties of Gypsum.

Material parameters	Gypsum
Uniaxial compressive strength (MPa)	15.50
Young's modulus (GPa)	1.04
Poisson's ratio	0.39
Tensile strength (MPa)	1.11

Table 2. Geometric properties of Gypsum sample.

Geometry of the specimen	Gypsum
Width (mm)	76.2
Height (mm)	152.4
Thickness (mm)	30
Flaw length, 2a (mm)	12.7
Flaw angle (β°)	15°–75°

2.2 *Testing apparatus*

For Uniaxial testing a compression testing machine of 500kN capacity is used. A low rate of loading of 0.031mm/min is adopted in order to capture the crack growth. To measure the crack initiation, stress a load cell is used along with a data logger and linear variable differential transformer to capture the load and displacement of the specimens at every second to get stress-strain plot as shown in Figure 2(a).

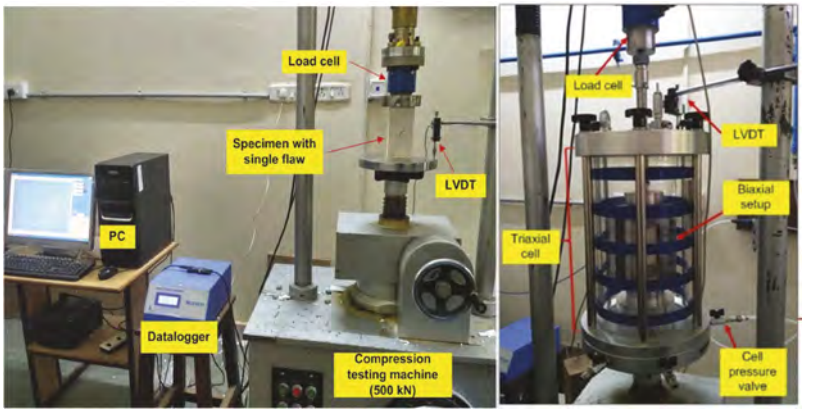

Figure 2. a) Compression testing machines for uniaxial test and its components b) Modified triaxial setup for biaxial loading.

For Biaxial loading, a heavy-duty large-diameter triaxial cell for 150 mm diameter sample sizes with maximum working pressure up to 2000 kPa is used as shown in Figure 2(b). Confining pressure is applied by air pressure regulator fitted with air filter to avoid water formed by condensation inside the PVC pipe getting into the air pressure regulator and also with the help of air booster to double the existing pressure. Two different confinement pressures are applied (0.65 MPa) and (1.24 MPa). In order to simulate biaxial condition in a triaxial apparatus a small arrangement using an acrylic plate fixed on either side of the specimen is made as shown in Figure 3. Due to this arrangement, the confinement stress is allowed to act through the specimen thickness and deviatoric stress acts along the height of the specimen. Due to Poisson's effect, a lateral deformation would enforce additional stress on the acrylic plate. An open-cell rubber foam membrane of thickness 5 mm was provided in-between the specimen and acrylic plate to absorb these stresses.

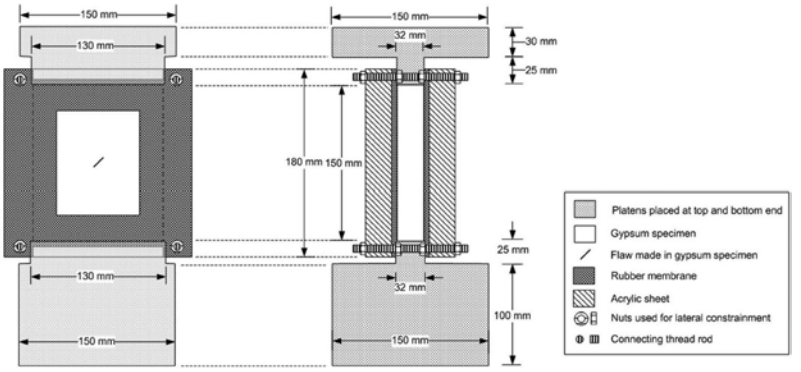

Figure 3. Modified biaxial setup to be kept inside the triaxial cell (Front view cross-sectional view).

2.3 *Experimental results*

2.3.1 *Crack growth and stress analysis in uniaxial loading*

During uniaxial loading (Sivakumar. G & V. B. Maji. 2018), the first crack formed was a tensile crack, which initiates from both the flaw tips in a direction oblique to the flaw surface for all flaw degrees. As the loading continues another crack of shear nature initiated in the quasi-planar direction from the flaw surface is formed. By further loading, the shear crack propagates along with the tensile crack until the material reaches its peak limit and extends in the direction of loading. Finally, the tensile crack grows in an unstable manner and later orients in the direction of major principal stress terminating at the boundary for 15° and 75°. The growth of the tensile crack subsided at a certain length for specimens with flaw angles of 30°, 45°, and 60°. The final failure pattern represents tensile splitting failure/shear failure, where the failure plane usually makes an angle of 0° to 45° concerning the vertical plane. The effect of closure between the flaw surfaces were found to vary at different flaw angles. The flaw surfaces were observed to be closed up to flaw angle 45°. For specimens with flaw angles of 60° and 75°, the flaw surface remained open. Surface spalling was observed at the tip of the flaw for low flaw angles. Peak stress was observed after crack initiation and followed a similar trend to crack initiation stress. There was a significant difference between the crack initiation- and peak stress for flaw angles ranging from 30° to 60°, and the maximum was observed for specimens with a 45° flaw angle as shown in Figure 4. The crack initiation stress decreases with an increase in flaw angle and attains a minimum value for the flaw angle of 45°, and subsequently increases with an increase in the flaw angle as shown in Figure 4. Furthermore, the curvilinearity of the wing crack was relatively high compared with other angles. For flaw angles of 15° and 75°, the wing crack initiated from the flaw tip and directly propagated in the direction of loading with a lesser curvilinear path. This caused the peak stress to occur immediately after the crack initiation stress.

2.3.2 *Crack growth and stress analysis in biaxial loading*

For Biaxial loading (Sivakumar. G & V. B. Maji 2022) due to the complicity in crack trajectory, there are four types of wing crack trajectories formed curvilinear wing-like tensile crack (T1), straight tensile crack (T2), mixed tensile/shear crack (T3) and anti-wing tensile crack (T4) [Wong and Einstein (2009)]. Tensile cracks were observed to appear in all the specimens irrespective of flaw angle and confinement levels and are generally open and their path is smooth. Shear crack follows a similar trend as uniaxial loading, but the shear crack surfaces are generally rough with an indication of slip between the face of the surface. T1 crack initiates from oblique to flaw surface, T2 crack initiates at quasi coplanar to flaw surface, T3 crack propagates in coplanar direction to shear cracks and finally T4 crack propagates parallel and opposite to T1 crack direction. Except for the T4 crack all other cracks shifts their alignment to the

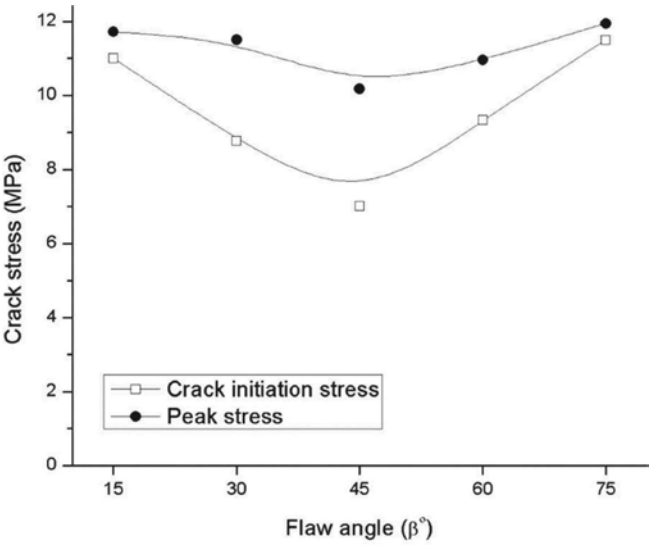

Figure 4. Crack initiation stress, coalescence stress, and peak stress observed in uniaxial loading.

direction of major principal stress. In all specimens, the crack is initiated by tensile cracks but the crack trajectory changes depending on the flaw angle. For the confinement of 0.65 MPa, T1 type and T3 type cracks are observed at both flaw tips for the lowest flaw angle of 15°. Similarly, a flaw angle of 75° T2 type wing crack is commonly observed. The crack grows further towards a nearby boundary and possibly gets linked with an external field crack (F) causing it to fail under lateral shear crack growth. For the confinement of 1.24 MPa, the propagated tensile crack does not completely reach the material boundary for 15° and 45°. Shear crack is also observed in 60° and 75° specimens but the propagated length limits within the material boundary and does not influence the material failure. Peak stress occurs immediately after the crack initiation stress for flaw angles ranging from 15° to 45°. The crack initiation stress was found to initiate sooner for a flaw angle of 45° in both confinements.

3 NUMERICAL STUDIES

3.1 *Modelling the laboratory condition*

To extend the behaviour of crack growth for other flaw configurations and to get a better understanding of the factors of unconfinement and the frictional coefficient for biaxial loading numerical simulation using XFEM in ABAQUS is done. In the present numerical model, rock is expected to behave in an elastoplastic manner. Rock behaves as elastic before the peak and as plastic post-peak. The presence of flaws is taken into account. Flaw is discontinuous and modelling it in a continuum is a challenge which can be overcome by the use of the Cohesive Zone Model. In CZM the pre-existing flaw is assumed to behave accordingly to the concept of traction–separation law, where a new crack is expected to initiate and propagate as per the assigned failure criterion along with the existing Elastoplastic model. Also, the growth of cracks initiated and their propagation accounting for the frictional behaviour influences the stress behaviour for narrow flaw specimens.

3.2 *Governing equations*

For Elastoplastic Model the following Equation 1 is used. The Elastic behaviour of rock is given by Hooke's law

$$\sigma = D^{el}\varepsilon^{el} \tag{1}$$

where σ = total stress, D^{el} = elastic constitutive matrix and ε^{el} = total elastic strain.

The Plastic behaviour is given by Equation 2

$$\sigma^{pl} = \sigma\left(\varepsilon^{pl}\right) \tag{2}$$

where (σ^{pl}) = plasticity stress, (σ) = material's yield stress, ε^{pl} = equivalent plastic strain

For CZM to describe the crack initiation of brittle materials such as rock and concrete the widely adopted maximum principal stress criteria were chosen for the current study. According to these criteria, the onset of crack initiation can be described by Equation 3

$$f = (\sigma_{max})/\left(T_{n,s}\right) \tag{3}$$

where f =maximum principal stress ratio, (σ_{max}) = assigned maximum principal stress value

($T_{n,\,s}$) = Traction in Tension/shear

To describe the dissipation of fracture energy, (Gd), after crack initiation, the term relative displacement (δ_m) was adopted which is given by Equation 4

$$\delta_m = \left((\delta_n)^2 + (\delta_s)^2\right)^{1/2} \tag{4}$$

where δ_n = separation of the discontinuity due to tension, δ_s = separation of the discontinuity due to shear.

To reduce the computational effort the concept of partition of unity, where nodes with discontinuity are enriched with additional degrees of freedom supplementing existing nodal shape functions is used in the Extended Finite Element Method. The approximate formulation of enriched displacement is given by Equation 5

$$u = {}_{I=1}{}^{n=1}\Sigma N_I(x)[u_I + H(x)a_I] \tag{5}$$

where $N_I(x)$= usual nodal shape functions, u_I = usual nodal displacement vector associated with the continuous part of the FE solution, a_I = second term is the product of the nodal enriched degree of freedom vector, H(x) = discontinuous jump function across the crack surface

3.3 *Input parameters*

The size of the specimen, Flaw length, properties of gypsum and loading rate is the same as experimental values. CZM requires two main parameters crack initiation stress and fracture energy dissipated after initiation to describe traction–separation behaviour. The value of the input parameters used are given in Table 3

Table 3. Input parameters in ABAQUS.

Material parameters	Values
Traction for Mode I (MPa)	1.217
Traction for Mode II (MPa)	1.465
Relative displacement under mixed mode (μm)	8.616
Damage stabilization cohesive	1×10^{-5}
Kinetic friction coefficient	0.28
Penalty stiffness	1.04 10^2

4 COMPARING EXPERIMENTAL AND NUMERICAL RESULTS

4.1 *Uniaxial loading*

The failure pattern of the experimental and numerical model under uniaxial loading is compared by Sivakumar. G & V. B. Maji. 2018 and shown below in Figure 5. During Uniaxial loading there was a higher concentration of tensile stress in the path of wing crack propagation and the shear stress concentration was higher in the direction of coplanar to the flaw surface for flaw angles 30°, 45° and 60° but in flaw angles of 15° and 75° they were absent. With an increase in flaw angle, the stress concentration is reduced due to the reduction in flaw closure and slippage between the surfaces. Crack initiation stress was found to be in good agreement with the experimental results and follows the similar behaviour of a decrease in crack initiation stress with an increase in flaw angle obtaining a minimum value for flaw angle of 45°. And then increasing again with the increase in flaw angle.

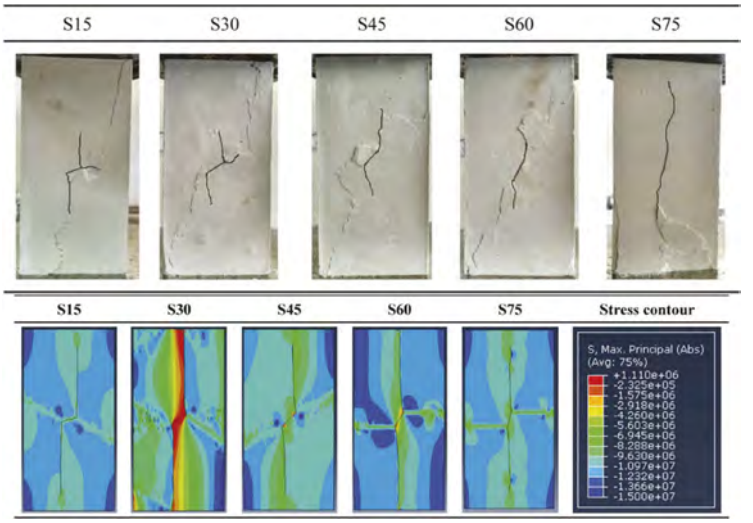

Figure 5. Failure pattern of uniaxially loaded specimen experimentally and numerically.

4.2 *Biaxial loading*

In the numerical simulation, the effect of confinement and friction coefficient can be changed in order to understand its effect clearly which is done by Sivakumar. G & V. B. Maji 2022. For no confinement by increasing the friction coefficient, the length of the tensile crack is relatively smaller, the path of the tensile crack is less curvilinear, and a sharper initiation is observed. On increasing confinement to 1.24 MPa, the crack initiates similarly as the perpendicular changes to an oblique direction, forming a type 1 tensile crack (T1). At a high friction coefficient, the crack initiates in a coplanar direction to the flaw surface and forms a type 3 tensile crack (T3) instead of (T2). The change of crack pattern due to the increase in confinement is shown experimentally and numerically for gypsum specimens of flaw angle 45° is shown in Figure 7. The effect of lateral confinement also alters the trajectory of crack propagation for different friction values. At a lower friction value, the initiated crack takes a curvilinear path for a smaller length and with the increase in confinement, their length reduces similar to the uniaxial condition. Unlike the uniaxial case, the propagated crack does not grow directly towards the major compressive loading direction. Instead, the crack takes a curvilinear outward direction and later near to the material peak, it aligns towards the major loading direction. Change of crack initiation stress, Peak stress with respect to confinement is shown in Figure 6

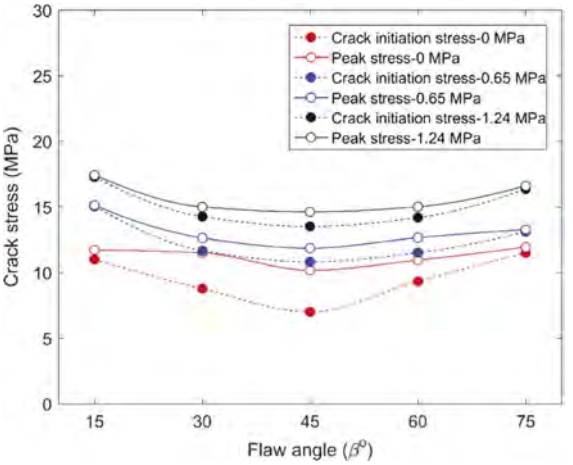

Figure 6. Crack initiation stress and peak stress observed in biaxial loading.

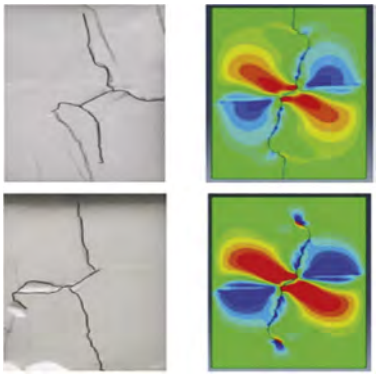

Figure 7. Crack growth pattern observed for 45° subjected to confinement of 0.65 MPa and 1.24 MPa experimentally and numerically.

5 CONCLUSIONS

Fracture initiation and propagation in rocks with pre-existing flaws under uniaxial and biaxial loading are studied both experimentally and numerically. The following conclusions can be drawn from the studies.

- Comparing open flaws to narrow flaws, the effect of closure differs with different flaw angles. The flaw surfaces were observed to be closed up to flaw angle 45°. For specimens with flaw angles of 60° and 75°, the flaw surface remained open. For uniaxial loading the crack initiation stress decreases with an increase in flaw angle obtaining a minimum value for flaw angle of 45°. And then increasing again with an increase in flaw angle.
- The adopted XFEM-based CZM was able to predict the crack growth and crack initiation stress for both uniaxial conditions and bi-axial conditions. CZM requires two main parameters crack initiation stress and fracture energy dissipated after initiation to describe traction-separation behaviour.
- For biaxial loading the favourable flaw angle to initiate the crack sooner is found to be closer to 45° for the lower confinements. Similar to the uniaxial loading, the crack stresses decrease and reach a minimum value and later increase making an undulant behaviour at

the intermediate flaw angles (30°-60°). But with increased confinements, the crack stresses at an intermediate angle the behaviour is relatively linear.

- Based on the shear force distribution monitored across the flaw surfaces, the shear force distribution is lower at a 30° flaw angle compared to a 45° flaw angle. Hence, the favourable flaw angle to initiate the crack mostly shifts closer to 30° at the higher confinements.
- Coefficient of friction and lateral confinement plays an important role in the crack length and propagation path. There can also be a change of crack type due to interference of these factors.

Physical properties of Tabriz gray marlstone, NW of Iran

N. Dadadszadeh, M. Hashemi & A. Gazifard
Department of Geology, University of Isfahan, Isfahan

E. Asghari-Kaljahi
Department of Earth Sciences, University of Tabriz, Tabriz

ABSTRACT: Tabriz is one of the largest cities in Iran, with a population of more than 2 million. Marlstone is the bedrock of most areas of the city. These marls, consisting of lime and clay, are found in different colors such as yellow, olive, and gray, which mostly belong to Baghmishe and Upper Red Formations. These marls have different amounts of organic materials and in high percentages cause the formation of lignite. The physical characteristics of the marl are different and the gray marl has a high density and strength. Another important characteristic of marls is the high rate of weathering which in excavations, changes over several months and turns into soil. Therefore, marl is considered both a weak rock and a hard soil. This study, by sampling and conducting experiments, presents the physical and mechanical characteristics of gray marls in different parts of Tabriz city. The carbonate content of the mentioned marls is between 30 and 60% and their dry unit weight is between 17.5 and 20.0 kN/m^3. The clay minerals in these marls also include illite, montmorillonite, etc.

1 INTRODUCTION

Marl is a term to describe the mixture of calcium carbonate and clay, normally between 35 and 65 percent (Pettijohn, 1975). Terzaghi and Peck (1967) have defined marl as a hard to very hard marine carbonate soil in green color. Sowers and Sowers (1979) introduced marl as a sandy deposit with silt and clay containing gray or green calcite and McCarthy (1977) stated that marl is soft limestone. Mitchell (1976), considers marl a soft, carbonated, and clay-rich material, and Bell (1981), has pointed out that marl is a term with different meanings, which is used for rocks with 35-65% carbonate and a large amount of clay. Qahvash (1989) introduced limestone sediments with 55 to 80 percent carbonates as marl.

In engineering geology and geotechnical engineering, terms such as colored soils, carbonate, and marl soils are used to specify the composition of fine-grained soil with carbonate minerals. The most important studies conducted on marls are: Bell (1981) conducted a study on the physical and resistance properties (unit weight, specific gravity, porosity and Young's modulus) of marls in the Middlebrook region of England. Qahvash (1989) conducted research on plastic properties, granulation, specific gravity, porosity, etc. in the Dhahran region of Saudi Arabia. El-Amrani et al. (1998), measured the uniaxial strength, deterioration index, carbonate percentage, dispersion index, water absorption, sulfate percentage, specific gravity, etc. in the Grande region of Spain. Hooshmand et al. (2012) studied parameters such as point load index, SPT, Young's and shear modulus, plasticity properties, specific gravity, porosity, and shear strength, in some areas of Tabriz city. Amirali and Katebi (2016) tested the carbonate content, color, strength, shear wave speed, and physical properties of Tabriz marls. Asghari-Kaljahi et al. (2019), studied parameters such as mineralogy, creep, and swelling behavior of marls in the Baghmisheh area of Tabriz.

Tabriz is one of the largest cities in Iran (Figure 1), with a population of more than 2 million. Marlstone is the bedrock of most areas of the city. The old area of Tabriz was

DOI: 10.1201/9781003299127-115

formed on smooth topographic surfaces and alluvial deposits. Still, with the growth and development of the city in the eastern side, a large part of the city's development in areas such as Valiasr town, Baghmisheh, Roshdieh, Marzdaran, and its extension to Ahar road in rough topographic, it is mostly placed on marlstone (NGDIR, 2004). Due to the development of the city on marl layers and the desire to build high-rise buildings and the need to place foundations in deeper layers, huge excavations have taken place in these layers and the future will be more than now will be required. To design the foundations of high-rise buildings, assess the risk of heavy constructions against possible earthquakes, and landslides, as well as guardian structures in deep excavations, it is necessary to exhaustively understand these layers from a physical and mechanical point of view. For this purpose, samples were taken from different parts of Tabriz tested for identification. The performed tests generally include moisture content, Atterberg limits, unit weight, specific gravity and uniaxial strength. On a group of samples, tests were performed to determine the percentage of calcium carbonate, percentage of organic matter, and mineral identification.

Figure 1. The location of Tabriz city on the Iran map.

2 GEOLOGY OF TABRIZ REGION

Marls of Tabriz are the carbonate sediments of lakes that are exposed in the eastern, northern, and southern areas of the city. Some pictures of these marls are illustrated in the Figure 2. The geology map of Tabriz region is showed on Figure 3. They form the bedrock in most areas of the city and are located under the alluvial sediments.

Considering that marls are often formed in warm and shallow lake areas, it can be concluded that such an environment prevailed in the current location of Tabriz city and the continental sediments in this area contained Lignite, shale, and fossil. The presence of gypsum and coal veins reduces the resistance characteristics of these deposits. In many marls, thin layers of gypsum are also observed. It seems that part of the carbonate materials required for the formation of marls in Tabriz is supplied from the limestone springs caused by the presence of Lake Urmia, and the presence of minerals and fossils such as coal, diatomite, sinerite, chlorite, and ferrous iron (Hooshmand, 2012). The marl layers are horizontal in most of the different areas, but in the northern parts of the city, due to the proximity to the Tabriz North fault and tectonic activities, it is inclined. From the point of view of soil mechanics, these materials are classified as clay or silty type with high plastic properties (Babazadeh and Ghobadi, 2013).

Figure 2. Some pictures of marlstone outcrops in the around of Tabriz city.

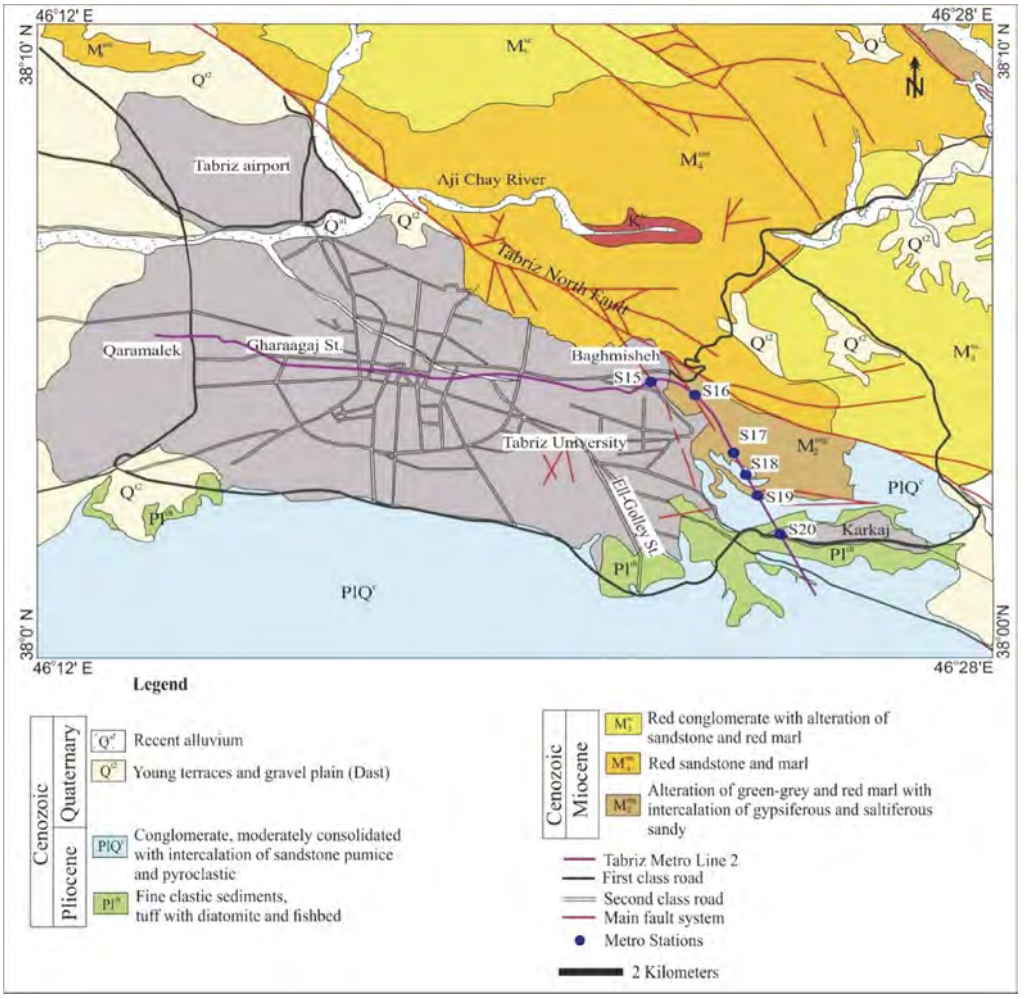

Figure 3. Geological map of Tabriz region (adapted from the geology map of GSI, 1996).

3 RESEARCH METHOD

During the visits to different areas of the city, taking pictures and taking samples in the places where geotechnical excavations were carried out, core samples were taken. Marls can be seen under the alluvial sediments in the central area of the city. In the reconnaissance excavations for the Tabriz metro project, gray marl layers have been observed at depths of 10 to 50 meters in the central areas of the city (Figure 4).

Figure 4. Outcrop of green and gray marls around Baghmisheh town.

4 TEST RESULTS AND DISCUSSION

The physical tests that have been performed on most of the samples include grading, Atterberg limits, specific gravity, and dry density. The test results are presented in Table 1. It can be seen that the soil unified classification of marls are MH, CL and CH. Atterberg limit tests performed on these marls have determined different liquid limits from 39 to 69.5% for yellow marls, 60 to 72% for olive green marls, and 40 to 80% for different types of gray marls. Their plastic index is from 17 to 46% for yellow marls, 38.5 to 42.5% for green marls, and 32 to 60% for different types of gray marls. Therefore, they have medium to high plastic properties. This is due to the change in their calcium carbonate content, the type and amount of clay minerals in them. Based on the Holtz and Kovacs diagram and comparing the results of the Atterberg limit test, it can be seen that the marl clay minerals of the studied area are illite, kaolinite and montmorillonite (Figure 5).

The different characteristics of marls in Tabriz are mostly related to the sedimentary environment and the conditions of their formation, so that layers of gray marl related to Baghmisheh Formation indicate their formation in a sweet lake environment and a large amount of

Table 1. The results of some physical tests.

Type of test	Upper limit	Lower limit	Average
Liquid limit (%)	80	39	52
Plastic limit (%)	58	15	35
Plastic index (%)	60	17	33
Dry density (kN/m^3)	19.0	15.0	15.6
Specific gravity	2.85	2.42	2.56

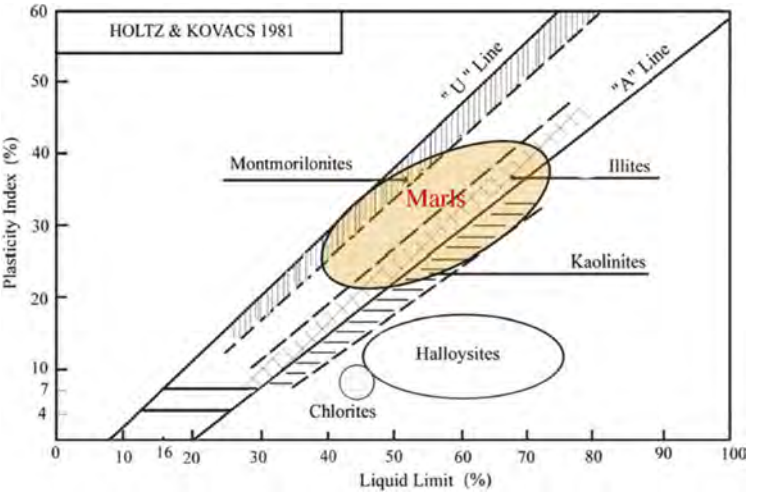

Figure 5. The relationship between the liquid limit and the plasticity index of marls on the Holtz and Kovacs) 1981) chart.

organic matter. Gray marl is an indication of reduced sedimentary environment and their formation next to joints and faults as a porous environment or reduction of iron due to changes in organic matter.

The gray marls of Tabriz contain a relatively large amount of calcium carbonate compared to the yellow and green marls, and by forming at greater depths due to the increase in confining pressure and the decrease in the porosity ratio with the depth and overburden pressure, they show the highest amount of resistance and the least deformation.

The minerals that makes Tabriz marls are not the same due to the difference in the way and time of formation, the way of deposition, the thickness of the layer, weathering conditions, as well as the conditions of the of the parent soil, and similar things. The main minerals in the X-ray diffraction test are quartz, albite, calcite, dolomite, chamosite, anorthite, and albite, and secondary minerals are illite, kaolinite, montmorillonite, hematite, and aragonite

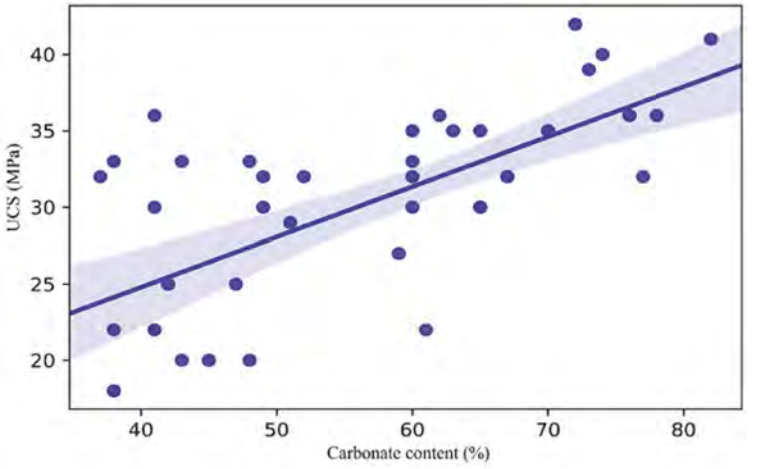

Figure 6. Relationship between calcium carbonate content and compressive strength in marlstone (Azarafza et al., 2019).

(Soleimani et al., 2019). From the geotechnical point of view, the presence of organic materials has a negative effect on soil characteristics. For example, they reduce the mechanical resistance of the soil and increase its settlement and creep. The maximum percentage of weight loss in the loss on ignition (LOI) test for organic matter is 2.6% for Tabriz gray marl, which can be concluded that the percentage of organic matter in Tabriz marl is very low and this value will not have much effect on properties (El Howayek et al., 2012). The amount of calcium carbonate can also affect the physical and mechanical characteristics of the soil. There is an inverse relationship between carbonate content and swelling behavior. Marls with high carbonate and high sulfate content as well as granular particles are easily compacted and their resistance parameters increase dramatically. Also, in these marls, the resulting compaction is irreversible (Figure 6).

Clay content appears to affect the maximum dry density in the case of the standard compaction test. This is attributed to adsorption of water by the clay minerals, whereas other clay-sized minerals such as carbonate do not have such an effect. The amount of calcium carbonate in Tabriz marl is between 10% and 30%, obtained during previous research, and this amount of carbonate does not have much effect on the behavior of marl and can be affected by the parent soil (Khamechian et al., 2000). Since the gray marl is known as the bedrock of Tabriz and continues to the thickness of 100 meters and more, the olive and yellow marl generally includes the surface layers of the soil. Practical experiments have shown that gray marl has more suitable characteristics in terms of resistance than olive marl. Regarding the resistance properties, there is a huge difference between the gray, olive, and yellow marls, and the results of the SPT and uniaxial compression tests are shown in Table 2.

Table 2. Results of SPT and uniaxial compressive strength tests.

Marl Type	SPT	UCS (MPa)	Modulus of elasticity (MPa)
Yellow Marl	7-25	0.25-1.0	<8
Green Marl	25-40	0.4-1.1	8.0-20.0
Gray Marl	28-50	0.65-1.9	10.0-30.0
Solid gray marl	>50	>1.9	>30.0

The above results and practical experiences in construction projects show that gray marl is in the very dense category in terms of SPT and at lower depths, it is like weak rock. The modulus of deformation in gray marl is higher than olive and yellow marl. This issue will cause high confidence in placing foundations of heavy structures in gray marl layers. Marlstones are among strong soil and weak rocks in engineering and behavior. This behavior depends on the amount of clay and calcium carbonate. By increasing the percentage of calcium carbonate and depth, the engineering behavior of marls is similar to weak rock, and by increasing the percentage of clay, this behavior is similar to hard soil. Marlstones are strongly affected by the conditions of their environment; for example, when they are exposed to moisture their primary structure disintegrates; in this situation, it is no longer possible to describe the stone's behavior based on its primary characteristics. The most important determining factor in the design of structures on marl is elastic, plastic, and ultimately rupture deformation. Due to rapid weathering and erosion, marls cause problems such as foundation and slope rupture, tensile cracks in streams, expansion of instabilities in natural slopes and trenches, and geotechnical projects. Dry and wet cycles has important effects on the behavior of marl soils. In a way that most ruptures occur after long rains. The strength and stability of structures in Tabriz city due to the extent of marl formations and weather conditions are associated with settlement and creep issues. So that the marl masses have caused severe landslides in the steep paths (Figure 7), Parsa et al., 2021).

Figure 7. Some pictures of the landslides that occurred in the marl layers in the east of Tabriz.

The results of mineralogical tests show the presence of very little quartz, calcite, dolomite, and feldspar minerals. Muscovite and gypsum are in the mineralogical composition of all marl samples. The color of green marls is mostly attributed to the presence of Hematite and the color of yellow marls is also attributed to the presence of yellowish brown limonite. The color of gray marls is also attributed to the presence of organic matter in them. The clay minerals of the studied marls are mostly Illite and in the next categories, montmorillonite and Kaolinite. Because the mineral type determination test provides only qualitative and descriptive results, it is not possible to obtain the percentage of minerals from its results, only the presence of minerals is mentioned. (Figure 8).

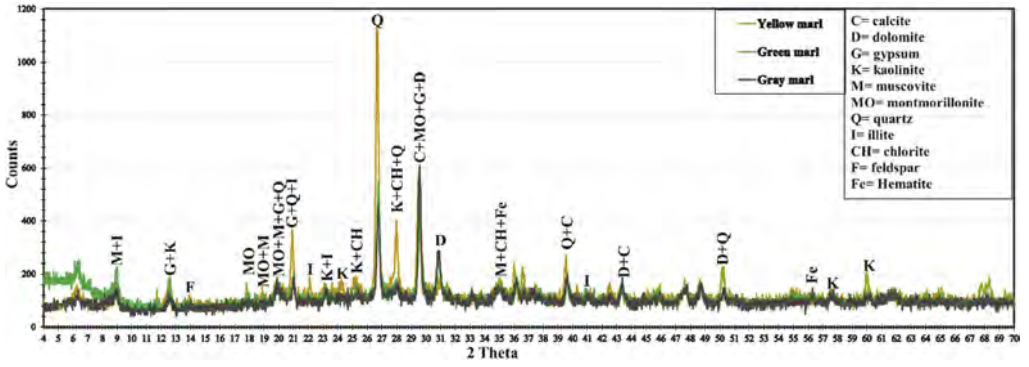

Figure 8. XRD for three types of Tabriz marls (Jalali-Milani et al., 2017).

5 CONCLUSION

Gray marlstone is the bedrock of most areas of the city. According to X-ray diffraction tests, the dominant minerals of Tabriz marls include quartz, illite, calcite, albite, and the dominant clay minerals are illite, montmorillonite, and kaolinite, but these minerals are not the same in different samples. The USCS of marly soils of Tabriz are CH, CL and MH. The percentage of organic matter in Tabriz marls is limited and generally less than 3% and is not included in the organic soil group in terms of classification.

According to the uniaxial compressive strength tests, yellow marls show the lowest strength and the most ductility due to stress and within the range 0.25-1.0 MPa, gray marls show the highest strength (0.65-1.9 MPa) and the least ductility. Green marls are intermediate between these two types and have uniaxial strength 0.4 to 1.1 MPa. The unit weight of marls increases with increasing depth, but this characteristic shows a decreasing trend with increasing moisture percentage. Dry density for the studied marls are between 15.0 and 19.0 kN/m^3.

The SPT values for yellow marl are between 7 and 25, green marl 25-40 and gray marl 28-50, which shows the high strength of gray marls.

Study of pore orientation in compacted crushed mudstone by SEM image

D.X. Sun, H. Komine, H. Wang, D. Ito & M. Takagi
Waseda University, Tokyo, Japan

ABSTRACT: Preferred orientation of pores result in the macroscopic anisotropy of soil. In this study, the SEM images of compacted crushed mudstone with different dry densities were analyzed and the orientation of pores were investigated. The results show that with the increase of dry density, the orientation distribution of pores appear anisotropy: the pore orientation distribution gradually concentrates on the direction which is perpendicular to and parallel to compacting direction.

1 INTRODUCTION

Clay-bearing rocks, mudstones and some other soft rocks including clay stones, siltstones and shales represent more than 60% of the sedimentary rocks exposed on earth's surface (Blatt, 1982). In Japan, crushed mudstone has been used in dam and highway embankment in recent years, which may sometimes cause disasters during earthquakes, such as the dam burst and slope failure (Kiyota et al. 2011, Takagi et al. 2010). Mechanical behavior of mudstone may lead to these disasters mentioned above. Recently, It has been proved that anisotropic mechanical behavior is affected by the anisotropy of soil structure (Hattab et al. 2015, Mitaritonna et al. 2014, Yimsiri & Soga, 2011). Scanning Electron Microscope (SEM) has been used in soil microstructure observation (Hattab & Fleureau, 2011, Tang et al. 2020). However, two-dimensional SEM images obtained from three-dimensional soil structures are difficult to be quantitatively analyzed due to coverage (Wang et al. 2008). Therefore, a resin injection method was introduced into SEM tests to obtain a plane in the section of specimen for quantitative analysis (Bai & Smart, 1997). In this study, SEM images of compacted crushed mudstone after resin injection is obtained and analyzed.

2 MATERIALS, EQUIPMENTS, PROCEDURES AND IMAGE PROCESS

A mudstone was used in this study and Table 1 shows its fundamental properties. The soil particles density is 2.729 Mg/m^3. Liquid limit and plasticity index of mudstone is 19.2% and 7.0 respectively. After completely drying in the oven, the mudstone was crushed and passed the sieve with an opening size of 425μm. Then, the mudstone was placed in a plastic ring and

Table 1. Fundamental soil properties.

Soil properties	Soil particle density (Mg/m^3)	Natural water content (%)	Liquid limit (%)	Plastic limit (%)	Plasticity index
Value	2.729	4.2	19.2	12.2	7.0

DOI: 10.1201/9781003299127-116

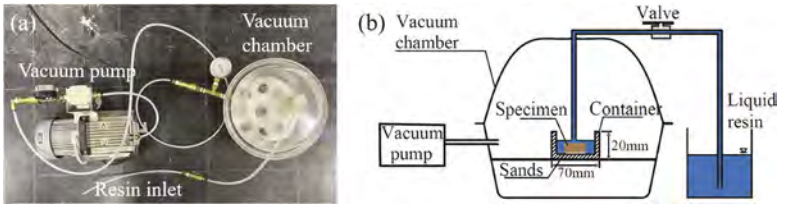

Figure 1. (a) picture and (b) schematic diagram of resin injection equipment.

compacted at 10kN pressure for 5min. Finally, the competed specimens (28 mm in diameter and 5mm in height) with dry densities of 1.60, 1.84, and 1.96Mg/m^3 were obtained.

As shown in Figure 1, compacted specimen was placed in a container with some coarse sands at the bottom, which can allow the resin to enter the sample pores more easily during injection process. The container with specimens was placed in a vacuum chamber and then kept vacuum for 10 min. After that, liquid resin was filled into the container at a uniform speed. Finally, the specimens were removed from the vacuum chamber and prepared for SEM tests. The SEM (JSM-IT100LA, JEOL) with magnification of ×50 (for specimens with dry density of 1.60 and 1.84 Mg/m^3) and ×70 (for specimen with dry density of 1.96 Mg/m^3) was used in observation. The acceleration voltage is 20kV, and the SEM image consists of 5120×3840 pixels.

A new pore orientation evaluation method is applied in this study. The specimen preparations for SEM tests and image processes can be seen in Figure 2. Specimen injected with resin were cut and sanded. The area close to the cross-section center of the specimen was observed using SEM (see Figure 2a). Some common image processes including Median Filter, Opening, and Closing were applied for denoising before thresholding process (Tang et al. 2020). After these, one thresholding value determined by artificial vision was performed on the SEM image for pores extraction. Skeletonization was carried out to create the skeleton of pores represented by a line and two nodes, where one line and two ending nodes are called a segment (Figure 2b). The length and orientation of skeleton were calculated by coordinates of two ending nodes. Details of skeletonizing can be seen in Figure 2c. Finally, skeleton orientations weighted by skeleton length were calculated for pore orientation analysis. Since the edges of the image gather skeletons, sheared round images (as shown in Figure 2b) instead of square ones were used for analysis in order to eliminate the affection of image edge. Due to the resolution of SEM image, extremely small pores consist of several pixels, resulting in orientation calculations of 0° or 90°. Therefore, pores with area larger than 12.6μm^2 were analyzed in this study.

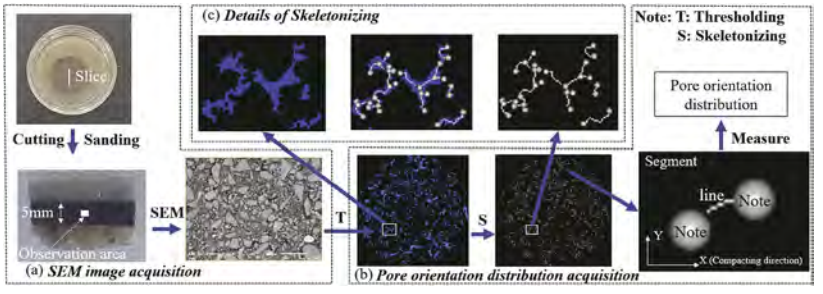

Figure 2. Typical image processing and data acquisition: (a) SEM image acquisition; (c) pore orientation obtained from skeletonized model; and (c) details of skeletonizing.

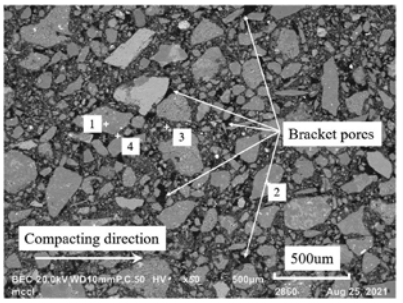
3 RESULTS AND DISCUSSION

In this study, the structure of mudstone was analyzed by energy dispersive X-ray spectroscopy (EDS) which can recognize the element contents in certain point or area. The SEM image of specimen after sanding can be seen in Figure 3.



EDS results

Points	Element (mass%)				
	Si	Al	Mg	Na	Ca
1	87.45	10.68	0.99	0.88	-
2	99.86	-	0.07	-	0.07
3	69.70	23.66	6.64	-	-
4	74.13	18.89	2.37	2.93	1.68

Figure 3. SEM image and EDS analysis of specimen with dry density of 1.60Mg/m^3.

There are large particles distributed in the specimen and the bracket pores can be seen between large particles. It can be seen from the EDS results that the silicon content of the large particles (Point 1 and 2 in Figure 3) is higher than that of the areas among large particles (Point 3 and 4 in Figure 3), while the clay element content in the area among large particles is higher than the large particles. Thus, the large particles should be quartz particles. In summary, the conclusion can be drawn from SEM image: structure of compacted crushed mudstone is composed of large particles, bracket pores and clay mineral. This conclusion will support the subsequent discussion of pore compression.

Skeletons with different orientation should represent different specific gravity in statistics due to different lengths. Therefore, the ratio of the sum of the skeleton length in each orientation interval to the total skeleton length is taken as the frequency of different directions (see Figure 4). The statistical orientation with the range of 180° are transformed into distribution results within the orientation range of 360° after common data processing (Hattab et al. 2015, Tang et al. 2020).

The orientation distribution of three specimens with different dry densities were shown in Figure 4. For the specimen with lowest dry density (ρ=1.60 Mg/m^3), the main orientation of the pores is not clearly visible. The frequency is distributed between 4.97% and 3.49% for different pore orientations. When the dry density of the specimen reaches 1.84 Mg/m^3, the orientations of pores are concentrated at 0°, 90°, 180° and 270°, reaching around 5% of frequency. Whereas the orientations of 0°, 90°, 180° and 270° have the smallest frequency, about 3%. The pore orientation distribution of specimen with dry density of 1.96 Mg/m^3 become not as obvious as that in specimen with medium dry density. This may be due to pores being squeezed into smaller ones which are beyond the observation range in the specimen with the highest dry density.

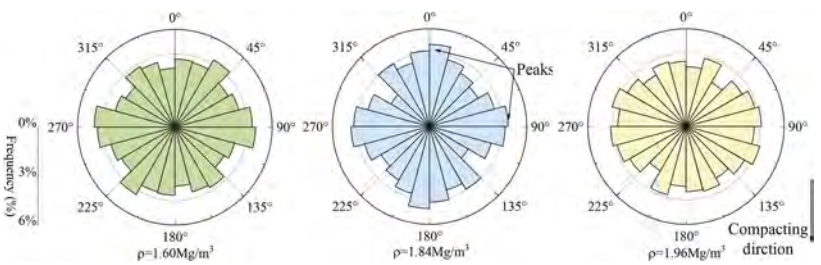


Figure 4. Rosette histogram of pore orientation distribution.

As can be seen in Figure 5, the pore orientation gradually concentrates on two orientations during the increase of dry density: perpendicular to and parallel to compacting direction. While the pore proportion in other directions decreases. In the process of compaction, particles were oriented and perpendicular to the compaction direction (Shi et al. 1998). Due to the rearrangement of particles and squeeze during compaction, the width of the bracket pores parallel to the compaction direction was reduced, thus forming pores perpendicular to the

compaction direction (see Figure 5b: Horizontal pores). Whereas, the pores parallel to the compaction direction are formed due to pores between oriented particles (see Figure 5b: Vertical pores). The conclusion can be used in the study of anisotropic mechanical behavior as mentioned in the introduction.

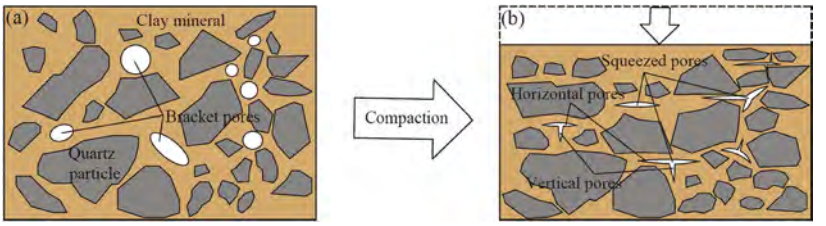

Figure 5. Evolution of pore orientation during compaction.

4 CONCLUSION

The results of SEM images show that with the increase of dry density, the pore orientation distribution gradually concentrates on the direction which is perpendicular to and parallel to compacting direction due to the squeeze of pores and the rearrangement of particles.

Constitutive model of expansive soft rock considering cementation and swelling nature

H. Kyokawa
The University of Tokyo, Tokyo, Japan

M. Kikumoto & Y. Cui
Yokohama National University, Yokohama, Japan

ABSTRACT: A novel constitutive modeling method which assumes expansive soft rock as the parallel composite mixture of rock matrix and expansive soil is proposed in this study. The rock matrix is modeled as the elastic damage model to represent the cementation on mechanical characteristics. The expansive soil is modeled by the double structure model for expansive soil to describe the mineralogical swelling due to wetting. The proposed model reasonably considers the interaction between cementation and mineralogical swelling on the mechanical characteristics of expansive soft rock and its transition.

1 INTRODUCTION

Expansive soft rocks become brittle due to the wetting/drying history because of the degradation of cementation on rock matrix, which is caused by the mineralogical swelling/shrinking of the contained clay minerals such as montmorillonite. Such swelling embrittlement (weathering) of soft rock causes slope failure and heave of tunnel (Pimentel, 2015), and its characteristic would depend on rock and ground water qualities, namely microscopic mineral properties (Chai et al., 2014). The design and construction on an expansive soft rock ground are comprehensively done based on several macroscopic index such as competence factor, slaking index, and montmorillonite content. Some numerical investigations especially on a tunneling in an expansive soft rock have also been conducted (Li et al., 2022). However, the most of them consider the mechanical characteristics at the predefined damaged area at the final weathered state, thus they cannot give a quantitative information on the deformation area and its transition due to surrounding environment such as the drying and wetting cycles.

In this study, a novel constitutive modeling method which assumes expansive soft rock as the mixture of rock matrix and expansive clay is proposed. The rock matrix is modeled as the elastic damage model to represent the influence of degradation of cementation on mechanical characteristics. Moreover, an expansive clay is modeled by the double structure model for expansive soil (Kyokawa, 2021) to describe mineralogical swelling due to wetting. The model validation is carried out by comparing with the observed results of the soaking and consolidation test in oedometer. It is indicated from the simulation of soaking under anisotropic stress state that the mineralogical swelling causes degradation of cementation and it results the failure with large deformation.

2 ISOTROPIC HETEROGENEOUS MATERIAL MODEL FOR SWELLING SOFT ROCK

2.1 *Modeling framework*

It can be seen from Figure 1 (after Cai et al., 2020) that swelling layered clay mineral, e.g., smectite, in sand stone (soft rock) causes the internal cracks at the cemented rock matrix, for

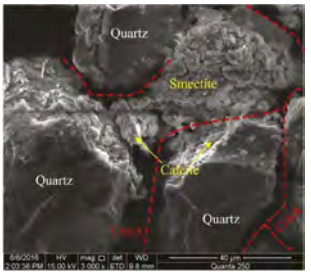

Figure 1. SEM image of Kunming sand stone (after Cai et al., 2020).

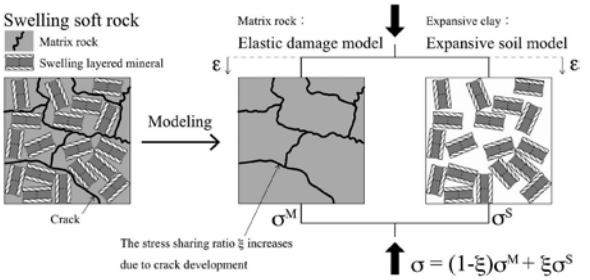

Figure 2. Modeling framework of expansive soft rock the isotropic heterogenous mixture.

instance, due to the drying-wetting cycles and it results the change in mechanical characteristics. In this study, swelling soft rock, which is the mixture of rock matrix and expansive clay, is modelled as the isotropic heterogeneous material shown in Figure 2.

The Bishop's effective stress is used for formulation of the proposed model to treat the unsaturated state and soaking (saturation) process. Assuming the spatially isotropic distribution of the matrix part (denoted by "M") and the expansive soil part (denoted by "S") in the soft rock, the total net stress is shared by each part. Then, adding a scalar state variable ξ to evaluate current stress sharing ratio, the total net stress is given by

$$\sigma_{\text{net}} = (1-\xi)\sigma^{\text{M}}_{\text{net}} + \xi\sigma^{\text{S}}_{\text{net}} \quad \text{where} \quad \boldsymbol{0} \le \xi \le \boldsymbol{1} \tag{1}$$

Considering same strain causes on both the matrix and expansive soil parts. Suction is independent from the stress sharing ratio ξ on the Bishop's effective stresses of each part, namely suction is the intensive property on stress. Assuming the effective stress parameter χ is equal to the degree of saturations of each part, the effective stresses are defined as

$$\sigma^{\text{M}}_{\text{net}} = \sigma''^{\text{M}} - S^{\text{M}}_r s\delta, \quad \sigma^{s}_{net} = \sigma''^{\text{S}} - S^{\text{S}}_r s\delta \tag{2,3}$$

For simplicity, the degree of saturations of each part are identical and it is given as a function of suction (van Genuchten model) in this study.

$$S^{\text{M}}_r = S^{S}_r = S_r(s) \tag{4}$$

The behavior of matrix part is described by the elastic damage model. Assuming the isotropic linear elasticity, namely Hooke's law, the relationship between the effective stress of matrix part and strain is given by

$$\boldsymbol{\sigma}''^{\text{M}} = \boldsymbol{D}^{\text{M}}_{\boldsymbol{e}}\varepsilon \tag{5}$$

In the first term on the right side of Equation (1), the stress sharing ratio ξ is equivalent to the damage index D in general damage theory. As the stress sharing ratio ξ approaches to 1, an apparent reduction of stiffness occurs, namely the degradation of cemented matrix is described. The stress sharing ratio is given by the following equation referring to Kurumatani et al. (2016).

$$\xi = 1 - \frac{\kappa_0}{\kappa}\exp\left(-\frac{E\kappa_0 h_e}{G_f}(\kappa - \kappa_0)\right) \quad \text{where} \quad \kappa(\varepsilon) \tag{6}$$

κ is the equivalent strain given as a function of the strain invariants. κ_0, E, G_f, h_e are the material parameters.

The behavior of expansive soil part is modeled by the double structure model for expansive soils (Kyokawa et al., 2021). Combining the behaviors of soil skeleton and clay mineral

crystals, this double structure model describes the hydro-mechano-chemical coupling behaviors of expansive soils. In particular with regard to the mineralogical swelling, both the crystalline swelling due to the adsorption of water molecule on a crystal, and the osmotic swelling due to the diffusion double layer of cations are considered in the model. Since the elastoplastic model is applied for the soil skeleton behavior, an increment type constitutive relationship of the double structure model is generally given as.

$$\delta\sigma''^{S} = \delta\sigma''^{S}(\delta\varepsilon, \delta \boldsymbol{S}_r^S, \delta \boldsymbol{s}, \delta \boldsymbol{d}), \quad \delta \boldsymbol{d} = \delta \boldsymbol{d}\left(\delta\sigma''^{S}, \delta \boldsymbol{c}, \delta \boldsymbol{S}_r^S\right) \tag{7,8}$$

d is the distance between mineral crystals, which is similar to the basal spacing. $\boldsymbol{c}$ is cation concentrations in pore fluid. Summarizing above equations, the total net stress is given by the following hydro-mechano-chemical coupling equation, in which strains, suction, cation concentrations are variable.

$$\delta\sigma_{\text{net}} = \delta\sigma_{\text{net}}\left(\delta\sigma_{\text{net}}^{\text{M}}, \delta\sigma_{\text{net}}^{\text{S}}, \delta\xi\right) = \delta\sigma_{\text{net}}\left(\delta\varepsilon, \delta\kappa(\delta\varepsilon), \delta \boldsymbol{s}, \ \delta \boldsymbol{S}_r^S(\delta \boldsymbol{s}), \delta \boldsymbol{c}\right) \tag{9}$$

3 MODEL VALIDATION

3.1 *Soaking and consolidation test*

To verify the applicability of the proposed model, the soaking and consolidation test on an expansive soft rock is simulated. The specimens were a natural (undisturbed) expansive soft rock rich in the smectite group mineral, and its disturbed specimen, which is reconstituted by compacting the crushed sample, for comparison. The initial air-dried specimens were loaded to a certain stress level in oedometer, and subsequently soaked by supplying the distilled water in the cell. After the soaking, a further consolidation process was conducted.

Material parameters for the matrix part are set by referring to the literature (Kurumatani et al., 2016) and a fitting. The parameters for the expansive soil part are basically same with those for the bentonite in previous study (Kyokawa, 2021), and the compression index and some parameters controlling swelling behavior are determined from a fitting. To consider the initial specimen disturbance in the simulation, the initial sharing stress ratio (the damage index) ξ_0 was calibrated. To reproduce soaking process in which the degree of saturation increases from almost zero at the air-dried condition to fully saturated condition, while suction was decreased in the water retention characteristic model, the cation concentration was also decreased from the saturated solution to the distilled water.

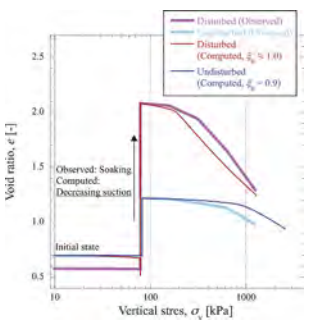

Figure 3. Observed and computed results of the swelling and consolidation tests.

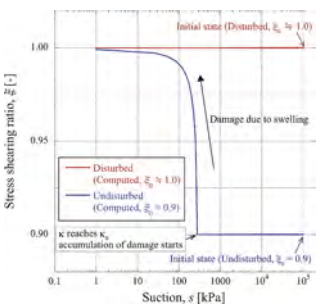

Figure 4. Transition of the stress shaering ratio during soaking process.

Figure 3 shows the relationship between vertical stress and void ratio, and Figure 4 shows the transition of the sharing stress ratio ξ during soaking process. It can be seen from Figure 3 that the proposed model can properly consider the influence of initial disturbance of specimen

not only on the magnitude of swelling due to soaking but also subsequent compression behavior. In Figure 4, the sharing stress ratio ξ of the undisturbed specimen accumulates as suction decreases, since the equivalent strain κ increases due to swelling (tension) strain.

It is indicated in Figure 2 that the stiffness of the proposed model can be regarded as the parallel composite stiffness of the rock matrix and expansive soil parts. Swelling of the expansive soil part due to soaking is initially suppressed by the stiffness of rock matrix. However, such expansive (tension) strain causes damage, and it results that the sharing stress of the matrix part decreases. As expansive strain accumulates, therefore, the behavior of the proposed model gradually becomes that of the expansive soil part.

3.2 *Soaking under anisotropic stress state*

Considering an actual ground condition, the simulation of soaking under anisotropic stress state was conducted. The undisturbed and disturbed soils, of which material parameters and initial conditions are same with those of above soaking and consolidation test, are sheared under the conventional triaxial compression. Moreover, another disturbed soil is sheared up to 100 kPa of deviatoric stress, and subsequently soaking under constant stress state is simulated.

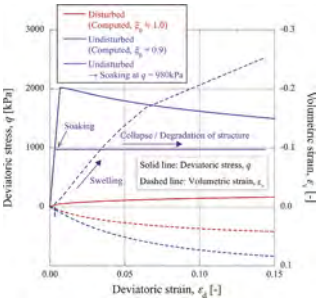

Figure 5. Simulation results of the monotonic compression tests and the soaking test under anisotropic stress state.

Figure 5 shows the stress-strain relationship (deviatoric strain – deviatoric stress – volumetric strain). The disturbed soil exhibits low strength and stiffness, which is equal to the behavior of expansive soil without the cementation effect. On the other hand, the undisturbed soil shows initially higher stiffness and strength. However, since accumulation of strain causes an increase in the sharing stress ratio ξ, namely the degradation of cementation on the matrix part, thus strain softening occurs from a certain strain level. In the case of soaking, development of deviatoric strain with large volume expansion can be observed. The mineralogical swelling of the expansive soil part due to soaking causes the degradation of cementation on the matrix part, and it is followed by the reduction of peak strength and the destabilization of soil structure. This soaking deformation process seems to capture the failure mechanism of expansive soft rock ground due to the drying-wetting cycles, namely swelling and squeezing.

4 CONCLUSIONS

The constitutive modeling method considering expansive soft rock as the parallel composite mixture of the rock matrix and expansive soil parts was proposed. Through the simulation of element test, it was indicated that the proposed model can reasonably describe the interaction between cementation and swelling nature of expansive soft rock. Conducting several element tests and analysis, the verification of model and setting the material parameters and initial condition will be discussed in future work.

Strength and deformability of large-scale clastic soils

ABSTRACT: This paper presents the results of determining the actual strength and deformability of large-block soils in laboratory conditions on model mixtures. The strength deformative properties of large-block soils were determined on a large-sized device, the minimum size of which should be five times larger than the maximum size of the fraction. The main factors influencing the results of the experiments include: soil characteristics, loading characteristics and device characteristics. At the same time, the large-scale effect associated with the decompression of the end and side surfaces of the soil samples, as well as the friction of the samples on the side surfaces of the device, resulted in more accurate determination of the actual properties of large-block soils.

In recent decades, coarse-grained soils have been increasingly used as a material for the construction of dams in hydraulic engineering and road construction. And at present, the share of coarse-grained soils in hydraulic engineering construction is 75 percent or more (Kazakbaev, 1978).

Coarse clastic soils include soils containing more than 50% of fragments with dimensions of more than 2 mm. These include boulders, stones, crushed stone, pebbles, gruss, gravel; to boulders (rounded) and stones (not rounded) rocks with a particle size of more than 200 mm. Pebble (rounded), crushed stone (not rounded) are fragments of rocks with a fraction size of 200=10 mm. Gravel (rounded), gruss (not rounded) rock fragments with a particle size of 10-2 mm (Ibragimov, 1997).

Although coarse-clastic soils have low deformability and high strength and resistance to external loads, their physical and mechanical properties have not been fully studied due to the significant size of the fraction, which requires labor-intensive, expensive experiments on large-sized installations and devices (Orman, 2003, Ibragimov, 2000).

Therefore, the analysis of data on the study of the physical and mechanical properties of coarse clastic soils is of considerable interest.

As is known, the property of such soils in laboratory and field conditions is determined approximately on instruments and equipment intended for fine-grained soils.

One of the possible ways to solve this problem is modeling, in which smaller model mixtures are used instead of natural soils.

The model mixture is made from natural soil material by reducing the fraction by several times, while maintaining porosity and density.

The strength properties of coarse-grained soils are determined on a large-sized shear device, subject to the following condition:

$$Dpr^{min} \geq 5d_{max} \quad (1)$$

DOI: 10.1201/9781003299127-118

where $_{Dpr}^{min}$ - minimum diameter or height of the fixture; d_{max} - maximum soil particle diameter.

As a result of numerous experiments in laboratory and field conditions, in the general case, factors affecting the strength of coarse clastic soils can be divided into three groups:

1. Soil characteristics
2. Loading characteristics
3. Characteristics of devices

Soil characteristics mainly include soil type, mineralogical composition, particle size and shape, composition, density and moisture (Ibragimov, 2017).

With regard to the characteristics of soil loading, there are two fundamentally different load schemes: static and dynamic.

It is well known that the behavior of soils in these two cases is significantly different. However, the experiments of P.L. Ivanov, L.R. Stavnitser, Yu.K. Zaretsky, it is shown that under dynamic loading, the Coulomb formula can be used, where the normal stress is taken into account together with additional stresses arising from the dynamic application of the load.

Under dynamic loading, the Coulomb equation is written in the following form:

$$\tau_{din} = (\sigma_c - \Delta\sigma_r)\text{tg}\gamma \tag{2}$$

where $\Delta\sigma_s$ -additional stresses arising from the dynamic application of the load; tgγ- friction angle corresponding to static loading conditions.

In construction practice, to determine the strength characteristics of coarse-grained soils, two flat shear devices and stabilometers are mainly used. As experiments performed by many authors show, that if the corresponding condition (1) is observed, where scale effects are not manifested, the results obtained on both devices are practically the same.

In plane shear devices, the parameters are directly normal б and shearing τ stresses in the shear plane, from which the shear coefficient is determined.

In stabilometers, two main voltages are measured: the maximum б1 and the minimum б3. In this case, the shear coefficient is determined taking into account these two principal stresses, i.e. maximum and minimum.

Normal and shear stresses are determined from the following expressions:

$$\begin{aligned} \sigma &= \frac{2\sigma_1 * \sigma_3}{\sigma_1 * \sigma_3} \\ \tau &= \frac{\sigma_1 - \sigma_3}{\sigma_1 + \sigma_3}\sqrt{\sigma_1 * \sigma_3} \\ K_c &= \frac{\sigma_1 - \sigma_3}{2\sqrt{\sigma_1 * \sigma_3}_1} \end{aligned} \tag{3}$$

To determine the deformability of coarse clastic soils, it is necessary to take into account several types of systematic errors associated with scale effects that significantly affect the results of experiments.

These are the following three types of scale effects related to coarse clastic soils:

1. Scale effect associated with the decompaction of the end surfaces of soil samples.
2. Scale effect associated with the presence of zones located on the side surfaces of the samples.
3. Scale effect associated with the friction of the samples on the side surfaces of the samples.

When determining the deformability of coarse-grained soils on conventional compression devices, scale effects are not taken into account. In this case, the error is 50 percent or more..

The deformative properties of coarse-grained soils are determined using a large-sized compression device, subject to the condition:

$$Dpr^{min} \geq 5d^{fr}{}_{max} \quad (4)$$

The deformation characteristics of gravel-pebble soils are determined taking into account the under-stamp effects and lateral friction along the device walls according to the following formula:

$$S_{tr}=S_{exp} + \Delta_1 - \Delta_2 \quad (5)$$

where S_{tr} – true sample deformation; S_{exp} – deformation of the sample measured in experiments; Δ_1 – error due to friction losses along the device walls; Δ_2 – error due to under-stamp effects, independent of sample height.

At present, there are two different approaches to take into account lateral friction along the device walls: constructive and computational-experimental.

The most well-known constructive solution that makes it possible to exclude the influence of lateral soil friction on the measurement results is the device designed by Ya.L. Kogan, which is an odometer consisting of individual metal rings separated by compressible soft rubber gaskets. This should ensure the joint deformation of the walls of the odometer and the ground, respectively, the exclusion of any additional stresses in the ground associated with friction on the side surfaces of the device (Teptsky, 2020).

Calculation and experimental methods for taking into account lateral friction in compression tests of soils in odometers were developed by G.I. Pokrovsky, H.A. Rakhmatulin. According to the method of H.A. Rakhmatulin, it is necessary to conduct parallel tests of two soil samples of different heights h and 2h. If there is a noticeable systematic error associated with under-stamp effects, the relative value of which is inversely proportional to the height of the sample, this can lead to a significant error in the calculations. H.A. method Rakhmatulina gives good results when tested with fine-grained soils (Ibragimov, 2017, Ibragimov, 2020).

The deformation of coarse-grained soils, taking into account the scale effect associated with lateral friction along the walls of the device and decompaction along the side surfaces of the sample, is determined by the following method.

Compression testing of specimens of the same size is carried out in parallel in two types of rigid wall odometer. One of the odometers is a conventional design with a hard bottom and a movable top die. The second odometer instead of a hard bottom has the same movable stamp as on top.

As a result, in the first odometer, the load is applied to the upper stamp, while the stress along the height of the soil sample continuously decreases towards the base, and in the second odometer, the load is applied simultaneously to both stamps (upper and lower) and the stress decreases in the same way towards the middle of the sample. As a result, the second sample can be represented as if it consists of two samples with a height reduced by half. In this case, it will be possible to use the same scheme as that of H.A. Rakhmatulin, which differs in that with the same total height of the samples in the first and second odometers, the influence of the under-stamp effect in them is the same and therefore does not affect the results of calculating the stress state of the sample (Ibragimov, 2017, Ibragimov, 2019).

Accounting for lateral friction along the walls of the device is carried out according to the method of Kh.A. Rakhmatulin with the solution of the differential equation of equilibrium.

The solution of the differential equation gives, to construct a curve of the true compressibility of the soil.

Experimental determinations of compressibility show that lateral friction has a very significant effect on test results. The true compressibility of coarse-grained soils can be 1.5-2.0 times higher than directly observed in odometers with rigid instrument walls.

The second group of errors in determining the compressibility in odometers is the scale effect associated with the decompaction of the end surfaces of soil samples.

To determine the deformation, taking into account the under-stamp effect, two experiments are carried out. The first experiment is the same as discussed above, with a fixed bottom and a movable stamp at the top.

In the second experiment, the sample in the odometer is divided into two identical layers between which an additional stamp is placed, resulting in four contact zones.

In this case, the total deformation, in each of the two experiments, is determined by the sum of the soil deformation in the central part and the soil deformation in the zones in contact with the stamp, and they can be written as:

For the first case;

$$\varepsilon_1 = \varepsilon_{tr} + 2\Delta\varepsilon$$

For the second case:

$$\varepsilon_2 = \varepsilon_{tr} + 4\Delta\varepsilon \quad (6)$$

where ε_{tr} – true deformation of the soil sample corresponding to the selected stress; $\Delta\varepsilon$ – additional deformation (error) due to the under-stamp decompression zone.

Then the relative deformation, taking into account the under-die effect, is determined from the following formula:

$$\varepsilon_{tr} = 2\varepsilon_1 - \varepsilon \quad (7)$$

where ε_1 - relative strain of a sample in a hard-bottom odometer; ε_2 - relative deformation of a sample in an odometer with a hard bottom and a stamp in the middle.

The final actual relative deformation (settlement), taking into account the above errors, is determined from the following expression:

$$\varepsilon_r = \varepsilon_{tr} - \varepsilon_1 + \varepsilon_{tr} \quad (8)$$

where ε_{tr} – true relative deformation taking into account the under-die effect; ε_{tr} – true relative deformation, taking into account lateral friction along the device walls and decompression of zones along the side surfaces of the sample.

Table 1 below shows the results of calculating the actual compressibility performed jointly with Petrov G.N. In this calculation, first, the correction for friction is determined, after which corrections for the influence of under-die effects are introduced to the obtained intermediate calculation. Simultaneously with the calculation of the actual compressibility values, the friction coefficients were also determined.

Table 1. The actual compressibility.

1 CONCLUSION

1. In the presence of sufficiently developed methods for calculating structures from coarse-grained soils, their physical and mechanical properties are currently determined quite approximately, with significant errors. Also, the methods of preparing and laying such soils in construction have not been sufficiently developed.
2. The physical models proposed taking into account the scale effects of the interaction of coarse-grained soils with the rigid walls of the devices make it possible to develop metrologically substantiated methods for determining the physical and mechanical characteristics of soils, as well as to obtain calculated dependencies and nomograms for determining the latter.

Calculation of the parameters of the base of waste rock dumps on a mountain slope

K.Ch. Kozhogulov & B.T. Djakupbekov
Institute of Geomechanics and Subsoil Development of the National Academy of Sciences of the Kyrgyz Republic, Bishkek, Kyrgyzstan

ABSTRACT: In calculations, the formation of waste rocks of upland deposits and the determination of the parameters of the base of the dumps is a rather difficult problem. Such parameters as the relief of the surface, the storage of a sufficiently large volume of waste rock and with small occupied areas, the steepness of the slope, as well as the minimum distance to the quarry are considered for the planning of dumps. The waste rock dump is the final product in the development of rocks in quarries. A prerequisite for dumping and warehousing is to ensure industrial and environmental safety.

Calculation of the volume of the stored dump in the minimum area. For this task, Google Earth aerial photographs were used and a 3D terrain model was created using the google sketchup software product.

When planning rock dump formations of upland deposits and determining the parameters for the foundations of dumps is a rather difficult problem. Such parameters as the complexity of the terrain, the storage of a sufficiently large volume of overburden and with small occupied areas, the steepness of the slope, as well as the minimum distance relative to the contour of the quarry are considered for the planning of dumps.

In a limited occupied area and a certain volume of the dump is poured into one or more tiers. The parameters of the height of the tier are determined by the stability, which depends on the properties of the base for the dump and the stored rocks, the relief of the surface, the length and speed of movement of the dump front, the rate of dumping of the dump.

The filling schemes define the process of compaction of rock masses of dumps and their strength properties.

A prerequisite for dumping and warehousing is to ensure industrial and environmental safety, as it is the final product in the development of rocks in quarries.

The stored dump on an inclined base is in a stable state as long as there is sufficient internal coupling in the medium forming them and the shear resistance exceeds the shear forces. The main condition for the successful solution of the problem of the stability of dumps is to understand the physical nature of shear resistance, which is a consequence of friction between individual particles of bulk material and between the particles and the solid base of the dump. Krasnoselsky. & Kalabin. 1975. Dumps. . .

For this task, where exact parameters of the surface area of the stored dump are needed, satellite images obtained from the Google Earth software product were used. For this example, we calculated the dumps of the Kumtor mine Figures 1 and 2.

In Google sketchup, based on the satellite images obtained, a 3D model of the surface relief of the selected section of the saved dump is automatically created. Based on the created 3D model, we start designing the placement of dumps taking into account the required conditions, such as the volume of dumps and the area of placement, Figure 3. Dzhakupbekov. 2016. Determination of dump. . .

DOI: 10.1201/9781003299127-119

Figure 1. Satellite image of the dumps of the Kumtor deposit of Kyrgyzstan.

Figure 2. Storage of the Kumtor mine dump.

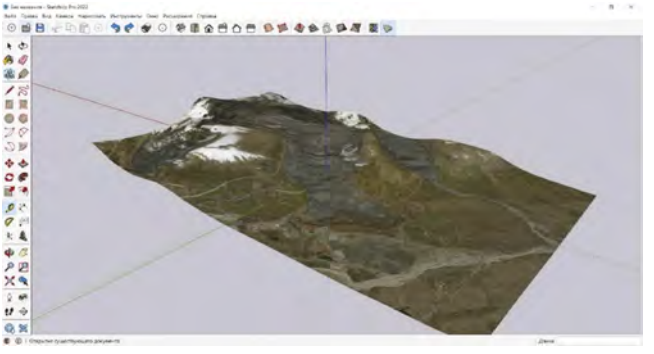

Figure 3. Based on satellite images, a 3D model has been created, a place for a dump.

Based on the 3D model, we obtain the required number of longitudinal and cross sections to calculate the stability coefficient taking into account the geometric parameters of the blade Figure 4.

To calculate the stability coefficient of the dumps, a study was also done to determine the physical and mechanical properties of the base rocks and the rocks of the dumps. The provided samples in laboratory conditions were determined the properties necessary for calculating the stability coefficient.

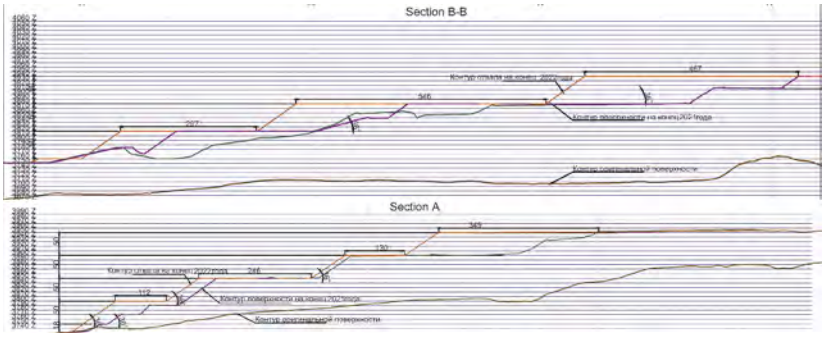

Figure 4. Cross section of dumps.

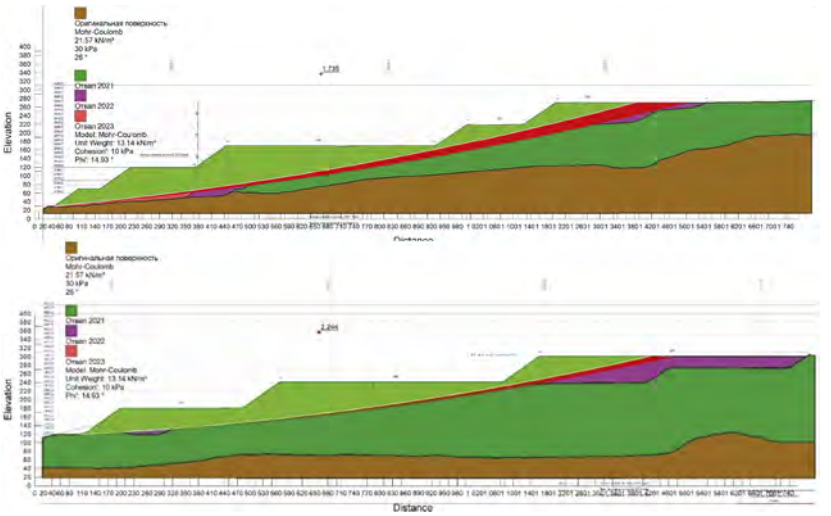

Figure 5. Cross-section stability coefficient calculations, GeoStudio slope/w software was used.

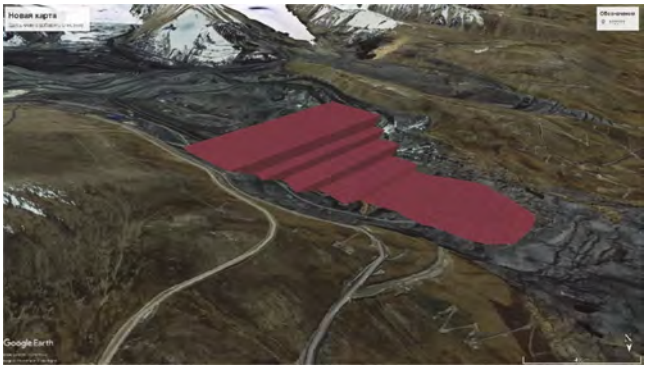

Figure 6. The final view of the 3D model of the dump on the slope, taking into account all Google Earth calculations.

According to the results of the obtained laboratory data, it was revealed that the average value of the bulk weight of the base rocks is $\gamma_н$ = 21.57 kN/m3. According to the results of determining the strength characteristics of rocks, it was found that the angle of internal friction of the base rock is φ = 260, and the adhesion is C = 30kPa.

Also, according to the results of the data obtained, the average value of the bulk weight of the dump rocks is un = 13.14 kN/m3. The angle of internal friction of the dump rock is φ = 14.930, and the adhesion C = 10kPa. Below are the results of calculating the stability coefficient, Figure 5.

You can also import the projected 3D model of the dump into the Google Earth software application with attached geo-positions to view the location of the dumps relative to the quarry, Figure 6.

1 CONCLUSIONS

This method of obtaining the parameters of the 3d model and the base for the dump allows you to calculate the minimum area occupied by the dump and calculate the stability coefficient in a short time.

1. Laboratory studies all the necessary work was carried out to calculate the stability of the dumps.
2. Based on the results of studying the satellite images, all the necessary 3D geometric constructions were made.
3. As a result of the performed studies of the state of the dumps, the calculation of the stability coefficient and the assessment of the stability of the dumps, it was established:
   - newly poured dumps are generally stable;
   - the overall stability of the dumps is within the generally accepted values: the value of the stability coefficient is more than Ky = 1.5.

Simulate the in-situ direct shear test of gravel and systematic evaluation its mechanical properties parameters based on the discrete element method

T.T. Wang*
Professor, Department of Civil Engineering, National Taiwan University, Taipei, Taiwan (R.O.C.)

ABSTRACT: Because the particle size of gravel exceeds the scale of conventional laboratory test equipment, its mechanical properties often obtain by in-situ direct shear tests. Several factors affect the mechanical properties of the gravel layer, including the particle size distribution, the particle arrangement and its stacking. However, due to the high cost and limited number of tests on site, it is difficult to acquire representative mechanical properties parameters of the gravel layer. In this study, discrete element particle flow software is used, and the design of experiments (DOEs) method is applied to determine combinations of microscopic parameters. The microproperties affects the mesoscale mechanical properties of gravel and its regression equations are obtained by the statistical analysis of variance (ANOVA). Combined with the in-situ direct shear tests, the range of the mechanical properties parameters of the gravel formation can be described.

1 INTRODUCTION

Gravel typically has particle sizes that range widely, on average exceeding 10 cm, and are easily impacted by the size effect. According to Marsal (1973), the size effect will have a considerable impact when the ratio of the specimen's diameter to its maximum particle size is less than six. Since the particle size of gravel exceeds the range of common, laboratory test equipment, larger-scale tests (Xu et al., 2011) or the use of numerical analytical software are more appropriate for examining the mechanical properties of gravel.

There are two different types of large-scale tests for gravel: large-scale triaxial tests and large-scale direct shear tests. Because of the limitation of equipment and space, the large-scale triaxial test is more difficult to carry out among them, so the large-scale direct shear test is the one that is most frequently utilized (Yagiz, 2001; Kuenza et al., 2004; Hamidi et al., 2012; He et al., 2021).

Large-scale direct shear experiments can be used to determine the mechanical properties of gravel, but they are expensive, few in number, and unable to measure contact number or force. As a result, the numerical analysis method has been rapidly developing in recent years. Researchers simulate biaxial compression testing by creating gravel models in MATLAB and importing them into Particle flow code (PFC) software (Ding et al., 2010; Liu et al., 2013; Lu et al., 2017).

Although previous research indicates that large-scale tests of gravel primarily rely on direct shear tests, the numerical simulation primarily uses the biaxial test to study the mechanical properties of gravel. As a result, this study simulates in situ direct shear tests by PFC-FLAC coupled numerical modeling.

2 NUMERICAL MODEL

This study simulates in situ direct shear tests by PFC-FLAC coupled numerical modeling. Figure 1a shows the layout of the in situ direct shear test. In order to reduce computation time, FLAC is used to generate the mesh to simulate the reinforced concrete, and the gravel specimen is simulated using PFC. (Figure 1b). To investigate the influence of particle shape, a model with elliptical gravel is adopted. A clump is employed to produce 2:1 axial ratio elliptical particles, each clump has three round particles. According to the design of experiment (DOE), the fixed ratio of round particles is replaced to simulate the gravel sample.

The microscopic parameters, particle size, number of particles, packing, and loading rate have an impact on the PFC simulation outcomes. Therefore, to reduce the influence of the particle size, number of particles, packing, and loading rate, a particular particle size distribution curve (Figure 2) and packing are selected, and a specific loading rate is chosen. A constant normal force is applied vertically on the top of the reinforced, while the whole reinforced travels from left to right at a preset rate along the shear plane to imitate in situ direct shear test. The normal force is set at 0.1, 0.2, 0.3, and 0.4 MPa, per the experiment data.

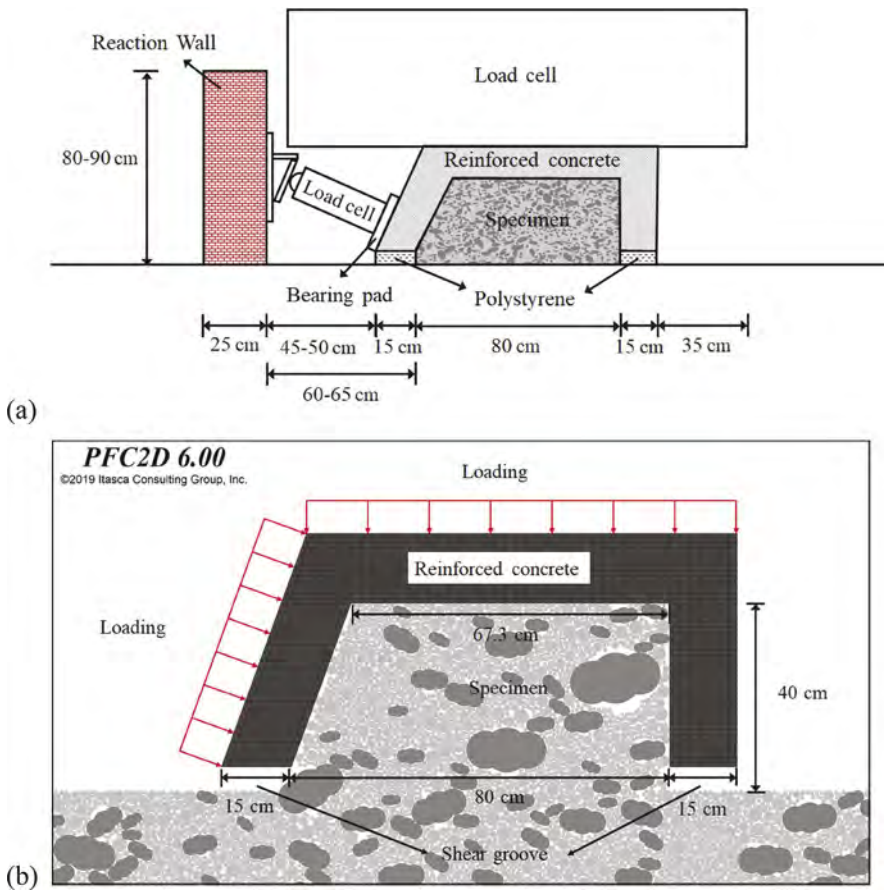

Figure 1. Schematic diagram (a) in-situ direct shear test, (b) numerical model.

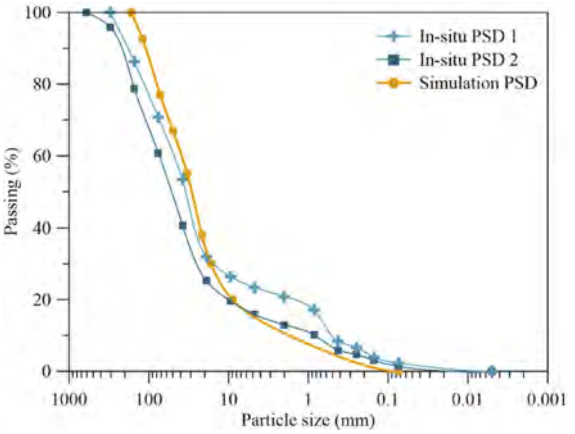

Figure 2. In-situ and numerical model particle size distribution curve.

3 MICROPROPERTIES BASED ON DOES

The input microscopic parameters are set using the DOE and orthogonal array (OA) tables to assess the effects of altering particular microproperties on the dependent variables, which are the mechanical properties. DOE is used to investigate the relationship between multiple input variables (factors) and output variables (responses), and the OA table is used to reduce the number of simulations. A statistical analysis of variance (ANOVA) is carried out to find the significant parameters that affect simulated cohesion (c) and friction angle (ϕ), which are then used for regression analyses and discussion.

3.1 *Two-level factorial experiments*

There are more than ten microscopic parameters needed for the PFC2D simulation. According to Potyondy and Cundall (2004), ten parameters are chosen in this investigation as the main microproperties that may affect the mesoscale c and ϕ of specimens. The Young's moduli of the particles (E_c) and bonds ($\bar{E}_c$) as well as the normal-to-shear stiffness ratios of the particles (k_n/k_s) and bonds ($\bar{k}_n/\bar{k}_s$) affect the deformation properties of specimens. The friction coefficient of particles (μ), the tensile strength of the bonds ($\bar{\sigma}_c$), the cohesion of the bonds ($\bar{c}$), and the friction angle of the bonds ($\bar{\phi}$) affect the strength properties of specimens. The geometry of specimens is influenced by the ratios and rotation angles (α) of clumps.

A full three-level and two-level factorial design of ten microscopic parameters require 59,049 and 1,024 distinct parameter combinations, respectively, which is numerous. However, many of which have a minimal impact on the simulated mechanical properties. Thus, this study employs the orthogonal table $L_{32}2^{10\text{-}5}$ setup factor to decrease the number of simulations and generate 32 sets of various parameter combinations in order to increase analysis efficiency.

According to statistical ANOVA results E_c $\bar{\sigma}_c$, $\bar{c}$ and μ are identified as the main factors that significantly influence the specimen's c and $\bar{E}_c$, μ, α and ratios of clump are identified as the main factors that significantly influence the specimen's ϕ since they are greater than the corresponding critical values at the 90% confidence level (P<0.1).

3.2 *Three-level factorial experiments*

To determine the nonlinear effects of independent variables on dependent variables, three-level factorial experiments are carried out using an orthogonal table. Seven microscopic parameters, E_c, $\bar{E}_c$, μ, $\bar{\sigma}_c$, $\bar{c}$, α and ratios of clump, are chosen as the primary components in

the factorial design per the findings of two-level factorial experiments. The orthogonal table $L_{81}3^{6\text{-}2}$ is used; the magnitudes of the parameters that are used in 3-level DOEs are listed in Table 1. The other three microscopic parameters, k_n/k_s, $\bar{k}_n/\bar{k}_s$, and $\bar{\phi}$ are set to 1.33, 1.00, and 12, respectively. The three-level factorial experiment involves 27 combinations of microproperties. The upper bounds and lower bounds of the simulated cs and ϕs of specimens are the same as those in the two-level experiment. According to statistical ANOVA results E_c are identified as the main factors that significantly influence the specimen's c and ratios of clump are identified as the main factors that significantly influence the specimen's ϕ.

Table 1. Microproperties for use in 3-level DOEs.

		Level			
Effect on the specimen	Items	-1	0	1	Unit
Deformation properties	E_c	$4.00*10^8$	$1.20*10^9$	$3.60*10^9$	Pa
	(k_n/k_s)	-	1.33	-	-
	$\bar{E}_c$	$6.67*10^6$	$2.00*10^7$	$6.00*10^7$	Pa
	$(\bar{k}_n/\bar{k}_s)$	-	1.00	-	-
Strength properties	μ	0.22	0.67	2.00	-
	$\bar{\sigma}_c$	$9.00*10^4$	$2.70*10^5$	$8.10*10^5$	Pa
	$\bar{c}$	$8.00*10^4$	$2.40*10^5$	$7.20*10^5$	Pa
	$\bar{\phi}$	-	12	-	°
Geometry	Ratios of clump	62	70	80	%
	α	0	45	90	°

4 DISCUSSION

Table 2 shows that, in addition to the one microproperties, E_c, μ interaction with E_c and $\bar{E}_c$, and $\bar{\sigma}_c$ interactions with $\bar{c}$, significantly affect the mesoscale c of specimen. Multiple linear regression is used to determine the relationships between the mesoscale c and the two microproperties and their interaction terms, yielding

$$c = 0.7380E_c * \mu + 0.3728\bar{\sigma}_c * \bar{c} - 0.3641\bar{E}_c * \mu - 0.2066E_c \tag{1}$$

with a coefficient of determination $R^2 = 0.786$.

Table 3 shows that, in addition to the one microproperties, Ratios of clump, $\bar{E}_c$ interaction with α, and μ interactions with Ratios of clump, significantly affect the mesoscale ϕ of specimen. Multiple linear regression is used to determine the relationships between the mesoscale ϕ and the two microproperties and their interaction terms, yielding

$$\phi = -0.5424\mu * \text{Ratios of clump} + 0.4102\text{Ratios of clump} + 0.2484\bar{E}_c * \alpha \tag{2}$$

with a coefficient of determination $R^2 = 0.665$.

Table 2. ANOVA based on three-level factorial experiment to determine influence of microproperties on simulated c.

	Coef.	SE Coef.	$t(22)$	p-Level(<0.1)
Residual	0.0000	0.0198	0.0000	1.0000
(1) E_c	-0.2066	0.0632	-3.2677	0.0035
(1) E_c*(5) μ	0.7380	0.0973	7.5862	0.0000
(3) $\bar{E}_c$*(5) μ	-0.3641	0.0775	-4.6984	0.0001
(6) $\bar{\sigma}_c$*(7) $\bar{c}$	0.3728	0.0697	5.3466	0.0000

Figure 3 plots associated 95% confidence level. The range of simulation results of cohesion (c) and friction angle (ϕ) includes the in situ data, and the in situ data are all within the 95% confidence interval, indicating that the formula obtained in this study can be used to predict the in situ data.

Table 3. ANOVA based on three-level factorial experiment to determine influence of microproperties on simulated ϕ.

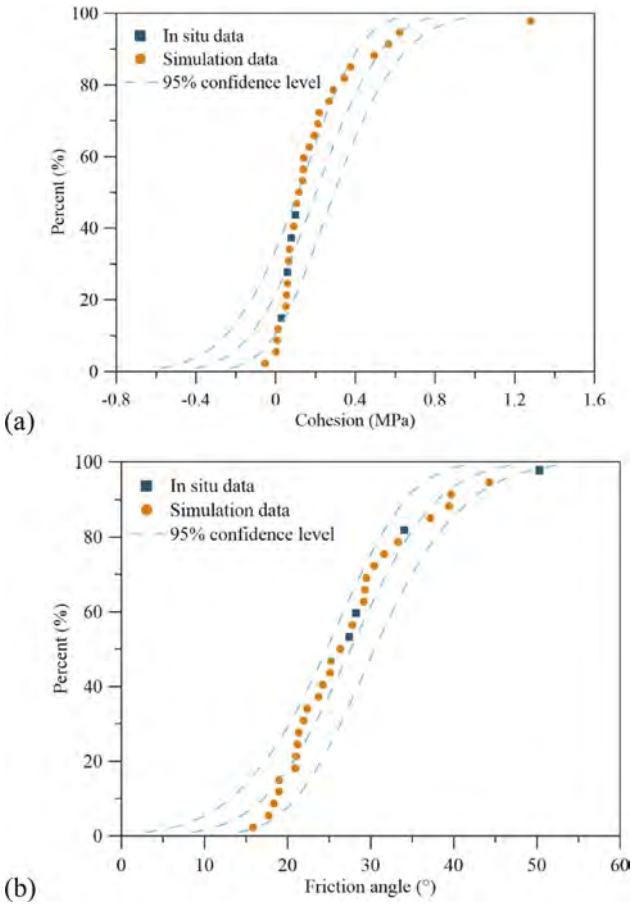

Figure 3. 95% confidence level of corresponding cohesion (a) and friction angles (b).

5 CONCLUSION

The design of experiment (DOE) method is used to determine the relationship between the microproperties and simulate mesoscale mechanical parameters of a rock specimen. Two- and

three-level factorial designs with related analyses of variances (ANOVA) are successively used to identify the microproperties that significantly affect the cohesion (c) and friction angle (ϕ) of a specimen. The following conclusion are drawn.

1. One microproperties, the Young's moduli of the particles (E_c) and μ interaction with E_c and $\bar{E}_c$, and $\bar{\sigma}_c$ interactions with $\bar{c}$, significantly affect the mesoscale c of a rock specimen.
2. One microproperties, the Ratios of clump and $\bar{E}_c$ interaction with α, and μ interactions with Ratios of clump, significantly affect the mesoscale ϕ of specimen.
3. Two multivariate regression equations (Equations (1) and (2)) are proposed to describe the relationships between the cohesion (c) and friction angle (ϕ), of a specimen and its aforementioned microproperties, with coefficients of determination of 0.786 and 0.665, respectively.

Assumptions and reality in ground models – the case of drift-filled hollows and associated subsurface features in London, United Kingdom

A.L. Flynn
Robert Bird Group, London, UK

P.E.F. Collins
Department of Civil and Environmental Engineering, Brunel University London, UK

ABSTRACT: The subsurface of London is often assumed to be relatively simple, with Late Cretaceous and Palaeogene strata sitting within and forming a synclinal structure (the London Basin). The surface has been modified by mostly fluvial processes during the Quaternary.

More recently, a picture of more complex conditions has begun to be developed, largely driven by the need for deeper foundations, groundwater control and tunnelling. One group of significant features are referred to as 'drift-filled hollows' (DFH). These are commonly closed depressions in the surface of the bedrock (typically the London Clay Formation), that are infilled by later deposits. Adjacent and underlying strata is sometimes disturbed

A new database shows that DFH are more widespread than previously thought, but also highlights issues in how they are classified. It also raises questions about the validity of the 'simple' geological model of London and highlights the danger of using assumptions when planning development, and for reconstructing past events.

1 INTRODUCTION

Understanding subsurface conditions is essential for infrastructure development and is integral to design codes such as Eurocode, where structures must "sustain all actions and influences likely to occur during execution and use" (BSI 2010, p26). Frequently, this understanding is expressed as a ground model that incorporates a range of site geological, hydrogeological and geotechnical information. Importantly, as proposed in the current draft of Eurocode 7 (under review, BSI 2022), the degree of ground variability and uncertainty must be acknowledged. This paper explores how ground variability and uncertainty can be affected by assumptions, particularly in contexts such as the London region in southern England where there is a long history of ground investigation and ground conditions are sometimes *believed* to be predictable. To aid this, a new compilation and assessment of data is presented.

2 STUDY AREA

2.1 *The assumed regional geological model*

The geological model that forms the start point of many ground investigations in the London region was first developed in the 19th Century (e.g. Reynolds 1849), and subsequently added to by many authors (e.g. Wooldridge and Linton 1939; Sumbler 1996; Royse et al. 2012).

DOI: 10.1201/9781003299127-121

This was originally based on surface exposures, small quarries and water wells. More recently, boreholes have been drilled for water and increasingly as part of site investigations, with around 80,000 records now available within the London area.

The generally-followed regional model is of a Palaeozoic basement, unconformably overlain by Cretaceous clays, sands and permeable Chalk. Overlying these is a suite of Palaeogene and Neogene strata, the most widely known of which is the London Clay. The Cretaceous and Palaeogene/Neogene strata form a syncline-like structure, with Chalk hills to the north, south and west, while the Chalk generally occurs at depth in the central London area. The current geological structure is traditionally interpreted as being the result of fairly gentle compression and folding between the later Cretaceous and the Miocene.

During the later Neogene, and particularly during the Quaternary, denudation formed the valley of the river Thames and its tributaries. The northern margin of the area was glaciated approximately 0.45 Ma before present but the area has experienced a periglacial climate for much of the past million years or so. River deposits, principally sand and gravel, are widespread as a series of terrace units (Gibbard 1985, Bridgland 1994). During warmer periods, a range of finer alluvial soils and peat was deposited. These occur locally within the river terrace deposits and beneath the modern floodplain. The modern surface is often characterized by human modification and is often referred to as 'made ground'.

2.2 *Recent modifications to the geological model*

Progressive improvement in ground investigation methods, and the availability of evidence, has permitted additional, principally local, detail to be added to the general geological model. For example, a significant number of high-quality borehole, tunnel and groundwater records have been collected as part of the Crossrail project (see e.g. Davis 2016). This has particularly improved understanding of the stratigraphy, showing that the Palaeogene strata under central London are spatially and vertically complex (e.g. Edgar et al. 2022).

The new attention paid to the detail of borehole and other data has also shown that there is, at least locally, structural complexity (e.g. Newman 2022) with a variety of faults that affect ground properties and drainage.

2.3 *Anomalous near surface features – drift-filled hollows*

Variability in the thickness of superficial deposits resting unconformably on Palaeogene strata in and beyond central London is well known (Berry 1979; Hutchinson 1980, 1991). There have been several investigations of individual features where an apparently closed depression in the basal Quaternary unconformity is infilled by an anomalously thick sequence of superficial deposits (e.g. Hawkins 1952; Collins et al. 1996; Lee and Aldiss 2012; Davis et al. 2018). Some, but not all of these features include significance disturbance of the Cretaceous and Palaeogene strata that they overlie, including diapiric structures, or are close to faulting. Some are known to penetrate through some or all of the Palaeogene strata to reach the Cretaceous Chalk. The term 'drift-filled hollows' (DFH) is generally used when this type of feature is encountered in London.

Potential risks associated with drift-filled hollows are due to significant horizontal and vertical variability in ground properties, including permeability and bearing capacity. There is also uncertainty over whether the features are all the result of past processes, or whether some are still actively developing, or could be reactivated in the future. As exploitation of deeper geology increases for deep foundations, excavations, tunnelling, and geothermal energy, it is important that the current uncertainty around these features is addressed.

Although many drift-filled hollows have been reported, detailed studies have been typically based on individual features, with different researchers dealing with apparently unique features. There is a need to consider them more holistically to see if there are common patterns.

Berry (1979) identified several drift-filled hollows in central London and attributed them to river scour. A similar scour hypothesis was proposed by Rose et al. (1980). In contrast, Hutchinson (1980, 1991) proposed a more complex suite of processes including artesian pressure, valley

bulging and particularly ground ice growth and decay (i.e. pingos). In a study to the west of London, Collins et al. (1996) considered a series of drift-filled hollows underlying the modern floodplain and valley-side river terrace deposits, and concluded that localized subsidence, possibly linked to passive (and possibly active) tectonic control was the dominant process. The robustness of evidence for massive ground ice in the hollows in central London was questioned by Collins (2013; also Banks et al 2015) as typical and unambiguous diagnostic features had not been found.

The review by Banks et al. (2015) of drift-filled hollows in central London identified some geographical clustering which supported Hutchinson's (1980) identification of areas most likely to have a drift filled hollow present i.e. areas where impermeable strata are thinner, and a confined/artesian aquifer.

New evidence continues to add to understanding, with the most recent compilation first reported in Flynn et al. (2020) and completed by Flynn (2022).

3 APPROACH

In the most recent work (Flynn 2022), a rigorous re-evaluation of existing evidence was completed with a deliberately non-genetic methodology that minimized the risk of interpretive bias. The bulk of the data was retrieved from the British Geological Survey's GeoIndex database (BGS 2020), with supplementary evidence provided through new site research, industry collaboration and a limited number of published studies e.g. Davis et al. (2018) who provided tunnel face logs.

Data quality was variable and required critical assessment and, where appropriate and possible, confirmation with other evidence. Records that did not meet strict quality criteria were excluded. A new database was established to manage the data and analysed using the ArcGIS 10.5.1 software. Features identified through this new analysis were named using a numbering system to a) maintain interpretative distance from previous work and b) retain confidentiality for sites where required.

4 RESULTS

Collation of the results confirm that the near surface stratigraphy of London is complex. Around 90 features that meet one or more of the commonly-used criteria used to identify a DFH were identified. The detail of the validated evidence collated has allowed the frequency of particular structures often associated with DFH to be assessed (Table 1).

Table 1. Number of features identified with the given characteristic (total of 87 features).

	Present	Absent	Unknown
Diapir	13 (15%)	14 (16%)	60 (69%)
Faulting	18 (21%)	6 (7%)	63 (72%)
Hollow penetrates through Palaeogene strata	25 (29%)	51 (59%)	11 (12%)
Full depth of feature known	34 (39%)	29 (33%)	24 (28%)

What is clear is that, even with higher than normal levels of site investigation evidence, potentially significant information is frequently absent in the assessment of ground conditions for development.

Where DFH depth can be reasonably reliably established, most appear to occur a continuum between a few metres to around 30 m depth. A number are noticeably deeper, with the deepest being in excess of 70 m.

The majority of the DFH occur beneath the floodplain and later Pleistocene river terraces, with the majority of the infilling materials including river gravels and alluvium, sometimes featuring disturbance since deposition. Known DFH hollows are spatially clustered mainly in central London, with a second group in eastern London and fewer in West London (Figure 1).

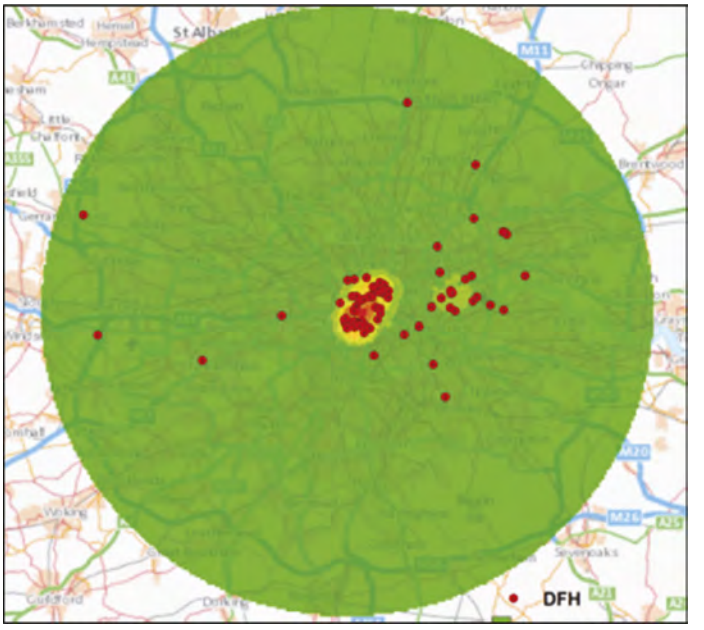

Figure 1. Heat map showing the distribution of known Drift Filled Hollows. The map is centered on central London.

5 CONCLUSIONS

The new, extended dataset confirms that Drift-filled Hollows are a common feature of near-surface geology in London. Sampling bias, due to the overall distribution of data points may mean that areas which show low frequency of features may simply reflect a paucity of data. This is most likely to be the case in the outer parts of the circle shown in Figure 1, where development has been less intense, but is probably a less significant factor for much of the mapped area.

There is some indication that the features are clustered, suggesting one or more spatial controls. Single climate influences, such as hypothesized permafrost and ground ice, or controls such as scour at river confluences might be expected to create a more uniform distribution, particularly along the valley floor. Similarly, simple geological controls such as the thickness of the impermeable London Clay might be expected to produce linear strips of DFHs.

A more likely explanation is that the distribution of DFH is, in part, controlled by linear geological structures, such as faults. Detailed investigations, often related to tunnelling e.g. Linde-Arias et al. (2018) and Morgan et al. (2021), show that such structures are more common than previously thought. These may have interacted with factors such as ground ice, localized erosion and geological material characteristics to allow, in an active or passive fashion, for hollow formation.

The identification of large number of drift-filled hollows, particularly in geographical clusters, provides a useful step forward in helping site developers and engineers assess likely hazards and risk in London. More work is required on the nature and origin of the features to better understand their impact on urban infrastructure and how they generate and influence the "actions and influences" which must be addressed under the Eurocode system.

The presence of such a large number of hard-to-predict ground features in an area such as London, with it's substantial volume of ground data has implications for other regions globally where current assumptions of ground predictability may be masking the true nature of risk.

Deep learning for microscopic rock image classification

W. Seo & T.S. Yun
Yonsei University, Seoul, Republic of Korea

ABSTRACT: The optical observation of rock thin section images leads to rock classification, which requires expertise in mineralogy. To overcome the subjectiveness and uncertainty inherent in conventional rock classification practice, this study introduces a deep learning-based classification procedure with a convolutional neural network (CNN). The microscopic images of six igneous rock types were prepared and processed for network model training. Transfer learning was implemented to train the ResNet152 model whose performance was investigated with classification methods at patch and image-levels. The trained model achieved a high accuracy of more than 90%. The results also showed that image-level classification from patches demonstrated the best performance depending on the spatial characteristics of comprising minerals. Based on this approach, it was shown that the CNN model can effectively identify the features in microscopic rock images, leading to reliable rock classification.

1 INTRODUCTION

The conventional rock classification is generally conducted via optical observation of rock thin sections using polarizing microscopic images, but this approach requires expertise in mineralogy. Recently, rock thin section analysis such as pore or grain characteristic extraction and mineral identification are being automated by image processing techniques. Asmussen et al. 2015 used seeded region growing algorithm to determine pore and grain parameters. Borazjani et al. 2016 extracted pore space and textural characteristics to classify carbonate rock using multi-layer perceptron (MLP) as a texture identifier. Ma & Gao 2017 identified pores and the rock skeleton with K-means clustering and support vector machine. Baykan & Yılmaz 2010 used MLP for mineral identification, and Izadi et al. 2013 also identified minerals with MLP based on texture features.

Recent studies have also used computer vision techniques to automatically classify rocks from microscopic images. Cheng & Guo 2017 classified coarse, medium granular, and fine feldspar sandstones using convolutional neural network (CNN). Su et al. 2020 used Concatenated-CNN to classify 13 rock types. Pires de Lima et al. 2020 used pretrained CNNs as backbone networks for transfer learning to classify five types of siltstones. Polat et al. 2021 also used transfer learning with pretrained CNN models for volcanic rock classification, and Seo et al. 2022 classified igneous rocks. By using pretrained CNN models, images can be analyzed without requiring manual extraction of features and parameters. Hence, the aim of this study is to classify six types of igneous rocks from their microscopic images using deep transfer learning with ResNet152 model as a convolutional backbone network.

DOI: 10.1201/9781003299127-122

2 MATERIALS AND METHODS

2.1 *Image dataset*

Six igneous rock types were selected to be classified: granite, diorite, gabbro, rhyolite, andesite, and basalt. Granite, diorite, and gabbro are plutonic rocks with larger mineral grain sizes and rhyolite, andesite, and basalt are volcanic rocks with smaller grain sizes. A total of 352 images with both open and cross nicol polarization were prepared (Table 1) from various sources. The original images were then resized to 896 × 672 pixels, preserving their aspect ratios, and we randomly divided the resized images for each rock type into training, validation, and test datasets in a 7:1:2 ratio. Images in each dataset were then cropped into 224 × 224 pixels to generate 12 image patches. Additionally, images in training dataset were augmented by 8 times by flipping and rotating.

Table 1. Number of images for each rock type.

Rock type	Open nicol	Cross nicol	Total
Granite	23	32	55
Diorite	20	26	46
Gabbro	25	36	61
Rhyolite	25	46	71
Andesite	37	18	55
Basalt	33	31	64
Total	163	189	352

2.2 *Deep transfer learning with CNN*

A CNN is a deep learning network widely used in computer vision tasks, and generally consists of convolutional, pooling, and fully connected (FC) layers. Convolution filters slide over the input images to extract features in convolutional layers, and parameters are updated by the error backpropagation. The pooling layers reduce the size of the input, and outputs from convolutional and pooling layers becomes the feature maps which are used as inputs to nonlinear activation function and the next layers. As a classifier, FC layers connect the flattened data from the final feature map to the final output.

When the size of the original image datasets is relatively small, transfer learning is an effective method to train the network model. Transfer learning adopts backbone networks pretrained with large datasets to optimize the model. Various types of the convolutional backbone networks for transfer learning have been proposed, and ResNet152 (He et al. 2016) were chosen in this study. ResNet152 model uses shortcut connections between convolutional layers to solve degradation problem of deep CNNs. ResNet152 has several convolution blocks which contain convolutional layers with shortcut connections. Global average pooling is applied after the last convolutional layer to collapse the spatial dimensions into a single dimension, instead of flattening.

Commonly, deeper layers of the CNN extract high-level global features of the input images. Therefore, to effectively optimize the model, the deeper parts of the convolutional layers and the FC layers were retrained (fine-tuned) to update parameters, while the parameters in the initial part were frozen. Since the model's purpose is the classification, cross-entropy loss was chosen for the loss function, and Adam was used as the optimizer. The sequences for the training and the architecture of ResNet152 is illustrated in Figure 1.

2.3 *Patch and image-level classification*

The trained model was tested by three different classification methods A, B, and C: the method A is patch-level classification, and the method B and C are image-level classification

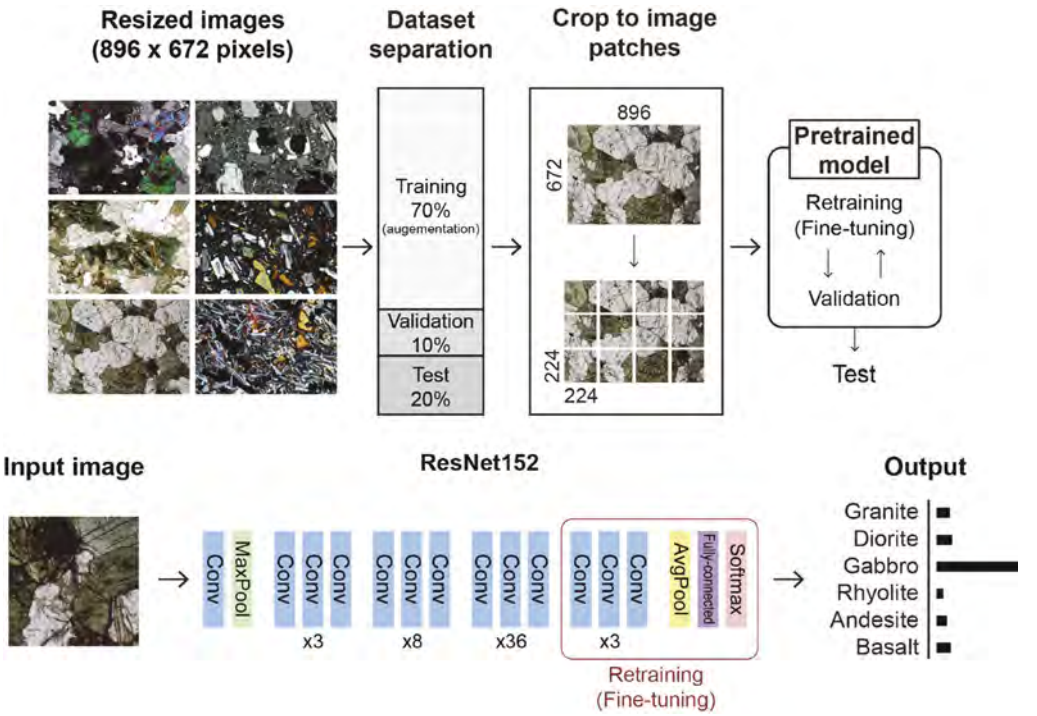

Figure 1. Sequences for image training, and the architecture of image classification network model (ResNet152) in this study.

(Figure 2). Each patch of an image is classified individually at patch-level by method A. In method B, each image patch is classified independently, followed by a majority voting procedure to classify the original image at image-level. In method C, the classification score, the output of the last softmax layer of the model, is first calculated. Calculated scores for each rock type are added up, and the original image is classified as the rock type with the highest summed score.

3 RESULTS AND DISCUSSION

3.1 *Patch-level classification*

The confusion matrix from the classification method A is shown in Figure 3. The overall classification accuracy was 86.90%, and the accuracy for gabbro was the lowest. In comparison to other rock types, classification for diorite and gabbro were relatively inaccurate, presumably because they are plutonic rocks with large mineral grain sizes. As they had relatively large grain sizes to fit in a single image patch, identifying them accurately was challenging for the model. Since the images from the same origin (plutonic rocks or volcanic rocks) share similarities in terms of texture and color, the model mostly misclassified images as belonging to the same origin. The result exhibited that the CNN model can adequately identify inherent features within rock microscopic images.

3.2 *Image-level classification*

The confusion matrix from the classification method B and C are shown in Figure 4. The overall classification accuracy for method B and C were 92.86% and 95.71%, respectively.

Both methods B and C classified more accurately than method A, while the accuracy for gabbro was the lowest similar to method A. Methods B and C are able to compensate for the misclassified image patches by using majority voting scheme and summing the classification scores, respectively, resulting in more accurate classification.

Rock thin section microscopic images often show the characteristics of several rock types in one image. Accordingly, method C, which uses the classification scores of all rock types within one image patch, was more accurate than method B, which only uses the highest classification score. In addition, unlike method B, where voting of compositional image patches can be tied, method C could always classify one rock type for one original image.

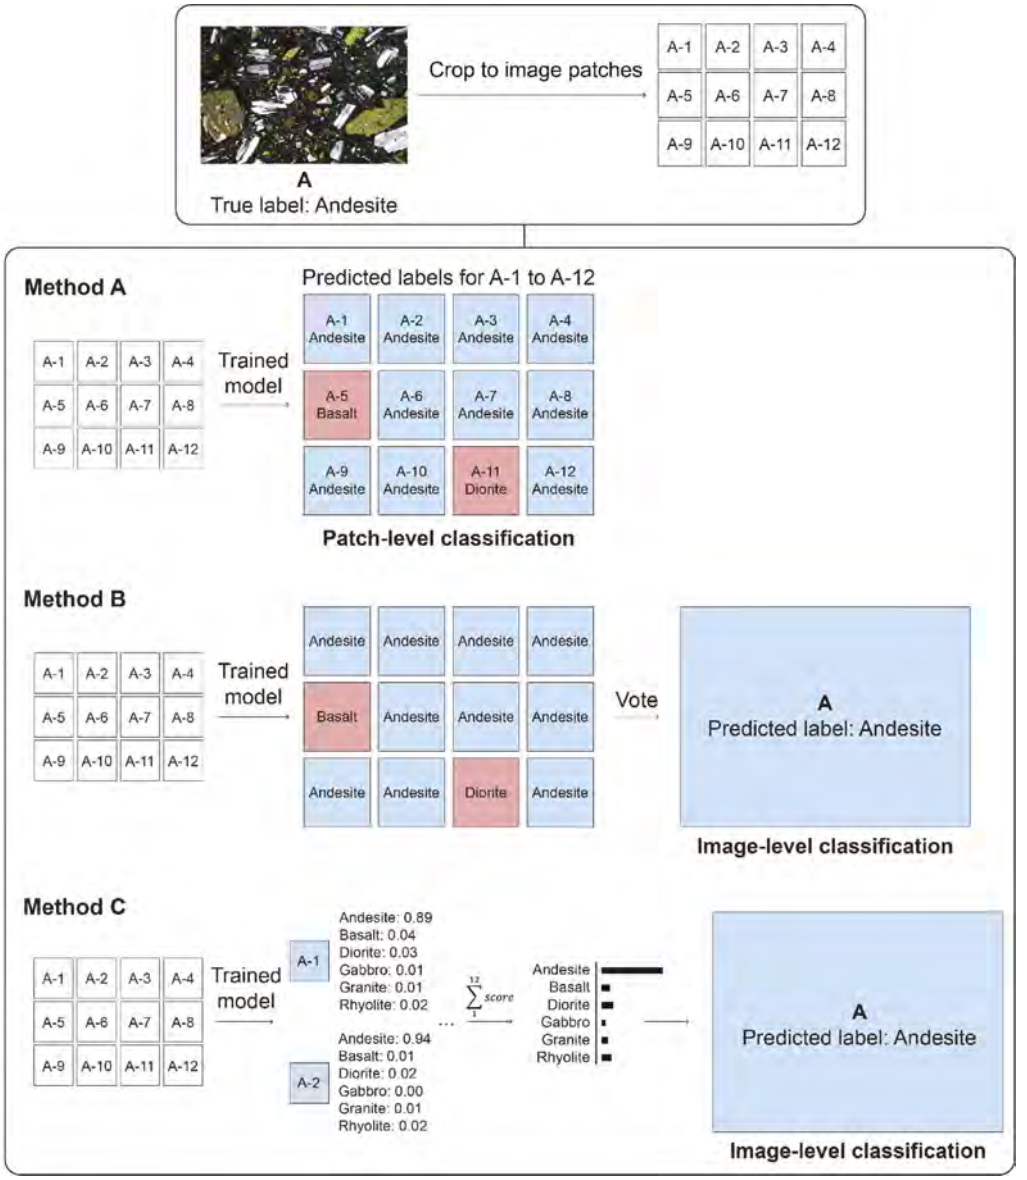

Figure 2. Process of classification methods A, B, and C.

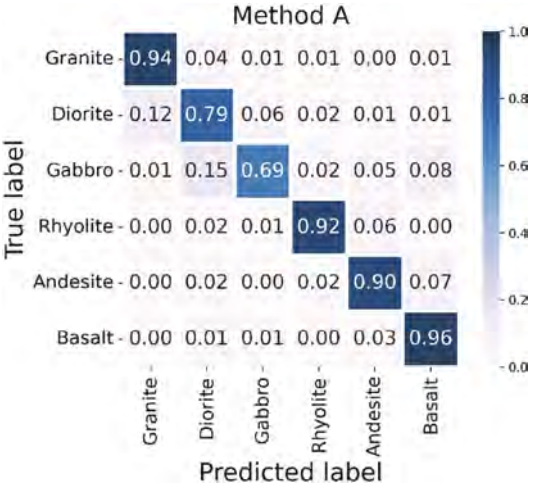

Figure 3. Confusion matrix for patch-level classification: method A.

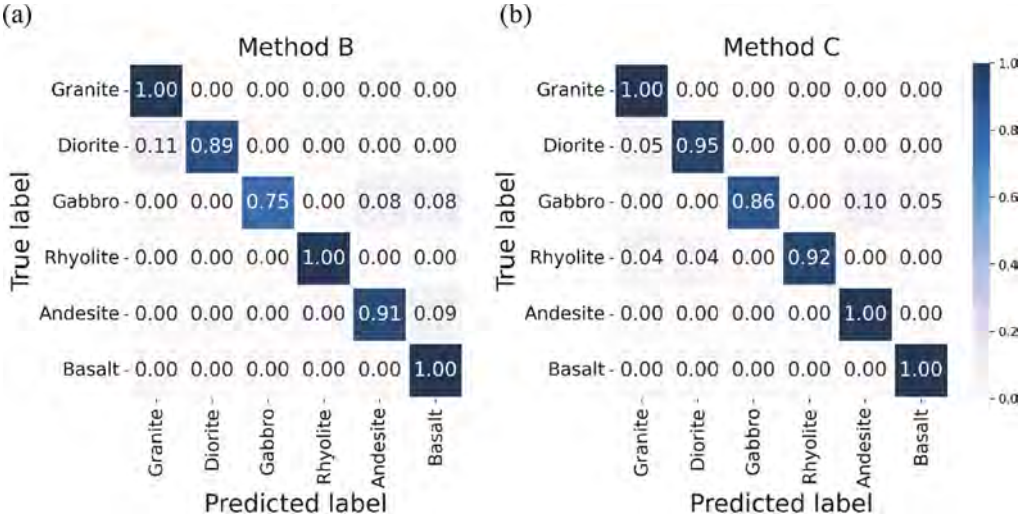

Figure 4. Confusion matrix for image-level classification: methods (a) B and (b) C.

4 CONCLUSIONS

This study conducted classification of igneous rock microscopic images using CNN-based deep learning model. Prepared original images were cropped into several image patches, and the model was retrained with transfer learning based on pretrained ResNet152 structure. The trained model was tested with three different classification methods A, B, and C at both patch- and image-levels and has been proven successful in classifying rock types.

Compared to the patch-level classification, the image-level classification produces better results since the effect of misclassified image patches can be mitigated. It appears that classification method C, which sums up the classification scores of image patches to make image-level decisions, is the most accurate classification method, since it considers the classification scores of all rock types.

Despite the limited database, the use of a CNN-based deep learning model for rock microscopic image classification was found to be valid from the perspective of objective decision regardless of the operator. This approach has the potential to be applicable to other rock types by overcoming ambiguities in conventional rock classification.

ABSTRACT: Mulitphysics processes have been commonly identified in geotechnical engineering practice. Researchers and field engineers often carry out multiphysics simulations to understand complex engineering responses. In field practice, a back analysis is typically required along with the simulations to calibrate the most representative model parameters. This would intensify the problem as it requires further simulations to assess the parameter sensitivity. Therefore, an efficient back analysis for multiphysics processes still remains a challenge in practice due to the numerical complexity and the low computational efficiency. With recent advances in AI techniques, opportunities have opened up for meta-model development for problems involving multiphysics processes associated with a large number of properties. This study entails a meta-model developed based on Artificial Neural Networks (ANN) that intelligently learn the correlations between model parameters and the reservoir responses. This efficient meta-model is combined with Genetic Algorithm-based back analysis to report the optimal case that provides the closest output to the target time histories. The results show that the AI-based metamodel can reproduce outputs of heavy computation of the multiphysics processes and thus efficiently perform back-analysis.

1 INTRODUCTION

Mulitphysics processes have been commonly identified in unconventional resource extraction practice (Guo et al., 2019; Mahdi et al., 2017). However, such complex processes are often difficult to model in the field or in the laboratory due to the coupling of multiphysics (Touran et al., 2017; Keyes et al., 2013). Therefore, researchers and field engineers in the oil and gas industry often carry out numerical simulations to understand the complex engineering responses during production. Such simulation practices are conducted via multiphysics numerical simulators (Moridis et al., 2011; Klar et al., 2013; White et al., 2020; Zhou et al., 2020).

In the rise of unconventional energy resources, one of the multiphysics complex processes is gas production from gas hydrate reservoir. production of gas from hydrate-bearing sediments involves change in pressure, temperature and also mechanical behavior, leading to coupled thermo-hydro-mechanical (THM). However, modelling of this complex processes is often computationally demanding and requires a large number of model parameters to represent multiple facets of the hydrate reservoir behavior (Uchida et al., 2016). Even when measurement of

DOI: 10.1201/9781003299127-123

gas and water production history is available, conducting back analysis to calibrate these parameters is significantly time-consuming and also confirming that the calibrated parameters are the best representatives of the site condition is challenging because of potential existence of multiple local optima. Therefore, there is a need for an efficient tool to assess the hydrate reservoir production potential and the complex sediment responses with minimal time cost and computational complexity.

With recent advances in artificial intelligence (AI) techniques (e.g., machine learning and data analytics), opportunities have opened up for meta-model development for problems involving multiphysics processes associated a large number of properties (Tripoppoom et al., 2020; Li et al., 2021; Park et al., 2021; Xu et al., 2020). The main goal of the meta model is to provide an alternative tool to replace a conventional THM simulator in a more timely and computationally effective way. Once this computational tool is provided, the uncertainty in data can be assessed through varying the input parameters and investigating the uncertainty propagation through the sensitivity study.

This study entails a meta-model developed based on ANN that deep learn the correlations between model parameters (i.e., hydrologic and geomechanical parameters of hydrate-bearing sediments) and the reservoir response (i.e., gas and water production), and is capable of reproducing the production results with much higher computational efficiency than coupled numerical simulators based on finite element or finite difference methods. An optimization network based on genetic algorithm (GA) is then proposed and combined with the trained ANN to conduct the back-analysis of the site measured production data, and thus the optimum model parameters can be obtained.

The capabilities of the proposed machine learning approach are demonstrated through the application to the 2013 Nankai offshore gas production test. The training and testing data for the ANN are produced by a series of coupled THM simulations. The assumed ranges of material properties of the simulations are based on the production site conditions and are varied across the multi-dimensional sample space. The ANN predictions suggest good agreement with the measured production data, while the obtained model parameters from back analysis can be regarded as important properties for researchers and field engineers to focus on for reservoir characterization.

2 SYNTHETIC DATASET

This study creates synthetic data numerically through varying 19 material properties and obtaining the corresponding reservoir responses, namely, the amount of produced gas, produced water and vertical strain (Figure 1). A THM numerical simulator, originally developed by (Klar et al., 2013), is adopted to create synthetic data. The simulator is based on a finite difference software, FLAC, and solves the multiphysics processes through the implemented coupled THM formulation derived for hydrate reservoir simulations by (Uchida et al., 2016).

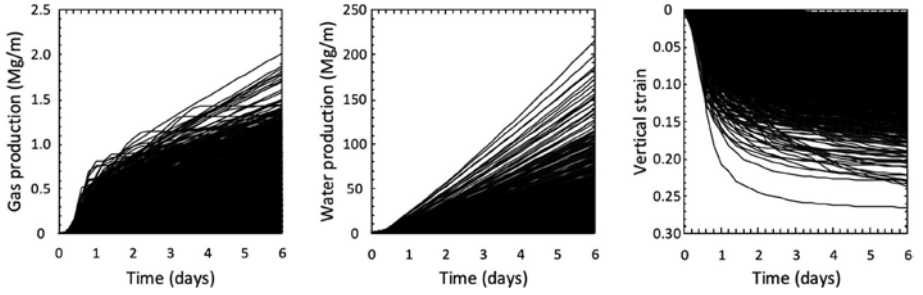

Figure 1. Synthetic data created by the THM analyzes.

Based on the Eastern Nankai Trough production site geometry, the targeted perforation region is between 280.7 m and 318.7 m below the seabed and the seabed is 998 m below the sea level. Figure 2 presents a hydrate reservoir considered for the creation of the synthetic dataset. It would be ideal if the model could explicitly simulate the heterogeneity of in-situ THM properties along the vertical direction, but that would impose a significant computational demand. Therefore, this study simplifies the complexity into a homogenized single radial layer. This simplification has a few shortcomings associated with the lack of thermal or fluid flow in the vertical direction, but the variations in the THM properties are considered in the form of the parameter range, while the most representative homogenized properties will be later determined through back analyses.

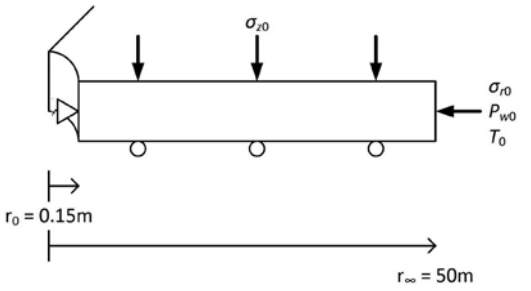

Figure 2. Hydrate reservoir model considered in this study.

The depth of the considered layer is assumed to be at 1297.7 m below sea level and 299.7 m below seafloor, which is the mid-depth of the production region and corresponding to the initial pore water pressure of 13 MPa and the initial effective vertical stress to be 3 MPa. The initial effective horizontal stress is assumed to be 1.5 MPa, which corresponds to the at-rest earth pressure coefficient of K0 = 0.5. The initial porosity is 0.4, the initial temperature is 285 K and the initial hydrate saturation is 61.3%, which is the average value over the production zone based on logging data (Konno et al., 2017). Under the initial temperature, the phase equilibrium pressure is 9.8 MPa. Depressurization is applied according to the measured bottom hole pressure during the 2013 test (Konno et al., 2017).

At the well boundary in the model, a free movement is assumed in the vertical direction while no radial displacement is allowed. The bottom boundary is fixed in the vertical direction and free in the radial direction. The top boundary has the constant total stress applied to facilitate vertical deformation. The outer model boundary is set at 50 m, where the pore pressure, the total radial stress and temperature remain unchanged. The layer is radially discretized into 35 elements with a size of 0.15 m adjacent to the well and increasing at a ratio of approximately 1.1.

This study utilizes the Latin hypercube sampling method (McKay et al., 1979) to ensure the multi-dimensional sampling domain is evenly explored with a relatively small number of simulations, resulting in 1000 simulation cases. Table 1 shows the maximum and minimum values of the 18 parameters adopted. The parameters are assumed to follow lognormal distribution, except the van Genuchten parameters, *b* and *c*, which are assumed to be normally distributed in the synthetic dataset. These simulation cases provide a history of reservoir production responses (gas production and water production), recorded at every 0.2 days for a 6-day period. Therefore, at every recorded time, there are 18000 data points regarding material properties (1000 times 18), which are "inputs" for the ANN. Meanwhile, there are also 2000 data points regarding reservoir production responses (1000 cases times 2) at each recorded time step, which are "outputs" for the ANN.

The established synthetic dataset is normalized, and 80% of the normalized data is selected as the training data and the remaining 20% is selected as the testing data. The normalization process facilitates the calculation by making all the data dimensionless. Additionally, it limits

Table 1. 18 model parameters selected for this study.

name	symbol	max	min
Hydrologic (8)			
initial intrinsic permeability	$\|\|K\|\|$	$10^{-4.8}m^2$	$10^{-7.2}$ m^2
effective permeability power	N	10.0	2.0

hydrate dependent modulus	E_{h0}	12GPa	8GPa
hydrate degradation factor	m	21	1

the range of data to only vary between [-1,1] and consequently controls the algorithm search domain, which results in less complexity and higher accuracy of the ANN predictions.

3 AI-BASED BACK ANALYSIS

The ANN is developed to approximate the gas production and water production time histories. In this study, a multi-layer perceptron (MLP) is used to implement the ANN. The ANN consists of the dataset, two hidden layers of neurons, and the predictions of the reservoir responses. The prediction consists of 2 classes, each with 30 neurons, which represent the simulation results of gas production and water production at the 30 time intervals (0.2-day intervals for 6 days). Two hidden layers are implemented in this study to accomplish accurate predictions. By adopting a trial-and-error method to change the number of neurons in each hidden layer, the MLP model with ten neurons in the first hidden layer and five neurons in the second hidden layer reveals the best performance of the data set analyzed in this study.

The initial MLP model is then generated using the training dataset with the proposed layer structure. The training data is introduced into the ANN to train the network by determining the biases and weights by minimizing the mean squared error (MSE). Once the minimum MSE is obtained, the network training process is completed and can be used to make predictions and evaluate the accuracy using the testing dataset.

The established ANN provides a computationally light method to predict the gas and water production from the 18 input model parameters. An optimization problem is defined for the back analysis, in which the objective function is the difference between the optimal production resulted from the ANN and the actual site measured production values. Conventional optimization techniques often involve determining the gradient of the objective function. Due to the complexity of this optimization problem, it is challenging to calculate the partial derivatives of the objective function because the established ANN is not an explicit function of the input variable. Therefore, derivative-based methods may not be able to solve this problem. As such, GA is used as an alternative solution in this study.

GA is an intelligent optimization method inspired by the theory of evolution by natural selection. This algorithm improves the initial population in the form of an iterative process

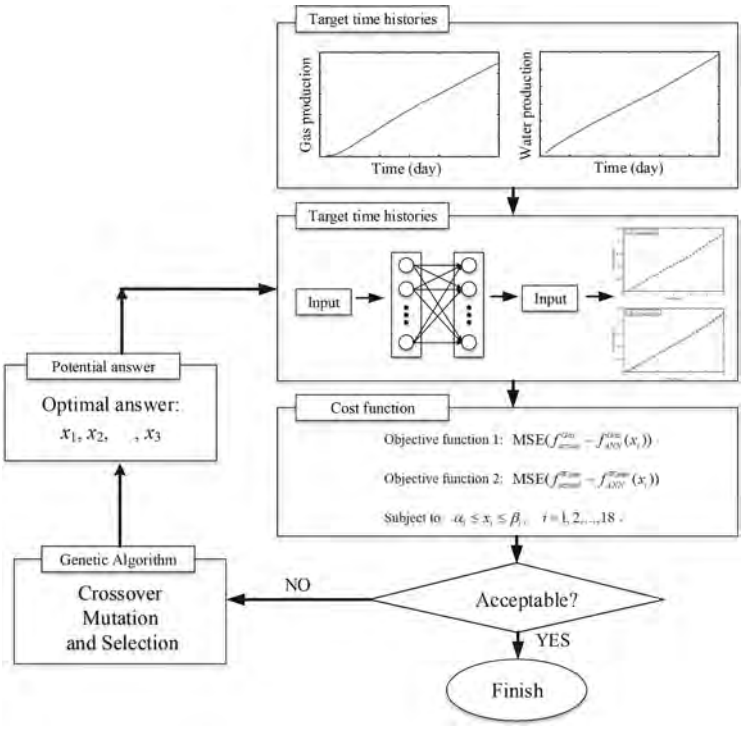

Figure 3. The schematic diagram of the proposed approach.

according to a quality criterion. In this respect, three operators of mutation, crossover, and selection are used to drive the evolution of candidate solutions towards the optimum in each generation. Because the algorithm is population-based and does not require the derivatives of objective function or constraint, it is widely used with implicit function, such as the ANN utilized in this paper. In addition, GA has the ability to search a large number of candidate solutions to converge to the global optimum. As with any iterative method, GA needs a set of termination conditions to determine when to stop and complete the analysis. The termination criteria used in this paper are as follows:

1. when the difference of optimum response in each two subsequent steps is less than 0.1%.
2. when the number of generations reaches 100.
3. when the algorithm reaches the time limit (5 minutes) set for the analysis.

When one of the above three conditions is met, the analysis considers the results as the optimal solutions.

4 RESULTS

The performance of the ANN was evaluated by comparing its predictions with the results of THM simulations, across the whole set of 1000 simulations (Figure 4). The error of the prediction results for both the training and the testing data are relatively small, which suggests that the proposed ANN can make accurate predictions. Hence, by selecting appropriate input model parameters, the established ANN can be used for history matching of the site measured production responses.

The back analysis was implemented in the form of an optimization problem and GA was utilized to provide a solution. It is worth noting that two objective functions are involved in this problem since both gas and water productions are considered in this study. In this study,

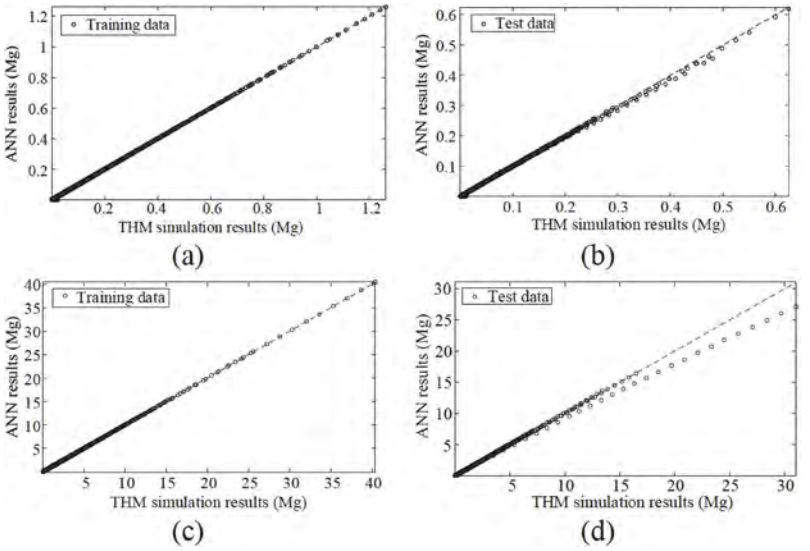

Figure 4. Comparison of the ANN predictions and the THM simulation results of (a) gas production comparison for training data, (b) gas production comparison for testing data, (c) water production comparison for training data, (d) water production comparison for testing data.

the gas and water production values per unit volume are used as the optimization target of the back analysis. Based on the site measured gas and water production rate, the total gas and water production values per unit volume for the first six days are computed and shown in Figure 5. Using the 18 input model parameters, the gas and water production per unit volume can be derived from the established ANN, and the predicted results are plotted in Figure 5 to compare with the target values. The comparison suggested a good match. Therefore, the proposed back analysis method works well for the history matching purpose.

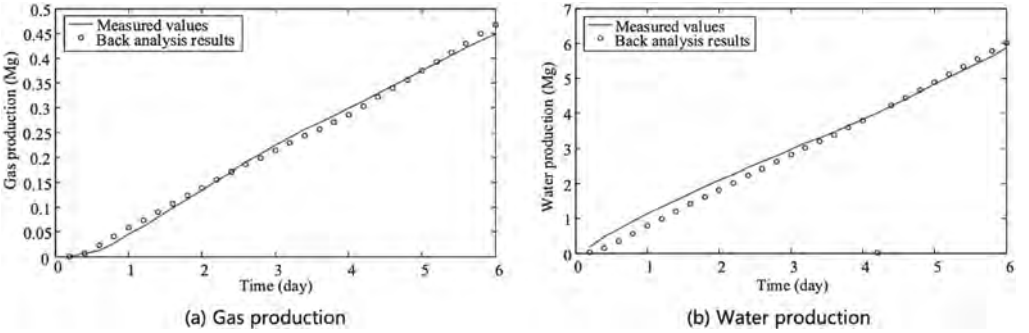

Figure 5. Comparison of the site measured production data and the predicted data based on the back analyzed input parameters: (a) gas production, (b) water production.

The computational efficiency of the proposed meta-model is demonstrated by comparing its processing time with the THM simulator for three specific reservoir cases (Case 300, 600, and 900). The numerical experiments for 8-day gas production were carried out on a desktop equipped with two GeForce GTX 1080 graphics processing units (GPUs), 64 GB of random access memory (RAM), and one Intel Core i7-5820K central processing unit (CPU). For 6-day gas production prediction, the execution time of the ANN and the FLAC THM simulator for three specific reservoir cases are shown in Table 2. It is seen that a typical calculating

of the FLAC THM simulator for 6-day gas production takes on average more than 1000 seconds while the ANN only takes less than 0.1 seconds.

Table 2. For 6-day gas production prediction, the execution time of the ANN and the FLAC THM simulator for Case 300, 600, and 900.

Prediction method	Case 300	Case 600	Case 900
First-block ANN	0.071 seconds	0.069 seconds	0.067 seconds
FLAC THM simulator	1400 seconds	7000 seconds	540 seconds

5 CONCLUSION

This paper utilizes a combination of an ANN and an optimization model for simulation of gas production operations in methane hydrate-bearing reservoir. The combined model enables back analyses of site response in order to obtain the corresponding site properties. The site measured production data in 2013 Eastern Nankai Trough production test is adopted in this study. The ANN successfully learns the relationship between the material properties and reservoir productions, while the optimization model demonstrated the capability of finding the optimum combinations of material properties to characterize the reservoir production.

The main advantage of the proposed approach lies on its computational efficiency for history matching and model parameter calibration, which can be ten thousands of times faster than the numerical analysis conducted via the thermo-hydro-mechanical simulator.

It should be noted that the proposed machine learning approach only learns what it is being taught. The effectiveness of the back analyses clearly depends on the geometries of the specific problem, and the site-specific hydrate and stratigraphy conditions. Nevertheless, the proposed framework allows real-time prediction to be made and adjusted according to the observed reservoir response as the process evolves with time at the production site.

Deformation properties and mechanism of destruction of a block structure rock mass

G.A. Kadyralieva, K.Ch. Kozhogulov & N.A. Aitkuliev
Institute of geomechanics and development of subsoil of the National Academy of Sciences of the Kyrgyz Republic, Bishkek, Kyrgyzstan

ABSTRACT: The management of the state of natural and man-made massifs during the open-pit mining of mineral deposits consists in a set of measures to maintain ledges, sides of quarries and dumps in a stable, close to the limit state by changing the geometric parameters of the slopes during the development process, which ensures economical and safe mining operations. The block structure of the side array is one of the parameters affecting the strength of the rock mass, and the fillers between the block spaces are the main factor in their deformation and destruction. In the sides of the upland quarries, not only individual blocks fall out, but also massive collapses are observed. This indicates that the filler between the block cracks has less strength than the level of the acting shear forces near the surface of the outcrop.

The development of mineral deposits by the open method is associated with the need to ensure safe mining conditions, in particular, the stability of the sides of quarries, where one of the main problems of upland quarries is the calculation of the geometric parameters of the side, taking into account the structure and parameters of the slope on which the quarry is being built.

The design schemes for assessing the condition of the side array used for flat, deepening quarries often leads to unreasonably underestimated parameters of the side of the quarry due to the high value of the structural attenuation coefficient, which leads to an increase in the volume of overburden, and applying the parameters of the quarry for an isotropic array – to the development of irreversible deformations of the side array and the collapse of the side.

The currently existing theoretical approaches to geomechanical substantiation of the possibility of increasing the slope angles of the sides of quarries do not take into account the real stress-strain state of rock massifs, believing that it is caused only by the own weight of the overlying rocks and the structure of rock massifs, equating the influence of structural disturbances of various ranks on the stability of the sides of the quarry as a whole and individual ledges.

The stress state of the rock mass is assumed to be due only to its own weight, although to date there is evidence that excessive horizontal stresses of a tectonic nature operate within the rock masses of more than 60% of ore deposits. As a result, a conclusion is made about the limiting angle of slopes of the sides of quarries on the final contour, which often does not exceed the angle of the natural slope of the fragmented mass of rocks 30^0-40^0, i.e. the real resource of the stability of rock massifs is not fully used.

The development of upland deposits in tectonically active areas, as in the conditions of Kyrgyzstan, is invariably accompanied by a change in the geological and, accordingly, geomechanical environment: the deformation and strength indicators of rocks change, vertical and horizontal stresses increase with depth, the stress concentration zone on the contour of the side of the quarry increases. All this leads to a deterioration of the mining conditions for the extraction of minerals and a decrease in the efficiency of the quarry. In this regard, the development of the theory of geomechanical substantiation of rational designs of quarry sides on the final contour during

DOI: 10.1201/9781003299127-124

open-pit mining based on the creation of geomechanical models of rock massifs is an important scientific and technical problem. (Kadyralieva, G.A., Kozhogulov, K.C., 2022)

In recent years, unplanned rock collapses have become more frequent at mining enterprises in Kyrgyzstan. Typical for upland deposits in the zones of influence of tectonic disturbances is the block structure (Figure 1) and to date, due attention has not been paid to ensuring the safety of mining operations in such fields. Stability assessment for such arrays is carried out according to existing methods, the block array is not acceptable for isotropic media.

Figure 1. Block structure of a rock mass of rocks.

Geomechanical models should take into account the real stress-strain state, hierarchical block structure and physical properties of rock massifs. The result of the geomechanical substantiation of the stability of the sides of the quarry is the creation of methods for controlling the state of the instrument array for each specific deposit.

The results of studies conducted at the gold deposits of Kyrgyzstan such as Makmal, Kumtor, Jeruy, Chaarat, Terekan, indicate a complex geological structure, block structure, properties of rocks and massif. The side array of these quarries has a block structure, the filler of the interblock space is weak, often represented by calcites with low strength characteristics.

In recent years, Kyrgyzstan has been paying more and more attention to the study of slow deformation events: the movement of glaciers, landslides in block-fractured rock massifs. At the same time, the structure and the ratio between the filler components have a strong influence on the distribution of deformation rates. Installations of the slider model type are used for laboratory research. Therefore, the assessment of the impact of the block structure of the rock mass on the development of geomechanical processes is a new approach to solving the problems of ensuring the safety of mining operations during the development of upland deposits in the zones of influence of tectonic disturbances.

Based on the analysis of foreign literature, it has been established that the assessment of the block structure and fracturing of the rock mass is a priority in mining geomechanics. However, the issues of influence on the development and management of geomechanical processes during the development of upland deposits in the mountainous-folded regions, to which Kyrgyzstan belongs, have not been given due attention to date.

In the applied methods for substantiating the parameters of stable sides of quarries developed by VNMI institutes (Methodological guidelines for determining...1972, Rules for ensuring the stability of slopes...1998, Temporary guidelines for managing the stability of the sides...1989), all factors acting in the array at the time of formation of the side are taken into account as much as possible: the physical and mechanical characteristics of the rocks composing the side array; the intensity of fracturing; the geometry of the side; hydrogeological conditions; indicators of shear resistance along the planes of cracks. According to these factors, the state of the array is estimated at the calculated value of the angle of inclination of the side.

In this case, the stability assessment is reduced to the calculation of the stability margin coefficient by the ratio of holding forces to shear forces for several variants of the calculated sliding surfaces, i.e. the calculation and assessment of the stability of the side array of fractured and block structure is performed as for an isotropic array, taking into account the structural attenuation coefficient. With this approach, only the weight of rocks is taken into account when assessing stability.

The high intensity of tectonic movements during the formation of the block structure of the massif can be evidenced by the steep fall of ore bodies with shale elements in contact with rocks of the hanging or recumbent sides. The extended rectilinear contacts of the ore body with the host rocks are very favorable for shear tectonic deformations in the side array due to the low strength properties of these contacts. Conversely, the complex morphology of the ore deposit creates tangible obstacles for inherited tectonic movements along the contacts.

The presence of dikes in the deposit indicates destructive deformation of the massif in the geological past under the influence of compressive stresses in the massif. Due to the limited permeability of the massif with the heterogeneity of the stress field, the magma of deep horizons was able to reach the upper floors of the earth's crust only with the development of large-scale destructive zones. Hence, the vein mass in a foreign rock mass is the result of high- and medium-temperature processes of mineral deposition. With a certain modern spatial distribution of tectonic forces, the process of formation of new or opening of healed cracks in the side array may resume, which will lead to the disintegration of the array and, as a consequence, to a decrease in its strength properties. (Miroshnikova, L.K., Mezentsev, A.Yu., Kadyralieva, G.A., Perepelkin, M.A., 2021)

So, it can be stated that almost every geological element in the structure of the massif emphasizes the predisposition of the massif to tectonic deformations in an anisotropic stress field, that is, each disjunctive reflects the sensitivity of a section of the massif to the shear form of deformations. In this case, the sensitivity is selective with respect to such parameters as the ratio of the main components of the stress field, the angle between the direction of the maximum component and the plane of the seam, the angle of friction and adhesion along the contact.

The disturbance of the array by cracks also affects its elastic properties. With an increase in fracturing, the elasticity of rocks decreases. It is revealed that the elasticity of a fractured rock mass is always less than the modulus of elasticity of a rock sample by about 5 – 15 times. The elastic modulus will be different for different sections of the array.

Geomechanical classifications of rock massifs are the basis of an empirical approach to assessing their stability and are widely used in the design of various objects in various foreign countries.

Based on the results of studying the stability of a block structure rock mass, the mechanism of destruction of blocks if there is a soft filler between them, a test experiment was conducted in laboratory conditions, the purpose of which was to establish the dependence of the resistance of blocks on separation at different types of block filler.

Artificial fillers between block cracks were prepared for laboratory tests. Clay and sand and their different ratios were chosen as aggregates (Table 1).

Table 1. Ratios of clay and sand for laboratory tests selected as a crack filler.

№	Clay	Sand
1	100%	100%
2	50%	50%
3	70%	30%
4	30%	70%

For testing, two marble blocks of the correct shape of the prism were taken, with dimensions:
length – 5cm,
width – 4.7cm
height – 9.7cm
weight – 662.85g (Figure 2)

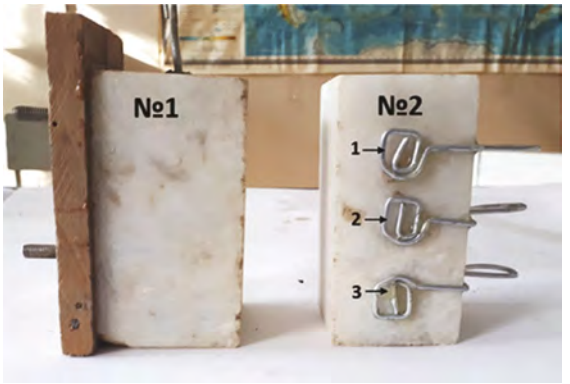

Figure 2. Marble blocks used for laboratory tests.

No. 1 – the first fixed block, No. 2 – the second fixed block, 1 – the first (upper) point of separation, 2 – the second (middle) point of separation, 3 – the third (lower) point of separation.

For testing, a wooden structure was made (Figure 3), with a fixed wall for fixing the 1-fixed block, with the possibility of removal and reverse fastening with nuts.

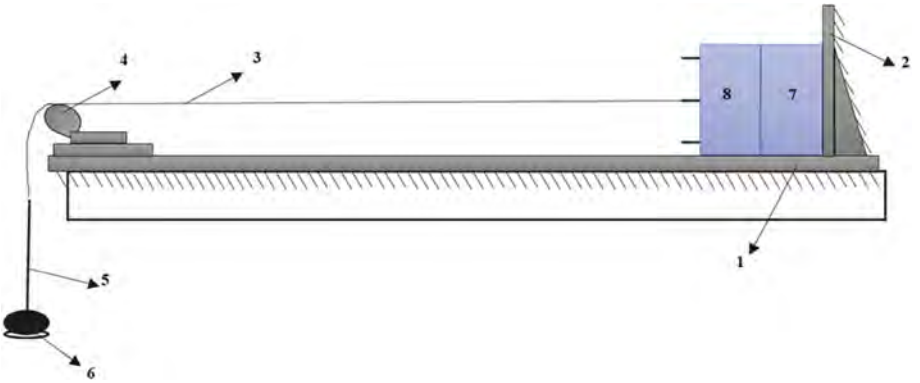

Figure 3. Design for testing blocks for separation.

1-the base of the structure, 2-the vertical supporting wall, 3-the cable for detaching the block, 4-the drum for the cable, 5-the attachment for the load, 6-the load of 100g, 7-the first fixed block, 8-the second movable block.

The results of the data obtained are shown in Figure 4, the dependence of the block separation resistance on the types of filler.

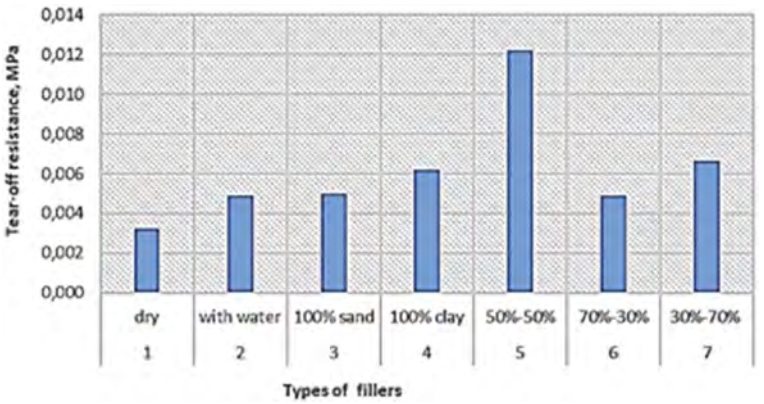

Figure 4. Dependence of the block's resistance to separation from different fillers.

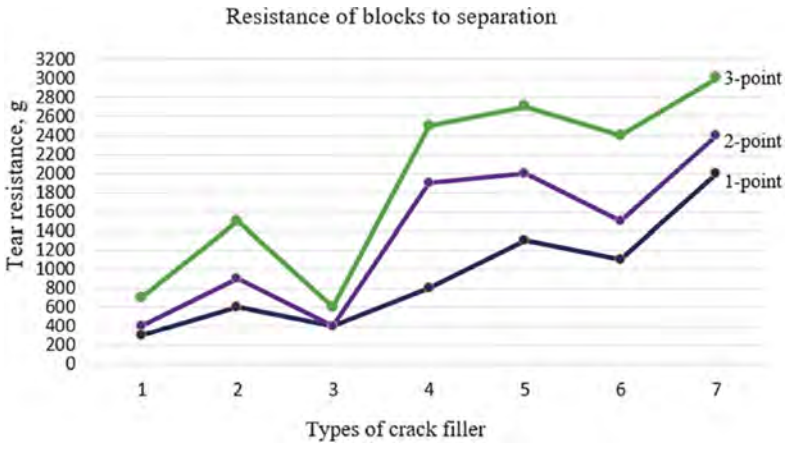

Figure 5. Design for testing blocks for separation.

1 – dry filler, 2 – water filler, 3 – sand filler 100%, 4 – filler clay 100%, 5 – filler sand 50% and clay 50%, 6 – filler sand 70% and clay 30%, 7 – filler sand 30% and clay 70%.

CONCLUSIONS

Based on the obtained laboratory data, it was revealed that:

1. The resistance of the block to separation depends on the type of aggregate, with the greatest resistance being provided by the aggregate, where the ratio is 50% sand to 50% clay.
2. The resistance to the separation of rock blocks depends on the type of filler, while clay fillers have the greatest resistance to separation in a ratio of 70% x30% with sand.
3. The resistance to the separation of rock blocks depends on the point of separation. The third (lower) point has the greatest resistance to separation.

When assessing the stability of the sides of the quarry and choosing their geometric parameters in the rock massifs of the block structure, it must be taken into account that the main factor in this is the filler between the block cracks, their strength, composition, humidity. Based on the results of a test laboratory experiment of the resistance of blocks to separation, it was decided to test the resistance of blocks to shear. In order to identify the main cause of the violation of the mechanism of the block structure rock mass.

Coupled CFD-DEM simulation of progressive failure of tunnel face

C. Zhou & J.G. Qian*
Tongji University, Shanghai, China

Z.Y. Yin
The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT: Extensive studies have been conducted to investigate the face stability of tunnelling by the discrete element method (DEM). However, the DEM simulation of tunnel face's failure considering water-soil interaction has not yet been available. In this paper, the coupled CFD-DEM method was adopted to simulate the progressive failure of the shield tunnel face in saturated sand, and the tunnel's failure in dry sand was also simulated for comparison. The dynamic mesh method was introduced to accurately simulate the CFD domain's variation due to the movement of the tunnel's face. The excavation face was moved forward or backward at a uniform displacement rate to simulate a passive or active failure, respectively. The ground surface movement and supporting force of tunnel face were analyzed to investigate the feature of tunnel face failure in saturated and dry sandy soils.

1 INTRODUCTION

The shield tunneling method is widely used in urban underground tunneling projects. Inadequate or excessive support forces on the tunnel face may cause tunnel destabilization(Peila, 1994; Mollon, Dias and Soubra, 2011). In the vicinity of the tunnel face, where soil deformation or even soil collapse may take place, it greatly challenges traditional continuous medium methods to reproduce the process of such a progressive failure. Thus the discrete element methods (DEM) were introduced to simulate the large deformation and soil transport. Nevertheless, previous discrete element numerical simulations fail to enable us to well understand water-soil interaction and commonly simulate tunneling in dry sand. The saturated soil involves water-soil interaction, which is a multidisciplinary process governed by the principles of soil mechanics and hydraulics. Therefore, a combination of computational fluid dynamics (CFD) and the discrete element method (DEM) is more appropriate to consider saturated sandy soils.

This paper simulates the progressive failure of shield tunnel face in saturated sand using coupled CFD-DEM method. By analyzing the surface displacement and face support force, the different failure behaviors of tunnel face in saturated and dry ground are revealed.

2 METHODOLOGY AND MODEL SETUP

2.1 *Governing equations*

In CFD-DEM method, the motion of the solid particles is governed by Newton's laws, while the velocity and pressure of fluid are calculated by the volume-averaged Navier-Stokes equations (Kloss *et al.*, 2012):

*Corresponding author:

DOI: 10.1201/9781003299127-125

$$m_i \frac{dv_i}{dt} = \sum_{j=1}^{j=n} F_{ij}^n + \sum_{j=1}^{j=n} F_{ij}^t + F_i^f + F_i^g \tag{1}$$

$$I_i \frac{d\omega_i}{dt} = \sum_{j=1}^{j=n} M_{ij} \tag{2}$$

$$\left(\partial \alpha_f\right)/\partial t + \nabla \cdot \left(\alpha_f u_f\right) = 0 \tag{3}$$

$$\frac{\partial \alpha_f u_f}{\partial t} + \nabla \cdot \alpha_f u_f u_f = -\alpha_f \nabla \frac{p}{\rho_f} - R_{pf} + \nabla \cdot \left(\alpha_f \tau\right) \tag{4}$$

where the particle index is denoted by subscript i; m_i is the particle's mass; v_i and ω_i represents the translational and angular velocity; F_{ij} is the inter-particle contact force while F_i^f is the particle-fluid force; F_i^g is the gravity of each particle; α_f is the fluid volume fraction; u_f and p denotes the fluid velocity and pressure, respectively; ρ_f is fluid density; τ represents the shear stress tensor of the fluid cell; R_{pf} is the exchange of momentum with the particulate phase.

2.2 *Model setup*

Spherical particles are adopted in the DEM simulation. The particle size distribution refers to that used in the previous study (Yin, Wang and Zhang, 2020). The particle size is enlarged by ten times to reduce the number of particles and satisfy computional power requirements, which is commonly adopted in DEM simulations. The largest and smallest particle sizes in the simulation are 30.7mm and 12.2mm, respectively. Some of the particle-related parameters are shown in Table 1. Four tests are carried out with the same model size, and both the dry and saturated surrounding soils are considered in this study. The excavation of the tunnel is simulated by the forward and backward movement of a rigid wall in the DEM. Due to the simulation situation's symmetry, half of the tunnel model is used to save computational resources (as shown in Figure 1). In addition, the gravitational acceleration used in the simulation has been magnified by a factor of 10, with reference to the centrifuge test method (Yin, Wang and Zhang, 2020). The actual size of the prototype is ten times the size set in the model. According to the similarity criterion, the corresponding fluid viscosity coefficients are scaled up by the same. Due to the complexity of excavation speed control in actual projects, this paper simplifies active and passive failure into two cases: tunnel backward and forward. As with previous numerical simulations and tests, the tunnel excavation speed is set to a constant speed of 0.01m/s for forward and backward movement to meet the quasi-static requirements. The total simulation time is the 20s, and the total distance of the forward and backward movements is 200mm.

Table 1. Parameters used in the simulations.

Particle density (kg/m^3)	2650
Young's modulus (MPa)	5×10^8
Poisson's ratio	0.3
Inter-particle friction coefficient	0.5
Rolling friction coefficient	0.1
Timestep (s)	2×10^{-5}
Restitution coefficient	0.3

3 RESULTS ANALYSIS

3.1 *Soil displacement field*

Figure 2 shows the particle displacement distribution in four tests with different tunnel movements (40mm, 100mm, 170mm, and 200mm). The particles with displacement less than a certain value (0.04m) are hidden in the figure. Firstly, for the active failure mode of the tunnel face, it can be seen from Figure 2(a)-(b) that the shapes of the displacement field in the dry sand and saturated sand cases are similar while the area of the destabilization zone in the dry sand is larger than that in the saturated sand. The destabilization angle in saturated sand (57.89°) is slightly larger than that in dry sand (52.56°). For passive failure, as shown in Figure 2(c)-(d), the destabilization zone reaches the ground surface in both cases of dry and saturated sand soils. In addition, it's found there is little difference in the size of the instability zone at the beginning of the tunnel face movement (40 mm, 100 mm). As the test proceeds, a significant difference occurs and the destabilization zone in the saturated sand is significantly larger than that in the dry sand.

3.2 *Ground surface displacement*

Surface displacements caused by tunnel excavation may affect nearby buildings, which has been one of the main concerns for urban tunnel construction. Figure 3(a)-(b) shows the surface displacements corresponding to backward movement (the selected location is X=0, -1.25<Y<1.25). It can be observed that the surface settlement increases with the movement of the tunnel and reaches its maximum value at the end of the test. The maximum settlement in dry sand occurs at -0.117 m from the initial position of the tunnel excavation surface (Y=0.95m), and the settlement value decreases rapidly on both sides of the maximum settlement, showing a "V" shape in the figure. The maximum settlement in saturated sand occurs at Y=1.054m, which is not significantly different from that of dry sand. In contrast, both sides' settlement decreases more slowly, and the overall settlement is greater than dry sand. Under the influence of water flow, the surface displacement at the end away from the tunnel face (Y<0m) shows a certain degree of fluctuation. Figure 3(c)-(d) shows the surface uplift when the tunnel moves forward. The amount of surface uplift is small at both ends and large in the middle, and the maximum uplift point is located in the center of the model. Meanwhile, the surface uplift in dry sand is smaller than that in saturated sandy soil.

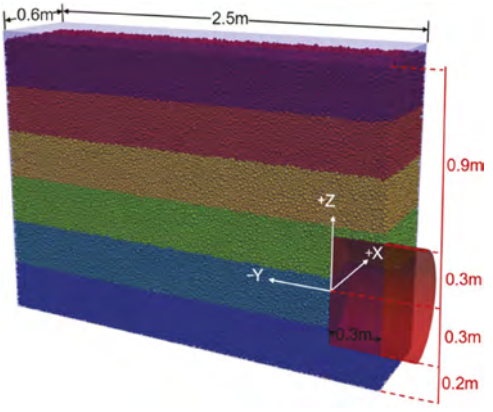

Figure 1. The DEM-CFD model to simulate the progressive failure of tunnel face.

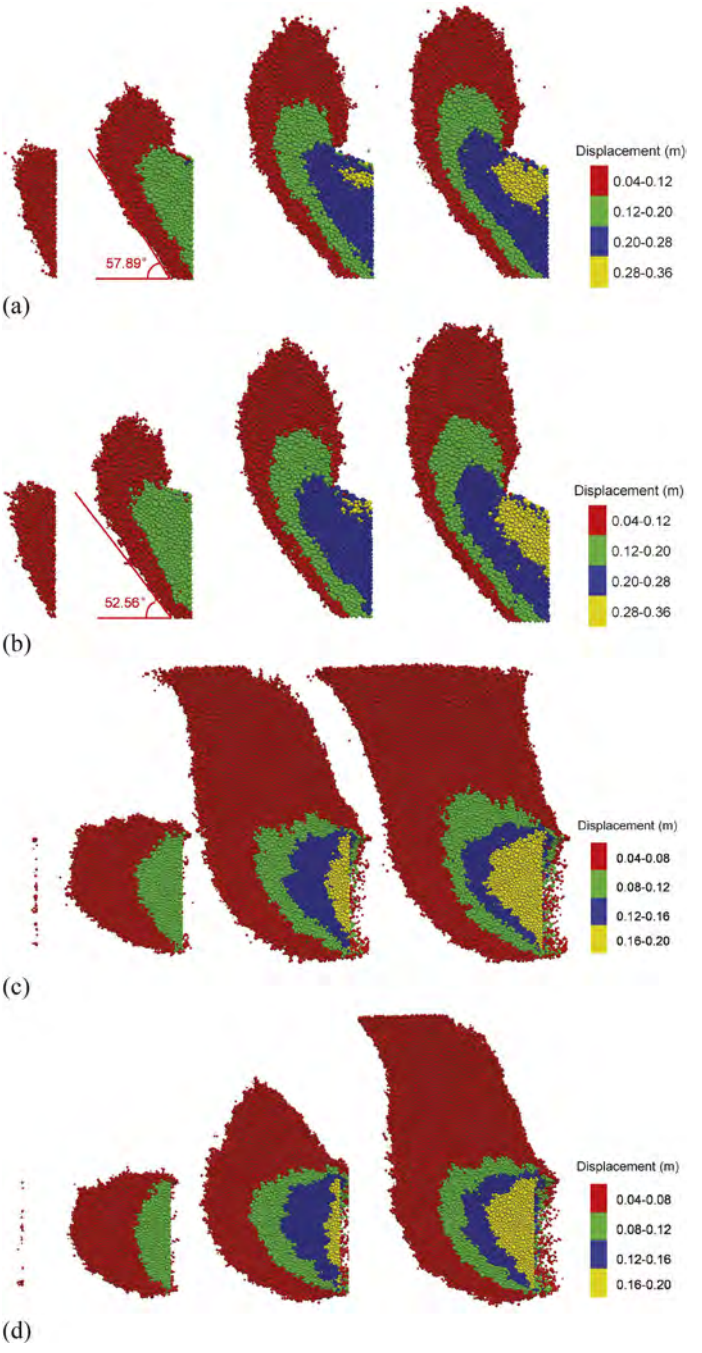

Figure 2. Particle displacement fields from left to right for 40mm, 100mm, 170mm, and 200mm tunnel displacements: (a) Backward displacement in saturated sand (b) Backward displacement in dry sand (c) Forward displacement in saturated sand (d) Forward displacement in dry sand.

3.3 *Supporting force-displacement curve*

The curve of the tunnel face support force versus tunnel displacement is shown in Figure 4, from which it can be seen that under the active damage case, the curve has two stages: the

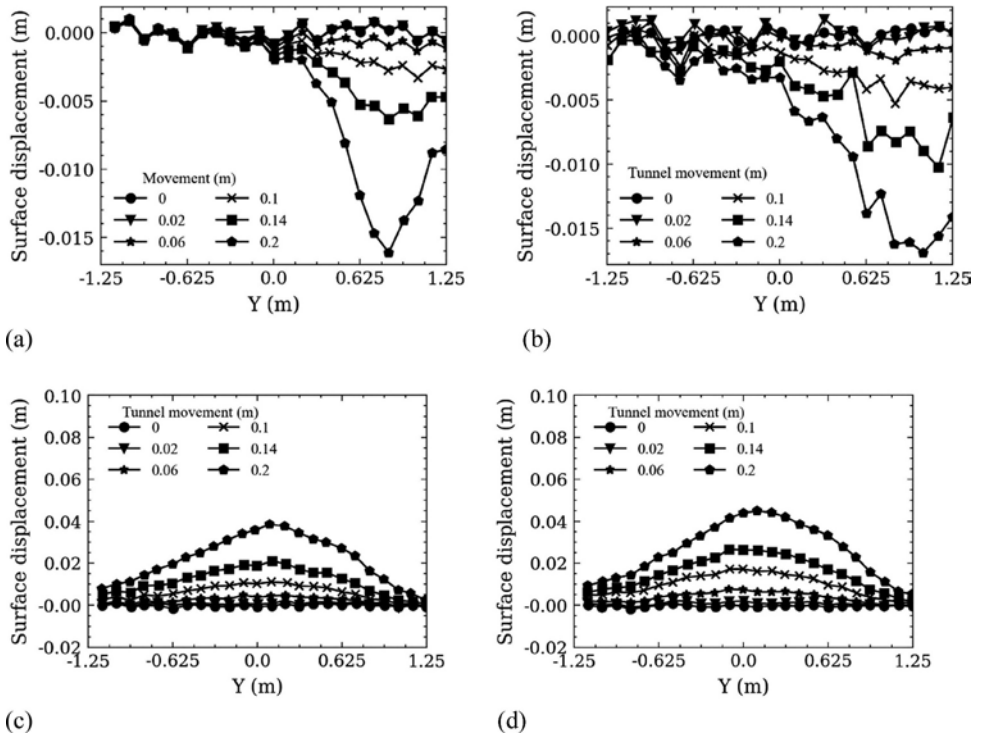

Figure 3. The surface settlement caused by tunnel face: (a) backward movement in dry sand; (b) backward movement in saturated sand; (c) forward movement in dry sand; (d) forward movement in saturated sand.

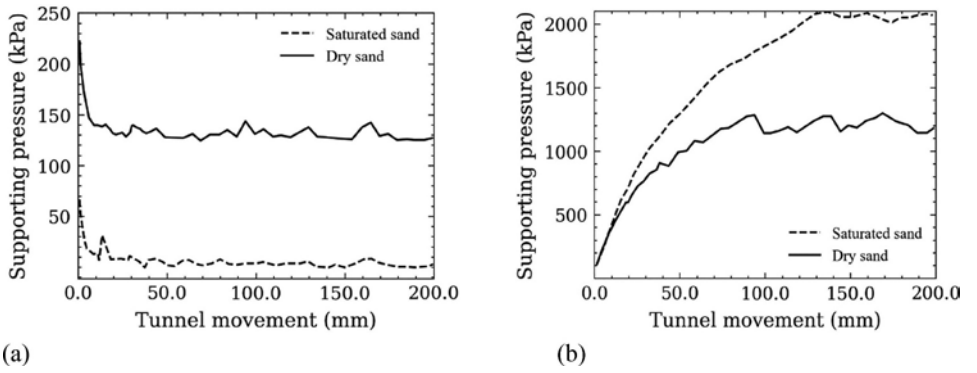

Figure 4. The surface uplift caused by tunnel face: (a) backward movement; (b) forward movement.

support force decreases rapidly with the increase of excavation face displacement in the first stage, and then maintains relative stability in the second stage to reach the ultimate support force. By comparing the two curves corresponding to saturated sand and dry sand, it is found that the ultimate supporting force in saturated sand is significantly higher than that in dry sand. In addition, the support force of dry sand almost decreases to zero, indicating that an arch has formed in the soil. As for the curve of passive damage, the support force is much greater than that for active damage. Unlike the active damage mode, there is no significant steep change in support force but rather a gradual increase to a limiting value as the displacement of the tunnel face increases.

4 CONCLUSION

In this paper, the coupled CFD-DEM method is used to simulate the progressive failure of the tunnel face in saturated sand. Meanwhile, the tunnel face in dry sand is also conducted using DEM as a comparison. Results show that the destabilization angle in saturated sand is slightly larger than that in dry sand for active failure. While in the case of passive damage, the destabilization zone extends to the surface and is significantly larger in saturated sands than in dry sands. In addition, the ultimate support force of the tunnel face for active damage is significantly higher in saturated sand than in dry sand. For passive damage, however, the ultimate support force at the excavation face is higher in dry sand than in saturated sand.

Prediction of tunneling-induced surface settlement using a Bi-LSTM model with high generalization performance

R.P. Chen, N. Zou, H.Z. Cheng & H.N. Wu
Research Center for Advanced Underground Space Technologies, Hunan University, Changsha, China
Key Laboratory of Building Safety and Energy Efficiency of Ministry of Education, Hunan University, Changsha, China
College of Civil Engineering, Hunan University, Changsha, China

ABSTRACT: Using Machine Learning (ML) and Deep Learning (DL) algorithms to predict ground surface settlement caused by shield tunneling has being a hot topic. However, previous developed models are general weakness in the generalization performance when solving the problem in multi-regions. Because the data were usually collected based on a certain project, resulting in the limitations of the data in quantity and representativity. In this study, numerous data were collected from shield tunnels derived in various stratum conditions from different cities of China. Then, the improved models were proposed to identify the relationship between shield tunneling and the settlement. The efficiency of a DL algorithm Bi-directional Long Short-Term Memory (Bi-LSTM), ML algorithms Back-propagation Neural Network (BPNN) and Random Forest (RF) were compared. The results indicated that the accuracy of the proposed models have superior performance on the prediction accuracy of surface settlement, compared with dedicated model trained using individual city data. Furthermore, Bi-LSTM is demonstrated as a better algorithm to predict surface settlement than BPNN and RF.

1 INTRODUCTION

Shield tunnels are widely used in lifeline projects such as underground transportation and public facility construction in China, which not only can construct quickly but also reduce the impact on the ground surface. However, surface settlement is inevitable leading to serious accidents in severe cases. Thus, the prediction of surface settlement has been an important work. Traditional surface settlement prediction methods are based on empirical formulations (Peck 1969, Attewell & Hurrell 1985), analytical and semi-analytical solutions (Sagaseta 1987, Verruijt & Booker 1998), and numerical simulations (Kasper & Meschke 2004, Meng et al. 2018). Shield tunneling-induced surface settlement can be seen as a time series processing problem. It should be predicted based on a section of data from many factors, including geological conditions and shield operation parameters. Previous studies have been proved that there is a complex interaction between surface settlement and these factors (Li et al. 2015). However, the characteristics of these complex relationships were be simplified in traditional methods. As a result, it is desire to develop a more high-accuracy of the predictive model for surface settlement.

With the rapid development of Artificial Intelligence in recent years, BPNN was first applied in the prediction of tunnel settlement by Suwansawat & Einstein (2006), in which three factors were taken into consideration, namely tunnel geometry, geological conditions, and shield operation factors. Base on the public database of Suwansawat & Einstein (2006), Pourtaghi & Lotfollahi-Yaghin (2012) and Kohestani et al. (2017) found that the prediction accuracy of surface settlement would be significantly improved using Wavelet Neural Network (WNN) and RF compared to BPNN. However, these studies still had some shortcomings, such as using numbers to simply distinguish strata. To provide a more adequate

DOI: 10.1201/9781003299127-126

representation of the geological information, Chen et al. (2019) proposed a new method to consider both the strength and distribution of the strata. Furthermore, the selection of shield operation parameters was also discussed (Boubou et al. 2010, Zhang et al. 2019). As well, when other important influencing factors, such as karst cave (Zhang et al. 2020a, Zhang et al. 2021) and shield stoppage (Zhang et al. 2020b), have been chosen as input parameters, the performance of the settlement prediction model will be further improved. However, the current studies are primarily based on data from an individual project (Goh et al. 2018), the performance of the settlement production model in other projects, which generally have various geological conditions, is rarely discussed.

To solve this problem, this study collected data from shield projects in three cities (i.e. Changsha Metro Line 4, Tianjin Metro Line 7 and Zhengzhou Metro Line 3). Several algorithms, including BPNN, RF and Bi-LSTM, were used for a comprehensive comparative study. Then, the performance of the proposed model based on the best-performing algorithm is assessed.

2 METHODOLOGY

2.1 *Bi-directional long short-term memory neural network*

Bi-LSTM was upgraded from LSTM, which is a modification of recurrent neural network (RNN). While RNN is a deep learning algorithm that can capture and store information in time dimension. LSTM based on RNN, enables it to capture events with longer intervals and delays in time series by introducing the structure of forget gate, input gate and output gate, which avoids the problems of weight matrix dimensionality explosion and disappearance of propagation gradient, as is quite common in RNN. Compared to LSTM, Bi-LSTM allows working in both forward and backward direction through two independent hidden layers, which means Bi-LSTM can save both past and future information at any point (Wang et al. 2021). In this way, Bi-LSTM solves the problem that LSTM is susceptible to the last set of input parameters and the influence of the first set is too low.

2.2 *Back-propagation Neural Network*

BPNN is a kind of Multilayer Feedforward Neural Network (FNN), one of the most commonly used machine learning algorithms. Its structure mainly consists of an input layer, one or more hidden layers and an output layer. The input layer is used to obtain the input parameters, then adjust the number of hidden layers and the weights and thresholds among the layers to perform inter-layer operations, eventually using the activation function to derive the output value and error. Moreover, the number of hidden layers and neurons is adjusted by backpropagation until the error is reduced to the set range.

2.3 *Random Forest*

RF is an integrated learning algorithm consisting of multiple decision trees, often used to solve classification and regression problems. The decision trees are generated non-parametric stochastically, and each decision tree is an independent predictor, employing averaging and voting to derive results for the regression and classification problems, respectively. When dealing with problems with a small database, RF has a greater advantage in handling problems such as classification and regression.

2.4 *Particle swarm optimization*

Particle swarm optimization (PSO) is an optimization algorithm designed to find the optimal value of a target, with the characteristics of fast search speed and small memory consumption (Chen et al. 2022). By defining the hyperparameters of the algorithm as particles, PSO can be used to reduce the error of the settlement prediction model through constant updating of the particles.

3 PROJECT OVERVIEW

The database used in this paper is collected from three earth pressure balance (EPB) shield projects (i.e. Changsha Metro Line 4, Tianjin Metro Line 7 and Zhengzhou Metro Line 3). Note that the surface settlement collected in this study was caused by the first one during the excavation of the double-line tunnel. The outer diameter and inner diameter of the segmental lining are 6.0m and 5.4m in Changsha, 6.6m and 5.9m in Tianjin, as well as 6.2m and 5.5m in Zhengzhou. The width of the segmental lining in all three projects is 1.5m.

Figure 1 shows the geological profiles of the three tunnels in this study. The selected Changsha Tunnel is 5.44 km long and consists of 6 stations and 5 sections. In comparison, the tunnels in Tianjin and Zhengzhou both consist of only 2 stations and 1 section, which are 1.90 km and 0.71 km long, respectively. The tunnel burial depths are range from 10 to 28m in Changsha, 9.5 to 21m in Tianjin, and 12 to 23m in Zhengzhou. The average groundwater depth of the Changsha project is about 3m, Tianjin is about 2m, and Zhengzhou is below 15m. During the excavation of the 5-section tunnel from LGL to FBH station in Changsha, the shield machine passed through a complex stratum, which mainly included weathered slate, tuff, weathered mudstone, and sandstone, with a few places crossing chalky clay and gravels. In MJN to WLZ station of Tianjin Metro Line 7, the shield machine mainly excavates in the water-rich silt sand stratum, crossing the silt sand, silty clay, clayey silt and clay, with low strength and high-water content overall. The geological conditions of Zhengzhou Metro Line 3 are quite similar to those of Tianjin Metro Line 7. From LGL station to FBH station, in about half of the distance, the soil type at the tunnel face is fine sand, while the other half is sandy silt and clayey silt. For more details, it can be referred from Chen et al. (2019) and Zhang et al. (2020b). In summary, the tunnel was mainly driven through weathered rock layers in Changsha Metro Line 4, while through soft geological chalk and sandy soils, a more uniform stratum in Zhengzhou Metro Line 3 and Tianjin Metro Line 7.

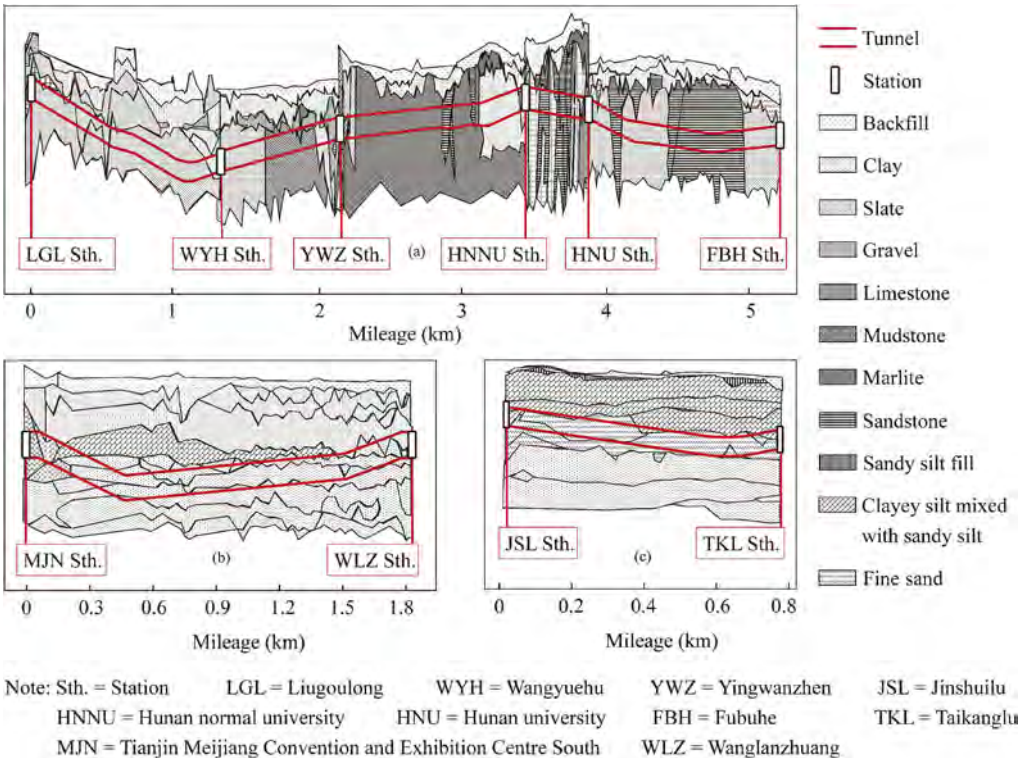

Figure 1. Geological profile of study area: (a) Changsha; (b) Tianjin; (c) Zhengzhou. (modified from (Zhang et al. 2020c)).

4 DEVELOPMENT OF PRODICTION MODEL

4.1 *Inputs and outputs*

The factors that influence surface settlement can be divided into 3 main categories: geometric factors, geological factors and shield operational parameters. Since the tunnel diameters in this study are basically the same, the burial depth of the tunnel is taken as the only geometric factor.

Regarding to the geological factors, in addition to the water table and the soil types at tunnel face (Zhang et al. 2020c), a method based on the correction for the depth and thickness of strata was used (Chen et al. 2019), where the modified standard penetration test blow count (MSPT), modified dynamic penetration test blow count (MDPT), modified uniaxial compressive strength (MUCS) were also chosen to represent the geological conditions in which they are located, expressed in Equations 1~3:

$$N'_{63.5} = \sum_{i=1}^{n} \frac{t_i}{h} \cdot \frac{h_i}{h} \cdot N_{63.5} \tag{1}$$

$$N' = \sum_{i=1}^{n} \frac{t_i}{h} \cdot \frac{h_i}{h} \cdot N \tag{2}$$

$$U' = \sum_{i=1}^{n} \frac{t_i}{h} \cdot \frac{h_i}{h} \cdot U \tag{3}$$

In which $N_{63.5}$ is the blow count of standard penetration test, N is the blow count of dynamic penetration test, U is the unconfined uniaxial compressive strength. As shown in Figure 2, $\frac{t_i}{h}$is the thickness index, representing the ratio of the thickness of the strata i to the tunnel depth h; $\frac{h_i}{h}$ is the depth index, representing the ratio of the depth of the strata i to the tunnel depth h. With these two indices, the thickness of each stratum and the distance between each stratum to the tunnel crown are concerned, which represents the influence of each stratum on the surface settlement.

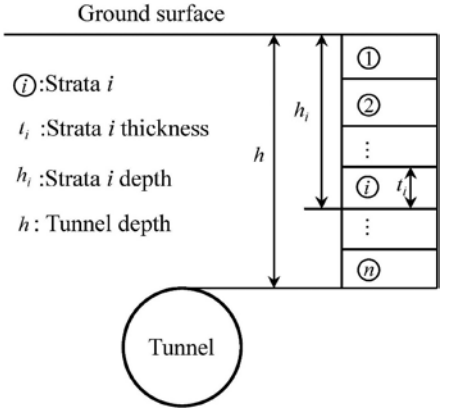

Figure 2. Illustration for the thickness index and depth index. (modified from (Chen et al. 2019)).

The shield operation generates many tunneling parameters, and the parameters most closely related to the magnitude of ground deformation are torque, penetration rate, thrust, chamber pressure and rotational speed (Chen et al. 2022). In addition, whether the shield machine is

stopped over 24 hour or not is also an input parameter, as the stoppage is strongly correlated with the surface settlement (Zhang et al. 2020b).

The histograms of the settlement data collected from the metro projects in Changsha, Tianjin and Zhengzhou are shown in Figure 3, respectively. There were 4215 field settlement records collected from Changsha, 535 from Tianjin, and 2028 from Zhengzhou. Settlement less than 10 mm accounted for most of the database in all projects, while 5 to 10 mm settlement was relatively high in the database of the Zhengzhou project. About 23% of the data in the Tianjin project are small ground uplifts. In comparison, settlement more than 10 mm occurred much frequently in Changsha than in Tianjin and Zhengzhou.

In summary, this paper constructs a database based on 6778 sets of settlement, geometric factors, geological factors and shield operational parameters, and the database structure, statistics of all parameter are listed in Table 1. It should be note that the training set accounted for 80%, and the test set accounted for 20%.

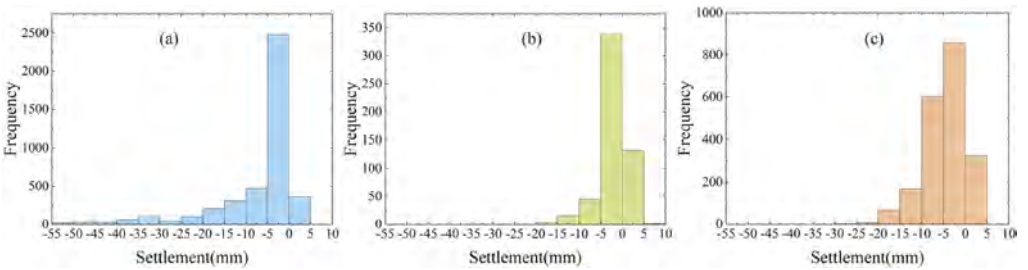

Figure 3. Settlement histograms of each city: (a) Changsha; (b) Tianjin; (c) Zhengzhou.

Table 1. Statistics of all used parameters.

Parameters	Parameter type	Minimum	Maximum	Average	Unit
Cover depth	Input	9.09	31.65	17.58	m
Torque	Input	0.14	4.82	2.41	MN·m
Penetration rate	Input	3.11	76.00	39.73	mm/min
Thrust	Input	1.77	23.80	11.99	MN
Chamber pressure	Input	0.39	2.84	1.15	bar
Rotational speed	Input	0.29	2.16	1.39	rpm
Water table	Input	0	25.11	6.10	m
Soil types at tunnel face	Input	1	4	/	/
MSPT	Input	0	37.92	7.96	/
MDPT	Input	0	22.17	0.25	/
MUCS	Input	0	39.42	4.90	MPa
Stoppage	Input	0	1	/	/
Settlement	Output	-89.13	6.97	-5.62	mm

4.2 *Performance analysis*

In order to demonstrate the accuracy of the constructed shield excavation surface settlement prediction model, three performance evaluation indexes were selected for this study, which is root mean square error (RMSE), mean absolute error (MAE) and Pearson correlation coefficient (R).

$$RMSE = \sqrt{\left(\frac{1}{n}\right)\sum_{1}^{n}(r_i - p_i)^2} \tag{4}$$

$$MAE = \left(\frac{1}{n}\right)\sum_{1}^{n}|r_i - p_i| \tag{5}$$

$$R = \frac{\sum_{i}^{n}(r_i - \bar{r})(p_i - \bar{p})}{\sqrt{\sum_{i}^{n}(r_i - \bar{r})^2(p_i - \bar{p})^2}} \tag{6}$$

where r_i and $\bar{r}$mean the actual and average values of surface settlement, respectively. The MAE and RMSE represent the magnitude of the mean error and the standard deviation between the predicted and measured values, respectively.

4.3 *Optimum hyper-parameters*

The selection of hyperparameters is strongly related to the performance of the ML and DL models. In the selection of BPNN and RF model's hyper-parameters, using 10-fold cross-validation with PSO, setting the MAE of the validation set to the fitness value, and conducting 300 generations, respectively (Zhang et al. 2020b). While the previous study has shown that using the PSO algorithm to find the optimal hyper-parameters of the LSTM model will result in an extremely rapid increase in computational cost (Zhang et al. 2020c). So the optimal hyper-parameters of the Bi-LSTM model in this paper are searched by the trial-and-error method. As shown in Figure 4, the iterative process of both the BPNN and RF models is completed within 25 generations, which indicates that PSO has a strong search capability and converges extremely fast. And the fitness value of the RF model is significantly smaller than that of the BPNN model, suggesting that the prediction performance of the RF model is noticeably better. The optimal hyper-parameters of BP, RF and Bi-LSTM are listed in Table 2.

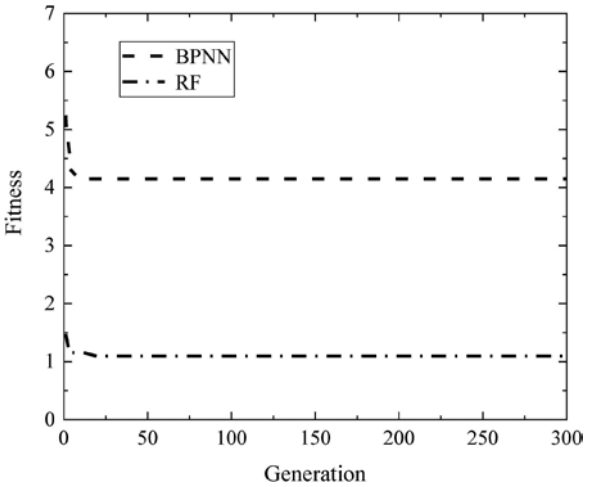

Figure 4. Optimized results of BPNN and RF.

5 RESULTS

Based on the previously mentioned database, three settlement prediction models were constructed using the BPNN, RF, and Bi-LSTM, respectively. The settlement prediction results are shown in Figure 5. The BPNN based model is unsuitable for predicting surface settlement because of its poor performance in R, RMSE and MAE. Meanwhile, the predicted settlement

Table 2. Values of optimum hyper-parameters in five machine learning algorithms.

Algorithm	Optimum hyper-parameters
BPNN	hidden_layer_neuron_num=12
RF	ntree=150
Bi-LSTM	hidden_layer_num=8 hidden_layer_LSTM_cell_num=60 time_step=3

is generally smaller than the measured settlement. The RF based model performs better, while R is above 0.9, and the RMSE and MAE in the test set are 3.01 and 1.67, respectively. The Bi-LSTM based model has the best performance among all, with the highest correlation coefficient and the lowest RMSE and MAE, which can not only accurately predict small settlement but also provide precise warning for excessive settlement even it is up to 90mm. It can be explained that the settlement of a predicted point depends on the tunneling information of the surrounding section, and the Bi-LSTM could capture this long interval information. When Bi-LSTM gives the output through the output gate, it can consider not only the current input but also the information beyond the current input through the forget and input gates, i.e., it considers the tunneling information of the surrounding sections at the same time. While at the same time, its bi-directional structure gives it a better ability to capture information that are closely connected before and after, making it possible to ensure that the influence of the tunneling at distant locations is not ignored.

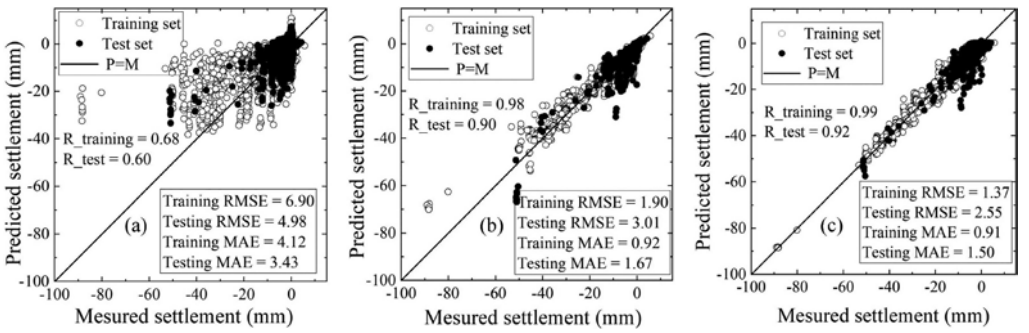

Figure 5. Settlement prediction results of each algorithm-based models: (a) BPNN; (b) RF; (c) Bi-LSTM.

Based on the results above, Bi-LSTM was chosen to construct two settlement prediction models respectively. Figures 6a, b, and c show the results of the dedicated model, which is built with data from Changsha only. Note that the data from Tianjin and Zhengzhou are used as the test set only in Figures 6b and c. The results of the improved model are shown in Figures 6d, e, f.

Even though the dedicated model performs well in Changsha, the predicted values of the Tianjin metro project are generally small, poorly correlated, and unable to provide effective guidance. The predictions for the Zhengzhou metro project are even worse, with almost no correlation between the predicted and measured settlement. The distribution of the predicted values is chaotic and hardly provides any reference meaning. This can be attributed to two possible reasons: 1) as described in Section 3, the geological conditions crossed by the Changsha project in this study are significantly different from those crossed by the Zhengzhou and Tianjin projects; 2) each project uses a different brand or model of earth pressure balance shield machine, which means that the shield operating parameters in different projects may not be compared directly.

As shown in Figures 6e and f, adding the data of the Tianjin and Zhengzhou projects to the database, Bi-LSTM has captured their features successfully. In the improved model, not only

the prediction results of Tianjin and Zhengzhou projects have been improved substantially, but also the accuracy of Changsha project has been further improved. The addition of new data not only increases the generalization ability of the model, but also allows the model to perform better in the part of original database. However, compared to the Zhengzhou project, the prediction model is relatively ineffective in the Tianjin project, with the correlation between the predicted and measured settlement in the test set only 0.79. This may be explained by the fact that the database size in the Tianjin part is 535, which is only 8% of the total database size, while the database size in Zhengzhou is 2028.

Such results suggest that the size of the database still plays a crucial role in the current research on surface settlement prediction. When the improved model in this paper is applied to a project where the geological conditions are significantly different from the current database, it may not always give an excellent result. To improve the generalization ability of the model, the increase of the database size, especially for different types of data, is highly recommended. Alternatively, building a physics-informed machine learning model is an important solution that is getting more and more attention.

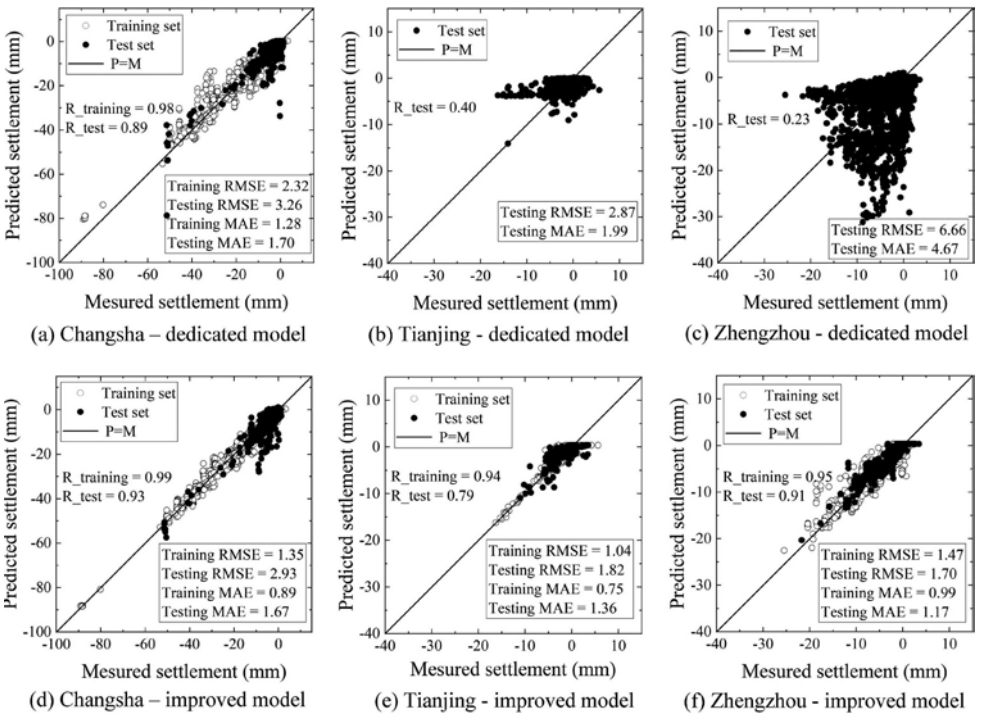

Figure 6. Settlement prediction results of dedicated model and improved model.

6 CONCLUSIONS

In this study, 6778 data from settlement monitoring points were collected based on Changsha Metro Line 4, Tianjin Metro Line 7 and Zhengzhou Metro Line 3. Bi-LSTM, BPNN and RF algorithms were used to establish 4 surface settlement prediction models. Comparing the three algorithms, it is found that the surface settlement prediction model constructed by the Bi-LSTM algorithm has the smallest error and can capture the intrinsic connection between each parameter and surface settlement accurately. Therefore, based on the overall performance of the prediction result, Bi-LSTM is more appropriate for the construction of the surface settlement model. Compared with the dedicated model based on the Changsha data, the improved

model not only has better prediction results in the Changsha metro project but also performs well in the Tianjin and Zhengzhou metro projects.

ABSTRACT: Composite rock stratum is commonly encountered during tunnel excavation, where the structural planes can easily cause large squeezing deformation, rock burst and other major disasters. Therefore, in order to reduce the risk of tunnel excavation, the discrete element method (DEM) with a new size-dependent contact model is employed to simulate the failure process of composite rock induced by tunnel excavation. Seven inclinations of structural plane are considered. The bond breakage, distribution of maximum principal stress, area ratio of surrounding rock disturbance area, and bond breakage ratio are analyzed. The results show that the bond breakage ratio decreases with the increase of inclination of the soft-hard interbedded rock structural planes. When the angle of the soft-hard interbedded rock structural plane is 0°, the tunnel excavation is found of the most risk.

1 INTRODUCTION

In response to the development needs, a series of long tunnels such as transportation and water conservancy are being constructed or are intended to be constructed in China. In these projects, it is inevitable to encounter the tunnel construction in composite rock mass. The structural planes in rock mass can easily cause disasters such as cutter ring crack, eccentric wear of cutters, TBM jamming and rock bust. Through discrete element simulation, Gong et al.(Gong et al., 2005, Gong et al., 2006a, Gong et al., 2006b) found that structural plane inclination has significant influences on cracking and propagation of fractures, and then on rock breaking mode of TBM. In the past few decades, many studies have been carried out on the influence of structural plane inclination on tunnel excavation.

As for experiments, Park and Adachi (Park et al., 2017) analyzed the distribution of pressure under different inclinations of structural plane. Zheng et al.(Zheng et al., 2019) and Han et al.(Han et al., 2018) studied the mechanical properties of rock mass under various inclinations of structural planes through uniaxial and triaxial compression tests. Sagong et al. (Sagong et al., 2011) simulated and studied the crack development mode and deformation mode under various joint inclinations. Although the laboratory tests can obtain the more

DOI: 10.1201/9781003299127-127

realistic responses of the rock during the tunnel excavation, only macroscopic failure can be achieved, meanwhile, it costs a lot.

The discrete element method (DEM), proposed by Cundall(Cundall and Strack, 1979) in 1971, can reproduce the failure process of materials and has been widely used in various aspects of geotechnical engineering. Wang et al.(Wang et al., 2017) used the jointed rock mass in laboratory tests and PFC2D to analyze the crack development and deformation modes around tunnel under the influence of joint inclinations. Jiang et al.(Jiang et al., 2009) used EDEM to study the impacts of different joint inclinations and joint spacing on tunnel excavation. Geng(Geng, 2015) used discrete element software UDEC^{2D} to study the stress redistribution and the rock deformation after tunnel excavation considering the following three factors, i.e., bedding with different inclinations, faults with different inclinations and different lateral pressure coefficient.

At present, the development of three-dimensional (3D) discrete elements is relatively mature, and the simulation results are more close to the actual situation. However, a large number of particles have to be created when studying boundary value problems such as tunnel excavation using 3D discrete elements. Based on the above studies and computational efficiency of the computer, in this study, we established a two-dimensional tunnel excavation DEM model implanted with a new size-dependent contact model(Jiang et al., 2005, Jiang et al., 2006). From the macro and micro perspective, the stability of surrounding rock of a tunnel excavated in deep composite strata with different inclinations of structural planes is explored, which provides a theoretical basis for reducing the damage risk of tunnel excavation in composite strata.

2 MICROSCOPIC CONTACT MODEL OF ROCK

2.1 *Mechanical response*

In general, according to the microstructure characteristic of a specific rock, thick bond or zero-thickness bond are adopted in DEM simulation. The mechanical response of cemented contact model is shown in the Zhang(Zhang, 2014). Figure 1 shows the bond and its failure state during the discrete element simulation. In the discrete element simulation, bond breakage means that the bond no longer bears any stress, that is, the calculation of the contact force is no longer takes into account the stress borne by the bond.

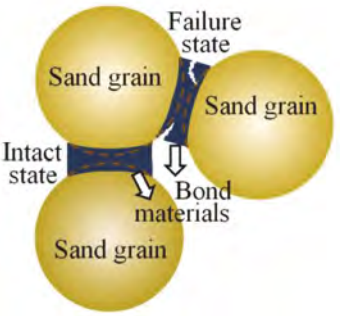

Figure 1. Bond state in discrete element simulation.

2.2 *Parameter calibration*

This paper takes the composite rock mass composed of granite (Martin, 1993) and limestone (Ciantia et al., 2015, Nova and Parma, 2011) as object. The micromechanical parameters of the two rocks are shown in Table 1.

Table 1. Microscopic parameters of rock samples.

Type	Microscopic parameters	Granite	Calcarenite
Particle part	Particle density ρ (kg/m^3)	2700	2700
	Particle normal stiffness k_n (N/m)	6.5×10^{10}	9.0×10^{8}
	Particle shear stiffness k_s (N/m)	4.33×10^{10}	3.6×10^{8}
	Particle friction coefficient μ	1.0	0.7
	Particle anti-rotation coefficient β	1.5	0.6
Bond part	Maximum bond thickness h_{max} (m)	1.30×10^{-4}	1.30×10^{-4}
	Bond tensile strength σ_t (Pa)	1.00×10^{9}	2.18×10^{7}
	Bond compression strength σ_c (Pa)	3.00×10^{10}	2.30×10^{8}
	Bond elastic modulus E_b (N)	3.75×10^{9}	1.10×10^{7}
	Bond elongation rate sp	0.15	0.15

3 DISCRETE ELEMENT SIMULATION OF TUNNEL EXCAVATION

This simulation is built on the deep-buried tunnel of Jinping secondary hydropower station (Zhang et al., 2010).The influence of the support structure is not considered. Discrete element simulation is mainly divided into 5 steps:

(1) Specimen preparation. In order to prepare uniform samples efficiently, the Layered Under Compaction Method proposed by Jiang et al.(Jiang et al., 2003) was adopted. The gradation curve is shown in Figure 2(a). The sample with 300 000 particles were prepared in eight layers, where 37 500 particles are in each layer, and the final void ratio was 0.2.
(2) Preload. Keep the left and right walls unmoved, through the servo mechanism of the upper and lower walls, the sample is consolidated and stabilized under the vertical pressure of 38.02 MPa to simulate the deep burial position of the rock sample.
(3) Add bond. Give the calibrated microscopic parameters of granite and limestone to the sample until equilibrium to simulate the real composite rock mass.
(4) Apply horizontal pressure. According to the actual in-situ stresses, the horizontal pressure of 30 MPa is applied to the rock sample until the sample reaches the equilibrium state, and the displacement and velocity of the particles are cleared.
(5) Tunnel excavation. Based on the principle of centrifuge test, a 200 g gravity field is applied before the excavation of the tunnel to simulate the real size of the tunnel 200 times larger than the discrete element sample, as shown in Figure 2(b). The tunnel with a radius of 0.035 m is excavated in the center of the sample. What needs illustration is that the green part represents soft rock and the blue part represents hard rock in Figure 2(b).
(6) Tunnel stability. Set local and global measuring circles to monitor macro and micro information, which is shown in Figure 3. When the number of bond breakage does not increase, the tunnel is balanced and the calculation is ended.

Figure 3. Positions of measuring circles in DEM specimen.

4 RESULTS AND ANALYSIS

In order to study the influence of structural plane inclination on the stability of tunnel excavation, the failure mechanism of tunnel excavation is analyzed by discrete element method under seven inclinations (0°, 15°, 30°, 45°, 60°, 75°, and 90°) of structural plane.

4.1 *Bond breakage*

Figure 4 shows the bond breakage number versus time caused by tunnel excavation under different structural plane inclinations. Limited to the space, This paper takes 30°, 45°, 60° and 90° as examples. It should be noted that the initial number of bond is approximately 1,000,000. When the inclination of the structural surface is larger than 45°, the number of tensile-shear bond breakage is more than that of compression-shear bond breakage. Based on the order of bond breakage number, strong and weak failure are classified. Strong failure occurs when the inclinations of soft-hard interbedded rock structural plane are 30° and 45°. In these cases, the number of bond breakage is over 10,000 and reaches the peak at a very slow speed. Weak failure occurs when the inclinations of soft-hard interbedded rock structural plane are 60° and 75°, and the number of bond breakage is less than 2000, and quickly reaches the peak value and becomes stable. The type of bond breakage is mainly the tensile-shear failure.

Through the above analysis, it can be observed that with the decrease of the inclinations of the structural plane, the bond breakage number increases, and the required time that achieves the failure stability is longer.

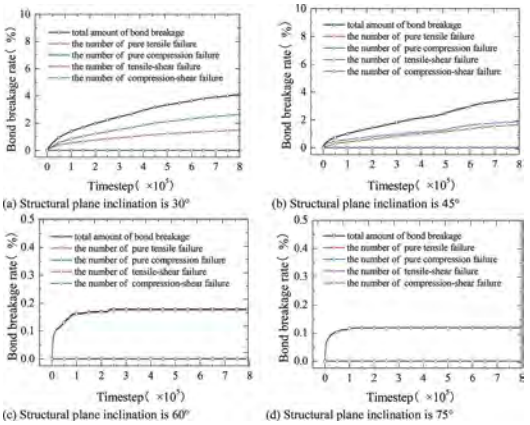

Figure 4. The relationship between the number of bond breakage and time step under different inclinations of the structural plane.

4.2 *Maximum principal stress*

Figures 5 and 6 shows the circumferential and radial distribution of maximum principal stress caused by tunnel excavation under different structural plane inclinations. Limited to the space, This paper takes 30°, and 60° as examples. In Figures 5(a) and 6(a), the longitudinal coordinate represents the magnitude of the maximum principal stress, and the polar coordinate represents the direction of the maximum principal stress. When the inclination of the structural plane is 30°, the circumferential direction of 150° to 330° is the area of hard rock, and when the inclination of the structural plane is 60°, the circumferential direction of 120° to 300° is the area of soft rock. The distribution of the maximum principal stress along the circumferential direction is teardrop-shaped and its cone tip is directly related to structural plane, mainly because the direction of maximum principal stress mainly exists in hard rock. From the radial distribution, the maximum principal stress increases with the distance to the tunnel center when the inclinations of structural plane is 30°. The main reason is the unloading effect of tunnel excavation(Jiang and Yin, 2012). For the structural plane inclinations of 60°, the maximum principal stress at 180° and 225° decreases gradually with the increase of the distance to the tunnel center, and the maximum principal stress at other angles increases gradually with the increase of the distance to the tunnel center.

Through the above analysis, it can be observed that the inclination of structural plane influences the failure form of rock by influencing the location of the maximum principal stress.

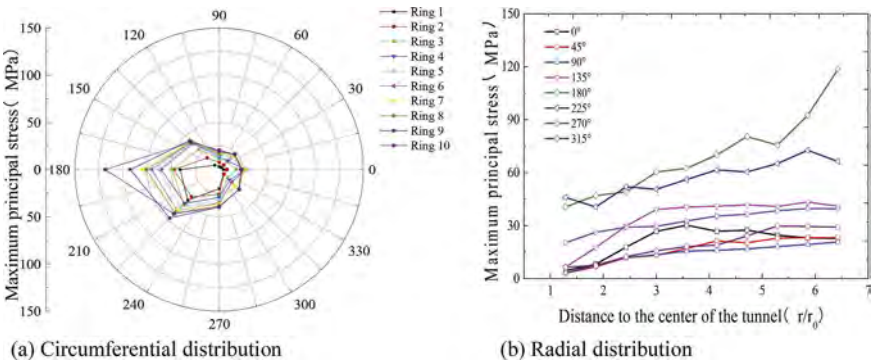

Figure 5. Distribution of maximum principal stress when structural plane inclination is 30°.

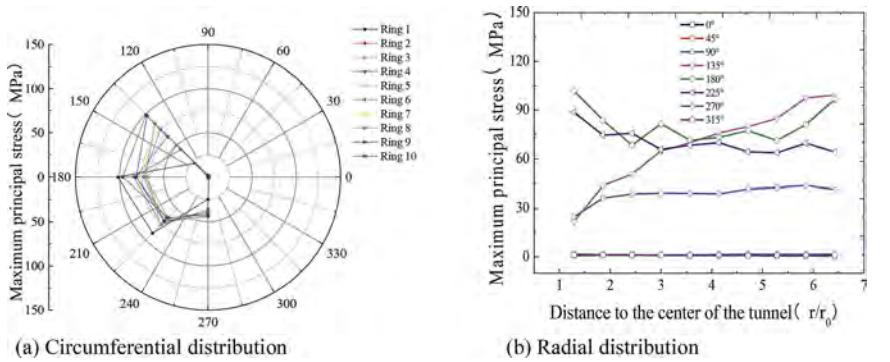

Figure 6. Distribution of maximum principal stress when structural plane inclination is 60°.

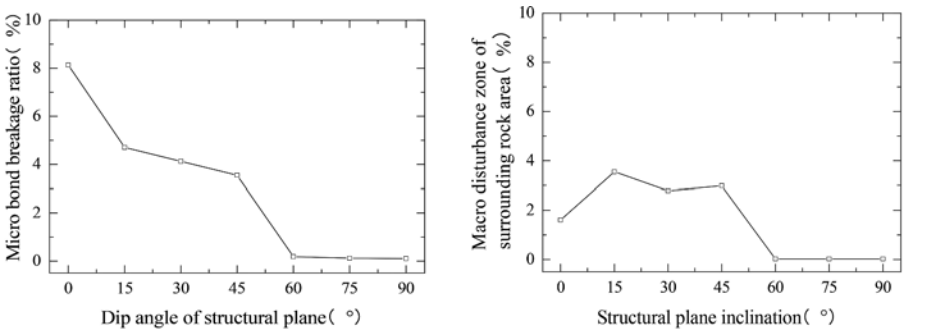
4.3 *Bond breakage ratio and area ratio of surrounding rock disturbance area*

Figure 7 shows the bond breakage ratio and the area ratio of surrounding rock disturbance area caused by tunnel excavation under different inclinations of the structural plane. The

larger the bond breakage ratio is, the more serious the micro-damage of surrounding rock. The larger the area ratio of surrounding rock disturbance area is, the more likely the large squeezing deformation occurs. With the increase of inclinations of soft-hard interbedded rock structural planes, microscopic bond breakage ratio decreases. This is mainly because different inclinations of structural planes represent different pressure perpendicular to structural plane. Due to the vertical pressure on the tunnel is larger than horizontal pressure, when the surrounding rock is soft on the top and hard on the bottom, the pressure perpendicular to structural plane is larger than that of the surrounding rock is soft on the right and hard on the left.

As can be seen from the Figure 7, when the inclination of structural plane is 0°, the micro bond breakage ratio is largest, and the area ratio of surrounding rock disturbance area is also large. At this time, the damage inside the tunnel is the most serious, that is, the tunnel excavation is found of the most risk.



(a) Micro bond breakage ratio (b) Area ratio of surrounding rock disturbance area

Figure 7. Micro bond breakage ratio and area ratio of surrounding rock disturbance area under different inclinations of structural plane.

5 CONCLUSIONS

In this paper, the failure of composite rock induced by tunnel excavation is analyzed by DEM implanted with size-dependent contact model. Various inclinations of soft-hard rock structural plane are considered. The following conclusions are obtained:

(1) The bond breakage ratio decreases with the increase of the inclination of the soft-hard rock structural planes. When the inclinations of the soft-hard interbedded rock structural plane is 0°, the tunnel excavation is found of the most risk.
(2) The distribution of the maximum principal stress along the circumferential direction is teardrop-shaped and its cone tip is directly related to structural plane. From the radial distribution, the maximum principal stress increases with the distance to the tunnel center when the inclinations of structural plane are small. When the inclination of the structural plane is large, the maximum principal stress at 180° and 225° decreases with the increase of the distance from the center of the tunnel, while the other angles are opposite.
(3) When the inclination of the structural surface is smaller than 45°, the bond breakage number is over 10,000 and reaches the peak at a very slow speed, while when the inclination is larger than 45°, the bond breakage number is less than 2,000, and the bond breakages happened mainly due to tensile shear.

Pilot project: Applying the tunnel-in-tunnel method on DB electrified routes

Dietmar Mähner
Institute for Underground Construction, FH Münster, Germany

Bodo Tauch
DB Netz AG, Frankfurt a. M., Germany

ABSTRACT: This report deals with the refurbishing of the Petersberg Tunnel. In this connection, for the first time within the scope of a pilot project, the tunnel-in-tunnel method was applied on an electrified line belonging to the DB. The tunnel cross-section was enlarged within the scope of the excavation. These activities were executed with the aid of a tunnel enlargement system (TES). Towards this end, the existing overhead line for electrification of the route had to be integrated in the excavation. Once the driving operations had been completed, the tunnel inner shell made of reinforced concrete was produced. Thanks to this project the spectrum of refurbishing tunnels has been considerably expanded, as the method can be deployed for other projects on the electrified route network.

1 DEPLOYING THE TUNNEL-IN-TUNNEL METHOD FOR DEUTSCHE BAHN

The tunnel-in-tunnel method has already been successfully tried out and further developed on several non-electrified routes in regional transportation. In this method, the tunnel cross-section is expanded by drill+blast or cutting tools with trains services still operating and a new reinforced concrete inner shell installed according to the valid requirements of the code of practice.

When construction starts, the track is relocated to the centre of the tunnel and services run in alternating directions for the duration of the scheme. Once refurbishing is over, the tunnel is once again provided with two running tracks. However, work on the track at the start and end of the tunnel enlargement scheme is undertaken during a scheduled complete closure phase; the route is kept open for traffic throughout the entire residual construction period.

Traffic must only be occasionally rerouted if at all. The tunnel-in-tunnel method has now been deployed on an electrified route for the first time to refurbish the Petersberg Tunnel (Figure 1).

2 PROJECT PRESENTATION

2.1 *Koblenz–perl rail route*

The Petersberg Tunnel lies near Bullay on the twin-track line from Koblenz to Perl, catering for mainline and commuter traffic. The route is of great significance for passenger transportation, linking Koblenz and Trier. It is also a vital artery for goods traffic as the most important link in the direction of Luxembourg.

As a result, it rates very highly on the DB's route network. The DB Netz AG's long-term objective is to maintain the Koblenz–Perl rail line as an integral part of the Trans-European Network (TEN). Thus, enhancing the safety level as well as maintaining the route for goods and passenger traffic is of great public interest.

DOI: 10.1201/9781003299127-128

Figure 1. The Petersberg rail tunnel will be refurbished by late 2019 by the tunnel-in tunnel method while rail services continue.

2.2 *Petersberg tunnel*

The Petersberg Tunnel is 368 m long and was completed in 1879. The existing masonry consists of slate and quarrystone some 0.85 m thick. The thickness is reduced to around 0.70 m at the portals. The tunnel masonry structure is designed with a mouth-shaped cross-section; the tunnel is drained at present.

The Petersberg Tunnel is located in the vicinity of the Moselle syncline, part of the Rhenish Uplands. The area consists of a thick geological sequence of sandstones, siltstones and mudstones. The rocks are in part intensively fissured and contain numerous faults due to the impact of tectonic activity. The maximum overburden height is to be found roughly at the tunnel centre and amounts to ca. 95 m.

The existing masonry of the tunnel has been redeveloped and improved on many occasions in the course of recent decades. During past maintenance operations, the masonry was provided with an extensive thin shotcrete shell. Prior to refurbishment, among other things, broken masonry, loose joints, spalling and cracks in the shotcrete as well as various moist patches were documented. Within the scope of regular controls, it became evident that the quality of the structure was deteriorating, which could not be rectified economically.

Furthermore, the Deutsche Bahn's valid code of practice calls for the track centre distance to be increased from its present 3.50 to 4.00 m. In addition, prior to renovation, there were merely individual emergency bays available rather than continuous escapeways. The task of refurbishing the Petersberg Tunnel was carried out in conjunction with maintaining train services as far as possible even while enlarging the tunnel cross-section and installing a new tunnel inner shell. Minor interruptions were only permissible for blasting operations during the enlargement phase and for lifting and lowering structural parts above the overhead line.

For this reason, the tunnel was enlarged by applying the tunnel-in-tunnel method. Construction activities began in 2017. The actual tunnel drive commenced in January 2018 and wound up in October of the same year.

3 THE TUNNEL ENLARGEMENT SYSTEM (TES)

3.1 *Concept*

Throughout the application of the Tunnel Enlargement System (TES) during construction operations, the running track was provided with a continuous protective housing. This was to ensure safe electrified train services and at the same time, separate rail traffic from ongoing

construction. Within this protective housing, a conductor rail is installed in the roof to carry the overhead line. The overbreak for the additional housing is largely compensated for by deploying the conductor rail and the related low installation height of the overhead line system. The TES is a steel structure and runs within two guide rails, which are installed on the strip foundation, supporting itself above the protective housing (Figure 2).

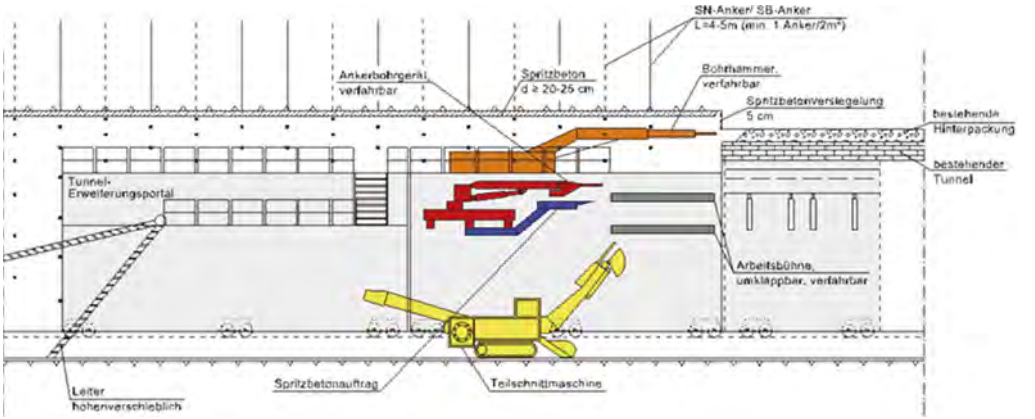

Figure 2. Longitudinal section of the tunnel enlargement system (TES).

The TES possesses an additional vault protective device that can be raised by hydraulic means. By deploying this structure, the objective is to prevent the masonry of the existing tunnel from loosening. For other projects a bolting system was installed in the existing tunnel to secure it in advance. However, this entails a considerable amount of extra work, something that was avoided by introducing the hydraulically raised vault protection device for the Petersberg Tunnel. The TES had to be devised in such a way that it was possible to excavate using a drill hammer at the roof.

Two roadheaders, which move along the tunnel base at abutment height, tackle the side walls (Figures 3–5). The support arches and mats can be installed by means of mobile, foldable work platforms. Two shotcrete manipulators and drilling rigs located at the sides of the TES place the shotcrete and create the drill holes for the anchoring system and the spiles. It must be observed here that the possibility of anchoring involving larger anchor diameters had to be taken into consideration when designing the anchor drilling rigs with regard to their effective capacity during the tendering stage.

The excavated material was removed by special dumpers behind the roadheaders, which must operate in very constricted conditions. The protective housing as well as the TES is set up on strip foundations, running in the longitudinal direction of the tunnel. These strip foundations must be capable of transferring the weight of the TES (approx. 225 t) and the housing safely into the subsurface.

Owing to the local circumstances in the Petersberg Tunnel, driving was carried out by excavators and blasting (Figures 6 - 7). This meant that the TES had to sustain all effects from drilling and blasting. Towards this end, the auxiliary foundations had also to be dimensioned accordingly. Figure 8 shows schematically how the TES was impacted by the effects of blasting. Owing to the high horizontal loads (blasting pressure on the TES) the foundations had to be back-anchored using pretensioned GEWI bars.

The work needed to accomplish this task took some considerable time, leading to the construction cycle being interfered with. Alternative concepts for sustaining this horizontal load should thus be scrutinised properly in advance and resolved.

Figure 3–5. Mobile TES installed on fixed housing.

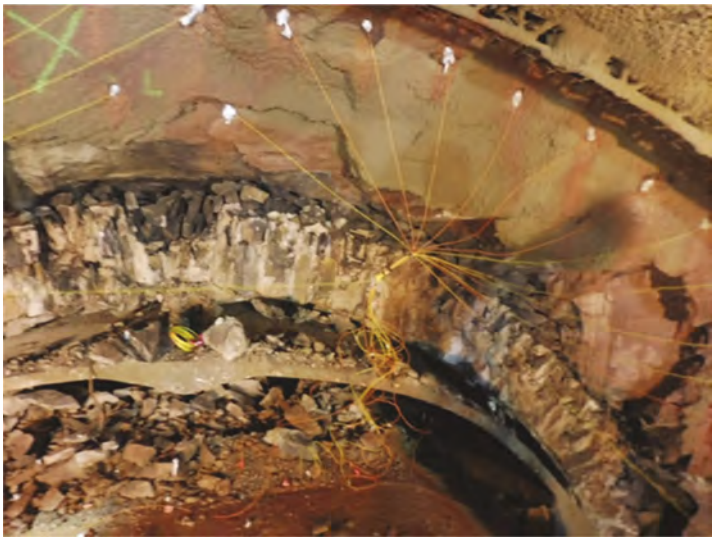

Figure 6. Excavation with drill hammer.

Figure 7. Drill+blast exavation.

3.2 *Construction phases*

Prior to the construction scheme, the route leading through the Petersberg Tunnel ran on two tracks. Within the scope of a four-week long closure of the route in May 2017, first of all the overhead line, the rails and the superstructure in the tunnel were removed. This was followed by the installation of the auxiliary foundations for the TES as well as the protective housing. In addition, the rail bed was produced with a track at its centre in order to enable rail traffic to pass through the tunnel in alternating operation during the entire construction phase.

The protective housing was set up at the end of the shutdown. In August 2017, the TES was hoisted from the construction site installation yard next to the tunnel portal on to the auxiliary foundations during an additional night-time shutdown. In February 2018, driving operations began from the south portal. Towards this end, the tunnel was extended upwards by some 2.5 m (roof) and by roughly 3 m at the side (abutment zone) protected by the TES and subsequently secured with shotcrete (20–30 cm), anchors, support arches and matting.

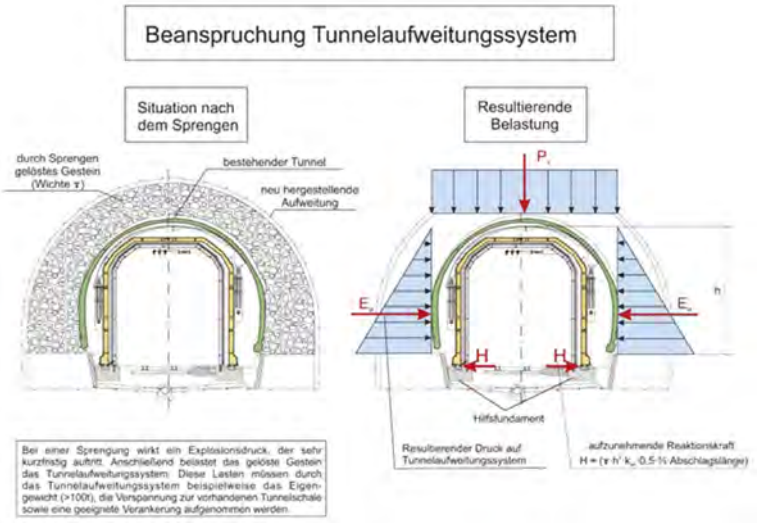

Figure 8. TES impacted by blasting: During blasting explosion pressure acts, which only lasts briefly. Subsequently, the loosened rock impacts the Tunnel Expansion System. These loads must be sustained by the TES, e.g. the dead weight (> 100 t), the bracing against the existing tunnel shell as well as by appropriate anchoring.

The lengths of advance varied between 0.75 and 1.75 m. The excavation over a distance of 330 m was concluded in October 2018. After the TES had been retrieved, the base was prepared for the foundations. Subsequently, the strip foundations were created as from January 2019.

After setting up and positioning the reinforcement carriage, the formwork carriage and three curing carriages, work on the vault blocks started from north to south. Within the framework of a four-week long total closure as from November 2019, among other things, the protective housing will be removed and the auxiliary foundations dismantled prior to producing the rail ballast with two tracks. During the same period, the rail engineering, installation of the drainage pipes and the overhead line will take place. After the shutdown, the tunnel will once again be ready for two-track operation. Figure 9 shows the described construction phases.

4 EXCAVATION CLASSES

The tunnel enlargement has been undertaken commensurate with the principles of the shotcrete method. During planning, a total of six excavation classes (EC = VKL) were devised. Installation of the supporting agents essentially had to be carried out from the TES. This actually meant that the placing of shotcrete, drilling of anchors and spiles as well as the installation of matting and support arches in the entire excavation area had to be accomplished from the TES.

The length of advance in the six excavation classes varied between 1.75 m (VKL 4A1) and 1.00 m (VKL 6A4). The thickness of the shotcrete ranged from 20–30 cm depending on the prevailing rock stresses. Q188 and Q257 mats were used to reinforce the shotcrete shell. These were always installed facing towards the rock and at the airside. During the excavation, spiles were used at certain places as advance supports; they are some 3–5 m long and possess a diameter of 32 mm. The spiles were set up at ≤ 25 cm gaps. The working face was sealed at certain points with 3–5 cm thick supportive layers of shotcrete. Face anchors were also placed in definitive fault zones. SN bolts or self-drilling anchors (anchor length 4–5 m, supporting force ≥ 245 kN, anchor pattern: one anchor every 2 or 3 m²) were deployed for securing the shotcrete shell.

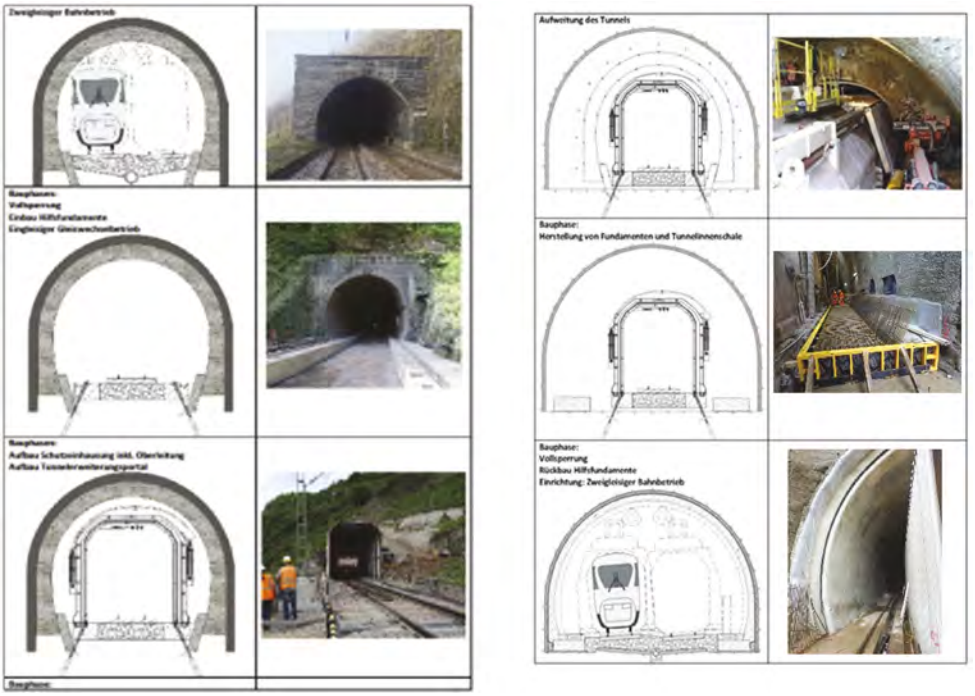

Figure 9. Individual construction phases during the application of the tunnel-in-tunnel method.

Self-drilling anchors up to 10 m in length were foreseen for back-anchoring to minimise the growth of deformations. The support arches were devised as 3-bar lattice girders. The driving concept initially foresaw the vault (height of excavation up to approx. 8.56 m) being tunnelled in advance. Subsequently the abutment (height of excavation approx. 1.00 m) was tackled once the intervening gap was sufficient (> 10 m). The length of advance for the abutment amounted to twice the length for the vault.

Once the first reference values had been accrued for this type of excavation, the method was optimised to such an extent that the vault could be tunnelled at the same time as the abutment without the need for a staggered approach. The support arches were extended to the base of the abutment so that the loads imposed by the rock could be transferred immediately (Figures 10 - 11). The loads imposed by the rock were monitored metrologically.

A daily measurement at up to five points per measuring cross-section was undertaken in the immediate working face area. On account of the low rate of advance, the measuring interval was increased as from roughly 30 m behind the working face. The maximum distances of the measuring cross-sections at the portal zones were restricted to 5 m in each case; in the tunnel, the gap amounted to ≤ 10 m. The outer shell was calculated and dimensioned in keeping with the finite element method. The deformations for the shotcrete shell determined accordingly were listed as permissible displacement values for the individual excavation classes.

In this connection, a warning value (2/3rds of the permissible value) was defined. It was agreed that if this warning value was reached, all involved parties were to be informed for a joint appraisal of the situation and to decide on how to proceed. It was observed that the deformations of the shotcrete shell determined in the FEM calculation were never actually attained during tunnelling. It should be noted here that for the calculation, a pre-reduction factor of the working face, i.e. a reduction of the E-module was applied. This pre-reduction value was set at 0.6.

Two main reasons are provided for the reduction. Firstly, the tunnel was initially completed back in the late 1870s. At the time, a massive masonry shell backfilled in the roof and wall areas served as the supporting structure. It seems probable that while building the tunnel, redistribution of the rock in conjunction with the formation of a protective zone around the tunnel cross-section took place.

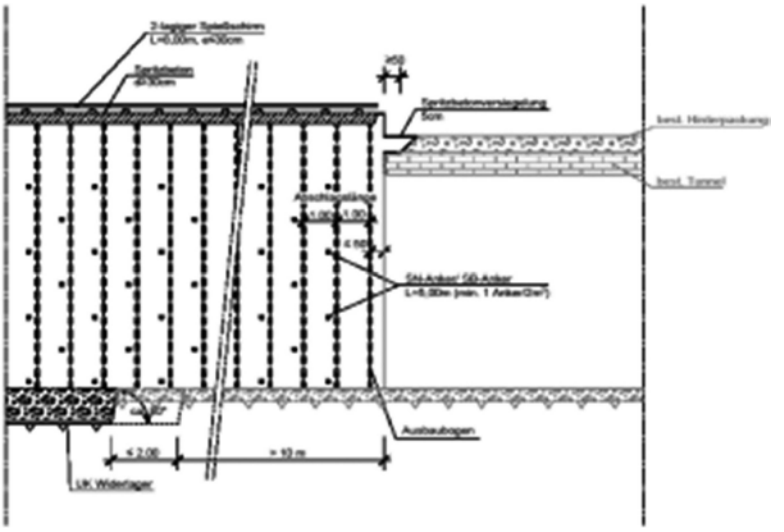

Figure 10. Excavation class 6A4 (staggered excavation of vault and abutment.

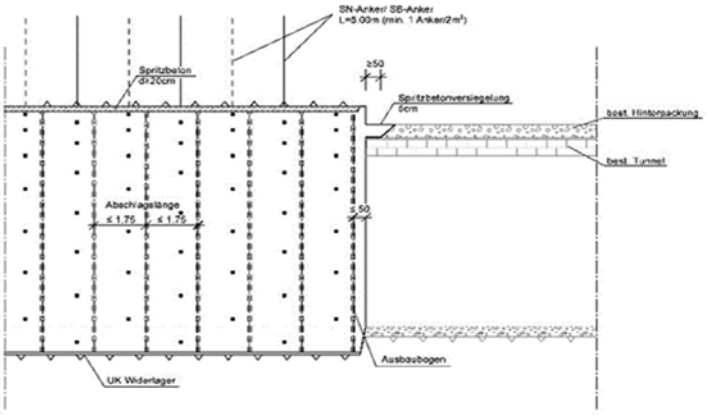

Figure 11. Excavation class 4A1 (simultaneous excavation of vault and abutment).

The tunnel enlargement by up to 3 m probably failed to change this state of tension existing in the rock to any major extent. Secondly, the geotechnical characteristic values for the rock had been so conservatively set that the determined deformations were influenced accordingly.

5 TUNNEL INNER SHELL

Once tunnelling had been completed, the reinforced concrete abutment was produced from the north portal. Then the tunnel inner shell was concreted, also using reinforced concrete. The inner shell is 40 cm thick and is produced from watertight concrete.

The block joint comprises internal FMS 350 joint strips with central hose and steel lugs. The block length amounts to ≤ 10 m in each case. A sliding layer is placed between the inner shell and the outer one. The tunnel is provided with lateral wall drainage and a longitudinal drainage system beneath the floor. After finishing the tunnel inner shell, it has to be furnished.

Towards this end, the route must be closed completely for a four-week period so that the protective housing together with the overhead line can be removed and the auxiliary

foundations as well as the central temporary track can be dismantled prior to reinstalling the overhead line and the tracks including ballast for two-track train services.

6 OUTLOOK, DISCUSSION

The pilot project was successfully completed. The experience gained shows that the method described here can also be used successfully for future tunnel renewals. More tunnels will be renovated in Germany in the next few years. However, it also turned out that some details could be solved even better. Various further investigations are currently underway.

K.S. Rao
Emeritus Professor, Department of Civil Engineering, IIT Delhi, New Delhi, India

ABSTRACT: True Triaxial Unloading (TTU) strength has utmost importance to study the actual behavior of intact rocks upon excavation as compared to traditional triaxial tests. It can be used to understand the mechanisms behind spalling and rockburst in construction of underground structures. The objective of the article is to derive unloading strength envelopes of different kinds of Indian rocks by unloading the minor principal stress (σ3), keeping the intermediate stress (σ2) constant from triaxial loading condition till failure and its influence on rockburst potential using poly axial strength testing machine at Rock Laboratory IIT, Delhi. Three different kind of rocks i. e, Jalore granite (Igneous), Makrana marble (Metamorphic) and Jodhpur sandstone (Sedimentary) were selected and tested for their triaxial loading and unloading strength envelopes in the laboratory to study the behavior of rocks under poly axial confinements. This research shows that the area between the true triaxial loading and unloading strength envelopes depict the zone of confinement in which rockburst will be observed. The results indicate that the potential of the rocks for strainburst increases with increase in separation of the failure envelopes mentioned above.

1 INTRODUCTION

Going underground is the way to the future, providing plethora of opportunities towards a faster and economical way of life. But every opportunity comes with its own set of challenges. As the structures going deep and under high stresses, the dynamic threat of rockburst, also quoted as "cancer of geomechanics" (Suorineni et al., 2014), is increasing with each step, threatening workers and equipment. Substantial research has been conducted emphasizing the mechanism and prediction of rockbursts (Akdag et al., 2020; Kaiser et al., 1996; Salamon, 1984; Zhao et al., 2014). Starinbursts are the most common type of rockbursts which occur under high overburden and low confinement (Diederichs, 2000) will be the focus of this research. Before excavation, rock is in a triaxial state of stresses in equilibrium and the stability of the rock under this stress state is estimated by true triaxial laboratory testing ($\sigma_1>\sigma_2>\sigma_3$) of rocks initially carried out by Mogi (1971) by utilizing a high pressure true triaxial test apparatus for hard rocks using rectangular prismatic specimen (Mogi, 1971). Many researchers since then improved and modified the true triaxial testing techniques and equipment realizing the influence of intermediate principal stress in the strength of the rock in in situ equilibrium condition (Chen & Feng, 2006; Wawersik et al., 1997).

Upon excavation, the principal stress in the direction of excavation axis becomes negligible and the stresses in other two directions significantly increase. These high stress concentrations increase the strain energy stored in rocks which is expelled instantaneously in the form of acoustic emissions, kinetic energy of rock fissile and seismic waves, giving rise to rockbursts in massive, strong, and brittle rocks. Li et al. (2015) depicted this mechanism in terms of radial (σ_r) and tangential stresses (σ_θ) where upon

DOI: 10.1201/9781003299127-129

excavation, radial stress on the free face is relieved completely and tangential stress increases gradually (Li et al., 2015). In conventional true triaxial tests, the study of mechanism upon laboratory true triaxial unloading of intact rocks is difficult. He et al (2010) developed a true triaxial test system through which dynamic unloading of loads from a true triaxial state in any of the principal stress direction independently (He et al., 2010). It allows to study the actual underground excavated surface behavior along with its stress state. He experimentally provided with a zone of confinement under the failure envelope where rockbursts are observed in intact rocks (Figure 1). Many researchers conducted true triaxial unloading tests on intact rocks for laboratory simulation of rockbursts and study the potential of rocks for rockbursts with acoustic emissions (He et al., 2010), infrared thermography (Sun et al., 2017), high speed cameras and decibel meters (Su et al., 2017).

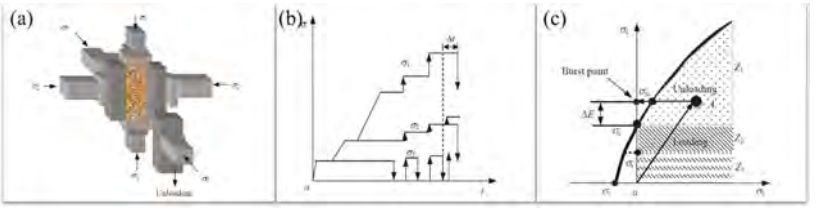

Figure 1. (a) Pictorial depiction of rockburst experiment, (b) Stress paths followed for unloading test, and (c) Zone (Z1) under H-B curve depicts the rockburst zone (He et al., 2012).

In this research, we focused on the stress state under which rockbursts will be observed in different Indian rocks by deriving the loading and unloading failure envelopes. A polyaxial testing machine designed and installed at rock laboratory IIT Delhi is used to conduct true triaxial strength testing and derive the H-B failure envelope (Rao & Tiwari, 2008). Then a series of true triaxial unloading tests have been performed under different confinement by unloading the minor principal stress axis to derive an unloading strength envelope and both have been compared to predict a rockburst zone. This study also involves the observation of free face of the rock specimen to understand the mechanical response of excavated surface of tunnels.

2 MATERIALS AND METHODS

2.1 *Sample selection*

Rajasthan is in the north-western part of India between Latitude 23°03'-30°12' N and Longitude 69° 29'- 78°17'E. It is the largest state in the country with an area of 342,239 sq. km., encompassing about 11% of the total geographical area of the country (Figure 2a). The state is the largest producer of rocks used in construction in the country, including the marble used in renowned Taj Mahal.

The three different rocks selected for the purpose of this research were Jalore granite (Igneous), Makrana marble (Metamorphic) and Jodhpur sandstone (Sedimentary) (Figure 2a). This varied selection of rocks enables us to understand the failure mechanisms in rocks with varying strength, brittleness, process of formation and granular structure. Rockburst is observed in high strength brittle rocks. Granites are igneous rocks of high strength due to the slow crystallization of minerals. SEM images shows surface morphology of granite rock with good interlocking of particles of sharp edges (Figure 2b). Irregular angular arrangement of particles gives higher strength on loading results in high capacity to store strain energy on rockburst. Marble is a metamorphic rock subjected to high pressure and temperature offering high strength. The surface morphology shows that the surface fracture marks are very rough. The particle lumps on the surface upon loading causes rough fracture on failure. The strength directly depends on the orientation of the grains. The grains are elongated and columnar as shown in Figure 2c, representing the direction of pressure acted on it in the past. Sandstones are sedimentary rocks with grain shapes semi rounded to rounded (Figure 2d). The grain boundaries are filled with clayey cementing material with ferrous minerals responsible for the red color. The strength in these rocks mostly depends on the cementation. The grain boundaries roll on over loading and utilize the energy imparted due to external loading in straining of rock. This phenomenon reduces the storage of strain energy hence the rockburst intensity is less compared to other brittle rocks.

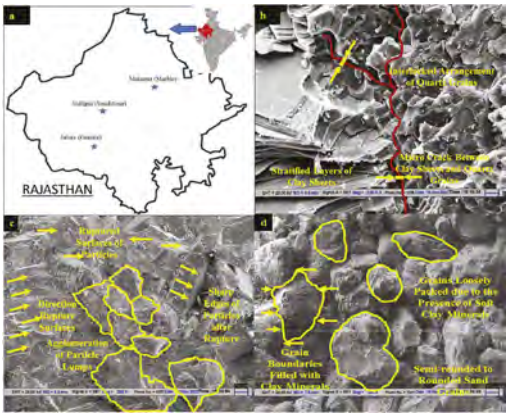

Figure 2. Rock samples selected, (a) Sites of rock collection in Rajasthan, (b) SEM image of Jalore granite, (c) SEM image of Makrana marble, and (d) SEM image of Jodhpur sandstone.

2.2 *Specimen preparation*

The specimen prepared for physical and mechanical testing after determining the number of tests required. The UCS and triaxial tests required 12 specimens of diameter 38 mm for each type of rock with L/d ratio of 2 as specified by ASTM standards C39 for cylindrical specimen. For Brazilian test 5 specimen for each rock were prepared for testing the tensile strength of the rocks. For strength testing cores were drilled from the block samples to prepare specimen with rock drilling using 38 mm drilling bit. For true triaxial unloading (TTU) tests using poly axial testing machine, rectangular prismatic specimen was required as per the machine specifications. The TTU tests were conducted on rectangular prismatic specimens of dimensions 55×55×110 mm as per the machine specifications (Figure 6a, a1, and a2).

2.3 *Polyaxial testing machine*

A servo controlled polyaxial testing machine has been designed and installed at the rock laboratory of IIT, Delhi which facilitates the loading and unloading of intact prismatic rock specimen in three different principal stress directions independently (Rao & Tiwari, 2008). The vertical loading fame can apply a load of 5000 kN through a hydraulic pumping unit, also equipped with a load cell (1000kN, sensitivity 0.1 kN) and a linear variable differential transformer (LVDT) (±20 mm, least count 0.01) for measuring load and axial deformation, respectively.

Figure 3. (a) Polyaxial testing machine installed at IIT Delhi, and (b) True triaxial loading setup of rock specimen.

The confining load is applied by a horizontal rigid frame fabricated by joining a pair of octagonal frames, can apply horizontal loads of 300 kN (Figure 3). Various plates can accommodate square and rectangular prismatic rock specimens of dimensions 55×55×110 mm, 60×60×60 mm and, 55×55×55 mm. A gap of 5 mm on each side of edges on platens are ensured for provision of

micro adjustments of platens during loading and straining of specimen. For the data acquisition three load cells and five LVDTs convert the mechanical signals into digital data through a data acquisition system and can be displayed and stored in a connected display unit.

3 TESTING OF ROCK SAMPLES

3.1 *Physical and strength testing*

The physical properties such as dry densities, porosity, void ratio, and specific gravity were determined for all rock types in their natural state following the standard IS test procedures suggested (IS13030, 1991). The specific gravity calculated as per standard procedures (IS1122, 1974). The results of the physical properties are listed in Table 1.

Table 1. Physical properties.

Property	Jalore Granite	Makrana Marble	Jodhpur Sandstone
Dry Density (g/cc)	2.78	2.84	2.16
Saturated density g/cc)	2.79	2.85	2.27
Porosity (%)	0.23	0.41	11.18
Void ratio	0.08	0.08	4.37
Specific gravity	2.85	2.67	2.62
Index quality (IQ)	99.30	98.08	87.48

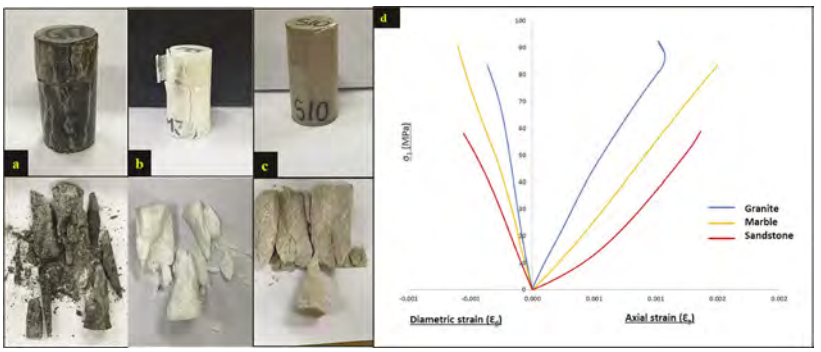

Figure 4. UCS testing, (a) Jalore granite, (b) Makrana marble, (c) Jodhpur sandstone, (d) Stress vs strain curves.

Table 2. Summary of parameters obtained from tests.

Parameters	Granite	Marble	Sandstone
UCS (MPa)	116.8	89	46.52
Elastic modulus (GPa)	78.8	55.61	41.72
Poisson's ratio	0.195	0.243	0.32
Cohesion (MPa)	17.3	11.78	7.65
Friction angle (ϕ)	52.6	55.5	50.90
σ_{ci} (MPa)	102.5	85	44.70
m	23.52	21.38	17.23
s	1	1	1

Strength characterization of rock samples is an important part of the investigation to predict the behavior of the in-situ rock mass under different stress conditions. The failure pattern and failure strains by the rock specimen hint us towards the brittleness of the sample. The

tests results are summarized in Table 2. The stress strain curves, and the failure pattern of the rock specimen are presented in Figure 4.

3.2 *True triaxial unloading (TTU) tests*

In the present research, the behavior of the rock specimen upon unloading of minor principal stress axis (σ_3) from a true triaxial equilibrium state has been observed. Here σ_1, σ_2 and σ_3 have been considered as major principal stress, intermediate principal stress and minor principal stresses respectively. For the test, rectangular prismatic specimen of rocks has been prepared with dimensions 55×55×110 mm. The cuboidal shape has less radial confinement due to the friction of the machine platens along the horizontal axis as compared to a cube specimen. Large radial stress increases the ductility of the specimen which takes the failure from strainburst to fault slip bursts (Diederichs, 2000). Figure 3b, shows the alignment of the specimen between the platens before loading. The specimen has been marked with stress directions for ease in studying the failure pattern. Before commencement of the tests, the failure envelope had to be adjusted for a rectangular prismatic specimen as the previous strength tests were performed of cylindrical specimen. There was a strength reduction of 10-20% observed in the rocks. The bigger specimen has more preexisting flaws than a smaller specimen. Also, the failure patterns observed in a prismatic specimen were mostly slabbing as the effect of slenderness is more in a larger specimen. Hence the failure envelope was derived accordingly.

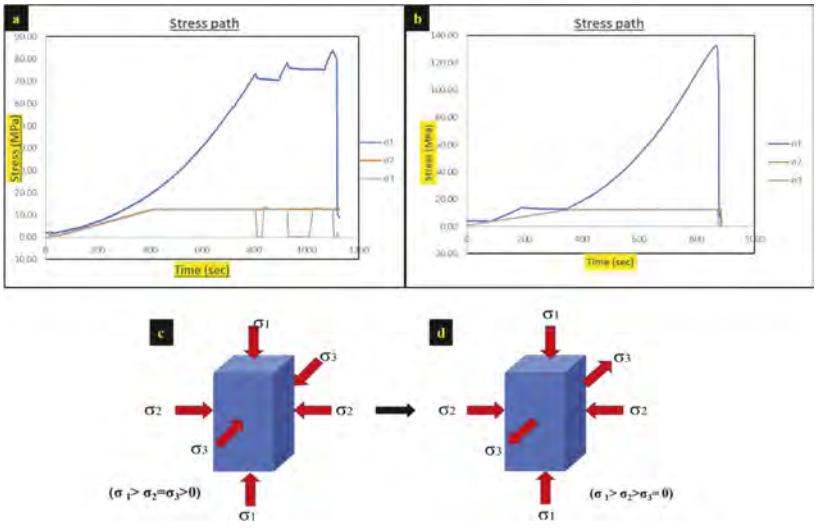

Figure 5. True triaxial unloading (TTU) test, (a) Stress path, (b) Improved confirmatory stress path, (c) Stress state before unloading, and (d) Stress state after unloading.

Stress paths were prepared from the failure envelopes and the decided confinement as shown in Figure 5. At first, all principal stress were increased simultaneously till it reaches the minimum principal stress (σ_3). After that keeping σ_2 and σ_3 constant loading for major principal stress (σ_1) was increased. The loading for σ_3 is removed from a predefined stress state as shown (Figure 5a) and kept for 120 seconds and then re applied the load if the specimen did not fail. The procedure is repeated till the failure of the specimen. Confirmatory tests were done upon improving the stress paths accordingly as Figure 5b and a minimum unloading stress state was derived at the specimen fails in the time frame (Figure 5c, d). Series of tests were done for different confinement for all three rocks and failure envelopes were prepared.

4 RESULTS AND DISCUSSIONS

4.1 *Failure pattern*

When a uniaxial load is applied on a specimen the grain boundaries tend to split in tension in the direction normal to the applied load showing brittle failure. With the increase in confinement the tensile splitting is restricted as it works against the splitting mechanism increasing the strength of the rock. In a UCS condition, there are four failure planes due to lack of confinement, the specimen tend to expand in the four unconfined face directions as shown in Figure 6b (Billings, 1972). This failure can be seen in mine pillars in case of pillar bursts.

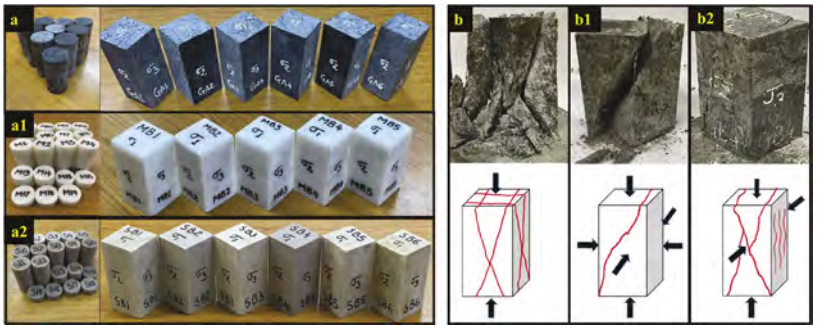

Figure 6. (a) Specimen preparation for strength testing, Jalore granite, (a1) Makrana marble, (a2) Jodhpur sandstone, (b) Effect of confinement of failure of granite specimen in UCS test (4 unconfined faces), (b1) True triaxial loading (no free face), (b2) true triaxial unloading (2 free faces).

In the true triaxial loading test the failure planes reduce to one (Figure 6b1) due to confinement from all the six faces and all the strain energy available is utilized in creation of a shear failure plane instead of tensile failure with expulsion of excess of kinetic energy giving rise to violent fault slip bursts as seen in deep mines with large confinement. In case of triaxial unloading tests, the rock tends to expand towards the unloaded faces and two failure planes form normal to the major and intermediate principal directions. On the unloaded faces, minor tensile cracks are observed. These splinters gain kinetic energy with an increase of σ1 and σ2 similar to the immediate strainbursts from excavated surface of a tunnel. (Figure 6b2).

4.2 *Failure envelopes*

He et al. (2010) identified a zone Z1 (Figure 1c) under H-B failure envelope for instantaneous rockburst and expressed a rockburst criteria in equation:

$$\Delta E = E(\sigma_{1c}) - E(\sigma_c) > 0 \tag{1}$$

Where, ΔE is the excess energy contributing towards the kinetic energy of the rockburst, E(σc) is Strain energy at UCS of the rock and E(σ1c) is the strain energy due to major principal stress. In this work, the influence of intermediate principal stress is not considered. Li et al. (2015) performed the unloading strength tests on Miluo granite, Shandong sandstone and cement mortar (Li et al., 2015). In this paper, materials were tested for both true triaxial loading (TTL) and unloading (TTU) strength and efforts have been made to compare them and identify an actual zone of confinement which depicts strainbursts considering intermediate principal stress. Figure 7a-c, show the fitted TTL and TTU curves of the three rocks.

In Figure 7(d), the plot area has been divided into three different zones. Zone U shaded in yellow above the TTL envelope depicts the unstable stress zone. In this zone, an intact rock will not be stable in situ and will utilize the stored strain energy (ΔE) in creation of cracks and

formation of new surfaces (Cook, 1965b) till a state of stress equilibrium is achieved. In the zone S depicted green shaded area under the TTU strength curve, an intact massive rock will be stable and will be able to withstand the increase in stress concentration in σ_1 and σ_2 direction due to excavation in σ_3 loading direction. The zone represented by red shading depicted as R is the zone of concern for the construction as the rock is stable till the excavation is conducted (unloading). The lower limit of the R zone closer to TTU curve is having less excess energy (ΔE) and hence the intensity of rockburst is minimum and slabbing is observed. The upper limit of the zone closer to TTL curve will be having the maximum stored strain energy (ΔE) which upon excavation will be expelled in the form of projectiles, acoustic emissions (AE), and seismic waves. This part of the stress state will produce severe violent rockbursts.

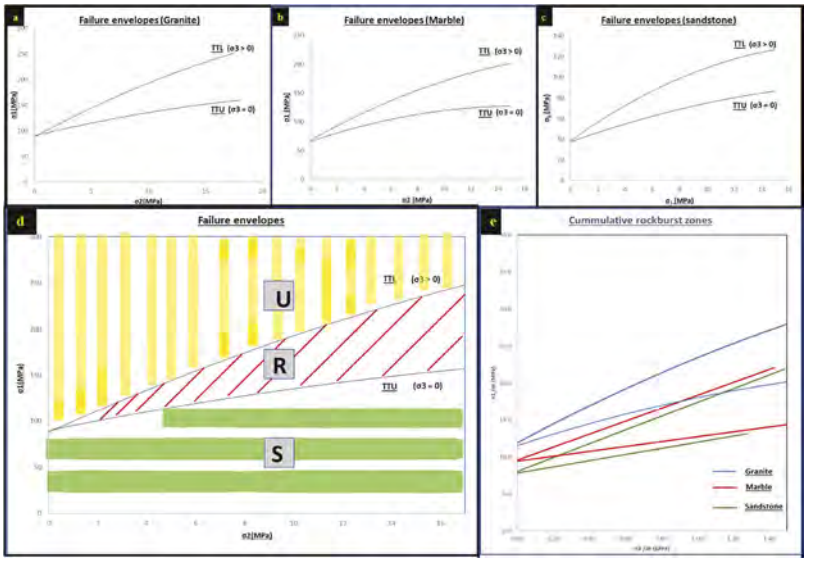

Figure 7. True triaxial loading (TTL) and unloading (TTU) failure envelopes (a) Jalore granite, (b) Makrana marble, (c) Jodhpur sandstone, (d) Stability zones for stress state, (e) Cumulative normalized rockburst zone plot.

Figure 7(e) represents the normalized rockburst zones of all three rocks by the tensile strength of the rocks (σ_t) so that the y-axis represents the brittleness of the rock. The rock with the highest σ_c/σ_t ratio displays high storage of strain energy hence more prone to rockburst. Upon cumulative plotting of the normalized curve, it is observed that when the ratio σ_3/σ_t is below 0.5, the rockburst zones of the three rocks are distant making the rockburst probability low. When this ratio is between 0.5 to 1 the curves start to overlap hinting towards medium rockburst and after this value exceeds 1 all the zones overlap. Here the probability of rock burst can be considered as the maximum

5 CONCLUSIONS

An experimental study has been conducted to identify zones of starinbursts for different Indian rocks on polyaxial testing machine designed and installed at IIT Delhi. Series of both true triaxial loading and unloading tests were conducted in attempt to understand the mechanics of strainburst. The plots of the failure curves were divided into three parts as per their stability conditions considering the effect of intermediate principal stress (σ_2). The failure patterns and rockburst potential were investigated in detail. Hence this experimental study provides a reference for the design and stability of tunnels against strainburst by deriving and comparing both the TTL and TTU curves.

ABSTRACT: Most urban tunnels are located at shallow depths which pass through stratified rockmass and are extremely vulnerable to impact loads such as falling heavy objects and projectiles. The present study aims to comprehend the behaviour and deformation pattern of twin tunnels in stratified rockmass under impact loads using finite element method (FEM) based numerical simulation. The analysis was carried out for various stratified rockmasses such as homogeneous, stratified horizontal layers of two, and three at an impact load of 20kg, 30kg, and 40kg. Deformation at the crown of a homogeneous rockmass is less than that at the spring line, and similar behaviour is observed in stratified horizontal layers of two and three. In comparison to stratified rockmass, homogeneous model exhibits the most damage and deformation. In the case of stratified horizontal layers of three, there was relatively less damage and deformation. This paper establishes that rockmass properties and formation thickness influences deformation under impact loads.

1 INTRODUCTION

Due to rising population and land scarcity, the demand for underground transportation, particularly metro tunnels in urban areas, has increased significantly. These frequently have to withstand both static and impact loads. Numerous studies on single tunnels in homogeneous rockmass have been conducted to investigate the effects of overburden, shape of tunnel, uniaxial compression, impact loading, blast loading, and varying geological conditions such as the presence of a weak interlayer and jointing orientations. Most urban tunnels are built at shallow depths and in layered rockmass. As a result, tunnels in layered rockmass must be protected from impact loading. Twin tunnels or new tunnels adjacent to existing ones can be built horizontally, vertically, or inclinedly.

Few researchers conducted an analysis for quantitative and reasonable estimation of general safety and local instability zones for underground structures such as multi-tunnels or caverns(Jiang et al., 2021). Several numerical and experimental studies (Mishra et al., 2022), (Mishra & Rao, 2017), (Sinha et al., 2021) have concentrated on single tunnels in anisotropic rockmass for various dynamic loads such as impact and blast loads. Several researchers conducted scale model studies to estimate the stability of twin tunnels with small clearances and discovered that models with wider pillars cracked under higher pressure than models with narrow pillars (Kim & Kim, 2013). A parametric study was conducted to predict the interaction of tunnel construction and piled foundations, and it was discovered that tunnelling can increase the axial and flexural loads on piles (Khabbaz et al., 2019).

The present study is an effort to understand the behavior and damage pattern of twin tunnels in stratified rockmass under impact loads using FEM-based numerical simulation.

2 GEOMETRY, MATERIALS AND METHODS

2.1 *Geometry of the model*

The current work employs finite element analysis with the ABAQUS/CAE 2017 software. The overburden depth is 5cm and pillar width is also 5cm (Figure 1a). The surrounding rockmass model measures 30cm in length, 30cm in height, and 40cm in width (Figure 1b). Twin tunnels of 5cm diameter each are extruded in the length direction. The numerical model is built with homogeneous rockmass, stratified horizontal layers of two and three, and unlined twin tunnels (Figure 1c-e).

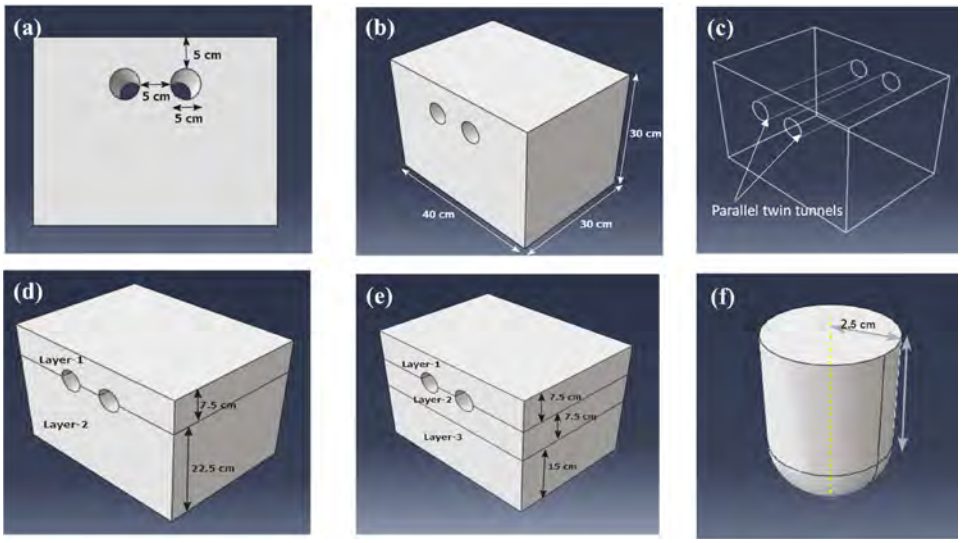

Figure 1. (a) Dimensions of tunnels, (b) Dimensions of rockmass model, (c) Alignment of tunnels (parallel twin tunnels), (d) Stratified horizontal layers of two, (e) Stratified horizontal layers of three, and (f) Hammer dimensions.

The hammer with a hemispherical nose is used to strike the twin tunnels. The hemisphere has a radius of 2.5cm and a height of 5cm (Figure 1f). The current study considered three impact hammer weight of 20kg, 30kg, and 40kg. The sizes of models have been selected as 30cm×40cm×30cm established by a boundary convergence study (Mishra, 2019).

2.2 *Model material properties*

Three geo-materials are modelled in this work, covering the spectrum of low strength rockmass. Geo-materials are synthetically modelled in the laboratory from distinct materials such as Plaster of Paris (POP), Kaolinite clay, Badarpur sand and Mica, and the resulting mixtures are known as geo-synthetic material: GM1, GM2, and GM3 (Mishra et al., 2021). Table 1 shows the composition and properties of various geomaterials. Steel hammer is used for impact loading and striking is done at the center of the top surface of the rockmass. The properties of the hammer are shown in the Table 1 (Mishra et al., 2021).

The GM3 material is used in the case of a homogeneous rockmass model (Figure 2a). Layer-1 is 7.5cm thick and made of GM3, while layer-2 is 22.5cm thick and made of GM2 (Figure 2b) and layer-1 is 7.5 cm thick and made of GM3, layer-2 is 7.5 cm thick and made of GM2, and layer-3 is 15 cm thick and made of GM3 (Figure 2c) In the case of stratified horizontal layers of two and three respectively.

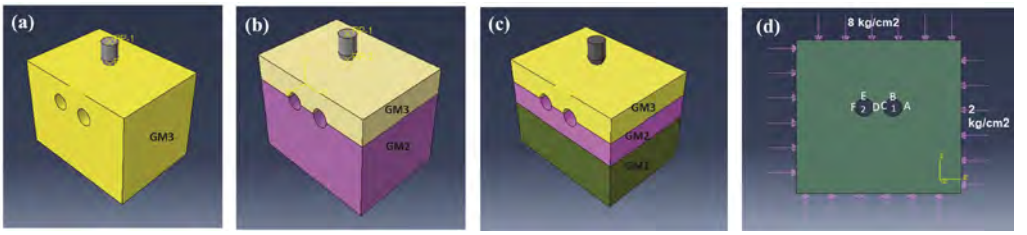

Figure 2. (a) Homogeneous model, (b) Two layered model, (c) Three layered model, and (d) Homogeneous rockmass FEM model subjected to static loading.

Table 1. Properties of geo-material and hammer (Mishra et al., 2021).

Property	GM1	GM2	GM3	Impact Hammer
Density (g/cc)	1.22	1.09	1.10	7.80
Modulus of elasticity, E_{t50} (MPa)	3675.24	2809.46	2480.84	200000
Poisson's ratio, υ	0.16	0.21	0.27	0.30
Sonic wave velocity (m/s)	1724.55	1555.16	1505.89	-
Tensile strength, σ_t (MPa)	0.97	0.59	0.35	-
Uniaxial Compressive Strength, σ_c (MPa)	3.52	1.97	1.14	-
Cohesion, c (MPa)	0.79	0.62	0.40	-
friction angle, ϕ (°)	39.12	31.40	22.65	-

2.3 *Loading, boundary conditions and meshing*

As shown in the Figure 3a, the model's base has been restrained in all directions while remaining sides and top surface are kept free. The dimensions of the rock model are considered larger than the size of the tunnel to minimize wave reflection from the boundaries (Rao et al., 2018.). The layer interaction is rough in the tangential direction and hard in the normal direction. General contact is used with the hammer. At the lower point of the hammer, a speed of 4.68m/s is employed for impact.

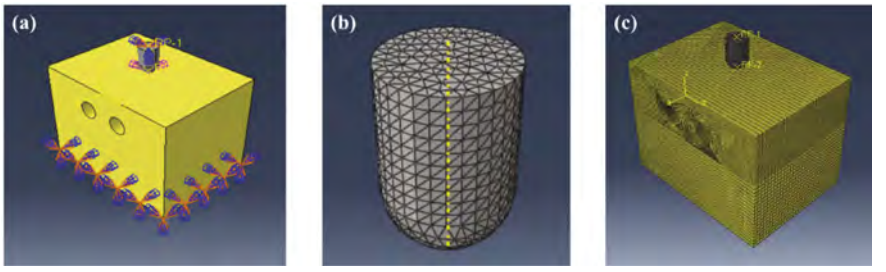

Figure 3. (a) Boundary conditions and loading, (b) Meshing of hammer, and (c) Messing of rockmass model.

The eight-node brick element (C3D8R) with reduced integration and hourglass control is used in the FE mesh for the rock model in Abaqus/Explicit. C3D8R linear hexahedral element type is used for rockmass. Linear tetrahedral elements of size 0.005 and type C3D4 are used for hammer (Figure 3b). Element sizes of various components have been established based on mesh convergence study of the finite element model. The global size of elements for rockmass is 0.01 and structured meshing technique is used (Figure 3c). The rock-mass is modelled using the Mohr-Coulomb plasticity model (Dhamne et al., 2018) whereas, hammer is modelled using linear elastic model.

3 VALIDATION

To ensure validity of the numerical modelling approach, a twin -tunnel problem was numerically modelled. It is validated using existing experimental, numerical, and theoretical results of mechanical behaviour of a twin tunnel in multi-layered formation(Chu et al., 2007). The material is made by combining different proportions of sand, plaster, and water (1.5:1:0.86), and the properties used are the same as those mentioned in the paper by Chu et al., 2007 (Figure 2d).

Table 2. Tunnel in homogeneous formations.

Points	Experimental (kg/cm^2)	FEM result(kg/cm^2)	% Error
Tunnel-1 at A	24.50	24.08	1.69
Tunnel-2 at B	26.60	25.80	3.01

It is important to note that the magnitude of stresses at different points from the numerical model (FEM model) agrees well with that of the physical model, as shown in Table 2.

4 RESULTS AND DISCUSSION

When an impact load with an impact velocity of 4.68m/s is applied at the centre of the top surface for 8 milliseconds, deformation is observed at different points. The spring line and crown (Figure 4a,b) of both tunnels are the most affected.

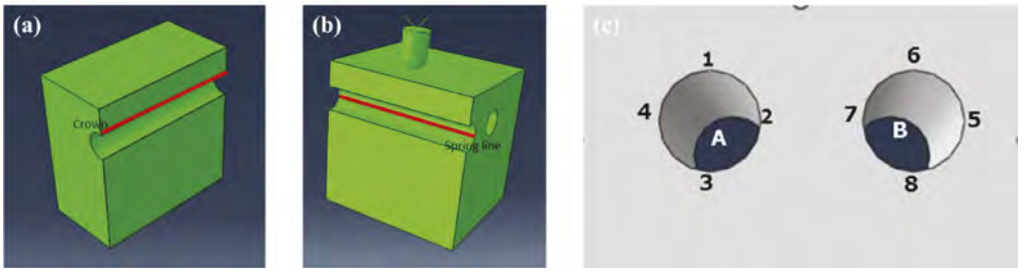

Figure 4. (a) Crown along tunnel length, (b) Spring line along tunnel length, and (c) Locations of crown (1 and 6), and spring (2,4,5, and 7) of tunnels A and B.

Due to loading and geometrical symmetry, both tunnels will have the same deformation and damage zone. Therefore, deformation is measured only in tunnel 'A' (Figure 4c).

4.1 *Homogenous*

The spring line has more deformation than the crown (Figure 5a). Deformation at the crown and spring line increases as impact energies increase (Figure 5b).

The damage zone is closer to the spring line because of the greater impact effect in this region. This material GM3 is relatively weak in comparison to GM1 and GM2, resulting in a lower modulus of elasticity and more damage and deformation. Large stress waves generated during impact will cause more damage.

4.2 *Stratified horizontal layers of two*

Deformation is greater at the spring line than at the crown (Figure 6a). As we increase impact energies, deformation at the crown and spring line increases (Figure 6b)

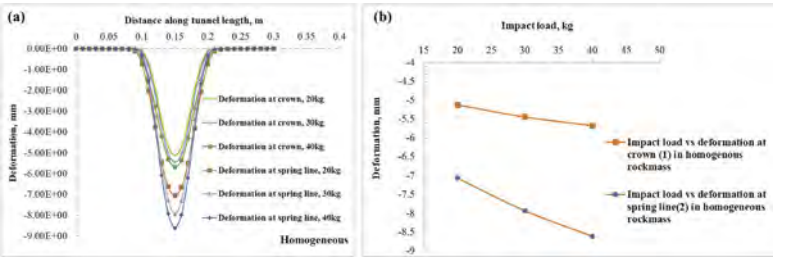

Figure 5. Deformation along tunnel length for crown and spring line, (a) Homogeneous rockmass, and (b) Impact load vs deformation.

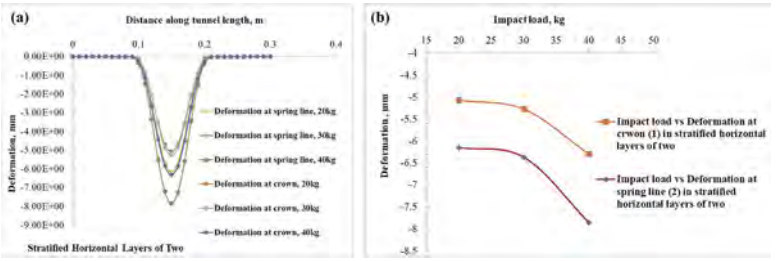

Figure 6. Deformation along tunnel length for crown and spring line, (a) Stratified horizontal layers of two, (b) Impact load vs deformation.

Comparatively weak material (GM3) is above, and hence, more deformation occurs in this layer. In stratified horizontal layers of two, the lower layer provides resistance to upper layer penetration, resulting in less deformation than in homogeneous rock mass.

4.3 *Stratified horizontal layers of three*

The spring line has more deformation than the crown (Figure 7a). As we increase impact energies, deformation at the crown and spring line increases (Figure 7b).

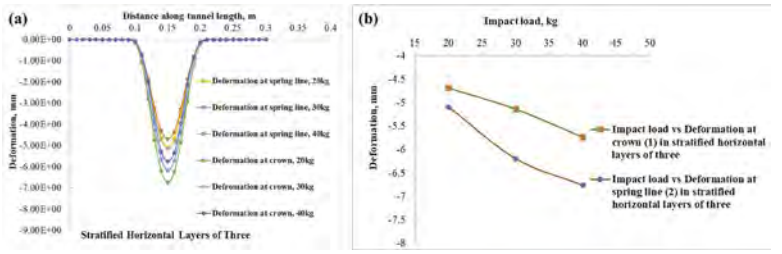

Figure 7. Deformation along tunnel length for crown and spring line, (a) Stratified horizontal layers of three, (b) Impact load vs deformation.

The effect of impact load is limited to the upper layers in this case because the other two layers provide support to the upper layer against deformation. In horizontal layering, lower layers provide more uniform resistance to upper layer deformation.

5 CONCLUSIONS

The current study is an effort to comprehend the deformation and damage in twin tunnels models under impact loading for various formations such as homogeneous rockmass,

stratified horizontal layers of two and three made of different materials (i.e., GM1, GM2, and GM3). The analysis has been carried out using finite element method.

- ✓ The results indicate that maximum deformation and damage occur at the spring line in all three cases. Deformation is less at the crown than at the spring line, and it varies between 38-52%, 20.8-24.8%, and 17.77-20.44% for homogeneous rockmass, stratified horizontal layers of two, and three, respectively.
- ✓ As the impact load is increased, deformation at both points (crown and spring line) increases in all the three cases. At crown, it varies between 4.22-6.25%, 3.94-19.35%, and 9.6-11.6%, and for spring line 8.56-12.30%, 3.57-23.23%, and 9.21-21.61% for homogenous rockmass, stratified horizontal layers of two, and three, respectively.
- ✓ Deformation at both points (crown and spring line) decreases as the number of stratified layers increases and it is 8.74-10.93% at crown and 8.93-13.88% at spring line. The reason is lower layers provide more uniform resistance to upper layers deformation.

The present study implies that the tunnels passing through weaker homogenous layer is more vulnerable to impact than the case where the tunnels pass through layered formations where weaker formation is overlain by stronger formations. The cases analyzed are useful to predict damage zone and deformation due to impact loads in existing tunnels. Deformation behavior can be predicted for different combination of impact load and number of stratified layers which will help to analyze a large amount of design problems and will help to improve the new guidelines generations. Combination of numerical and experimental study gives better understanding of tunnel behavior and tunnel designers can make engineering judgement in complex situations.

ABSTRACT: A sink hole was found at ground surface in a residential area in Tokyo in October 2020. The site was above a construction line of earth pressure balance shield tunnel with16.1 m in diameter and the crown at the depth of GL-47m. Further study revealed the dense sand layer above the tunnel has been loosened along the tunnel for about 200m length from the tunnel face.

3DFEM simulation based upon the site conditions showed a possibility of the loosing stability of the face when the ground is dense sand with little fine component.

A digital twin observational method is proposed to discuss the face stability and to keep digging safe.

1 UNEXPECTED ACCIDENT BY EARTH PRESSURE BALANCED SHIELD

1.1 *A sink hole above 47m of earth balanced pressure shield of 16.1m in diameter*

A sink hole was reported by East Nippon Expressway Co. Kanto Regional Head Office on October 18, 2020(ENE). A depression of ground surface appeared on a narrow road in front of a private house on Sunday around 12:30 October 18, 2020 in Chofu-city, Tokyo. It was reported the location was just above the tunneling site of the Tokyo Outer Ring Road (Tomei-Kan-etsu) main line tunnel (southbound). The size of the depression was 5m x 2.5m on the ground surface as shown "Sink hole" in Figure 1.

The shield had passed below the sink point with about 47m below the surface on September 14, 2020, about one month earlier than the sink hole appeared. Based upon razer scanning and seismic survey along the shield line, additional void zones were identified as shown in Figure 1.

1.2 *Loosening ground above the shield tunnel*

Based upon borings before the construction, the area was recognized as thick dense sand ground with a thin gravel layer of Pleistocene with SPT N>50 covered by alluvium soft loam Holocene layer.

After the sink was found, several borings were performed to study the geotechnical conditions. The depth distributions of the SPT, N values for these borings are shown in Figure 2. The

DOI: 10.1201/9781003299127-131

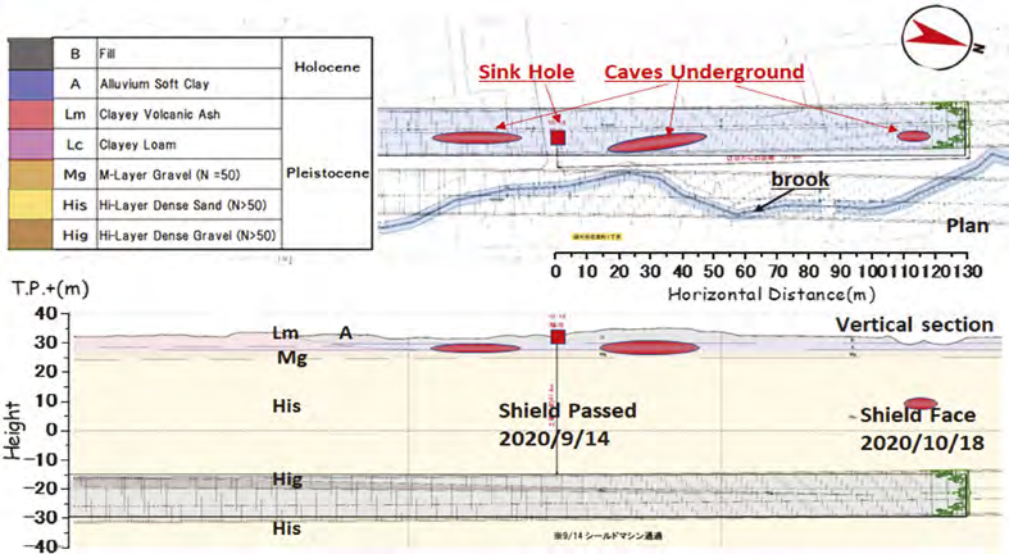

Figure 1. A sink hole and caves underground above a shield tunnel in Chofu-city, Tokyo.

N-values above the shield tunnel for the His Sand layer shows significantly decreased values compared to those before the construction. The N-values in the zone above the shield tunnel shows less than 50 (N<50) not only below the sink and the caves but also other points where no sink or cases was identified. The decreased N-values from N>50 to N<5-50 are found along the tunnel line of 200m from the face. The loosening of the dense sand ground above the shield tunnel was caused by tunneling and induced to create caves and sink holes just above the shield tunnel.

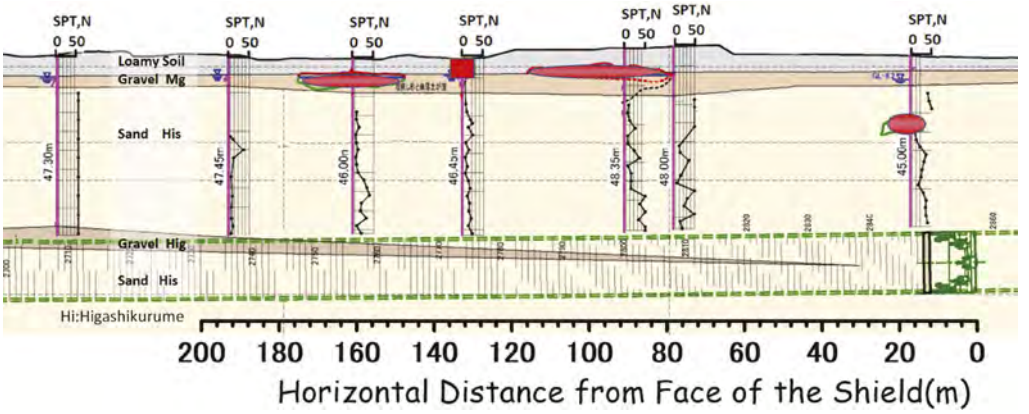

Figure 2. The loosened dense sand layer above the shield about 200m from the face.

1.3 *Chamber pressure*

To keep the stability of the face, the chamber pressure should be kept within some safety range as well as the mud in the chamber under liquid plastic state for the pressures to be distributed smoothly all over the face with a large diameter of 16.1 m.

Monitoring mud pressures in the chamber is a common practice in the earth balanced pressure tunneling. Figure 3 shows the position of the earth pressure sensors. Outer pressure sensors and inner pressure sensors were installed to monitor the chamber pressure.

Figure 4 shows earth pressure distribution near the face of shield machine. Distribution of pressures in front of the face consists of horizontal earth pressure σ_h and water pressure σ_w. On the other hand, the chamber pressure that should be balanced against the earth pressures.

1.4 *Monitored chamber pressure*

Monitored chamber pressures during the process of tunneling in the area where the sink surface and caves underground were found are plotted in Figure 5. Monitored data are found to be grouped into two types of digging and stopping phases.

The chamber pressures at the crown level are the same of the water pressure for both groups. The pressure increment with depth is 12 to 14 kN/m2 for digging phase, which is the same as the unit mass density of mud in the chamber. When the shield machine is under stopping phase, no mixing of the mud in chamber and the pressure increase with depth is the same as the density of water.

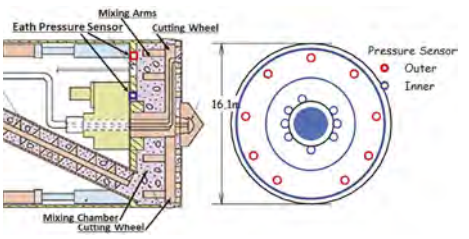

Figure 3. Positions of earth pressure sensors in chamber.

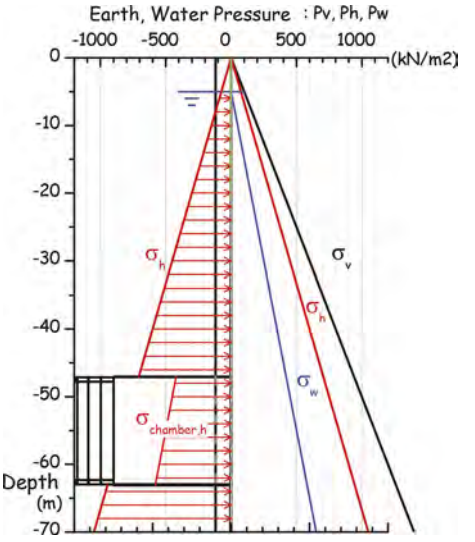

Figure 4. Earth and chamber pressures.

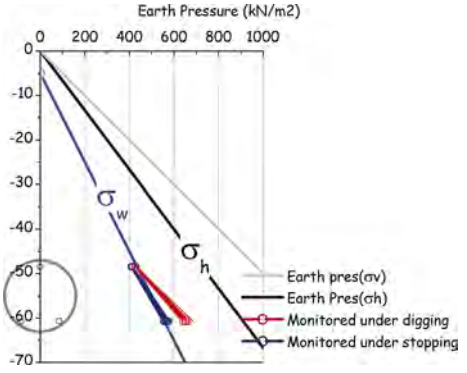

Figure 5. Monitored chamber pressures.

Table 1. Monitored chamber pressure.

Phase	Digging	Stopping
Pressure at crown(kN/m2)	38	38
dp/dz(kN/m3)	12~14	10

Water pressure at the crown = 42(kN/m2)

2 ESTIMATION OF FACE STABILITY

2.1 *Analytical model*

An analytical model for discussion of face stability of the pressure balanced shield of the site as 3D FEM model by Plaxis is shown in Figure 6. The half sectional model of the dimension of 200m in width, 100m in length, and 90m in depth.

2.2 *Properties of ground for analysis*

The ground at the level of the shield and about more than 30 m above the shield consists of dense sand or dense gravel formations of Hs and Hg which shows SPT, N>50. The internal friction angle of sand and gravel was proposed to have a relationship with SPT, N1 as shown in Figure 7 (Hatanaka). N1 is a function of SPT, N as follows,

$$N1 = N/\left(\sigma_v'/98\right)^{0.5}$$

The effective vertical stress at the mid-level of the face (d=55m) under water level of WL=GL-5m and unit mass of sand of 20kN/m3 is obtained as

$$N1 = 50/((20 \times 55 - 10 \times 50)/98)^{0.5} = 20.4$$

The internal friction angle is obtained as

$$\phi = 40^{o} \text{ for } N1 = 20.4$$

The cohesion of sand and gravel soil is a function of the contents of fine soil of clay and silt. The change of the grain size distributions which were obtained by soil test of the excavated mud soils is shown in Figure 8. The fine content of the sand layer in the loosened zone for dense sand above the shield is less than 7.5-5%. The relationship between the cohesion and the fine contents of sand and gravel soil (Kim) as shown in Table 2. The estimated cohesion is around C' = 0 (kN/m2).

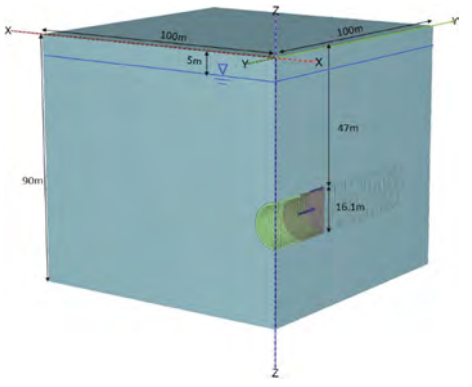

Figure 6. FEM model.

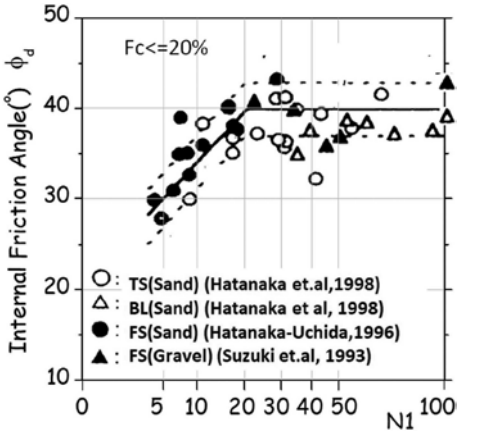

Figure 7. Relationship between N1 and friction angle.

2.3 *3D FEM simulation on face stability for stopping phase*

The force of the shield machine against the face is the sum of the thrust force and the chamber pressure. During the stopping phase of installing of tunnel segments after digging 1.6m of the

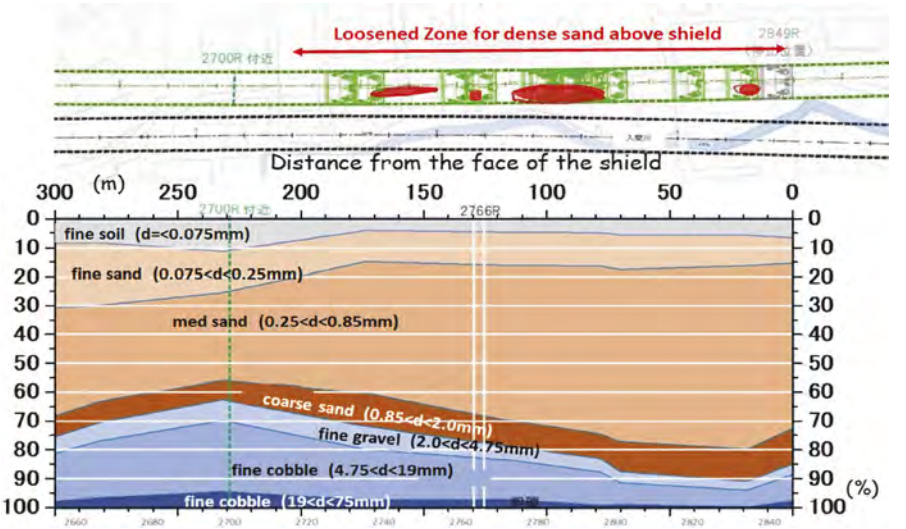

Figure 8. Change of the grain size distribution of the excavated mud.

Table 2. Cohesion of sandy soil and fine contents ratio.

Fine contents Ratio Fc(%)	10	25	40	50
Cohesion C'(kN/m2)	0.0	10.0	13.1	16.0

segment length, the monitored chamber pressure was smaller than digging phase and was used as the model pressure for the analysis.

Young's modulus is estimated as E=2800N(kN/m2), where N is a value of SPT, N for the ground and N=50 for the sand ground above the shield.

3D FEM simulation is performed for different parameters as shown in Table 3. The results for the Model F40C20 are shown in Figure 9. The yielding zone is mainly concentrated at the face and the horizontal displacement is concentrated at the center of the face. When the cohesion is greater than C≥10(kN/m2), the plastic deformation is stable. However, the cohesion is decreased to less than about C<10 (kN/m2), the plastic deformation becomes unstable, and the numerical solution was found to become uncontrolled condition of unlimited deformation. The plastic zones for C=10 (kN/m2) as stable and for C=7.5 (kN/m2) as unstable cases are shown I n Figure 10. As far as the plastics zones are concerned, the zones are rather limited very near the tunnel face, which is due to the confinement condition of the shield machine. The relationship between the cohesion of the sand layer and displacement is plotted in Figure 11.

Table 3. Ground property.

Model	E	ν	ϕ	C	dUy	stress state, stable or unstable
	(kN/m2)		(°)	(kN/m2)	(cm)	
Elastic	140,000	0.3		.	2.71	elastic
F40C40	140,000	0.3	40	40.0	4.90	plastic, stable deformation
F40C20	140,000	0.3	40	20.0	5.72	plastic, stable deformation
F40C10	140,000	0.3	40	10.0	12.5	plastic, stable deformation
F40C75	140,000	0.3	40	7.5	>24.5	plastic, unstable deformation
F40C05	140,000	0.3	40	5.0	>304.2	plastic, unstable deformation
F40C00	140,000	0.3	40	0.0	>500.	plastic, unstable deformation

In the zone of 200m from the face shown in Figure 8 and Table 2, the cohesion is expected as C=0.0. The face stability was anticipated as unstable and induced unlimited displacement for stopping phase.

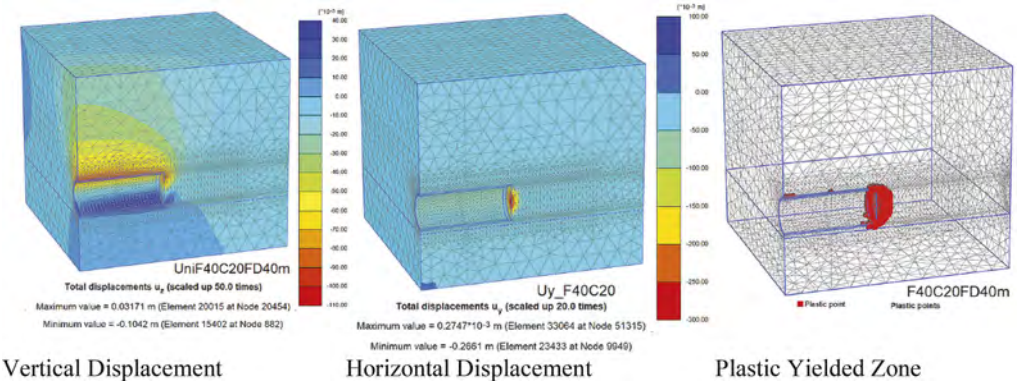

Figure 9. Results of the simulation for F40C20.

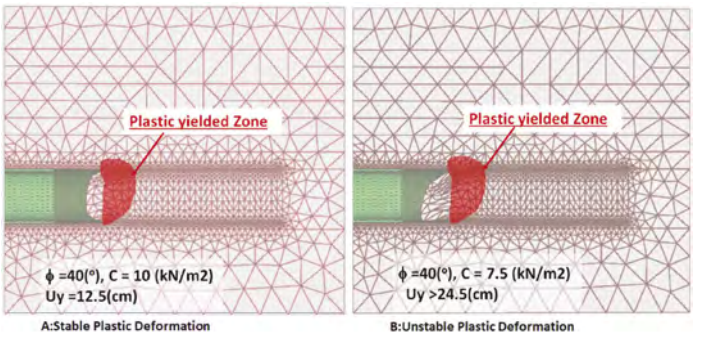

Figure 10. Stable and unstable yielded failure.

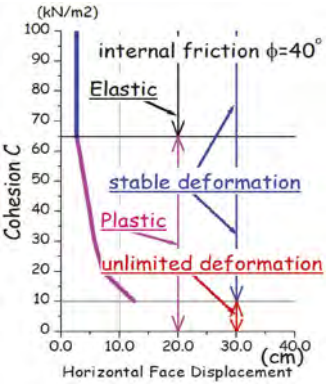

Figure 11. Face stability and cohesion.

Since no free space in front of the shield machine, the unstable plastic condition does not imply the direct failure of the face. However, Once the shield machine begins to dig, the rotation of cutting wheel easily allows for the plastic soil to come out without any control with water flow into the face, which finally results in loosening dense sand ground.

3 DIGITAL TWIN OBSERVATIONAL METHOD TO CONTROL FACE STABILITY

3.1 *Face loading/unloading tests*

To obtain proper chamber pressure for the site, face loading/unloading test may be performed. If displacement around face with changes of chamber pressure, possible sets of the geotechnical parameters of the ground can be estimated. Based upon these parameters, digital simulation can be performed and can be used to predict the shield tunnel performance. Digital observation of the shield tunneling shall be compared with digital simulation. A flow chart is shown in Figure 12 to show the general approach of the digital twin observational method to control face stability.

3.2 *Digital twin observational method*

One of the key factors for the face stability is to control the chamber pressure. Direct in-situ method and evaluation is proposed to obtain the appropriate range of the chamber pressure and to modify them by digital twin method of the Flow chart as shown in Figure 11.

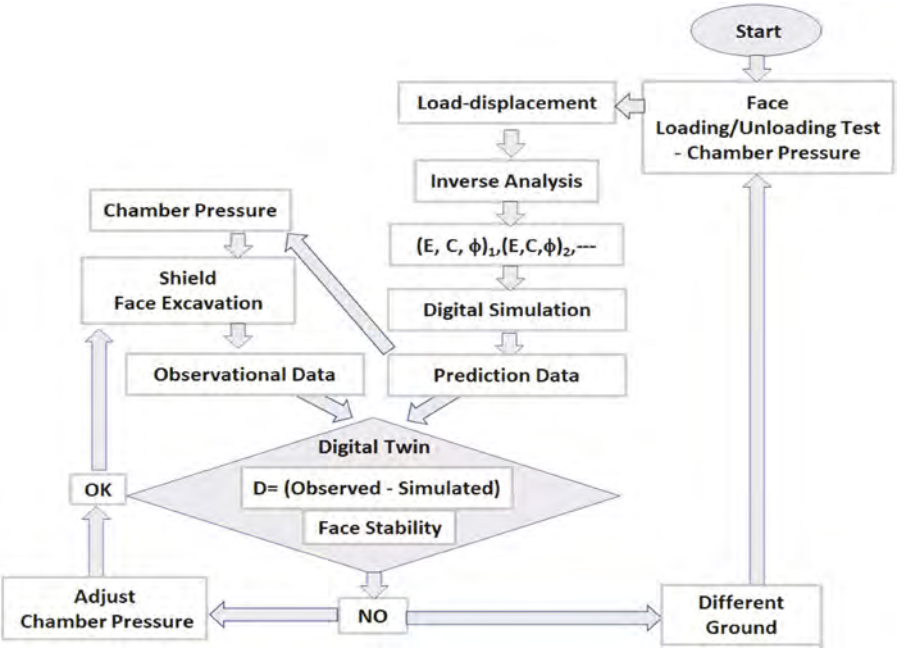

Figure 12. Flow chart of digital twin observational method.

4 CONCLUSIONS

Loosening of dense sand layer above shield tunneling for 200 m length is due to the strength characteristics of no cohesion which induced in unstable shield face and resulted in sink hole as well as caves underground. It may be estimated the appropriate range of the chamber pressure but it is much more practical and straight forwards to carry out face loading/unloading test at the site.

For the safety of face stability, digital twin observational method is proposed by face loading and face unloading tests to obtain the appropriate chamber pressure. Geotechnical parameters shall be obtained by inverse analysis for the tests and further used for simulation of tunnel performance in the next step with different boundary conditions.

Face-less tunnelling with monitoring and control system of friction cut plates

K. Komiya & M. Endo
Chiba Institute of Technology, Japan

K. Funakoshi & T. Nakamura
Uemura Engineering Co., Ltd, Japan

ABSTRACT: The Face-Less Tunnelling Method (FLTM) is a new simple tunnel construction method without a working face excavation. In FLTM, the sliding steel plate called Friction Cut Plate (FCP) is placed between a box culvert and its surrounding soil to reduce frictional forces during the jacking process of the box culvert. In this study, the FCP monitoring and control system (FMCS) that is a real time control system to fix the FCP automatically during the box culvert advancement is developed. The system restrains the FCP by monitoring the displacement of FCP and controlling tensile forces acting between control jacks and the FCP. The FCP is systematically controlled via the solenoid valve control unit while switching between high pressure and low pressure states for each control jack based on the measurement of stroke sensors. The FMCS was applied to FLTM tunnelling work in Nagano, Japan. The measured horizontal displacements of locations along the railway track due to the construction showed less than plus/minus 3 mm.

1 INTORODUCTION

The face-less tunnelling method (FLTM), is one of non-excavation methods used for constructing an underpass tunnel underneath a railway line or road without disrupting traffics for shallow earth coverage (Funakoshi, 2015). In this method, square-shaped steel elements called guide boxes are placed along the outer periphery of a box culvert into the ground across the existing railway/road to protect the tunnel face and railway/road. Subsequently, a box culvert placed behind the guide boxes is pushed forward and replaced with the box culvert in place. An advantage of this method is that it can construct an underpass tunnel with shallow earth coverage without leaving guide boxes as a protective shield in the ground. A sliding steel plate called friction cut plate (FCP) is placed between a box culvert and its surrounding soil to reduce frictional forces during the jacking process of the box culvert. Further, the FCP plays an essential role in suppressing ground deformation. The FCP needs to be fixed in the construction yard of the launch side because the drag force acts on the FCP during the advancement of the box culvert.

In order to effectively perform the box jacking operation while minimizing railroad track displacement during the advancement of the box culvert, the guide boxes incorporating automatic controlled system including the railroad track monitoring, construction operation and mitigation measures is developed.

This study presents construction cases for adopting a FCP fixing method called an automatic friction plate monitoring and control system (FMCS) comprising stroke sensors, hydraulic pumps, solenoid valve control unit, FCP control jacks and control computer. FMCS is a real time control system that automatically controls to restrain the FCP by monitoring the behaviour of the FCP and tensile forces acting between control jacks and the FCP. The FMCS is used to a FLTM construction work of a four span rectangular tunnel under passing a railway track in Nagano prefecture, Japan.

DOI: 10.1201/9781003299127-132

2 OVERVIEW OF FLTM AND FMCS

2.1 *Face-less tunnelling method (FLTM)*

The FLTM is a refined the box jacking tunnelling method and it is a simple tunnel construction method without a working face excavation.

As shown in Figure 1, the guide boxes and FCP are placed along the outer periphery of a box culvert so that soil is enclosed by these elements in the undercrossing area. Then, the guide boxes connected with the box culvert is pushed out towards the arrival side. During the advancement of the box culvert, the FCP is separated from the guide boxes and anchored to the arrival shaft to reduce friction between the box culvert and soil. After the guide boxes and soils enclosed within the guide boxes are pushed towards the arrival shaft, guide boxes are disassembled and soils are removed.

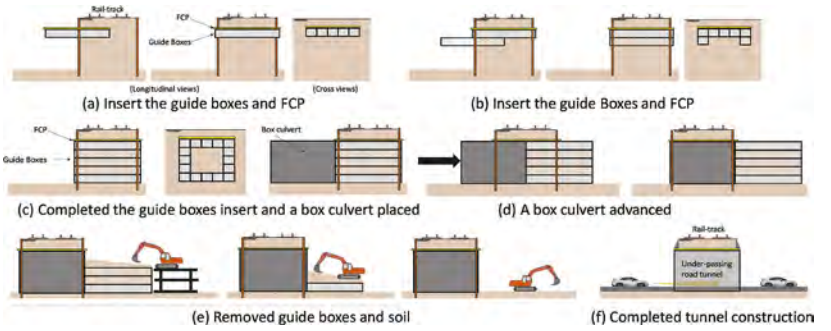

Figure 1. Schematic diagram for FLTM.

2.2 *Friction cut plate monitoring and control system (FMCS)*

FMCS is the automated control system to restrain the FCP by monitoring the displacement of the FCP and tensile forces acting between control jacks and the FCP. FMCS comprises stroke sensors to measure the horizontal displacement of FCP, hydraulic pumps, solenoid valve control unit, FCP control jacks and control computer. The FCP is automatically controlled via the solenoid valve control unit while switching between high pressure state and low pressure state for each control jack based on the measurement of stroke sensors. When the displacement of the FCP exceeds the control value defined in advance, each control jack is automatically switched to high pressure control.

In the high pressure state, the pressure required for the control jack to correct the displacement of the FCP is estimated using the dead load above the FCP. In the low pressure state, the control jack to apply constantly transmits the tensile force to the FCP during the advancement of the box culvert and to maintain the horizontal position of the FCP. In this way, FMCS repeatedly switches to the low pressure state for maintaining the horizontal position of the FCP and the high pressure sate for correcting the displacement of the FCP if it exceeds the control value.

3 FIELD INVESTIGATIONS

3.1 *Construction overview*

A construction work was conducted in Nagano prefecture, Japan. In this project, a single layer four span box culvert was constructed at the intersection of a rail track and a road. In this construction site, a total of 56 rows of guide boxes with a 12m long (3m * 4 pieces) culvert was arranged (Figure 2), and guide boxes integrated with the box culvert was moved forward. Using the FLTM, a cast-in-place RC structure with a width of 24.4 m and a height of 7.7 m was placed 0.66m deep under the earth's surface at a section of 11.604 m.

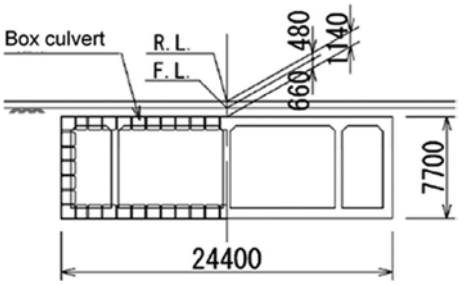

Figure 2. Cross section of box culvert.

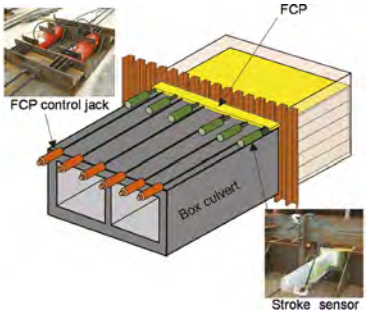

Figure 3. Schematic diagram for FLTM.

3.2 *Implementation of FMCS*

3.2.1 *FMCS equipment*

The FMCS is to restrain the FCP by measuring relative displacement of the FCP with respect to the main girder connected to the FCP using stroke sensors. The displacement of the FCP is adjusted by FCP control jacks when the FCP slides over the setting value during the advancement of the box culvert (see Figure 3).

3.2.2 *Setting value for low pressure*

A setting value for low pressure is calculated using the following equation based on the idea that the frictional resistance as the tensile force acts on the FCPs due to the dead load above the advancing box. Table 1 presents the values calculated using Equation. 1.

$$T = W \cdot A \cdot \mu \tag{1}$$

where T: Tensile force acting on FCP (kN)
W: Dead load acting on FCP (kN/m^2)
A: Top surface area of box culvert (m^2)
μ: Coefficient of friction (0.5 for assumed value)

Table 1. Calculated value of tensile force action on FCP.

	Calculated value	Note
Dead load acting on FCP: Z	20.56 kN/m^2	Railway truck structure + Earth coverage
Top surface area of box culvert: A	243.83 m^2	Width 24.4 m x Length 9.993 m
Tensile force acting on FCP: T=2,506.6 kN		

Since 12 control jacks were used in this site, the setting value for low pressure X becomes X ≧6.83 (MPa). During the construction, the value of 8 MPa was used as the initial setting and the degree of pressure was adjusted as the construction progressed.

3.3 *Horizontal displacement of railway track*

During the advancement process of box culvert, the railway line inspection was conducted to check rail gauge, vertical and horizontal level and rail distortion. Additionally, the lateral displacement of the railway track was measured at the construction site. The main purpose of this measurement was to compensate for the horizontal displacement of the railway track due to the movement of the FCP controlled by FMCS. A total of 12 measurements located 5 m apart (6 locations/railway line × 2 lines) were selected along the inbound and outbound railway lines where the box culvert crossed (Figure 4).

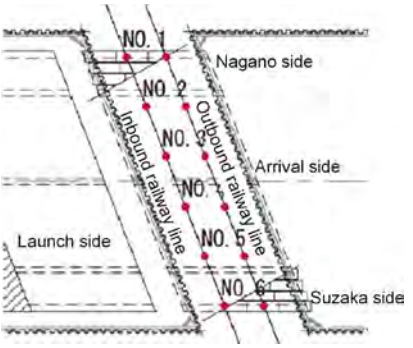

Figure 4. Measurement locations for horizontal displacement of railway track.

Table 2 lists the measurement results for the inbound railway line during the advancement process of the box culvert. Since the construction site was located within the straight railway section, the reference line of 190 mm apart from the rail was set along the railway track. The horizontal distance of the railway track for each location was measured on the basis of the reference line. The initial values presented in the table were measured before the advancement of the box culvert; these values were used as the reference values.

Table 2. Measurement results for inbound railway line during the advancement process of the box culvert.

				Before advancement (mm)		After advancement (mm)		Direction of displacement To launching side → To arrival side ←

4 CONCLUSIONS

This study described a new face-less tunnelling method with the friction cut plate monitoring and control system. The face-less tunnelling method was used to in the construction work of four span rectangular tunnel under passing a railway track in Nagano prefecture, Japan. The integrated friction cut plates were adjusted via six control jacks attached to the top of the box culvert and the railway line inspection was also conducted to check rail gauge, horizontal level and rail distortion during the advancement of the box culvert. Overall, in most of the measurement locations over 108 locations, horizontal displacements along the railway track indicated less than plus/minus 3 mm. So far, the adoption of the friction cut plate monitoring and control system can be anticipated to control displacements of the Friction cut plates and railway track effectively in the face-less tunnelling method.

The reaction of the Earth's surface to twisting and normal loads moving through the tunnel

V.N. Ukrainets, S.R. Girnis, G.A. Zhukenova & K.T. Sakanov
Toraighyrov University, Pavlodar, Kazakhstan

S.T. Mussakhanova

ABSTRACT: The problem of the action on the surface of a circular cylindrical cavity located in an elastic half-space (array) uniformly moving along its forming normal and twisting loads is solved. Dynamic equations of elasticity theory are used to describe the motion of the array. On the basis of the obtained solution, the stress-strain state of the Earth's surface is investigated under the action of axisymmetric loads of this type uniformly moving along an unsupported tunnel of shallow laying.

1 INTRODUCTION

The stress-strain state (SSS) of the earth's surface under the action of a twisting load uniformly moving along an unsupported tunnel is investigated in the article [1]. In this paper, a similar study was carried out in the case when, in addition to the twisting load, a normal load moving at the same speed acts on the tunnel. Such an impact occurs, for example, when cleaning devices are operating in a circular tunnel.

2 MATERIALS AND METHODS

The research uses the method of mathematical modeling involving models of the theory of elasticity.

Formulation and analytical solution of the problem.

For research, we will present the design scheme of the tunnel in the form of an extended circular cylindrical cavity with radius R, located in a linearly elastic, homogeneous and isotropic half-space (array), assigned to fixed Cartesian x,y,z and cylindrical r,θ,z coordinate systems, the z axis of which coincides with the axis of the cavity and is parallel to the load-free horizontal boundary of the half-space (Earth's surface), the x – axis – perpendicular to this boundary: $x \le h$ (Figure 1), where h – is the distance from the axis of the cavity to the boundary of the half–space (earth's surface). The physical and mechanical properties of the array are characterized by the following constants: v – Poisson's ratio, μ – shear modulus, ρ – density.

In the direction of the z axis, the normal $P_r(\theta, \eta)$ and twisting $P_\theta(\theta,\eta)$ loads move along the surface of the cavity with the same constant velocity c

$$\sigma_{rr}|_{r=R} = P_r(\theta, \eta), \quad \sigma_{r\theta}|_{r=R} = P_\theta(\theta, \eta), \quad \sigma_{r\eta}|_{r=R} = 0. \tag{1}$$

where $r, \theta, \eta = z - ct$ – movable cylindrical coordinate system, σ_{rj} – components of the stress tensor in the array, $j = r, \theta, \eta$.

DOI: 10.1201/9781003299127-133

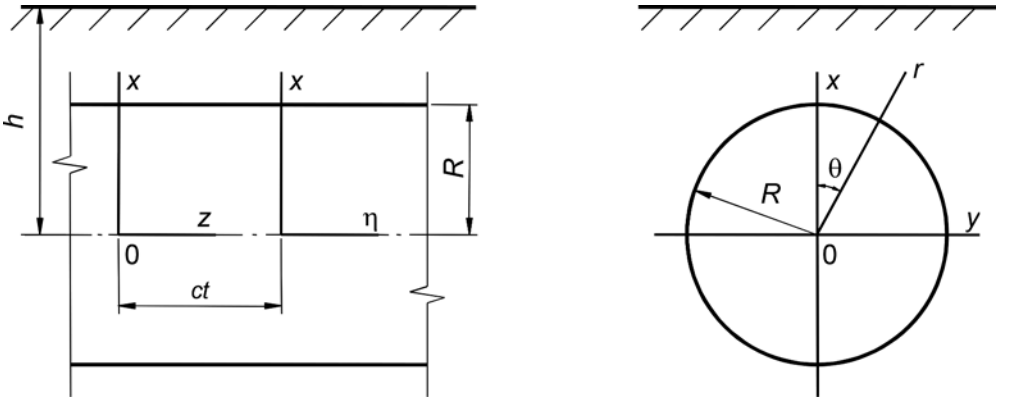

Figure 1. Design diagram of an unsupported tunnel.

Since the boundary of the half-space is free of loads, then, for $x = h$

$$\sigma_{xx} = \sigma_{xy} = \sigma_{x\eta} = 0 \tag{2}$$

To describe the motion of the half-space, we use the dynamic equations of the theory of elasticity in a moving coordinate system [2]

$$\left(M_p^{-2} - M_s^{-2}\right)\text{grad div}\mathbf{u} + M_s^{-2}\nabla^2\mathbf{u} = \partial^2\mathbf{u}/\partial\eta^2, \tag{3}$$

where $\mathbf{u}$ – displacement vector of elastic medium; $M_p = c/c_p,\ M_s = c/c_s$ – Mach numbers, $c_p = \sqrt{(\lambda + 2\mu)/\rho},\ c_s = \sqrt{\mu/\rho}$ – velocities of expansion-compression and shear waves in the medium, $\lambda = 2\mu\nu/(1 - 2\nu)$, ∇^2 – Laplace operator.

We transform equation (3) by expressing $\mathbf{u}$ in terms of Lame potentials [3]

$$\mathbf{u} = \text{grad}\,\varphi_1 + \text{rot}\left(\varphi_2\mathbf{e}_\eta\right) + \text{rot}\,\text{rot}\left(\varphi_3\mathbf{e}_\eta\right), \tag{4}$$

where $\mathbf{e}_\eta$ – ort of the η axis.

It follows from (3) and (4) that the Lame potentials φ_{jj} satisfy the equations

$$\nabla^2\varphi_j = M_j^2\frac{\partial^2\varphi_j}{\partial\eta^2},\ j = 1,\ 2,\ 3,$$

where $M_1 = M_p,\ M_2 = M_3 = M_s$.

Applying the Fourier transform with respect to η to the last equations, we obtain

$$\nabla_2^2\varphi_j^* - m_j^2\xi^2\varphi_j^* = 0,\ \ j = 1,\ 2,\ 3, \tag{5}$$

where ∇_2^2– two-dimensional Laplace operator, $m_j^2 = 1 - M_j^2,\ m_1 \equiv m_p,\ m_2 = m_3 \equiv m_s$, $\varphi_j^*(r, \theta, \xi) = \int\limits_{-\infty}^{\infty}\varphi_j(r, \theta, \eta)\ e^{-i\xi\eta}d\eta$.

By expressing the components of the stress-strain state of the medium through the Lame potentials and applying the Fourier transform according to the η, it is possible to obtain expressions for stress σ_{lm}^* and displacement u_l^* transformants in cylindrical $(l, m = r, \theta, \eta)$ and Cartesian $(l, m = x, y, \eta)$ moving coordinate systems as a function of φ_j^*. To determine the stress-strain state of the array, you need to find φ_j^*.

If we limit ourselves to the case when the speed of movement of loads is less than the speed of propagation of shear waves in the array ($c < c_s$), then $M_s < 1$ $(m_s > 0)$ and the solutions of equations (5) can be represented as follows [2]

$$\varphi_j^* = \Phi_j^{(1)} + \Phi_j^{(2)}, \tag{6}$$

where $\Phi_j^{(1)} = \sum\limits_{n=-\infty}^{\infty} a_{nj} K_n(k_j r)\, e^{in\theta}$,

$\Phi_j^{(2)} = \int\limits_{-\infty}^{\infty} g_j(\xi,\zeta) \exp\left[iy\zeta + (x-h)\sqrt{\zeta^2 + k_j^2}\right] d\zeta$.

Here $K_n(k_j r)$ – MacDonald functions, $k_j = m_j\xi$; $g_j(\xi,\zeta)$, a_{nj} – unknown, to be determined, functions and coefficients, j = 1,2,3.

It follows from [2] that when representing potentials in the form (6), expressions for transformants of potentials in the Cartesian coordinate system have the form

$$\varphi_j^* = \int\limits_{-\infty}^{\infty} \left[\frac{e^{-xf_j}}{2f_j} \sum_{n=-\infty}^{\infty} a_{nj}\Phi_{nj} + g_j(\xi,\zeta) e^{(x-h)f_j}\right] e^{iy\zeta} d\zeta, \tag{7}$$

where $f_j = \sqrt{\zeta^2 + k_j^2}$, $\Phi_{nj} = \left(\frac{\zeta + f_j}{k_j}\right)^n$, $j = 1, 2, 3$.

The functions $g_j(\xi,\zeta)$ are expressed in terms of coefficients a_{nj} from the boundary conditions (2), rewritten for voltage transformers taking into account (7). To do this, it is necessary to allocate the coefficients at $e^{iy\zeta}$ and equate them, due to the arbitrariness of y to zero. Then:

$$g_j(\xi,\zeta) = \sum_{k=1}^{3} \frac{\Delta_{jk}}{\Delta} e^{-hf_k} \sum_{n=-\infty}^{\infty} a_{nk}\Phi_{nk},\ j = \ 1,\ 2,\ 3. \tag{8}$$

Here $\Delta = \left(2\rho_0^2 - \beta^2\right)^2 - 4\rho_0^2\sqrt{\rho_0^2 - \alpha^2}\sqrt{\rho_0^2 - \beta^2}$, $\alpha = M_p\xi$, $\beta = M_s\xi$, $\rho_0^2 = \xi^2 + \zeta^2$. The type of algebraic complements Δ_{jk} is defined in [2].

It should be noted that $\Delta(\rho_0)$ – is the Rayleigh determinant, which, as is well known, has two real roots: $\pm\rho_R = \pm\xi M_R$. Here $M_R = c/c_R$ – Mach number, c_R – Rayleigh surface wave velocity ($c_R < c_s$) in an elastic half-space. Since the corresponding $\pm\zeta_R = \pm\xi\sqrt{M_R^2 - 1}$, Z, then $\Delta(\rho_0)$ does not turn to zero on the real axis if $M_R < 1$, or $c < c_R$ (Dorelean speeds of movement of loads). In this case, all integral functions in (6) are continuous and tend to zero rather quickly at infinity. Therefore, integrals exist and satisfy the conditions of attenuation at infinity. To calculate integrals (7), you can use one of the numerical integration methods, having previously determined the coefficients a_{nj}.

For $c < c_R$, taking into account (8), the relations (7) will take the form

$$\varphi_j^* = \int\limits_{-\infty}^{\infty} \left[\frac{e^{-xf_j}}{2f_j} \sum_{n=-\infty}^{\infty} a_{nj}\Phi_{nj} + e^{(x-h)f_j} \sum_{k=1}^{3} \frac{\Delta_{jk}}{\Delta} e^{-hf_k} \sum_{n=-\infty}^{\infty} a_{nk}\Phi_{nk}\right] e^{iy\zeta} d\zeta. \tag{9}$$

Using the known decomposition $e^{ikr\cos\theta} = \sum\limits_{n=-\infty}^{\infty} i^n J_n(kr) e^{in\theta}$, can get $\exp\left[iy\zeta + (x-h)\sqrt{\zeta^2 + k^2}\right] = \sum\limits_{n=-\infty}^{\infty} I_n(kr) e^{in\theta} \left(\frac{\zeta + \sqrt{\zeta^2 + k^2}}{k}\right)^n e^{-h\sqrt{\zeta^2 + k^2}}$ and, using (8), represent (6) in a cylindrical coordinate system:

$$\phi_j^* = \sum_{n=-\infty}^{\infty} \left[a_{nj} K_n(k_j r) + b_{nj} I_n(k_j r)\right] e^{in\theta},$$

where $b_{nj} = \sum\limits_{k=1}^{3} \sum\limits_{m=-\infty}^{\infty} a_{mk} A_{nj}^{mk}$, $A_{nj}^{mk} = \int\limits_{-\infty}^{\infty} \frac{\Delta_{jk}}{\Delta} \Phi_{mk}\Phi_{nj} e^{-h(f_k + f_j)} d\zeta$.

The coefficients a_{nj} Z are found from the boundary conditions (1), rewritten as

$$\sigma^*_{rr}\big|_{r=R} = P^*_r(\theta,\xi), \cdots \sigma^*_{r\theta}|_{r=R} = P^*_\theta(\theta,\xi), \quad \sigma^*_{r\eta}|_{r=R} = 0,$$

where $P^*_j(\theta,\xi) = p_j(\theta)p^*_j(\xi)$, $p_j(\theta) = \sum\limits_{n=-\infty}^{\infty} P_{nj}e^{in\theta}$, $p^*_j(\xi) = \int\limits_{-\infty}^{\infty} p_j(\eta)\, e^{-i\xi\eta}d\eta$, $j = r, \theta$.

When the coefficients of the Fourier-Bessel series are equated at $e^{in\theta}$, an infinite system of linear algebraic equations with a determinant of normal type is obtained, for the solution of which the reduction method or the method of successive reflections (approximations) can be used [2]. Moreover, as calculations show, the determinant of this system can turn to zero only when $c \geq c_R$.

After determining the coefficients a_{nj}, applying the inverse Fourier transform to the displacement and stress transformants, it is possible to calculate the components of the stress-strain state of the array in cylindrical and Cartesian coordinate systems.

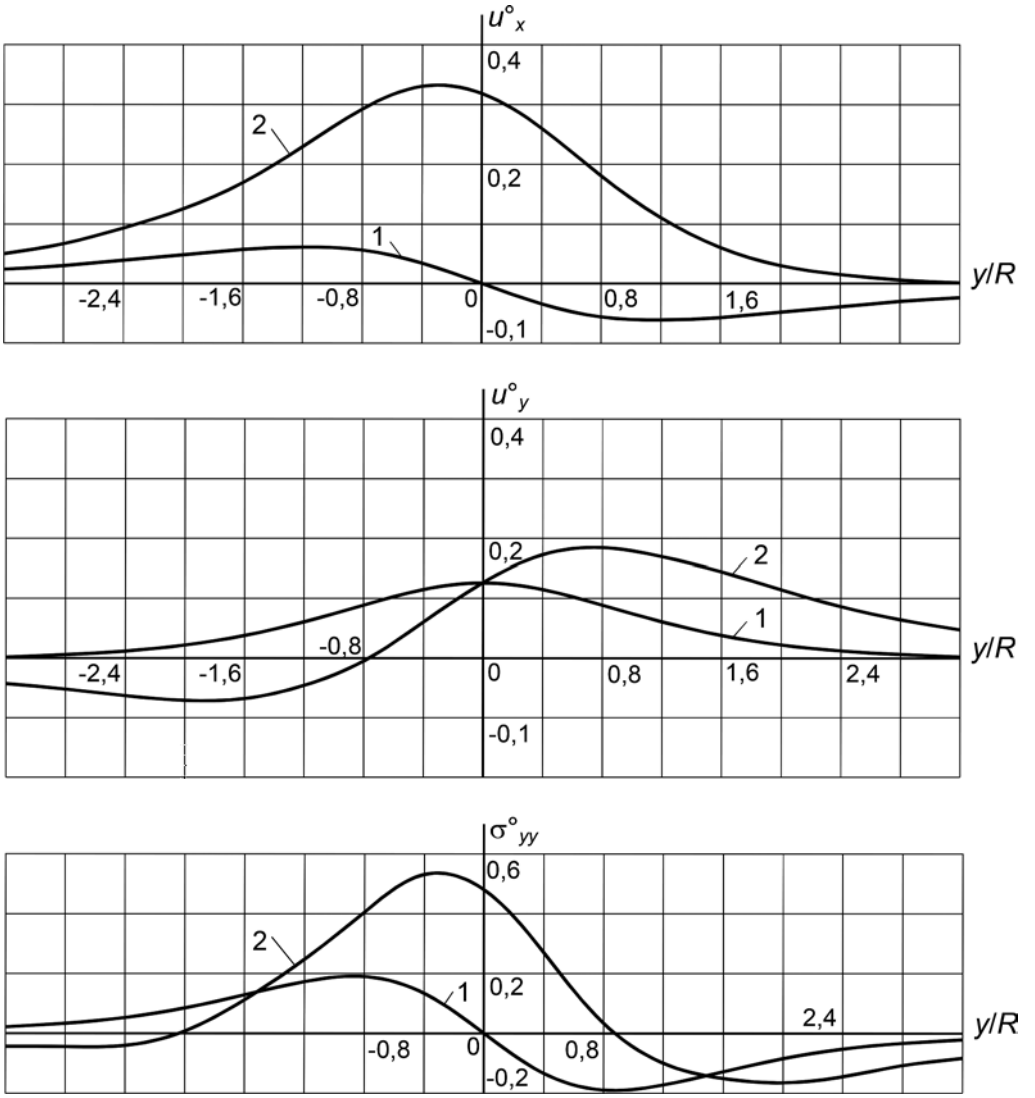

Figure 2. Change u°_x (м), u°_y (м) and σ°_{yy} on the Earth's surface in the coordinate plane xy (η=0).

3 RESULTS AND DISCUSSION

To study the dynamic effect of the loads discussed above on the stress-strain state of the Earth's surface, consider a circular cylindrical tunnel with a radius of R = 1 m and a depth of laying $h = 2R$ H in a siltstone massif (ν = 0,2, μ = 2,532·10^9 Pa, ρ =2,5·10^3 kg/m^3, c_p = 1643,4 m/c, c_p = 1643,4 m/c, c_R=917 m/c).

Axisymmetric compressive normal P_r and twisting P_θ loads of intensity q (Pa), uniformly distributed over the tunnel surface in the interval $|\eta| \leq l_0 = 0,2R$ Z=G, move in the direction of the z Y axis with a constant Dornel velocity c = 100м/с. The intensity q of each of the loads is selected in such a way that the total load along the entire length of the loading section $2l_0$ is equal to the equivalent concentrated ring load intensity $P^{\circ\circ}$ (N/m), that is, $q=P^{\circ\circ}/2l_0$.

Let 's introduce the notation: $u_x^\circ = u_x\mu/P^\circ(\text{M})$, $u_y^\circ = u_y\mu/P^\circ(\text{M})$, $\sigma_{yy}^\circ = \sigma_{yy}/P^\circ$, where $P^\circ = P^{\circ\circ}$/m (Pa).

Figure 2 shows the curves of change u_x° (м), u_y° (м) and σ_{yy}° on the Earth's surface in the coordinate plane xy (η=0). Curves 1 correspond to the action of a twisting moving load only on the tunnel, curves 2 correspond to the joint action of moving twisting and compressing normal loads.

As follows from the analysis of the behavior of curves, with the combined action of twisting and compressing normal moving loads on the tunnel, the maximum displacements and stresses on the earth's surface are significantly greater than with the action of twisting loads alone. Therefore, in the case of calculating the stress-strain state of the Earth's surface on the load from the work of cleaning devices moving along the axis of the tunnel and rotating relative to it, it is possible to represent their impact on the tunnel as a moving twisting load only when the pressure exerted on its surface is much less than the intensity of the twisting load.

4 CONCLUSION

In a strict mathematical formulation, the problem of the action of normal and twisting loads uniformly moving along its generatrix on the surface of a circular cylindrical cavity located in an elastic half-space is solved. The solution obtained for the Dorelev speeds of the movement of loads and the software package developed on its basis allows using mathematical modeling methods to study the dynamics of the rock mass under the influence of these loads at different depths of the tunnel laying.

Assessment of the state of ventilation of high-Mountain Road Tunnels in Kyrgyzstan

S.U. Isagalieva & Zh.M. Ganiev
Kyrgyz Mining and Metallurgical Institute named after Academician U. Asanaliev at the Kyrgyz State Technical University named after I. Razzakov, Bishkek, Kyrgyzstan

ABSTRACT: The article describes the current state of ventilation of high-mountain road tunnels at the Too-Ashuu and Kok-Art passes. The natural factors affecting the mode of air movement through automobile tunnels in high altitude conditions are indicated. The features of the conditions of the highlands are extremely peculiar and are distinguished by a complex relief, a sharp change in climate and seismicity. An assessment was made of ventilation systems for automobile tunnels, based on the actual flow of vehicles today. As a result of the tunnel ventilation calculation, the amount of air required to ensure normal movement through the tunnel, it is necessary to switch to a more efficient way of ventilating high-mountain road tunnels. Safe, productive and high-quality ventilation is one of the main conditions for the operation of road tunnels. Tunnel traffic must be safe, comfortable and reliable.

The territory of Kyrgyzstan covers powerful mountain systems like the Tan Shan and Pamir. Almost 60% of the country's territory is located more than 1500 meters above sea level, with complex types of relief and a rarefied atmosphere. Currently, over 95% of domestic transportation in Kyrgyzstan is provided by passenger and freight vehicles. Roads connecting individual regions of the country pass through high mountain passes such as Too-Ashuu, Ala-Bel, Otmok, Kok-Art, Dolon and others.

At present, the Bishkek-Osh road is the only road in the country connecting the north with the south. In fact, it connects the capital with the western, southwestern and southern regions to maintain the economic, social and political integrity of the country.

On 129-132 km of the Bishkek-Osh highway, the K.Kolbaev tunnel passes on the Too-Ashuu lane. Its construction began in 1957, and it was commissioned in 1964. The tunnel will be 58 years old this year. The tunnel was reconstructed for the first time in 2001 and for the second time in 2003. In addition to the Kolbaev tunnel, four more tunnels have been constructed on the Bishke-Osh highway in the area between the city of Kara-Kul and Tash-Kumyr. Unlike the Kolbaev tunnel, these tunnels have a small length, and they are ventilated due to natural traction. The parameters of the road tunnels of the Bishkek-Osh highway are given in Table 1.

In 2014, the construction of an alternative North-South highway began. The construction of an alternative North-South route along the route Balykchi-Kochkor-Chaek-Aral-Kazarman-Jalal-Abad, 433 kilometers long, with the acquisition of a place by Kyrgyzstan, independence determines the place as the country's top priority project, 200 kilometers along these roads pass through where there are no transport messages. The total cost of the project is estimated at 850 million dollars.

The benefits that the Kyrgyz Republic will receive from the construction of the alternative North-South road are as follows:

1. An additional continuous road transport route will be created between the North and South of the country, which is geographically separated from the existing Bishkek-Osh

DOI: 10.1201/9781003299127-134

route by the mountain range. This route will run at a great distance from the line of state borders with neighboring states, which is important for the country's security.
2. Access to mineral deposits and development of land and agricultural land in Toguz-Toro, Ak-Tala, Jumgal, Kochkor regions will be provided, which is of great interest to the local population and investors who are interested in processing agricultural products.
3. The connection of this road with the roads of Kazakhstan and Russia in the north of the country and Tajikistan in the south will create a through transit along the route Russia-Kyrgyzstan-Tajikistan, which is of particular relevance to fulfilling obligations within the CIS, the Eurasian Economic Union, the CSTO and the Customs Union.

The automobile tunnel is located on the Kok – Art pass at an altitude of 2500 meters above sea level. The tunnel will be 3890 meters length, 10 meters width, and 9 meters height. The tunnel com-plex includes a road tunnel with a longitudinal service (multifunctional) tunnel. Upon completion, the tunnel will be the longest tunnel in Kyrgyzstan. Completion is planned by the end of 2022, and it is planned to be commissioned in 2023. Figure 1 shows a map of the main operating and alternative highway of Kyrgyzstan.

The problem associated with the ventilation of the Kolbaev automobile tunnel is important because of its strategic location and because it is the only road that currently connects the regions of the country. Almost 60 years have passed since the operation of the tunnel, the tunnel ventilation project was not designed for the flow of cars that we see to-day. According to the project, the tunnel is intended for the passage of passenger cars and small trucks, but now numerous multi-ton trucks are moving along it. In 2001, after reconstruction, 11 jet fans were installed in the tunnel by Samsung company (see Reconstruction of the K. Kolbaev tunnel. 1999). The fans are located in the roof of the tunnel as shown in Figure 2. After 12 years in 2013, the fans were replaced with new fans by The best company, but the ventilation system remained the same. The technical characteristics of the fan SDS-7,1-2P-6-30 are given in Table 2.

Table 1. Parameters of road tunnels of the Bishkek-Osh highway.

		Tunnel parameters		
Tunnel name	Location	Length, m	Height, m	Width, m
Tunnel named after K.Kolbaev	At 129-132 km of the Bishkek-Osh highway to the pass Too-Ashuu pass 3201 m above sea level	2510	5	6,2
Tunnel #1	On 409 km of Bishkek-Osh highway, Jalal-Abad region, Kara-Kul city	313	5,5	8,4
Tunnel #2	On 410 km of Bishkek-Osh highway Jalal-Abad region	355	5,5	8,4
Tunnel # 3	On 427 km of Bishkek-Osh highway Jalal-Abad region	694	5,5	8,4
Tunnel # 4	On 455 km of Bishkek-Osh highway, Jalal-Abad region, Tash-Kumyr city	260	5,5	8,4

Table 2. Technical characteristics of the fan.

Fan Type	SDS-7,1-2P-6-30
Air flow, m3/s	16,5
Engine rotation speed in min, rpm	2900
Output air velocity, m/s	41,6
Engine power, kW	30
Food	380v/50Hz
Wire cross section (copper)	3/14
Release date	2012/08

The calculation of emissions of pollutants from vehicles located in the tunnel is carried out according to the value adopted for 2010 (see Code of Rules. 2017).

Emissions Q of pollutants CO, (in terms of), g/h, and soot,, for light cars and light trucks with gasoline and diesel engines are calculated by the formula

$$Q = q \cdot f_h \cdot f_\tau \cdot f_{cm} + q_{BB} \quad (1)$$

where $q_{баз}$ = the basic value of CO and soot emissions for passenger cars and light trucks with gasoline and diesel engines, depending on the average speed and road slope of tunnel i, g/h or (see appendices A-B) (see Code of Rules. 2017);

$q_{вв}$ = emissions of suspended particles formed as a result of the destruction of the road-way, brake pads, (see appendix D) (see Code of Rules. 2017).

The correction factor is determined according to appendix D (see Code of Rules. 2017).

Then Q=192,8·1,0·1,0·1,5+0,56=289,76 g/h.

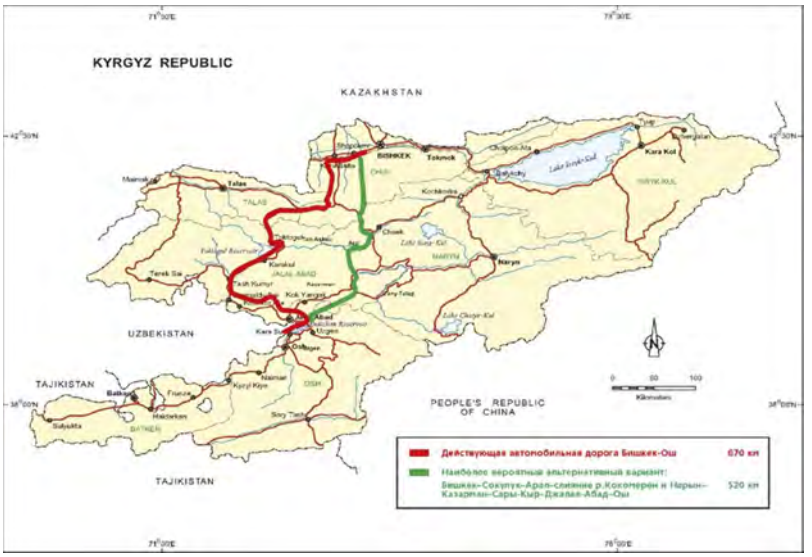

Figure 1. Map of the main highways of Kyrgyzstan.

Gas contamination inside the tunnel occurs due to a large flow of trucks that are passed unilaterally due to the size. When trucks enter the tunnel against the natural draft of the air inside the tunnel, trucks pull the gas blown by fans in the opposite direction and create an obstacle for timely cleaning of the air inside the tunnel. Due to the large flow of motor vehicles, namely trucks, they are passed along the reverse direction Bishkek-Osh-Bishkek. When trucks pass through the tunnel, exhaust gases are emitted in the tunnel. Since the traffic in summer time per day is from 3500 cars to 4500 cars per day, and in winter from 1500 cars to 2500 cars. There is clearly an excess of the maximum permissible concentration of carbon monoxide in the tunnel. Driving through it, drivers must necessarily close the windows and turn off the air conditioners. If the CO norm is exceeded by 17%, a gas contamination sensor is triggered in the tunnel in these cases, the tunnel service operators stop the cargo vehicles, thereby turning on the fans to output exhaust gases in the direction of the wind to output exhaust gases from the tunnel, these cases create long traffic jams of trucks on several serpentines of the highway pass, thereby creating inconvenience to other motor vehicles. the funds move freely.

Having studied the disadvantages of this method of ventilation, we have considered the main ones available. The first drawback in the tunnel is there is no clear separation of polluted air from fresh, the second is the suction and blowing of air occurs through the same channel, that is,

through the tunnel, clean and polluted air are mixed. Since jet fans are in-stalled, they supply the same amount of air that they receive from the outside. The third disadvantage is the wind rose, winds blow from both portals in the mountainous area, due to the lack of a third exit in the tunnel, frequent air reversal occurs, and a stagnant zone forms inside the tunnel.

The fourth disadvantage is the sequential ventilation connection (see Figure 2). With such a connection, each fan passes the same amount of air that it receives from the previous one, because of this we have a smaller amount of air for a larger amount. If one of the intermediate fans fails, the ventilation system is disturbed and a stagnant zone is formed.

The power of each of the 11 fans is 30 kW, then a total of 330 kW of electricity is consumed per hour, and the required amount of air will still not be supplied. The calculation of electricity consumption is shown in Table 3. If viewed from an economic point of view, the operating and capital costs for fan maintenance and subsequent replacement of fans with new ones at the end of their service life increase.

Table 3. Calculation of electric power consumption by fans.

Per hour, kW	Per day, kW	Per month, kW	Per year, kW	Price per 1 kW, som	Total cost of electricity per year, som
330	7920	237600	86724 000	3,4	294 861 600

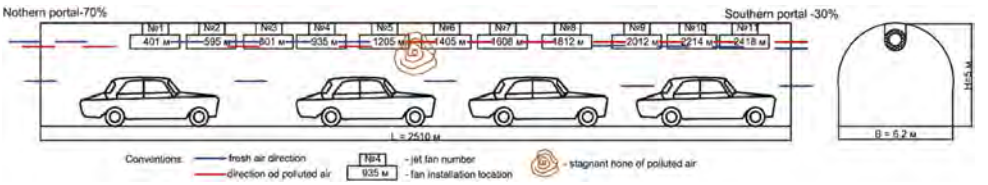

Figure 2. Ventilation scheme of the tunnel at the Too-Ashuu pass with the movement of vehicles in opposite directions using jet fans.

As can be seen from Figure 2, a fresh stream of air moves from both portals at the bot-tom of the portal, with the help of natural traction, exhaust gases in the form of warm polluted air rises to the top and a stagnant exhaust gas zone is formed.

Jet axial fans are multifunctional: they are designed for both normal ventilation and smoke removal during a fire. Composed of axial fans in a special configuration, they are mainly used in longitudinal ventilation and extract air. Jet fans are used in tunnels with bi-directional traffic or when the wind can have a significant effect on the airflow in the tunnel. Jet fan designs. It is based on an axial fan equipped with inlet and outlet pipes. Advantages: 1. Compact design for efficient ventilation; 2. High thrust with low power consumption; 3. Low noise; 4. Excellent corrosion resistance; 5. According to the signals from the sensors, switching to the smoke removal mode occurs immediately after a fire occurs. The disadvantages of jet fans include an increase in the concentration of harmful impurities along the length of the tunnel, susceptibility to natural draft, which depends on thermal and wind pressure, and insufficient fire safety. The amount of ventilation air required depends mainly on the conditions within the tunnel.

Recently, cases of fires of passenger cars running on gas have become more frequent in the tunnel. One of the reasons is the strong gas contamination of the tunnel. Due to the fire, the electrical cables that fed the fans failed and the tunnel was closed for repairs with partial admission of only passenger cars, and cargo vehicles were not allowed to pass. They stood in the cave for a long time in the summer due to this, vegetables and fruits brought from the south of the country deteriorated.

The above disadvantages of tunnel ventilation showed that it is necessary to radically change the tunnel ventilation system, since the existing system does not cope with the main tasks of ventilation systems in the tunnel.

The main tasks of ventilation systems in the tunnel are:

- provide the working environment with fresh air;
- ensure fire safety;
- elimination of exhaust gases;
- elimination of the risk of an explosion of a cloud of the fuel-air mixture, the release of poisonous gases, liquids and biological agents.

The above disadvantages of tunnel ventilation have shown that it is necessary to radically change the tunnel ventilation system.

Having assessed the ventilation conditions of the automobile tunnel, we offer two options for the ventilation scheme of the tunnel. The first option, based on the location of the tunnel (see Figure 1) on the Bishkek-Osh highway, it can be seen that 70% of the air is blown from the northern portal, and 30% of the air is blown from the southern portal, approximately in the zone marked in the diagram (see Figure 2.) the greatest stagnation occurs. Therefore, it is possible to drill a large-diameter well in the specified location with the installation of a powerful VOD-11P fan to the wellhead that will work for suction. The depth of the well at this point will be about 300 meters, the layout of the well is shown in Figure 3. This method has its advantages, we know that exhaust gases are much lighter than atmospheric air and therefore they accumulate in the roof of the tunnel, and thanks to natural traction they themselves will rise up. Since the direction of the flow of natural thrust coincides with the direction of the air created by the fan that works for suction. Table 5 shows the calculation for the consumption of electricity by the VOD-11P fan. Specifications of the VOD-11P fan are shown in Table 4.

Table 4. Technical characteristics of the VOD-11P fan.

Impeller diameter, mm	1100
Air flow, m3/s	7-33
Rated feed	21
Pressure, daPa	110-370
Rated pressure	338
Efficiency static	0,8
Electric motor power, kW	132
Voltage, V	380/660
Impeller speed, min-1	1500
Length, mm	6690
Width, mm	1870
Height, mm	1860
Fan weight with electric motor, kg	4560

Table 5. Calculation of electricity consumption by the VOD-11Pfan.

Per hour, kW	Per day, kW	Per month, kW	Per year, kW	Price per 1 kW, som	Total cost of electricity per year, som
132	3168	95040	34689600	3,4	117944600

Figure 3 shows the movement of clean and exhaust air. The exhaust air is sucked out of the well by the VOD-11P fan. Based on the calculation of electricity, it can be concluded that one powerful fan is more profitable and the performance is high compared to local jet fans, and the stagnant zone is eliminated with the reduction of CO_2 emissions to the MPC. The second option is the method of drilling two wells due to natural traction, polluted air will be removed through the wells without installing fans.

Axial fans are the technology of choice for large air volumes and are ideal for lateral or semi-transverse tunnel systems. They are also suitable for collecting smoke.

The advantages of axial fans include several factors:

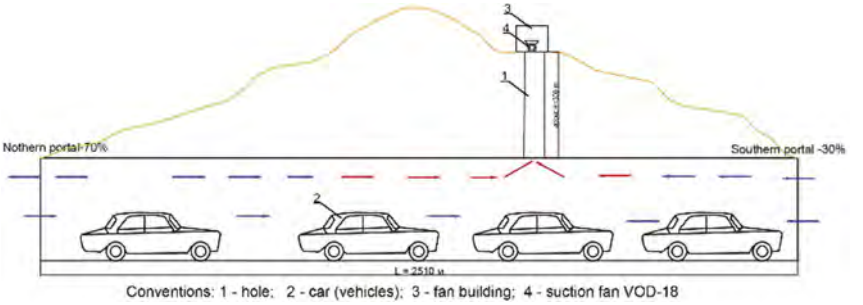

Figure 3. The layout of the hole.

- low noise level during operation;
- high efficiency;
- easy to operate;
- low cost and simplicity of design;
- low power consumption;
- long service life;
- engine protection against overloads, sparks, moisture;
- the ability to change the speed of rotation of the blades by changing the speed of the engine.

Conclusion: Based on the fact that at this stage a fresh stream of air enters and exits through the mouth of the tunnel, fresh and polluted air stream mix with each other (see Figure 2), which complicates the ventilation of the tunnel and provides fresh air. For the above reasons, there is always poor visibility in the stagnant zone, the smell of exhaust gases gets inside vehicles even through closed windows and doors. The methods we have considered change the existing method of tunnel ventilation by separating a fresh stream of air from a polluted one. Our proposed option is shown in Figure 3, the essence of this scheme is that it is necessary to conduct a vertical well on the mountainside, taking into account the terrain. Capital costs for drilling a well and building a building for a fan. We plan to come up with an idea at a meeting at the Ministry of Transport and Communications of the Kyrgyz Republic. According to the plan, ventilation reconstruction and replacement of fans is planned for 2023.

Experimental study on the feasibility assessment of using biopolymer-treated clays as a slurry material for TBM excavation

Sojeong Lee
School of Engineering and Information Technology, University of New South Wales, Canberra, Australia

Ilhan Chang
Department of Civil Systems Engineering, Ajou University, Republic of Korea

ABSTRACT: Bentonite-based slurry is commonly used for tunnel boring machine (TBM) excavation practices. However, the use of bentonite-based slurry accompanies environmental concerns and expansive after-use treatments. Meanwhile, biopolymer-based soil treatment (BPST) has been recently introduced to geotechnical engineering and has shown promising effects including shear strength increase, hydraulic conductivity decrease. In a previous study, xanthan gum biopolymer was attempted as a possible slurry substitute for mechanical tunneling. Biopolymer-based hybrid slurry mixtures were tested through a series of experimental programs including rheology assessment, hydraulic conductivity measurement, and swelling behavior assessment. As a result, biopolymer-based hybrid slurry has shown high competitiveness and feasibility to be used as a slurry material during TBM excavation.

1 INTRODUCTION

1.1 *Research background*

Tunnel Boring Machine (TBM) has been widely utilized in recent days due to its advantages such as adjacent ground disturbance minimization, and higher tunneling efficiency (Liu et al., 2016). While different types of TBM have been invented depending on the ground conditions, TBMs could be mainly classified into two categories (Park et al., 2021). They are 1) earth pressure balance (EPB) TBM and 2) slurry shield TBM, which are grouped from the manner of maintaining pressure at TBM face. Thus, EPB TBM is mainly applied at granite- or rocky ground while tunnelling at the ground with higher moisture content is commonly performed by slurry shield TBM. For EPB TBM, a bentonite-based conditioner is injected to improve excavated muck transportation efficiency. In contrary, bentonite is mixed with slurry, for slurry shield TBM. The excavated muck, consequently, contains high amounts of bentonite, which renders higher possibility to absorb hazardous materials during excavation and after excavation (Ren et al., 2016). This study aims to reduce the amount of bentonite usage among TBM excavation in order to ease the environmental concern related to muck disposal.

1.2 *Introduction of xanthan gum*

Xanthan gum biopolymer is recently introduced in geotechnical engineering, with its soil coagulation effect and natural degradation feature (Kwon et al., 2019, Lee et al., 2019). In details, xanthan gum biopolymer enhances shear strength when the xanthan gum – soil matrix is developed (Cabalar and Canakci, 2011, Soldo et al., 2020, Soldo and Miletić, 2019). Another previous study proved that xanthan gum biopolymer hydrogel effectively decreases hydraulic permeability (Cabalar et al., 2017, Tran et al., 2019). Meantime, xanthan gum has shown its economic efficiency with decreasing trend of the unit price (Mendonça et al., 2020). In this study, xanthan gum is chosen as a target

DOI: 10.1201/9781003299127-135

biopolymer since it has a high workability within a wide range of temperature (García-Ochoa et al., 2000), as well as the shear strength and compressive strength improvement with soil, and economic efficiency in practice.

2 MATERIALS AND METHOD

2.1 *Xanthan gum*

Xanthan gum biopolymer is an extracellular biopolymer cultivated from the bacteria, *Xanthomonas campestris*. Xanthan gum is a compose of repeating units including a main glucuronic backbone structure and a side chain which consists two mannoses and a glucuronic acid (García-Ochoa et al., 2000). When xanthan gum is dissolved in water, its phase renders a hydrogel form. The xanthan gum hydrogel renders pseudoplasticity and shear thinning properties (Ong et al., 2019).

2.2 *Bentonite and Kaolinite*

Bentonite and kaolinite are the representative clayey soil types in geotechnical engineering. Bentonite contains montmorillonite minerals and other smectite minerals. It has repeated 2 silica: 1 alumina layer structure. It has a strong water adsorption capacity owing to its structure. Kaolinite clay has repeated 1 silica: 1 alumina layer structure and each layer is connected via hydrogen bonding. In this study, research-grade bentonite and kaolinite are used (Sigma-Aldrich, CAS number: 1302-78-9, CEC = 64.1 meq/100gl Sigma-Aldrich, CAS number: 1332-58-7, CEC = 6.1 meq/100g).

2.3 *Sample preparation*

All tested samples are hydrated and, heretofore, each sample is referred as a slurry in this study. 7.5% bentonite slurry is set as a control group because 3 – 8% of bentonite is contained in the ordinary TBM slurry (Swartz, 2021). The hybrid slurry candidates are suggested in this study. They are 5% bentonite + 0.5% xanthan gum, 2.5% bentonite + 0.75% xanthan gum, 10.0% kaolinite + 0.5% xanthan gum, and 5.0% kaolinite + 0.75% xanthan gum. Each slurry candidate is prepared by mixing powder type- clay and biopolymer and then dissolved into deionized water. An electronic hand mixer is used to ensure homogeneous mixing.

2.4 *Experimental methods*

Referring that plastic viscosity is commonly used to assess the properties of drilling mud (American Petroleum Institute, 2020), rheological properties are measured from steady state measurement, using a rheometer (Malvern Kinexus Pro Rheomoter). Shear rate is controlled between 0.001 to 1000 s^{-1}. Hydraulic conductivity is tested by measuring the extracted water amount from the slurry containing reservoir under 250 kPa condition. After 30 minutes of duration, filtrate volume is measured.

3 RESULTS

3.1 *Rheology measurement*

7.5% bentonite shows distinctive shear thinning property which decreases viscosity with increasing shear rate as shown in Figure 1. The shear thinning behaviors are similarly monitored when bentonite content is decreased under existence of xanthan gum (Figure 1). While plastic viscosity of 7.5% bentonite is estimated as 0.0486 Pa·s, 5% bentonite + 0.5% xanthan gum and 2.5% bentonite + 0.75% xanthan gum are calculated as 0.0499 Pa·s and 0.0496 Pa·s, respectively. The difference between pure bentonite slurry and bentonite-based hybrid slurries is less than 2.7%. Interestingly, kaolinite-based hybrid slurries show the accordant shear thinning behavior to bentonite 7.5% (Figure 1). The shear thinning behavior is not obviously affected by kaolinite and xanthan gum contents. Their plastic viscosities are approximated as 0.0315 Pa·s and 0.0188 Pa·s, resulting the

relative error less than 61.3% (0.0298 Pa·s). The shear rejuvenation is clearly monitored in all cases, as shown in Figure 2. Yield point could be adjudged from approximation of critical point starting the shear rejuvenation. Although the yield point of bentonite 7.5% is higher than other hybrid slurry candidates, a little difference less than a dozen shear stress pascal is appeared between bentonite slurry and hybrid slurry candidates. In addition, the difference between bentonite-based hybrid slurries and kaolinite-based hybrid slurries is mimic.

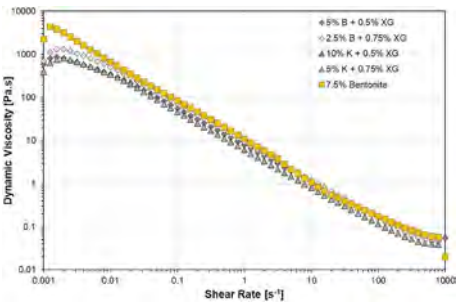

Figure 1. Shear thinning behavior of bentonite and hybrid slurries.

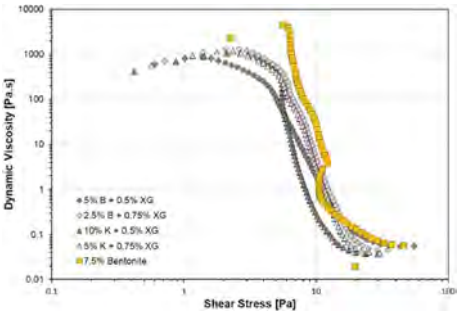

Figure 2. Shear rejuvenation of bentonite and hybrid slurries.

3.2 *Hydraulic conductivity*

As shown in Figure 3, the filtrate volume is decreased under existence of xanthan gum. Regardless of clay content, decrement of filtration is higher in case of higher amount of xanthan gum. Hydraulic conductivity of bentonite 7.5% is calculated as 4.7×10^{-6} m/s whereas bentonite-based hybrid slurries show 1.20×10^{-6} m/s (5% B 0.5% XG) and, 1.56×10^{-6} m/s (2.5% B 0.75% XG), respectively. Moreover, hydraulic conductivity of kaolinite-based hybrid slurries is found as 1.41×10^{-6} m/s (10% K 0.5% XG), and 1.36×10^{-6} m/s (5% K 0.75% XG).

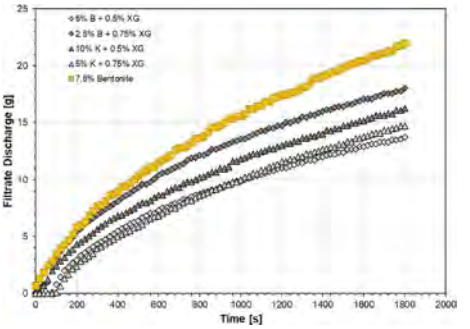

Figure 3. Hydraulic conductivity of bentonite and hybrid slurries.

3.3 *Inferential statistical analysis*

In this study, plastic viscosity and yield point are assessed as rheological properties. In addition, hydraulic conductivity is measured as a physical property. For inferential statistical analysis, these measured values are normalized based on 7.5% bentonite. Under importance order of measured properties is not revealed, random weight factor of units of integer (from 1 to 10) is applied to each measured property. Thereafter, closest slurry candidate condition to bentonite 7.5% is counted as a best case, and secondary closest condition is allocated to a second-best case. This procedure is repeated until all random combinations of weight factors are analyzed. The inferential statistical analysis shows

that 2.5% B 0.75% XG and 5.0% K 0.75% XG are the most feasible slurry candidates. For best case counting, 2.5% B 0.75% XG records 46.75% while 5.0% K 0.75% XG accounts 46.3%. Both configurations are enumerated as 26.0% and 48.7% respectively.

4 CONCLUSION

This study aimed to assess feasibility of sustainable slurry candidates containing xanthan gum. Through a series of laboratory assessment of bentonite-based and kaolinite-based hybrid slurry candidates are verified to be highly feasible in practices. The shear thinning properties of hybrid slurry candidates are similar to bentonite 7.5% regardless of clay and xanthan gum content, and hydraulic conductivity is decreased under existence of xanthan gum in all slurry configurations. This indicates that xanthan gum amends the engineering properties of slurry with less amount of bentonite than common content. Additionally, the inferential statistical analysis shows that 2.5% B 0.75% XG and 5.0% K 0.75% XG are the most feasible as a sustainable slurry alternative. While further studies are necessitated to implement tunnelling with sustainable hybrid slurry containing xanthan gum, this study proves the potential of xanthan gum in TBM excavation, through engineering property assessment.

ABSTRACT: Maintenance of tunnel structure involves investigation of tunnel wall with Ground Penetration Radar (GPR). By analyzing GPR investigation images, engineers determine the locations of steel ribs, thickness of concrete lining and the location and size of void if any. The identification of defects, however, requires experience and also is a time-consuming work. YOLO (You Only Look Once) and Mask R-CNN are CNN (Convolutional Neural Network) algorithms with single-stage detection and two stage detection, respectively. In this study, a model based on YOLO was trained to detect the steel ribs in GPR images and Mask R-CNN was trained to detect the concrete lining, and tested. Overall, both of the CNN algorithms provided satisfactory results; however, the images with severe scattering resulted in lower accuracy.

Keywords: GPR, Convolutional Neural Network, YOLOv5, Mask R-CNN, Image Detection

1 INTRODUCTION

Tunnels are built to pass through mountains or the sea in the shortest distance. As of 2020, there are 2,472 tunnels in Korea, and the number is gradually increasing. Tunnel maintenance survey is conducted often by the ground penetrating radar (GPR), a non-destructive method to investigate the lining conditions. GPR data analysis often requires experienced engineers. If GPR data can be analyzed by deep learning algorithms, it would increase the easiness and rapidity of the maintenance tasks. In this study, YOLO (You Only Look Once) and Mask R-CNN are CNN (Convolutional Neural Network) algorithms with single-stage detection and two stage detection, respectively, are used to analyze tunnel GPR data.

2 BACKGROUND

2.1 *Principle of Ground Penetrating Radar (GPR)*

Exploration using GPR is conducted by emitting electromagnetic waves from the surface of the structure to the inside in frequencies of several MHz to GHz. When electromagnetic waves

DOI: 10.1201/9781003299127-136

are radiated into a structure to be probed, reflection and diffraction occur due to the difference in permittivity between media. Through the interpretation of these data, it is possible to distinguish the steel support, lining, underground cavity, pipeline, and soft layer of the tunnel (AL-Qadi & Lahouar, 2005). An example of tunnel GPR image is presented in Figure 1.

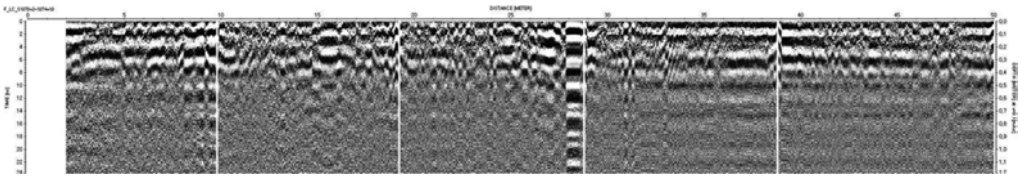

Figure 1. Tunnel GPR image.

2.2 *Convolutional Neural Networks (CNN)*

It is a neural network technique that detects the characteristics of an image by applying a filtering function to the artificial neural network. It classifies images by automatically learning each filter represented by a matrix to be suitable for data processing. In this classification method, the layer next to the input layer extracts low-level features, and the layer behind uses the low-level features obtained earlier to predict successive target values or class labels (Girshick et al., 2014). CNN that performs these functions is largely divided into three structures. Convolutional layer, pooling layer, fully connected layer.

2.3 *You Only Look Once (YOLOv5)*

Yolov5 is an object detection algorithm based on CNN. One-stage object detection is a deep learning technique that predicts objects by segmenting them in a grid form from the entire image, rather than predicting objects step by step, enabling high-speed prediction while maintaining high precision (Ieamsaard et al., 2021).

2.4 *Mask R-CNN*

Mask R-CNN detects an object through bounding box and proceeds with segmentation for each case. The final goal of Mask R-CNN is instance segmentation, which is an activity that identifies each object's area as a rectangular bounding box and then narrows it down more precisely to determine whether it belongs to a class in pixel units (He et al., 2020).

3 EXPERIMENTS

Figures 2 and 3 show the overall flow of analyzing images and deriving feature points using YOLOv5 and Mask R-CNN, respectively. Data labeling is the task of setting feature points required for learning. Labeling types used in this experiment are bounding box labeling and polygon labeling. YOLOv5 uses bounding box labeled data to detect steel ribs. Mask R-CNN uses polygon labeled data to detect concrete lining.

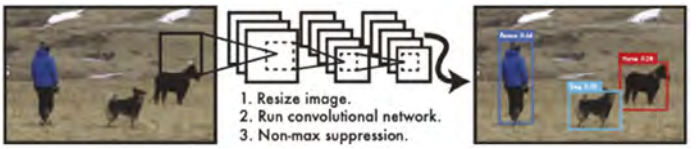

Figure 2. YOLO detection system (Redmon et al., 2016).

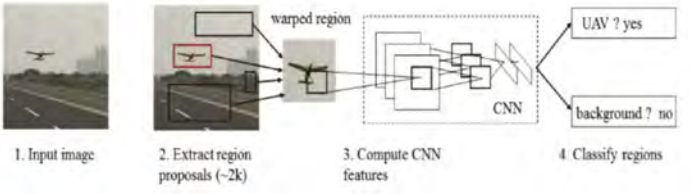

Figure 3. Mask R-CNN detection system (Yang et al., 2017).

Total number of data used in the experiment is 220. Among 220 datasets used, 200 datasets were randomly assigned for training, 10 for validation, and the rest for test. Experiments to detect steel rib and concrete lining were conducted three times each.

Figure 5 is the YOLOv5 detection accuracy graph. It was confirmed that the y value representing the accuracy in the graph converged to a value close to 95.7% accuracy when the x value was 250 epochs or more. Therefore, In the analyses presented here, the maximun epoch was set to be 300. The average time for the detecting steel ribs were 41 minutes. The average of image detection accuracy was about 95.7%. Figure 4 is the result of the steel rib detected from the GPR data.

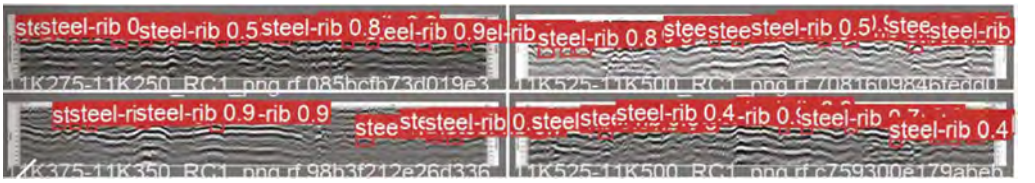

Figure 4. Detecting steel ribs using YOLOv5.

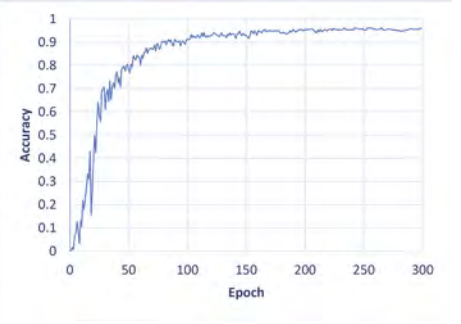

Figure 5. YOLOv5 detection accuracy graph.

Figure 7 is Mask R-CNN detection accuracy graph. Iterations are the number of mini batches required to complete 1-epoch. For the sizes of image and batch used in the analyses,100 iterations corresponds to 1 epoch in this case. It was confirmed that the y value representing the accuracy in the graph converged to a value close to 96% when the x value was 25000 iterations or more. In the analyses presented here, the maximun iteration was set to be 30000. The average time for the detecting concrete lining was 3 hours 25 minutes. The average of image detection accuracy was about 96%. Figure 6 is picture of concrete lining detected using Mask R-CNN. Red line is the concrete lining detected by the experienced engineer, and the purple area is the section detected by Mask R-CNN.

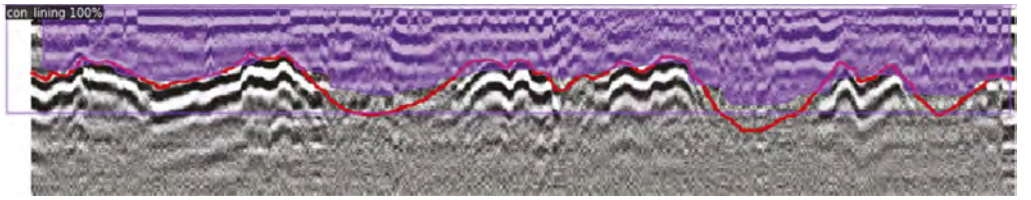

Figure 6. Detecting concrete lining using mask R-CNN.

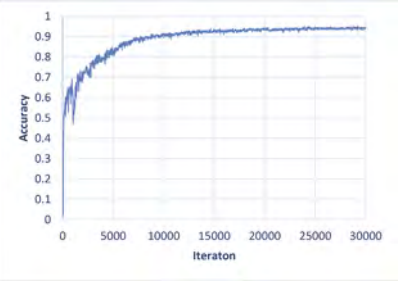

Figure 7. Mask R-CNN detection accuracy graph.

4 CONCLUSION

Experiments were conducted to detect steel ribs and concrete linings in tunnel GPR images based on CNN based algorithms. Steel rib was detected by YOLO, resulting in an average accuracy of about 96%. Concrete lining detection was performed by Mask R-CNN, again with a satisfactory accuracy of 96%. Concrete lining detection using Mask R-CNN was very close to the decision of experienced engineer; however, it predicted smoother curve than engineer's work. Follow-up study would be necessary to have better accuracy for the images with high scattering.

Investigation of micro cracks evolution around an opening in artificial rock samples: Inclined shear test with acoustic emission and DEM simulations

A.A. Owayo
Technical University of Kenya, Kenya

F. Teng
National Taiwan University of Science and Technology, Taiwan

W.C. Chen
National University of Kaohsiung, Taiwan

ABSTRACT: This research aimed to study micro-cracking in cement mortar made of hollow artificial rock. Via the new discrete element modeling (DEM) technique, ambiguity associated with the excavation damaged zone (EDZ) definition was meant to be clarified. Additions relating to the stress state were meant to be annexed to the EDZ definition. The influence of aggregate shape and water binder (w/b) ratio on the crack behavior of cement-based materials was also investigated. Inclined shear test (IST) was conducted on scaled hollow samples made of differently shaped aggregates (angular, A, and rounded, R) at varying w/b ratios. Further DEM simulations of the tests were carried out and the output both from tests and simulations were compared. New definitions of the EDZ incorporating the stress state have been proposed. The crack mechanism under varying shear angles, w/b ratio, and differently shaped aggregates have been studied.

1 INTRODUCTION

Over the years several methods of crack analysis have been proposed. Continuum-based analysis methods are perhaps the oldest numerical tools in this regard. Continuum-based analysis methods consist of finite element method (FEM) and finite difference method (FDM). They inherit advantages of classical continuum theory, while the constitutive law of elements allows for simulation of objects with complex geometry, these methods cannot solve discrete element (DEM) problems (Lisjak et al., 2014; Pietruszczak and Haghighat, 2015; Owayo et al., 2021). Over the last two decades,other methods such as discrete element methods, DEM (Gálvez et al., 2002; Bono, 2013; Owayo et. al, 2021; University of Edinburgh, 2022) have been introduced. Several authors have investigated the crack evolution of brittle materials (Martin, 1997; Blair and Cook, 1998; Tham et al., 2005; Lisjak et al., 2013; Choinska et al., 2017; Ghamgosar et al., 2017) using various analysis methods and tests. However, the recently introduced DEM modeling technique is yet to be well understood. In fact, so far, the qualitative descriptive method is still the best way to present the comparison between the DEM model with experimental results (Momozu et al., 2000; Tanaka et al., 2000; Owayo, 2022). Chen et al. (2018) developed a novel inclined shear test (IST) coupled with the acoustic emission (AE) technique to investigate the crack evolution of cementitious material from the microscale to the macroscale. The shear test apparatus has an open shear box design to allow for crack growth visualization. In this study, inclined shear test (IST) and acoustic emission (AE) experiments were conducted on hollow artificial rock samples to investigate the effects of crack evolution in brittle materials.

DOI: 10.1201/9781003299127-137

Several studies have analyzed concrete damage in numerical simulations with the finite element method (FEM) (Hu et al., 2004; Miller et al., 2011; Mackie, 2015; Liu et al., 2015; Moharrami and Koutromanos, 2017; Wu et al., 2017; Forti et al., 2020). FEM methods are often based on continuity principles (continuum mechanics), in which meshes cannot disjoin, even when the limiting stresses are attained. Some modified FEMs, such as the extended FEM (XFEM) framework, can have meshes that disjoin; however, these modified FEMs involve procedures that are computationally very expensive. Crack evolution thus cannot be analyzed using FEM. Currently, DEM, which takes into account discontinuity principles, has been used. (Wang and Gutierrez, 2010) conducted a DEM study of the micromechanics of granular materials via a direct shear test. (Nguyen et al., 2017) using DEM provided insight into the fracturing of concrete-like materials, and (Nitka and Tejchman, 2020) performed mesoscale mechanical modeling of damage in concrete, while (Ma and Huang, 2021) looked into the effect of shear bond failure on the strength of quasi-brittle materials.The discrete element contacts of the DEM can be disjointed to enable the visualization of crack initiation, growth, and development. Therefore, it was adopted to analyze the crack evolution of IST in this study in order to enhance the understanding of the crack evolution behavior of brittle materials.

2 INCLINED SHEAR TEST (IST)

Traditional direct shear test (DST) is applicable in studying shear behavior and determining strength parameters, such as cohesion (c) and friction angle (ϕ). To improve the DST, a novel shear apparatus with an open-shear-box design for IST was developed by (Chen et al., 2019) for application, in conjunction with AE technique, in identifying the distribution of micro-cracks in samples. In IST, normal and shear-force components varied during the process. Open-shear box design facilitates installation of extensometer and AE sensors, producing a complete loading curve with accompanying AE events.

A hollow sample with no support on its walls undergoing inclined shear test is shown in Figure 1a. Figure 1b shows a hollow sample with its walls supported undergoing inclined shear test. Figure 2 shows the relationship between the load and the sample faces. The test method was extensively discussed by (Chen et al., 2013). IST's design allows for the installation of AE sensors; which is unachievable in DST, due to its closed-box design. The sample measured 70 mm x 70 mm x 40 mm and were tested at various shear angles; 25°,45°, and 65°. The positions of micro-cracks were located with high precision, thanks to a set-up of eight AE sensors.

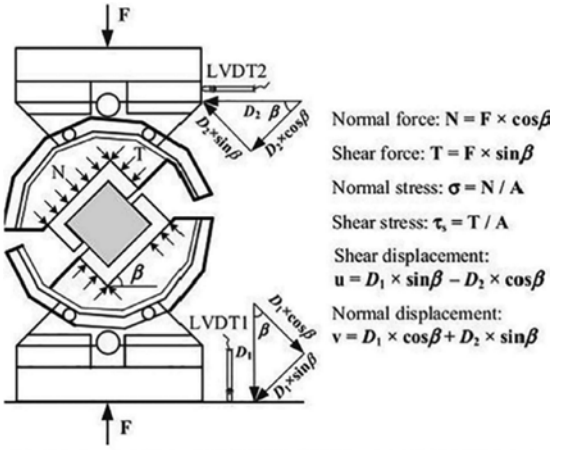
Figure 1. IST set-up used for the EDZ study on hollow samples.

3 DEM SIMULATION

3.1 *Numerical model setup*

The numerical specimens measured 70 mm x 70 mm x 40 mm, similar to the physical samples. In general, for the sake of reducing computational cost, the DEM shear rate is usually considerably higher than those in the test (Brown, 2013; Fakhimi and Hemami, 2017; Owayo et al., 2021; Owayo, 2022). Figure 3(a) and (b) exhibit the numerical setup for non-hollow and hollow sample models respectively. Figure 4(a) shows a triple sphere representation of angular aggregates in DEM and Figure 4(b) shows a single sphere representation of rounded aggregates in DEM. To ensure computational efficiency, the sizes of the particles in the simulation should not be too small. Reasonably compact samples were produced, when particles particle constituting the numerical models were produced using normal distribution statistical technique. The mean size and standard deviation of the generated particles had to be related to the actual particle size distribution of the sand particles in the physical samples. The loading plates were simulated as steel plates.



Note: β is the shear angle, **F** is loading force provided by MTS, **A** is the contacted area between specimen and shear box, $\mathbf{D_1}$ is the displacement measured by LVDT1 and $\mathbf{D_2}$ is the displacement measured by LVDT2

Figure 2. Relationship between load and sample faces in the novel test on a hollow sample.

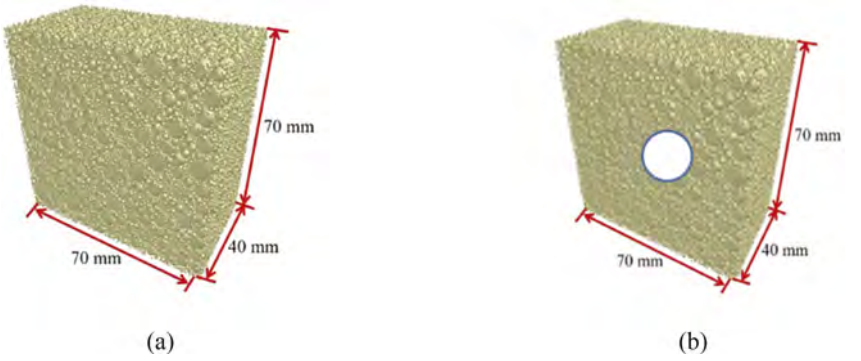


Figure 3. DEM simulation models: (a) Setup with no opening (b) Setup with opening.

Figure 4. (a) Triple-sphere representation of angular aggregates; (b) single-sphere.

3.2 *Macroparameters in the simulation*

Table 1 shows the macroparameters used in the simulation, these values are consistent with those set in the previous work (Owayo et al. 2021). The coefficient of restitution was judged to be near zero for civil engineering, whose calculations revolve around equilibrium of static forces. The values of the coefficient of static friction, coefficient of rolling friction, Poisson's ratio, mean particle bulk density, and Young's modulus were obtained from the literature, as reported in reference (Owayo et al. 2021) or experiments, in addition to recommendations by software. Other values, such as the shear modulus, were automatically computed by software based on Young's modulus and Poisson's ratio inputs. The porosity of the sample is implied in the bond parameters (Owayo et al. 2021).

Angular aggregates have a greater interlocking effect than their rounded aggregate counterparts, and as a result, the coefficient of static friction for the cement-angular aggregate mixture ought to be higher, see Table 1. A higher value of the coefficient of friction was chosen to cater to the additional interlocking effect in the angular aggregates. In addition, just like in the test, in order to minimize the end-bearing effect, the coefficient of static friction for steel-cement interaction has to be quite low.

Table 1. DEM macroparameters.

Macroparameter	w/b ratio and aggregate type				Steel	Cement-steel interaction
	0.35R	0.35A	0.23R	0.23A		
Coefficient of restitution	0	0	0	0	0	0
Coefficient of static friction	0.7	10	0.7	10	0.5	0.01
Coefficient of rolling friction	0.01	0.01	0.01	0.01	0.01	0.01
Poisson's ratio (v)	0.17	0.17	0.15	0.15	0.3	-
Mean particle bulk density (kg/m^3)	2100	2100	2120	2120	7800	-
Young's modulus, E (GPa)	25.4	25.4	28	28	205	-

3.3 *Calibration of the variable bond property model*

Cement mortar made of rounded aggregates with a w/b ratio of 0.35 was chosen for calibration purposes. Eq. sets 1a to1d were initially established from a sample tested at a shear angle of 80°, and confirmed by the results of samples tested at 70° and 65°. Later on, a new set of materials were used as a new set of materials against which the calibrated data were compared. These new set of materials were: cement mortar made of angular aggregates and rounded aggregates with a w/b ratio of 0.23 and cement mortar made of angular aggregates with a w/b ratio of 0.35. A simplified linear variable bond parameter model proposed in the previous work of (Owayo et al., 2021; Owayo, 2022) for use in DEM was applied in this work.Tests and simulations were done at shear angles of; 25°,45°, and 65° respectively.

The previous work (Owayo et al. 2021) showed that microparameters can be computed via the equation set Eq. (1a-1d). Table 2 displays the values of the coefficients and the constants

of equation set Eq. (1a-1d), based on aggregate type. Peak confinement stresses (see (Owayo et al., 2021; Owayo, 2022)) are divided into incremental values over the number of time steps for use in the entire simulation. Afterward, the confinement stresses are applied incrementally throughout the simulation time steps and substituted in equation set Eq. (1a-1d), thereby obtaining the respective microparameters for each time step. Further details of the model can be obtained from (Owayo et al., 2021).

$$bp_\tau = \left[c_1 e^{c_2\beta}\sigma_n + b_\tau\right] \times 10^6 \tag{1a}$$

$$bp_\sigma = \left[c_1 e^{c_2\beta}\sigma_n + b_\sigma\right] \times 10^6 \tag{1b}$$

$$bp_{ss} = \left[c_1 e^{c_2\beta}\sigma_n + b_{ss}\right] \times 10^{10} \tag{1c}$$

$$bp_{ns} = \left[c_1 e^{c_2\beta}\sigma_n + b_{ns}\right] \times 10^{11} \tag{1d}$$

c_1 and c_2 are constants dependent on aggregate shape. bp_τ is the bond parameter associated with the critical shear strength in Pa, compared with bp_σ as the bond parameter associated with the critical normal strength in Pa, bp_{ss} as the bond parameter associated with the shear stiffness per unit area in N/m^3, bp_{ns} as the bond parameter associated with the normal stiffness per unit area in N/m^3, β as the shear angle in degrees, and σ_n as the normal confinement stress in MPa. b_τ is a 'cohesion-like' term related to the critical shear strength in Pa, compared to b_σ, as the critical normal strength in Pa, and b_{ns} is a 'cohesion-like' term related to the normal stiffness per unit area in N/m^3 and b_{ss}, as the shear stiffness per unit area in N/m^3.

Table 2. Coefficients and constants in Equation (1a-1d) according to aggregate type.

	R.- aggregates	A.- aggregates
c_1	0.15	1.1
c_2	0.0326	-0.01
b_τ	1.0	3.0
b_σ	1.0	3.0
b_{ss}	1.0	3.4
b_{ns}	1.0	3.4
bdr (mm)	1.0	1.2

4 RESULTS & DISCUSSION

4.1 *Stress-strain characteristics*

4.1.1 *Tests without internal balancing pressure, pi*

In this set of results (Figure 5a), the samples were loaded in order to achieve a constant value of stress (7.7 MPa) on one of the sample's faces (the face experiencing shear stress). Displacement-controlled loading was used for this particular set of results. The phenomenon already reported by (Chen et al., 2018) i.e., low w/b ratio and low shear angles lead to stiffer sample response in test, are can be seen in curves in Figure 5.

An interesting observation can be made in Figure 5(b); most curves in tests, at the same shear angles coincide, despite the samples being constituted with different aggregate shapes. Figure 5(b) suggests that samples made of w/b=0.23, are strongly anisotropic (Figure 5(a)) for both A and R-aggregate constituted samples. On the other hand, samples made of w/b=0.35 regardless of whether A or R-aggregate seems to approach isotropic behavior. Samples made of w/b ratio of 0.23 contain less water and more cement and the mix is likely to be less homogenous due to an expected strong cement-aggregate bond. Samples constituted in w/b ratio, of 0.35 has more water and less cement, therefore, the resultant mix is likely to be more homogeneous regardless of its aggregate constituent as shown in the figures due to a relatively weak cement-aggregate bond.

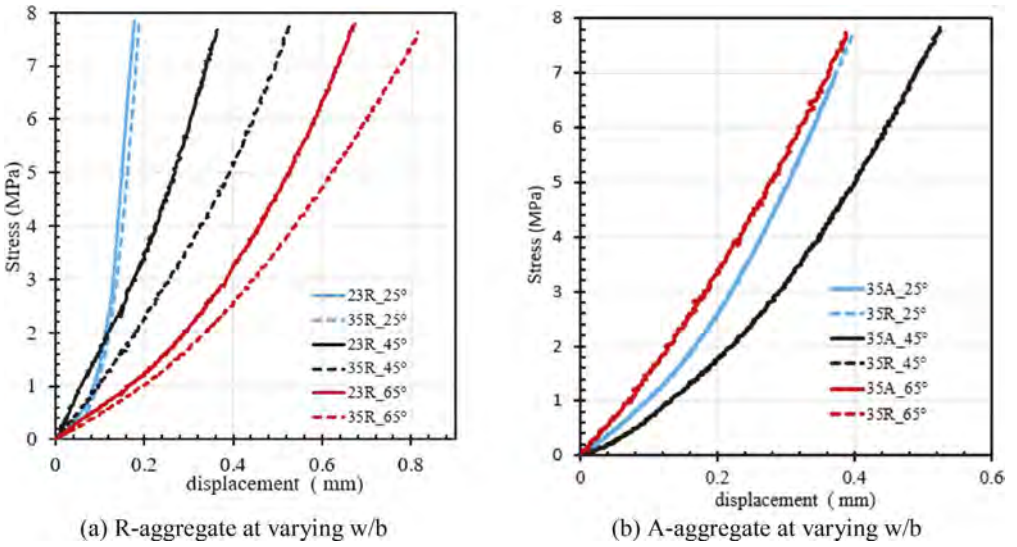

Figure 5. Stress-strain relationship in samples with no internal balancing pressure.

4.1.2 *Tests with internal balancing pressure, pi*

In this set of results (Figure 6), a fixed vertical force was applied to the sample through force-controlled loading in the test, and the maximum value of stress on the samples faces was controlled by the shear angle. Figure 6 indicates the stress-strain curves for cases where internal balancing pressure, p_i. was applied to balance the walls of the hollow opening during the tests. This was meant to simulate scenarios of different K_0 in-situ conditions. With these samples, the trend of stiff response with lower shear angles and low w/b ratio is only partially clear. It appears the presence of the internal support pressure, p_i. on the opening seems to enunciate the anisotropic behavior associated with A-aggregate constituted cement mixes and samples constituted at w/b ratio, 0.23. Furthermore, the presence of the opening in the sample with or without the internal balancing pressure, p_i on the hollow opening walls under tests, seems to have more profound effects on the A- aggregates constituted samples as opposed to their R-aggregate constituted counterparts. The findings regarding the A-aggregate constituted samples largely agree in behavior and mechanics however the presence of factors such as the opening, seems to have some effects. The said effects are thought to be a result of the uniformity of rounded aggregates and non-uniformity of their angular counterparts. The uniformity of rounded aggregates results in uniform stress distribution under loading therefore the behavior of a wide range of samples is bound to remain fairly consistent despite introduction of imperfections (like the opening) in the sample. The irregularity in shape of angular aggregates, on the other hand, may lead to stress concentrations under loading, therefore, imperfections (like the opening) introduced in samples may lead to some variations/inconsistencies in behavior as has been pointed out.

4.2 *Macrofracture pattern behavior around the opening*

The aim was to simulate cases of realistic fixed in-situ loads under varying values of K (K is synonymous with varying values of K_0 in in-situ site conditions) which typically do not reach failure loads (peak strength). Figure 7 shows cracks highlighted at a distance ranging between 3R-5R from the opening (R is the radius of the opening).

4.3 *DEM Simulations of cracking around the hollow opening*

EDEM's broken bonds were digitized and plotted together with the AE events. The analytical solution when the sample was tested with no p_i was obtained from the Kirsch solution while the solution for the sample tested with pi, was obtained from FEM. Figure 8 represents a comparison between EDEM's broken bonds and AE events in samples made of R and

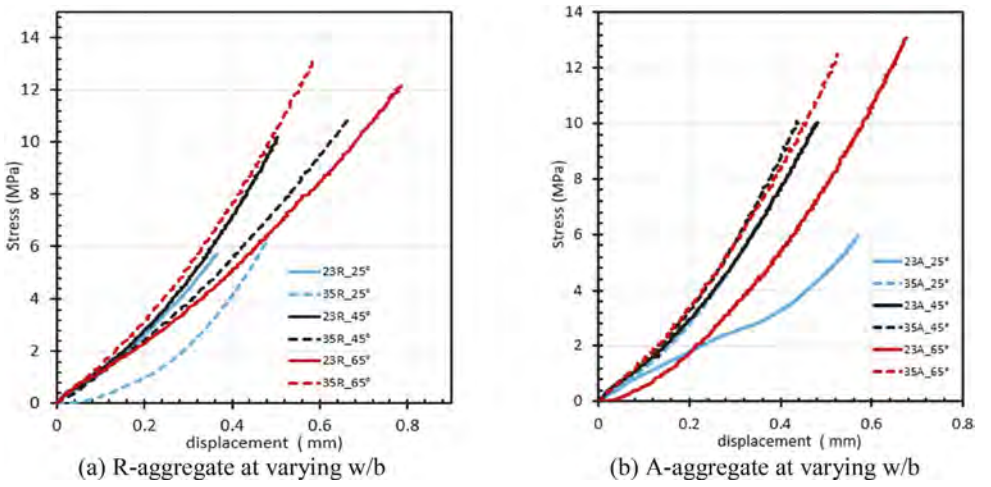

Figure 6. Stress-strain relationship in samples with internal balancing pressure.

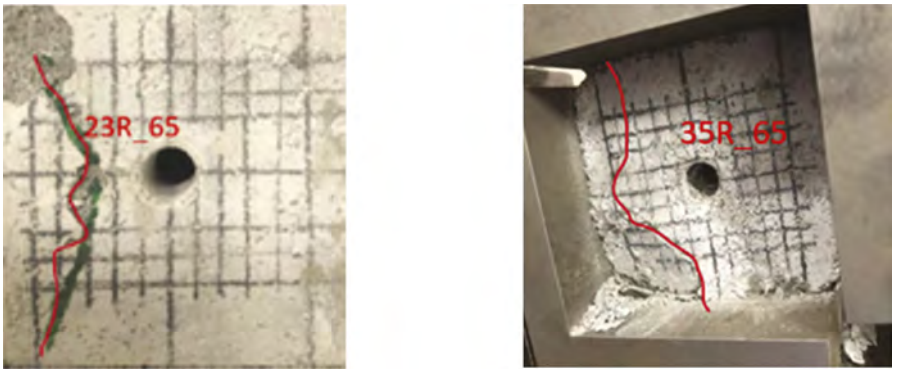

Figure 7. Macro-cracks on the tested samples.

A-aggregates respectively. Also shown alongside the figures is a typical stress state in the material element expressed in MPa. For the anisotropic loading cases, EDZ in the minor principal directions seems to extend more than that in the major principal directions by between 10-30% as indicated in the figures.

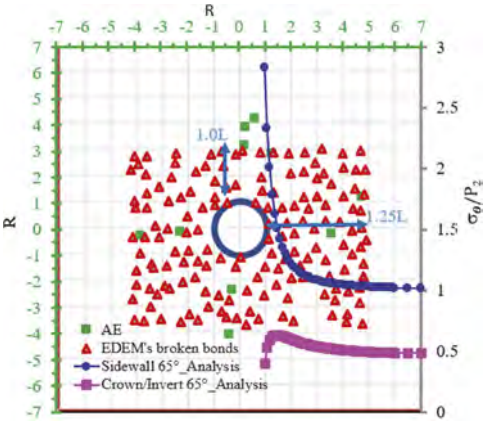

Figure 8. Comparison between EDEM's broken bonds and AE events in samples made of R -aggregates (w/b=0.23 tested at 65°) with no internal balancing pressure, p_i during the tests.

EDZ extent in the minor principal stress direction is between (1-1.3) times longer than the extent in the major principal stress direction. For unsupported opening, the average of the ratio of current stress to the major principal stress associated with the EDZ in the minor principal stress (P1) direction (EDZ1) ranges between 1.5-3.8 (Figure 9), on the other hand, the average of the ratio of current stress to the major principal (P2) stress associated with the EDZ in the major principal stress direction (EDZ2) ranges between 0.45-1.5. The reference values presented in this section are the average values in the reported range. For supported opening, the average of the ratio of current stress to the major principal stress associated with the EDZ in the minor principal direction ranges between 1.09, while the average of the ratio of current stress to the major principal stress associated with the EDZ in the major principal direction, on the other hand, ranges between 0.5-1.09.

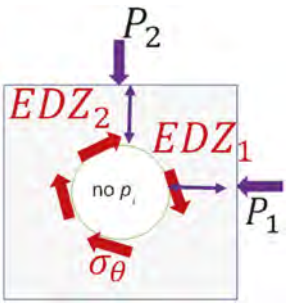

Figure 9. EDZ without internal balancing pressure.

5 CONCLUSIONS

- In anisotropic loading cases ($K \neq 1$), cracks around the opening, in samples with supported walls (with p_i), are less severe.
- The EDZ for all cases (tests and simulations) lies between 4 times the radius of the opening to 6 times the radius of the opening ($4R$-$6R$).
- Cracking in cement mix with rounded aggregates is relatively more intense and widespread around the opening, while the cracking around the opening in cement mix made of angular sand/aggregates is more concentrated and relatively sparse.
- EDZ extent in the minor principal stress direction is between (1-1.3) times longer than the extent in the major principal stress direction.
- For unsupported opening, the average of the ratio of current stress to the major principal stress associated with the EDZ in the minor principal direction ranges between 1.5-3.8; on the other hand, the average of the ratio of current stress to the major principal stress associated with the EDZ in the major principal direction ranges between 0.45-1.5.
- For supported opening, the average of the ratio of current stress to the major principal stress associated with the EDZ in the minor principal direction ranges between 1.09-3.5, while the average of the ratio of current stress to the major principal stress associated with the EDZ in the major principal direction, on the other hand, ranges between 0.5-1.09.

ABSTRACT: Many excavations are made adjacent to existing foundations, especially in urban areas. In order to prevent the damage of the adjacent structures induced by the excavation, it is important to predict the retaining wall deformations caused by excavations. However, the uncertainty of subsurface conditions and the nonlinear interactions between multiple agents (e.g., soils, groundwaters, excavation support structures, and excavation activities) make the prediction of the response of retaining wall induced by excavation a rather difficult and complex task. This paper proposes a method to solve this problem by using machine learning techniques, where information is generated from the interaction processes between soils, structures, and excavation activities for predicting retaining wall deformations. First of all, an artificial neural network (ANN) model is proposed, and the soil properties, groundwaters, excavation support structures and excavation activities are considered. Then a mixed sample database of retaining wall deformations is generated based on high-fidelity numerical simulations and field measurements in Shanghai. Finally, the model is trained by the mixed database to recognize the patterns of the complex interactions between retaining wall deformations, excavation geometries, support structures, and soil properties. The results show that the accuracy of predicting the retaining wall deformations is less than 2 mm compared with high-fidelity numerical simulations. In the meanwhile, the mean accuracy of predicting the retaining wall deformations is 2.62 mm compared with the field monitoring data of an engineering case in Shanghai. The strategy of machine learning techniques with the model can predict the maximum retaining wall deformations induced by excavation with high accuracy.

1 INTRODUCTION

With the continuous promotion of urbanization, urban land resources are increasingly scarce, the demand for underground space development is growing rapidly, and the excavation scale of foundation pits is becoming larger. In urban construction, foundation pits are often adjacent to existing buildings and underground pipelines. Retaining wall deformations caused by excavation will lead to the displacement of the surrounding soil, and eventually affect the adjacent infrastructures, which may even have a huge impact on retaining wall and surrounding environment (Finno and Calvello, 2005). Therefore, controlling the retaining wall deformations caused by excavation is very important, which is based on predicting retaining wall deformations – one of the research highlights for many years.

DOI: 10.1201/9781003299127-138

Traditional methods of predicting retaining wall deformations are: 1) Empirical methods: based on a large amount of data, the parameters strongly related to retaining wall deformations are selected, and the formulas of retaining wall deformations are given by curve fitting (Goldberg et al., 1976; Mana and Clough, 1981; Ou and Tang, 1994; Kung et al., 2007; Goh et al., 2017). Although these methods are convenient and simple, it ignores the influence of construction factors (Finno and Calvello, 2005); 2) Theoretical methods: the retaining wall deformations and soil displacement caused by excavation are calculated based on soil mechanics and structural mechanics (Peck, 1969; Hsieh and Ou, 1998; Xu and Poulos, 2000; Zhang et al., 2011). These methods are more theoretical compared with empirical methods, but still based on some assumptions different from reality, which will affect the calculation accuracy (Cao et al., 2014); 3) Finite element methods (FEM): the relationship between key parameters and deformation characteristics of retaining wall can be directly analyzed (Clough and Duncan, 1971; Borja and Ronaldo, 1990; Li et al., 2021), overcoming the limitations of empirical methods. However, the theories of numerical simulation are complex, and the calculation workload is large, which needs a lot of time and is difficult for engineers to use (Mu et al., 2020).

For excavation with strong randomness, fuzziness and nonlinearity, the above methods can not comprehensively consider the influence of relevant factors on retaining wall deformations (Jamali et al., 2013), and is difficult for dynamic prediction during construction. As the requirement of foundation pit deformation control is increasing, a more intelligent method is needed to achieve the rapid and dynamic prediction of retaining wall deformations. Artificial neural networks (ANN) perform excellent in solving nonlinear multivariable problems such as geotechnical engineering. Compared with the traditional methods mentioned above, ANN can calculate faster and achieve dynamic update (Goh et al., 1995). BP neural network (BPNN), with good self-organization and generalization, can use the original monitoring data for learning and training, and predict the later deformations of retaining wall (Hu et al., 2013). Goh et al. (1995) used BPNN to learn the FEM results, and obtained reasonable prediction results of retaining wall deformations in clay. However, the input parameters (especially soil parameters) of the ANN in this study were too few, which was not conducive to establishing the mapping relationship under different soil layers and construction conditions (Gao et al., 2002). The prediction accuracy of BPNN increases with the abundance of training data. Therefore, in order to ensure the accuracy of prediction, a large amount of engineering data must be provided (Yuan et al., 2000; Hu et al., 2013). However, the monitoring data is often poorly collected in engineering for various reasons, such as equipment damage and operation errors, and it is a long and cumbersome process to collect and sort out the engineering data. In order to solve this problem, many scholars have combined other intelligent algorithms to improve BPNN (Ma et al., 2008; Cao et al., 2014; Wang et al., 2019; Zhang et al., 2020; Cui et al., 2021). Most of these enhanced prediction models focus on improving the algorithms by reducing the scale of training set and calculation time, but the mapping relationships ignore the influences of soil conditions, retaining structure parameters and construction conditions on retaining wall deformations.

Considering the advantages of ANN in solving geotechnical problems and the shortcomings of BPNN in predicting retaining wall deformations, this paper presents a new method. Soil parameters considering small-strain properties, foundation pit geometries and retaining structure parameters are taken as the input parameters of the BPNN model. In this way, the new method can effectively consider the effects of each soil layer properties, the positions and mechanics of each support, and the excavation conditions on the maximum retaining wall deformations. The finite element (FE) samples is generated by PLAXIS, and the engineering data samples are obtained from the monitoring data of 18 foundation pit projects in Shanghai. Then a mixed sample database is generated by combining the FE samples and engineering case data samples, which reduces the influence of lacking engineering data on the training effect of BPNN. Based on the mixed sample database, the BPNN is trained to generate a prediction model of the maximum retaining wall deformations. The prediction results of the model for 50 FE examples verify the rationality of the input parameters after comparing with the corresponding FEM results. Then the model is applied in an engineering case in Shanghai to estimate the accuracy.

2 BPNN MODEL

2.1 *BPNN structure*

A BPNN model generally has a structure consisting of input layer, hidden layers, and output layer. As shown in Figure 1, the input layers of our BPNN model consist of key parameters that affect retaining wall deformations, while the output layer is the maximum retaining wall deformation.

As shown in Table 1, the input parameters can be categorized into three groups: soil parameters considering small-strain properties, foundation pit geometries and retaining structure parameters.

HSS model (Benz, 2007) takes into account the mechanical properties of soil in small-strain stage, which has been proved to be suitable for simulating deep excavation (Burland, 1989; Whittle et al., 1994; Kung et al., 2007; Clayton, 2011). Therefore, 5 HSS model parameters(reference secant modulus E_{50}^{ref} and reference loading-unloading modulus E_{ur}^{ref} in triaxial drained shear test, reference tangent modulus E_{oed}^{ref} in consolidation test, initial shear modulus G_0^{ref}, and shear strain $\gamma_{0.7}$) are selected to describe soil mechanic properties, which add the unit weight γ, thickness h, effective cohesion c', and effective friction angle φ' up to 9 parameters for each soil layer. However, the number of input parameters is usually fixed, which makes it difficult to apply the same model to cases with different soil conditions. To solve this problem, the soil within the retaining wall into 9 layers, which means that there are 81 soil parameters in the input layer.

In order to cover most of engineering situations, the number of supports is set to 4. As shown in Table 1, 3 parameters are selected for each support, which means that there are 12 support parameters in the input layer.

Therefore, the constructed BPNN, connected to an output layer of maximum retaining wall deformation by 5 hidden layers (98-86-52-39-32), has an input layer of 98 parameters including the other 5 parameters.

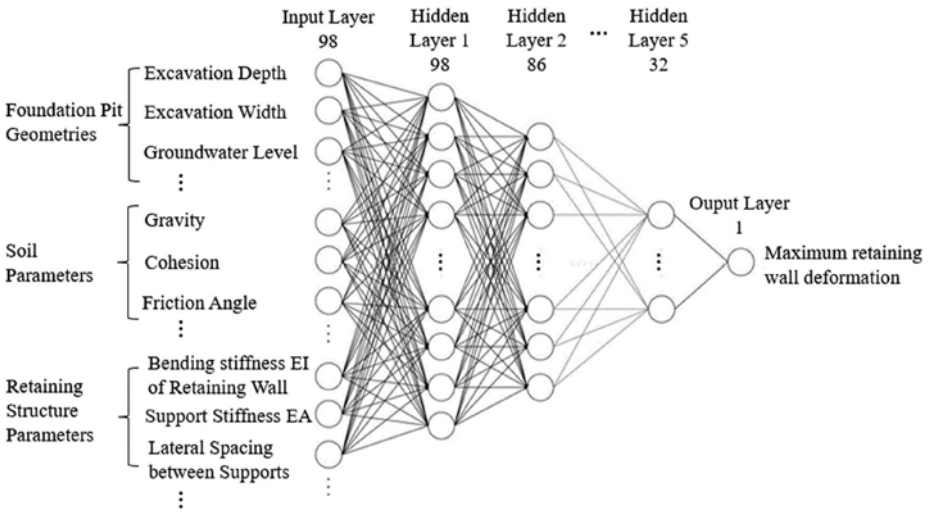

Figure 1. Structure of the BPNN.

2.2 *Sample database*

The lack of engineering data leads to poor training effect of BPNN. Therefore, this paper combines FE samples with engineering data to generate a mixed sample database, which is used to train the BPNN model. The construction process of the mixed sample database is as follows.

Table 1. The input parameters of the model.

Category		Parameters
Soil parameters		Thickness, unit weight, c', φ', E_{ur}^{ref}, E_{oed}^{ref}, E_{50}^{ref}, G_0^{ref}, $\gamma_{0.7}$
Foundation pit geometries		Excavation depth, excavation width, groundwater depth
Retaining structure parameters	Support parameters	Stiffness EA
		Lateral spacing between supports
		Distance from supports to top surface
	Retaining wall parameters	Bending stiffness EI
		Longitudinal length

Step 1: the FE sample database is established based on a large amount of FE samples. In order to ensure that the parameter values and excavation conditions of each calculation sample are independent, an automatic modeling program is prepared based on the Python interface in PLAXIS. The program can perform batch automatic modeling and calculation of foundation pits, and automatically write the maximum retaining wall deformations and the corresponding material parameters in each calculation example into the database. Each sample in the database has 98 input parameters and 1 output parameter. The output parameter - maximum retaining wall deformation is shown in Figure 2. The values of all input parameters in FE samples are based on the fluctuation ranges encountered in the engineering cases collected in this research (e.g., lateral spacing between supports varies from 6 m to 10 m, excavation width varies from 50 m to 336 m). To comprehensively consider the construction conditions such as different number of supports and different parameter values of each support, different input parameters can be taken. For example, for the working conditions not involved in the excavation (such as some supports have not been set), it is considered by taking the parameters of the corresponding supports as 0. Parameters and PLAXIS calculation results of 87368 calculation examples are recorded to build the FE sample database.

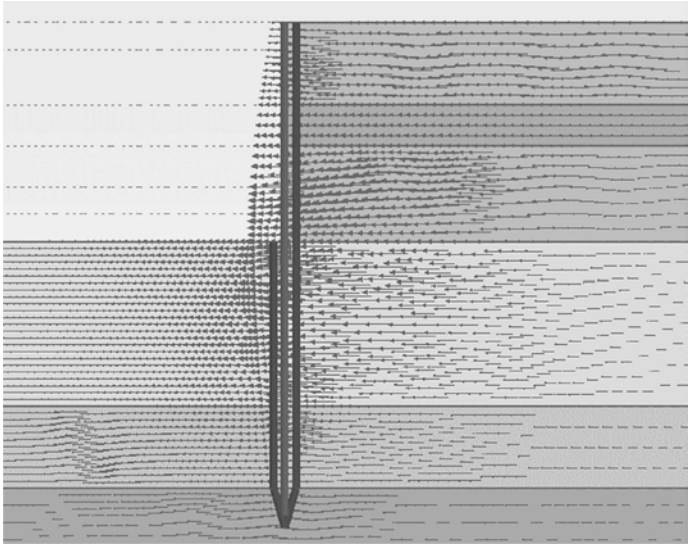

Figure 2. Schematic diagram of maximum retaining wall deformation.

Step 2: 3005 engineering samples from 18 excavation projects in Shanghai are collected for the engineering sample database. The materials required to be provided about the projects are: geotechnical investigation report, foundation pit design and construction drawings, monitoring data (monitoring report of deep horizontal displacement of retaining wall, etc.). Since some HSS model parameters cannot be directly obtained from the engineering data, the empirical method given by Gu et al. (2021) is used, which is obtained by converting pore ratio e and compression modulus Es. The conversion relationship is shown in Table 2.

Step 3: The FE sample database and the engineering sample database are combined into the mixed sample database, having 90373 samples totally. Examples of the samples are shown in Table 3 (*parameters of soils and supports are excluded due to space limitations).

Table 2. The suggested values of HSS model parameters for Shanghai soils.

Parameter	Empirical method
E_{oed}^{ref}	Clay: E_{oed}^{ref}= -4.34ln(e)+3.51 MPa (Based on laboratory test) E_{oed}^{ref} = 0.81$E_{s1\text{-}2}$ (Both clay and sandy soil)
E_{50}^{ref}	Clay: E_{50}^{ref} = -5.33ln(e)+3.95 MPa (Based on laboratory test) E_{50}^{ref} = 1.02$E_{s1\text{-}2}$ (According to this formula if there is no test data for sandy soil)
E_{ur}^{ref}	Clay: E_{ur}^{ref} = -28.8ln(e)+24.5 MPa (Based on laboratory test) E_{ur}^{ref} = 4.2$E_{s1\text{-}2}$+7.24 (According to this formula if there is no test data for sandy soil)
G_0^{ref}	Clay (Clayey silt): G_0^{ref} = 67.5$e^{-1.57}$ MPa (Based on on-site wave velocity test data) Sandy soil (Sandy silt): G_0^{ref} = 98.9$e^{-0.45}$ MPa (Based on on-site wave velocity test data)
$\gamma_{0.7}$	Clay (Clayey silt): $\gamma_{0.7}$ = 2.4~4.4×10^{-4}, the mean value is 3.2×10^{-4} (Based on laboratory test) Sandy soil (Sandy silt): $\gamma_{0.7}$ = 2.9~5.2×10^{-4}, the mean value is 3.9×10^{-4} (Based on laboratory test)

* e is pore ratio; I_p is plasticity index.

Table 3. Examples of the samples in the mixed database.

Foundation pit geometries			Retaining wall parameters		Wall deformation
Depth	Width	Groundwater depth	Longitudinal length	EI	
m	m	m	m	GPa·m^4	mm
18.38	58.14	2.81	55.61	3.49	29.69
17.66	103.46	1.86	59.77	0.71	77.27
11.41	74.66	3.32	24.45	0.55	13.32

2.3 *Model training*

The proposed model is trained by BP algorithm coded in PyTorch module. The activation function for BPNN nodes is rectified linear unit (ReLU), the loss function is mean sum-of-squares error (MSE), and the optimization function is Adam. Among the mixed database, 89834 samples are used to train the model.

3 PREDICTION FOR FE CASES

This paper has calculated 40 examples in total from the proposed model and FEM. Figure 3 (a) to (d) respectively show the prediction of maximum retaining wall deformations when the number of supports is 1, 2, 3, 4. In the FE calculation examples randomly generated, the general trend is that the greater the excavation depth, the more supports are set and the larger maximum retaining wall deformations are. However, the absolute error of the model barely

change with the increase of the corresponding retaining wall deformation, almost within 2mm. The mean absolute error and relative are only 0.81 mm and 4.6%, which shows that the model maintains a high accuracy under different excavation conditions generated by FE. Therefore, the selected parameters of the model are rational.

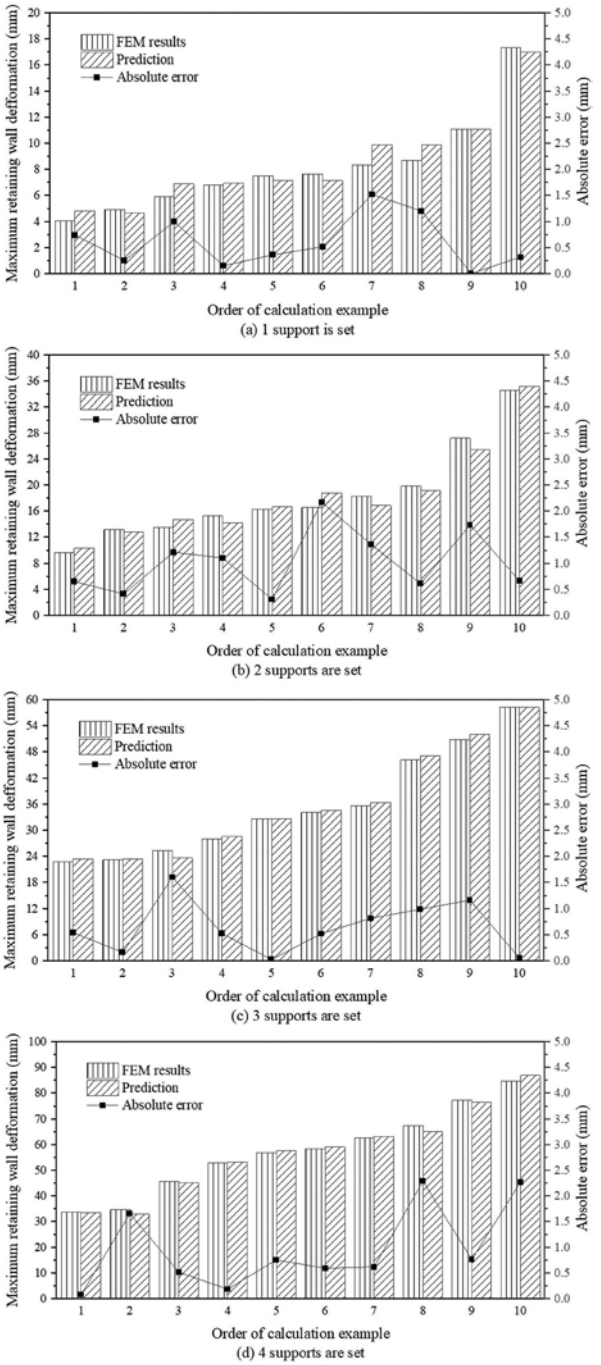

Figure 3. Comparison between prediction and FEM results.

4 PREDICTION FOR AN ENGINEERING CASE

In order to estimate the practical accuracy of the proposed model, it is used to predict the maximum retaining wall deformations in the following engineering case.

Baoshan River-side Business Center Project is located in Baoshan District, Shanghai. Layout and support profile of the foundation pit are shown in Figure 4-5, and the soil parameters and retaining structure parameters are shown in Table 4-6. The proposed model is used to predict the maximum retaining wall deformations when excavating to the bottom. In order to estimate the prediction accuracy of the model more comprehensively, the data of different monitoring points (CX30, CX31, CX32, CX33) are collected for comparision.

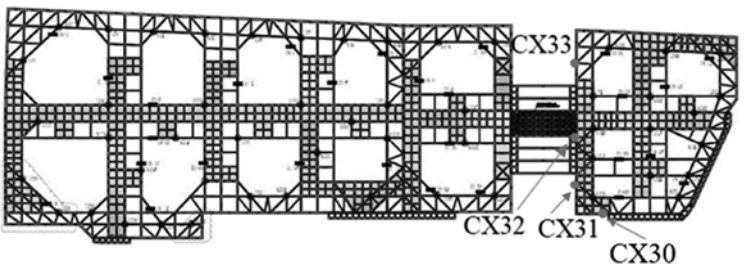

Figure 4. Layout of the foundation pit (Baoshan River-side Business Center Project).

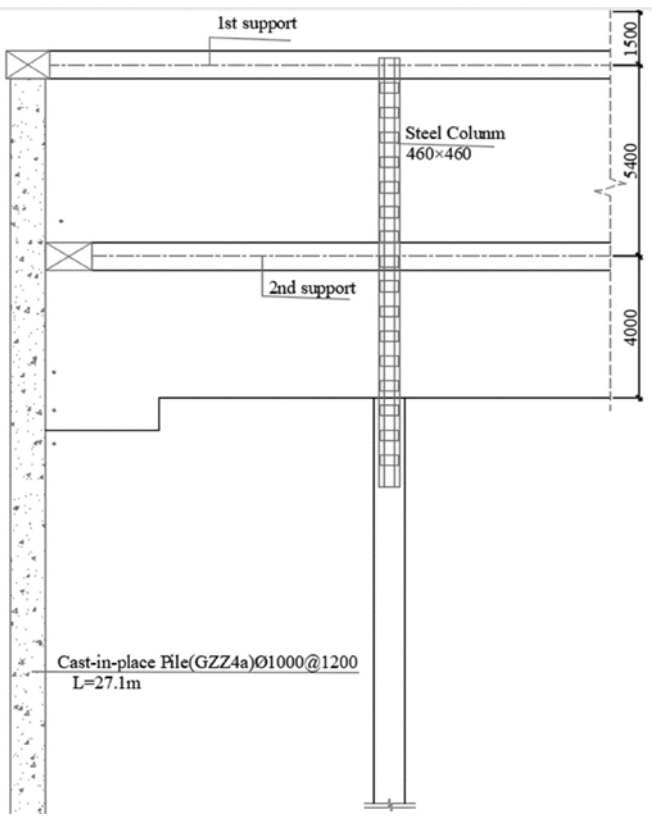

Figure 5. Layout of the foundation pit (Baoshan River-side Business Center Project).

The results in Figure 6 show that the prediction results fluctuate to a certain degree, but the mean absolute error and relative error are only 2.62 mm and 11.9%, meeting the accuracy requirements of actual projects. Therefore, the model can practically predict the maximum retaining wall deformations in satisfactory accuracy.

Table 4. Soil parameters (Baoshan River-side Business Center Project).

Soil layer	h m	γ kN/m^3	c' kPa	φ' °	E_{50}^{ref} MPa	E_{oed}^{ref} MPa	E_{ur}^{ref} MPa	$\gamma_{0.7}$ 10^{-4}	G_0^{ref} MPa

CX30-CX33	1st	20.16	8.5	1.5
	2nd			6.9

5 CONCLUSIONS

By collecting a large amount of monitoring data and FE calculation results, this paper generates a mixed sample database of maximum retaining wall deformations, trains the BPNN, and obtains a prediction model of maximum retaining wall deformations. Then an engineering case is used to verify the model. The following conclusions are obtained:

1) The proposed model can maintain a high accuracy for the prediction of FE examples, and the absolute errors are mostly less than 2mm, showing that the selected parameters of the model are rational.
2) The mean absolute error and relative error of the model for the case prediction are 2.62 mm and 11.9%, meeting the engineering requirements.
3) The accuracy of the model for the case is volatile but still within a reasonable range acceptable to engineering, not as good as that for the FE cases. Therefore, the diversity of

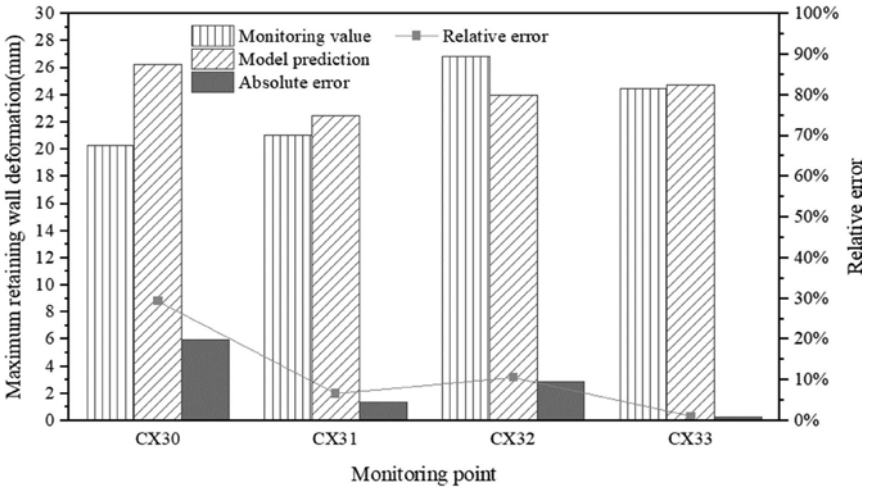

Figure 6. Comparison between prediction and the case (Baoshan River-side Business Center Project).

database can be improved through long-term statistics of more engineering data, so as to improve the prediction accuracy.

Seismic analysis and design of braced secant pile walls for excavations in Manila, Philippines

P.A.Y. Selda, M.P.V. Follosco, R.A.C. Luna & J.M.I. Tanap
AMH Philippines, Inc., Quezon City, Philippines

ABSTRACT: Typical design of temporary retaining wall systems mainly deals with the lateral pressure induced by both the retained material and the additional surcharge loads. However, earthquakes can also induce considerable destabilizing forces while permanently degrading the effective strength of the subsurface. Seismic analysis is essential when evaluating stability and deformation of deep excavations and high/steep slopes, especially in seismically-active regions like the Philippines. This paper discusses the design criteria, approach and methodology adopted for deformation analyses of a secant pile wall system braced with reinforced concrete struts for an excavation project in the Philippines. Emphasis is placed in the approach adopted when considering the seismic demand for temporary structures. Displacements were estimated and reported to be excessive. Recommendations were, however, ignored, and observed damages to the adjacent structures were later on reported during the excavation stage.

1 INTRODUCTION

With the implementation of the "*Build Build Build*" program of the current Philippine government underway, numerous investors come into the country to capitalize on the vast multitude of opportunities. The rapid economic growth of the country resulted in the upsurge in demand of many high-rise buildings. One particular condominium in Pasay City (Metro Manila), Philippines, was proposed to have a 12.77-meter deep basement. The study area is located just across reclaimed land. As such, a temporary secant pile wall system braced with struts was designed to support the walls of the excavation pit in consideration of the shallow groundwater table and the loose/soft subsurface. Although just a temporary system, consideration of seismic loads is still paramount and should not be overlooked especially since the site is only about 6.5 km away from the West Valley Fault (Mw7.2). This purpose of this study is to provide the developer with technical support services by way of reviewing the design of the proposed system and evaluate its stability.

2 SECANT PILE WALL

A secant pile wall is a type of retaining wall typically used for excavation protection. In this case, it is designed to be a system of bored piles that intersect each other at a uniform interval. Although not necessarily required, secant pile walls can be composed of two piles with different strengths: (1) the primary pile, which is typically weaker, often unreinforced, and whose embedment length can be relatively shorter; and (2) the stronger, reinforced secondary pile, which serves as the main lateral force resisting system. For the proposed system, the Designer opted for jet grout primary piles with an approximate 28-Day Compressive Strength (f'_c) of 5 MPa. On the other hand, the f'_c of the secondary piles is 35 MPa. Figure 1 shows a section of the proposed secant pile wall system. As can be seen, the centerlines of the primary and secondary piles are staggered by 200 mm, and the piles have a center-to-center spacing of 1.20 meters. It should also be noted that two levels of reinforced concrete (RC) struts are used to support the secant pile wall.

DOI: 10.1201/9781003299127-139

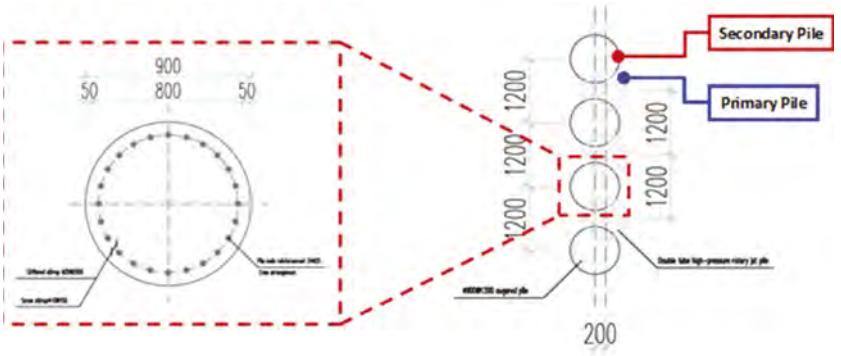

Figure 1. Blow-up section of secondary pile.

3 SUBSURFACE CONDITIONS

3.1 *Geotechnical investigation*

The geotechnical investigation (GI) program for this study consists of seven (7) drilled boreholes where Standard Penetration Tests (SPT) and several lab tests were conducted. The results of the GI program reveal that loose to medium dense sands and silts were encountered up to around 6.0 meters of depth from the surface. The succeeding layers have SPT N-values that are generally indicative of dense to very dense relative condition, with lenses of very dense and/or hard soils interspersed within the upper layers of the subsurface. In addition, the groundwater table was found to be as shallow as 0.65 to 0.80 meters below the existing grade level.

Table 1. Idealized subsurface profile.

Depth (m)	USCS	SPT N-Value	Relative Condition/Consistency
0 - 6.0	SP/SP-SM/SM	7 - 16	Loose to Medium Dense
6.0-12.0	SM/SP-SM	'*refusal*'	Very Dense
12.0 - 16.5	SM/ML/MH	28 - 38	Medium Dense to Dense
16.5 - 22.5	SM/ML	'*refusal*'	Very Dense
22.5 - 25.5	SM/MH	31 - 38	Dense
25.5 - 60.0	CH/SM/ML/MH	'*refusal*'	Very Dense/Hard

3.2 *Site class*

Site class is an indicator of how stiff the subsurface is. Among the different dynamic properties, the average shear wave velocity of the top 30 meters (V_{s30}) is generally accepted as an appropriate measure of an area's site class. Due to the lack of geophysical data, the site class

Table 2. Site class or soil profile types (Source: NSCP 2015 Table 208-2).

		Average Soil Properties for Top 30 m of Soil Profile		
Soil Profile Type	Generic Description	Shear Wave Velocity, V_{s30} (m/s)	N-value	Und. Shear Strength, S_u (kPa)
S_A	Hard Rock	> 1,500		
S_B	Rock	760 to 1,500		
S_C	Very Dense Soil and Soft Rock	360 to 760	> 50	> 100
S_D	Stiff Soil	180 to 360	15 to 50	50 to 100
S_E	Soft Soil	< 180	< 15	< 50
S_F	*Soil Requiring Site-Specific Evaluation*			

will be determined from the harmonic mean of measured SPT N-values with respect to depth, as referenced from the National Structural Code of the Philippines (NSCP) 2015 Table 208-2.

The distribution of in-situ SPT N-values correspond to a value of 30. This value lies within the 15 to 50 range, which suggests that the subsurface underlying the study area can be classified under the S_D (stiff soil) site class.

4 DESIGN CRITERIA

4.1 *Surcharge loads*

Existing structures found within the vicinity of the study area will induce additional surcharge loading to the proposed excavation protection system in the form of lateral earth pressure based on Boussinesq's theory. Figure 2 shows the layout of the adjacent buildings, as well as the sections used in analysis. Given surcharge loadings generally range from 15 kPa (roadway) to 45 kPa. The 7-storey building, however, is assigned a surcharge load of 105 kPa (15 kPa per storey).

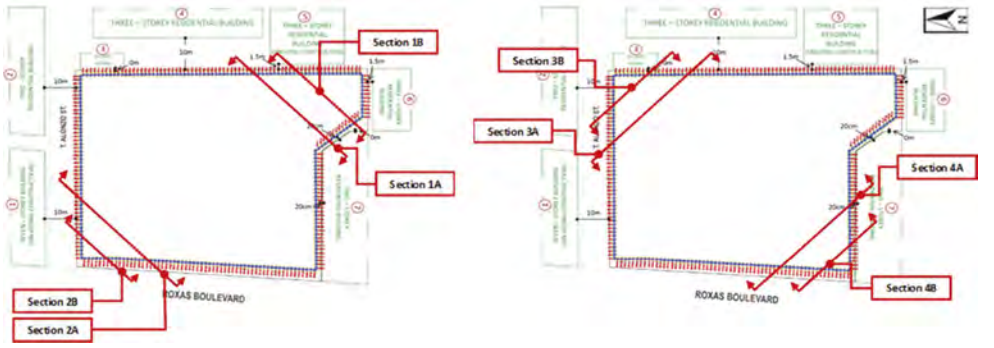

Figure 2. Layout of adjacent buildings.

4.2 *Seismic loading*

Aside from the static lateral earth pressure due to the surrounding structures, earthquakes can also induce considerable destabilizing inertial forces. Seismic loads permanently degrade the shear strength of the soil mass due to the stress and fatigue resulting from the prolonged exposure to cyclic loading. Seismic analysis is therefore essential when evaluating the stability and deformation, especially in seismically-active regions/countries like the Philippines.

In 2017, the Philippine Institute of Volcanology and Seismology (PHIVOLCS) published an atlas called the "Philippine Earthquake Model" (PEM), which comprises of maps containing isolines of equal acceleration, based on the regional probabilistic seismic hazard analysis study conducted by Peñarubia et al. (2017). According to the PEM PGA map of Metro Manila (Figure 3), the 475-year surface PGA on-site is 0.40g.

The secant pile wall system is said to be a temporary retaining structure only. For temporary structures, although oftentimes not required, it is still prudent to at least consider seismic loading associated to an earthquake with a lower hazard level (i.e. return period) than that of the 475-year design level earthquake. In the absence of site-specific studies or regional hazard maps for lower-hazard seismic demand, return period conversion factors (such as in New Zealand Standard 1170 Part 5 Table 3.5, 2004) can be used to convert the reference 475-year PGA to the target/warranted return period.

In lieu of the aforementioned technique, the seismic demand shall be taken as 70% of the 475-year PGA in this study, as agreed upon by all concerned parties or proponents. The resulting seismic demand is close to what would be a 225-year hazard. As such, the design PGA for the temporary structure will be 0.28g. Correspondingly, the horizontal (k_h) seismic coefficient (k_v) for pseudo-static analysis shall be taken as one-half of the design PGA, in accordance with the approaches developed by Hynes-Griffin & Franklin (1984) and Kavazanjian et al. (1997).

Figure 3. 475-Year Stiff Soil PGA map of Metro Manila (Source: PHIVOLCS, 2017).

4.3 *Deformation limits*

The primary criterion for designing excavation protection systems is the serviceability performance in terms of both vertical displacement (e.g. settlement, heaving) and lateral deflection. In the Philippines, it is common practice to set a vertical displacement limit of 25.0 mm for foundation design. Under seismic loading, the vertical deformation limits will be increased to 34.0 mm (approx. one-third increase from its static counterpart).

Moreover, the Philippines has no standard criterion for allowable lateral deflection of excavations. Nevertheless, data from many case studies have been collated over the years, and these provide a relative estimate of the expected lateral deflection of braced cuts. Most data points are said to fall within the range of 0.2% to 0.6% of the exposed height (H_e) for a combination of soil types. Given that the sections in consideration are for a two-level braced excavation pit, the lateral deflection is not expected to reach the upper bound of the aforementioned range. Otherwise, internal forces in the struts will be quite large. As such, stringent limits of $0.2\%H_e$ and $0.3\%H_e$ are adopted in this study for static and pseudo-static conditions, respectively.

5 NUMERICAL ANALYSIS

5.1 *Finite element method*

In order to establish the displacements during and after excavation, deformation analysis will be carried out by way of Finite Element Method (FEM) using the numerical analysis tool, PLAXIS 2D 2018. FEM is a numerical technique used for finding approximate solutions by continuum-based methods wherein the governing equations describing the flow of water and deformation of the body are derived on the principles of conservation of mass, momentum, and energy. These equations, together with the prescribed boundary conditions, result in a nonlinear boundary value problem. The main advantage of FEM is its ability to estimate the deformations leading up to the failure or time point of interest. These deformations correspond to the movement of the soil mass showing how it will behave upon application of loads.

5.2 *Constitutive model*

The constitutive model adopted in this study is the Hardening Soil Small-strain (HSS) model (Schanz et al., 1999; Benz, 2007). The HSS model has the ability to vary stiffness depending on the stress state of the soil elements, even when at small strain levels. This is an ideal constitutive model for excavation projects because certain regions of the soil mass may possibly experience different stress state and conditions than those adjacent to them.

It should be noted that the HSS model utilizes the Mohr-Coulomb (MC) yield criterion and the model's corresponding shear strength parameters. Due to the lack of advanced lab testing, the

HSS parameters were correlated from reported/published values of soil samples with similar relative conditions and/or consistencies to the soil samples obtained from the study area. As it is not the objective of this study to focus on the parameters, the adopted MC and HSS parameters will no longer be presented.

6 RESULTS

6.1 *Displacements*

From the numerical analyses of the sections at static conditions, the maximum calculated deflection, settlement, and heave are 25.0 mm, 27.5 mm, and 27.5 mm, respectively. Although deflection is within the tolerable limit, settlement, and heave both exceed the allowable value by a small margin. As pseudo-static conditions, the maximum calculated deflection, settlement, and heave are 45.0 mm, 45.0 mm, and 40.0 mm, respectively, which all exceed the allowable limits. Table 3 summarizes the maximum calculated displacements for both conditions. In addition, Figures 4-5 show the exaggerated deformed mesh and deformation contour plot of Section 4A for both conditions, as reference and for visualization of the results.

Table 3. Summary of maximum calculated displacements.

	Static		Pseudo-static	
Deformation	Allowable	Calculated	Allowable	Calculated
Deflection (mm)	25.5	25.0	38.3	45.0
Settlement (mm)	25.0	27.5	34.0	45.0
Heave (mm)	25.0	27.5	34.0	45.0

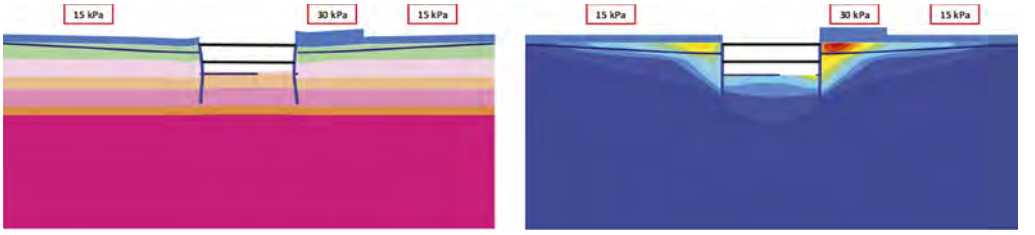

Figure 4. Section 4a Static: (a) exaggerated deformed mesh & (b) deformation contour plot.

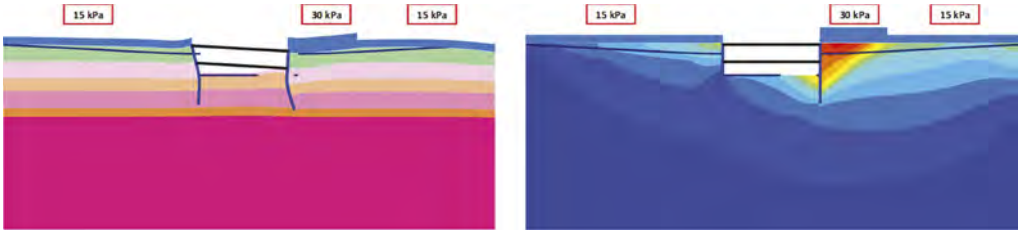

Figure 5. Section 4a Pseudo-static: (a) exaggerated deformed mesh & (b) deformation contour plot.

6.2 *Internal forces*

Aside from estimated displacements, the internal forces of the secant pile wall can also be extracted from the numerical analyses. Table 4 summarizes the maximum unfactored internal axial force, shear force, and bending moment of the secant pile wall elements for both static and pseudo-static conditions.

Table 4. Summary of maximum calculated secant pile wall internal forces.

Scenario	Axial (kN)	Shear (kN)	Bending Moment (kN-m)	
Static	487.18	675.43	(+) 899.83	(-) 1013.67
Pseudo-static	595.78	960.44	(+) 1464.77	(-) 1421.51

7 FINDINGS

Based on the foregoing numerical analyses using the available and inferred/correlated information, results show that estimated displacements are slightly excessive even at static conditions. The tolerable limits are further exceeded for pseudo-static conditions, despite not even considering the full seismic demand brought about by a 475-year earthquake. The developer was informed of this that some protective measures must be undertaken prior to construction, such as replacing the RC struts with steel sections, decreasing the spacing between struts, and even increasing the f'_c of the primary piles. Unfortunately, construction was pushed through, and observed damages to the adjacent structures were later on reported. Figure 6 shows some of the reported damages.

Figure 6. Reported damages: (a) damaged floor tiles & (b) lateral displacement of perimeter wall.

8 CONCLUSIONS

For slopes and cuts, the standard practice in the Philippines is simply to perform a pseudo-static idealization of the seismic demand to check for stability. Full non-linear dynamic analyses are only done in the design of large dams and/or high-rise buildings. In this study, the temporary secant pile wall system was subjected to a lower-level earthquake level, estimated to be 70% of 475-year seismic hazard. Although no earthquakes have occurred yet near the study area, the approach is surmised to be sufficient, and is in agreement with actual conditions given the reported damages.

Moreover, the displacement acceptance criteria used in this study are somewhat arbitrary, selection of the adopted limits are based on actual observations taken from numerous case studies, and thus, have merit. As such, these should not be ignored despite not having been standardized in local codes. In any case, the reported damages shown above validate how significant empirical data is, and how crucial the role of monitoring is in any engineering work.

ABSTRACT: The paper describes some geotechnical aspects of the reconstruction of the Russian State Academic Bolshoi Theatre, which was undertaken in the period of 2005-2008 with direct authors' involvement. The reconstruction of the underground section of the Theatre was carried out under the preserved superstructure. A 20 meters deep excavation was constructed in close proximity of other buildings. An observational method for strengthening foundation was applied. The method involved constantly performed monitoring and settlements management on the base of the monitoring results. The paper discusses design problems of supporting structures with regard to changes in their stress-strain state during reconstruction. A case history of the application of the observational method throughout the entire reconstruction period is considered.

1 INTRODUCTION

It is common knowledge that UNESCO designates the Russian Bolshoi Theatre as the world cultural Heritage site. Architect Albert Kavos and sculptor Peter Klodt designed the Theater building in 1857, and it still preserved its original architectural features. It was not reconstructed or repaired until 2005, by which time some supporting structures were in breakdown condition and many structural members were 50% worn out. It was evident, that further building operation should envisage the complete modification of the stage equipment and auditorium facilities, restoration of already lost décor members or maintenance of those still survived, as well as modification of installations.

All those factors confirmed the inevitability of the reconstruction of the Bolshoi Theatre. It took more than a dozen years to develop a reconstruction project. The project had undergone many alterations made before or within the reconstruction. The paper discusses technical aspects of the reconstruction process, emphasizing design features of the underground section of the UNESCO Heritage Site.

Figure 1. The Bolshoi Theatre before the reconstruction, in the mid-20th century.

2 GEOTECHNICAL ASPECTS OF THE BUILDING BEFORE THE RECONSTRUCTION

The building comprised brick supporting walls with singular pillars inside and outside the building (portico), arched and slab ceilings made of brick or concrete. Foundation consisted of rubble footing, brick strip footing, and independent footings of various cross-sections, whose bottom depth varied from 3.5 m to 6.0 m. There had never been serviceable underground space. The auditorium rested on a concrete slab designed by I. Rекberg. The slab was laid in the 20's of the nineteenth century, following a dangerous settlement of semicircular auditorium walls. When it happened, during a performance, the doors of the auditorium jammed and spectators were evacuated through side boxes.

It is important to note, that all supporting structures of the Theatre rested on three different footings, which carried three superstructures sequentially erected at different times: the wooden Peter's Theatre, the wooden Imperial Theatre, and the brick theater building erected in 1856. Thereby, the footings' depth and cross-section dimensions varied depending on stiffness of the structures they supported (concrete or wooden) and on the corresponding load, they carried. Due to the differential settlement, the portico pillar had deviated from the vertical up to 30 cm since the footing settlement was first recorded in the nineteenth century.

In the beginning of the 2000th, the load-bearing structural members, as well as underground supports were found in a partially functional state and some of them were even out of function.

In the second half of the twentieth century, some supporting structures were strengthened with respect to safety requirements to the building operation, actual for that time. For strengthening the foundation, a grouting method was applied with using materials modern in those days. However, from the technical condition viewpoint, the building required some conservative measures to be applied for ensuring its safe operation for the following operational period (more than a hundred years for structures of KS-3 class designed for mass presence of people, GOST 27751).

In the authors' opinion, adverse impacts responsible for the poor technical conditions of the supporting structures were as follows:

- Design features of the building that rested on mixed foundation carrying different structures and loads.
- Timber piles and beds exposed to rotting and uneven decay across the entire building became the reason for the partial or complete loss of bearing capacity of supports and supporting structures.
- In-service wear and tear of the structures' material caused a significant decrease in bearing capacity of structural members and individual structures, and, finally, of the whole building.
- Changes in geotechnical environment triggered changes in hydrogeological conditions and in soil properties, which in turn led to uneven settlement of footings.

Among the above factors that affected the building, the last one deserves a particular attention. It is a matter of discussion in this paper.

It is obviously worth beginning with the fact that the building was located on the Neglinka river flood plain, close to the dead arm of the river and a sewer built in the period of 1887-1889. In those days, the river was enclosed in a pipe and lowered beneath its original bed then. As a result, a water table lowered and hence intensified the decay of timber piles, thereby triggering uneven settlement of footings.

Geological cross-section of the site comprised Upper Quaternary deposit represented by silty to gravel alluvial sand, with thickness varying from 3,0 to 16,0 meters, underlain by Jurassic clay of varying thickness and consistency. All soil unites of Upper Quaternary deposit were uncertain, varied in plane and with depth, and wedged out in places. There were some areas of erosion indicated by Carbonic limestone overlaid with Upper Quaternary deposit.

An Aquifer was represented by alluvial sand. A water table level varied from 6.0 to 10.0 meters below the day surface. Such magnitude of the water table level was caused not only by the seasonal water flooding or by leakage through underground water supplying pipelines, but also by dewatering of the underground subway structures. The water of Upper Jurassic Aquifer was non-aggressive towards W4-concrete. The second Aquifer was associated with limestone and did not affect the underground structure of the building.

Talking about dangerous geological processes, the site was affected by karst, which occurred in the upper roof of the limestone deposit overlaid by thin Upper Quaternary or Jurassic clay. The karst phenomena at the site could be explained either by shallow occurrence of limestone deposit or by man-made effect. The thin clay layer did not protect the site from the karstic impact. For instance, due to karst occurrence in the neighboring area of the Maly Theatre and Metropole Hotel, jet-grouting technology was used for strengthening foundations at the site.

Originally, the building could be classified as a KS-3 class building designed for mass presence of people (more than a hundred, according to GOST 27751), and without any design features.

Therefore, from the geotechnical viewpoint, the building was a unique KS-3 class structure, with longitudinal and transverse supporting walls made of bricks of different configuration in plane. The supporting structures rested on strip foundations made of rubble, bricks and limestone, and on timber bed and piles. The soil foundation comprised different types of soil, the hydrogeological conditions of which varied causing uneven foundation settlement.

3 SOME GEOTECHNICAL ASPECTS OF THE RECONSTRUCTION PROCESS

The reconstruction design provided strengthening of the basic supporting structures with installation of additional elements necessary for the building operation. The geotechnical aspect was that the design envisaged installation of the underground structure slated to provide mechanical safety of the superstructure, accounting for the following factors: hydrogeological conditions, dangerous geological processes or man-made impact, and the influence of surrounding buildings. The design also had to meet requirements to the installation of the modern stage equipment.

Actually, six floors were designed below the day surface almost under the entire theater building, except for the auditorium. Several underground floors were additionally designed in front of the building and behind it, in Kopyevskiy Lane. Underground work was carried out in strict compliance with requirements to limiting deformations of a base under the preserved superstructure (less than 0.0007 - the relative difference in settlement with regard to emergency strengthening of the superstructure).

The design of the underground structure included an excavation enclosed with a “diaphragm wall”, which would serve as both supporting structure and groundwater protection. Since the underground structure was constructed under the retained superstructure, a “top-down” construction technique was selected, according to which the excavation at each level alternated with subsequent installation of supporting walls and floors at that level. In that case, the word “excavation” denoted the soil volume encompassing the installed underground supporting structures.

The new image of the theater with its newly arranged underground space should have looked as shown in Figure 2.

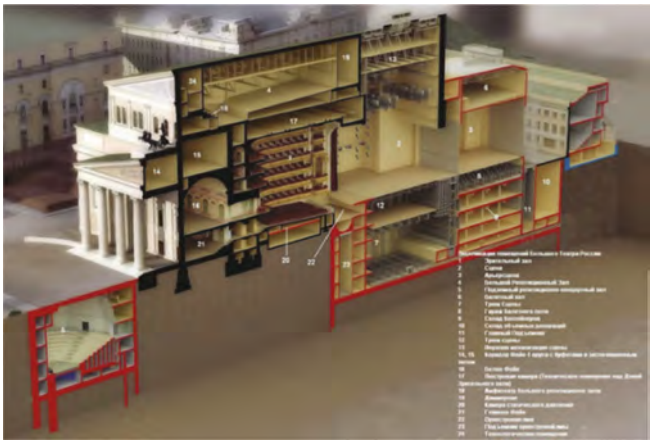

Figure 2. The concept of underground space of the Theatre Building, following the architect guru view.

The following measures were developed to meet the reconstruction design solution:

- Retained load-bearing structural members were temporarily or permanently strengthened for installation of temporary or permanent underground supports.
- Load-bearing concrete pile caps reinforced with rolled elements were arranged under the retained supporting structures (walls, columns).
- Temporary supports (jacked piles inside and end bearing piles outside the building) were installed under the retained supporting members (walls and columns).
- Temporary supports of retained superstructure were put into action, and old footings were taken out of service.
- Enclosing structures were installed outside and inside the building. The outside enclosure was executed as a diaphragm wall. The inside enclosure was installed along the contour of the auditorium, and it comprised secant wall made of small-diameter piles (300 – 350 mm) with a soil lock made using deep mixing technology.
- A pile cap mat executed as a rigid frame disk was arranged for putting caps installed under walls and columns into action, and for excluding horizontal movements.
- Excavation of the first subsoil level and dismantling of the old foundations.
- Temporary supports were braced and combined, thereby making a spatial frame structure that provided the stability of each member (piles, braces) and temporary structures in general. To protect the enclosure, struts bearing lateral soil pressure were arranged.
- Installation of the underground permanent supporting walls and floor of the second level.
- Excavation was performed in-stages. On finishing each excavation stage, temporary spatial frame structure comprising temporary supports (piles) and bracing members was arranged.
- Additional load was applied to piles for improving their capability to bear a load from permanent supporting structures (floor walls) and from elements of the enclosure strut system, as well as from permanent walls and ceilings subsequently constructed at each floor.
- Installation of the foundation slab at the design level.
- Permanent supporting structures and supports (walls, ceilings and foundation slab) were put into operation at minimum deformation, thus ensuring ultimate limit settlement and disabling temporary pile supports together with bracing members.
- Dismantling of temporary supports (piles, bracing members).

Figure 3 shows the general scheme of temporary structures location.

Structurally, both temporary and permanent underground members possess the following basic characteristics:

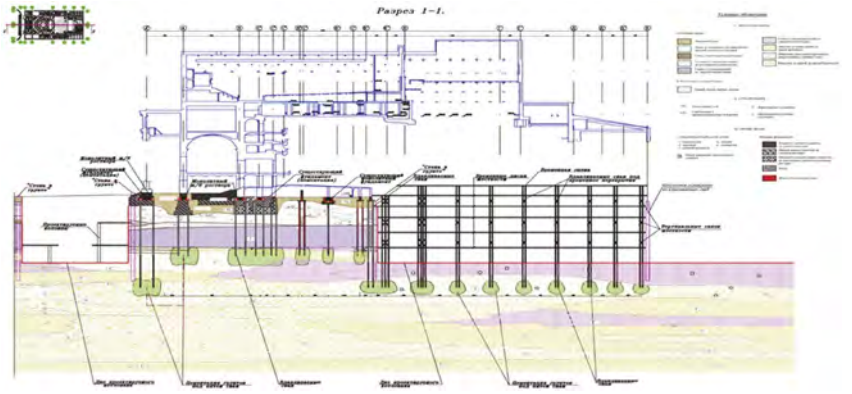

Figure 3. A layout of the underground permanent and temporary structures.

- The total load transferred from the preserved superstructure to temporary supporting frame structure, which included jacked piles and bracing members, was 170 thousand tf, and 230 tf with regard to newly erected underground structures.
- The traditionally installed "diaphragm wall" was 30-35 meters high and 800 mm thick.
- Temporarily supporting jacked pile originally carried the designed load of 80.0 tf and up to 100.00 tf when worked in the framed system then. Piles were 219 mm in diameter, made of weldless hot-formed pipes joined together in a section-by-section manner. The length of each section was 1-2 m, the total pile length was 16.0-26.0m.
- Temporary end bearing supports with a diameter of 630-820 mm and length 25.0-30.0 m carried the design load of 250-300 tf.
- 700 mm thick pile cap mat made of B30 concrete was rigidly reinforced under walls and columns. In spans, the pile cap mat was reinforced with frame made of individual metal rods of A500C class.
- 1500 mm thick foundation slab made of B30 or W12 concrete was reinforced with individual metal rods of A500C class.
- The "Triade Holding" specific non-shrink mortars for putting permanent load-bearing structures into operation was injected into gaps between walls and ceilings, formed while grouting in sequence ceiling-wall.

The geotechnical design of the underground structure was performed by Podzemproekt" LLC and "Baltiy" LLC. The "Podzemproekt" designed installation of the "diaphragm wall" and foundation slab. The "Baltiy" Company designed installation of pile caps under the retained structures, temporary supporting piles, and the installation of the underground structures. It also designed reinforcing piles installed outside the new underground structure, and excavation enclosures installed inside the building area. It should be noted, that a constant geotechnical monitoring performed by LLC "IC"Kreal" had accompanied the construction of the new underground structure for the whole construction period. Authors together with designers provided scientific and technical support to the construction process.

Constantly performed monitoring gave the possibility to make necessary adjustments during the construction without changing the fundamental design solutions. That was exactly what defined as an observational design method, in the regulatory documents. Thus, for example, the constant monitoring of the stress-strain state of the temporary support (jacked piles) was performed when the load was increasing due to newly erected underground structures, or when the stress was changing due to the installation of braces that provided piles stability in the excavated area. Jacking load was regulated for each pile individually on the base of the monitoring results, thereby demonstrating the technical support during the construction.

The monitoring and technical support had accompanied the whole process of the underground construction. This enabled engineers:

– To promptly elicit changes in the technical condition of the retained supporting structures by monitoring settlements and observing existed cracks or newly formed.
– To set up measures necessary to ensure the mechanical safety of individual load-bearing elements (already in place or newly constructed).
– To avoid deformations, which could dramatically reduce the capacity of the structural members and the whole building.
– To complete the construction of the new underground facility under the preserved building of cultural heritage in accordance with the adopted schedule.

The Theater building acquired a new "geotechnical appearance" including the underground part comparable in volume to the superstructure, and at the same time retained its historical appearance, visible to all of us.

4 CONCLUSIONS

The performed reconstruction involved pioneer geotechnical methods and structures installed. They comprised:

– Construction of the deep excavation under the retained structure. The 20 meters deep excavation was enclosed with "diaphragm wall" installed along the outer perimeter of the entire building to the depth of 32 m. Inside the building, along the contour of the auditorium, a 22 m deep enclosing secant wall made of small-diameter piles (300 – 350 mm) was arranged with a soil lock made using deep mixing technology.
– A stepwise installation of the capping raft. The procedure included installation of the caps under the retained walls, combined into a single capping raft after temporary supporting piles were constructed.
– Different types of the temporary supporting piles: small-diameter piles of 219 mm in the diameter and with the length of 21-22 m, cast-in-place end bearing piles of 600-280 mm in the diameter, 28-30 meters long piles reinforced with pipes of 420 mm in the diameter.
– The installation of small-diameter piles took place in confined space inside the building, using the combination of different technologies: drilling through the fill, which included members of the existed foundations and communication lines, pile jacking with soil displacement and thereby producing the preliminary design load that considered only the retained members of the superstructure and the new capping raft, increase in design load by applying additional load to the piles for improving their bearing capacity when the newly erected underground supports, namely, floors and vertical supporting structures were put into operation. Thus, the load applied before excavating was 80 tf, and it was 110 tf when the excavation was finished.
– Temporary cast-in-situ supporting piles were installed in casings outside the building and they carried the design load of 250-300 tf.
– Single piles were combined into a spatial structure, while excavating.
– A stepwise excavation was performed to the depth of a level. After excavation, permanent vertical and longitudinal supporting structures were installed. The structures served as struts resting on temporary pile supports.
– Installation of the foundation slab was followed by putting permanent underground supports into operation. Concurrently, temporary supports were taken out of operation.

Analytical methods for calculating passive ground pressure in the construction of ground berms

I.B. Bashmakov
Saint-Petersburg State University of Architecture and Civil Engineering, Saint-Petersburg, Russia

ABSTRACT: This article reveals various methods of accounting for retaining berm in the calculations of the slurry wall construction. For one calculation case, the calculation results were compared using the basic approximate methods for estimating passive pressure when installing ground berms. To validate the existing approximate methods, method of characteristics in limit equilibrium method (*LEM*) was developed, allowing us to obtain a mathematically rigorous solution. The result of the work is a graph of the distribution of passive pressure along the slurry wall construction. The proposed rigorous mathematical method showed high convergence with the CPM method. The suggested approach allows us to obtain characteristic zones of the structure where the passive pressure formed by the soil berm works.

Keywords: passive ground pressure, ground berms

1 INTRODUCTION

In construction practice, to reduce the deformations of the diaphragm wall structures of the pit and increase their stability, various methods of bracing are used, such as the device of a strut system, anchors and soil berms [4]. The simplest and most economical method is the last option, due to the lack of need for additional materials, but at the same time difficulties arise from the point of view of engineering calculations. Classical methods for determining passive pressure, such as Coulomb theory or Rankin theory, associate natural stresses σ_z with passive pressure through the passive pressure coefficient K_p [7].

In modern engineering practice, the Poncelet formula for the passive pressure coefficient (1) has become widely used:

$$K_p = \left(\frac{\cos(\varphi - \alpha)}{\cos(\alpha) \times \left(1 - \sqrt{\frac{\sin(\varphi+\delta)\ \sin(\varphi+\beta)}{\cos(\alpha+\delta)\ \cos(\alpha+\beta)}}\right)} \right)^2 \quad (1)$$

where φ – the angle of internal friction of the soil, degrees, α – the angle of inclination of the wall structure's surface to the vertical, degrees, β – the angle of inclination of the soil surface to the horizontal, degrees, δ – the angle of friction at the contact "wall structure – soil".

This formula allows us to take into account in the calculation the inclined surface of the slurry wall construction and the friction between the wall structure and the soil but does not allow us to take into account the complex layout of the soil mass, which has a significant impact on the stress-strain state of the system. [8]

Therefore, the use of more useful calculation techniques is necessary to estimate the passive pressure during the construction of ground berms. [9, 10]

DOI: 10.1201/9781003299127-141

So that, in this work, a comparative analysis of different approximate methods for calculating passive pressure of ground berms was performed. A high spread of results was obtained.

Because it is difficult to estimate the actual values of passive pressures in field and laboratory conditions, the estimation of the applicability of the approximate methods was performed on the basis of a mathematically rigorous calculation method of soil mechanics.

2 LITERATURE REVIEW

In modern practice, there are the following approximate methods for calculating the passive pressure of the soil when installing ground berms occurred:

1. Additional equivalent load method (*AELM*) [1,6];
2. Method of increasing the level of the pit bottom (*ILPBM*) [1, 5, 6];
3. Modified method of increasing the level of the pit bottom (*Modified ILPBM*) [1, 6];
4. The Coulomb Prism Multiple Method (*CPMM*) [1, 5, 6].

The main condition of these methods are presented below.

The method of additional equivalent load (*AELM*). In this method, the weight of berm (W) is substituted by an equivalent uniformly distributed load (S), which is applied at the bottom level of the pit (Z). The load value (S) is determined by the formula (2):

$$S = \frac{W \ tan(\theta)}{d} \tag{2}$$

where W – the weight of berm, θ - the sliding surface's angle (except for soil-wall friction as calculated by $(45° - \varphi / 2)$, d – the amount of wall embedded in the ground.

The calculation scheme for this method is shown in Figure 1b.

The method of increasing the level pit bottom (*ILPBM*). The essence of the method is that the real berm is substituted by a berm with the same width of the lower base B_{bottom} which equal to real berm, but having a slope of 1:3, then the maximum height of the berm becomes equal to B/3. The calculated berm is taken into account by raising the level of the bottom of the pit by a value of B/6.

The berm area extending beyond the new geometry (the shaded part in Figure 1c) can be taken into account in the calculation as an additional equivalent load. It is worth noting that the method of increasing the level of the pit bottom, in contrast to the method of additional equivalent load, takes into account both the vertical pressure from the berm and partially the lateral pressure that the berm apply on the wall.

Modified method of increasing the level of the bottom of the pit (Modified *ILPBM*). This method is a combination of assumptions accepted in the *AELM* and *ILPBM*.

In contrast to the previous method, this method takes into account not only the geometry of the berm, but also its weight (W). The level of the layout increases by the value y, calculated by the formula (3):

$$y = \frac{W \ tan(\theta)}{\gamma d} \tag{3}$$

where W – berm weight, θ - angle of the sliding surface, γ – specific gravity of the berm soil, d – the amount of wall embedding in the ground.

The calculation scheme for this method is shown in Figure 1d.

The Coulomb Prism Multiple Method (CPMM). This method is based on the equilibrium equations of the Coulomb prism, which is constructed on the basis of the assumption of rectilinear sliding surfaces in the soil mass.

The forces acting in this prism is shown in Figure 2. By decomposing the forces into vertical and horizontal components, we obtain formulas (4) and (5).

$$F = (N + c`l\cot(\varphi))\tan(\varphi)\sin(\theta) + (N + U_R)\cos(\theta) - \ U_W \tag{4}$$

where N – normal reaction to the collapse surface, $\boldsymbol{c`}$ и $\boldsymbol{l}$ – adhesion along the surface and collapse surface length, respectively, $\boldsymbol{\varphi}$ – the angle of internal friction of the soil, $\boldsymbol{\theta}$ - angle of the sliding surface, $\boldsymbol{U_R}$ – pore pressure of water acting on the surface of a theoretical collapse, $\boldsymbol{U_W}$ – pore pressure acting on the wall.

$$N = \frac{c`l(\cos(\beta) + \sin(\beta)\tan(\delta)) + U_R(\cos(\beta)\tan(\delta) - \sin(\beta)) + W - U_W\tan(\delta) + cl_w}{\sin(\beta) - \tan(\varphi)\cos(\beta) - \tan(\varphi)\sin(\beta)\tan(\delta) - \cos(\beta)\tan(\delta)} \tag{5}$$

where $c`l$ – resultant adhesion along the collapse surface, β – angle equal to 90°- θ, δ – the friction angle of the soil against the wall, U_R – pore pressure of water acting on the surface of a theoretical collapse, W – weight of the collapse prism, U_W – pore pressure acting on the wall, cl_w – resultant coupling along the ground/wall surface (where l_w – the depth of the collapse prism under consideration with an abutment to the wall, $\boldsymbol{c}$ – specific gravity of the soil with a wall).

The calculation procedure suggest splitting the surface of the wall into equal sections in depth, after which a search is performed for the angle of inclination of the collapse prism β for each split point, at which the minimum passive resistance of the soil mass is provided. Following the completion of the calculation of the distribution of total passive pressure along depth, a plot of the passive ground pressure is constructed using the differentiation method.

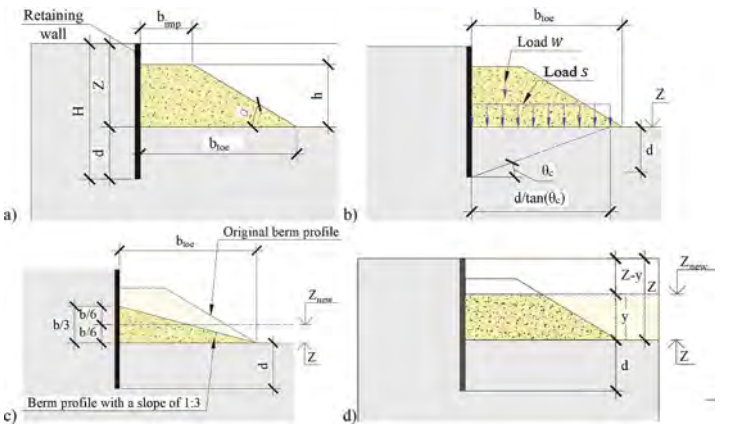

Figure 1. Soil berm calculation schemes: a) geometry of the soil berm; b) additional equivalent load method; c) increasing the level of the pit bottom method; d) modified ILPBM.

3 MATERIALS AND METHODS

3.1 *Mathematically rigorous solution*

Due to the significant differences between the calculation assumptions and the results of calculations according to the above approximate methods, their verification is necessary for their application in practical engineering. For this purpose, it is advisable to compare the results of calculations using existing methods with a mathematically rigorous solution.

In this case it is accepted to use the method of characteristics within the theory of the limit equilibrium method (*LEM*), developed by V.V. Sokolovski [3]. This method is based on the joint solution of the differential equilibrium equation of the plane-strain problem and the Coulomb-Mohr condition (6).

Based on this system of equations, as well as the relationship between the direction of the main stress σ_1 and the direction of the sliding surfaces of the first and second families, a system of four differential equations containing four unknowns can be obtained. This system of equations can be solved by the finite difference method by sequentially solving a number of boundary value problems [2].

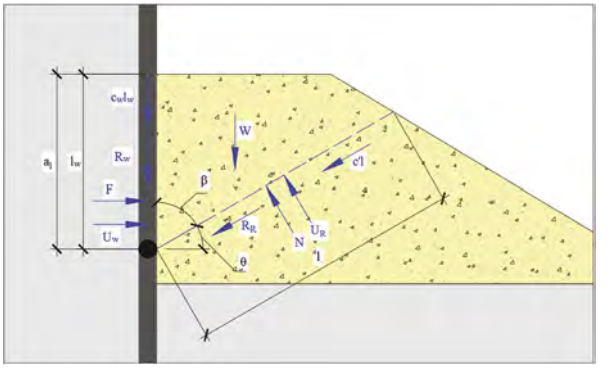

Figure 2. Calculation scheme of the method of multiple prisms.

$$\begin{cases} \dfrac{\partial \sigma_x}{\partial x} + \dfrac{\partial \tau_{xz}}{\partial z} = 0 \\ \dfrac{\partial \tau_{xz}}{\partial x} + \dfrac{\partial \sigma_y}{\partial z} = \gamma \\ \dfrac{\sigma_1 - \sigma_3}{\sigma_1 + \sigma_3 + 2\,c` \cot(\varphi)} = \sin(\varphi) \end{cases} \tag{6}$$

The proposed calculation scheme for assessing the passive pressure of the soil when installing a soil berm is shown in the Figure 3. In this diagram, the numbers indicate the order of solving boundary value problems, yellow – the first boundary value problems, blue – the second, green – the third and pink – the second boundary value problems with a special fan point.

4 RESULTS AND DISCUSSIONS

The main assumption of this research was the patten that the work of the soil berm is quite complex and approaches to its description with an equivalent load or an increase in the level of the pit bottom leads to an incorrect solution to the definition of passive pressure.

From the point of view of practical application, a significant disadvantage of the method of characteristics in LEM is complicated in application in case of nonlinear stratification of the foundation soils.

To compare the calculation results by the proposed method with the calculation results by approximate methods, Figure 4 shows a summary graph of the distribution of passive ground pressure by depth.

As can be seen from Figure 4, the characteristics method and the Coulomb prism multiple method show a fundamentally different nature of the passive pressure distribution over the depth than the other calculation methods. This is because the method of characteristics and the method of Coulomb prisms multiple allow us to take into account the actual complex geometry of the ground surface, while the other methods assume simplifying the design scheme to the horizontal layout of the bottom of the pit. This can also explain the high values of passive pressures that are obtained by the method of characteristics: unlike CPMM and ILPBM, this method takes into account the actual geometry of the soil berm, and does not simplify it as raising the level of the bottom of the pit below the base of the soil berm.

Analyzing the results of calculations, it is important to note that when taking into account the actual geometry of the soil berm, the character of its work corresponds to the case of horizontal layout only on the upper part of the plot, in particular, at a depth of 0 to 2 m.

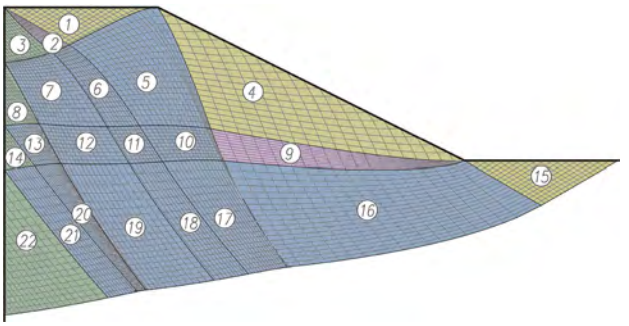

Figure 3. Calculation scheme and sliding surfaces in the soil mass when calculating the passive pressure during the installation of the soil berm by the characteristics method.

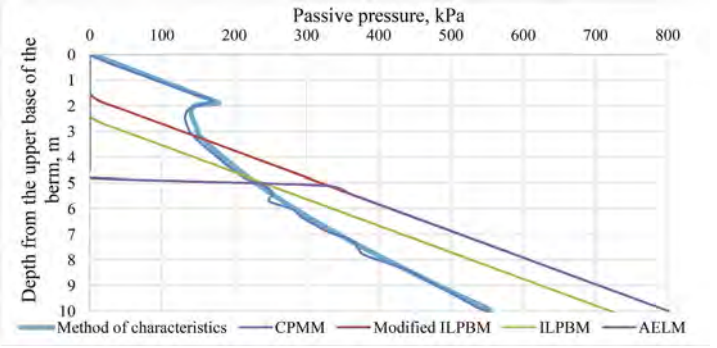

Figure 4. A summary graph of the results of calculating the passive ground pressure by the depth of the wall using various approximate methods and the method of characteristics (*LEM*).

The analysis of the plots of the distribution of passive soil pressure in depth with different geometric parameters of the soil berm allowed us to identify 3 main sections, shown in Figure 5.

The nature of the passive pressure plot in the first zone corresponds to the case of the vertical day level to the mark of the apex of the berm.

For the second zone, the distribution of passive pressure corresponds to the case of an inclined ground surface at an angle equal to the angle of the soil berm and can be determined by the formula (1).

For the third zone, the distribution of passive pressure in depth corresponds to the method of additional equivalent load, but taking into account the nonlinear determination of the value of the additional load.

Testing in a laboratory or in the field is required to validate the theoretical solutions presented in this article.

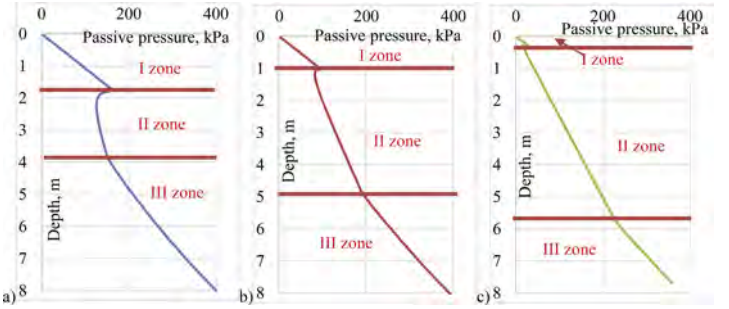

Figure 5. Plots of the distribution of passive soil pressure along the depth of the wall for a soil berm with an upper base of a) 5m, b) 3m, c) 1m, a lower base of 15m and a height of 5m.

5 CONCLUSIONS

1. A calculation scheme is proposed for determining the passive pressure of the soil by the method of characteristics within the theory of limit equilibrium method (LEM).
2. According to the results of the comparative analysis, a high convergence was obtained between the results of the calculation of the passive pressure of the soil during the installation of soil berms by the method of multiple prisms and the method of characteristics (*LEM*). The use of this approximate technique can be recommended for practical calculations, because this approximate method allows us to estimate the passive pressure corresponding to the fundamental laws of soil mechanics.
3. The selected characteristic areas on the obtained plots can be used as the basis for a new simplified method for calculating the passive pressure of the soil when installing ground berms.

Calculation method of determining the earth pressure on the diaphragm wall considering the undrained soil behavior

R.A. Mangushev, I.P. Diakonov, I.B. Bashmakov & D.A. Paskacheva
Saint Petersburg State University of Architecture and Civil Engineering, Saint Petersburg, Russian Federation

ABSTRACT: In this article is shown a method of analytical calculation of soil pressure on the diaphragm wall of the pit, considering the of excessive pore pressures in the soil. Consideration of the undrained behavior of the soil is performed using the parameters of the Skempton. An analytical solution is obtained for active and passive earth pressures in view the possibility of formation of excess pore pressure. Recommendations are given for calculating the stability of pits in weak clay soils, taking into account with state of excessive pore pressures.

Keywords: passive earth pressure, active earth pressure, excess pore pressure, undrained behavior, Skempton's coefficients

1 INTRODUCTION

Developing of the underground space, the main object of study is the retaining wall structure. A correct assessment of the stress-strain state in the structures helps to avoid failure, as well as excessive reserves of capacity.

To a greater extent, this is relevant for underground construction with a significant thickness of weak soils characteristic in the St. Petersburg region [1], [2]. In relation to the geological conditions of St. Petersburg it is rational to consider time dependence pressure on the diaphragm wall caused by filtration processes in water-saturated weak clay soils.

The purpose of this research is to develop computational method for determining the pressure on the diaphragm wall, taking into account the undrained behavior of the soil. Taking into account the above objective and relevance of the research, the following tasks were set:

- analysis of existing methods of calculating soil pressure on retaining wall;
- derivation of active and passive pressure formulas according the parameters of the undrained behavior in the soil;
- comparison of the results of drained and non-drained calculation of soil pressure on the diaphragm wall.

2 LITERATURE REVIEW

2.1 *Undrained behaviour*

To analysis and control the results of numerical calculations, it is necessary to develop a methodology for approximate analytical calculation, which allows us to estimate the quantitative and qualitative impact of the parameters of undrained strength (coefficients of Skempton) on the stress-strain state in the soil.

DOI: 10.1201/9781003299127-142

The influence of undrained strength parameters on the results of triaxial consolidated-undrained tests (CIUC) within the ideal elastic-plastic model [3] and for hardening models [4], [5] was considered. It is well-known that the results of undrained calculations are largely influenced by the chosen model for describing of the soils strain [6]. A model correctly selected for the calculated situation allows us to obtain high convergence of the calculated data with the results of geotechnical monitoring [7].

2.2 *The concept of active and passive ground pressure*

The problem of determining the limiting pressure of the soil on the enclosing structure is attributed to the problems of the theory of limit equilibrium method (*LEM*) [8].

Studies of the pressure of the soil mass on the diaphragm wall structure were started by W. Rankine [9], he also derived the coefficients of active and passive pressures for ideally loose soils:

$$K_a = \frac{1-\sin\varphi'}{1+\sin\varphi'} = \tan\left(\frac{\pi}{4}-\frac{\varphi'}{2}\right)^2; K_p = \frac{1+\sin\varphi'}{1-\sin\varphi'} = \tan\left(\frac{\pi}{4}+\frac{\varphi'}{2}\right)^2 \quad (1)$$

where φ' – is effective angle of internal friction.

Additions for connected soils were made by A. Bell [10]. For analysis in full stresses under undrained conditions, the ground pressure on the retaining wall can be determined as follows:

$$\sigma_a = \sigma_z - 2\cdot c_u; \sigma_p = \sigma_z + 2\cdot c_u \quad (2)$$

where σ_a – is the active ground pressure; σ_p – is the passive ground pressure; σ_z – is the vertical stresses in the ground; c_u – is the resistance to undrained shear.

Considering the friction on the soil-structure contact, the coefficients of passive and active pressure can be determined by the following formulas:

$$K_a = \frac{\cos(\varphi')^2}{[1+\frac{\sqrt{\sin[\varphi'\cdot(1+\gamma_k)]\cdot\sin(\varphi')}}{\cos(\varphi'\cdot\gamma_k)}]^2}; K_p = \frac{\cos(\varphi')^2}{[1-\frac{\sqrt{\sin[\varphi'\cdot(1+\gamma_k)]\cdot\sin(\varphi')}}{\cos(\varphi'\cdot\gamma_k)}]^2} \quad (3)$$

where γ_k – is a coefficient that takes into account the decrease in strength characteristics at the "soil-structure" contact.

The coefficients of active and passive pressure can be represented as a determining value in the ratio between the contact pressure at the "soil-retaining structure" boundary and the displacement of the wall [11]. Decisions on the implementation of passive and active ground pressure, considering the displacement of the wall structure, are obtained by numerical methods.

3 METHODOLOGY

3.1 *Analysis of undrained behavior in case of active ground pressure*

Considering the undrained behavior in the case of active pressure, we assume that there is no effect of soil friction on the retaining wall or vertical stresses in the soil. Then, in the case of active pressure, there is no change in the total vertical stresses in the ground. We will describe the change in total vertical stresses in the ground through K. Terzaghi's law, expressing effective stresses:

$$\Delta\sigma_z = u_d + \Delta\sigma'_z \rightarrow \Delta\sigma'_z = -u_d \quad (4)$$

where $\Delta\sigma'_z$ – is the change in effective vertical stresses in the soil mass; Δu_d – change in excess pore pressure during deviatory loading.

The change in excess pore pressure under deviatory loading, based on A. Skempton's additions to Terzaghi's law [3], is defined as:

$$u_d = A_f \cdot B \cdot \Delta q \tag{5}$$

where A_f, B – are the Skempton's coefficients; Δq – change of the stress deviator in the soil mass.

The change in horizontal stresses considering expression (4) can be represented as follows:

$$\Delta\sigma'_x = \sigma'_{z0} \cdot (K_a - K_0) - u_d \cdot K_a - 2 \cdot c' \cdot \sqrt{K_a} \tag{6}$$

where σ'_{x0} – is the effective horizontal stresses in the soil mass before excavation; K_0 – coefficient of lateral ground pressure at rest; σ'_{z0} – effective vertical stresses in the soil mass before excavation of the pit.

Then expression (5) will take the form:

$$u_d = \frac{\sigma'_{z0} \cdot (K_0 - K_a) - 2 \cdot c' \cdot \sqrt{K_a}}{\frac{1}{A_f \cdot B} - K_a + 1} \tag{7}$$

Let's write down the formula for determining the active pressure on the wall structure, taking into account the excess pore pressure:

$$\sigma_{xa} = \sigma'_z \cdot K_a - 2 \cdot c' \cdot \sqrt{K_a} + u_d + u_0 = (\sigma'_{z0} - u_d)K_a - 2 \cdot c' \cdot \sqrt{K_a} + u_d + u_0 \tag{8}$$

where u_0 – is the hydrostatic pressure in the soil mass.

Let's present formula (8) in the form of a standard formula for determining the active pressure for a trained calculation, considering the coefficients that take into account the influence of the formation of excess pore pressure:

$$\sigma_{xa} = C_1 \cdot \sigma'_{z0} \cdot K_a - 2 \cdot C_2 \cdot c' \cdot \sqrt{K_a} + u_0 \tag{9}$$

where $C_1 = 1 + [K_0/K_a - K_0 - 1 + K_a]/\left[1 - K_a + 1/(A_f \cdot B)\right]$;
$C_2 = 1 + \left[A_f \cdot B \cdot (1 - K_a)\right]/[1 + A_f \cdot B \cdot (1 - K_a)]$.

3.2 *Analysis of untrained behaviour in the case of passive ground pressure*

In the case of passive soil pressure, the occurrence of excessive pore pressure is due to two reasons:

- anisotropic unloading of the soil mass caused by the excavation;
- deviatory loading of the soil mass caused by the transfer of horizontal loads from the enclosing structure.

Consider the first component of excessive pore pressure. In the case of undrained behavior, the volumetric deformation of the soil (elastic unloading of the bottom of the pit) is due only to the compressibility of the pore water. Volumetric deformations of the soil are determined based on changes in the average effective stress in the soil mass according to R. Hooke's law:

$$\varepsilon_v = \varepsilon_v^e = C_s \cdot \Delta p' \approx 0 \tag{10}$$

where ε_v – are the relative volumetric deformations of the soil; C_s– relative elastic volumetric deformations of the soil; ε_v^e– elastic component of soil compressibility; $\Delta p'$– change in the average effective stresses in the soil mass.

Then, taking into consideration the expression (10), we conclude that there is no change in the effective average stress during excavating. We will reveal the average effective stress through effective Cartesian stress:

$$\Delta p' = \frac{\Delta\sigma'_z + \Delta\sigma'_x + \Delta\sigma'_y}{3} \tag{11}$$

$\Delta\sigma'_z, \Delta\sigma'_x, \Delta\sigma'_y$ – change of Cartesian effective stresses in the soil.

Using the assumption of the absence of overcompaction in the soil and the equality of horizontal stresses, we obtained:

$$\Delta\sigma'_x = \Delta\sigma'_y = K_0\Delta\sigma'_z \tag{12}$$

Then, taking into account (12), expression (11) will take the form:

$$\Delta p' = \frac{\Delta\sigma'_z \cdot (1 + 2 \cdot K_0)}{3} = 0 \tag{13}$$

The change in the vertical effective voltage, taking into account the conclusion that there is no change in the average effective stress, will be zero.

Using K. Terzaghi's law, we obtain a change in excess pore pressure with comprehensive compression:

$$u_a = \Delta\sigma'^{dr}_z - \Delta\sigma'_z = \sigma'^{dr}_z - \sigma'_{z0} \tag{14}$$

where u_a – is the pore pressure caused by the unloading of the base during the development of the pit. In this case, the pore pressure will "inhibit" the change in effective stresses, preventing the soil from elastically decompressing.

Consider the second component of excessive pore pressure. When the resting pressure changes to passive pressure, the stress deviator and, accordingly, the excess pore pressure change in accordance with expression (5).

The change in the effective vertical stress and the change in the effective horizontal stress are determined similarly to clause 2.1.

Let's express the excess pore pressure under deviatory loading:

$$u_d = \frac{\sigma'_{z0} \cdot (K_p - K_0) + 2 \cdot c' \cdot \sqrt{K_p}}{K_p - 1 + \frac{1}{A \cdot B}} \tag{15}$$

Let's write down the formula for determining the passive pressure on the diaphragm wall, taking into account the excess pore pressure:

$$\sigma_{xp} = (\sigma'_{z0} - u_d) \cdot K_p + 2 \cdot c' \cdot \sqrt{K_p} + u_a + u_d + u_0 \tag{16}$$

Let us present formula (16) in the form of a standard formula for determining passive pressure for a drained calculation taking into account coefficients that consider the influence of the formation of excess pore pressure:

$$\sigma_{xp} = C_1 \cdot \sigma'_{z0} \cdot K_p + 2 \cdot C_2 \cdot c' \cdot \sqrt{K_a} + C_3 \cdot \gamma_{sb} \cdot d + u_0 \tag{17}$$

where $C_1 = 1 - [A_f \cdot B \cdot (K_p - 1) \cdot (1 - K_0/K_p)]/[A_f \cdot B \cdot (K_p - 1) + 1]$;
$C_2 = 1 - \left[A_f \cdot B \cdot (K_p - 1)\right]/\left[1 + A_f \cdot B \cdot (K_p - 1)\right]$;
$C_3 = 1 - K_p + \left[A_f \cdot B \cdot (K_p - 1) \cdot (K_p - K_0)\right]/\left[1 + A_f \cdot B \cdot (K_p - 1)\right]$; γ_{sb} – specific gravity of the soil in suspended state; d – excavation depth.

4 RESULTS AND DISCUSSION

The authors have obtained formulas for determining the magnitude of active and passive ground pressures on the diaphragm wall, taking into account the possibility of excessive pore pressures in the soil.

The Skempton's coefficients A_f and B are parameters of undrained behavior. The coefficient B depends on the degree of soil consolidation and allows you to take into account the time dependence excess pore pressure change. So, for the moment of time "0" (the beginning of the calculation), it will be equal to 1, and for the moment of time "∞" – 0 (drained statement).

The Skempton's coefficient A_f – is a particular value of the Skempton's coefficient A in case of collapse. It depends on the type of soil and is determined by the results of field or laboratory tests. For some soils, the coefficient was determined by Skempton based on the results of consolidated-untrained tests [3].

Table 1. Values of the Skempton coefficient A_f for different types of soils [3].

Type of clay soil	Coefficient value A_f
Clays with high sensitivity	0,75 to 1,5
Normally consolidated clay soils	0,5 to 1
Consolidated sandy clay soils	0,25 to 0,75
Slightly overconsolidated clay soils	0 to 0,5
consolidated gravelly clay soils	-0,25 to 0,25
Highly overconsolidated clay soils	-0,5 to 0

According to the formulas (9) and (17) obtained by the authors, it is possible to represent the pressure of the soil on the diaphragm wall as a function of several defining parameters:

$$\sigma_x = f(\varphi', c', A_f, B, z) \tag{18}$$

According to the graphs shown in Figure 1, it can be seen that the active pressure slightly depends on the excess pore pressure, while the passive pressure varies within 100% at different values of the Skempton parameter A_f.

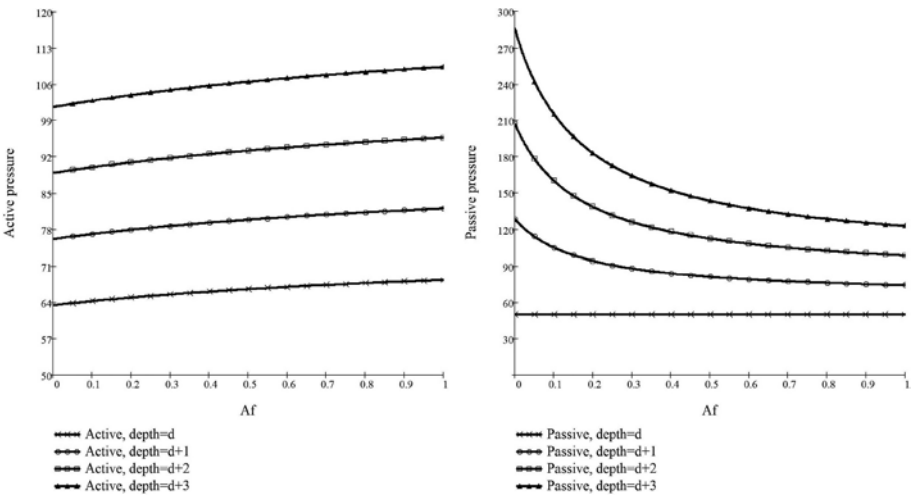

Figure 1. Dependence of the change in the total active pressure on the Skempton's coefficient A_f.

Let's compare the results of the drained and undrained calculation for different soils. The calculation parameters are presented in Table 2.

If soft soils are considered as clay with a high angle of internal friction, it is possible to obtain a passive pressure on the diaphragm structure in an undrained calculation less than the pressure in a drained type. In this case, the results of the drained calculation may be overly optimistic.

Table 2. Comparison of the results of undrained and drained calculations at a depth of 4 m below the bottom of the pit.

Effective friction angle φ`, °	Effective cohesion c`, kPa	The Skempton's coefficient A_f	P_{ae}/P_{ad}*	P_{pe}/P_{pd}**
30	5	0,33	0,981	0,655
		0,5	1,038	0,533
		1	1,060	0,444

		0,5	1,028	0,982
		1	1,046	0,878
10	5	0,33	1,006	1,360
		0,5	1,009	1,334
		1	1,016	1,279

*The ratio of active pressure in an undrained setting to a drained one.
**The ratio of passive pressure in an undrained setting to a drained one.

According to the results of field tests and numerical calculations for soft soils in deep pits, there are dependences of changes in passive pressure on the displacement of the retaining wall structure during the time [12], which also indicates a lower value of passive pressure at the initial time.

It is worth noting that in the classical consideration, the results of the drained calculation for pits are considered more conservative when estimating capacity of the soil by the failure method [13], [14].

A significant influence on the pressure on the diaphragm wall is exist by excessive pore pressure u_a, which forms a jump in effective stresses in the level of the bottom of the pit [15]. Such a "suction" effect can be noticed by the results of monitoring [16], however, further research is needed to determine the duration and accuracy of this effect.

To justify the applicability of the obtained formulas further verification of the convergence of the solution with experimental data is required.

5 CONCLUSION

This article analysis the influence of the formation of excessive pore pressure in the soils of the base on the example of the task of excavating the soil under the protection of the diaphragm wall.

Analytical solutions have been obtained for determining the active and passive pressure on the retaining wall structure, taking into account the formation of excessive pore pressure.

The results of comparison of calculation schemes with different soil parameters show that for normally compacted clays and high sensitivity soils, the passive pressure in the undrained calculation is significantly less than in the drained one. This suggests the need for an undrained stability analysis when calculating pits in the presence of certain types of soils.

For further analysis of the undrained behavior in the calculation of pits, it is necessary to study in detail the phenomenon of "suction" forming a jump in effective stresses in the bottom of the pit due to negative pore pressure u_a, and also take into account the impact of the implementation of pressure on the diaphragm wall from its displacement.

Reverse analysis of geotechnical monitoring results for the estimation of the diaphragm walls stress-strain

I.P. Dyakonov, I.B. Bashmakov, M.B. Zavodchikova & A.P. Cheremhina
Saint Petersburg State University of Architecture and Civil Engineering, Saint Petersburg, Russian Federation

ABSTRACT: The article considers low level convergence problem of bending moments in diaphragm wall is considered in this article. The article presents the main calculation methods that have become widespread in modern design practice. A comparative analysis of stress-strain state calculating results of a trench diaphragm wall for deep pit in the conditions of soil in St. Petersburg. To estimate the accuracy of the calculation methods, the calculation results were compared with the data of inclinometric monitoring in the trench diaphragm wall. At the same time, in order to be able to verify the obtained calculation results not only by the values of deformations, but also by the values of the calculated forces, a method for estimating bending moments in a trench diaphragm walls in the ground via inclinometric monitoring data is suggested. Comparative analysis of geotechnical monitoring data and various calculations showed high convergence with the results of the calculation, taking into consideration the possibility of excess pore pressure, nonlinear soil behavior and nonlinear rigidity of reinforced concrete.

Keywords: geotechnical monitoring, diaphragm wall

1 INTRODUCTION

In modern practice, the construction of deep pits in the engineering and geological conditions of St. Petersburg, a common solution is used to create a trench diaphragm wall in the ground as an retaining structure. One of the most significant parameters is the maximum bending moment that occurs in the wall structure [1, 2, 8, 9].

The existing standards for the design of flexible retaining walls do not provide specific guidance on the definition of bending moments arising in structures. As a consequence, when calculating the same structures by different organizations, the values obtained may differ several times.

In order to assess the applicability of certain calculation methods within the framework of geotechnical monitoring, it is necessary to assess the actual bending moments that occur in structures during the development of the pit [3]. In the modern practice of geotechnical monitoring, estimation of the internal stresses performed using special stress gauge [4]. However, for a full analysis of the nature of the bending operation of the structure, it is necessary to install a significant number of sensors. Since the location of the most loaded section in the height of the structure does not always correspond to the calculated one, it is necessary to install a number of height sensors. In addition, taking into account the stage of work, it is necessary to perform several rows of sensors in the plan. As a consequence, such an approach to monitoring efforts in the wall in the ground requires significant financial supply.

Thus, there is shortage data of stress-strain conditions of diaphragm walls along the ground excavation, which leads to the impossibility of verifying existing calculation methods [5].

2 SITE STUDY

This construction site considering a deep excavation with 6.2 m and 9.0 m depth under the protection of a trench diaphragm walls in the ground with a thickness of 600 mm and a depth of 19 m.

The stage construction of this pit assumed the create the slurry wall with the protection of a soil berm, and then under the protection of struts. During the work at the new construction site, the technology of work production was disrupted, and therefore the actual geometry of the ground berms significantly different from the project. The actual sequence of work on the development of the pit for the section of the pit with a depth of 9 m is shown in Figure 1a, for the section with a depth of 6.2 m in Figure 1b.

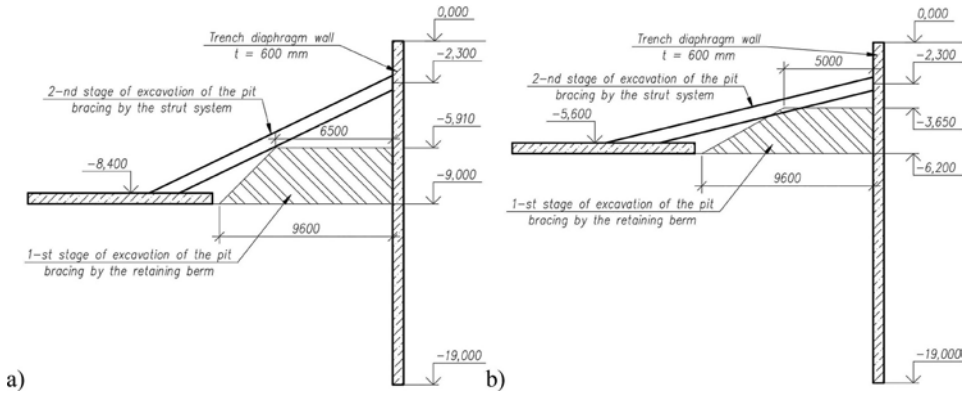

Figure 1. The actual sequence of work on the development of a pit.

The engineering and geological conditions of the construction site under consideration are represented by the occurrence of loams of fluid-plastic and fluid consistency to a depth of up to 20 m. A diagram of the results of testing the foundation soils by static sounding in the considered sections of the pit is shown in Figure 3.

When performing engineering and geological surveys, the strength parameters of the soil were determined by means of a direct shear box test (*DSB*), and the deformation parameters were determined on odometrical tests (*Oed*).This method of assessing the mechanical parameters of the foundation soils is widespread in the conditions of St. Petersburg, although it does not allow to fully estimate the strength and deformation characteristics of soils. In this case, the results of these tests were used to estimate the applicability of the existing methods.

As part of geotechnical monitoring, inclinometric tubes were installed in the ground directly in the panels of the trench diaphragm walls to monitor the deformations of the pit fence.

3 METHODS

3.1 *Calculation methods*

In the modern practice of designing pit fences, calculation methods using software systems based on the finite difference method and the finite element method (*FEM*) have become the most widespread.

The computational analysis based on the finite difference method is based on the equation of an elastic beam on an elastic base [6]:

$$EIw''''(z) + k(z)w(z) = P(z) \tag{1}$$

where, $\boldsymbol{E}$ – is the elastic modulus of the material of the structure in question, kPa; I – is the moment of inertia of the section of the structure in question (one linear meter of the structure for a trench diaphragm walls in the ground), taking into account the direction of movement, m^4;

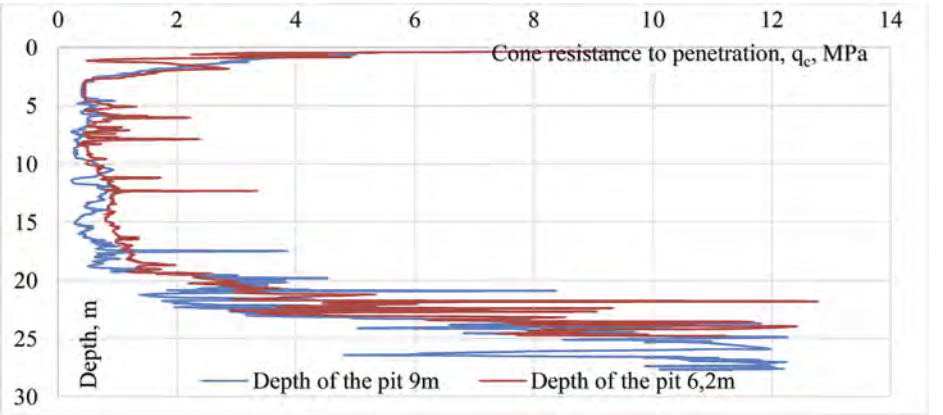

Figure 2. The actual sequence of work on the development of a pit with a depth of 6.2 m.

$\boldsymbol{w}(\boldsymbol{z})$ – is a mathematical function describing the movement of the axis of the curved beam in the direction normal to the initial position of the axis, m; $\boldsymbol{k}(\boldsymbol{z})$ – is the coefficient of the bed, determined depending on the type of soil and the depth of the point under consideration, kN/m^3; $\boldsymbol{P}(\boldsymbol{z})$ – is the initial pressure on the enclosing structure, defined as the sum of the ground rest pressures from the side of the excavation and from the outside of the excavation, kPa.

In this case, the value of the product $k(z)w(z)$ is limited by the values of active and passive ground pressure. The calculation scheme of this calculation method is shown in Figure 3.

When calculating the wall of pit by the finite element method, the most widespread use was of the Hardening Soil model (*HSM*), which implements the hardening mechanism both during compaction of soils and during deviatory loading [10].

When performing comparative calculations, several options for setting the parameters of the Hardening soil model were considered:

1) setting the calculation model in a drained formulation with the setting of strength parameters according to the results of testing soil samples by the method of single-plane rapid cut.
2) setting a computational model in an untrained formulation using an Undrained B behavior model. At the same time, the determination of strength parameters was carried out according to the data of static sounding of the soil of the base on the surface:

$$s_u = q_c/19 \tag{2}$$

where $\boldsymbol{q_c}$ – cone resistance to penetration, MPa.

3.2 *Back-analysis of monitoring results*

It is well-known from the theory of elasticity, the displacements of a loaded structure and the bending moments arising in it are connected by an integral dependence. This dependence can be described by the differential equation of the axis of a curved beam [7]:

$$EIw''(z) = -M(z) \tag{3}$$

where $\boldsymbol{M}(\boldsymbol{z})$ – is a mathematical function describing the values of the bending moment causing the displacement of the axis of the structure, kNm.

Thus, having data on full-scale observations of horizontal displacements and knowing the rigidity of the structure, it is possible to evaluate the bending moments arising in it.

To be able to apply expression (3), it is necessary to bring the full-scale data to a mathematical function. The least squares method is well suited for this purpose, but first of all it is necessary to choose a general form of the function describing the dependence of the horizontal displacement of the trench diaphragm walls in the ground on the depth. Given the assumption that the

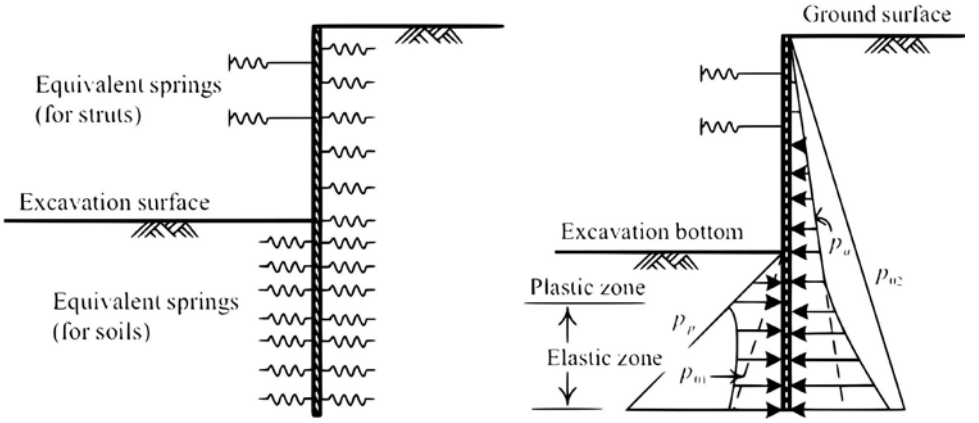

Figure 3. The design scheme of the pit enclosure when calculated by the finite difference method.

dependence of the pressure on the enclosing structure on the depth can be described by a linear function, it is rational to use a fifth-degree polynomial to describe the function of horizontal displacements of the trench diaphragm walls in the ground. In this case, the problem of conducting full-scale data to a mathematical function is reduced to solving the equation:

$$P(A,B,C,D,E,F) = \sum_{i=1}^{n} \left(S_i - Az_i^5 - Bz_i^4 - Cz_i^3 - Dz_i^2 - Ez_i - F\right)^2 \rightarrow min \tag{4}$$

where $\boldsymbol{P}(\boldsymbol{A},\boldsymbol{B},\boldsymbol{C},\boldsymbol{D},\boldsymbol{E},\boldsymbol{F})$ – is a function of the dependence of the sum of the quadratic deviations of the values of the desired function from the field data on the coefficients of the desired dependence; $\boldsymbol{S_i}$ - is the full-scale value of the horizontal displacement according to the results of inclinometric observation, for the i-th point in height, m; $\boldsymbol{z_i}$ – is the height coordinate of the i–th point, m; $\boldsymbol{n}$ – is the number of points at which the inclinometer readings were taken.

And the desired function will take the form:

$$S(z) = A \times z^5 + B \times z^4 + C \times z^3 + D \times z^2 + E \times z + F \tag{5}$$

The results of conducting field data to the function are shown in Figure 4.

When applying expression (3), the second important aspect is the correct assessment of the bending stiffness of the structure in question. As is known, reinforced concrete structures when working on bending have the properties of nonlinearity, and therefore the bending stiffness of the trench diaphragm walls in the ground must also be considered in a non-linear formulation.

To construct a nonlinear relationship between the bending moment and the bending stiffness of the structure, it is advisable to apply a numerical method. In this work, a LIRA-CAD was used to build this dependence. At the same time, the nonlinear diagram of concrete deformation under tension and compression, the actual scheme of reinforcement of the structure and the location of the longitudinal reinforcement in the section of the structure were taken into account. The dependence of the bending stiffness of the structure on the effective bending moment obtained by the calculation results is shown in Figure 5.

4 RESULTS AND DISCUSSIONS

The diagrams of bending moments in the diaphragm wall were obtained from the result of calculation and reverse analysis are shown in Figure 6.

In case of design the construction by the finite element method (*FEM*), a calculation scheme with nonlinear rigidity of the trench diaphragm wall was additionally considered. The nonlinearity parameters were assigned according to Figure 5.

According to the results of comparing the maximum values of bending moments, a high convergence of the results of reverse analysis of monitoring data with the results of calculation

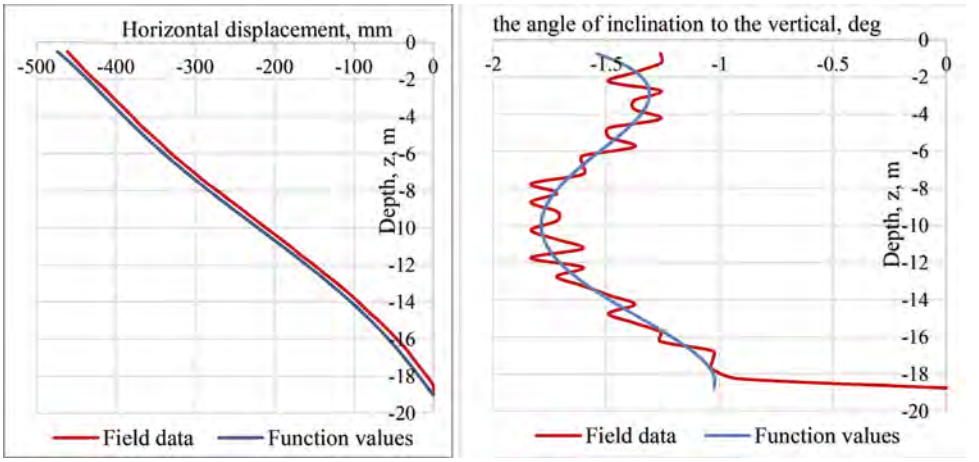

Figure 4. Results of reduction of natural data to a mathematical function.

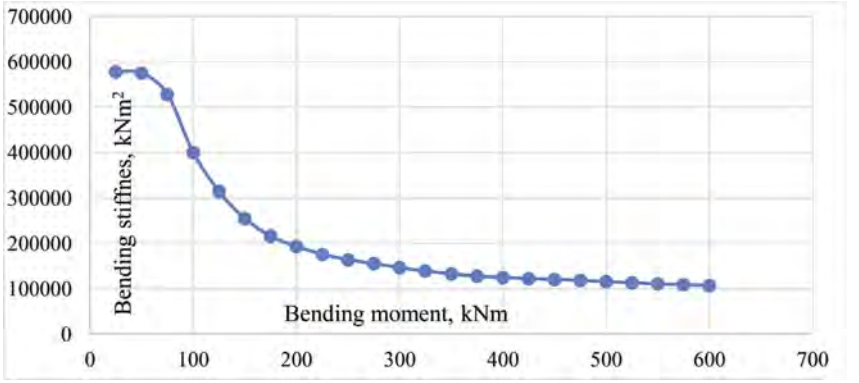

Figure 5. The obtained relationship between the bending moment and the bending stiffness of the structure.

in an undrained state, taking into account the nonlinear operation of reinforced concrete, was obtained. The convergence of the results was 90%.

Comparing the results obtained for the section of the pit with a depth of 9 m and a depth of 6.2 m, it is important to note that with an increase in the depth of the pit by 1.5 times, the variation in the calculated bending moments obtained by various methods increases from 60% to 200%.

The greatest influence on the calculation results is provided by taking or not taking into account the undrained behavior of the soil. For a section of the pit with a depth of 9 m, growing in a drained setting leads to an increase in the maximum bending moment by 80% in relation to the undrained setting. Therefore, it is reasonable to consider the calculation method taking into account the undrained behavior of the soil as a more correct calculation method for analyzing the stress-strain state of the wall in the ground during the phased development of the pit.

5 CONCLUSIONS

1. A method is proposed for estimating the actual bending moments in a trench wall in the ground using reverse analysis of inclinometric monitoring data for horizontal displacements of the structure.
2. Based on the analysis of the results obtained, it was found that when calculating the justification of the fences of deep pits in conditions of weak clay soils, it is advisable to perform calculations in an undrained post, taking into account the nonlinear operation of reinforced concrete.

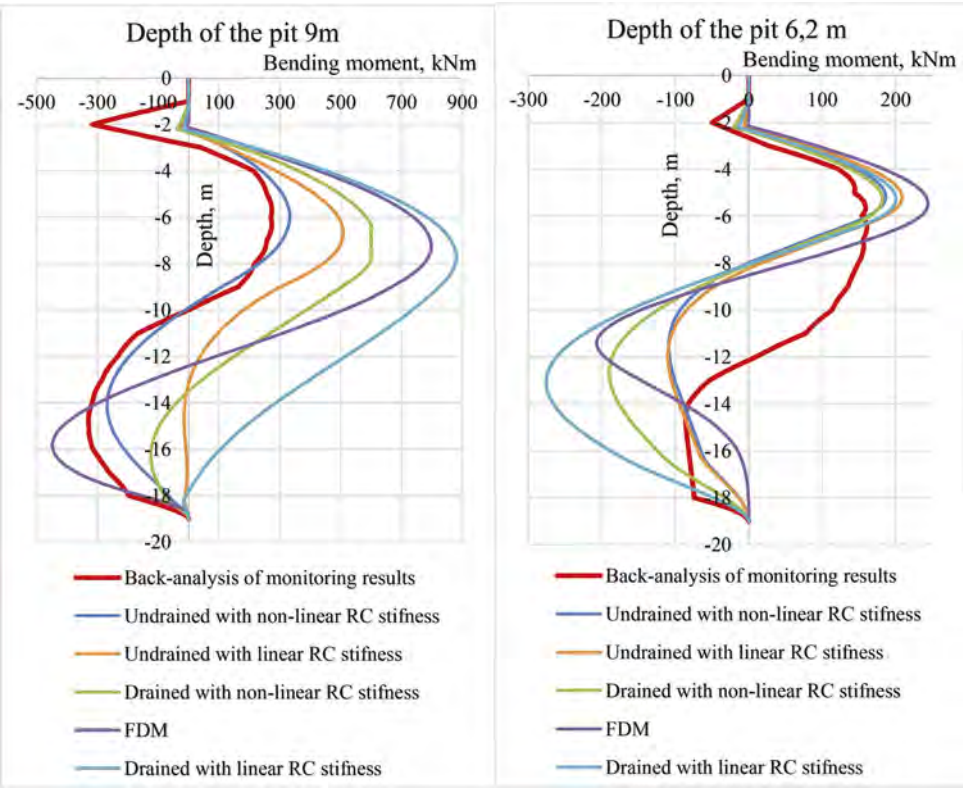

Figure 6. Resulting graphs of reverse monitoring analysis data and calculation results using various methods.

3. The results obtained for the calculation by the finite difference method showed low convergence with geotechnical monitoring data. In this regard, it is necessary to modify this calculation method for conditions of weak clay soils.

Experimental study on the stress-strain behavior of underground structures affected by adjacent excavation in a carbon rod geometry

Munkyeong Baek
Graduate Student, Department of Civil Systems Engineering, Ajou University, South Korea

Ilhan Chang*
Associate Professor, Department of Civil Systems Engineering, Ajou University, South Korea

ABSTRACT: In this study, the stress and strain variations of an existing tunnel according to adjacent tunnel excavation have been evaluated via laboratory model testing. Since the tunnel has been a typical structure under the plain strain condition, the laboratory model tests were conducted using carbon rods which represents a weathered rock geometry. The stress and strain (deformation and rotation) variations of an existing tunnel model due to adjacent ground relaxation have been assessed with embedded load transducers and particle image velocimetry (PIV) analysis. Different vertical and horizontal spacing conditions between the ground relaxation (tunneling) point and the existing tunnel location were considered. The simultaneous load and PIV analyses data clearly verifies the acceptable construction guide for adjacent tunneling in weathered rock stratum.

1 INTRODUCTION

Underground tunneling construction has been recently increased to relieve urban traffic problems. A new tunnel excavation generally affects to deformation of surrounding ground and existing tunnels. Previous studies have been performed by the similarity to empirical equations and numerical analysis to investigate the effect of tunnel excavation on surrounding ground and existing tunnels. Alejano et al. (2012) studied the longitudinal deformation of the existing tunnel and the ground relaxation around the new tunnel excavation. The presence of adjacent tunnels within the plastic zone caused by ground relaxation will be affected. Because of ground relaxation after tunnel excavation, the load acting on the adjacent tunnel and the surrounding ground relaxation area changes. Recent studies have assessed the effect of ground relaxation through physical model experiments (Kumar and Kumar Shrivastava, 2022), numerical analysis (Baziar and Dehghani, 2021), field observations (Fargnoli et al., 2015), empirical/analytical methods (Franza and Marshall, 2019) and finite element method (FEM) (Zárate et al., 2018; Zakhem and El Naggar, 2020; Zhou et al., 2020).

In this study, stress-strain behavior of underground structure and surrounding ground under adjacent tunnel excavation was assessed through a carbon rod experiment. The effect of a new tunnel location to an existing tunnel was investigated. While a parallel alignment was assessed as a control group, effect of a diagonal alignment was evaluated (Figure 1b).

The tunnels of parallel lines must be taken into consideration in this analysis despite the fact that the floors are different as the underground area is enlarged and numerous tunnels, including water and sewage, electric power, subway, and road tunnels, are built. As shown in Figure 1(a), it is necessary to investigate the feasibility of constructing a new tunnel that is constructed lower than the existing tunnels constructed near the ground and parallel as shown in Figure 1(b).

2 EXPERIMENTAL PROGRAM

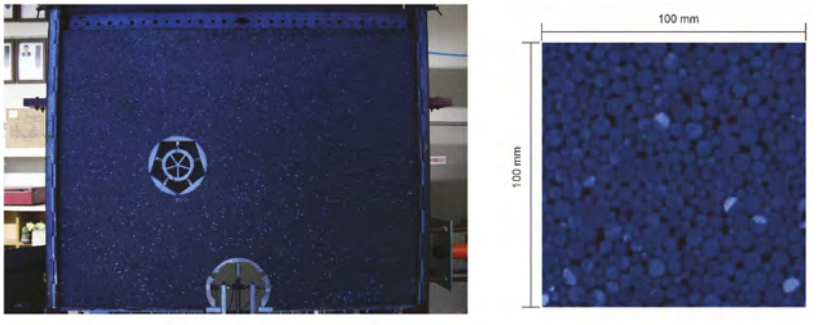
2.1 *Test geometry*

The test bed was designed to have a dimension of 1500 mm × 1500 mm. The test bed reflected soil made of carbon rods with a groud unit weight of 1.43 kN/m^3, an internal friction angle of 35 °, and a clearance ratio of 0.39. Carbon rods were used to comprise the test bed. The carbon rods were 55 mm long and have different diameters of 3 mm, 5 mm, and 7 mm (Figure 2). The carbon rod amount ratio to compose the test bed was 4: 2: 1.

2.2 *Tunnel modeling*

The new tunnel made of steel, was set at the bottom of the experimental frame, and endure the load as shown in Figure 2a. The new tunnel is divided into three parts a top segment and two side segments. The cross section of the new tunnel was deformed to simulate the ground deformation after excavation. It was initially set to a diameter of 260 mm, but finally adjusted to 250 mm in cross-sectional diameter by vertical rearranging of inner support bars.

The existing tunnel was located at the diagonal direction as shown in Figure 2a. The exact location was set to be a symmetric ratio of vertical 1D: horizontal 1D. The existing tunnel was 250 mm in diameter and the central portion were connected to a load transducer to guarantee that each component of the existing tunnel behaves as a single unit.



(a) (b)

Figure 2. Test view. (a) Test view (Vertical 1D, Horizontal 1D); (b) Test geometry.

3 RESULTS

To proceed with the analysis, particle image velocimetry (PIV) analysis, which can measure displacement using pixel changes, was conducted using tow images. Experimental photos were used to perform PIV analysis. In PIV, the pixels from the first picture were used to create a grid of a certain size, and the progressing images tracked throughout the experiment to monitor the differences between the initial picture and the target picture in terms of displacement and deformation. The tunnel deformation picture was used as the final image to track and analyze the movement of the carbon rod representing the ground particles. The PIV analysis showed the relaxed area to the top of the new tunnel after tunnel excavation in the absence of an existing tunnel. When the existing tunnel was located in the vertical direction, a relaxation load was generated on the upper part of the new tunnel. In a diagonal alignment (1D:1D configuration,), the ground deformed gradually as the tunnel deformed. As a result, there was a load shift that causes compressive stress in the next segment of the existing tunnel. However, as the ground deformation progressed, the entire tunnel moved to the submerged stage, and a relaxation load was applied to the part facing the new tunnel.

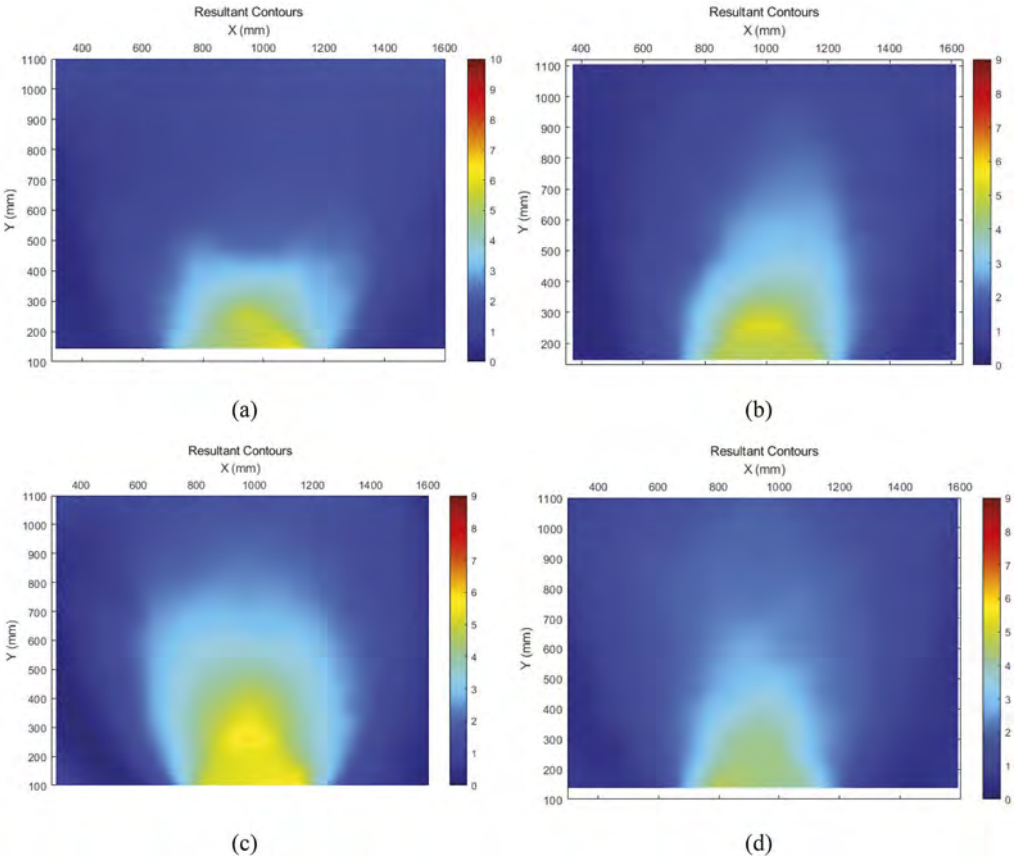


Figure 3. Contours as a result of final displacement (PIV). (a) Location of the existing tunnel (Vertical 1D: Horizontal 0); (b) Location of the existing tunnel (V 1D: H 1D) (c) Location of the existing tunnel (V 1D: H 2D) (d) Location of the existing tunnel (V 2D: H 0).

4 CONCLUSIONS

The PIV basis research indicates that the tension and relaxation of the subsurface are caused by tunnel excavation. There is less distortion due to ground relaxation when there is an adjacent

existing tunnel. As the ground relaxed, the measured load values in the existing tunnel segment changed. The new tunnel direction experienced tensile force, and the adjacent section experienced compressive load, when the existing tunnel was in the diagonal direction. The research's findings indicate that the stress placed on the present tunnel segment varies depending on how far the existing and new tunnels are apart. In this study, it was confirmed that the effect was small when the distance was more than twice the diameter of the tunnel to the left. The consequences of compressive and tensile loads, if any, must be taken into account when excavating a new tunnel.

ABSTRACT: Underground space such as undersea tunnels and high-level nuclear waste disposals are constructed in bedrock due to the stability and safety. When the bedrock has unexpected joints and cracks, groundwater inflow and nuclide outflow through joint can occur in underground structures. Grouting in joints is essential for reinforcement and waterproof. Grouting injection performance is affected by parameters (e.g., injection time, injected pressure, viscosity of grouting material or joint aperture size.) Thus, it is difficult to predict for grouting injection performance. In this study, the grouting injectivity was analyzed according to the rock joint characteristics under a single rock joint condition using Universal Distinct Element Code (UDEC) numerical program. This study is helpful to evaluate the rock grouting performance for underground structures.

1 INTRODUCTION

Deep-depth rocks are independent of the external environment, they are advantageous for installing tunnel-like structures compared to ground conditions that are greatly affected by mountainous areas and marine conditions (Kim et al., 2017; Li et al., 2016). When a tunnel is constructed in such a deep-depth rock, it is necessary to verify the characteristics of the deep-depth rock in order to achieve a reasonable design and construction. The bedrock contains various forms of discontinuities (e.g., joint, stratified, fault, or gap). Since the discontinuous surfaces are more affected by the properties of discontinuous surfaces than by the mechanical properties of the rock itself, it is important to consider discontinuities when simulating the behavior of the rock (Choi et al., 1999).

In particular, when a plurality of irregular joints is connected to each other, the joint may be a flow path of surrounding groundwater (Moon, 2013). When the surrounding groundwater flows into the underground space through such a joint, the utilization of the underground space is degraded due to the flooding of the tunnel. This poses a risk of major economic damage (Panhi and Nilsen, 2005; Joo et al., 2010). Therefore, for underground space development, it is essential to improve the watertightness of rock joint (such as using rock grouting) (Jeong et al., 2021).

In this study, the variables required in the grouting injection design are determined to be injected pressure and aperture size. In addition, the injection pattern (injected distance) and performance (injection time) of the grouting with a single joint are estimated using UDEC (a discontinuous flow analysis program).

DOI: 10.1201/9781003299127-145

2 A THEORETICAL SOLUTION OF A ONE-DIMENSIONAL LINEAR FLOW

The flow of grouting injection fluid can be represented by Newtonian fluid characteristics and non-Newtonian fluid characteristics (Warner, 2004). In the case of a Newtonian fluid, when shear stress is applied for flow generation, shear rate is generated regardless of yield strength (Figure 1). On the contrary, in the case of a Bingham fluid, when shear stress exceeding yield strength is applied, shear deformation occurs, that is, a flow of fluid occurs. Representative Newtonian fluids include water or chemical solution type grouting materials, and Bingham fluid includes cement suspension. Bingham fluid model for quantity of flow is shown as Equation (1).

$$Q = \frac{\Delta p}{I}\frac{b^3}{12\mu_g} \tag{1}$$

Where Q = quantity of flow; I = penetration length; Δp = injected pressure; μ_g = viscosity; b = aperture size.

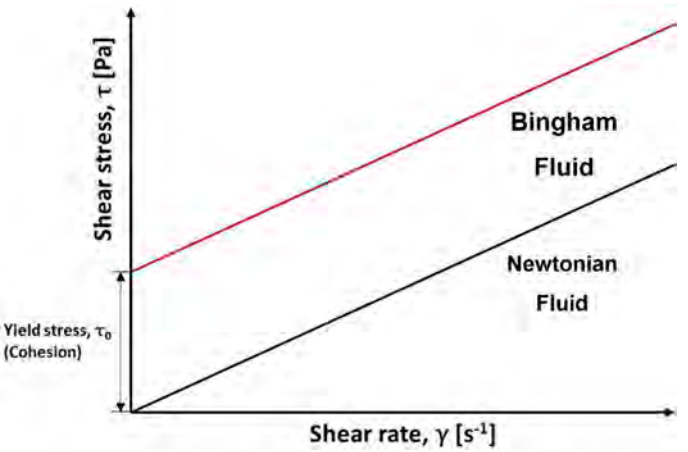

Figure 1. The characteristics of Bingham fluid (after Alfred et al., 2000).

The penetration distance of the injection material is proportional to the square root of the injection time, proportional to the square root of the injected pressure, linear proportional to the initial joint gap, and inversely proportional to the square root of the injection viscosity (Lee et al., 2017).

3 NUMERICAL MODEL

3.1 *Rock model with a single joint*

In this study, the injection behavior of the rock grouting injection material was simulated in a single type of joint (refer to Figure 2). The rock block was assumed to be in a rectangular shape with a length of 50 m and a height of 1 m, and the joint was simulated with a straight line with a length of 0.1 mm in the length direction of the rock block. The input properties of the rock block were set to the density of 3,000 kg/m^3, the volume coefficient of 10 GPa, and the pre-stage number of 3 GPa. As the material of the grout, micro-cement that can be injected into a fine joint. For the physical properties of the injection material (micro-cement), the water/cement mixing ratio is 1.0 in which viscosity is 0.0056 Pa · s in 20°C (Refer to table 1, obtained in Lee at el., 2017). The input properties of the grout material were set to the density of 1,290 kg/m^3, the bulk modulus of 2 GPa and the yield stress of 0.296 Pa.

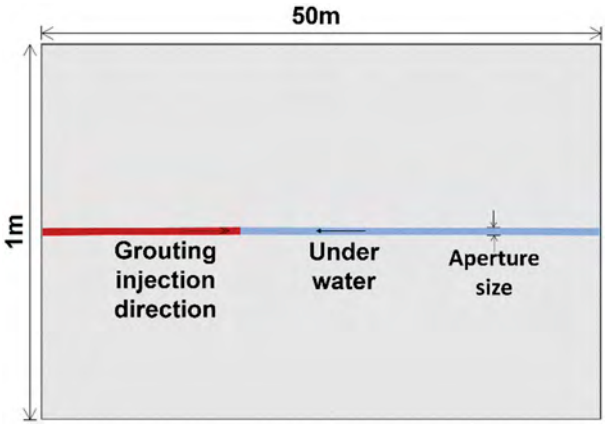

Figure 2. The single joint rock model for numerical simulation.

3.2 *Injection parameters*

The deep-depth rock is located greater than 40 m from the surface. As the depth increases, the pore pressure of groundwater increases. When the rock grouting is performed, it is necessary to inject it with a pressure stronger than that of groundwater pressure. Therefore, in this study, a simulation analysis was considered to inject grouting at a depth of 50 m, 150 m, and 200 m with setting the grouting pump pressure to 2.5 MPa. When the target depths are 50 m, 150 m, and 200 m, the pore-pressure would be 0.5 MPa, 1.0 MPa, and 2.0 MPa, respectively. Therefore, the injected pressure was calculated as the value obtained by subtracting the pore-pressure from the grouting pump pressure so that injected pressure was determined to be 2.0 MPa, 1.0 MPa, and 0.5 MPa, respectively. A decrease in injected pressure means that the depth of the rock deepens.

In the previous study, the aperture size in the large depth bedrock considers 0.138 mm (Yoon et al., 2021). Based on the literature review, the aperture size was set to 0.05 mm, 0.1 mm, 0.2 mm, and 0.4 mm with the joint roughness of JRC 0-2. In this model, friction of joints was not considered. And, total amount grouting material is no limit. The injection performance of the analyzed grouting material was evaluated by the injected distance and injection time.

4 RESULT AND ANALYSIS

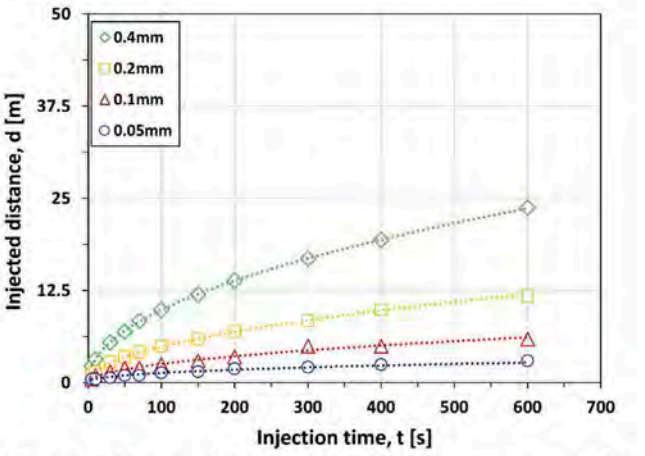
4.1 *Injected distance*

Micro-cement grouting material was injected with pressure for 600 seconds. It was confirmed that as the depth increase, the injected pressure decreases due to an increase in pore-pressure. In addition, as the injection time increases, the viscosity of the cement grouting injection material increases, so the injected distance per unit time decreases. The form of increase is a non-linear exponential function (Figure 3(a)-(c)).

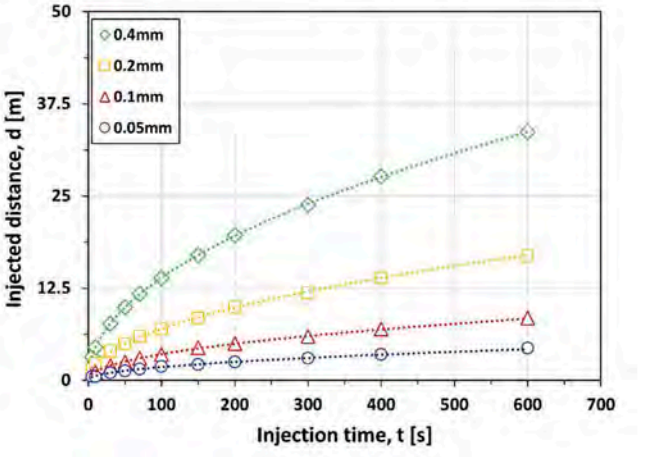
When the aperture size is 0.4 mm at the depth of 50 m (injected pressure: 2.0 MPa) injected distance is the longest. The result shows that the injected distance is 47.5 m. It is 41.6 m larger distance than the smallest aperture size of 0.05 mm at the same injected pressure. The injected distance is 23.8m at the aperture size of 0.4mm and 0.5MPa. Accordingly, the injected distance is proportional to the aperture size and injected pressure.

4.2 *Result of parameters*

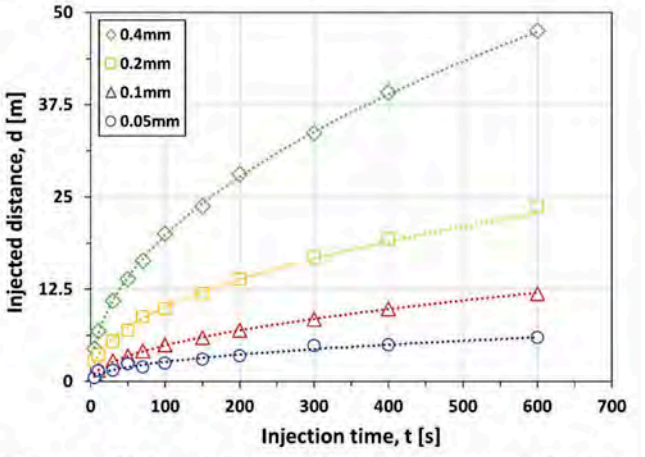
Given results, the time (required to reach 1 m) with aperture size was analyzed (Figure 4). When the injected pressure is 1.0 MPa at the aperture size of 0.05 mm, the time is estimated to be 30 seconds. When the injected pressure increases to 2.0 MPa, the arrival time is decreased by 62%. When the injected pressure decreases to 0.5 MPa, the arrival time is increased by 39%. As the



(a) Result of injected distance for injected pressure 0.5 MPa



(b) Result of injected distance for injected pressure 1.0 MPa



(c) Result of injected distance for injected pressure 2.0 MPa

Figure 3. Result of injected distance according to change of injected pressure.

aperture size is the wider at the same injected pressure, the time is the shorter. The relationship between injection time and aperture size shows a nonlinear exponential curve.

The reach according to the aperture size within the same injected pressure based on the injection time of 300 seconds was also analyzed. When the injected pressure is 1.0 MPa with the aperture size of 0.4 mm, the arrival distance at 300 seconds is 23.8 m. When the injected pressure is increased to 2.0 MPa, the reach at 300 seconds is increased by 29.3%. When the injected pressure is decreased to 0.5 MPa, it is decreased by 29.4%. This increment showed a linear relationship (Figure 5).

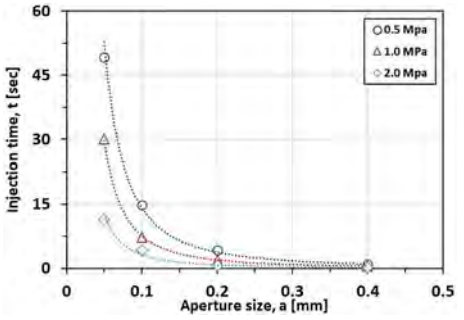


Figure 4. Injection time with aperture size at the injected distance of 1 m.

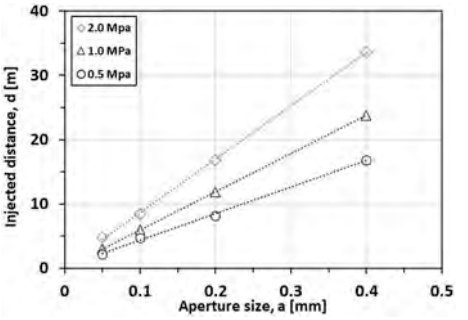

Figure 5. Injected distance with aperture size at injection time of 300 seconds.

5 CONCLUSION

In this study, the performance analysis was conducted by micro-cement grouting injection with the fine single joint in deep depth bedrock using UDEC. The main findings are follows:

- The grouting injection material has a nonlinear increase pattern in which the injected distance per unit time is shortened due to the increase in viscosity over time.
- At the constant injected pressure, the injection time to reach the target distance is decreased by increasing the aperture size.
- With the injected pressure, the injected distance of the grouting filler linearly increases as the aperture size increases at the same injection time.
- In this study, there are limitations that do not consider changes in viscosity of cement grout over time, resistance due to friction of joints, JRC, and deformation of joints due to applied stress. For further studies, effective parameters will be considered to perform experiments for better understanding of the rock grouting characteristics.

Investigation of excavation stability with buttress and cross wall

Ari Surya Abdi & Chang-Yu Ou
Department of Civil and Construction Engineering, National Taiwan University of Science and Technology

ABSTRACT: The buttress and cross wall is an excavation support system that has been widely used for the protection of the adjacent building during excavation. However, their mechanism in resisting the basal heave stability has not yet been fully understood. In this study, a series of three-dimensional finite element analyses were conducted to assess the influence of buttress and cross walls on basal heave stability in deep excavations. The results showed that the frictional resistance acting on the contact surface area between the wall (including buttress and cross wall) and the surrounding soil plays an important role in resisting the basal heave failure. Hence, increasing the dimension of the buttress and cross walls could enlarge the frictional area, which resulted in enhancing the factor of safety. Furthermore, a new simplified method considering the buttress and cross wall properties was proposed, which was validated by the finite element method.

Keywords: basal heave stability, buttress wall, cross wall, deep excavation, factor of safety

1 INTRODUCTION

Deep excavation in undrained clay usually cause the large soil movement. In such a case, the implementation of a buttress wall (BW) and cross wall (CW) could be used as a measure to prevent damage to the adjacent building induced by deep excavation. Many researchers have studied the mechanism and characteristics of BW and CW in restraining excessive wall displacement (Hsieh and Ou 2018; Lim et al. 2016; Ou et al. 2006). However, no study has conducted the excavation stability with BW and CW.

In this study, a series of three-dimensional finite element methods (3D FEM) was conducted to investigate the excavation stability with BW and CW. The strength reduction method was adopted in the stability analysis to determine the factor of safety against basal heave at the final excavation stage (Abdi and Ou 2022; Goh et al. 2019). Moreover, a new simplified method was proposed to calculate the factor of safety, which was validated by the 3D FEM results.

2 FINITE ELEMENT MODELING

The commercial geotechnical software PLAXIS 3D v.21 was used to perform the three-dimensional (3D) finite element analysis. The diaphragm wall (DW), floor slab (FS), BW, and CW, were modeled as plate elements with linear-elastic structural behavior. The compressive strength (f_c') of the DW and FS was assumed to be 21 MPa, while the BW and CW were 14 MPa. The nominal value of Young's modulus for all concrete materials was estimated by using $E = 4700\sqrt{f_c'}$ (MPa). The thickness of the DW, BW, CW, is set to be 0.7 m, while the FS is simply assumed to be 0.4 m, following the typical properties of the retaining system in deep excavations.

Furthermore, the Mohr-Coulomb with the total stress undrained analysis was adopted to simulate the undrained behavior of the clay. The normalized undrained shear strength (s_u/σ_v')

DOI: 10.1201/9781003299127-146

and soil modulus ratio (E_u/s_u) were assumed to be 0.30 and 500, followed by the typical properties of Taipei clay. The slippage behavior between the wall (including DW, BW, and CW) and soil was modeled by the interface element, which is controlled by the frictional resistance ratio between the wall adhesion and soil cohesion ($\alpha = c_w/s_u$).

The wished-in-place (WIP) method is adopted for modeling the DW, BW, and CW in the analyses. The excavation depth (H_e) was assumed to be 15 m, while the upper part of BWs was demolished along with the excavation, as presented in Figure 1. The BW length, penetration depth, and spacing were denoted as L_{bw}, D_{bw}, and s_{bw} respectively. On the other hand, the CW penetration depth and spacing were referred as D_{cw} and s_{cw}, respectively.

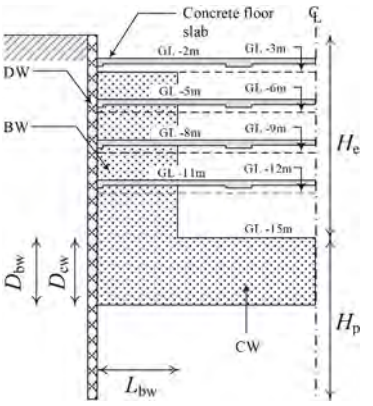

Figure 1. Excavation profile and construction sequence.

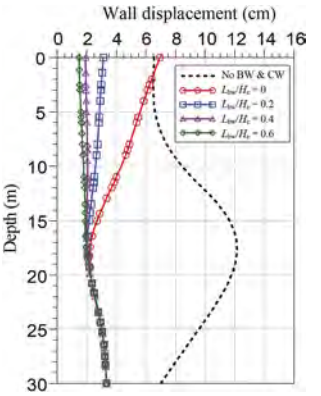

Figure 2. Computed wall displacement at the final excavation stage ($D_{bw} = D_{cw} = 6$ m; $s_{bw} = s_{cw} = 12$ m; $H_p/H_e = 1.0$; $B = 30$ m).

3 DEFORMATION CHARACTERISTIC OF BW AND CW

As shown in Figure 2, the largest wall displacement was found near the final excavation level ($\delta_{h,m} = 12.18$ cm) for the case without BW and CW. When only CW was implemented below the excavation level ($L_{bw}/H_e = 0$), the wall displacement below the excavation level was reduced significantly. However, an excessive wall displacement still occurred above the excavation level due to lower stiffness. Hence, the CW was further combined with BW at the upper part ($L_{bw}/H_e > 0$), which is found to be a useful method in reducing the wall displacement along the depth. The reduction rate of wall displacement begins to slow as the BW length increases (indicated by $L_{bw}/H_e = 0.4$ - 0.6).

4 EXCAVATION STABILITY WITH BW AND CW

4.1 *Basal heave mechanism of excavation with BW and CW*

The factor of safety (FS_{fem}) for the case without BW or CW was 2.717. For the case with rigid friction on BW and CW ($\alpha_{bw} = \alpha_{cw} = 1.0$), the FS_{fem} values were 2.852 and 2.816, respectively. In comparison, the FS_{fem} values for the case without friction on BW and CW ($\alpha_{bw} = \alpha_{cw} = 0.1$) were 2.680 and 2.707, respectively, which is similar to those without BW and CW.

The deformed mesh of soil at divergence conditions was further observed to clarify the above findings (Figure 3a–d). The basal heave could be resisted for the BW and CW with the rigid surface ($\alpha_{bw} = 1.0$). In contrast, for the case of BW and CW without friction ($\alpha_{bw} = \alpha_{cw} = 0.1$), the BW and CW could not resist the heave inside the excavation. This implies that the basal heave resistance was highly governed by the frictional resistance on the interface between the wall (BW and CW) and surrounding soil.

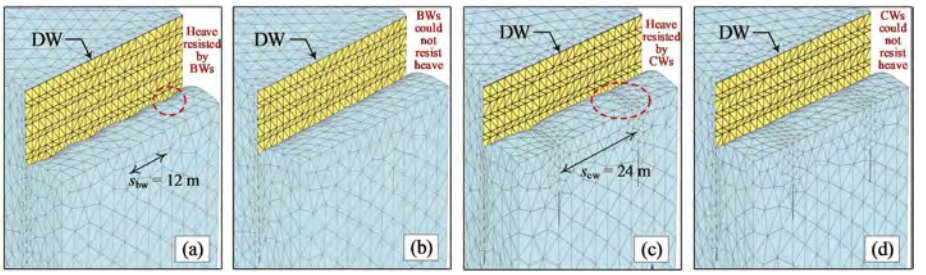

Figure 3. Deformed mesh of soil at divergence condition with H_p/H_e = 1.0; B = 30 m (L_{bw}/H_e = 0.6, D_{bw}/H_p = 1.0, s_{bw} = 12 m for BW only; D_{cw}/H_p = 0.4; s_{cw} = 24 m for CW only): (a) α_{bw} = 1.0; (b) α_{bw} = 0.1; (c) α_{cw} = 1.0; (d) α_{cw} = 0.1.

4.2 *Effect of BW and CW dimension*

Figure 4 plots the variation of factor of safety (FS_{fem}) for different BW and CW dimension. The results showed that the FS_{fem} values increased significantly as the CW depth increased (below abscissa). Similarly, increasing the BW length could enhance the FS_{fem} values (above abscissa). However, the FS_{fem} values for BW case were increased non-linearly as compared to that of CW case, in which the short BW length (e.g., L_{bw}/H_e = 0.2) has an insignificant effect on the basal heave resistance. It is due to a larger heave occurred in the middle of the excavation than that near the diaphragm wall (indicated in Figure 3a-d). Hence, the closer the BW to the middle of the excavation, the higher the basal heave resistance, and vice versa. In such a case, implementing CW has a better effect than that of BW in enhancing the basal heave resistance for the same frictional area, particularly for a small frictional area (L_{cw}/H_p < 0.8 or L_{bw}/H_e < 0.8).

In addition, the effect of L_{bw}/H_e and D_{cw}/H_p in enhancing the FS_{fem} value became more pronounced for larger BW or CW spacing (s_{bw} or s_{cw}). Finally, these findings exhibit that enlarging the BW and CW dimension inside the excavation could enhance the frictional area, which could contribute to the basal heave resistance. This also implies that, for the same required FS values, a reduction of wall penetration depth (H_p) could be considered when implementing BW or CW inside the excavation, which is good for economical manner.

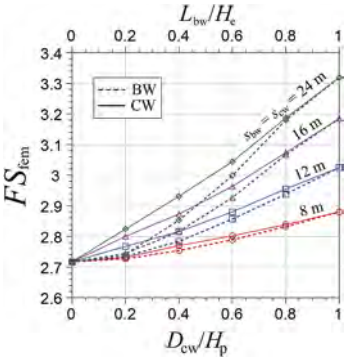

Figure 4. Variation of factor of safety for different BW and CW dimensions (α = 1.0; D_{bw}/H_p = 1.0; H_p/H_e = 1.0; B = 30 m).

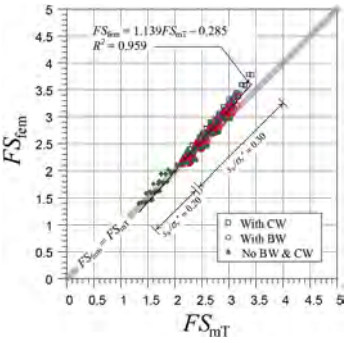

Figure 5. Comparison of FEM results and modified Terzaghi's method.

5 PROPOSED SIMPLIFIED METHOD

A simplified method was proposed to calculate the factor of safety against basal heave in excavations with BW and CW, which was derived based on Terzaghi's bearing capacity theory (Terzaghi, 1943). Some modification is made by extending the center point from the final

excavation level to the wall toe so that the frictional resistance acting along the H_p level is taken into account (α_{dw}) in the formula. Additionally, the frictional resistance acting on the two sides of BWs ($2\alpha_{bw}$) and CWs ($2\alpha_{cw}$) could also be considered by adding the BWs properties (β_{bw}) and CWs properties (β_{cw}) into the formula. Thus, the factor of safety for the proposed modified Terzaghi's method (FS_{mT}) can be expressed as:

$$FS_{mT} = \frac{5.7s_{u,3}B' + s_{u,2}H_p(1+\alpha_{dw}) + s_{u,bw}\beta_{bw} + s_{u,cw}\beta_{cw}}{\gamma H_e B' - s_{u,1}H_e} \quad (1)$$

$$\beta_{bw} = \frac{2\alpha_{bw}L_{bw}D_{bw}}{s_{bw}};\ \beta_{cw} = \frac{2\alpha_{cw}D_{cw}0.5B}{s_{cw}} = \frac{\alpha_{cw}D_{cw}B}{s_{cw}} \quad (2)$$

where γ is the unit weight of the soil, B is the excavation width, $B' = B/\sqrt{2}$ is the radius of the failure surface; $s_{u,1}$, $s_{u,2}$, and $s_{u,3}$ are the average undrained shear strength at the ground surface to the final excavation level, at the final excavation level to the wall toe, and at the wall toe to the radius of failure surface ($B' = B/\sqrt{2}$), respectively. $s_{u,bw}$ and $s_{u,cw}$ are the average undrained shear strength at the level of BW and CW penetration depth.

Figure 5 shows the comparison of the factor of safety between the FEM results and modified Terzaghi's method. A total of 304 different cases were analyzed, involving the case without BW and CW (s_u/σ_v' = 0.2 – 0.3; α_{dw} = 0.5 – 1.0; H_p/H_e = 0.6 – 1.2; B = 30 – 40 m) and with BW or CW (s_u/σ_v' = 0.3; $\alpha_{bw} = \alpha_{cw}$ = 1.0; L_{bw}/H_e = 0.2 – 0.6; D_{cw}/H_p = 0.2 – 1.0; $s_{cw} = s_{bw}$ = 12 – 48 m; H_p/H_e = 0.6 – 1.2; B = 30 – 40 m). As shown in Figure 5, all comparisons were generally close to each other, even for a lower normalized undrained shear strength (s_u/σ_v' = 0.2). Linear regression was adopted, in which the relationship between the FEM results and modified Terzaghi's method can be expressed as $FS_{fem} = 1.139FS_{mT} - 0.285$ with the coefficient of determination (R^2) being 0.959. These imply that the results from the modified Terzaghi's method are similar and consistent for the case with and without BW or CW.

6 CONCLUSION

A series of three-dimensional finite element methods (3D FEM) was conducted to investigate the performance of the buttress wall (BW) and cross wall (CW) in resisting the basal heave induced by deep excavation. The results showed that the basal heave mechanism of excavation with BW and CW is highly influenced by the frictional resistance acting on the contact surface area between the wall (BW and CW) and surrounding soil. Furthermore, the following conclusion can also be drawn:

1. Enlarging the BW or CW dimension inside the excavation could enhance the frictional area, resulting in a higher basal heave resistance
2. The effect of BW in resisting the basal heave failure is insignificant for a short BW length (e.g., L_{bw} = 3 m). Hence, an appropriate BW length should be considered to enhance the basal heave resistance effectively.
3. A new simplified method was proposed to calculate the factor of safety against basal heave, namely the modified Terzaghi's method. It is found that the results from the modified Terzaghi's method are similar and consistent with the FEM results for the case with and without BW or CW, implying that the proposed method could be reasonably adopted.

A study of the ground volume loss modeling technique influence the soil displacement in course of shield tunneling

R.F. Sharafutdinov, O.N. Isaev & D.S. Zakatov
Research Center of Construction - Gersevanov Research Institute of Bases and Underground Structures (NIIOSP), Moscow, Russia

ABSTRACT: The paper presents results of the study dealing with the influence of various techniques for modeling volume loss on soil deformation. From the surrounding soil deformation viewpoint, the contraction method the effect of weight loss CMW produces the most correct results. It was shown that the application of Hardening soil models (HS, HSS) realized in PLAXIS software does not always give adequate results. These models do not consider the position of yield surface changing, which affects the deformation behavior of soil in the process of unloading/reloading or non-linear stress paths (as in the case of tunneling). In this regard, the ground surface settlement is overestimated by 1.5……2 times for normally consolidated soil (OCR=1), and underestimated for over consolidated soil (OCR>1). Recommendations for prediction of settlement associated with tunneling were stated.

1 INTRODUCTION

Tunneling is an essential part of underground development. Like any other type of geotechnical work, tunneling is associated with changes in stress-strain state of the soil (Figure 1). An importance of the reliable settlement prediction increases when constructing tunnels in close proximity to other structures, water and gas supply conduits.

Methods for prediction tunneling settlement were categorized into empirical, analytical and numerical. Presently, numerical methods based on FEM and realized in geotechnical software (PLAXIS, MIDAS GTS, Z-SOIL) are the most advanced displacement prediction tools which can accommodate non-linear behavior of soil (close to realistic).

Considering unloaded ground surface, the settlement trough can be well described by an error function curve (Attewell et al., 1986; Mair, 1996; Peck, 1969; Pushilin et al., 2007):

$$S_i = S_{\max} \exp\left(-\frac{{x_i}^2}{2i^2}\right) \tag{1}$$

where S_i is a surface settlement at a transverse distance x_i from the tunnel center; $S_{\max}$ is a maximum settlement (at x = 0); i is the horizontal distance from the tunnel axes to the point of inflection of the settlement trough.

Maximum settlement $S_{\max}$ is derived from the ratio:

$$S_{\max} = \frac{V_L \pi \left(\frac{D}{2}\right)^2}{2.5i}, \tag{2}$$

where V_L is a volume loss at tunneling (hereinafter volume loss), D is a tunnel outer diameter.

The volume loss V_L is an integral characteristic, which reflects influence of tunneling on surrounding ground (Il'ichev et al., 2011; Isaev & Sharafutdinov, 2012, 2015; Mair, 1996; Mair & Taylor, 1997; O'Reilly & New, 1982; Strokova, 2008; Ter-Martirosian et al., 2021). Generally, V_L takes into account soil deformations associated with original stress relief, soil softening and soil sampling in a tunnel face (1) and shield lateral plowing (2); ground movement into

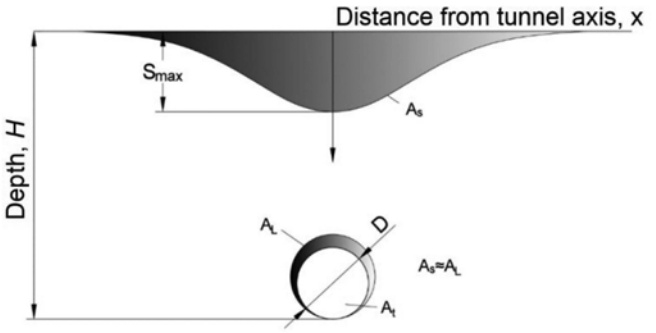

Figure 1. Shield tunneling induced ground surface settlement.

the gap between shield and lining (3); deformation of the lining (4); ground movement due to the shield and tunnel subsidence and consolidation (5) (Figure 2):

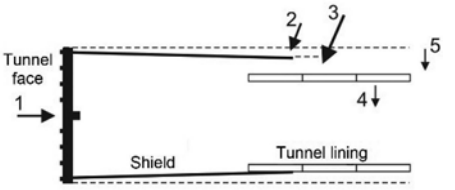

Figure 2. Reasons for ground deformations associated with shield tunneling (Mair & Taylor, 1997; Möller, 2006).

The volume loss is obtained from results of the settlement trough measurement performed during tunneling, using the following equation (Figure 1):

$$V_L = \frac{A_S}{A_t} 100\%, \tag{3}$$

where A_S is an area between horizon and the curve describing settlement of the unloaded ground surface, A_t is a tunnel cross-section area.

V_L values may vary with a considerable scatter. Thus, according to (Mair, 1996; Möller, 2006), in sands V_L can only be 0.5%, whereas in clays it can achieve 2.0%. In the layered ground V_L can range from 2.0 to 4.0% (Mair, 1996; Möller, 2006). Technical manual of U.S. Department of Transportation (Hung et al., 2009) specifies V_L as a soil stiffness and construction experience dependent value, which can range from 0.5 to 4.0% and wider. Thus, depending on soil composition and method for pumping grout into a ground-lining gap, average V_L values range from 1.5 to 5.5% in utility tunnels (Isaev & Sharafutdinov, 2012; Petrukhin et al., 2015). In micro tunnels, the V_L value depends on soil content in the gap between a pipeline and a tunnel wall and falls into a range of 0.4...3.6 % (Isaev & Sharafutdinov, 2015).

Numerical analyses of the tunneling-induced deformations of the surrounding soil may be carried out using two principally different approaches: (I) 3D-modeling of the tunneling working stages, (II) 2D\3D-modeling with considering the determined V_L. The former recently found its application for construction of the most critical tunnel sections. The latter solves a larger number of problems and envisages utilization of various computational methods for modeling. Methods applied can have an influence on the results obtained.

When conducting 2D-modeling of the tunneling influence, the following methods for volume loss modeling tend to be common.

The Contraction method (*CM*) developed by (Vermeer & Brinkgreve, 1993) includes two calculation phases. In the first phase, tunnel excavation is simulated by removing ground elements inside the tunnel while at the same time lining is activated. As the weight of the removed ground is larger than the weight of the lining, the lining will move upwards. In the second

phase, tunnel lining is uniformly contracted until the prescribed contraction ratio c_p, is reached, as Figure 3 shows.

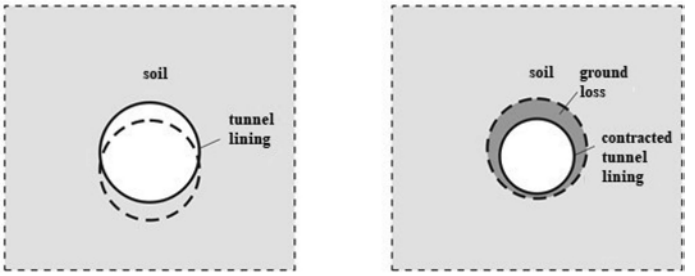

Figure 3. A scheme of the ground loss modeling using contraction method *CM* (Möller & Vermeer, 2005).

The *CM* possesses some peculiarities. Thus, when removing ground elements inside the tunnel, elastic or elastoplastic continuum modeling soil mass unloads. Ordinarily, volume loss and effect of ground removal are not considered separately because these processes occur simultaneously and most researches are focused on volume loss. Zang et al proposed a *contraction method without considering weight loss* (*CMW*) (Zang et al., 2019). In this method, a distinction between the weight loss and volume loss, authors showed that unloading had an effect on calculation results.

The *stress reduction method* (*SRM*) initially was developed for modeling open-face tunneling. In the first phase, the soil elements inside the tunnel are deactivated and equivalent pressure $\beta \cdot p_0$ is activated. Therein, p_0 is initial ground pressure; β is a load reduction factor satisfying the equation $0 < \beta < 1$ and often taken around 0.5. In the second phase, the lining is installed and the ground pressure $\beta \cdot p_0$ is transmitted to the lining. In the case of small β-factor, ground deformations will be relatively large whilst structural forces in the lining will be relatively low. A larger β-factor leads to smaller ground deformations and larger structural forces in lining (Möller, 2006).

The *SRM* has also been proposed to simulate installation of close-face shield tunneling (Addenbrooke et al., 1997; Möller, 2006). Firstly, the stresses inside the tunnel are reduced with concurrent volume loss control. As soon as the prescribed V_L at a corresponding pressure p_A is reached (point A in Figure 4b), the lining is activated. Hence, the β-factor is chosen so that it matches a given volume loss V_L.

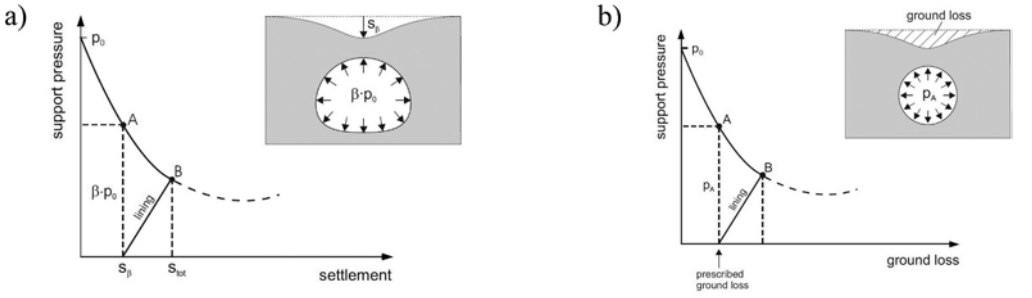

Figure 4. Scheme of the Stress reduction method (Möller, 2006): a – original; b – modified (Addenbrooke et al., 1997).

The *grout pressure method* (*GPM*) proposed in (Möller, 2006) postulates limitation of the ground deformation by the thickness of the ground-lining gap and by grout pressure distribution, while filling the gap. When modeling tunnel installation, ground elements inside the tunnel are deactivated and grout radial pressure is applied to the ground (considering a hydrostatical increase with depth) (Figure 5).

The simulation procedure affects not only predictable deformation of the surrounding soil, but also V_L values received from back analyses of the calculation results. Traditionally, V_L

was evaluated on the basis of the measurement results by describing a settlement trough with Equation (1) (O'Reilly & New, 1982; Peck, 1969). Significant development and advance of numerical methods has given the opportunity to assess V_L by back analysis in geotechnical software complexes (Aldiamar et al., 2021; Elarabi & Mohamed, 2017; Likitlersuang et al., 2014; Möller & Vermeer, 2005; Ter-Martirosyan et al., 2020). For this purpose, both simplified and more comprehensive non-linear soil models have been used at the moment.

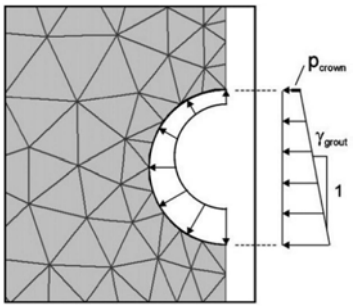

Figure 5. Display of the grout pressure method (Möller & Vermeer, 2008), where p_{crown} is a grout pressure in the upper tunnel arch, γ_{grout} is a grout unit weight.

However, application of comprehensive models often produces uncertain results. Thus, for instance, (Aldiamar et al., 2021; Çelik, 2017; Petrukhin et al., 2014b, 2014a) show that the Hardening soil model (hereinafter HS) and Hardening soil with small strain stiffness (hereinafter HSS) overestimate the settlement value by 1.3. . .2.3 times. This indicates that such tunneling problems should be solved using verified models and approaches. As pointed out in (Elarabi & Mohamed, 2017; Petrukhin et al., 2015), the ideal elastoplastic Mohr-Coulomb model (hereinafter MC) gives more adequate surface settlement than HS.

There is a mutual effect of method for modeling volume loss and applied geomechanical model on soil deformation. Therefore, the paper provides the results of the effect of various plain-strain volume loss models and geomechanical models on settlements associated with shield tunneling. Recommendations for prediction reliable calculated results of the settlement induced by closed tunneling are stated.

2 METHODS

Numerical analyses were performed in PLAXIS 2D. A round-shaped tunnel of 6.0 m in diameter rested at a depth of 24.0 m. Tunnel lining was assumed to be 0.3 m thick and with elastic modulus of 30 GPa. There were no aquifers in the scheme. The calculation was made for drained conditions. The following three soil models were considered in this study: MC, HS and HSS. The study comprised two phases.

In the first phase, various methods of volume loss modeling were analyzed. In consideration were taken *CM*, *CMW*, *SRM* and *GPM* methods described above. Volume loss V_L was assumed to be 2%. For *CM* and *CMW* methods, V_L was directly prescribed using c_p. For the *SRM* method, β-factor was selected so that the volume of the moved soil matched the designed V_L value. For the *GPM* method, radial grout pressure was selected in correspondence with the prescribed V_L value. The V_L was monitored over the ground movement around the tunnel. Medium dense sand was taken into consideration. Soil parameters are listed in Table 1.

HS and HSS soil models take into account the relationship between stiffness and levels of both volume and shear strain. In the shield tunneling, the strain levels depend on V_L when modeling.

In the second phase, numerical analyses of the volume loss influence on ground surface deformation were performed. *CM* and *CMW* methods were taken for the study. V_L was assumed to be 0.5, 1 and 2 % for dispersive soil, such as: sand of various density, normally consolidated and overconsolidated clay (Table 1).

Ground surface movement and the ratio of the trough area to the excavation area n were analyzed. The ratio n is based on the assumption that trough area and excavation area are comparable, and $A_S \approx A_L$ (Ahmed & Iskander, 2011; Cording & Hansmire, 1975; Mair & Taylor, 1997; Petrukhin et al., 2014a) (Figure 1), what makes it possible to assess the adequacy of the calculation results. The denoted assumption is true for most types of dispersive soil (except for soil with explicit dilatancy, $A_S < A_L$). Hence, the following ratio was used for assessing the adequacy of the calculation results:

$$n = \frac{A_S}{A_L} \leq 1 \tag{3}$$

Although this criterion is to a great extent conditional, it is an important tool in the analysis of the numerical calculations results. For example, if n is greatly larger than 1, one can draw a conclusion that the chosen method gives inadequate results. On the contrary, proximity of n to 1 indicates the adequacy of the calculation results.

3 NUMERICAL ANALYSES RESULTS

3.1 *Effect of volume loss modeling method*

Figure 6 shows calculation results obtained from various methods of volume loss modeling performed for medium dense sand.

It was found that volume loss modeling technique had a moderate effect on prediction of the ground surface deformation. *CM* and *CMW* methods with MC-model with *n*-factor differing from 1 less than 10% produced most adequate settlement values. Computation with *SRM* and *GPM* methods overestimated ground surface settlement by 13-20% when compared with *CMW*. From the authors' point of view, all described methods are suitable for calculation of the ground surface settlement. (Ahmed & Iskander, 2011) made a similar conclusion, though methods possessed some limitations. Thus, *CM* and *CMW* produced unrealistic lining forces, and the *GPM* method inserted pore pressure inaccuracy.

However, soil models have a significant influence on prediction of the ground surface settlement. Thus, all methods provide minimum settlement value ranging from 17 to 24.8 mm and most adequate *n*-factor value varying from 0.91 to 1.21, when using MC-model. Settlement values computed with HS model are 70...87 % above those computed with MC-model for all other methods, and *n*-ratio ranging from 1.92 to 2.35 indicates both inadequacy of the computation results and overestimation of settlement by 2 times. The HSS model also produces overestimated and

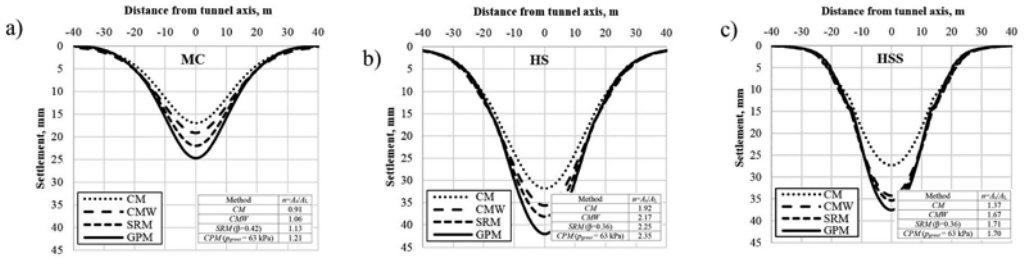

Figure 6. Ground surface settlement profile produced by various modelling methods: a) MC; b) HS; c) HSS.

inadequate settlement values. Thus, settlement values calculated with HSS model were 52. . .61 % above those calculated using MC-model, therefore *n*-ratio varied from 1.31 to 1.71. Considering the above, one can draw a conclusion that the HS and HSS models integrated in PLAXIS software inadequately describe tunneling induced settlement, whatever method of modeling.

Further analyses used *CM* and *CMW* methods.

3.2 *Influence of volume loss on ground surface deformation*

Figure 7 represents ground surface settlement values calculated using various soil models for *CM* and *CMW* methods.

In general, *CM* and *CMW* methods produce similar results (Figure 8). Difference in *n*-ratio does not exceed 10%. Meanwhile, method of modeling has a significant influence on soil models with small deformation modulus when using MC model. Thus, in sand, the difference reaches 117% and in normally consolidated clay, it achieves 525%. Moreover, as Figure 9 shows, the shape of the settlement trough changes indicating the inadequacy of the results. At the same time, when using HS and HSS models, the results of the calculations weakly depend on the method of ~~ground~~ volume loss modeling. Further on, a *CMW* method was used.

Assessment of the V_L influence on the *n*-ratio shows the following. For the MC model, *n* ranges from 0.80 to 0.96 for all considered types of soil and V_L values. This ratio indicates the greatest adequacy of the calculation results. When applying HSS model in normally consolidated soils (*OCR*=1), a significant overestimation of settlement is observed indicating inadequate results.

For the HSS model, when *OCR*=1, *n* ranges from 0.75 to 1.40, and *n*-ratio increases with increasing V_L. For small deformations, when V_L is 0.5%, *n*-ratio lies in an adequate range of 0.75-1.09. It was revealed that the model behavior is more adequate at small strains. This is because a ratio of the stiffness to the shear strain level is in full consideration in the HSS model.

At the same time, in overconsolidated soil with *OCR*=2, HS and HSS models produce *n*-ratio ranging from 0.31 to 0.54, which indicates an underestimation of settlement values. Figure 10 presents areas of elastoplastic deformation of normally consolidated (*OCR*=1) and overconsolidated (*OCR*>1) soil, plotted on the base of comprehensive numerical analyses (with application of HSS model, which provides the qualitative assessment of elastoplastic deformation area).

It can be noted that in normally consolidated soil, zones of plastic failure occur around the tunnel and pass into zones of shear and volume-shear hardening. As V_L increases, the boundaries of these zones shift. Besides, alongside and above the tunnel, at a distance of up to 2D, volumetric hardening zones begin developing. Usually, the development of volumetric hardening zones indicates soil consolidation that occurs when an additional compressive load is transferred. However, in tunneling problems, due to the complex changes in the soil stress-strain-state, unloading accompanied with a change of the yield surface position appears (Fadeev, 1987). The HS and HSS models are isotropic (that is, the yield surface does not change its position) and do not take into account the soil softening, which is typical for tunneling problems. This is associated with significant overestimation of the settlement.

In the case of overconsolidated soils, only shear hardening surfaces are observed around the tunnel at a width of about 1D (with increasing V_L, the width increases). The rest of the soil

tends to have elastic behavior. The shear hardening results in an “arch effect”, which is observed in cohesive soil above the tunnel.

Considering the above stated, when computing deformations associated with tunneling, models with fluctuating yield surface position should be applied. Otherwise, the MC models provide more reliable results, when using *CNW* (Zang et al., 2019) method.

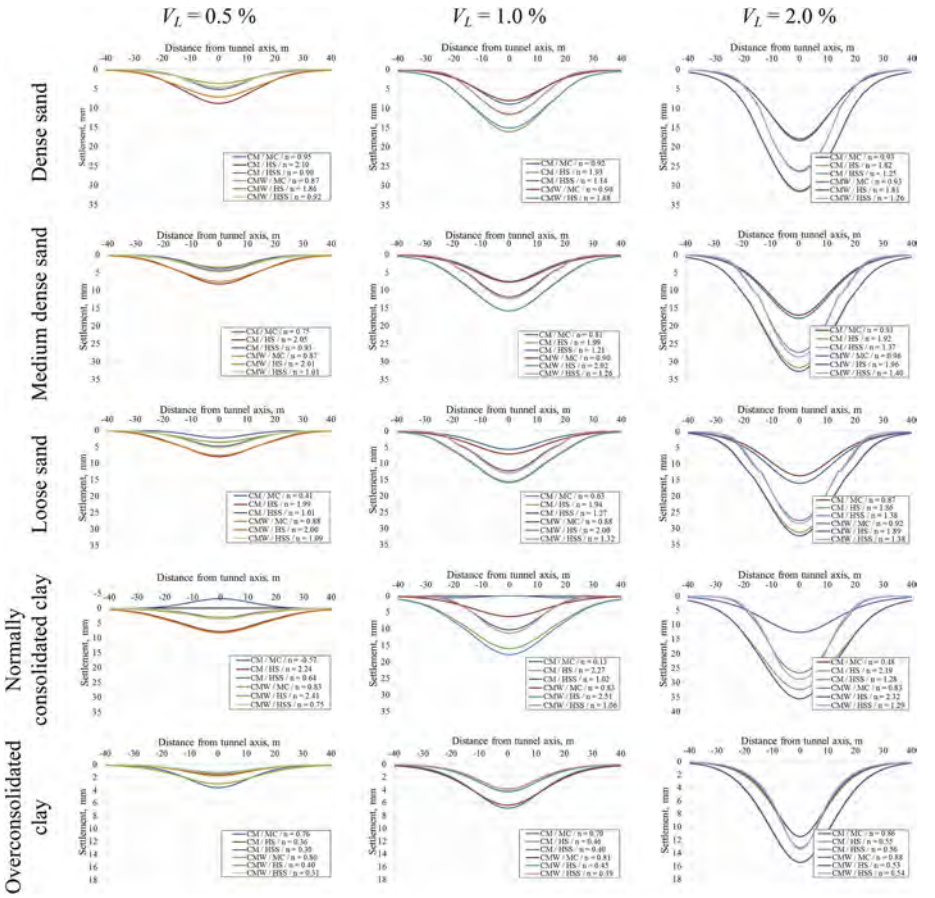

Figure 7. Surface settlement profile produced by different simulation methods for MC, HS and HSS models.

4 DISCUSSION

The performed numerical studies on normally consolidated and overconsolidated soil make it possible to reconsider the applicability of HS and HSS models for predicting tunneling induced settlements. Although a number of authors (Çelik, 2017) conclude that it is necessary to use advanced soil models, their application should be verified. Advanced models, of course, allow researchers to more realistically simulate the soil behavior. However, each model is developed for specific problems and it is necessary to confirm its adequacy to ensure a reliable result. The criterion of truth in geotechnics is monitoring data. However, a lack of coincidence is often attributed to natural, man-made or human factors.

Considering an example of the Double-O-Tube (DOT) tunnel installation in Taiwan, (Chen et al., 2016) performed three-dimensional numerical analysis of tunneling with the use of MC, HS and HSS models. Like this study, they obtained maximum settlement values for HS model, and minimum for MC model. Field data did not completely match the calculated

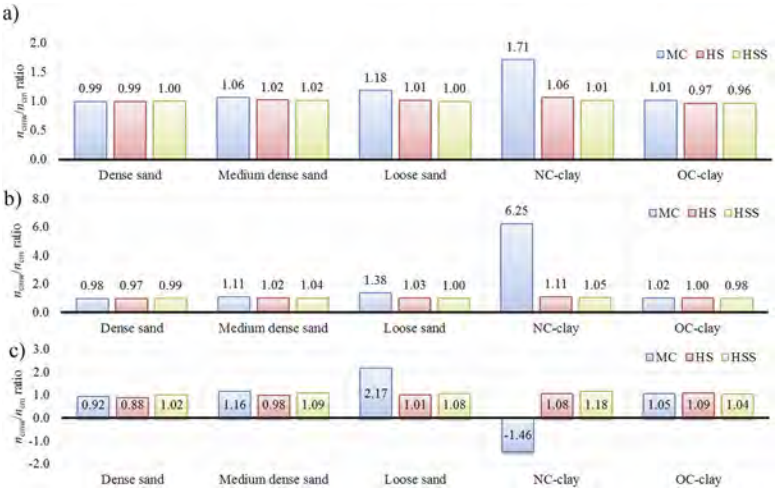

Figure 8. The comparison results of the n_{cmw}/n_{cm} ratio of different soil models at V_L=2 % (a); V_L=1 % (b); V_L=0.5 % (c).

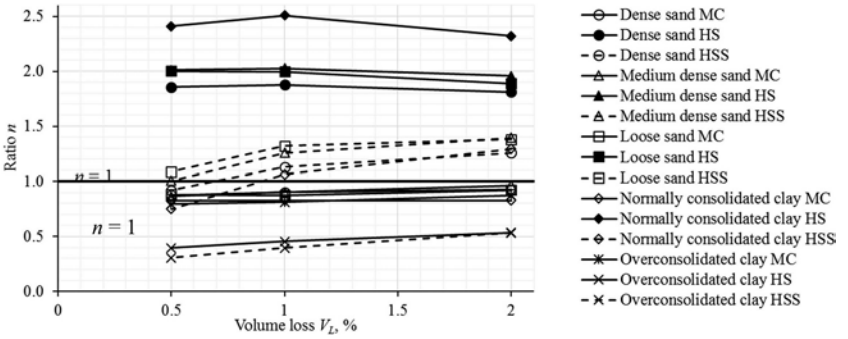

Figure 9. Relationship between *n*-ratio and ground loss in various models and soil types.

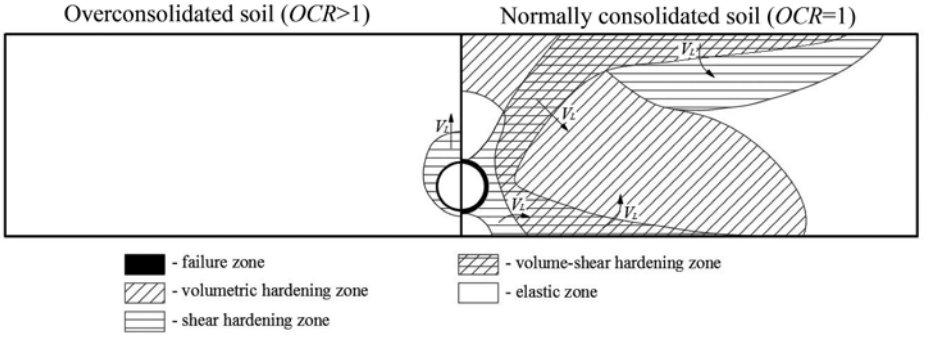

Figure 10. Elastoplastic strain zones for normally and over consolidated soil.

values. Similar comparisons made by (Çelik, 2017) showed that the designed volume loss and the measured settlement differed by 1.39…1.63 times. The considered studies did not analyze the *n*-ratio, and, accordingly, it was impossible to make conclusions about the adequacy of the accepted boundary conditions and models.

The data obtained indicate that tunneling induced settlement predicted for normally consolidated soils with using the HS and HSS models is overestimated. When applying these models, one should use *n*-ratio in order to additionally confirm an adequacy of the calculation results. When the volume loss is estimated by back calculation considering monitoring data, the assessment using *n*-ratio criterion provides adequate V_L value.

The results of the performed study provide a conclusion that if one uses *n*-ratio criteria to assess the adequacy of the tunneling induced settlement values, the MC model should be preferred alongside *CMW* two-dimensional analysis for volume loss modeling.

5 CONCLUSIONS

Tunneling is a part of underground development. Like any other type of geotechnical work, tunneling is associated with a change in the state of stress in the ground and with corresponding strains and displacements. Deformations induced by closed tunneling have been often predicted using numerical analyses integrated in geotechnical software complexes developed on the base of FEM (PLAXIS, MIDAS GTS, Z-SOIL). This tool takes into account complex mechanical soil behavior close to realistic.

Method for modeling ground loss moderately affects strain calculation results. *CM* and *CMW* methods provide the most adequate results. However, as (Ahmed & Iskander, 2011) showed, the methods considered have an influence on the lining forces.

HS and HSS models incorporated in geotechnical software complexes do not provide adequate calculation results. When using the HS model for normally consolidated soil (OCR=1), a significant settlement overestimation (n = 1.81…2.06) is observed. This result is inadequate. For the HSS model, n ranges from 0.75 to 1.40 and increases with increasing V_L. In the case of small strains, when V_L is 0.5 %), *n*-ratio ranges adequately from 0.75 to 1.09. In the HSS model, this phenomenon is associated with a more complete consideration of the stiffness to shear strain level ratio. However, in overconsolidated soil, HSS models provide n ranging from 0.31 to 0.54, indicating a significant underestimation of settlement.

A reason for inadequate results is that applied HS and HSS models with isotropic hardening do not consider the position of yield surface changing which affects on the deformation behavior of soil in the process of unloading/reloading or non-linear stress paths (as in the case of tunneling). Hence, the MC model should be preferred alongside *CMW* two-dimensional analysis for ensuring adequate calculation results.

Stability assessment of typical Taiwan slopes under steady unsaturated seepage conditions

A.J. Li, J.W. Mburu & Z. Qian
National Taiwan University of Science and Technology, Taipei, Taiwan

ABSTRACT: Rainfall seepage analysis forms an integral part of slope stability studies. Traditionally, seepage flow was only considered in the saturated zone which is not valid for cases where slope failure occurs in the unsaturated zone. Current understanding on the physics of flow in the unsaturated layer has led to development of several analytical solutions which can quantify the negative pore pressure distribution above the water table for use in slope stability analyses. This paper assesses the effectiveness of an analytical framework considering steady unsaturated seepage conditions for typical slopes in Taiwan. Hypothetical slope and infiltration conditions relevant to Taiwan are chosen for slope stability analyses. Parallel numerical seepage and slope stability analyses are conducted and the resultant pore pressure and factor of safety values are compared to the analytical solutions to examine the utility of the proposed framework. Preliminary findings show that the numerical and analytical results are in agreement.

1 INTRODUCTION

Rainwater infiltration is widely understood to be the main trigger of slope failures particularly in tropical and subtropical climatic regions such as Taiwan. The topography in Taiwan consists of high mountain ranges and high level of discontinuity prone to mass movements. Past earthquake events such as the 1999 Chi-Chi earthquake resulted in the loosening of sediments and lowering the threshold of rainfall required to trigger slope failure (Chen et al., 2015).

Research on rainfall-induced slope failure has grown tremendously over the past 3 decades. Several methods ranging from rainfall intensity-duration thresholds, field/laboratory tests, analytical and numerical methods have been adopted to study the failure mechanisms of slopes under rainwater infiltration, develop early warning systems of landslides and effective mitigation measures in landslide-prone areas. Rainfall intensity-duration (I-D) thresholds have been developed for different regions considering meteorological, geotechnical and hydrological conditions which if exceeded may lead to slope failure (Chen et al., 2015) but largely focus on rainfall intensity and duration as the main controlling parameters not much consideration is given to rainfall seepage processes such as evolution of pore water pressure profiles within the unsaturated soil layers (Segoni et al., 2018).

A considerable number of analytical solutions have been proposed to describe the rainfall seepage process in unsaturated soil slopes. These analytical solutions may involve infinite series or integrals that need to be computed numerically. For two-dimensional (2D) slope stability problems, the analytical solutions are derived with various simplifications and assumptions such as homogeneous soil layers and simplified geometries and boundary conditions (Zhang et al., 2018). For verification purposes, the accuracy of the analytical solution could be checked against numerical analyses results.

This study assesses the applicability of Lu and Griffith's (2004) analytical formulation to hypothetical slope cases relevant to Taiwan. The pore water pressures are exported to a 2D finite element software, Optum G2 (2020) for slope stability analysis to calculate the safety

DOI: 10.1201/9781003299127-148

factor, *FoS*. The output results mainly in form of pore water pressure profiles and calculated *FoS* are compared to Finite element (FE) seepage and stability results generated from computer software package Geo-studio, 2012 (SEEP/W, SLOPE/W) (2012a; 2012b).

2 THEORETICAL BACKGROUND

For practical slope stability problems, Lu and Griffiths (2004) proposed a matric suction profile formulation is based on Darcy's governing flow equation (1856) and Gardner's (1958) model, with suitable initial and boundary conditions as shown in equation 1.

$$(u_a - u_w) = \frac{-1}{\alpha}\ln[(1 + q/k_s)e^{-\alpha\gamma_w z} - q/k_s] \tag{1}$$

where, q = flow rate per unit area, negative for downward infiltration and positive for upward infiltration, (u_a - u_w) is the matric suction, α (approximately the inverse of the air-entry value) and n (related to breadth of soil pore size) are fitting parameters used in Van Genuchten's (1980) soil water characteristic curve (SWCC) model, k_s is the saturated hydraulic conductivity (m/s), γ_w = unit weight of water, the boundary condition of (u_a - u_w) = 0 is applied at the water table when z (distance above water table) = 0

The cohesion under variably saturated conditions,C_{app} can be estimated using equations 2 and 3. is the soil friction angle.

$$C_{app} = -\sigma^s \tan\ \phi' \tag{2}$$

$$C_{app} = \tan\ \phi' \frac{(u_a - u_w)}{(1 + [\alpha(u_a - u_w)]^n)^{(n-1)/n}} \tag{3}$$

3 METHODOLOGY

3.1 *Slope model and analysis methods*

To investigate the effectiveness of Lu and Griffiths (2004) analytical solution to slope stability analysis, the software package SEEP/W and SLOPE/W were used to conduct rainfall seepage and stability analysis based on the chosen slope parameters. Since the analytical solution under consideration is based on steady-state conditions, the equilibrated pore pressures from the SEEP/W software are compared to Lu and Griffiths (2004) matric suction profiles. This is followed by slope stability analysis comparison between limit equilibrium software SLOPE/W and finite element limit analysis (FELA) software Optum G2. It is noteworthy that the slope stability analysis in Optum G2 adopts matric suction profiles in the unsaturated zone in form of apparent cohesion whose expression is given in equation 5. Also, the groundwater profile in SEEP/W at steady-state conditions is replicated in Optum G2 to make a reasonable comparison. A 2D plane strain slope model was adopted in this study, similar to Li et al., (2022) as seen in Figure 1. A suction cutoff of 100kPa was set to prevent generation of excessive negative pore water pressures (Sorbino and Nicotera, 2013).

3.2 *Slope and hydrological properties*

This study uses one set of soil mechanical and slope geometry parameters, Effective cohesion, c' = 5 kPa, ϕ' = 25 °, γ = 18 kN/m^3, slope height, H = 5m, slope angle, β = 30°. To capture the hydrological response of different soils to rainfall infiltration, a series of hydraulic and hydrological properties are adopted. The soil types considered range from silty sand to silty clay. The Van Genuchten's (1980) equation is used to describe the soil water and characteristic curve (SWCC) and permeability function (HCF).

The hydrological parameters are drawn from the Taiwan Central Weather Bureau (CWB). Three rainfall scenarios are selected, (1) light rainfall over prolonged period of 15 days and (2)

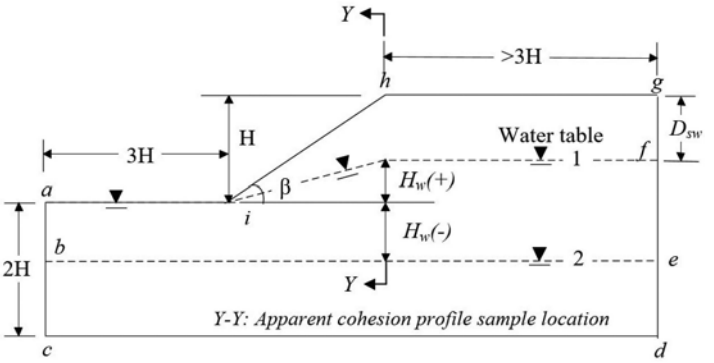

Figure 1. 2D slope model adopted for this study.

heavy rainfall over a 4 day period and (3) torrential rainfall over a period of 2 days. Generally, light rainfall events 0-20mm/day form the majority of rainfall events particularly in Taipei, and may range in duration from 1 to 18 days. Heavy rainfall events (>80mm/day) may range from 1 to 4 days. Torrential rainfall (350 – 500mm/day), normally attributed to typhoons, can last up to 2 days (Taiwan, CWB). For convenience purposes, the soil types are summarized as follows Sandy silt (S-1): $\alpha = 0.1$, n= 4, $k_s = 10^{-4}$ m/s; Silt (M-1, M-2): $\alpha = 0.02$, $n = 2$, $k_s = 10^{-5}$, 10^{-6} m/s and Clayey silt (C-1, C-2): $\alpha = 0.01$, $n = 1.4$, $k_s = 10^{-5}$, 10^{-6} m/s. The parametric study parameters are divided into three main study set categories as shown in Table 1.

The number of analyses for each study set A, B and C is controlled by the hydrological loading limit $q/k_s \leq 1.0$ and the time to reach steady state conditions. For example, soil types M-2 and C-2 could not be assessed using Lu and Griffith's analytical method for heavy and torrential rainfall since $q/k_s > 1.0$. Additionally, the corresponding low k_s may translate to a longer period to reach steady-state conditions. Similarly, slopes with deeper water table, (smaller H_w/H) take longer to reach steady state conditions, beyond the specified rainfall duration. As such, such slope cases are not considered.

Table 1. Parametric study set categories.

Study set	Soil type	Water table (H_w/H)	Rainfall scenario	Hydrological loading (q/k_s)	No. of analyses
A	S-1	0.5, 0.3, 0.0, -0.5	Light Rainfall	0.0017	20
	M-1			0.0170	
	M-2			0.1700	
	C-1			0.0170	
	C-2			0.1700	
B	S-1	0.5, 0.3	Heavy Rainfall	0.0116	6
	M-1			0.1157	
	C-1			0.1157	
C	S-1	0.5, 0.3	Torrential	0.0471	6
	M-1		Rainfall	0.4711	
	C-1			0.4711	

The SLOPE/W stability analysis employs Vanapalli's expression (1996) shown in equation 4 since it captures the non-linear relationship between matric suction and shear strength. The calculated *FoS* is compared to the result drawn from Lu and Griffith's apparent cohesion expression, equation 3, inputted in Optum G2 for stability analysis.

$$\tau = c' + (\sigma - u_a)tan\phi' + [(\theta_w - \theta_r/\theta_s - \theta_r)tan\phi'] \quad (4)$$

4 RESULTS AND DISCUSSION

4.1 *Time to reach steady state conditions*

In this study, the time to reach steady state conditions is based on subjective judgement. The pore water pressure profiles from numerical seepage analyses in SEEP/W are plotted with time. Steady state conditions were assumed when the pore water pressures barely change with time. At least 2 monitoring locations were chosen for each slope case. Slopes with water table above or at the slope toe ($H_w/H \geq 0.0$) had two monitoring locations, vertical profiles from the slope crest and mid-slope to the water table location. Slopes with water table below the slope toe ($H_w/H < 0.0$) had an extra monitoring location at the slope toe.

4.2 *Suction and apparent cohesion profiles*

4.2.1 *Different soil types*

The suction and apparent cohesion profiles presented in Figures 2a - f encompass a wide range of soil slopes (sandy silt to clayey silt) under light rainfall conditions. The initial water table location for the presented cases was 7m below the ground surface. Generally, slopes with soil type M-2 and C-2 undergo loss of suction coupled with a rise in water table leading to critical conditions. As seen in Figure 2c, there is a notable rise in water table location at the steady-state condition. Lu and Griffith's analytical solution yields quite similar pore water pressure and apparent cohesion profiles at initial and steady state conditions to SEEP/W 2D seepage results, with a difference of about 10kPa. It is seen that the difference in pore water pressures and apparent cohesion is most pronounced at the slope crest.

For highly permeable soil slope S-1 subjected to rainfall infiltration, with high water table ($H_w/H = 0.5, 0.3$) water tends to seep out at a faster rate than rainwater accumulating within the soil pores resulting in a lowering of the water table as shown in Figure 2e. Also the pore water pressures generated from the numerical SEEP/W analysis and analytical solution are significantly different at the slope crest, by about 40 kPa, as seen in Figure 2e. For the S-1 soil slope, Lu and Griffith's formulation predicts significantly smaller apparent cohesion values at initial conditions in comparison to SEEP/W results. This trend is observed for all the water table locations and rainfall scenarios analyzed in this study. Interestingly, the apparent cohesion profiles for S-1 soil type at steady-state conditions are quite similar, as shown in Figure 2f.

4.2.2 *Different water table locations*

This study analyzed soil slopes with four water table locations, one above the slope toe ($H_w/H = 0.5$), one at the slope toe, ($H_w/H = 0.0$) and another water table location below the slope toe ($H_w/H = -0.5$). Figures 3a - f present pore water pressure profiles for a typical soil slope, M-1, with moderate permeability and different water table locations under light rainfall conditions. The difference in pore water pressures predicted using the SEEP/W seepage analysis and Lu and Griffith's formulation increases with depth of the water table and is most pronounced at the slope crest. The difference in pore water pressure values ranges from 10 – 15 kPa for shallow water table locations (above slope toe) to about 50 kPa for deep water table locations (below the slope toe) as seen in Figures 3a, e. The difference in apparent cohesion profiles from the two methods is not significantly influenced by the change in water table locations. As shown in Figures 3b, d and f, for slopes with different water locations, the apparent cohesion difference is mostly 3 - 15kPa. Nevertheless, practicing engineers should take caution when using Lu and Griffith's analytical solution to estimate suction profiles for soil slopes with deep water table.

4.2.3 *Different in rainfall scenarios*

The rainfall events considered range from light rainfall over a prolonged period of 15 days, heavy rainfall over a period of 4 days and torrential rainfall over a period of 2 days. The rainfall duration was selected based on typical rainfall periods recorded around Taiwan for the past 10 years (Taiwan Central Weather Bureau). The recorded times to reach steady state conditions are largely within the rainfall durations chosen for this study and applicable to the

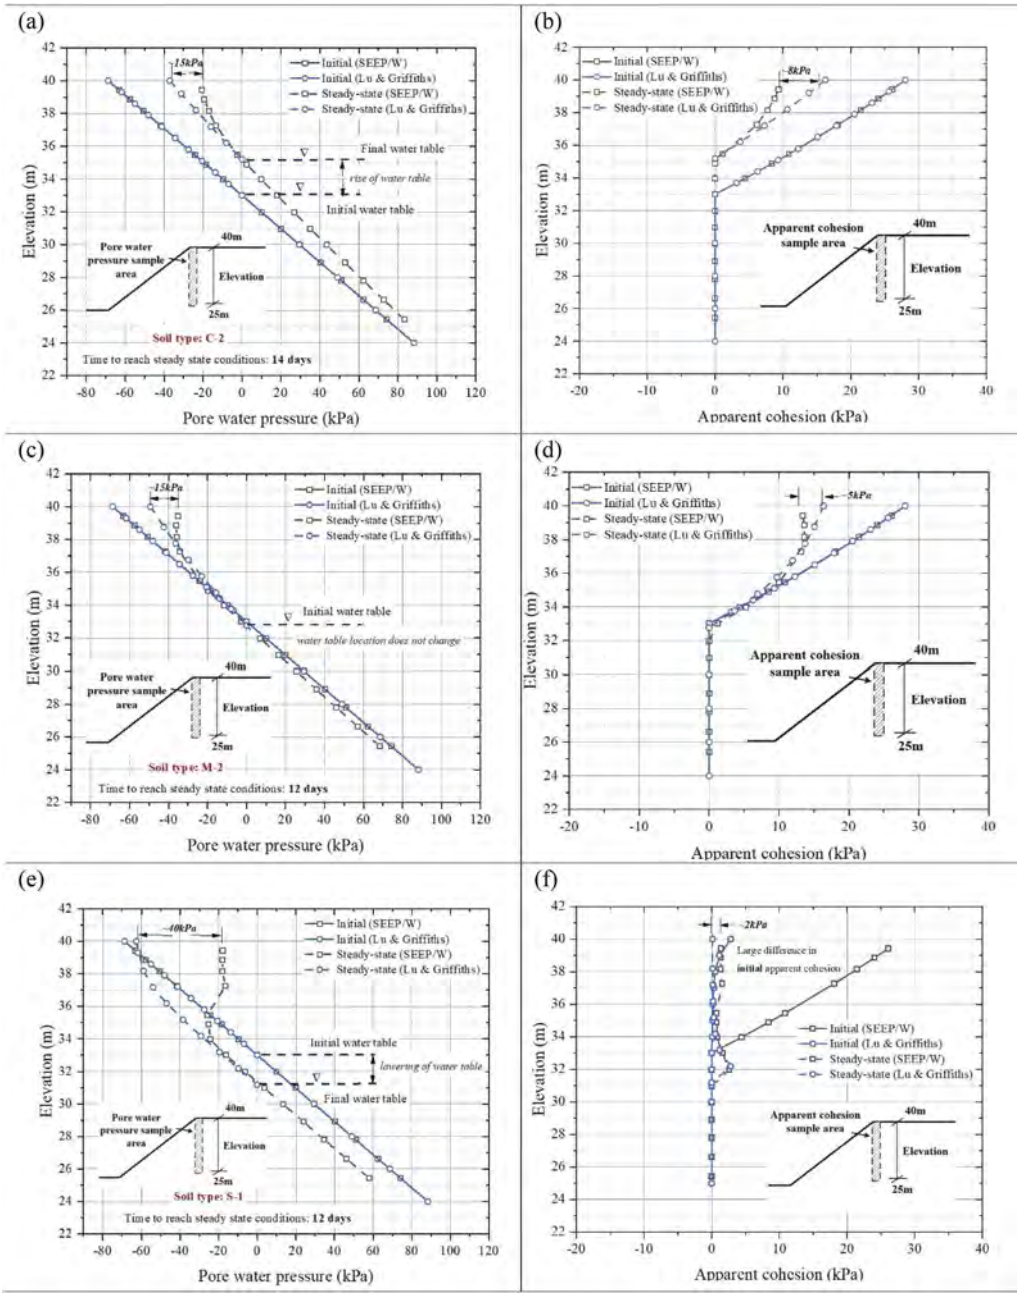

Figure 2. Pore pressure and apparent cohesion profiles for different soil slopes (a) and (b): C-2, (c) and (d): M-2, (e) and (f): S-1.

Taiwan context. It should be noted, however, that a comparison between the numerical seepage method and analytical method for study set C, soil types M-1 and C-1 was not feasible since the slope is fully saturated over the course of the torrential rainfall. Additionally, within study set C, soil type S-1, steady state conditions are reached after 28 hours, beyond the specified rainfall duration of 2 days. Thus, an appropriate comparison of the two seepage analysis methods cannot be made for this case.

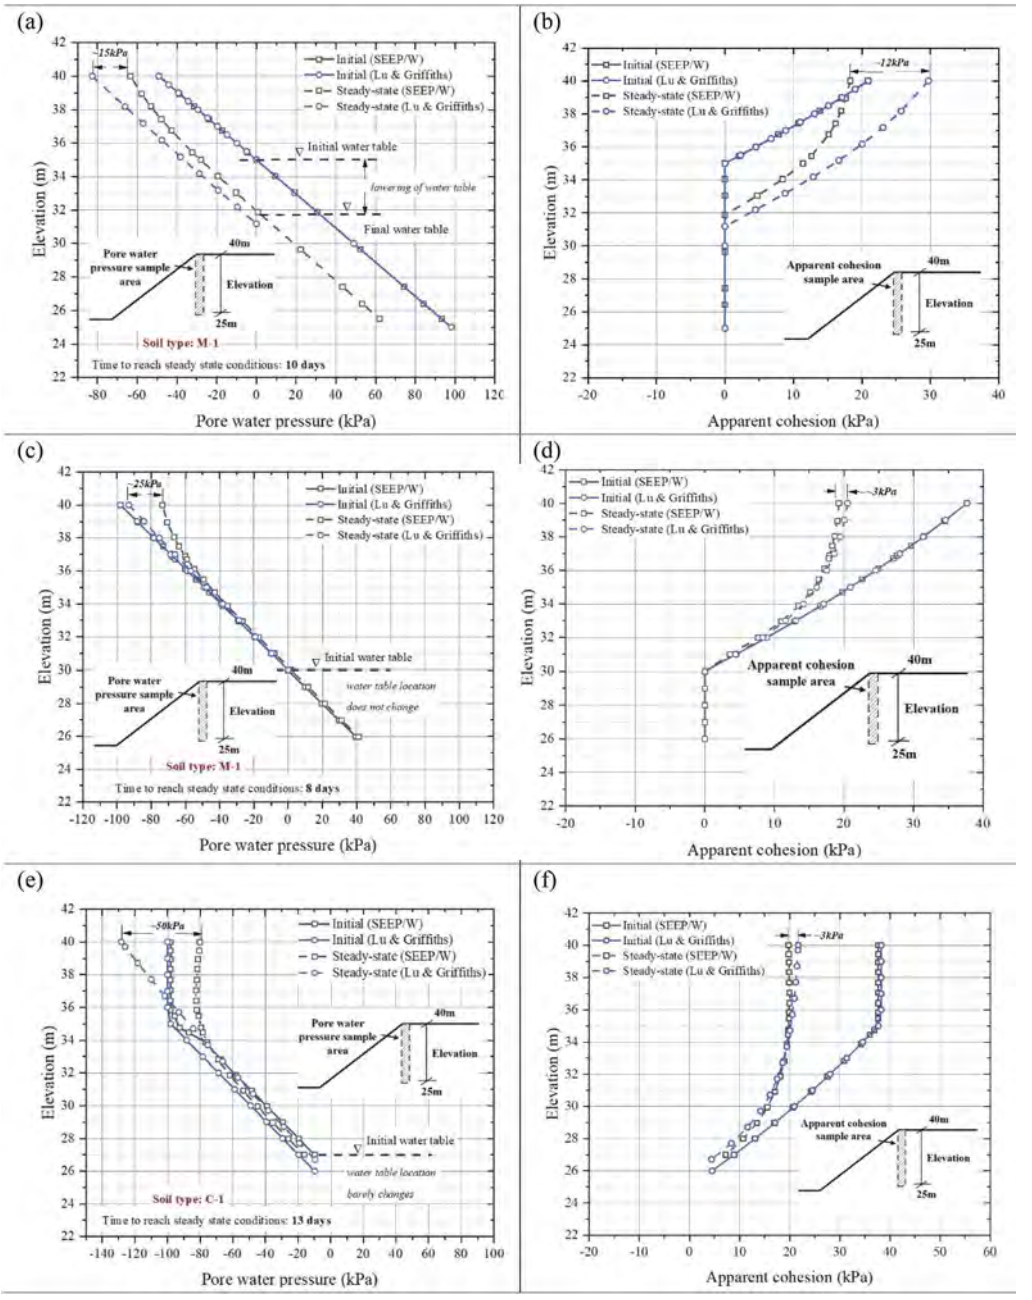

Figure 3. Pore pressure and apparent cohesion profiles for different water table locations (a) and (b): H_w/H = 0.5 (c) and (d): H_w/H = 0.0, (e) and (f): H_w/H = -0.5.

Pore water pressure and apparent cohesion profiles for silty soil slope, M-1, for the two rainfall scenarios in Figures 4a - d demonstrate that the two seepage analysis methods show good agreement with differences of about 10 kPa. Lu and Griffiths formulation is applicable over the range of rainfall intensities chosen for this study.

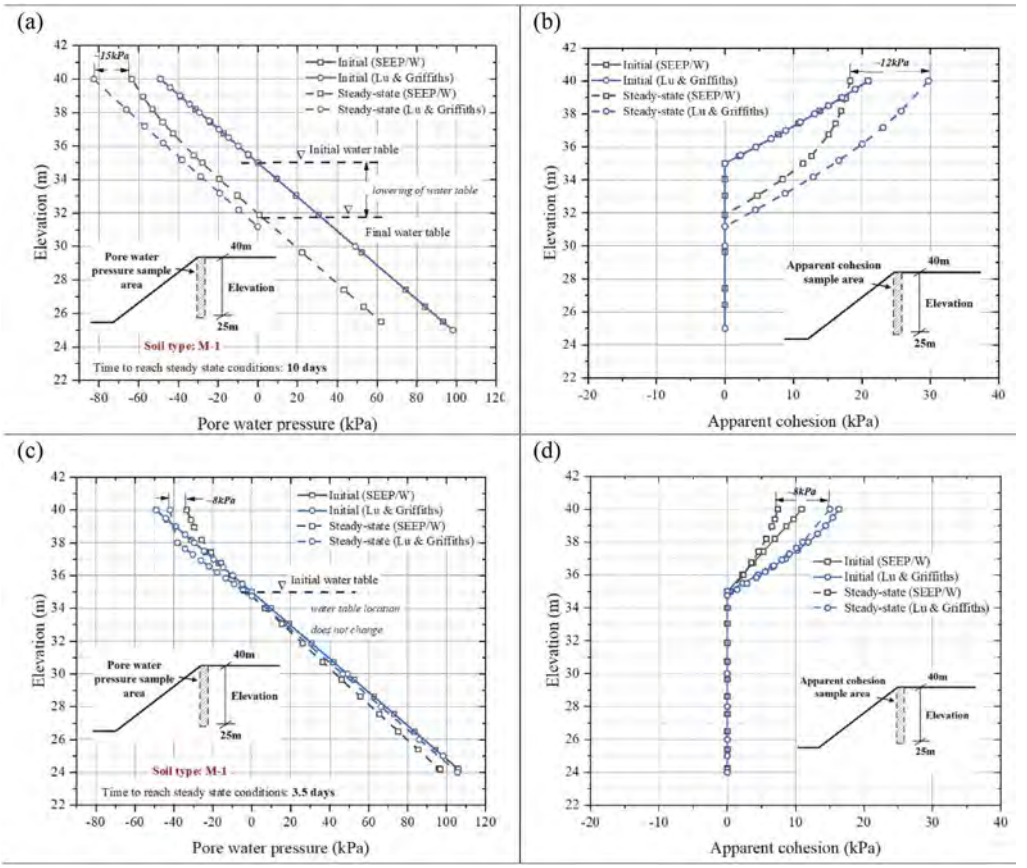

Figure 4. Pore pressure and apparent cohesion profiles for different rainfall events (a) and (b): Light rainfall (15mm/day) (c) and (d): Heavy rainfall (100mm/day).

4.3 *Slope stability analysis comparison*

The slope *FoS* at initial and steady-state conditions from SLOPE/W and Optum G2 are compared. SLOPE/W is a limit equilibrium slope stability program that integrates the calculated pore water pressures from SEEP/W to evaluate the stability of the slope. Pore water pressures estimated from Lu and Griffith's analytical solution are manually inputted in form of cohesion (equation 3) to FELA-based software, Optum G2 for stability analysis. The *FoS* is calculated using the strength reduction method (Krabbenhoft and Lyamin, 2015).

The initial *FoS* calculated using the two approaches is quite similar having a maximum of 10% difference for soil slopes, M-1,2, C-1,2 with water table locations H_w/H = 0.5, 0.0 and -0.5. Notably, the initial *FoS* predicted based on pore water pressures from the analytical approach in soil slope, S-1, is much smaller than SLOPE/W *FoS*. This is due to the large difference in apparent cohesion between the two methods as seen in Figure 2f. In fact, for S-1 slopes with water table location, H_w/H = -0.5, the initial *FoS* % difference was quite large, approximately 46%. Table 2 presents the initial *FoS* values for a section of slope parameters.

The *FoS* comparison at steady state conditions is presented in Tables 3 and 4 for a section of slope and hydrological parameters. The *FoS* % difference between SLOPE/W and Optum ranges from 1 – 24%, showing good agreement.

The failure surfaces shown in Figure 5a-d are for soil slope M-1 with water table location H_w/H = 0.3 at steady state conditions after light or heavy rainfall. The two software programs locate the failure surface by limit equilibrium method (LEM) and by calculation of stresses

Table 2. Initial *FoS* estimated from SLOPE/W and Optum software programs.

Soil type	Water Table H_w/H	Factor of safety, *FoS*

5 CONCLUSION

The utility of a widely used analytical solution is assessed for slope conditions relevant to Taiwan under different rainfall conditions. The results in form of pore water pressure and apparent cohesion profiles and factor of safety are compared to seepage and stability analyses using Geo-studio (SEEP/W and SLOPE/W) software package. The following findings are made:

1. The analytical solution yields reasonable pore water pressures and apparent cohesion profiles for the slope and hydrological parameters considered in this study. There is good agreement with the numerical seepage and stability analysis results.
2. The analytical solution predicts comparatively smaller apparent cohesion values at the initial stage of analysis for highly permeable soil slopes, S-1, leading to very conservative factor of safety values.
3. Notable differences in pore water pressures or apparent cohesion between the analytical and numerical seepage results are most prominent at the slope crest, particularly for slopes with deep water table location (below the slope toe). Engineers may need to take caution when applying the analytical solution to these kind of slopes. Further investigation is still needed for soil slopes with a deeply located water table.
4. The predicted *FoS* at steady state conditions from SLOPE/W and Optum G2 software programs show good agreement for the parameters selected in this study. This can be attributed to the closeness in apparent cohesion profiles obtained from the numerical and analytical solution. The observed failure surfaces, mainly toe failure, are quite similar.

5. The analytical solution assessed in this study assumes steady-state conditions, soil homogeneity and is mostly applicable to simplified slope geometry and boundary conditions. Also, movement of water table due to rainwater infiltration is not accounted for. As such, combining the pore water pressures with the 2D finite element software such as Optum for slope stability analysis should be considered for initial study purposes only. Additionally, engineers could use regional data on water table movement during the rainy season to predict a reasonable water table location when using the analytical solution.

ABSTRACT: Fibrous peat soil is a type of soil which comprises of fibrous organic materials, changed and fossilized to be a soil in wetland. This type of soil is generally deposited in the lowlands of East Sumatera, Central and South Borneo, and West Sulawesi Indonesia. However, due to poor characteristics associated with low shear strength, high compressibility and high-water content, the tropical fibrous peat soil has become problematic for sub-grade embankment of road constructions. The use of helix pile to reinforce the tropical fibrous peat soil for road embankment has been recently investigated. However, load-transfer mechanism of the helix pile in peat soil with more fiber content is not yet fully understood. Therefore, this paper presents laboratory scale experiment and numerical model of helix pile in fibrous peat soil under compression loadings. The effect of helix pile numbers and dimension of helices were investigated through laboratory model tests. In addition, numerical model with back-calculated input parameters from the experimental tests was also undertaken by using ABAQUS in order to examine load-displacement on the helix pile with various number of helices during loading. The results show that bearing capacity of the helix pile much influenced by the number of helices. This is due to the bearing capacity is more contributed from the bearing of helices, at about 60% - 70% of the total capacity, while the shear resistance in between helices just contributes 23% - 35%. The existence of fiber in the peat soil, could increase the shear resistance by factor of 1.30, while the increase of number of helices in the pile would increase the bearing by 5%. Hence, a new formula of predicting bearing capacity of the helix pile in the fibrous peat soil is proposed by modified Mitsch & Clemence Formula (1985) with modified Meyerhof & Adam's (1968) Nq value to accommodate typical fibrous peat soil characteristics, with the accuracy of the prediction of 98% – 99% of the bearing capacity from the experimental tests.

1 INTRODUCTION

Fibrous peat soil is a type of organic soil which has low shear strength with further high secondary, and even continuous tertiary compressibility. In Indonesia, the soil is very dominant in the lowland areas such as those areas in Central and South of Borneo, East of Sumatera, and West of Sulawesi. As a result, the soil become problematic for infrastructure developments throughout the country. A number of studies has been conducted to investigate the mechanical characteristics of peat soil. The primary compressibility of peat soil is 5 to 20 times to the primary compressibility

DOI: 10.1201/9781003299127-149

of soft clay (Mesri and Ajlouni 2007). In addition, the permeability of peat soil is about 1000 times the permeability of soft clay (Mesri and Ajlouni 2007), while its undrained shear strength is just 3 kPa to 15 kPa (Kazemian et al. 2011). Having these characteristics, ground improvement is required such as soil replacement, piled geotextile, and pile-slab to ensure the soil can be used as good foundation for infrastructure. The use of helical piles has been recently investigated for the condition of fibrous peat soil. Several studies focused on the bearing capacity of helix pile in fibrous peat soil (Fatnanta et al 2016; Parlan et al. 2016, Arsyad & Herdiman et al. 2017, Arsyad et al. 2018). The studies performed experimental tests on helix piles drilled to fibrous peat soils, and others undertook numerical analysis of modeling the raft-helix pile. However, detailed study of load transfer mechanism of helix pile to fibrous peat soil is not yet understood, particularly the effect of soil's fiber on the bearing capacity of pile. Therefore, this study aims to investigate the bearing capacity of helix pile in the fibrous peat soil by conducting a lab-scale test of compression loadings, and to examine the stress-strain in each component of the helix pile (helice plates, shaft, and shear failures zones) by numerical modeling with back-calculated parameter to the lab-scale experimental tests. Theoretical analysis was proposed to predict the bearing capacity of the helix pile based on experimental tests and numerical-back calculated model.

2 LABORATORY EXPERIMENTS

2.1 *Properties of fibrous peat soil and dimension of helix pile*

The model test was conducted in a laboratory scale testing apparatus. Figure 1 shows a schematic diagram of the apparatus used in the study. An 800 mm diameter × 1200 mm cylinder steel tank was fabricated for conducting the model tests on helix piled fibrous peat soil. The wall of the tank was made smooth and rigid to create plain strain condition in the tank. A fibrous peat soil bed of 1000 mm depth was prepared in this test tank. Undisturbed samples were taken from the bed for determining the density, moisture content, shear strength of fibrous peat soil bed. The properties of the fibrous peat soil bed are given in Table 1. In general, the properties of fibrous peat soil bed suggested that the soil is a fibric peat soil with fiber content of about 72% of the total soil, with a very high-water content of 151.02%. Its density is 12.9 kN/m^3 while the undrained shear strength is 0.94 kPa and 45^o internal friction angle.

After levelling the fibrous peat soil, helix pile was formed on the top of the soil bed layer by screwing the pile to the soil. The helix pile was made from a pipe with 25.4 mm diameter, and 500 mm height, and the spacing of helices is 100 mm. Three variations of helix pile were created for model test, type A with one helice, type B with two helices, and type C with three helices (Figure 2).

Static load was applied on the helix pile using a hydraulic jack, and the intensity of the load was increased gradually. Loading was done in accordance to the ASTM standards in which

incremental load applied when deformations reached a steady state value. The load was measured using a proving ring. Dial gauges were place at a certain location at the helix pile to measure vertical and horizontal displacement. Figure 3 shows the profile of fibrous peat soil bed in the tank, and experimental setup for load tests on helix pile, showing the positions of various dial gauges.

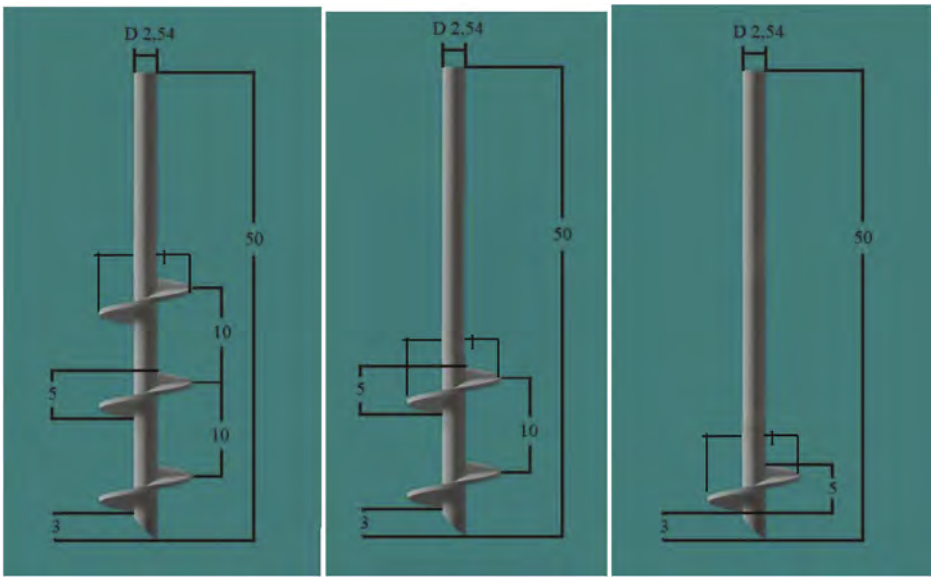

Figure 2. Dimension of helix pile in the experimental test.

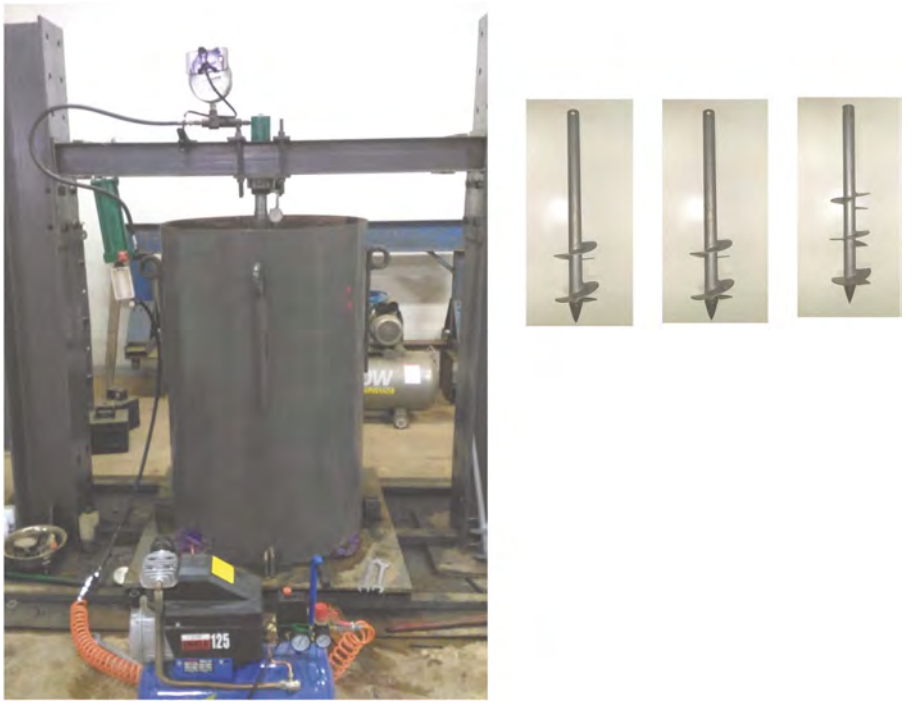

Figure 3. Experimental set up of helix pile under compression loading.

2.2 *Numerical analysis and parametric study*

The performance of the helix pile on the fibrous peat soil bed was investigated. Tests were undertaken on the model testing of helix pile, varying parameters like number of helice plates. In addition, numerical analysis was conducted to investigate the detail stress-strain in each helice plate during loading test. In this way, FEM model ABAQUS was used in which the model is shown in Figure 4. Input parameter of the helix pile is shown in Table 3. The weight volume is 7850 kg/m3, Young Modulus is 1×10^8 kPa, and Poisson ratio is 0.3. On the other hand, input parameter for fibrous peat soil in the FEM model was derived from laboratory tests, except for elastic

3 RESULTS AND DISCUSSIONS

3.1 *Experimental results*

In all the model tests conducted, during loading tests, failures were the result of the displacement of helix pile which is 10% times diameter of the pile (ISSMFE, 1985). There were three variations of the helix pile: single, double, and triple helices. Each variant was trial within three samples to test its reproducibility. In the single helice of helix pile tests, the ultimate loads were maximum 20 kg for displacements of 10% diameter (Figure 5), while, in the double helice of helix pile tests, the ultimate loads were maximum 29 kg (Figure 6), and in the triple helices, the maximum ultimate loads were 34 kg (Figure 7). It can be observed that helice plates in the helix pile have exhibited higher ultimate capacity. The results reveal that number of helices in the helix pile affect the ultimate bearing capacity. The increase of helice numbers, would increase the ultimate bearing capacity of helix pile (Figure 8). Axial stiffness of the helix pile with increasing helice plates numbers in the fibrous peat soil would increase considerably. The helix pile with a single helice plat have generated a 20 kN/m, while that with double helice plates yielded 29 kN/m, and triple helices generated 34 kN/m.

3.2 *Numerical analysis*

The results of experiments on model tests were back-calculated FEM modeling using a ABAQUS program. The computer program developed for conducting FEM model of helix pile in the fibrous peat soil. Figure 9 show the stress – strain in the FEM model of fibrous peat soil with loading on the helix pile. During the loading in the model of helix pile with a single helice plate, failure zones with stress developed was seen at the soil below the helice plate, reaching at maximum 80 kPa with mean stress of 44.6 kPa. The bearing capacity seems to be contributed from

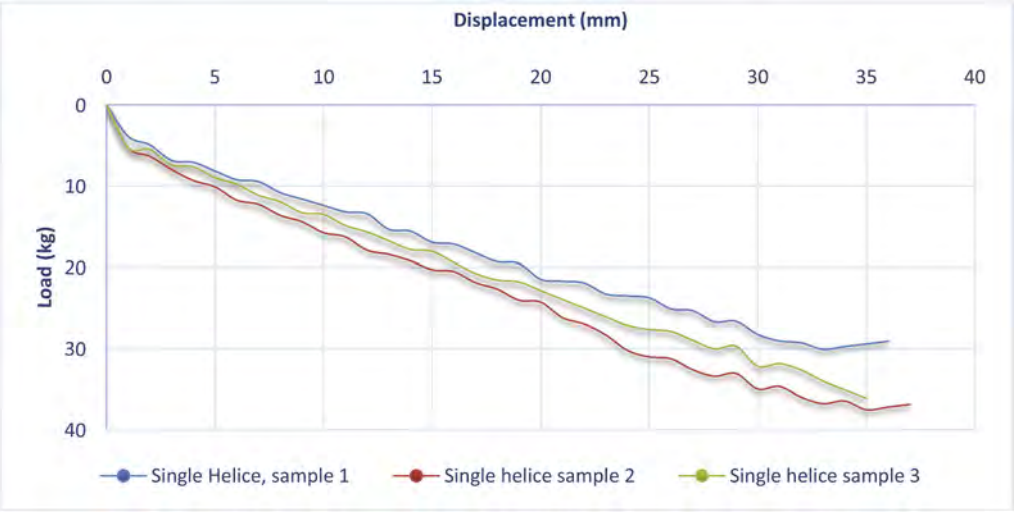

Figure 5. Load – displacement of helix pile with a single helice under compression loading.

Figure 6. Load – displacement of helix pile with double helices under compression loading.

compressive strength of the soil below the helice plate, while the friction between the pile rod and soil just contributed small value of 2.08 kPa. The displacement of the soil below the helice plate was found to be maximum 0.04 m.

On the other hand, the helix pile with a double helice plates (Figure 10) generated a different pattern of failure during the loading. The failure zones were obvious in area below lower helice plates, tip of helix rod, shaft of the rod, and shear failure areas in the area between helice plates. Stress developed at below lower helice plates at maximum 80 kPa, and below the upper helice plates at maximum 44.5 kPa, and shear failure in between helice plates at 30.4 kPa. Maximum displacement was found at the area in between the helice plates, at 0.04 m.

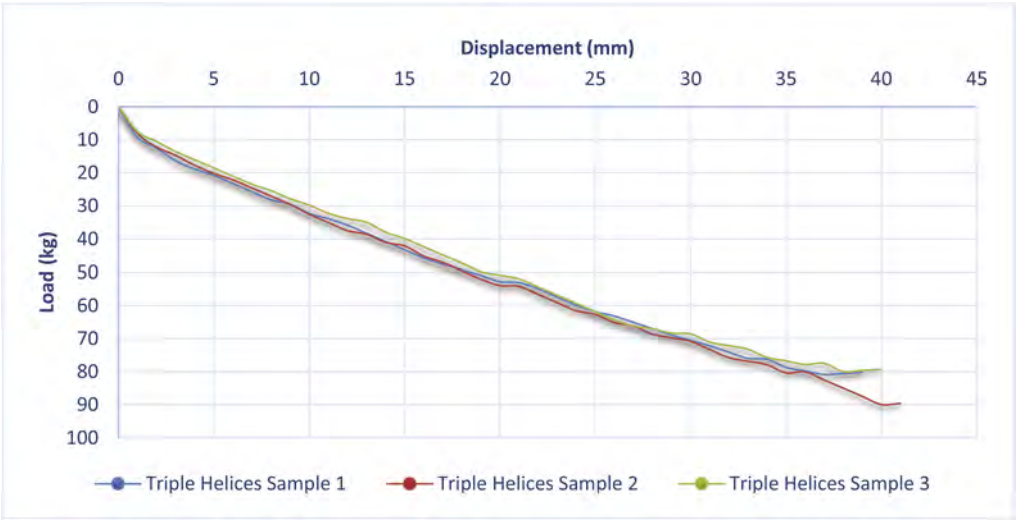

Figure 7. Load – displacement of helix pile with triple helices under compression loading.

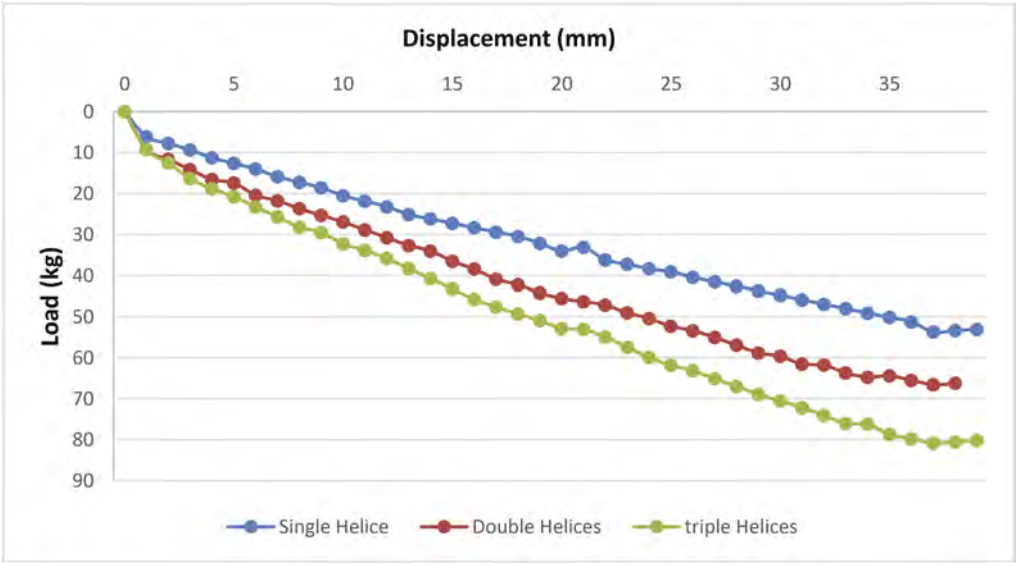

Figure 8. Load – displacement of helix pile with various number of helices under compression loading.

In regards to the helix pile with a triple helice plates (Figure 11), the failure zones were similar to the failure pattern in the double helices pile. However, due to three helices plates, the bearing capacity of the pile derived from the three helice plates with failure zones below, tip of pile rod, and failure shear in between helice plates. The stress developed below the helice plates, was accounted for maximum 80 kPa di lower helice plates, 37.5 kPa at the middle helice plates, and 23.3 kPa at the upper helices plates. Meanwhile, shear failure zones in between helice plates were at 9.16 kPa.

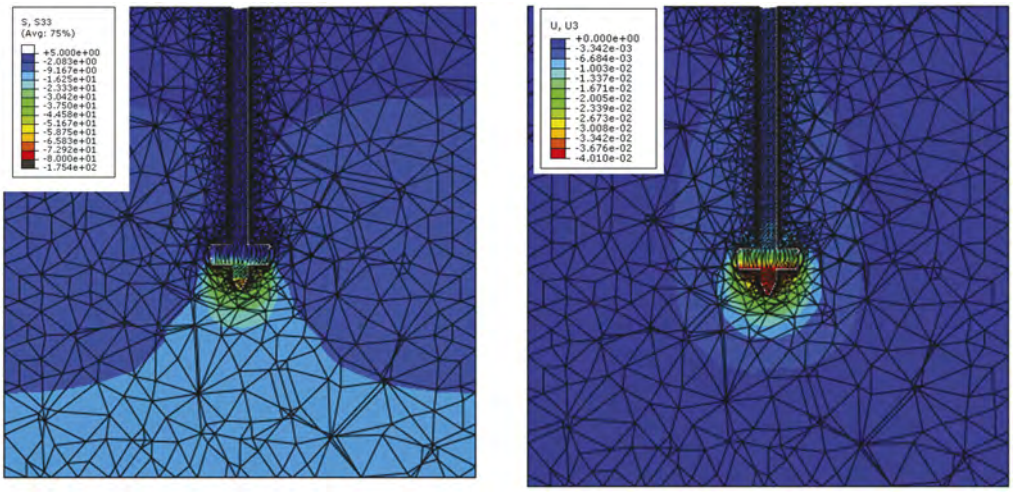

Figure 9. Experimental back-calculated FEM based stress – strain at the helix pile with a single helice.

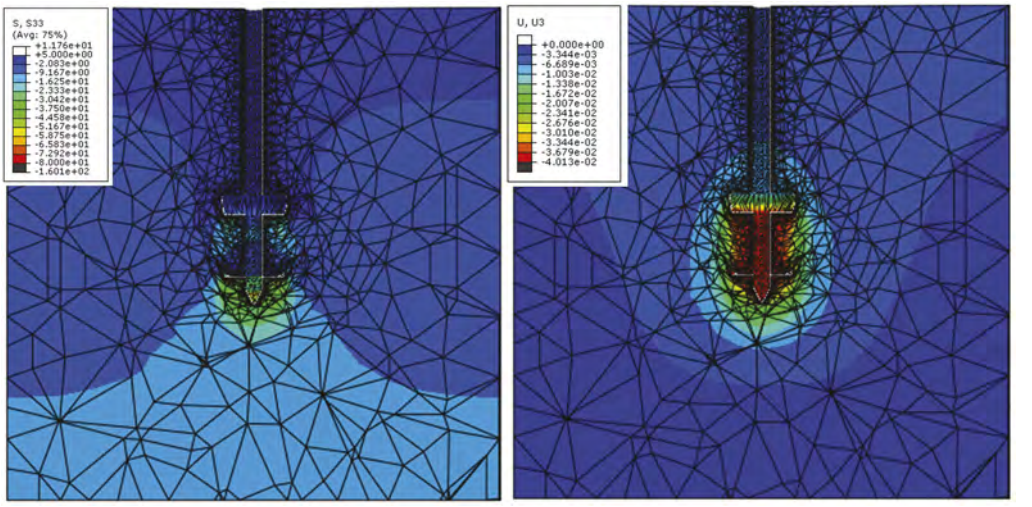

Figure 10. Experimental back-calculated FEM based stress – strain at the helix pile with double helice.

4 THEORITICAL ANALYSIS

Based on both measured and simulated behaviour of the helical piles in fibrous peat soil considered in this study, a method for predicting the axial compressive capacity of the pile is presented. The geometry of the failure area for calculation of the compressive axial capacity of the system can be derived from numerical model with back-calculation of experimental tests. The geometry of the failure area is very important to calculate bearing capacity of the pile. As seen in Figure 11, the failure area between the two lowermost helices is observed to closely follow the profile of the helices. The failure area at the lowermost helices seems to be larger than that in the upper two helices. It can be suggested that the bearing mechanism of the helix pile is contributed by all bearing helice plates, however the lowermost helices comprise more bearing capacity than the others. Above the top of uppermost helices, there is no significant

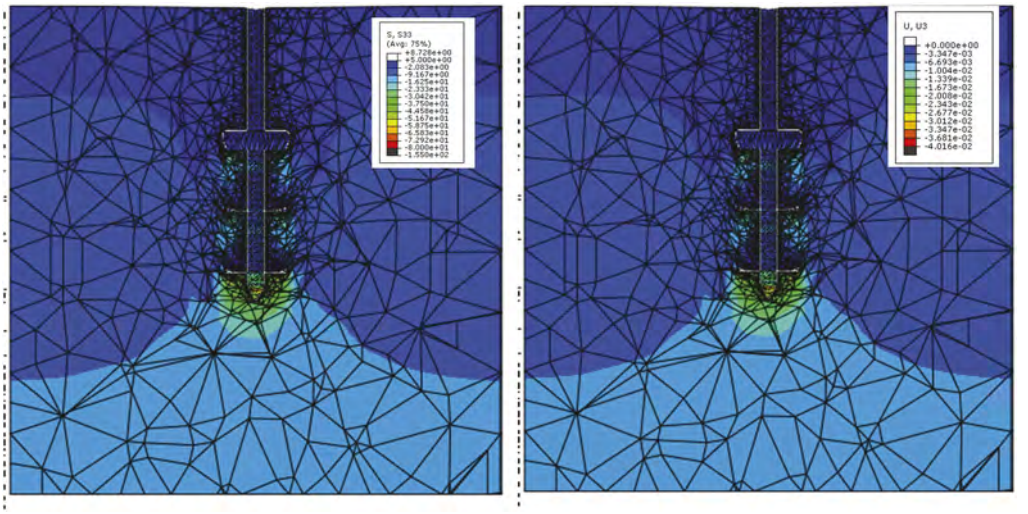

Figure 11. Experimental back-calculated FEM based stress – strain at the helix pile with triple helices.

deformation during the compressive loadings. Considering load transfer mechanism under compressive loading, bearing capacity of the helix pile can be described (Livneh & Naggar, 2008; Mohajerani et al., 2016) as follow: (i) shear resistance derived from a cylindrical failure surface along the interhelical soil profile or Q_{helix}, and (ii) bearing of the bottom helix on the soil below ($Q_{bearing}$) and (iii) friction resistance of the pile shaft along the pile rod to the surrounding soil (Q_{shaft}). As mathematical model, compressive bearing capacity of helix pile in a cohesionless soils was introduced by Mitsch and Clemence (1985) (Mohajerani et al., 2016) as seen in Eq. 1 – 5.

$$Q_c = Q_{helix} + Q_{bearing} + Q_{shaft} \tag{1}$$

$$Q_{helix} = 0.5\pi D_a \gamma' \left(H_b{}^2 - H_t{}^2\right) K_s tan\varphi \tag{2}$$

$$Q_{bearing} = \gamma' H A_H N_q \tag{3}$$

$$Q_{shaft} = 0.5 P_s H_{eff}{}^2 \gamma' K_s tan\varphi \tag{4}$$

$$Q_c = 0.5\pi D_a \gamma' \left(H_b{}^2 - H_t{}^2\right) K_s tan\varphi + \gamma' H A_H N_q{}^* + 0.5 P_s H_{eff}{}^2 \gamma' K_s tan\varphi. \tag{5}$$

where D_a = average helix diameter; H_a = depth to bottom helix; H_t = depth to top helix; K_s = coefficient of lateral earth pressure in compression loading; A_H = area of the bottom helix; P_s = perimeter of the screw pile shaft.

The values of the pile capacity calculated using Eq. 5 are summarized in Table 6 and are compared with numerical back-calculated experimental tests. The calculated capacities are found to be in good agreement with the measured, except for the $Q_{bearing}$ which is far larger than the computed values. The use of Nq in the Eq. 3 is based on internal friction angle (ϕ), as shown in formula of Meyerhof & Adams (1968). The N_q for ϕ' = 45° is 134.87, which is too conservative for fibrous peat soil. The characteristics of the soil is somewhat unique due to very low undrained shear strength, and very high effective internal friction angle. Since the experimental tests show a low $Q_{bearing}$, the N_q must be reduced by factoring 0.4 of ϕ, to accommodate the characteristics of the soil. As result of the N_q becomes 5.15, and the $Q_{bearing}$ values are very good agreement with the experimental tests, as shown in Table 7. It must be noted, that the increasing number of helices also affect the $Q_{bearing}$,

by increase of 5%. The additional 2 helices into the helix pile with a single helice would increase $Q_{bearing}$ by 10%. Besides the $Q_{bearing}$, the computed Q_{helix} also shows a difference, compared to the experimental tested Q_{helix}. Since the Q_{helix} is derived from shear failure zones along the soil between the helice plates, the lateral earth pressure during the compression loading (K_s) and internal friction angle (ϕ) play significant role. However, the effect of fibers in the peat soil must be taken into account. In this experimental study, it was found the fibers effect could increase the Q_{helix} by 30%. Therefore, the factor of 1.30 is used to satisfy this effect. By using the factors considered in the results of the study, the bearing capacity of the helix pile in the fibrous peat soil can be proposed as:

$$Q_c = 1.3.\ 0.5\pi D_a \gamma'^{\left(H_b{}^2 - H_t{}^2\right)K_s} tan\varphi\ + \left(\left(1 + (0.05(n-1))\gamma' H A_H N_q{}^*\right) + 0.5 P_s H_{eff}{}^2 \gamma' K_s tan\varphi \right. \tag{6}$$

$$N_q = \ e^{\pi \tan(0.4\varphi)} tan(45 + (0.4\varphi)/2)^2 \tag{7}$$

Table 5. Bearing capacity of the parts of the helix pile obtained from numerical model with back calculation analysis of experimental model.

Bearing Capacity	Experimental tested forces (kg)

Comparison Q predicted/experimented	100.6%	98.93%	99.16%

5 CONCLUSSIONS

A comprehensive investigation was conducted into the axial performance of the helix piles in the fibrous peat soil. The findings of the numerical model are in good agreement with the laboratory- scale load test results, yielding the following noteworthy conclusions:

- The load–displacement curves of the piles tested displayed typical trends, namely an initial linear segment, followed by a non-linear segment.
- Bearing capacity of the helix pile tested show different results, considerably influenced by helices number. The more helice attached to the pile, the higher bearing capacity would be. In this study, the bearing capacity of the helix piles for a displacement of 10% of diameter is 20 kg, 29 kg, and 34 kg for corresponding single, double, and triple helices attached to the piles.
- Numerical model with back-calculated parameter from the experimental tested, show that the bearing capacity from helices contributed major portion of the total bearing capacity of the helix pile, at around 60% - 70%, while the contribution of friction along the pile shaft is around 5% – 7%. The shear failure zone in between the helices contributes the rest, 23% - 35%.
- Due to the existence of large fiber in the fibrous peat soil, the bearing capacity of the helix pile must be corrected. In this way, the Nq values are determined based on 0.4 x ϕ, and shear failure resistance are factored by 1.30, and the effect of helices number on bearing is the increase of 5%. Therefore, new formula of predicted bearing capacity is proposed.

A limit equilibrium method for estimating pull-out resistance of flip-type ground anchors in sand grounds

S. Yoshida
Daisho Co., Ltd. Shiga, Japan

X. Xiong
Kanazawa University, Ishikawa, Japan

ABSTRACT: Flip-type ground anchors (hereinafter referred to as "flip anchors") are a kind of ground anchor that does not require grouting to obtain the pull-out resistance. The flip anchors are directly driven into the ground. When pull-out forces act on the anchors, their anchor heads rotate and open in the ground. Unlike ordinary pre-embedded plate anchors, there are few studies on flip anchors. To estimate the pull-out resistance of flip anchors in sand grounds, a calculation method based on 3D ground failure modes by limit equilibrium method is proposed. The calculated values of pull-out resistance agreed with the measured values from pull-out experiments using 5 sizes of actual flip anchors in full-scale model sand grounds.

1 INTRODUCTION

Flip anchors are kind of ground anchors that do not require grouting to obtain pull-out resistance. As shown in Figure 1, flip anchors are driven directly into the ground. After being driven to the designed depth, the anchor head rotates and opens when a tensile force acts on the anchor.

Although the flip anchors have convenient workability, estimating the pull-out resistance depending on ground conditions is more difficult compared to general pre-embedded plate anchors, due to their specific resistance mechanism. A number of previous research on pull-out capacity of the plate anchors were conducted so far, such as Baker & Kondner (1966) and Das & Seeley (1975); however, there are few studies on flip anchors (Niroumand & Kassim, 2013).

In this study, a calculation method of pull-out resistance of flip anchors in sandy ground is proposed. And the calculated values are compared with measured values of field experiments.

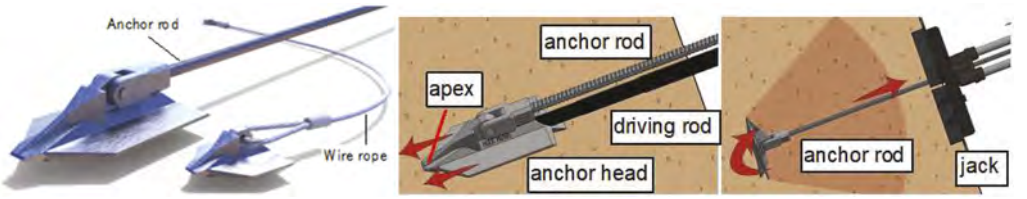

Figure 1. Flip anchors (percussion driven ground anchors).

DOI: 10.1201/9781003299127-150

2 FIELD PULL-OUT EXPERIMENTS OF FLIP ANCHORS EMBEDDED OR DRIVEN IN A SAND GROUND

2.1 *Experimental conditions*

A full-scale model sand ground was prepared in a test pit of 4.0 m in length, 4.0 m in width, and 2.5 m in height in a field. The internal friction angle ϕ' of the sand, which was measured by direct shear tests, was 42 degrees. The ground was compacted using a vibration tamper to have a relative density D_r of around 80% and a dry density ρ_d of around 1.745 t/m^3.

As shown in Figure 2, five sizes of actual flip anchors made of ductile iron were buried in the ground during ground preparation at designated embedment depth H under Opened or Closed head conditions. In driven installation condition, the anchors were driven into the ground from the ground surface. After that, each anchor was pulled out with a hydraulic jack, and pull-out force F and pull-out displacement w were measured.

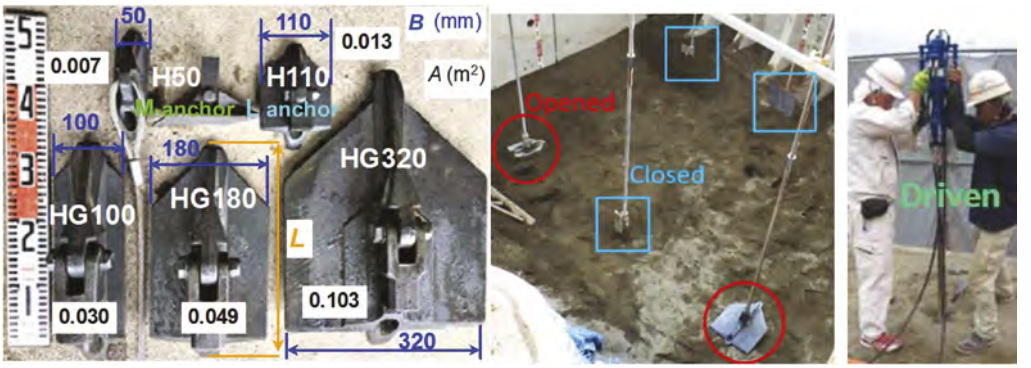

Figure 2. Actual flip anchors and installation conditions in the field pull-out experiment.

2.2 *Experimental results*

Maximum pull-out resistance F_{max} of flip anchors increased as the projected area of the anchors A increased, which will be shown in Section 3 in detail. F_{max} of Driven anchors were equivalent to F_{max} of Closed anchors. F_{max} of Driven anchors, which is corresponding to the practical installation condition of flip anchors, reached about 80% of F_{max} of horizontally embedded plate anchors (Opened anchors). From the results of the field experiment, pull-out displacement w required for the flip anchors to open sufficiently in the dense sand could be the same amount as the length of an anchor plate L or about 1.5 times L.

3 CALCULATION METHODS FOR MAXIMUM PULL-OUT RESISTANCE OF FLIP ANCHORS BY LEM

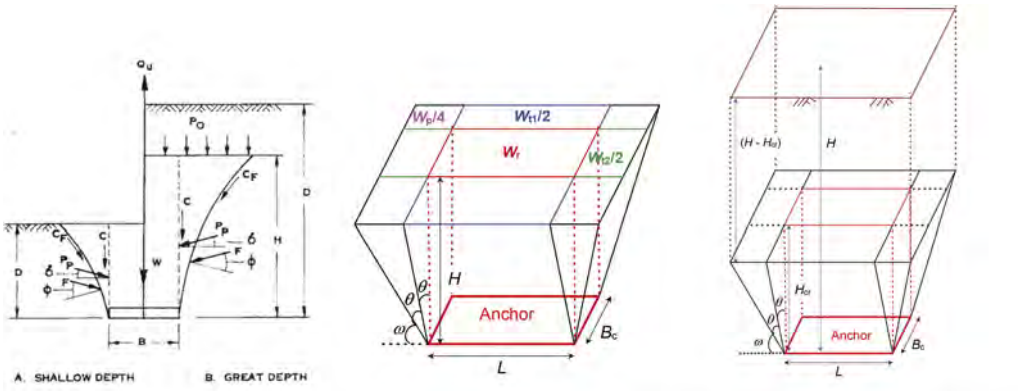
3.1 *Three-dimensional ground failure model*

Pull-out resistance of pre-embedded plate anchors have been estimated based on the ground failure models (Balla 1961, Majer 1955, Mors 1959). As shown in Figure 3(a), the ground failure models need to be divided into "Shallow anchor" model or "Deep anchor" model according to the embedment ratio H/L (H = embedment depth of anchor head, L = length of anchor plate). It is because the slip lines extend from edges of an anchor plate do not reach the ground surface when the anchor is installed deeper than the critical embedment ratio $(H/L)_{cr}$. If H/L is smaller than the $(H/L)_{cr}$, the failure pattern appears as a "Shallow

anchor" model, and if H/L is equal or greater than $(H/L)_{cr}$, the pattern appears as a "Deep anchor" model.

In this study, to estimate F_{max} of flip anchors, three-dimensional ground failure models are proposed. In Figures 3(b), (c) and 4, γ is the unit weight of the soil, W_r is the weight of the rectangular soil mass, W_{t1} is the weight of the triangular soil mass having a length of L, W_{t2} is the weight of the triangular soil mass having a length of B_c, W_p is the weight of the triangular soil mass at four corners, θ is the angle of slip line from the vertical direction, N is the normal force acting on a failure plane, S_{t1} is the shear force acting along failure plane having a length of L, S_{t2} is the shear force acting along failure plane having a length of B_c, S_p is the shear force acting along failure plane at four corners, σ_n is effective normal stress on a failure plane, $(1 + K_0)\ \sigma_v/2 + (1 - K_0)(\sigma_v/2)\cos 2\omega$, ω is the angle of slip line from the horizontal direction, σ_v is effective vertical earth pressure, K_0 is coefficient of lateral earth pressure at rest. For the calculation, because the flip anchor has a unique shape, the shape is approximated to a rectangle having the same A by adjusting the width of an anchor B as B_c.

F_{max} of flip anchors largely affected by θ. And $(H/L)_{cr}$ needs to be determined to choose the suitable model for calculation. In practice θ can be regarded as a function of the internal friction angle of soil ϕ. According to Meyerhof and Adams (1968), θ ranges from $1/3\phi'$ to $2/3\phi'$. As in Table 1, $(H/L)_{cr}$ also can be set in relation to ϕ'



(a) 2D model (Mayerhof & Adams, 1968) (b) 3D Shallow anchor model (c) 3D Deep anchor model

Figure 3. Two-dimensional (a) and Three-dimensional (b & c) ground failure models above a flip (plate) anchor under uplift load.

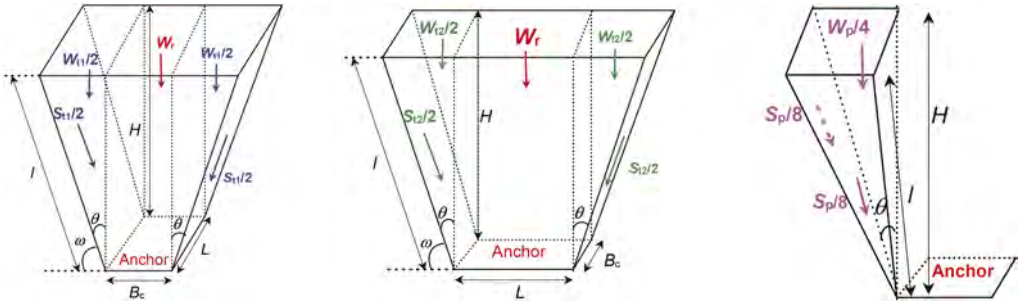


Figure 4. Three-dimensional ground failure models divided into several components for calculation.

Table 1. $(H/L)_{cr}$ depending on ϕ (Meyerhof & Adams, 1968).

ϕ	20°	25°	30°	35°	40°	45°	48°
$(H/L)_{cr}$	2.5	3	4	5	7	9	11

3.2 *Calculation of F_{max} of flip anchors from the 3D ground failure models*

Once θ and $(H/L)_{cr}$ are set, the shape of the 3D ground failure model (Figure 4) is fixed. Now F_{max} of flip anchors can be calculated based on the model. For "shallow anchor", F_{max} of shallow anchors $F_{max(s)}$ can be calculated by Equation 1.

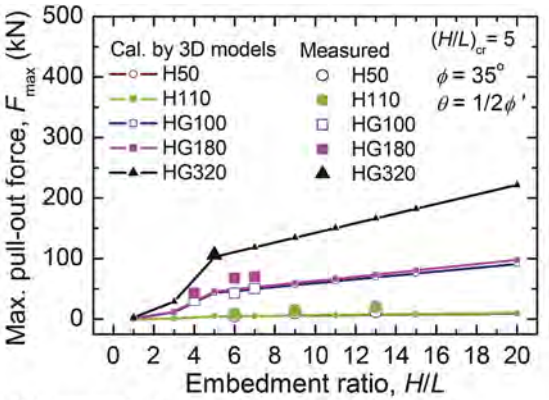
$$F_{max(s)} = \left(W_r + W_{t1} + W_{t2} + W_p\right) + \left(S_{t1}\cos\theta + S_{t2}\cos\theta + S_p\cos\theta\right) \quad (1)$$

For "deep anchor", F_{max} of deep anchor $F_{max(d)}$ can be estimated by Equation 2. $F_{max(d)}$ increases linearly in proportion to the increase of $(H - H_{cr})$.

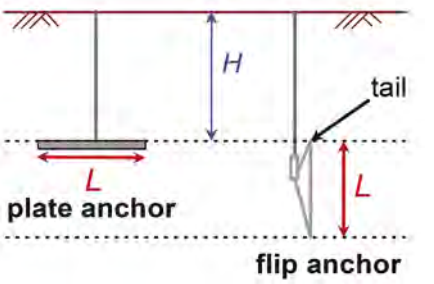
$$F_{max(d)} = F_{ax(s)} + \left[\{L + 2(H_{cr}\tan\theta)\}\{B + 2(H_{cr}\tan\theta)\}\left(H - H_{cr}\right)\right] \times \gamma \quad (2)$$

where H_{cr} is a critical H at $(H/L)_{cr}$.

Figure 5(a) shows calculated F_{max} based on the 3D models ($\theta = \phi'/2$) vs. measured F_{max} of actual flip anchors (Section 2). The calculated values agreed with measured values. The difference between calculated F_{max} of anchors having same L but different B, is more apparent when θ is larger than $\phi'/2$, such as $\theta = 2/3\phi'$. As shown in Figure 5(b), H for flip anchors should be the depth from the anchor tail to the ground surface after being driven. It is because flip anchors need w at least equivalent to the L to open sufficiently to meet the same installation condition as pre-embedded plate anchors.



(a) Measured F_{max} vs. calculated F_{max}



(b) Difference in H between plate anchor and flip anchor in calculation

Figure 5. F_{max} vs. H/L.

4 CONCLUSIONS

In this study, a calculation method of pull-out resistance of flip anchors in sandy ground was proposed. And the calculated values were compared with measured values of field experiments.

Main conclusions in the paper are as follows:

1) F_{max} of flip anchors need to be calculated separately based on "Shallow anchor" model or "Deep anchor" model according to H/L.

2) F_{max} of flip anchors at $(H/L) < (H/L)_{cr}$ increases exponentially; whereas at $(H/L)_{cr} \leq (H/L)$, F_{max} increases linearly.
3) $(H/L)_{cr}$ and θ can be determined according to the empirical values of Meyerhof and Adams (1968).
4) F_{max} of flip anchors can be calculated based on ground failure models similarly to ordinary embedded plate anchors if w until the anchor head sufficiently opens (= L or 1.5 times of L) is taken into consideration besides H.

ABSTRACT: This study uses remote sensing technology and data sharing. It tries to establish the analysis model of slope displacement data, evaluate slope debris production, and multi-sequence debris migration and transition analysis using synthetic aperture radar and other sensing technics. To build a database, this study collects multi-phase SAR images, LiDAR, and aerial photography DEM data. UAV aerial photography modeling is used to collect recent research data. This study uses the SAR intensity interpretation method to analyze the collapse range. Compare the difference with satellite collapse interpretation. Good interpretation results are obtained in both ALOS and Sentinel-1 satellite images. In the analysis of slope displacement information, use 7 DSM, DEM, and 26 satellite images to organize the recent changes in the study area. Combined with SBASInSAR, the slip rate analysis was performed to evaluate the extent of the potential landslide area. Finally, the mechanical model was used to infer the potential slip depth and volume, and the potential of the upstream collapse area was calculated. The sliding volume is about 11 million cubic meters. It is reasonable and feasible to verify the results of DSM analysis as an evaluation method for soil sand production.

1 INTRODUCTION

In Taiwan, the geological phenomenon of broken terrain, high mountains, high currents, and short streams is caused by the extrusion of plates. The geographical location is vulnerable to typhoons and heavy rain. The current trend of climate change has resulted in frequent and more serious sloping land disasters in recent years. Although the sloping land disaster has a wide range of influence and high frequency, it is the most difficult to predict its occurrence and impact. In recent years, due to the advancement of telemetry technology, the above difficulties have the opportunity to be solved. Because telemetry can perform continuous slope monitoring more quickly and at a lower cost, it can help to detect potential hazards earlier.

Slope disasters will bring a lot of soil and sand accumulation to the river. The migration of soil and sand also causes changes in the river course and causes subsequent secondary disasters. Assessing soil and sand volume for sloping land hazards is an important topic before subsequent analysis. Accurate numerical terrain can be obtained by using aerial photography or lidar measurement, but it requires manpower, is limited by weather, and the frequency of data acquisition is also limited. In this study, differential interferometric synthetic aperture radar (DInSAR) is used as a telemetry tool for volume analysis. Synthetic Aperture Radar (SAR) has the advantages of being free from weather interference, large area, and fixed period. SAR

DOI: 10.1201/9781003299127-151

can record information including intensity, polarization, phase, etc. DInSAR technology analyzes the image phase difference of the two repeated orbits and restores it to the surface deformation. Under good conditions, millimeter-level deformation accuracy can be obtained.

This research proposes a plan to establish DInSAR technology to establish an evaluation process for the sloping land disaster areas in Kaohsiung Baolai. Multi-time series collapse volume analysis is carried out, and the failure mechanism of slope sliding is discussed with the slip situation of each time series. Use the high-precision numerical terrain produced by LiDAR and UAV to verify the collapse volume and range. Confirm the accuracy of this assessment, to establish a complete and rapid assessment method of collapse volume.

2 METHODOLOGY

In this study, the NDSI analysis was used to establish a rapid collapse range detection technology, and the collapse range was judged by combining the existing satellites to complete the verification of the analysis results. The NDSI analysis process needs to perform multi-view averaging on the two images and then combine the images. Filtering to remove noise, followed by geographic coordinate projection and radiometric correction to normalize the image. The backscatter normalization index (NDSI) was calculated from the two processed images. Set the NDSI threshold and deduct the more severely affected areas of the terrain effect. To extract the results of mountain changes, it is necessary to set a slope threshold value to remove non-slope areas. The resulting image after completion merges adjacent images into one block.

The NDSI analysis is somewhat noisy due to the characteristics of aboveground vegetation. Filter out using area threshold. Depending on the satellite resolution used, noise filtering needs to be performed. For the ALOS1, ALOS2, and Sentinel satellites used in this study, different filtering thresholds need to be established. Initially, 4 x 4 pixels are used as the minimum filtering standard, and the optimal threshold value is gradually found. Past studies have shown that more than 73% of the collapse range interpreted by ALOS1 SAR can be successfully matched to the real collapse area (Wang et al. 2019).

The preliminarily calculated surface deformation is the surface change (Line of Sight, LOS) in the observation direction, and is projected into the vertical component, which is used as the slip reference. If the brushing depth or sliding phenomenon occurs in the sliding area, theoretically, the vertical change amount will change significantly. By accumulating the analysis results of multiple periods, the sliding volume in the collapsed area can be counted. Regress the

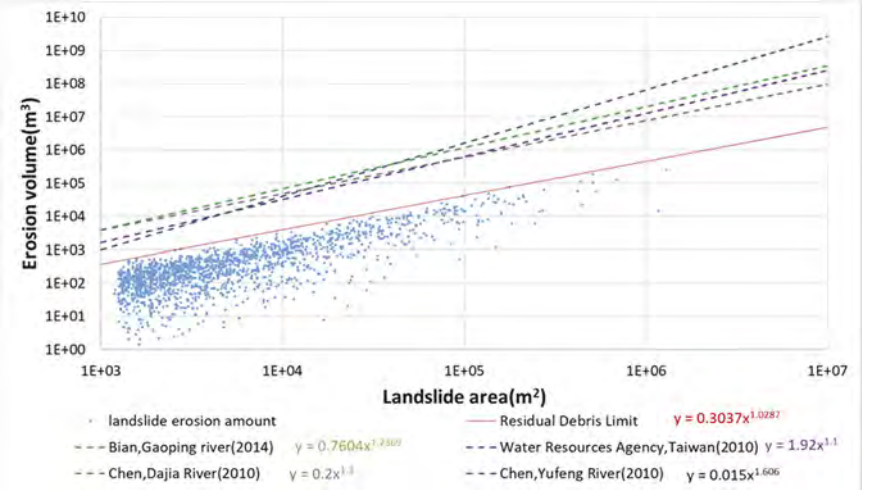

Figure 1. Analysis of residual debris outflow (Wang et al., 2019).

relationship between the collapse area and the volume. Previous studies have shown that the upper limit of the residual volume outflow from the collapse in the Anongxi area is $V= 0.3037A^{1.0287}$ (V is the lost volume and A is the landslide area) (Figure 1, Wang et al., 2019).

3 PROCEDURES AND RESULTS

(1) Analysis of NDSI landslide scope detection and interpretation scope
This study cites the NDSI suggested range of $-1<NDSI<\mu-1.75\sigma$ proposed by Wang et al. (2019). where μ represents the overall image mean and σ represents the image standard deviation. Using this value range, the areas with obvious changes in the NDSI image can be analyzed, and the NDSI values of each period can be separated in this way. After taking it out, the collapse position was compared with the SPOT5 satellite image, and the result is shown in Figure 2. The figure shows the panchromatic images of each SPOT5 satellite before and after each event, and the SPOT5 satellite false-color image of the year that overlaps the NDSI interpretation results. The NDSI interpretation results in each event are quite consistent with the landslide position of the optical image interpretation. The optical image was compared with the NDSI interpretation pixel set to 10m resolution, and the classification results of the statistical classification pixels were removed after the pixels affected by the terrain effect were removed. In the classification results from 2007/8/18 to 2007/10/3, the accuracy rate of pixel interpretation as landslide is 21%, the overall interpretation accuracy rate is 88.7%, and the kappa value is 15.2%. In the classification results from 2008/7/5 to 2008/8/20, the accuracy rate of pixel interpretation as landslide is 38.2%, the overall interpretation accuracy rate is 91.4%, and the kappa value is 21.9%. In

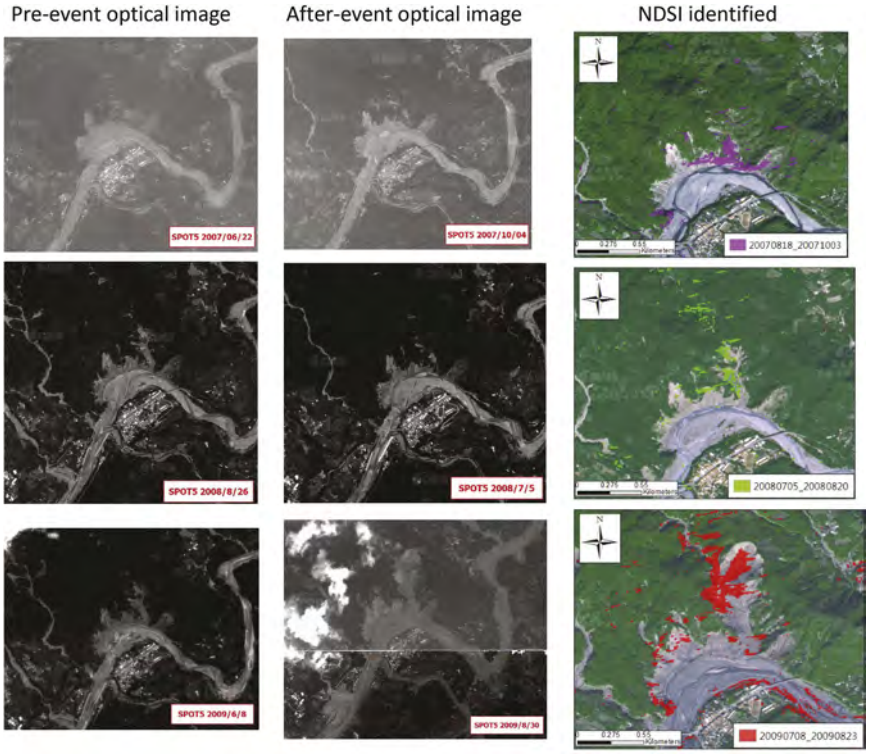

Figure 2. Comparison of NDSI and SPOT5 optical satellites.

the classification results from 2009/7/8 to 2009/8/23, the accuracy rate of pixel interpretation as landslide is 52.4%, the overall interpretation accuracy rate is 84.73%, and the kappa value is 33%. Although the NDSI technology of SAR is not as accurate in interpreting the collapse range as the optical image is. There is still enough reference for judging the area where the collapse occurred, and it is not limited by weather. Application during a disaster can provide another benchmark for quick judgment.

The results of the four main event analyses are overlaid on the orthophoto in 2017, and the results are shown in Figure 3. The brown area in the picture is the collapse catalog in 2007. Since August 2007, the collapsed area has further expanded and has been developing upward year by year. This trend is also clearly shown in the previous NDSI judgment results, ranging from purple (2007/8/18~2007/10/03), green (2008/7/5~2008/8/20), blue (2008/8/20~2009/7/8), red (2009/7/8~2009/8/23), representing 4 events respectively. The most impactful event was the Morakot cyclone in 2009. From the figure, it can be found that the collapse range determined by each event is quite consistent with the final collapse range after fitting.

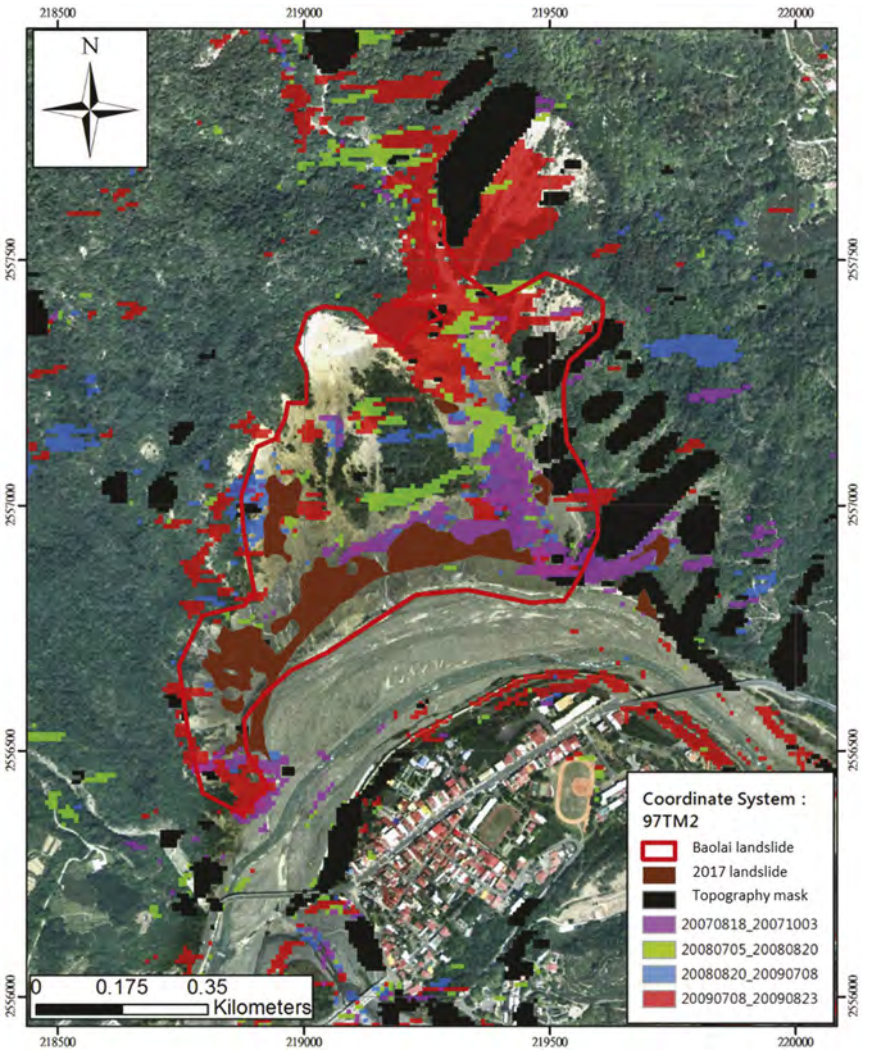

Figure 3. ALOS1 NDSI nesting results for each event from 2007 to 2009.

(2) Landslide slip volume analysis

The landslide area of Baolai is different due to the different product ranges of satellite data. Therefore, it is divided into two periods. In the early period of 2006/12/31~2011/02/26, ALOS1 SAR was used. Sentinel-1 SAR was used from 2016/12/22 to 2020/06/28. After analyzing the displacement of the collapsed land in each period with SBASInSAR technology, the total change is counted.

Changes from satellite imagery are shown in Figure 4. The collapsed site of Baolai began to develop in 2005, expanded significantly in 2006, and further developed in 2009 due to the impact of the Morakot typhoon. In 2017, it collapsed and extended upwards. Therefore, it is speculated that the potential collapse range will continue to the ridgeline. The potential range of the main collapse area with the red dotted line circled in the 2011 LiDAR scan image. In this study, the collapse volume statistics were carried out in this potential range.

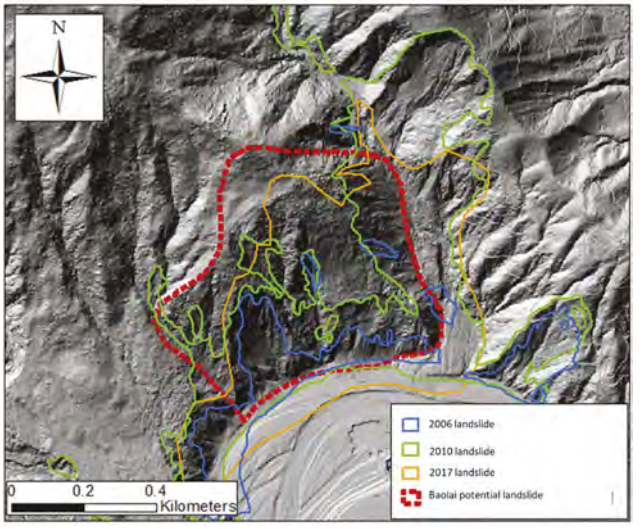

Figure 4. The evolution of the landslide and statistical area.

Twenty ALOS-1 SAR images and 103 sentinel-1 SAR images were collected in this study. After the SBAS point cloud is generated through the SBASInSAR process. The average change of the point cloud in each period in the statistical range is multiplied by the area. Statistics of the collapse volume in each period.

The point clouds of the two periods are calculated after the amount of change in each period. Figure 5 shows the cumulative change in the slope potential area between time series. Figure 5 shows the cumulative changes in the ALOS-1 analysis from 2006 to 2011. From 2006/12/31 to 2007/08/18, the volume change showed an upward trend. It is speculated that the reason may be the accumulation caused by some of the potential sliding ranges located on the edge of the channel. At the same time, after the slope instability before 2006, the phenomenon of sagging and other phenomena began to appear near the sloping site. After that, the slope began to slide continuously until the statistical sliding amount reached -7803 cubic meters on February 26, 2011. The statistical period includes three rainfall events marked by red arrows, including the 2009 Morakot cyclone. There should be a large amount of soil and sand flowing out, but because the sliding body has exceeded the L-band detection range. After the phase saturation is reached, the phase cannot be recovered correctly, and it will become a source of errors in the volume statistics in the analysis.

Figure 5. Cumulative slope deformation volume of each time series analyzed by ALOS-1 SBASInSAR.

During the period from 2016/12/22 to 2020/06/28, 103 sentinel-1SAR images were used to analyze the cumulative change of the slope. The Sentinel-1 satellite has a revisit period of 6 to 12 days, and a shorter time baseline for the analysis can reduce missing correlations. But it uses the shorter wavelength of the C-band, so it is easier to achieve phase saturation.

At the beginning of 2016, there was a clear sliding trend in the collapse of Baolai. Because it is located on the attacked bank of the river, the foot of the slope continues to be washed away, and the scope of the collapse continues to expand to the upper layer. Two rainfall events in 2017 and 2018 are included in Figure 6. From the statistical results, when a large rainfall event (red arrow) triggers the collapse, the speed of the slope slide over a while also increases. stabilized after a while. Statistics up to 2020/6/28, the cumulative slippage is -44635 cubic meters.

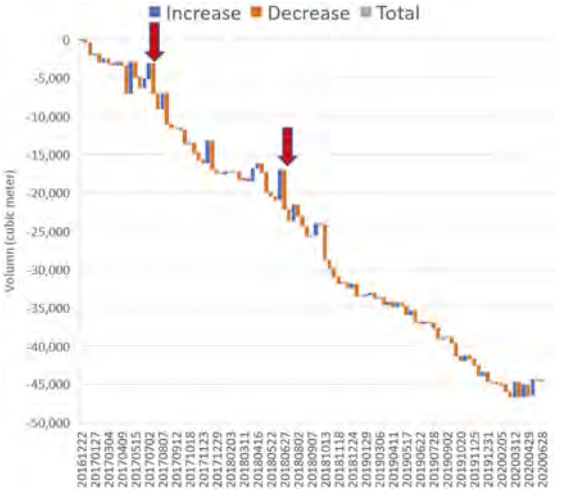

Figure 6. Cumulative slope deformation volume of each time series in Sentinel-1 SBASInSAR analysis.

(3) Landslide Potential Scope Assessment

Combined with the interpretation of lidar images, the results of radar satellite collapse interpretation, and the surface change rate analyzed by SBASInSAR, etc. The collapsed cliff blocks of the Baolai Collapsing Land can be divided into 6 blocks (as shown in Figure 7), of which block 1 has been destabilized in 2005. The destruction of Block 1 in 2008 was further expanded. Block 2 starts to run off at the foot of the slope. The extent of

its damage can be seen in NDSI's analysis. In the analysis of SBASInSAR, it can also be observed that block 4 begins to accumulate deformation. Then in blocks 2, 3, and 4, the destruction begins after the Morakot storm. The NDSI analysis is consistent with the extent of the damage. Blocks 2, 3, and 4 began to destroy and expand in 2015 and developed into the existing collapse area in 2018.

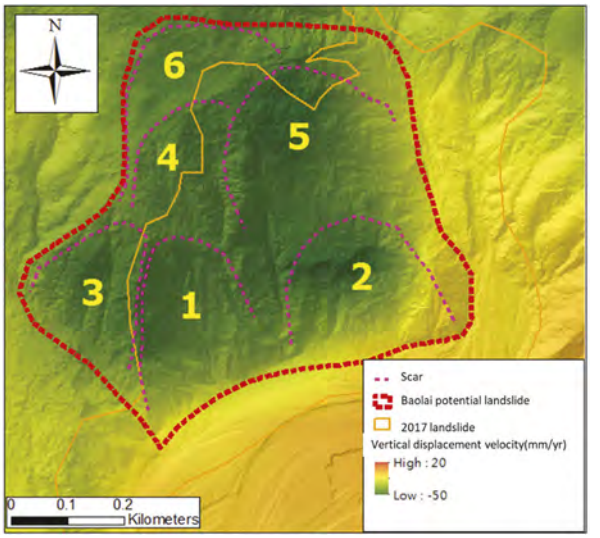

Figure 7. The sliding block inferred by the collapse of Baolai.

4 CONCLUSIONS

This study completed the applicability of DInSAR analysis technology and screened the available analysis interval. Subsequent DInSAR analysis will be performed based on the applicable results, as well as the sliding range and sliding volume. The analysis results of the collapse range were completed by NDSI technology and compared with the optical image interpretation range of each event. The feasibility of this technique for the detection of collapse range is confirmed. Then, according to the analysis results of different bands, suggested analysis parameters are proposed, and a complete collapse range detection technology is established.

In the second stage, the DInSAR technology combined with the numerical analysis mode is used to complete the volume analysis of the previous collapses. Based on the ALOS-1 and Sentinel-1 satellite data, the slope slip statistics in the two periods of 2006-2011 and 2016-2020 were carried out respectively. The potential slips of -7803 and -44635 cubic meters were calculated respectively.

In the third stage, this study combines DInSAR and NDSI analysis techniques to discuss the correlation between collapse and surface deformation between time series.

Groundwater table of slopes with horizontal drains and effect of pipe inclination

S.O.A.D.Mihira Lakruwan, Akiyoshi Kamura & Motoki Kazama
Tohoku University, Sendai, Miyagi, Japan

ABSTRACT: The complex three-dimensional (3D) geometry of the groundwater table (GWT) profile of a slope with horizontal drains (HDs) demands complex 3D numerical simulations to capture the complete effect of HDs on slope stability enhancement. Alternatively, a novel semi-empirical method is proposed in this study to obtain the steady state GWT profile of a slope with HDs subjected to constant recharge from the top. As HD pipes are generally installed with an inclination to facilitate drain out under gravity, the proposed method was subsequently extended for inclined HDs and verified by a numerical case study. Although a high pipe inclination is favorable for rapid discharge of water, that will reduce the slope stability enhancement. The results of this study showed that the inclination of the HDs should be kept minimum, especially in the presence of slip surfaces with mild inclinations.

1 INTRODUCTION

1.1 *HDs for slope stabilization*

The rise of the GWT can be identified as one of the major causes of slope instabilities in the world. Rainwater infiltration is the main source of the GWT rise. The rise of the GWT increases the porewater pressure (PWP) of a slope reducing the effective stress and finally resulting in a reduction of shear strength and slope stability. Therefore, lowering the GWT is the primary slope stability enhancement method for such slope instabilities. The HDs, which are perforated pipes wrapped with geotextile envelopes, are used as an efficient method for GWT lowering.

1.2 *GWT of a slope with HDs*

The steady state GWT between the HDs takes a semi-elliptical shape (Figure 1b). As the HDs were initially being used in the agricultural lands, the deterministic methods of obtaining GWT of HDs are developed focused on agricultural drains. Those methods assume long, parallel, and horizontally installed HD pipes, which results in uniform distribution of the GWT along the HD pipes. Therefore, a two-dimensional (2D) semi-elliptical distribution of GWT between HD pipes was considered. Among several such methods (Hooghoudt 1940, Ernst 1954, Kirkham 1958), Hooghoudt (1940) method is widely used.

However, unlike in agricultural lands, HDs in slope stabilizations are short in length and installed with an inclination to facilitate water discharge under gravity. Therefore, GWT between HDs varies along the pipe and takes complex 3D geometry. Although some have suggested using the Hooghoudt (1940) method (Greg et al 2013), its applicability for HDs in slopes is limited. Moreover, the GWT behind the HD field, which is critically important in slopes, is not considered in the above methods. Therefore, Crenshaw & Santi (2004) proposed an empirical method to obtain the GWT of short HDs in slopes (Cook et al 2012). However, this method also has several limitations such as the requirement of GWT height at 20ft (6.1 m) behind the HD field and does not sufficiently describe the GWT behind the HDs. Also, the inclination of HDs is not considered.

DOI: 10.1201/9781003299127-152

1.3 *Objective and methodology*

To address the mentioned knowledge gap, the objectives of this study were established as follows;

- To develop a semi-empirical method to determine the steady state GWT profile of a slope, which is subjected to contact recharge from the top, with short and inclined HDs.
- To evaluate the effect of the pipe inclination based on the porewater force (PWF) on the slip surface.

A series of finite element (FE) flow analyses was performed to develop the novel semi-empirical method. Then the PWF acting on a predefined slip surface was calculated by linear integration between the GWT and slip surface profiles and subsequently evaluated the HD inclination effect.

2 NOVEL METHOD TO OBTAIN GWT OF A SLOPE WITH HDS

2.1 *Semi-empirical method to obtain GWT of HDs*

A typical steady-state GWT profile at the mid-section between parallel HDs obtained from a series of PLAXIS 3D (CONNECT Edition V20) (PLAXIS 2020) FE flow analysis is presented in Figure 1a. The GWT was arbitrarily divided into three zones. Then, empirical relationships were established to the GWT heights at the boundaries between Zone 1 & 2 (h_c) and Zone 2 & 3 (h_e) (Figure 1a). Linear distributions were established for the GWT in Zone 1 and 2. The GWT of Zone 3 was established based on Dracy's law and Dupuit-Forchheimer assumption. This profile is the maximum GWT at the mid-section between the HDs. Finally, an average GWT profile (Figure 1b) was established for the semi-elliptical distribution between HDs as,

$$Z_w = \begin{cases} \frac{\pi}{4}\frac{h_c}{L-S}X + D; & if\ X \le L - S\ (Zone\ 1) \\ \frac{\pi}{4}\frac{h_e - h_c}{S}(X - L + S) + h_c + D; & if\ L - S \le X \le L\ (Zone\ 2) \\ H_e^2 + \left[\frac{H_i^2 - H_e^2}{(B-L)} + n(B-L)\right](X-L) - n(X-L)^2; & if\ L \le X\ (Zone\ 3) \end{cases} \quad (1)$$

where Z_w= average GWT; $H_c = h_c + D$; $H_e = h_e + D$; and other parameters as in Figure 1a.

Figure 2 Presents the corrections introduced for the inclined HDs. First, the value of the h_i at the head at the back of the slope is to be corrected with reference to the elevations of the HD at the boundary of Zone 1 and 2, and HDs end. Then the corrected GWT heights are to be obtained from the empirical relationships presented in Figure 1a and pipe elevation is added (Figure 2).

2.2 *Verification of the proposed method*

A numerical case study was performed on the slope section shown in Figure 3 to validate the proposed method. The GWTs at the mid-section between the HDs, with different lengths and inclinations, obtained from the FE flow analysis and the proposed method are compared in Figure 3. The compatibility of the GWTs verifies the accuracy of the proposed method to obtain GWT.

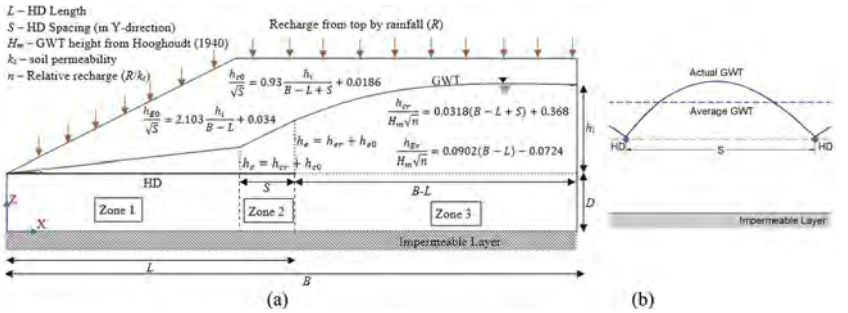

Figure 1. GWT of a slope with HDs; (a) along the HDs; and (b) between HDs (cross-section).

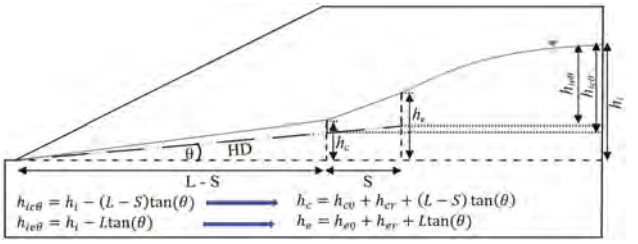

Figure 2. Correction for inclined HDs.

3 EFFECT OF DRAIN INCLINATION ON THE PWF ON SLIP SURFACE

3.1 *Obtaining PWF on predefined slip surface*

As suggested in several studies (Conte & Troncone 2012, Conte & Troncone 2018, and Tsao et al. 2005), the effectiveness of HDs on slope stability enhancement can be evaluated using the PWF acting on a slip surface. Therefore, the PWF acting on a predefined slip surface was obtained by linear integration between the GWT profile (Zw) and slip surface profile (Zs) (Figure 4) as,

$$PWF = \int_0^{X_0} (Z_w - Z_s)(\rho_w g)(sec\alpha)dX \tag{2}$$

3.2 *Effect of HD inclination*

The design parameters of HDs (length, spacing, elevation, and inclination) can be evaluated by the PWF acting on the slip surface. However, this study is limited to the evaluation of HD inclination. Figure 5a presents the variation of PWF acting on the slip surface with inclinations (α) of 10°, 15°, 20°, 25°, 30°, and 35° for HD inclinations (θ) from 0 to 10° (for c = 6m, d = 4m, h_i = 6m, and n = 0.1 (refer to Figures 1 and 4 for notations of the parameters)).

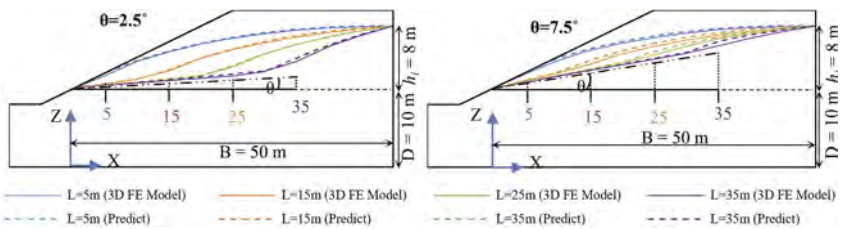

Figure 3. Comparison of GWTs at mid-section between HDs from the proposed method and 3D FE model.

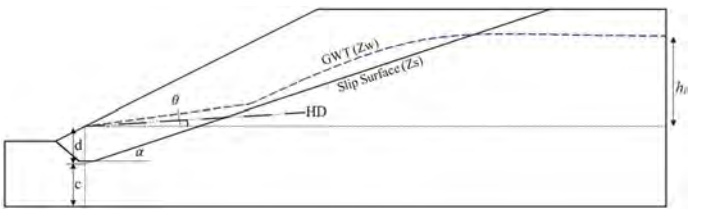

Figure 4. Predefined slip surface and GWT.

The PWF generally increases with the increment of the θ. The PWF increment is significant in small α values but not in higher α values. The variation of the PWF value with $\alpha - \theta$ illustrated in

Figure 5b confirms that. Therefore, it is important to use small inclinations in HDs to ensure low PWF on a slip surface, particularly in small α values. However, the HD pipe should be inclined enough to ensure water drain out under gravity. Therefore, a tradeoff exists in the selection of the drain inclination. The inclination of the HDs can be limited to 5° to 10° as suggested in previous studies (Cook et al. 2012) and should not use higher inclinations, particularly in mild slip surface angles (α) unless there is a special requirement.

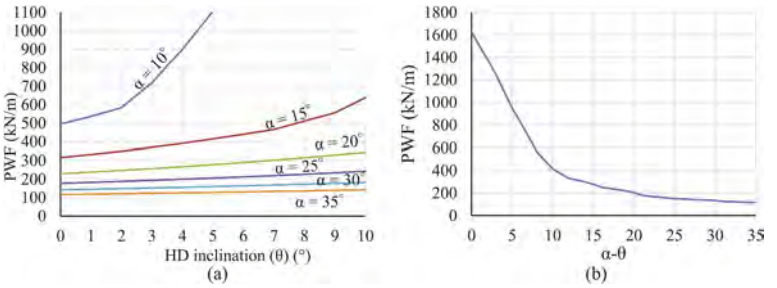

Figure 5. (a) Increment of PWF with θ; (b) Reduction of PWF with α-θ.

4 CONCLUSIONS

A novel semi empirical method was introduced in this study to obtain a steady-state average GWT profile for a slope with HDs. The proposed method was verified by a numerical case study. Subsequently, it was extended to obtain the PWF acting on a predefined slip surface, and an evaluation of design parameters can be done based on that. This study is focused on evaluation of HD inclination and the results showed that the HDs inclination should be minimum to ensure low PWF on a slip surface, particularly in small α values.

Numerical analysis on failure mechanism of unsaturated slope due to rain

T. Yoshikawa & T. Noda
Nagoya University, Nagoya, Japan

ABSTRACT: Slope failures have occurred frequently due to heavy rains. Causes of the failures are considered as reduction of strength due to rise in pore pressure and increase in the degree of saturation, and increase of self-weight due to water absorption. However, the detailed failure mechanism has not been elucidated. To elucidate the mechanism, this study conducted deformation and failure simulations of unsaturated slopes in rainfall model tests using a soil-water-air coupled elastoplastic finite deformation analysis code considering inertia force. As a result, we succeed in reproducing the deformation-to-failure behavior of the model slope due to rainfall infiltration. The soil element on the slip surface exhibits "softening behavior with plastic volume expansion" above the critical state line in $p' - q$ skeleton stress space. In addition, we reproduce deformation and failure patterns according to rainfall intensity.

1 INTRODUCTION

In recent years, rainfall-induced slope failures have occurred frequently, such as Heavy Rain of July 2018 and Typhoon Hagibis 2019 in Japan. Causes of the failures are considered as reduction of strength due to rise in pore pressure and increase in the degree of saturation, and increase of self-weight due to water absorption. However, the detailed failure mechanism has not been fully elucidated. Normally, a combination of seepage and stability analysis has been used to predict slope failure due to rainfall. However, the stability analysis, which determines failure based on whether the safety factor exceeds 1 or not using the stress state obtained from seepage analysis, is not sufficient to elucidate the failure mechanism. It is necessary to analyze the behavior from deformation to failure caused by seepage. In addition, since failure is accompanied by accelerated motion, inertial forces must be taken into account even if the external force is rainfall. Furthermore, to numerically simulate large deformation behavior from deformation to failure, it is essential to use an analytical method based on finite deformation theory that takes into account geometric nonlinearity.

Based on the above insight, this study conducted deformation and failure simulations of unsaturated slopes in rainfall model tests (Chueasamat et al. 2018) using a soil-water-air coupled elastoplastic finite deformation analysis code considering inertia force (Noda & Yoshikawa 2015, Yoshikawa & Noda 2020, Yoshikawa & Noda 2022). The results showed that, as in the model tests, the unsaturated slope deformed and failed due to rainfall infiltration, and that the slip failure was caused by the soil elements which exhibited "softening behavior with plastic volume expansion" above the critical state line in $p' - q$ skeleton stress space.

2 OVERVIEW OF REFERENCE EXPERIMENTS AND ANALYSIS CONDITIONS

We referred to rainfall model tests of Chueasamat et al. (2018) because soil water characteristics of the soil materials are clearly shown. Figure 1a shows an overview of the experimental

DOI: 10.1201/9781003299127-153

model. The surface layer composed of Kasumigaura sand was constructed on the foundation of DL clay in a 1G gravity field, and water was sprayed from above. The experiments were conducted under three conditions of 0, 25, and 50 % relative density of Kasumigaura sand (the degree of saturation: about 29-34%) and three conditions of 25, 50, and 100 mm/h rainfall intensity, for a total of nine cases. The degree of compaction of the DL clay foundation is 100 % (the degree of saturation: about 61%). Water pressure was measured at points P1-18 in Figure 1. This paper describes the analytical results of three cases with different rainfall intensities. The experimental results are presented together with the analytical results in the next section.

Figure 1b shows the analytical cross section. The analysis was performed under the 2-D plane strain condition and the dimensions of the analytical cross section were set the same as in the experiment. The analytical cross section was created by adding finite elements of soil layers to reproduce the stress history in the experiment. The left and bottom edges were set to undrained and unexhausted conditions, the right edge to seepage face boundary and unexhausted conditions, and the ground surface to seepage face boundary (during construction)/rainfall boundary (during watering) and exhausted conditions. Horizontal and vertical displacement were fixed at the lower end, and horizontal displacement was fixed at the left and right ends.

The constitutive model of the soil skeleton is the elastoplastic constitutive equation SYS Cam-clay model (Asaoka et al. 2002) considering the unsaturated effect (Yoshikawa & Noda 2020). The skeleton stress equation (Jommi 2000) was used for the stress equation. The material constants of DL clay were given from the previous study by the authors (Yoshikawa & Noda 2020) and the same initial void ratio was given as in the experiment. The mechanical test results for Kasumigaura sand were not obtained, so the same material constants as for DL clay were used here, and a loose condition (the degree of compaction of about 80%) was set as the initial value. The van Genuchten (1980) and Mualem (1976) models were used as the unsaturated seepage characteristic model. The material constants were set to reproduce the soil water retention test results of the water absorption process of each material (Chueasamat et al. 2018), and the same initial degrees of saturation were given as in the experiment.

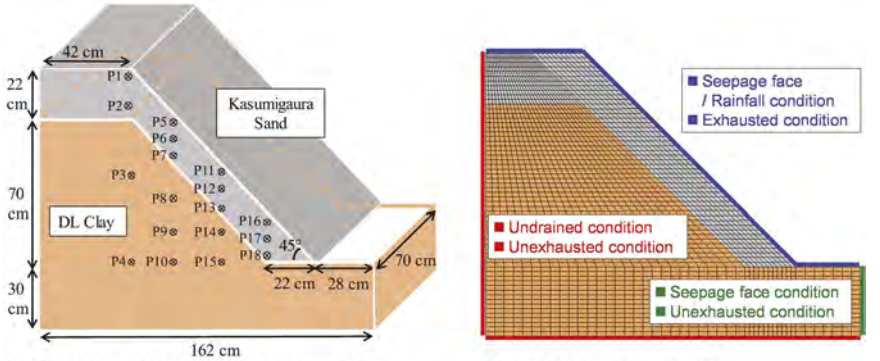

Figure 1. Experimental and analytical conditions.

3 ANALYSIS RESULTS

Figure 2a shows the experimental and analytical results of pore water pressure distribution for a rainfall intensity of 100 mm/h. Only the slope portion is shown enlarged. The comparison between the two shows that the analysis was able to reproduce the infiltration process of rainfall from the ground surface. Figure 2b shows the slip failure behavior at a rainfall intensity of 100 mm/h. The analysis reproduced the slip failure behavior over the entire slope from toe to top of the slope.

Figure 3 shows the mechanical behavior of the soil element at toe of the slope located on the slip line shown in Figure 2b. In Figure 3, ● indicates the state immediately before rainfall, and time passes in the order of ●→▲→■→○. First, from ● to ▲, the increase in the degree of saturation and the rise in pore pressure due to rainfall infiltration caused plastic deformation and it caused the loss of overconsolidation and structure (increase in R and R^*) described by SYS Cam-clay model (Asaoka et al. 2002). Next, from ▲ to ■, overconsolidation and structure were lost further, and softening behavior with plastic volume compression due to the loss of structure occurred. Finally, from ■ to ○, softening with plastic volume expansion above the critical state line q=Mp', which is a characteristic of Cam-clay model, occurred, leading to a large deformation.

Figure 4 shows the difference in slip failure behavior and pore pressure distribution for rainfall intensities of 50 mm/h and 25 mm/h. Together with Figure 2 for a rainfall intensity of 100 mm/h, it can be seen that the analysis reproduced the slip line up to the mid-slope when the rainfall intensity was 25 mm/h, while the analysis reproduced the slip line over the entire slope when the rainfall intensity was 50 mm/h and 100 mm/h. This is because the higher the rainfall intensity, the higher the pore water pressure to the top of the slope.

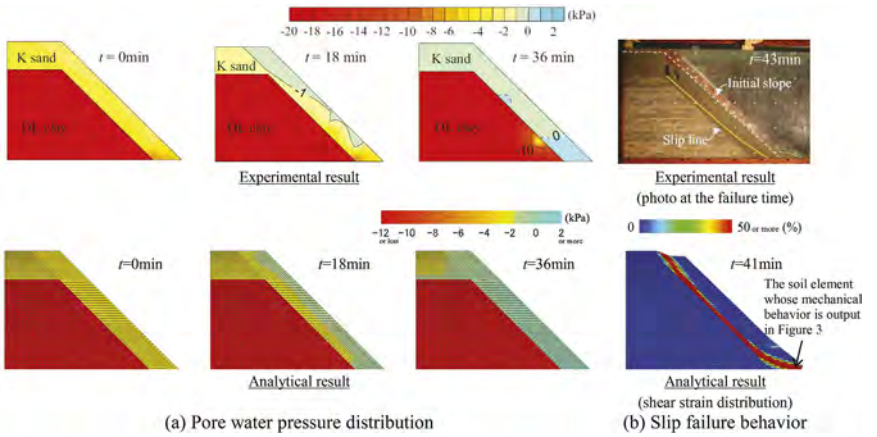

Figure 2. Experimental and analytical results for a rainfall intensity of 100 mm/h.

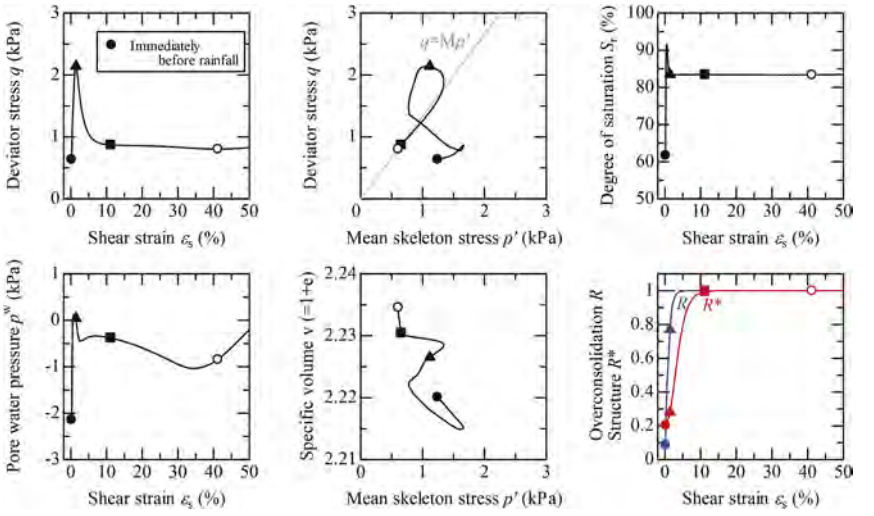

Figure 3. Mechanical behavior of the soil element located on the slip line shown in Figure 2b.

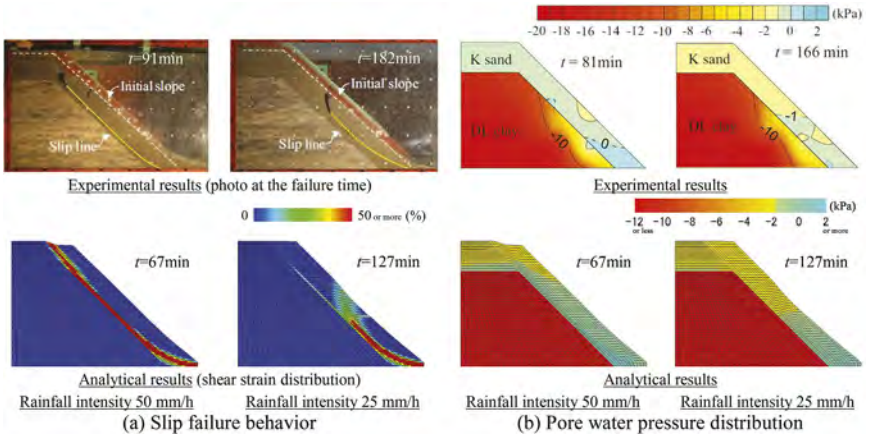

Figure 4. Experimental and analytical results for rainfall intensities of 25 and 50 mm/h.

4 CONCLUSIONS

We have succeeded in reproducing the behavior of unsaturated slope from deformation to failure in rainfall model tests (Chueasamat et al. 2018) using the soil-water-air coupled elastoplastic finite deformation analysis code considering inertia force (Noda & Yoshikawa 2015, Yoshikawa & Noda 2020, Yoshikawa & Noda 2022). It has been found that the soil element on the slip surface exhibits "softening behavior with plastic volume expansion" above the critical state line q=Mp', which leads to slip failure of the slope. In addition, differences in deformation and failure behavior have been reproduced for three different rainfall intensities of 25, 50, and 100 mm/h. Furthermore, it has been shown that large accelerations of 1 G or more occurs at the time of slip failure, though the results were omitted here because of space limitation.

In the future, we will reexamine the material constants and initial values of the failure layer. In addition, we will apply this analysis code to real problems, such as elucidating the failure mechanism of Atami Embankment that occurred in July 2021.

Centrifuge modeling of sand-clay slopes subject to rainfall

Fan Luo, Sujia Liu & Ga Zhang
State Key Laboratory of Hydroscience and Engineering, Tsinghua University, China

ABSTRACT: Rainfall is one of the main causes to slope failure. In this study, centrifuge model tests are conducted to observe the response of the sand-clay layered slopes subject to rainfall. The rainfall induces significant deformation and failure of the sand-clay layered slope that is affected by the rainfall infiltration characteristics of the dual structure. The slope failure is progressive and caused by a few local failure cycles one by one as the rainfall increases. The wetting front moves from the slope surface to the interior as the rainfall increases and the move rate is significant greater in the sand than in the clay. The water accumulates on the top surface of the clay layer and becomes the main sources of the water infiltration of the clay layer. The sand layer has an obvious effect on the deformation of neighboring clay layer of the slope during the rainfall.

1 INTRODUCTION

Rainfall is one of the main causes to slope failure. More than 90% of the landslides are related to rainfall. Previous studies on the behaviors of slopes subject to rainfall put their focus on the homogeneous slopes (Lim et al., 1996, Adrin et al.2007, Zhang et al. 2011, Ma et al.2021). It should be concerned that practical slopes often consist of various soil layers such as sand layer and clay layer. The sand-clay layered slope may exhibit different seepage, deformation and failure behaviors from the homogeneous slope. However, few studies have been conducted on the sand-clay layered slopes under rainfall condition yet.

Centrifuge model tests have been widely employed to investigate the behavior of soil slopes under various conditions (Zhang et al. 2011, Luo et al. 2018, Liu et al. 2020). In this study, centrifuge model tests are conducted to observe the response of the sand-clay layered slopes subject to rainfall. The fundamental rules on the infiltration and deformation behavior of the sand-clay layered slopes are investigated on the basis of the full field measurement of slope displacement under rainfall conditions. The progressive slope failure due to rainfall is analyzed on the basis of test observations and displacement measurement results.

2 TEST

2.1 *Equipment*

The centrifuge model tests were conducted with the geotechnical centrifuge of Tsinghua University, of which the centrifugal acceleration can reach 250 g. The model box, which is 600 mm long, 200 mm wide and 500 mm high, is made of aluminum alloy to install the slope model and rainfall simulation system. It is equipped with a 40mm-thick transparent plexiglass on one long side. A camera is fixed in front of the glass to observe and record the deformation and failure of the slope during the centrifuge model test.

The rainfall simulation system consists of the water tank and a few nozzles. During the test, the water is transported through the pipes from the water tank to the nozzles. Then under the air pressure, the nozzles release the water into the model in forms of spray, thus simulating the natural rainfall. The rainfall intensity can be adjusted by changing the air pressure.

DOI: 10.1201/9781003299127-154

2.2 *Model*

The slope model, 24-cm-high and 15-cm-wide, is 0.75:1 in gradient and consists of two layers with a horizontal boundary in the middle (Figure 1). Both the sand layer and clay layer are 12 cm in height. The top layer is made of the Fujian standard sand with a dry density of 1.55 g/cm^3. The bottom one is made of a silty clay with a dry density of 1.55 g/cm^3 and a moisture content of 18%. Besides, a 50-mm-deep foundation is made with the same silty clay at the bottom to reduce the effect of the model box on the soil slope. Silicon oil is smeared on the both contact sides between the model box and slope model to reduce the friction.

An orthogonal coordinate system is set up with the toe of the slope as the origin, and the positive directions of x-axis and y-axis are defined as rightward and upward respectively (Figure 1(b)).

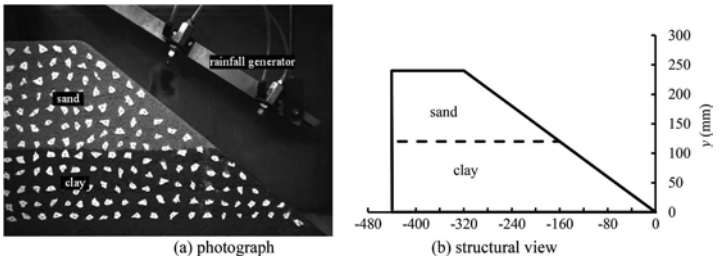

Figure 1. Schematic view of the slope model.

2.3 *Procedure*

At the beginning of the test, the slope model was installed in the centrifuge and accelerated to 50 g gradually, then maintained at a level of 50 g. After the slope settlement stabilized, the rainfall began at an intensity of 3 mm/min using the rainfall simulation system throughout the test. When the deformation and failure of the soil slope could be obviously observed, the rainfall stopped at a final magnitude of 20 mm.

2.4 *Measurement*

During the rainfall, the deformation and failure of the slope were recorded by the camera constantly. The acquired images can be sued to determine the displacement at an arbitrary point of the slope by using correlation-based analysis algorithm (Zhang et al. 2009).

According to the similarity law of the centrifuge model test, the displacement and rainfall of the prototype is 50 times that of the model. The measurement results are presented in the model dimension in this paper.

3 SLOPE FAILURE

The rainfall caused the slope failure (Figure 2 (a)). Figure 2 (b) shows the slip surface of the slope according to the observations on the images of the slope at failure. The slip surface is a continuous curve and extends from the sand layer to the clay layer. The slope is divided into base body and sliding body based on the slip surface.

The slip surface was observed to be caused by the rainfall through a few local failure cycles. Figure 3 exhibits the first local failure cycle that consists of three stages. To analyze the failure process of the cycle, four points were selected at different failure bodies to measure their histories of the vertical displacements (Figure 4). It can be seen from Figure 4 that the vertical displacements of the points increase relatively slowly at the beginning of the rainfall, and then exhibit a rapid increase at some certain rainfalls. It can be inferred that a slope local failure

occurs at the surrounding area of the point at the inflection point on the history curve of vertical displacement. According to the histories of the four inflection points, a local failure cycle can be described with three stages as follows:

(1) The displacement history curves of points A and B, which are located in the top of clay layer, exhibit an inflection point at first. It can be inferred that the local failure first occurs in the top of the clay layer as the rainfall increases. This result implies that sand-clay interface has obvious effect on the failure of the slope.
(2) The displacement history curve of point C, which is located at the bottom of the sand layer, exhibit an inflection point after that of points A and B. It can be inferred that the local failure in the top of the clay layer expands upwards to the bottom of the sand layer across the boundary of sand and clay.
(3) The displacement history curve of point D, which is located in the sand layer, exhibit an inflection point after that of point C. It can be speculated that the local failure at the bottom of the sand layer continues to expand upwards in the sand layer during the rainfall.

The local failure cycles occur one by one as the rainfall increases and induce the final slip surface (Figure 2).

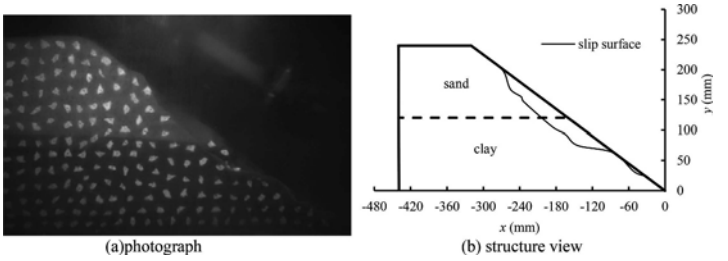

Figure 2. Slip surface after the rainfall.

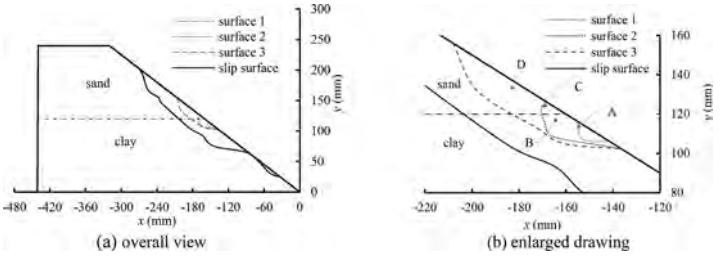

Figure 3. The first cycle during the process of slope failure.

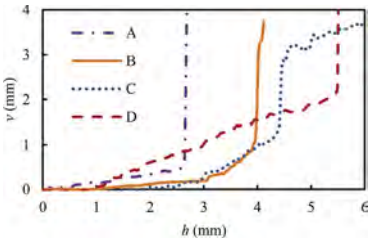

Figure 4. Histories of vertical displacements of typical points (point locations are indicated in Figure 3 (b)). *h*, rainfall; *v*, vertical displacement.

4 SLOPE DISPLACEMENT BEHAVIOR

Several points are selected in different soil layers on both sides of the slip surface to explore the displacement behavior of the slope. Figure 5 shows the histories of vertical displacements of those points during rainfall. It can be seen that the displacements of the points in the base body (points E and G) are fairly small and become nearly invariable when the rainfall increases to a value. On the other hand, the displacements of the points in the sliding body (points F and H) increase slowly at the beginning of the rainfall, and exhibit a rapid growth at a certain rainfall due to the slope failure. The vertical displacement of the sliding body in the clay layer exhibits the rapid growth a bit earlier than that of the sliding body in the sand layer. Therefore, it can be concluded that the slope displacement exhibits different characteristics in different zones during rainfall.

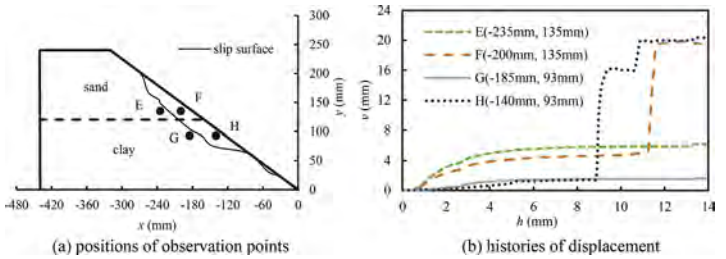

Figure 5. Histories of displacement of points of the slope during rainfall. *h*, rainfall; *v*, vertical displacement.

Figure 6 shows the displacement vectors of the slope at different rainfalls. It can be seen that the slope displacement distributes nearly homogenously when the displacement is fairly small at a rainfall of 2 mm. When the rainfall increases to 14 mm, the displacement distribution tends to be unevenly. The displacement in the sliding body becomes significant and different from the displacement in the base body. Moreover, the displacement of the clay layer seems more synchronous with that of the sand layer when it is closer to the sand layer.

For a closer examination on the displacement behavior, Figure 7 show the horizontal distribution of vertical displacement in the base body at different rainfalls. It can be seen that the vertical displacements of both the sand and clay layers have an inflection point, and the inflection point is farther from the surface of the slope as the elevation decreases. And compared with the rainfall of 2 mm, the vertical displacement at the rainfall of 14mm distributes more evenly on the inner side of the inflection point. In other words, when it is closer to the sand layer, the displacement of the clay layer is more synchronous with that of the sand layer. It indicates that there is a significant interaction between the sand layer and the clay layer during the rainfall.

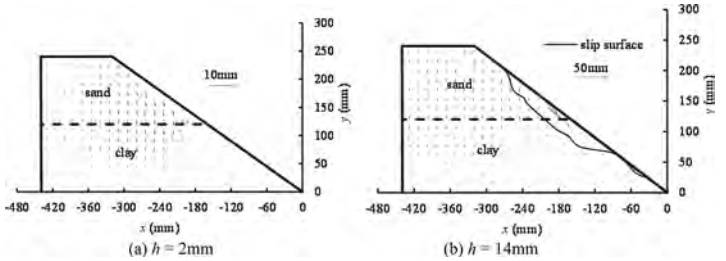

Figure 6. Displacement vectors of the slope.

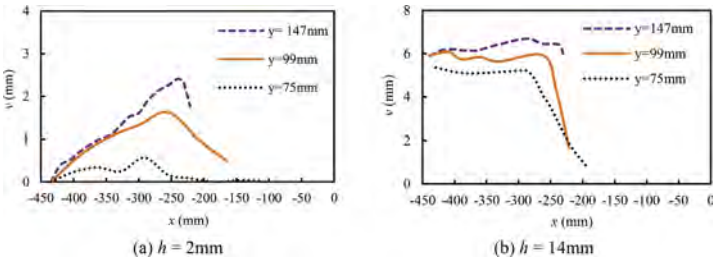

Figure 7. Horizontal distribution of vertical displacement at various elevations and rainfalls. *h*, rainfall.

5 SLOPE DEFORMATION AND INFILTRATION RULE

The vertical strain of the slope was determined on the basis of displacement measurement results to analyze the slope deformation and infiltration rule. Figure 8 shows the histories of vertical strain of typical points at different horizontal lines of the slope during the rainfall. It can be seen that the vertical strain is nearly zero at the beginning of rainfall and starts to increase from zero at a rainfall. It can be deduced that the inflection point can be used to determine the time when the water infiltrates there as the variation of the water content is the main cause to the soil deformation.

In the sand layer, the rainfalls at the water infiltration are close for different positions (Figure 8 (a)). This result indicates that the rain water infiltrates in the sand layer fairly quickly. On the other hand, the rainfalls at the water infiltration are significantly dependent on the positions due to low permeability of the clay (Figure 8 (b)). The closer to the slope surface, the water infiltration is earlier. Closer comparison on the vertical strains between the sand and clay layer shows that the rainfall induced deformation of the clay layer is greater than that of the sand layer at the same vertical line.

The wetting front of the slope can be determined according to measured water infiltration time. Figure 9 shows the wetting front at different rainfalls. It can be seen that the wetting front moves from the slope surface to the interior as the rainfall increases. It is worth noting that the wetting front moves rapidly in the sand layer and thus the water accumulates on the top surface of the clay layer. The sand layer has been totally soaked at the rainfall of 2 mm and then the wetting front is entirely located in the clay layer and becomes mostly horizontal line. Therefore, it can be inferred that most of the rainfall concentrates on the top surface of the clay layer, and the sand layer becomes the main sources of the water infiltration of the clay layer. That rainfall infiltration characteristic significantly affects the deformation behavior of the slope with sand-clay layer.

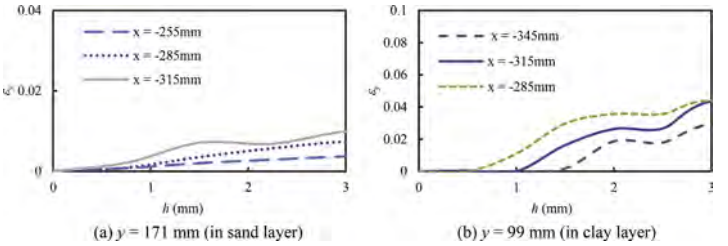

Figure 8. Horizontal distribution of vertical strain of the slope at different layers. ε_y, vertical strain; *h*, rainfall.

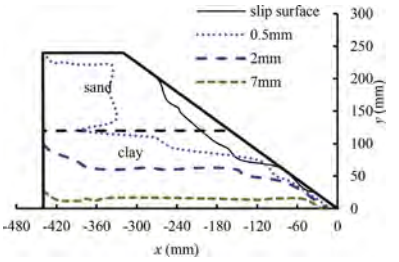

Figure 9. Wetting fronts of the slope during the rainfall.

6 CONCLUSION

The infiltration, deformation and failure behavior of the soil slope with dual structure of sand-clay layers were investigated on the basis of centrifuge modeling under rainfall condition. The main conclusions are as follows:

(1) The rainfall induces significant deformation and failure of the sand-clay layered slope that is affected by the rainfall infiltration characteristics of the dual structure.
(2) The final slip surface is continuous from the sand layer to the clay layer. The slope failure is progressive and caused by a few local failure cycles one by one as the rainfall increases. In a local failure cycle, the local failure first occurs in the top of the clay layer and expands upwards to the of the sand layer across the boundary of sand and clay.
(3) The wetting front moves from the slope surface to the interior as the rainfall increases and the move rate is significant greater in the sand than in the clay. The water accumulates on the top surface of the clay layer and becomes the main sources of the water infiltration of the clay layer.
(4) The sand layer has an obvious effect on the deformation of neighboring clay layer of the slope during the rainfall.

Stages of developing a prototype landslide forecasting framework using geotechnical monitoring: A case study from India

Neelima Satyam
Department of Civil Engineering, Indian Institute of Technology, Indore, India

ABSTRACT: Landslides have become a major problem in the Darjeeling Himalayas region of India and authorities are seeking ways to reduce the risk of these events through the development of an early warning system. A forecasting framework is the critical part of early warning system, where the occurrence of landslides is predicted using field or remotely based observation. One strategy for predicting landslides is to use rainfall thresholds, but this approach can result in a high number of false alarms. To address this limitation, it is necessary to monitor unstable slopes in real-time using cost-effective methods. In this study, MicroElectroMechanical Systems (MEMS) sensors were used to monitor slopes in the Chibo village of Darjeeling Himalayas and integrated the data with rainfall thresholds to develop a prototype landslide forecasting framework. The results showed that the combination of MEMS sensors and rainfall thresholds is a promising approach which overcomes the limitations of both methods when used separately.

1 INTRODUCTION

Landslides are natural processes that can cause significant damage to human environments, and the increasing population and urbanization of hilly areas is increasing the risk of these events (Dowling and Santi, 2014; Petley, 2012). It is important for authorities to implement risk reduction strategies, such as the development of a Landslide Early Warning System (LEWS). An LEWS should be able to predict the likelihood of landslides in a specific area and provide sufficient time for intervention. One commonly used method for forecasting landslides is the use of rainfall thresholds, which define specific precipitation conditions that may lead to slope failures (Baum and Godt, 2010; Devoli et al., 2018). The threshold defines specific rainfall conditions when exceeded, may trigger slope failures in the region (Segoni et al., 2018). These conditions be derived using physics-based approaches or data-driven approaches. Physics based or process based approaches are generally preferred for site specific studies (De Vita et al., 2017; Fusco et al., 2019; Napolitano et al., 2016; Segoni et al., 2018), and statistical approaches are applied for regional and global scales (Aleotti, 2004; Bordoni et al., 2019; Caine, 1980; Guzzetti et al., 2007). The thresholds are characterized by three rainfall parameters, the event (E), duration (D) and intensity (I). Event rainfall is the total quantity of precipitation, duration is the time period, and intensity is the ratio of event to duration. The thresholds are defined using two of these parameters, I or E on the y axis and D on x axis. Mathematically, the thresholds follow a power law and can be represented as a straight line on logarithmic scale. Sistema Integrato Gestione Monitoraggion Allerta (SIGMA) is an advanced statistical model which uses the standard deviation of rainfall data for landslide forecasting, first developed for Italy (Martelloni et al., 2012). This study uses both these rainfall thresholds for the study area.

Considering the rainfall threshold based approach, the method is simple and can be easily reconstructed (Abraham et al., 2021b, 2021a; Segoni et al., 2021). However, the lower boundary thresholds often results in higher number of false alarms (Bulzinetti et al., 2021). Also, statistical

DOI: 10.1201/9781003299127-155

thresholds which considers both short term and long term rainfall performs even better than the conventional approaches (Lagomarsino et al., 2015). To overcome these limitations, this study proposes the use of geotechnical field monitoring instruments along with rainfall thresholds for landslide forecasting (Abraham et al., 2021a). MicroElectroMechanical Systems (MEMS) based tilt sensors are established to be a cost effective and reliable approach for slope monitoring (Towhata et al., 2015; Uchimura et al., 2011). To be effective, tilt meters should be installed in strategic locations where they can provide early warning of landslides. They can be easily installed on slopes or other areas prone to landslides, and they do not require a lot of maintenance. In addition, they are resistant to extreme weather conditions, making them well-suited for use in the hilly region of Kalimpong, where landslides are often triggered by heavy rainfall. This study involves the use of sensors to monitor unstable slopes in the Kalimpong region of West Bengal, beginning in July 2017. The goal of the study is to determine the effectiveness of tilt sensors in predicting slope failures and how they can improve the performance of conventional rainfall thresholds. The two methods are combined using a decisional algorithm that can be used to forecast slope failures in the region.

2 DETAILS OF STUDY AREA

Kalimpong is a hilly town located in the Darjeeling Himalayas with steep, unstable slopes on the western side, composed of loose debris and prone to erosion during heavy rains (Figure 1). The town's bedrock is made up of golden to silver colored quartz mica shist, which is highly jointed and weathered and prone to stability issues. The increased human activity and resulting land use changes have increased the likelihood and risk of landslides in the region, which are often influenced by slope cuts and untrained mountain streams (jhoras). The most vulnerable locations for landslides are near these jhoras, and the sensors in this study have been installed on a slope near such a stream, called the Pyarieni jhora, in the Chibo village of Kalimpong (Figure 1).

The data for this study was collected from daily rainfall records maintained by Save The Hills and a landslide catalog compiled from various sources, including the Geological Survey of India, media reports, and communication with local residents (Dikshit and Satyam, 2018).

3 METHODLOGY

3.1 *Conventional rainfall thresholds*

This study evaluates the effectiveness of conventional rainfall thresholds and tilt meters when used individually and in combination. Previous researches (Dikshit and Satyam, 2018; Teja et al., 2019) has determined empirical thresholds for the study area on the ED plane as:

$$E = 4.2\ D^{0.56} \tag{1}$$

3.2 *SIGMA model*

SIGMA model defines different rainfall threshold lines, based on the statistical distribution of precipitation data. As the name indicates, the standard deviation of the data plays a key role in the definition of rainfall threshold. Each threshold curve is defined as a function of the standard deviation, 'σ' ($y = a\sigma$).

The first step is the calculation of cumulative rainfall for 'n' days, where n varies from 1 to 365. The rainfall is cumulated (z) at n days shifts at daily timesteps with the same width. The cumulative distribution function ($CDF(z)$) for each timestep was then calculated, and compared with standard distributions as target function (Martelloni et al., 2012). With cumulative rainfall data of Kalimpong was following asymmetric distributions, for lesser value of n, the distribution is similar to log normal distribution and for larger values of n, it is similar to normal distribution. To calculate the probability of exceeding a certain threshold, gaussian distribution was selected as the target function. Different threshold curves or σ curves can be plotted for each value of n, which are the input for SIGMA algorithm. The cumulated rainfall value for any duration is compared with the corresponding value in the σ curves, to issue the warning. The duration to be considered for each warning and the multiple of σ to be used, are determined by a trial-and-error process. For Kalimpong, the customised algorithm derived in a previous study has been used as the starting algorithm for this work (Figure 2).

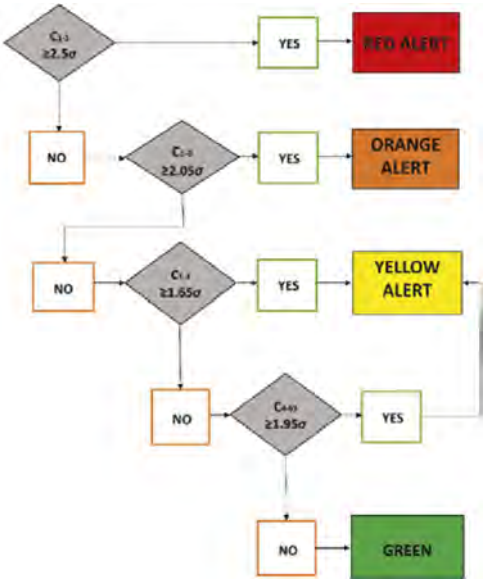

Figure 2. Decisional algorithm used for SIGMA model of Kalimpong (Abraham et al., 2021a).

3.3 *Tilt meter*

In July 2017, three sensor units (S1, S2 and S3) consisting of a volumetric water content sensor, a tilt sensor, and a control unit were installed on unstable slopes near the Pyarieni jhora in the Chibo village of Kalimpong. (Figure 1). The positions of the sensors were carefully selected following field surveys, consultation with the Geological Survey of India, and input from local residents.

The sensor readings were related with observations from the field, to assess the dependability of the recorded data (Abraham et al., 2020b; Dikshit et al., 2018). The records acquired from the tilt meters for the duration of monitoring period implies that large displacements are always associated with heavy rainfall.

3.4 *Combined approach*

The combined approach uses both historical rainfall data and tilt sensor readings. When testing the rainfall thresholds for Kalimpong, it was found that the model also issued false alarms on days when there were no observed displacements. These false alarms can decrease the credibility of the Landslide Early Warning System (LEWS) and reduce the public's response to the warnings. It is important to minimize the number of false alarms to increase the effectiveness of the LEWS.

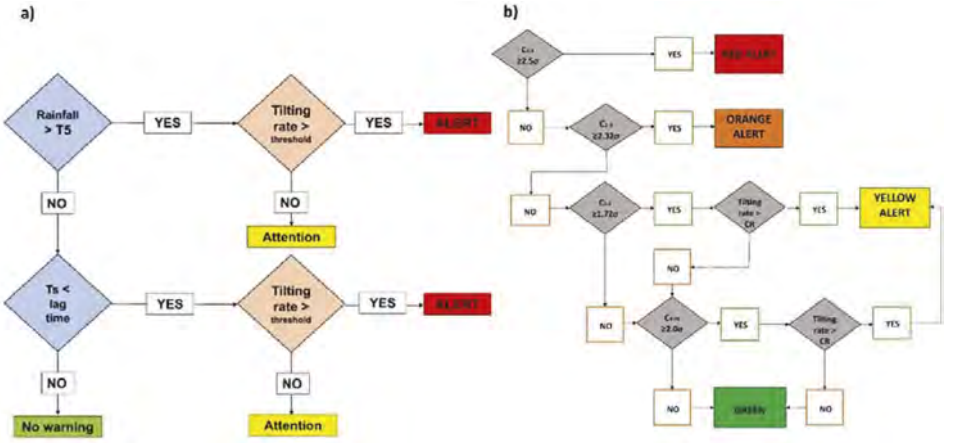

Figure 3. Decisional algorithm used for combined approach a) ED+tilt (Abraham et al., 2020a) and b) SIGMA+tilt (Abraham et al., 2021a).

The algorithm in Figure 3 uses the critical tilting rate (CR), which can be customized for each region through trial and error. For Kalimpong, the CR value has been calibrated at 0.03 degrees per hour. The algorithm first checks if the threshold condition is crossed as per the thresholds. After crossing the threshold, it then checks the maximum tilting rate from the previous day. If that rate is also above the CR value, an alert is issued. The term T_5 in Figure 3 indicates the threshold line with 5 % exceedance probability.

4 RESULTS

The performance of different models was evaluated using slope failure and rainfall data from July 2017 to September 2020. During the years 2017-2019, no major landslides were recorded near the sensors, and the slope failures were in the form of displacements and minor cracks in

roads near the sensors. All of these events were of minor criticality, requiring observation by authorities for any emergencies. In 2020, multiple landslides occurred in Kalimpong along with major cracks in roads near sensor 2, with events near the sensor locations ranging from minor to moderate criticality, resulting in the disruption of a main road to Chibo village and isolation from the rest of the town. The performance of the different models was compared using a confusion matrix, in which the model's predictions were compared to the occurrence or non-occurrence of slope failures. A true positive (TP) was recorded when the model predicted a slope failure and one occurred, and a true negative (TN) was recorded when the model predicted no slope failure, and none occurred. False predictions were divided into false positives (FP), when a slope failure was predicted but none occurred, and false negatives (FN), when no slope failure was predicted but one occurred. The sensitivity and specificity of the model can be calculated using the attributes from the confusion matrix, and the performance of different models can be compared using a Receiver Operating Characteristic (ROC) curve, which plots sensitivity against 1-specificity. Sensitivity is the ratio of is the fraction of TPs among all the landslides considered for validation, and specificity is the fraction of TNs among all the non-landslide das considered. The point (0,1) on the plot represents a perfect model with a sensitivity and specificity of 1 and an area under the curve (AUC) of unity. The higher the AUC, the better the model.

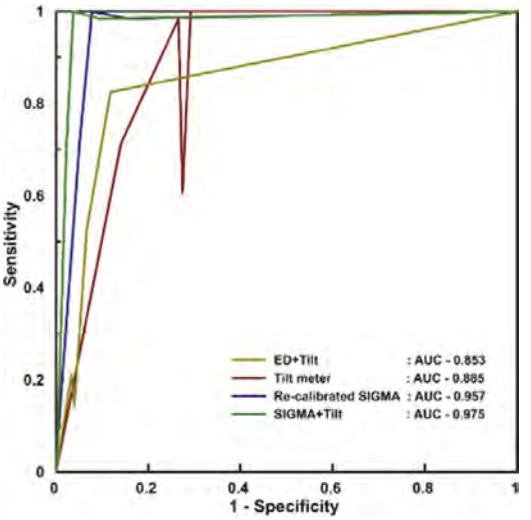

Figure 4. ROCs plotted for different methods considered in the study.

The combined approach using SIGMA and tilt sensors had the highest AUC value of 0.975 and was the best performing model (Figure 4). The curve for the combined approach was closer to the y-axis, indicating that it was more specific and issued fewer false alarms compared to the other models. The points for the tilt meter were farther from the y-axis, indicating a higher number of false alarms. Th recalibrated SIGMA model also has better performance than both ED+tilt and tilt meter alone. The SIGMA model and combined approach had points closer to the perfect point and relatively consistent performance over the years, while the performance of the tilt meter varied significantly each year. The majority of missed alarms with the tilt meter occurred in 2018, when the field displacements were minor and not associated with heavy rainfall. The combined approach is an attempt to improve the prediction performance of the SIGMA model and determine its potential as an operational LEWS for Kalimpong. The results show that the proposed method can significantly reduce the number of false alarms, but do not address alarms missed by the SIGMA model. When comparing the different threshold models

for Kalimpong, the new approach proposed in this study, which enhances the conventional SIGMA model, performed better than previously derived thresholds. However, the model has certain limitations that must be addressed to turn it into an operational LEWS.

5 CONCLUSIONS

This study explains the process of developing a prototype to forecast the occurrence of slope failures in Kalimpong, a town in the Darjeeling Himalayas. The first method relied solely on the rainfall threshold, which assumes that extreme rainfall triggers landslides and that the historical relationship will hold true in the future. The second approach used real-time field monitoring data from three MEMS tilt sensors installed on the western slopes of Kalimpong to understand the field conditions and issue warnings. The third method was a combination of the first two approaches, using a complex algorithm to issue different levels of warnings based on the severity of rainfall and tilt rates recorded in the field. The results showed that both the thresholds and the tilt meters, when used separately, issued numerous false alarms, making them unsuitable for use in a LEWS. The combined approach performed better than either approach when used individually, as verified using a ROC analysis, which showed that the area under the curve values for the ED+tilt, tilt meters, SIGMA model, and SIGMA+tilt were 0.853, 0.885, 0.957, and 0.975, respectively. The combined approach was also compared to other rainfall thresholds developed for the region and was found to be the best-performing threshold for Kalimpong to date. Its minor shortcomings will be addressed and the model will be refined for use as a potential tool in developing an LEWS for the region.

Centrifuge model test study on the micro pile reinforcement of soil slopes under drawdown condition

Ziang Wang, Sujia Liu & Ga Zhang
State Key Laboratory of Hydroscience and Engineering, Tsinghua University, China

ABSTRACT: Micro anti-slide piles are an effective reinforcement approach for slopes. Centrifuge model tests were carried out to explore the deformation and failure behavior of micro pile reinforced slopes under drawdown condition. The slip surface is discontinuous and divided into two parts by the micro pile group. The slip surface occurs at the top of the slope after the instability of micro piles and develops to the bottom and as the water level decreases. There is a significant coupling effect between slope deformation localization and local failure. The micro piles restrict the deformation localization and greatly improves the stability of the slope structure. The reduction of pile spacing can cause deformation distribution of the slope more uniform and increase the stability of the micro anti-slide pile group.

1 INSTRUCTIONS

Landslide is one of the most serious geological disasters in the world. The variation of water level is an important cause of slope failure. For example, many landslides were induced by step-like annual fluctuation in the water level of the Three Gorges reservoir (Li et al. 2019). Piles have proved to be an effective reinforcement method for soil slope under various conditions (Anbarasu et al. 2010; Liu et al. 2021). There have been some studies on the reinforcement mechanism of anti-slide piles (Zhang et al. 2017).

The micro anti-slide piles have been shown as an effective reinforcement tool for soil slopes (Dong et al. 2018). Compared with traditional piles, the micro anti-slide piles have many advantages such as small construction equipment, economy and flexible layout. Therefore, it is very important to study the reinforcement behavior and mechanism of micro anti-slide pile to promote its application.

Centrifuge model tests have been widely used to study the deformation and failure behavior of slopes. The bearing capacity and influence factors of pile-reinforced slopes were investigated using centrifuge model tests under loading conditions (Yu et al. 2010; Wang and Zhang 2015). Whereas, few centrifuge model test researches have been performed on the micro pile reinforcement under drawdown conditions. This paper conducted centrifuge model tests to investigate the deformation and failure behavior of the slope with micro anti-slide piles, and clarify the reinforcement mechanism of micro anti-slide pile under drawdown conditions.

2 TEST

2.1 *Device*

The 50g-ton geotechnical centrifuge of Tsinghua University is used in the centrifugal model test. The centrifuge can achieve ultimate centrifugal acceleration of 250 g. The slope model is designed to be 500 mm long, 200 mm wide and 290 mm high (Figure 1). The slope model is placed in an aluminum alloy model container. An organic transparent glass with a thickness of 40 mm is installed on one side of the model container along the length direction. A camera is placed in front of the glass to observe the deformation of the slope and the movement of micro anti-slide piles during the tests.

DOI: 10.1201/9781003299127-156

2.2 *Test scheme*

The main research purpose of this paper is to explore the deformation and failure of micro anti-slide pile reinforced slope under drawdown conditions considering the influence of the pile spacing. Therefore, two micro anti-slide pile reinforced slopes with various pile spacings are simulated in the tests. Two pile spacings, 6.3 and 4.7 times the pile diameter, are used to consider sparse and dense pile layouts that are often adopted in practical cases. The slope reinforced with dense and sparse pile group are abbreviated DP slope and SP slope, respectively. The two tests ensure that other factors are completely the same except the pile spacing.

2.3 *Model*

The soil of the slope model is a kind of silty clay with a height of 24 cm (Figure 1). Three rows of micro anti-slide piles are continuously inserted in the slope. The piles are inserted at the bottom 24 cm away from the top of the slope, and the horizontal spacing between the outermost row of anti-slide piles and the foot of the slope is 9.5 cm. The gradient of the slope is 1:1. The pile spacings in the SP slope and DP slope are 55.1 mm and 41.3 mm, and the other parameters are the same for the two slopes. Some small white particles are evenly embedded on the sides of the slope model provides a significant grayscale difference, enabling more accurate observation of soil changes and measurement of soil displacement.

According to the unified soil classification system (USCS), the cohesive soil in the tests can be classified as CL-ML. The soil is compacted layer by layer and the thickness of each layer is 40 mm. The dry density of the soil is 1.6 g/cm^3 and the initial water content of the soil is 18%. The permeability coefficient, cohesion and internal friction angle of cohesive soil are 10^{-5} cm/s, 27 kPa and 25°, respectively, according to the permeability and triaxial compression tests.

The micro anti-slide pile is simulated with an aluminum solid tube with a square section with a side length of 8.7 mm.

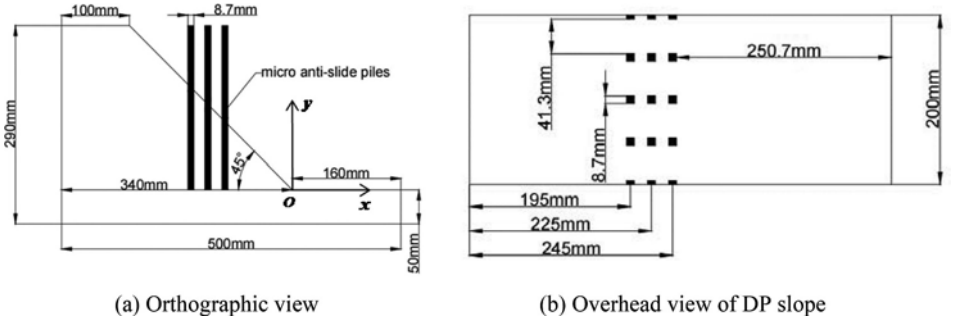

Figure 1. Schematic view of the slope model.

2.4 *Procedure*

The centrifuge model tests are mainly completed in three steps.

First, the centrifugal acceleration is raised from 1 g to 50 g. The g level do not increase until the slope settlement stabilized when the centrifugal acceleration increase to the integer multiple of 10 g.

Second, the water level is gradually increased from 0 to 160 mm after the centrifugal acceleration reach 50 g and the slope deformation became stable. The next impoundment is carried out until the deformation of the slope became stable when the water level increase to the integer multiple of 40 mm.

Finally, the water level decrease from 160 mm to 0 at a rate of 0.7 mm/s in one step.

2.5 *Measurement*

The whole process of the two tests is recorded by the camera in front of the model container. The images are imported into the software and analyzed by relevant algorithms to determine

the displacement at any point of soil and micro anti-slide piles at any time (Zhang et al. 2009). A Cartesian coordinate is established with the foot of slope as the origin and the positive directions of x-axis and y-axis are rightwards and upwards, respectively (Figure 1a). According to the similarity ratio of the centrifuge model test, the water level and displacement of the prototype are both 50 times that of the model.

3 ORSERVATION

Figure 2 shows an obvious slip surface in the slope reinforced with sparse piles. The slip surface is curved, discontinuous and can be divided into two parts by the micro pile group. On the inner side of the micro pile group, the slip surface runs from the top of the slope to the lower middle part of the micro anti-slide pile. And on the outer side of the micro pile group, the slip surface runs from the bottom of the piles to the toe of the slope. In addition, there is no obvious slip surface in the slope reinforced with dense piles. Therefore, the reduction of pile spacing can improve the reinforcement effect of pile group.

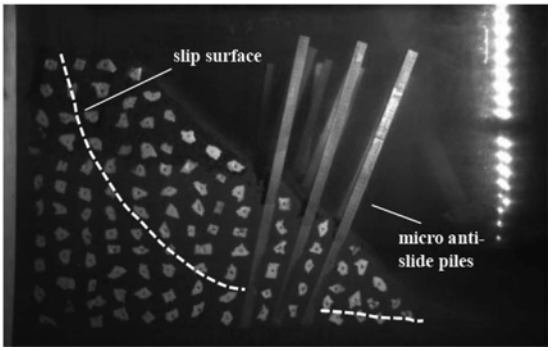

Figure 2. Photograph of the slope reinforced with sparse piles after failure.

Figure 3 shows the history of rotation angle of the middle micro anti-slide pile. The pile is considered as a rigid body and found to rotate around the tip from the captured images. The rotation angle of the pile is small at the beginning of drawdown and then increases rapidly after an inflection point for the slope reinforced with sparse piles, which can be regarded as the occurrence of pile instability. On the contrary, the rotation angle of the piles in the slope reinforced with dense piles is very small during drawdown and there is no inflection point in the history curve. This result indicates that the reduction of pile spacing can increase the stability of the micro anti-slide pile.

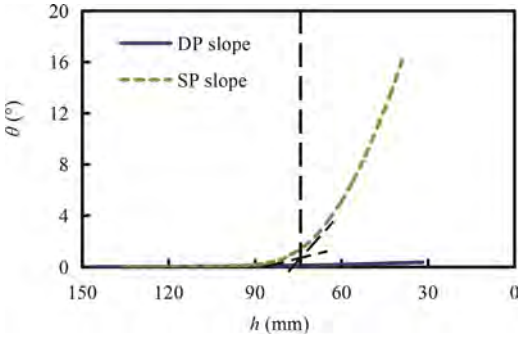

Figure 3. History of rotation angle of the middle micro pile in different tests. h, water level; θ, rotation angle.

The point couple method is used to determine the failure moment of slope during the tests. The point couple consists of a pair of adjacent points on both sides of the slip surface. The relative displacement of the point pair couple is decomposed into tangential and normal directions of the slip surface. The positions of the four point couples selected on the slope reinforced with sparse piles are shown in Figure 4.

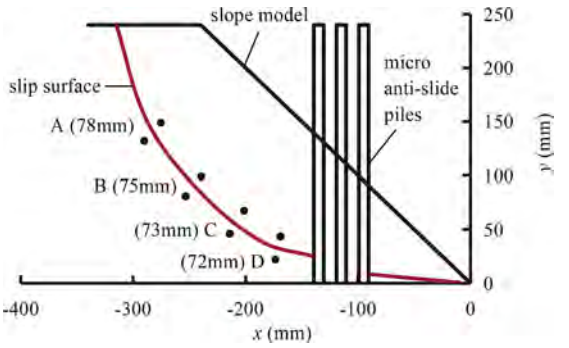

Figure 4. Failure process of the slip surface of the slope reinforced with sparse piles. The water levels corresponding to local failure are included in the round brackets.

Figure 5 shows the relative displacement histories of the selected point couples. It can be seen that the tangential relative displacements of point couples all increase slowly but with small values at the initial stage of water level decrease, and then increase rapidly at a certain inflection points. The inflection point can be regarded as the local failure moment of the slope. The normal relative displacement of the point couple is relatively small. This result indicates that shear failure occurs on the slip surface. The slip surface develops from the top of the slope to the bottom. The water levels at the local failure are shown in round brackets in Figure 4. Compared with Figure 3, the instability of micro anti-slide piles occurs before the failure of slope on the inner side of the pile group.

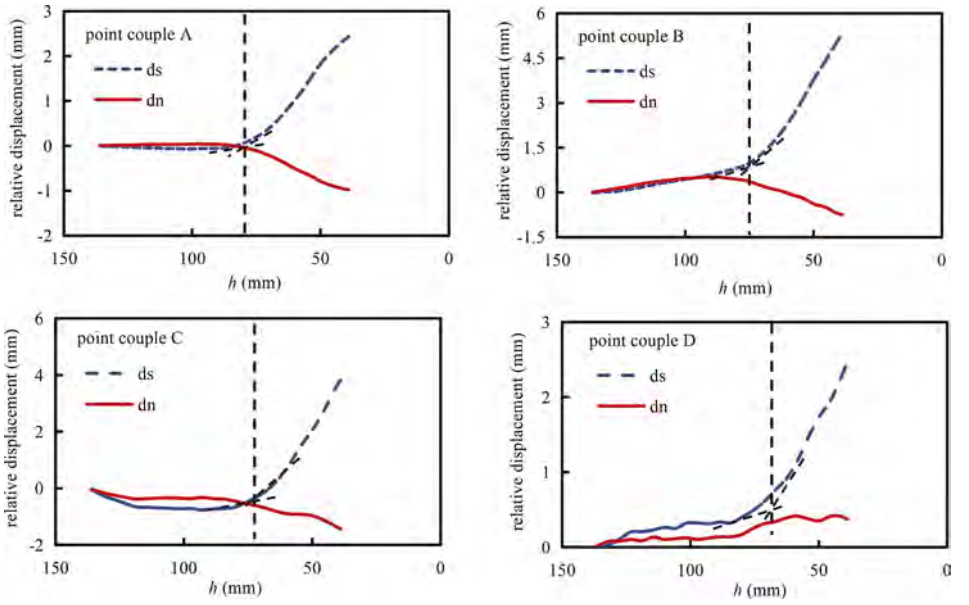

Figure 5. Relative displacement histories of point couples (locations shown in Figure 4). *ds*, the tangential relative displacement; *dn*, the normal relative displacement; *h*, the water level.

Figure 6 shows the slope displacement vectors of the slope. The displacement distributes nonuniformly and decreases from the exterior to the interior of the slopes. The sliding body and base body can be clearly distinguished according to displacement vector distribution. The displacement of the slope reinforced with dense micro anti-slide piles is much smaller than that of the sparse micro anti-slide pile. And the displacement distribution of the slope reinforced with dense micro anti-slide pile is more uniform. Therefore, it can be concluded that the decrease of pile spacing makes the soil deformation distribution more uniform, thus playing a better reinforcement effect.

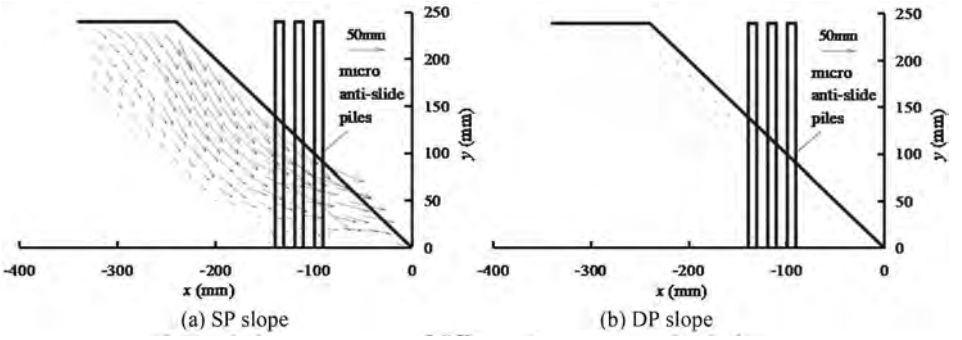

Figure 6. Displacement vectors of different slopes at a water level of 50mm.

Figure 7 shows the vertical distributions of the horizontal displacements of the soil in SP slope on the inner side of the piles (x = -219mm) and on the outer side of the piles (x = -81mm) under drawdown condition. On both sides of the pile, the horizontal displacement shows a trend of increase as the elevation increases. There is an obvious inflection point on the distribution curve near the inner side of the piles with the same location of the slip surface. The displacement of the soil inside the piles is small near the bottom of slope and increases rapidly at the inflection point. However, the vertical distributions of displacement of the soil outside the piles is approximately linear with the elevation and the slip surface outside the piles is close to the bottom. This confirms that the slope deformation behavior on both sides of piles is different. It can be inferred that the deformation of the soil outside the piles is affected by the compaction of the unstable piles during drawdown.

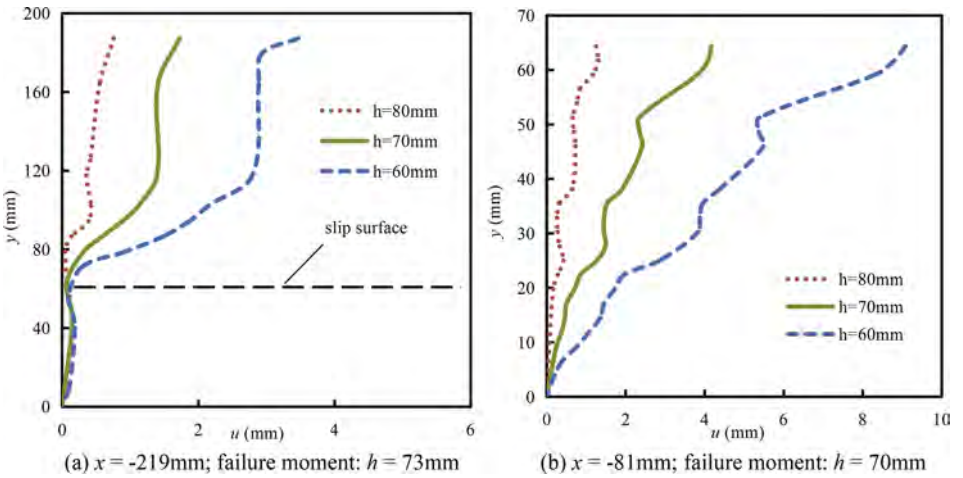

Figure 7. Vertical distributions of horizontal displacement of the soil on the both sides of piles in SP slope. u, horizontal displacement; h, water level.

4 REINFORCEMENT MECHANISM

Figure 8 shows the horizontal distributions of horizontal displacement at different elevations before and after failure of the slope reinforced with sparse piles. It can be seen that the displacement exhibits a uniform distribution. As approaching the foot of slope, the horizontal displacement of soil appears inflection point, which indicates that there is obvious deformation concentration. The displacement of slope increases gradually with decreasing water level. Therefore, the horizontal distributions of the gradient of the horizontal displacements are analyzed to explore the failure mechanism of the slope.

Figure 9 shows the horizontal distributions of the gradient of the horizontal displacements at different elevations. The slope deformation is obvious and its distribution is unevenly. The deformation increases as the water level decreases and there is an obvious peak near the slip surface. The deformation localization is confined within a region and the slip surface occur in this area. This indicates that the deformation localization of the slope leads to the local failure of the slope and the local failure of the slope strengthens the deformation localization of the slope. Therefore, there is a significant coupling effect between slope deformation localization and local failure.

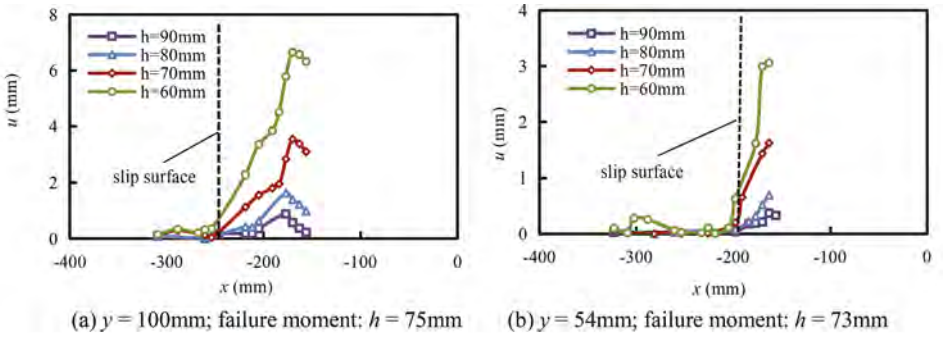

Figure 8. Horizontal distributions of the horizontal displacements of SP slope. *h*, water level; *u*, horizontal displacements.

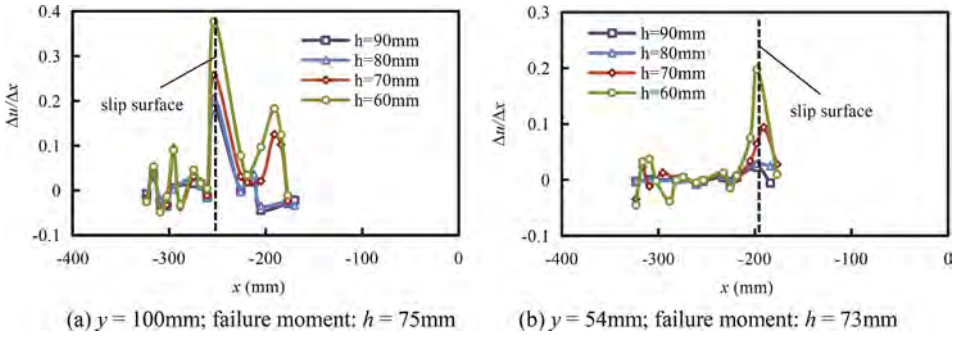

Figure 9. Horizontal distributions of the gradient of the horizontal displacements of SP slope. *h*, water level; *u*, horizontal displacement.

Figure 10 shows the horizontal distributions of the horizontal displacement gradient at the elevation of 100 mm in the two tests. The horizontal displacement gradient of the slope reinforced with sparse piles is larger than that of the slope reinforced with dense piles. There is no obvious peak of the horizontal displacement gradient in the slope reinforced with dense piles. This indicates that the decrease of pile spacing will make the horizontal displacement gradient smaller and the deformation more uniform. It can be deduced that the micro anti-slide piles restrict the deformation localization and thus increase the slope stability level.

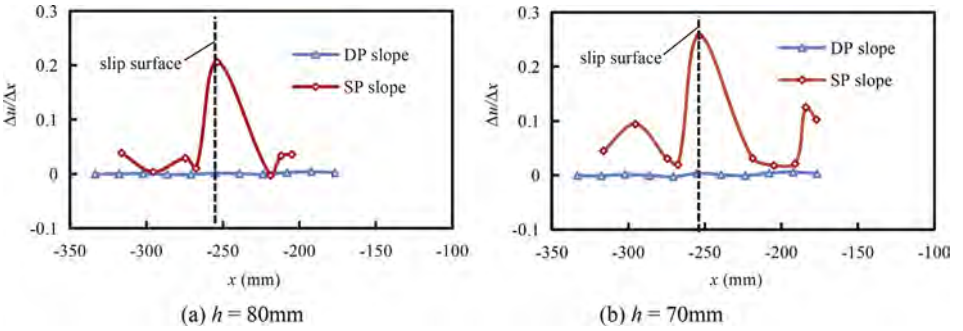

Figure 10. Horizontal distributions of gradient of horizontal displacements of slopes (y = 100mm; failure moment: h = 75mm). h, water level; u, horizontal displacements.

5 CONCLUSION

(1) The slip surface is discontinuous and is divided into two parts by the micro anti-slide pile group under drawdown conditions.
(2) The slip surface develops from the top of the slope to the bottom. The instability of micro anti-slide piles occurs before the slip surface appears on the inner side of the pile group.
(3) As the water level decreases, the slope deformation gradually increases, and the deformation localization appears. The slope deformation localization promotes the local failure of slope, and the local failure intensifies the slope deformation localization. There is a significant coupling effect between slope deformation localization and local failure during drawdown.
(4) The micro piles restrict the deformation localization and greatly improves the stability of the slope structure. The reduction of pile spacing can cause deformation distribution of the slope more uniform and increase the stability of the micro anti-slide pile group.

ABSTRACT: Seismic fragility of slopes has been commonly assessed without the input ground motions in a vertical direction. This study addresses the influence of the vertical component of the input ground motions on the seismic fragility using finite element simulations. We consider 9 slope geometries comprising a combination of three slope heights (10 m, 20 m, and 30 m) and three slope angles (20°, 30°, and 40°). A total of 450 earthquake recordings are collected from NGA-West2 database that contain two horizontal (300=2×150) and one vertical (150) components. Each horizontal component is coupled with the vertical component, resulting in two sets of the input ground motions that produce 300 permanent slope displacements for one slope model. We compute the seismic fragility curves of slopes for three damage states based on a probabilistic seismic demand model. Results show that the probabilities of the slope damage subjected to the vertical-horizontal components of the input ground motions are greater than those subjected to the solely horizontal component. It turns out that the vertical component of the input ground motion affects the seismic fragility curves of the slopes.

1 INTRODUCTION

Seismic fragility of slopes has been mostly assessed through numerical modeling where slope models are subjected to input ground motion in an only horizontal direction. Recent research demonstrated the influence of the input ground motion in a vertical direction along with the horizontal component on the seismic responses of a slope (Zhang et al., 2016) and a bridge (Bhanu, 2018). In this study, we investigate the impact of the input ground motion in the vertical direction on the seismic fragility of slopes using finite element (PLAXIS 2D) simulations. 9 slope geometries (i.e., a combination of 3 slope heights and 3 slope angles) were created that were subjected to two groups of the input ground motions one of which are only with the horizontal components and the other of which are with both the horizontal and vertical components. With permanent slope displacements computed from the simulations, the seismic fragility curves of the slopes were generated based on the probabilistic seismic demand model (PSDM) for the two groups of the input ground motions, which were compared across the slope heights and angles.

2 FINITE ELEMENT SIMULATIONS

2.1 *Geometry and material properties of slope model*

Figure 1 shows a slope geometry generated in the PLAXIS 2D that consists of five geometric parameters (i.e., H_{slope} = a slope height, β = a slope angle, D = a depth below the slope height, L = a horizontal length of the slope model, and h = a thickness of sublayer of the slope model). We only considered a variation in the H_{slope} and β, resulting in 9 slope geometries

*Corresponding author: byungmin.kim@unist.ac.kr

DOI: 10.1201/9781003299127-157

derived from a combination of 3 slope heights (i.e., H_{slope} = 10 m, 20 m, and 30 m) and 3 slope angles (β = 20°, 30°, and 40°). The L, D, and h across the 3 slope angles were input as L = 108 m, D = 10 m, h = 5 m for the H_{slope} = 10 m, L = 215 m, D = 20 m, h = 10 m for the H_{slope} = 20 m, and L = 322 m, D = 30 m, h = 15 m for the H_{slope} = 30 m across 3 slope angles. The equally divided sublayers of the slope model were intended to account for the dependence of the normalized shear modulus reduction curves on the confining pressure. A nonlinear constitutive relationship for the slope material was described by the HSsmall model implemented in PLAXIS 2D. The strength and stiffness parameters required for the HSsmall model are a cohesion (c), friction angle (ϕ), and the initial shear modulus (G_{max}). We input the c = 10 kPa and ϕ = 30° for the strength parameters and four different values of the G_{max}.

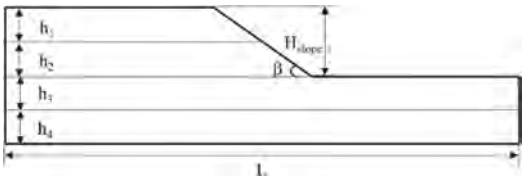

Figure 1. Considered slope geometry in PLAXIS 2D.

2.2 *Input motions and boundary conditions*

A suite of earthquake records was collected from the Next Generation Attenuation West 2 (NGA-West2) database that are 450 for two horizontal (H1 and H2) and one vertical (V) components (i.e., 150 for each component). Figure 2 shows 5% damped response spectra of the collected input ground motions for each component, accounting for a broad range of intensity and frequency contents of the input ground motions. The first group of the input ground motions contains only two horizontal components (i.e., the H1 and H2, 300 motions), and the second group is composed of each horizontal component coupled with the vertical component (i.e., the H1 with V and the H2 with V, 300 motions). They were applied to the 9 slope models, producing 2,700 maximum slope displacements on the slope surface for each group of the input ground motions.

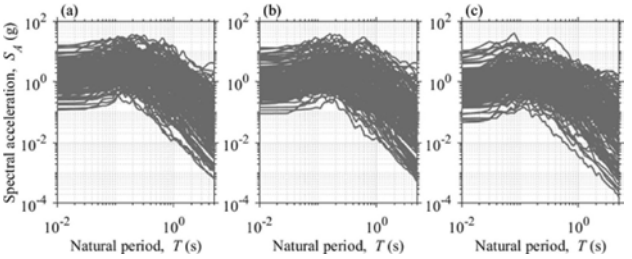

Figure 2. 5% damped response spectra of the 150 ground motions: (a) the first horizontal components; (b) second horizontal components; and (c) the vertical components.

Two conditions for the slope model boundaries are needed for the dynamic analysis, which are free-field condition for the slope model's left and right sides and compliant base condition for the slope model's bottom. Each condition was intended to simulate the semi-infinite boundaries analogous to a realistic ground condition by minimizing the reflected waves at the lateral and bottom boundaries.

3 FRAGILITY ANALYSIS

3.1 *Probabilistic Seismic Demand Model (PSDM)*

The multiple finite element simulations produced the maximum slope displacements (D) on the slope surface of which scatter plots against a peak ground acceleration in the horizontal

direction (PGA_H) are shown in Figure 3 for the slope models with the H_{slope} = 10 m across the three β = 20°, 30°, and 40°. The displacements at the low levels of PGA_H (i.e., $PGA_H \leq 0.05$ g for the slope with slope angle of 20°, and $PGA_H \leq 0.07$ g for the slope with slope angle of 30° and 40°) for the horizontal motions coupled with the vertical motions are mostly greater than those for the solely horizontal motions, however, the difference between the two groups of the input motions becomes negligible at the larger levels of PGA_H.

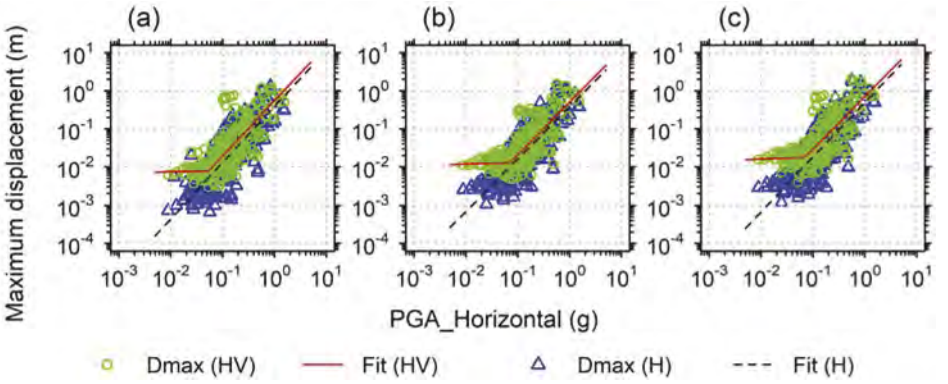

Figure 3. Relative permanent displacement against the PGA of horizontal motion for a slope height (H_{slope}) of 10 m and three slope angles (β) of (a) 20°; (b) 30°; and (c) 40°.

We adopted a probabilistic seismic demand model (PSDM), which describes a relationship between the PGA_H and slope displacement, to compute a probability of slope damage as follows:

$$\ln(D) = \ln(a) + b \cdot \ln(PGA_H) \tag{1}$$

where D is a median prediction of the maximum slope displacement, and a and b are coefficients of the linear regression analysis in natural log of the D and PGA_H.

3.2 *Seismic fragility assessment of slopes*

The fragility curve of the slopes is computed by a conditional probability of exceeding a certain slope displacement value for a given intensity measure (IM) level of the input ground motion as follows (Padgett et al., 2008):

$$P\left[Dd|IM\right] = \phi\left(\frac{\ln(D) - \ln(d)}{\sqrt{\beta_{D|IM}^2 + \beta_C^2 + \beta_M^2}}\right) \tag{2}$$

where $P\left[Dd|IM\right]$ is a probability of the demand exceedance, D is a seismic demand, $d$is values of the limit state, $\beta_{D|IM}$ is a logarithmic standard deviation of the seismic demand, β_C is a logarithmic standard deviation accounting for the uncertainty in the limit state that is assumed 0.3 based on Wen et al. (2004), and β_M = logarithmic standard deviation describing the modeling uncertainty that is assumed 0.3 based on HAZUS-MH (2003).

The $\beta_{D|IM}$ is calculated as below:

$$\beta_{\mathrm{D|IM}} = \sqrt{\frac{\sum\left(\ln(d_i) - (\ln(a) + b \times \ln(IM_i))\right)^2}{\mathrm{N} - 2}} \tag{3}$$

where d_i is the slope displacement computed from the finite element simulations, N is the number of the input ground motions that is 300 for only H1 and H2 component and 300 for the H1 and H2 coupled with V components.

Calculation on the fragility curves requires to specify limit states associated with certain threshold values. We selected three threshold values of slope displacement (i.e., 5 cm, 15 cm, and 30 cm) based on California Geological Survey (CGS) (Perez et al., 2012) which define limit states of the slope represented by the slope displacement exceeding the certain threshold values. Three limit states of the seismic slope displacement were considered that are minor (D < 5 cm), moderate (5 cm < D < 15 cm), and extensive (15 cm < D < 30 cm). The PGA_H was selected for the IM in this fragility analysis.

Figure 4 presents the calculated seismic fragility curves for the slopes with the three slope heights across the three slope angles. The probabilities of exceeding limit states for the motion group of the H1 and H2 combined with V are greater than those for the only H1 and H2 components, indicating that considering both vertical and horizontal components of the input ground motions make slopes more vulnerable than only horizontal components of the input ground motions for all slope models. In addition, the damage probabilities increase with slope angles as well as slope heights, which conforms to the fact that the factor of safety for slope stability analysis decreases with the slope angle and height.

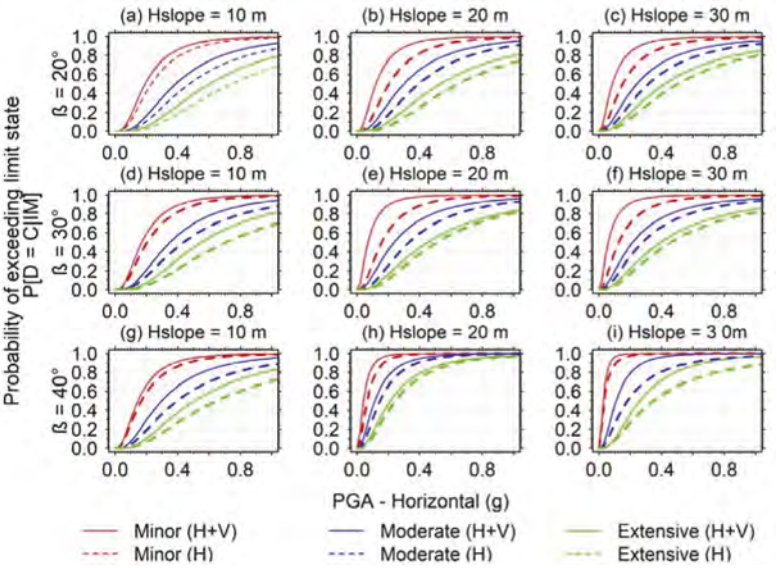

Figure 4. Seismic fragility curves for slope with three slope angles (β), as well as various slope heights (H_{slope}) under the two ground motion characteristics: (a) 20°, 10 m; (b) 30°, 10 m; (c) 40°, 10 m; (d) 20°, 20 m; (e) 30° 20 m; (f) 40°, 20 m; (g) 20°, 30 m; (h) 30° 30 m; and (i) 40°, 30 m.

4 CONCLUSIONS

This study investigated the effect of the ground motions' vertical component along with the ground motions' horizontal component on the seismic fragility curves of the slopes. The parametric finite element simulations were performed to calculate suites of the 5,400 maximum slope displacements for the two groups of the input ground motion that consist of the only horizontal component and the horizontal component together with the vertical component. The probabilities of exceeding limit states for the slopes were computed based on the PSDM for the two groups of the input motion. It was observed that the fragility curves for the motion group with vertical component were generally larger than those for the motion group containing only horizontal component across all the slope heights and angles, implying that the vertical component of the input ground motion had influence on the seismic fragility analysis of the slopes.

Influence of pore pressure parameter on seismic stability analysis of geosynthetic reinforced soil slope

P.K. Meena
PhD Research Scholar, Department of Civil Engineering, IIT Roorkee, Roorkee, Uttarakand, India

K. Chatterjee
Assistant Professor, Department of Civil Engineering, IIT Roorkee, Roorkee, Uttarakand, India

ABSTRACT: An accurate seismic external stability analysis of geosynthetic reinforced soil slopes under pseudo-static conditions using limit equilibrium method is presented. The effect of variation of different parameters, such as slope angle, soil friction angle, seismic acceleration coefficients (k_h & k_v), surcharge, cohesion and water forces on required length of reinforcement (L) is presented. The combined effect of parameters like surcharge loading (q), pore pressure ratio (r_u), cohesion (c), hydrostatic & hydrodynamic pressure (p_{st} and p_{dy}) and formation of tension cracks Z_c are also considered in the analysis and their effect on L are discussed. All the computations have been carried out by writing a computer coded program in MATLAB. The present study shows that with the increase in c values, the magnitude of L decreases, while it increases with an increase in q and k_h to resist failure. Further as the pore pressure ratio increases, the length of reinforcement also increases to resist failure.

1 INTRODUCTION

Steep soil slopes are more susceptible to failure. To prevent failure, additional support should be provided to the soil to improve its shear strength. There are several methods to enhance the shear strength of soil, the reinforcement technique is one of them and is also worldwide popular nowadays because of its easy installation and better performance while in service. Analysis of these reinforced soil structures was done by Ling et al. (1997); Baker (1981). As per the available literature, most of the previous studies was done for cohesionless soil, considering dry backfill [Jewell (1990); Leshchinsky and Bodecker (1989)], few of them also considered the effect of water on both sides, but effect of vertical seismic acceleration coefficient was ignored Annapareddy and Pain (2019). Similarly, Agarwal and Pain (2021) considered the effect of k_v, but the effects of submergence were ignored.

In this present study, all the possible forces that cause failure and create the most critical condition for the reinforced soil slope are considered. The combined effect of cohesion, surcharge, hydrostatic, and hydrodynamic pressure is presented in this paper. Based on the previous literature, reinforced soil structures rarely fail in overturning. Therefore, although the primary focus is on direct sliding failure, but the analysis is done for both failure modes. As soil is weak in tension and when tensile forces generated in the soil exceed the tensile strength of soil, then cracks are formed on top surface of the slope. The soil in this tension crack zone already fails due to the formation of cracks; therefore, this soil is not contributing to shear strength but acts as a surcharge over the remaining slopes. In the stability analysis of reinforced soil slope, the effect of tension cracks should not be ignored [Abd and Utili (2017), Utili (2013)].

2 PROPOSED METHDOLOGY

A two-part wedge mechanism is used to analyze the external stability of geosynthetic reinforced soil slope against direct sliding and overturning modes of failure. A similar mechanism which was

DOI: 10.1201/9781003299127-158

used by Ling and Leshchinsky (1998) in their analysis, has been modified in the present study. This entire slope is divided into two wedges wedge A (abdf) is the quadrilateral shape, and wedge B (def) is the triangular shape. For better understanding, analysis is done separately for both wedges. For equilibrium of forces between two wedges, an inter-wedge force P is introduced (P_a and P_b). For the case $K_h = 0$ and $K_v = 0$, hydrodynamic pressure is zero and only hydrostatic pressure is generated, but for all other cases (K_v & $K_h \neq 0$), both hydrostatic and hydrodynamic pressures are considered. Due to the submergence of the soil, instead of using unit weight (γ), equivalent unit weight (γ_{eq}) is used [Ebeling and Morrison (1993)], which is formulated as:

$$\gamma_{eq} = \left(\frac{h_{wd}}{H}\right)^2 \gamma_{sat} + \left[1 - \left(\frac{h_{wd}}{H}\right)^2\right] \gamma_d \tag{1}$$

$$\gamma_{we} = \gamma_w + \left(\gamma_{eq} - \gamma_w\right) r_u \tag{2}$$

where r_u= pore pressure ratio; h_{wd}= height of water on downstream side; γ_{eq}= equivalent unit weight of soil γ_{we} = equivalent unit weight of water.

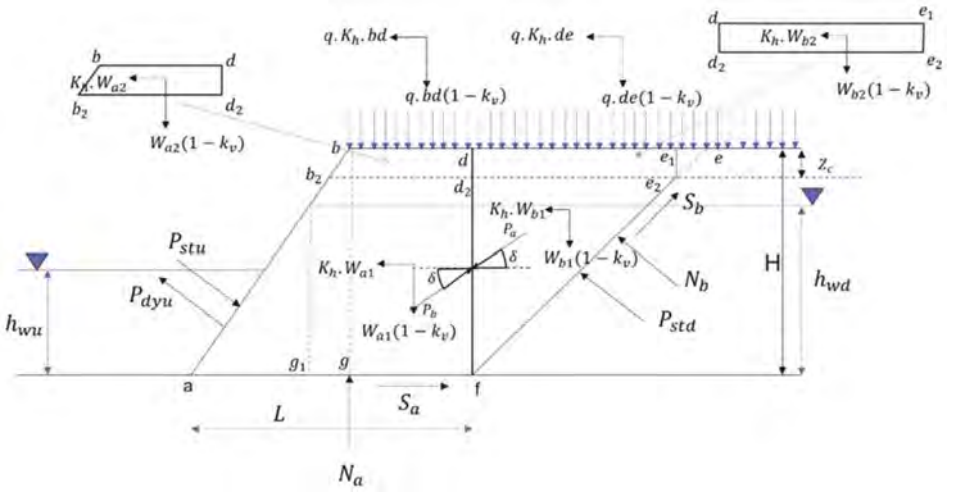

Figure 1. Free body diagram of soil slope for wedge A and B.

2.1 *Force equilibrium of wedge B*

The free body diagram is shown in Figure 1. To evaluate the inter-wedge force P_b equilibrium of forces in horizontal and vertical direction is done ($\Sigma F_y = 0$, $\Sigma F_x = 0$) for the case when formation of tension cracks is considered.

$$\sum F_y = -W_{b1}(1-k_v) - W_{b2}(1-k_v) - q(1-k_v)de_1 + S_b \sin\theta + (N_b + P_{std})\cos\theta + P_b \sin\delta \tag{3}$$

$$\sum F_x = -W_{b1}k_h - W_{b2}k_h - k_h de_1 q - (N_b + P_{std})\sin\theta + S_b \cos\theta + P_b \cos\delta \tag{4}$$

And therefore, expression for inter-wedge force (P_b) is obtained as:

$$P_b = \frac{\sin\theta(N_b + P_{std}) - k_h(W_{b1} + W_{b2} + q\cot\theta) - S_b\cos\theta}{\cos\delta} \tag{5}$$

where $P_{stu} = \frac{1}{2}\gamma_w h_{wu}^2$ and $P_{dyu} = \frac{7}{12}\gamma_w k_h h_{wu}^2$; P_{stu}, P_{dyu} are the hydrostatic and hydrodynamic pressure on upstream side; P_{std} is hydrostatic pressure on downstream side $= \frac{1}{2}\gamma_{we} h_{wd}^2$; k_h and k_v are seismic acceleration coefficients in horizontal and vertical directions.

2.2 *Force equilibrium of wedge A*

The force diagram is exemplified in Figure 1. Present study considered wedge A as rigid for analysis and hydrostatic and hydrodynamic thrust (P_{stu} and P_{dyu}) acting on upstream side is calculated by replacing γ_{we} with the γ_w. The minimum required length of geosynthetic reinforcement L becomes L_s for direct sliding and L_o for overturning conditions, respectively.

2.3 *Depth of tension crack*

In the present analysis, vertical cracks are considered and depth of tension crack which is a part of failure is evaluated by the expression $Z_c = \frac{2c}{\gamma_{eq}\sqrt{K_a}}$, where K_a is the coefficient of lateral earth pressure [Mononobe and Okabe (1926, 1929), Kramer (1996)].

2.4 *Minimum length of reinforcement against direct sliding and overturning*

Minimum required length of geosynthetic reinforcement against direct sliding is evaluated by using driving forces and resisting forces.

$$F_r = N_a C_{ds} \tan\phi + P_{stu} \sin\beta \tag{6}$$

where N_a is calculated by $\Sigma F_y = 0$ and C_{ds} is interaction coefficient between soil and particles.

$$F_d = (qbd + W_{a1} + W_{a2})k_h + P\cos\delta + P_{dyu}\sin\beta \tag{7}$$

where $P = P_a = P_b$, and $P_{dyu} = \frac{7}{12}k_h\gamma_w h_{wu}^2$. Hence, minimum length of reinforcement is calculated corresponding to FS=1.

$$FS = \frac{F_r}{F_d} \tag{8}$$

where weight of tension crack zone is W_{a1} and remaining soil of slope is W_{a2}.

Similarly, minimum required length of geosynthetic reinforcement against overturning is evaluated by using driving and resisting moment about toe.

$$M_d = P\cos\delta\frac{H}{3} + W_{a1}k_h CG_{y1} + W_{a2}k_h((H - Z_c) + CG_{y2}) + P_{dyu}0.4\frac{h_{wu}}{\sin\beta} + k_h qHbd \tag{9}$$

$$M_r = P\sin\delta L + q(1 - k_v)bd\left(ag + \frac{bd}{2}\right) + W_{a1}(1 - k_v)CG_{x1} + P_{stu}\frac{h_{wu}}{3\sin\beta} \tag{10}$$

$$FS = \frac{M_r}{M_d} \tag{11}$$

where, $ag = H\cot\beta$; $bd = L - ag$; $Z_c = \frac{2c}{\gamma_{eq}\sqrt{K_a}}$

3 RESULT AND DISSCUSSION

Analysis for input parameters mentioned in Table 1 are carried out and results have been discussed in this section. All the computation part is done using a computer coded program in

MATLAB for evaluating the required minimum length of the reinforcement against sliding and overturning modes of failure. The optimum value of inter-wedge force P is calculated with respect to assumed failure plane which is inclined at an angle θ with the horizontal. The value of k_h varying between 0.0 - 0.2 with an interval of 0.05. Instead of direct using cohesion (c) and surcharge (q) values, normalized values $c_n = c/\gamma_{eq} H$, $q_n = q/ \gamma_{eq} H^2$ are used in the analysis.

Table 1. Input parameters used in the present analysis.

Soil Properties	Values
H	5 m
β	60˚
ϕ	30˚
$c/\gamma_{eq} H$	0.02, 0.04, 0.06, 0.08, 0.1
$q/\gamma_{eq} H^2$	0.05, 0.1, 0.15, 0.2, 0.25
k_h	0.05, 0.1, 0.15, 0.2
k_v	$k_h/2$
h_{wd}/H	0.75
h_{wu}/h_{wd}	0.75
δ/ϕ	1

Results for varying parameters with different combination to evaluate the required minimum length of the reinforcement against sliding ($L_s = l_{ds}/ H$) and overturning ($L_o = l_{ot} / H$) is obtained. The possible critical conditions are presented and compared with the previous study of Choudhury and Ahmad (2009). When c_n and q_n values are considered, the obtained results are lower than the results of Choudhury and Ahmad (2009) as shown in Figure 2.

3.1 *Effect of k_h on length of reinforcement for sliding and overturning*

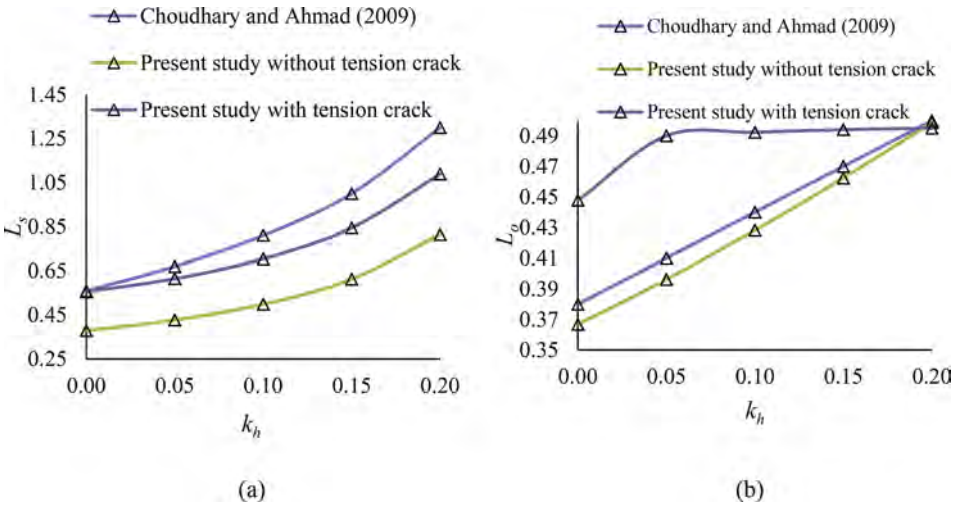

Figure 2. Variation of required minimum length of geosynthetic against (a) sliding, L_s (b) and overturning, L_o for c_n=0.06, q_n=0.15, k_v=k_h/2, β=60˚, ϕ=30˚, H=5 m, h_{wd}=0.75H, h_{wu}=0.75h_{wd}.

It can be seen from the Figures 2(a) and (b) that with increase in k_h from 0 to 0.2, the percentage increase in L_s and L_o are 53.36% and 26.48% (without tension crack), and 48.96% and 9.55% (with tension crack) respectively, for c_n=0.06 and q_n=0.15.

The value of L_s and L_o increases with the formation of tension crack due to reduce in the resisting forces. However, the percentage increase in L_s with the formation of tension crack is less as compared to the condition when there is no tension crack. Hence, for k_h value 0.2, the percentage decreases in L_s compared to Choudhury and Ahmad (2009) are 59.84% and 19.44% respectively for the conditions without tension crack and with tension crack.

3.2 *Effect of c_n and q_n on length of reinforcement for sliding and overturning*

It is observed from the Figure 3(a) and (b) that as the value of c_n and q_n increases, the length of reinforcement in sliding and overturning decreases respectively. It can be seen from Figure 3(b) for higher values of cohesion and surcharge, with increase in k_h there is negligible change in L_o.

With increases in k_h from 0 to 0.2 the percentage decreases in L_s are 55.94% and 92.32% respectively, when c_n increases from 0.02 to 0.1 for q_n is 0.05, and 34.64% and 60.59% respectively for q_n is 0.25.

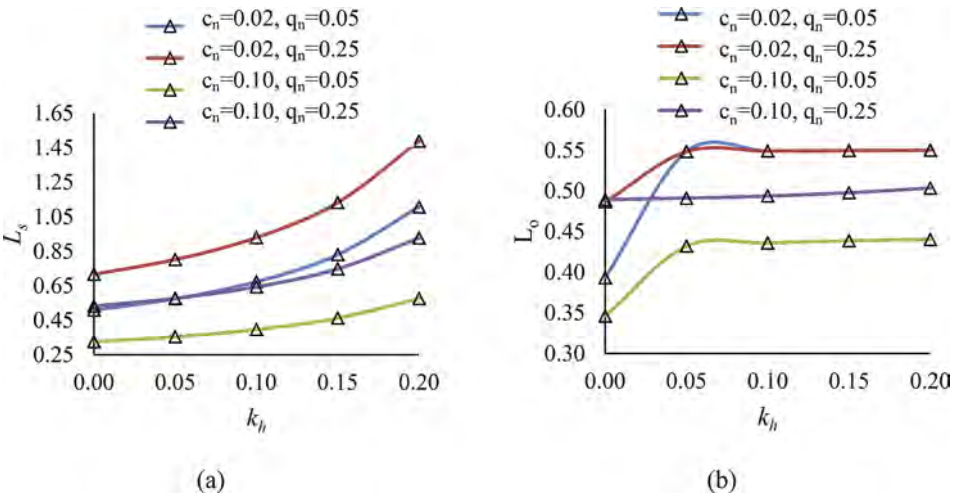

Figure 3. Variation of required length of reinforcement (a) against sliding, L_s (b) against overturning, L_o for different values of cohesion (c_n) and surcharge (q_n).

3.3 *Effect of pore water ratio on L_s*

It is observed the from results that with an increase in pore water ratio, the required length of the reinforcement against sliding and overturning modes of failure increases. However, increase in L_s with the formation of tension crack is higher than the condition when there is no tension crack. It can be observed from Table 2 that as the r_u changes from 0 to 0.4, L_s increased by 3.64% and 11.11% with tension crack, and 4.71% and 10.38% without tension crack corresponding to k_h = 0 and 0.2 respectively. An increase in k_h from 0.0 to 0.2,

Table 2. Variation of r_u over L_s for different k_h values.

	with tension crack		without tension crack	
k_h	r_u=0.0	r_u=0.4	r_u=0.0	r_u=0.4
0.0	0.55	0.57	0.36	0.40
0.05	0.60	0.63	0.41	0.45
0.10	0.69	0.72	0.48	0.52
0.15	0.83	0.86	0.58	0.64
0.20	1.06	1.11	0.77	0.85

percentage increases in L_o are 26.87%, 26.48% and 26.13% for different values of r_u, 0, 0.2 and 0.4 respectively corresponding to k_h vary from 0 to 0.2 for the condition when Z_c is zero.

4 CONCLUSION

The major conclusions that can be made from the present study are as follows:

- The required length of reinforcement against sliding and overturning depends upon the cohesion, surcharge, pore water ratio and k_h.
- As the k_h increases, the length of the reinforcement increases for given value of cohesion and surcharge. For the condition when tension crack is considered the increase in L_s is comparatively less than that of without tension crack condition.
- L_s decreased by 62.27% with increase in cohesion from 0.02 to 0.1, corresponding to k_h value is 0.05.
- for higher values of cohesion and surcharge, with increase in k_h there is negligible change in L_o.
- As the pore water ratio increases, the length of reinforcement against sliding increases for both the situations with and without formation of tension crack.

ABSTRACT: Modeling of debris flow is very challenging due to the presence of multiphase heterogeneous materials and their complex interactions. For debris flows occurring in a hilly terrain, the width of the flow channel (or gully) and the aspect ratio of the dislodged mass significantly influences the final run-out distance and velocity profile of the flowing debris. In this regard, granular column collapse studies present a simplistic approach to comprehend the intricacies of such flows. In the present study, a 3-D Discrete Element Method (DEM) based simulation of dry granular column collapse has been carried out emphasizing the effect of initial aspect ratio of collapsing mass and channel width. Additionally, the influence of side wall friction of the channel on the depositional morphology of the flowing mass has been investigated.

1 INTRODUCTION

Understanding the behavior of geophysical flows such as debris flow is vital as its occurrence leads to catastrophic influences on life and property (Iverson 2014). These flows involve complex inter-particle interactions that govern the mass movement (Lajeunesse et al. 2004). It is therefore important to model such phenomena in order to understand the flow characteristics and the associated potential extent of damage. In this regard, several attempts have been made in the past by implementing physical models and different numerical methods; however, each of these approaches have its own merits and shortcomings (Iverson 2014, Kavinkumar et al. 2021). Discrete Element Method (DEM) is an effective numerical technique used for modelling such granular flows owing to its unique feature of capturing particle-particle interactions at every time step (Utili et al. 2015; Kavinkumar et al. 2021). Moreover, granular column collapse aids in creating dry granular debris flow in a simplistic manner, which could be conducted both experimentally (Lajeunesse et al. 2004) and numerically using DEM (Utili et al. 2015).

In hilly regions, the widths of the flow channel (or gully) and the aspect ratio of the dislodged mass appreciably affects the flow behavior and the depositional morphology. Hence, it is prudent to understand the effects of these parameters on the dry granular debris flow emanating from granular column collapse. In this study, granular columns of different aspect ratios have been allowed to collapse freely under gravity on a horizontal rigid bed within the gullies

DOI: 10.1201/9781003299127-159

of different widths. Very recently, an attempt has been made by Zhang et al. (2021) to study the effect of the uniform column thickness on such granular column collapse phenomenon. Keeping parity with the practical scenarios, the present work focuses on the channel geometries in which only the gully width is varied. Further, the influence of side wall friction on the run-out distance of the flowing mass has also been explored.

2 METHODOLOGY

2.1 *Defining run-out distance and validation study*

In DEM simulations of granular column collapse, measuring the run-out distance of dry granular flows is challenging as many particles that are leading the flow, roll to very large distances and, thus, cannot be accommodated in the measurement of run-out. Attempts to define the run-out distance based on certain parameters, such as number of particles (Utili et al. 2015) and coordination number (Kavinkumar et al. 2021), are available in the literature. However, these definitions of run-out distance could not suffice for different conditions of channel bed and granular column modelled using DEM. Considering the fact that run-out is directly related to the velocity of the flowing mass, a definition for the same has been chosen in this study based on the average particle flow velocity. Run-out distance has been defined by considering the flow length within which particles have velocity lesser than 1% of maximum average particle velocity attained during the flow. Such an estimation of run-out distance has been done at a significantly larger time scale so as to incorporate majority of the flowing particles within the run-out distance.

For performing the 3-D DEM simulations, an open-source software, LIGGGHTS (DCS Computing GmbH, Linz, Austria) has been used. The results of the computations have been visualized through a post-processing software called Paraview (Kitware Inc., New York, USA). Using the chosen definition of run-out distance for DEM simulations, granular column collapse simulations over a horizontal bed has been simulated and validated against the experimental results of Shi et al. (2018). The associated model geometry details and the employed model parameters are given in Table 1. Figure 1 shows the results of the validation study. It could be observed that the run-out distance predicted from the DEM simulations agrees well with the experimental results of Shi et al. (2018).

Table 1. Micro-mechanical properties and granular column geometry details considered while validating with the results of Shi et al. (2018).

Parameters/Properties used in validation study	Values
Micro-mechanical properties:	
Particle diameter (d) (m)	0.0021
Particle density (ρ) (kg/m^3)	2700
Modulus of Elasticity of particles (E) (N/m^2)	5×10^6
Coefficient of friction for interaction between column particles (μ)	0.7
Coefficient of friction for particle-wall and particle-gate interactions (μ')	0.424
Coefficient of rolling friction (μ_r)	1.25
Poisson's Ratio (v)	0.31
Coefficient of Restitution (e)	0.7
Packing porosity of the column (n)	0.43
Contact Model used	Hertz tangential history (H – MD) with rolling friction constant directional torque (CDT)
Granular column geometry details:	
Column width (m)	0.05
Column height (m)	0.05
Column thickness (m)	0.09

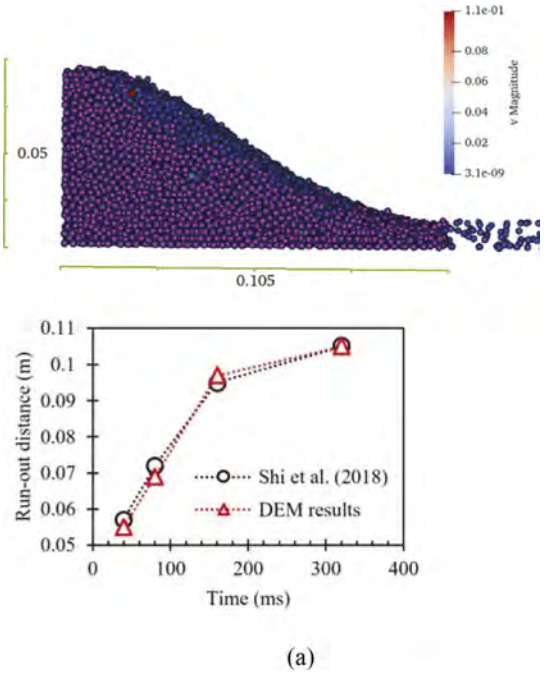

Figure 1. Validation of the experimental results of Shi et al. (2018) using DEM.

2.2 *Model geometry for flow path configuration*

For understanding the effects of gully width on the debris flow behavior using DEM, the particles in the granular column are allowed to flow through a trapezoidal (hopper shaped) channel (Figure 2) before entering the main constricted gully (of uniform width) so as to direct the entire granular mass within the gully. Such a flow path is generally encountered in hilly terrain by the dislodged mass and the same scenario has been mimicked though the chosen geometry condition. The micro-mechanical parameters and other relevant geometry configurations used in this set of DEM simulations are given in Table 2.

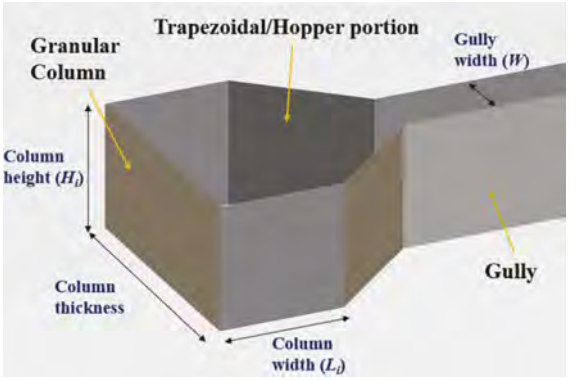

Figure 2. The hopper/trapezoidal channel configuration employed for conveying the initial granular column into the constricted gully.

2.3 *Simulation of flow process*

In this study, four different aspect ratios (a) of the granular column have been taken, i.e., 1, 2.8, 4.6 and 6.4. The particles have been first inserted within the column (rectangular) and then the confining gate has been removed instantaneously to initiate the flow. The granular particles of the collapsing column have been allowed to flow over a frictional planar horizontal bed. In order to carry out effective comparisons, the simulation output parameters have been normalized as per Eq. 1. The width of the gully (W) has been normalized with respect to the particle diameter (d) as given in Table 1.

$$[L] = L_f - L_i/L_i \tag{1a}$$

$$[H] = H_f/L_i \tag{1b}$$

$$[V] = V/\sqrt{gH_i} \tag{1c}$$

$$[T] = T_f/\sqrt{H_i/g} \tag{1d}$$

where L_f is the final run-out distance; L_i is the initial column width; $[L]$ is normalized run-out distance; H_f is the residual column height, i.e., the height of the particles of the column in the final deposited state after the collapse; H_i is the initial column height; $[H]$ is the normalized residual column height; V is the flow velocity; $[V]$ is the normalized flow velocity; T_f is the duration of flow; and $[T]$ is the normalized duration of flow.

Table 2. Micro-mechanical properties and specifications of model geometry considered for DEM simulations of granular column collapse and flow through gully.

Parameters/Properties	Values
Micro-mechanical properties:	
Particle diameter (d) (m)	0.006
Particle density (ρ) (kg/m^3)	2700
Modulus of Elasticity of particles (E) (N/m^2)	5×10^7
Coefficient of friction for interaction between column particles (μ)	0.6 (same for the side walls and gate)
Poisson's Ratio (v)	0.3
Coefficient of Restitution (e)	0.7
Packing porosity in the column (n)	0.43
Contact Model used	Hertz tangential history (H – MD)
Specifications for granular column collapse model:	
Column width (L_i) (m)	0.06
Column thickness (m)	0.12
Aspect ratio ($a = H_i/L_i$)	1, 2.8, 4.6, 6.4
Specifications for trapezoidal channel and gully:	
Length of the trapezoidal/hopper region (m)	0.05
Channel/gully width (W) (m)	0.09, 0.06, 0.03
Normalization of the channel/gully width with respect to particle diameter:	
Normalized channel/gully width (W/d)	5, 10, 15

3 RESULTS AND DISCUSSION

3.1 *Variation in run-out distance with gully width and aspect ratio*

Dry granular debris flow behavior has been studied for different gully widths (W/d) using granular columns of different aspect ratios (a). Particle configuration in the final deposited state of the collapsed granular column is shown in Figure 3. For the sake of brevity, the depositional configurations are depicted only for a = 2.8. Similar particle configurations have

been obtained for other aspect ratios as well. Figure 4 represents the variation in run-out distance with respect to W/d and a. It can be observed that as the gully width increases, the run-out distance increases for all values of a. This indicates that a wider gully increases the reach of disastrous geophysical flows. Moreover, the run-out distance of the flow increases with the increase in the value of a. Hence, the aspect ratio of dislodged mass can significantly influence its flowing distance and reach. Interestingly, it could be observed that the influence of gully width on run-out distance is more prominent for larger aspect ratios.

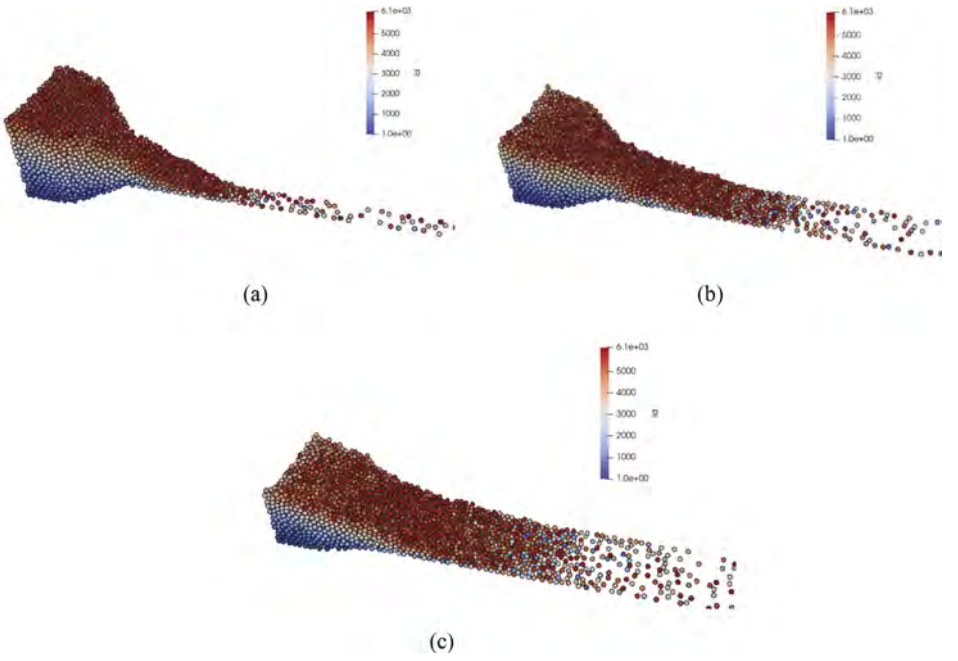

Figure 3. Particle configuration in the final deposit of the collapsed granular column for (a) W/d = 5, (b) W/d = 10 and (c) W/d = 15 for a = 2.8 (color contour shows the particle number).

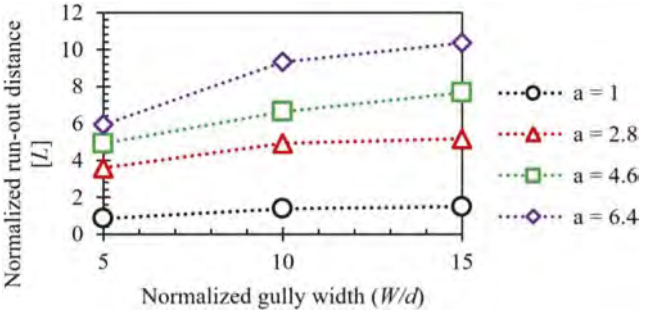

Figure 4. Variation of the normalized runout length [L] with normalized gully width (W/d) for different aspect ratios (a) of the column.

Figure 5 shows the variation in residual column height with W/d and a. It could be inferred that as the gully width increases, the residual column height decreases due to increase in the free movement of the particles. Moreover, residual column height increases with the increase in the value of a, indicating that higher aspect ratios could yield thicker deposits. Similar to the previous observation on run-out distance, residual column height for larger aspect ratios is more affected by gully width variation.

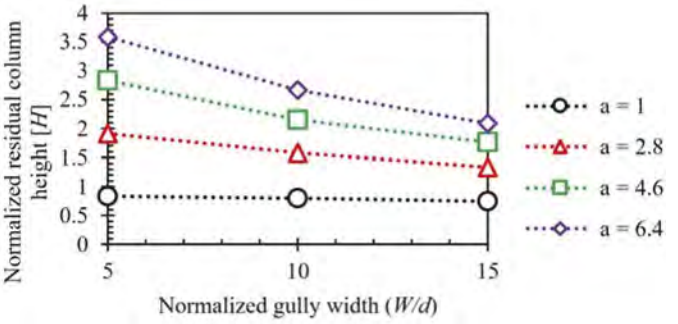

Figure 5. Variation of the normalized residual column height [H] with normalized gully width (W/d) for different aspect ratios (a) of the column.

3.2 *Variation in velocity profile with gully width and aspect ratio*

Figure 6 shows the velocity profiles of flow for different values of W/d and a. These velocity profiles are the plots of average particle velocity (V) with respect to the flow duration (T). Average particle velocity has been obtained by averaging the velocity magnitudes of all the particles at each time step. It could be observed from Figure 6 that as the gully becomes wider, the average velocity of the particles increases for each of the aspect ratios. A direct implication of this behavior is reflected by an increased run-out distance in wider gullies. To investigate the effect of aspect ratio on flow velocity, the variation in maximum of average particle velocity (V_{max}) has been plotted with respect to a for different values of W/d as shown in Figure 7. It could be noticed that as the value of a increases, V_{max} also increases for all gully widths. This implies that

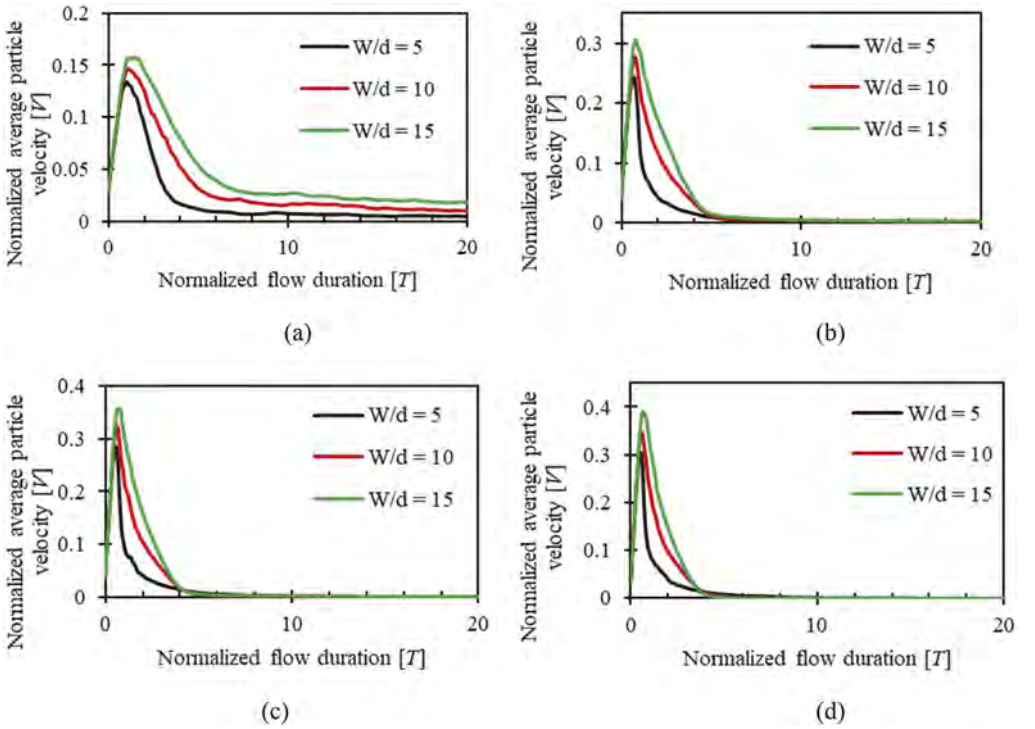

Figure 6. Velocity profiles of the dry granular debris flow represented as variation of normalized average particle velocity [V] with normalized flow duration [T] for (a) a = 1, (b) a = 2.8, (c) a = 4.6 and (d) a = 6.4 at different values of W/d.

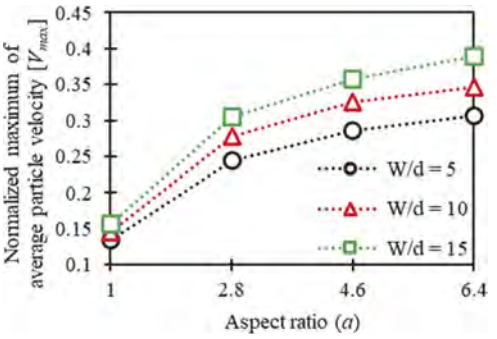

Figure 7. Variation of normalized maximum of average particle velocity [V_{max}] with aspect ratio (a) of the column for different normalized gully widths (W/d).

with the increase in the aspect ratio of the granular column, its initial total energy increases which causes higher kinetic energy and leads to higher velocity as the flow progresses.

Figure 8 depicts the variation of bulk (average) coordination number ($\bar{C}$) of the particles with respect to flow duration (T). $\bar{C}$ represents the average number of particles which are in contact with any specific particle within the flowing mass. It could be observed that as the gully width increases, the bulk coordination number decreases for each of the aspect ratios. This means that as the gully becomes wider, each of the particles have lesser number of neighboring particles in contact and, hence, such particles are more disconnected, thereby leading to an enhanced free movement. The initial sharp reduction in the values of bulk coordination number reaching a trough is related to the attaining of maximum particle velocity (and/or maximum kinetic energy). Therefore, a decrease in the bulk coordination number with the increase in gully width indicates a simultaneous increase in the value of the velocity of the particles, as apparent from Figure 7. On the other hand, for a particular aspect ratio, lesser residual values of the bulk coordination number for higher values of W/d qualitatively indicates larger run-out distances.

Additionally, with the increase in the value of a, the minimum bulk coordination number attained decreases, thereby indicating large particle velocities for higher aspect ratios. Similar observations regarding the effect of aspect ratio on bulk coordination number have been reported by Kavinkumar et al. (2021). However, the bulk coordination number is greatly affected by the initial mass or initial number of particles in the granular column. This is apparent from the fact that the residual values are getting closer for different gully widths as the magnitude of a increases (i.e. initial number of particles in the column increases). Contrary to this behavior of residual values of bulk coordination number which represent the reach of the flow, larger aspect ratios have shown prominent variation in the values of run-out distance based on different gully widths (Figure 4). Hence, it is not wise to correlate the variation in the bulk coordination number quantitatively with the variation in the velocity or run-out distance, especially, when the comparison is done for different aspect ratios having different initial number of particles within the column. Furthermore, the observations made by Zhang et al. (2021), showcasing the relation between particle velocity and bulk coordination number for different thicknesses of the granular column, are not in parity with the findings of this study for different gully widths. This is attributed to the reason that for a particular aspect ratio, the initial number of particles in the column remains the same for each of the gully width considered in the present study; whereas, this is not the case with the increase in column thickness as reported by Zhang et al. (2021).

Figure 9 Shows the plots of total dissipated energy (E_{diss}) with respect to a for different values of W/d. E_{diss} is calculated according to Utili et al. (2015) as mentioned in Eq. 2.

$$E_{diss}=E_0-E_p-E_k \tag{2a}$$

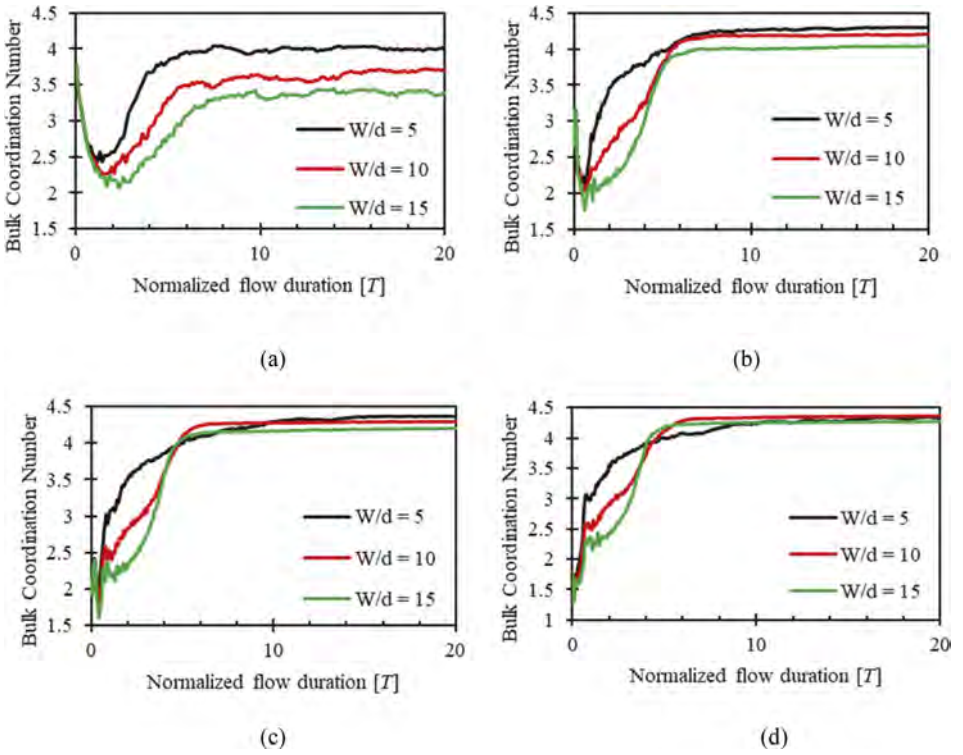

Figure 8. Plots of bulk coordination number ($\bar{C}$) with respect to normalized flow duration [T] for (a) $a = 1$, (b) $a = 2.8$, (c) $a = 4.6$ and (d) $a = 6.4$ at different values of W/d.

$$E_0 = mgH_i/2 \tag{2b}$$

where E_0 is the initial total energy of the column calculated as per Eq. 2b; m is the total mass of particles inside the column; E_p and E_k are the total potential energy and the total kinetic energy, respectively, at the end of the flow. It could be observed that the total dissipated energy (E_{diss}) increases with an increase in the gully width. This is due to the reason that as the gully becomes wider, owing to enhanced free movement of particles, there is a significant increase in particle-particle collisions along with their interactions with the bed and the side walls. This leads to larger energy dissipation. The same is true for the increase in the value of a as well.

3.3 *Effects of side wall friction, coefficient of restitution and rolling friction on the run-out distance*

The depositional morphology of the dry granular debris flow is also governed by the friction of side walls of the gully in hilly terrain. In order to investigate the effect of side wall friction on the depositional behavior of flow emanating from granular column collapse using DEM, four different values of friction coefficient have been chosen, i.e., 0, 0.2, 0.4 and 0.6. The same has been visualized for all the considered gully widths. However, for brevity, only two extreme aspect ratios, i.e., $a = 1$ and $a = 6.4$ are considered in this study. Figure 10 shows the variation in run-out distance and residual column height with respect to the side wall friction coefficient for the chosen cases.

It could be observed from Figure 10 that, for all the gully widths, as the coefficient of side wall friction increases, there is a reduction in the run-out distance with an augmentation in the residual column height. However, such a variation is noted to be more pronounced for $a = 6.4$ than that observed for $a = 1$. This indicates that the effect of side wall friction of the gully on the

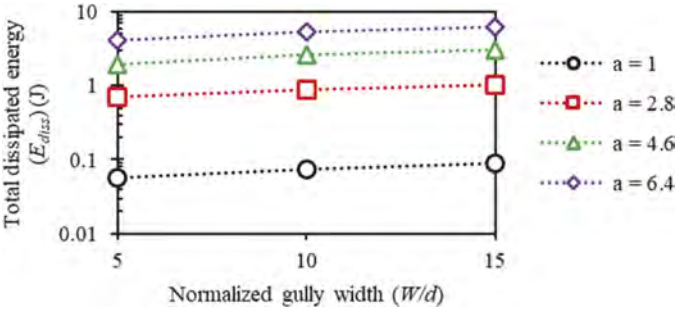

Figure 9. Variation of total dissipated energy (E_{diss}) with normalized gully width (W/d) for different aspect ratios (a) of the column.

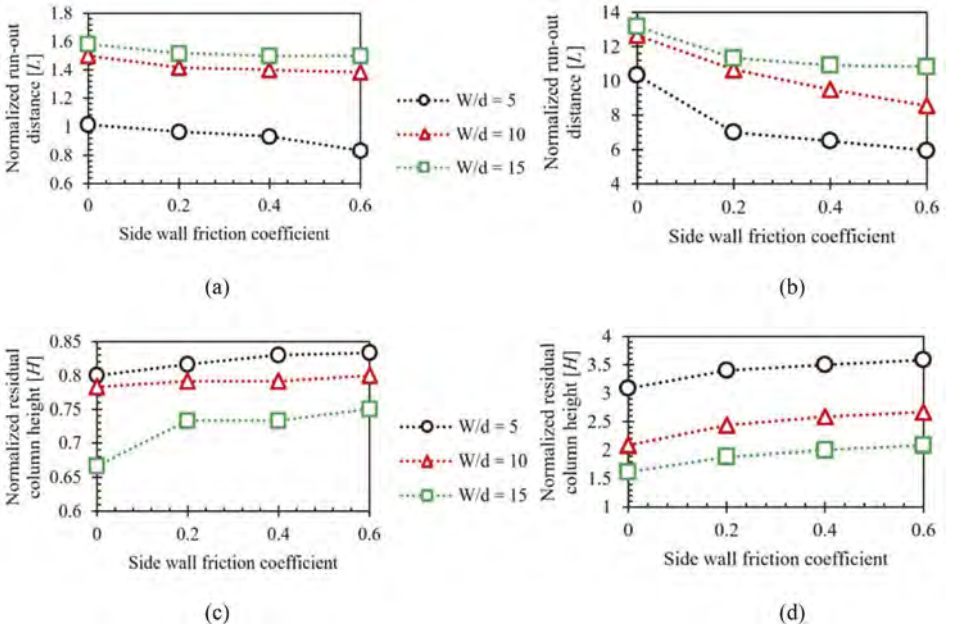

Figure 10. Variation in the values of normalized run-out distance [L] and normalized residual column height [H] for (a, c) a = 1 and (b, d) a = 6.4, respectively with side wall friction coefficient for different values of W/d.

depositional morphology of the collapsing mass is significantly influenced by its initial aspect ratio. Moreover, it is apparent that as the gully becomes wider, the effect of side wall friction on the run-out distance becomes lesser for both the aspect ratios considered in the present study.

4 CONCLUSIONS

Dry granular debris flows in hilly terrains are expected to propagate through gullies of constricted widths which can in turn affect their flowing behavior and depositional morphology. In this study, the influence of gully width has been studied for the flows emanating from dry granular column collapse using DEM. Additionally, the effects of initial aspect ratio of the column on the velocity profile and deposition characteristics of such flows have also been examined. It has been found that as the gully becomes wider, the run-out distance of the flow increases and the residual column height reduces. The obtained velocity profiles show that the

particle flow velocity increases for wider gullies and for larger aspect ratios of the granular column. Similar inferences could also be made on the basis of the variations in bulk coordination number. Moreover, the total dissipated energy during the flow increased with the increase in gully width and aspect ratio of the column. Hence, it could be concluded that larger is the aspect ratio of the dislodged mass and more is the width of the flow channel or gully, larger would be the reach of the flowing particles. Side wall friction of the gully also influences the deposition behavior of the dry granular debris flows, especially those originating from columns of larger aspect ratios. Apparently, wider gullies have lesser effect of side wall friction on the run-out distance.

Classification of zero-order basins on the basis of valley development and risk assessment of sediment runoff

N. Nakajima
Chiken Co., Ltd, Kochi City, Kochi Prefecture, Japan

T. Hara
Kochi University Kochi City, Kochi Prefecture, Japan

ABSTRACT: In Japan, sediment runoff at zero-order basins has become a serious issue from the viewpoint of disaster prevention and mitigation. Our urgent task is establishing an effective and integrated method of assessing its risk. This study analyzes topographical characteristics of zero-order basins in the actually affected three areas. We show sediment runoff is closely related to valley development and figure out the possibility of assessing the risk at differently featured zero-order basins by categorizing them into four classes; Youth, Adolescent, Mature and Old, and only by measuring their total length.

1 INTRODUCTION

With recent worldwide climate changes progressing, Japan has experienced frequent intensive heavy rains and has been affected by increasing number of sediment disasters annually. To combat these disasters, various countermeasures are now being applied both tangibly (such as debris barriers) and intangibly (such as designating warning zones and informing the residents of them). Of late, sediment runoff from small basins at steep slopes are emerging as new problems. Such sediment disasters cause damages to buildings or cut off roads although they are local and of small scales. Extracting these risky basins is an urgent issue in discussing the countermeasures for them. These small basins are defined as zero-order basins, smaller by one order then first-order basins by Horton-Strahler scales (Tsukamoto et al., 1973). By the Basic Guideline about debris flows (Ministry of Land, Infrastructure, Transport and Tourism, 2016) zero-order basins are defined as a place which has a concave contour line with the ratio of valley frontage width to depth, one to less than one.

Some experts have suggested the methods for extracting dangerous spots at steep slopes including zero-order basins. Kanai et al. (2016) suggested the method for extracting dangerous spots by studying the gradient of slopes and the depth of loose sediment layers. Shirasawa et al. (2018), by using DEM. Kinoshita et al. (2019), by focusing on the number of basins at a specific slope. Murakami (2016) in his site investigation estimated the volume of sediment flows at dangerous basins including zero-order basins and presented the method to extract dangerous basins that would cause damage to high-ways. Their studies are about assessing the possibility of slope failure and the resulting damage but not about assessing the danger of sediment runoff and the volume of its damage in a simple and integrated way.

We organized the data of the topography geological features and the scale of damage at the zero-order basins affected in the incident of Heavy Rain, July 2018 and discussed the extracting methods of dangerous basins. (Nakajima et al., 2019) In this study we tried to categorize zero-order basins focusing on the relation between the topography of the basins and the volume of sediment runoff. We tried to get the rough risk assessment method at zero-order basins by combining this result with the volume of damage.

DOI: 10.1201/9781003299127-160

2 SAMPLE LOCATIONS AND ANALYSIS METHOD

Three locations studied in this study are shown in Figure 1. These locations are situated in Chugoku and Shikoku and affected by the Heavy Rain in July 2018. Tachibanaura, Otsuki-cho, Hata-gun, Kochi is 36km northwest from Ashizuri Cape at the east end of Kochi and has a 530m-wide slope facing east with 6 zero-order basins. Shiraura, Yoshida-cho, Uwajima-City, Ehime is situated 55km north from above mentioned Tachibanaura, and has 370m-wide slope facing north with 14 zero-order basins. Yasuura, Kure-City, Hiroshima is situated 165km north from Tachibanaura and has 520m-wide slope with 8 zero-order basins. Sediment disasters occurred at three basins in Tachibanaura, four in Shiraura and three in Yasuura. In all three locations, the roads were temporarily blocked and building damage was confirmed in Tachibanaura.

We adopted topographical analysis in analyzing, figuring out the average slope gradient adding to total valley length and b/a as in Figure 2. Valley total length is the range with contour lines situated above flat place with houses. The ratio b/a is measured in every specific from 5 to 10m height. The average slope angle is measured using the total valley length and the difference in elevation between the two ends. For topographical analysis we used Sabo Fundamental Geospatial Data prepared before the disaster and a topographical map based on Aerial laser data. We conducted a field survey, checking visually the valley slopes and the source head in the zero-order basins. Three years had passed before our field survey but still evident were the failure and erosion in the zero-order basins. We recognized the damage situation through interviews with the local people and by the aerial photomaps taken just after the disaster. In this study, we defined the surface failure on the source head as failure, the sediment flow reaching the road or the houses at the foot of the slope as sediment runoff, the sediment accumulating at the end of the slope as runoff sediment.

3 CLASSIFICATION OF ZERO-ORDER-BASINS ON THE BASIS OF THE STATE OF DEVELOPMENT

The data of topographical features were gathered from 28 zero-order basins distributed in these three areas. The narrow slopes, even under the same condition of rainfall showed different damage situation, different total valley length and different b/a. Total valley length and estimated amount of runoff sediment are shown in Figure 3. Although our analysis is limited, we found out the estimated runoff sediment increases as the total valley length become longer. In the case of the zero-order basin longer than 80m, sediment runoff begins to be seen, and runoff sediment amount show a sudden big increase when it becomes longer than 200m. It isn't always the case, but the amount of runoff sediment and total valley length are related to some extent. The total valley length is one of the factors influencing the amount of runoff sediment. We classified the development process of zero-order basins according to the total valley length. Table 1 shows a relation between the classified topographical features and the estimated amount of runoff sediment. Zero-order basins are classified into four, in length order, Youth, Adolescent, Maturity and Old. The zero-order basin classified as Old has a low average slope angle of 22 degrees and has no sediment runoff though it has the biggest length of 451m.

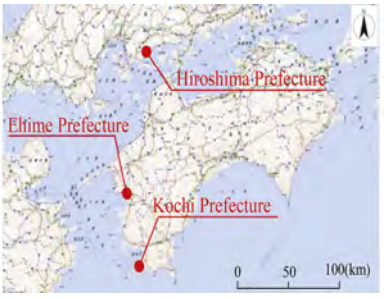

Figure 1. Survey position.

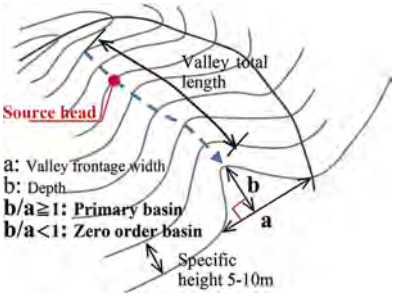

Figure 2. Topography and interpretation schematic of the zero-order basin.

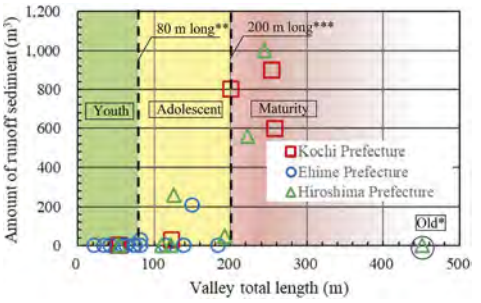

Figure 3. Total length of the valley and amount of runoff sediment.

*Average valley slope is 22 degrees. **Line where sediment outflow begins. ***Line where the amount of runoff sediment increases.

Table 1. Development classification and topographical features of the zero-order basin.

Development classification	Valley total length (m)	Maximum b/a	Valley slope (°)	Amount of runoff sediment* (m^3)
Youth	~ 80	~0.2	35~	0
Adolescent	80 ~ 200	0.2 ~0.4	30~34	0 ~ 500
Maturity	200 ~ 450	0.4 ~	25~29	500 ~ 1000
Old	450 ~		~24	0

* It was calculated by measuring the sedimentary layer thickness and range from field surveys and aerial photographs.

4 DETAILED CLASSIFICATION AND RISK ASSESSMENT

Sediment runoff at zero-order basins occurred by collapse triggered by heavy rain. Collapse of zero-order basins are caused when rainwater from above flow into a valley and the slope becomes unstable. Zero-order basins at steep slopes are narrow and can hold limited amount of water. On the other hand, the valleys at gentle and stable slopes don't collapse. Zero-order basin situated at such a gentle slope with almost no factor of slope failure is classified as Old.

Table 2 is about the relation between the total valley length and estimated amount of runoff sediment and about the possibility of damage to the social infrastructure. Youth is a zero-order basin with the length of under 80m and has no sediment runoff. It is a steep slope with small maximum b/a and in the stage of birth. The valley is slightly lower than the land at both sides. The slope and the trace of streams around here are scattered with protruding bedrocks. Bedrocks are hard to erode, and long time is needed before such places grow to the condition of causing sediment runoff. Adolescent is a zero-order basin with the length of from 80 to 200m and has a possibility of sediment runoff. They are visible valleys from 1 to 2m-wide. Maturity is a zero-order basin with the total length of longer than 200m and has high possibility of sediment runoff, possibly with much amount of runoff sediment. They are over 2m wide. Both sides are fiercely eroded, which is the evidence of a large amount of sediment runoff.

Table 2. Development classification and disaster risk.

Development classification	Valley total length (m)	Amount of runoff sediment (m^3)	Possibility of damage*
Youth	~ 80	0	Low
Adolescent	80 ~ 200	0 ~ 500	High
Maturity	200 ~ 450	500 ~ 1000	Very high
Old	450 ~	0	Low

* Damage means disruption of roads or damage to houses.

Adolescent disaster cases and Maturity disaster cases and the situation of Old are shown in Figure 4. In Adolescent, there was a case of practical road damage and debris flow on the protection net. In Maturity, cases of road disruption and building damage. To summarize Table 2, the possibility of damage is high in Adolescent and higher in Maturity.

Figure 4. Situation of the zeroth basin. a: Adolescent disaster cases. b: Maturity disaster cases. c: Old situation.

5 CONCLUSIONS

As a result of our survey on the slopes affected by Heavy rain in July 2018, we obtained the knowledge below about the risk assessment of zero-order basins. i) Total valley length is a very important factor about the risk assessment of zero-order basins. Sediment runoff is seen in zero-order basins with the total length of over 80m and the volume of sediment greatly increases in zero-order basins with the total length of over 200m. ii) Zero-order basins are classified into four classes on the basis of the total valley length. Adolescent and Maturity have a high risk of sediment runoff damage with the houses damaged and the roads cut off. iii) The factor crucial for risk assessment is total valley length, which is easily computed on the desk. Sabo Fundamental Data and Aerial Survey Data, which are necessary for computing, are now being organized nationwide. Speedy risk assessment is thus possible for wider areas.

The risk assessment we suggested this time is a rough method conducted in limited three areas. To brush up extracting methods, further site investigation and analysis is essential.

ABSTRACT: Traditional methods to mitigate landslide disasters often have the shortcomings of high cost or high energy consumption, therefore Early Warning System (EWS) is considered a practical approach in a cost-effective manner. This research proposes an EWS with various sensors and a wireless operating platform for data collection, transmission, and analysis based on Internet of Things (IoT). The EWS setup is supported by an off-grid solar photovoltaic system that can ensure one week of operating without any sunshine. The study presents the design, and development of EWS and conducts a case analysis of typical sandy slopes to confirm the feasibility of the system. Experimental validations prove that the EWS could effectively predict the risk and send warning notifications. Research guarantees the accuracy of the EWS while operating in a low-cost and sustainable manner. Therefore, the newly developed EWS can be put into use in both developed and developing countries.

1 INTRODUCTION

All over the world, the risk of landslide disasters due to frequent rainfall is increasing in mountainous regions. Various methods are continuously being studied and implemented to mitigate rainfall-induced disasters (Hazarika et al. 2016). There are four typical methods as follows: (1) hard type measures by piles or reinforcement material; (2) numerical simulation methods such as *FEM* or *SPH*, (3) statistical or probabilistic method*s*; (4) large-scale monitoring system like *InSAR* and *GNSS*. Soft type approaches such as IoT-based early warning systems (EWS) are also becoming increasingly popular. The evaluation of different methods mainly considers the following points: (1) a good reinforcement effect; (2) a good predictability to carry out evacuations before disasters; (3) easy to operate even without professional skills; (4) good economics to reduce development costs; (5) sustainable enough to reduce energy dependence and environmental damage. Figure 1 shows the effectiveness evaluation results of various methods, in which a larger evaluation value represents a better effect. It can be found that different methods have different advantages. For example, hard type measures can protect slopes, but sometimes may not be economical. The statistical method and the numerical method are very cost-effective, but they are less predictable. After comparing various methods, this study found that the IoT-based EWS with some portable sensors is a practical approach, which can be cost-effective and sustainable (Kanaya et al. 2016; Liu et al. 2021).

DOI: 10.1201/9781003299127-161

Although many researchers are trying to develop EWS, those systems still suffer from cost-benefit, sustainability, and predictive accuracy. To address the shortcomings of the current EWS, the proposed IoT-based EWS will provide an operational platform for comprehensive data storage and analysis. To accurately capture the movement of the soil, the computer vision–based device is also incorporated into the EWS. Additionally, the entire system will be powered by an off-grid solar photovoltaic system to make the operation sustainable. A model test was conducted to check the feasibility of the proposed EWS. This research will be able to provide a cost-effective and sustainable EWS, which can be implemented in all countries of the world.

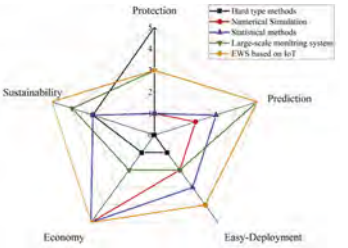

Figure 1. Effectiveness evaluation of various disaster reduction methods.

2 PROPOSED EARLY WARNING SYSTEM

2.1 *Schematic of EWS*

As shown in Figure 2, the proposed IoT-based EWS intends to provide an operational platform for comprehensive data storage and quantitative analysis. Data collected from embedded sensors such as soil moisture sensors and pore water pressure sensors are used to determine the degree of rainwater infiltration and change in the groundwater table, and data from 3D accelerometers are utilized to measure the deflection angle. Real-time images from Raspberry Pi with digital cameras are used to determine landslide time and track the displacement of the monitoring points by motion analysis. A sustainable solar panel is used to power the entire system. All the data can be stored in the cloud and operators can monitor the system remotely. Furthermore, once the monitoring parameters reach predetermined threshold limits, the system sends warning signals.

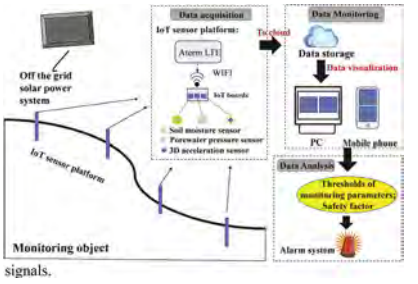

Figure 2. Schematic diagram of EWS.

2.2 *The determination method of threshold*

In this research, these threshold limits depict the transition of slope in each state: Monitoring state, Alert state and Triggering state (Liu et al. 2021). The threshold limits are based on four key soil indices: soil moisture content, pore-water pressure, slope deflection angle, and factor of safety (F_s). Initially, the threshold limits of warning indices are set into the system, which is determined by the type of soil and the terrain of the slope. The current research uses the following thresholds: 1. Soil moisture thresholds M_{c_t1} and M_{c_t2}, which represent the critical stable value of sandy slope before saturation and saturated volumetric moisture content respectively; 2. Pore-water pressure thresholds: P_{w_t1} and P_{w_t2}, P_{w_t1} is the state when the

pore-water pressure is first captured, which is generally 0-0.1 kPa, P_{w_t2} is the critical value before landslide; 3. Small deflection angle thresholds D_{t1} and big deflection angle thresholds D_{t2} before landslide; 4. The threshold of F_s is usually 1, and the slope is in danger state when F_s <1. F_s was obtained from the improved equation based on (Lu et al. 2012). These thresholds help the system in sending warning signals to residents and the concerned authorities for evacuation much ahead of the actual triggering of the landslide.

3 MODEL TEST SETUP AND SENSOR LAYOUT

A laboratory-scale slope model is prepared in a transparent, lucite box to evaluate the performance of the EWS under varying rainfall intensity conditions (Figure 3). The base layer height of the model is 100 mm, while the height of the sloped section is 350 mm. An artificial rainfall simulator is built using pipes with sprinkler nozzles along with a flowmeter to control rainfall intensities. To obtain the soil moisture distribution, 6 soil moisture sensors (S1-S6) are distributed in different parts of the slope, 3 porewater pressure sensors (P1-P3) are located at the bottom to map the movement of the groundwater table and 4 acceleration sensors (M1-M4) are arranged along the slope surface to capture the shallow deflection angles of the slope while movement. Two cameras are placed on the front and side of the model to monitor particle movement.

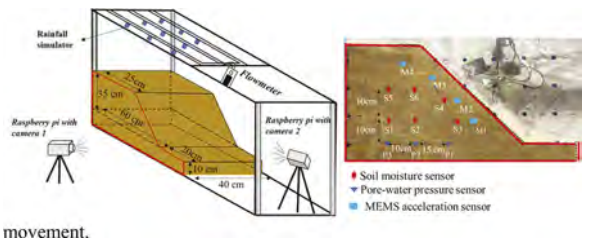

Figure 3. Model test set-up and sensor layout.

4 RESULT AND DISCUSSION

Based on the observations, it can be ascertained that before the rection of the porewater pressure sensor, the soil moisture increases to M_{C_t1}, then keeps stable. After this stage, the slope will gradually become a saturated state (M_{C_t2}) due to the rise of the groundwater table, and the deflection angle will be monitored by 3D acceleration sensors before the landslide. Thresholds generally appear in the following order: M_{C_t1}, P_{w_t1}, M_{C_t2}, P_{w_t2}, D_{t1}, F_{s_t} and D_{t2}. The test result is consistent with the threshold setting principle proposed in this study.

The responses of the pore water pressure sensor, the soil moisture sensor, the acceleration sensors are recorded and plotted against the time and compared simultaneously with the factor of safety (F_s) to evaluate the performance of the system under a rainfall intensity of 70 mm/h. It can be seen in Figure 4 that after the initial landslide, the displacement will accumulate rapidly, and multiple landslides will occur in a short period to the final deep landslide. It only takes 7 mins from the 3rd signal to landslide for rainfall intensity of 70 mm/h. Therefore, it is necessary to start the evacuation in dangerous areas after the first signal is issued, and the transfer work of personnel and assets is completed when the second signal is issued. Using particle tracking technology, the position of the points in any time period can be obtained easily and displacement can be calculated by the distance from the initial position point. The time of each shallow landslide is 82min, 91min and 98min. The motion velocity of the particle at three different landslides is shown in Figure 5 from the analysis of Particle Image Velocimetry. It can be seen clearly that at the time of the three landslides, the motion velocity of the particles is mainly concentrated near the sliding surface, which is also consistent with the observed sliding area of the slope. The maximum velocity of the monitoring point in the slope is 0.188mm/s and the displacement of the monitoring point reached 240 mm.

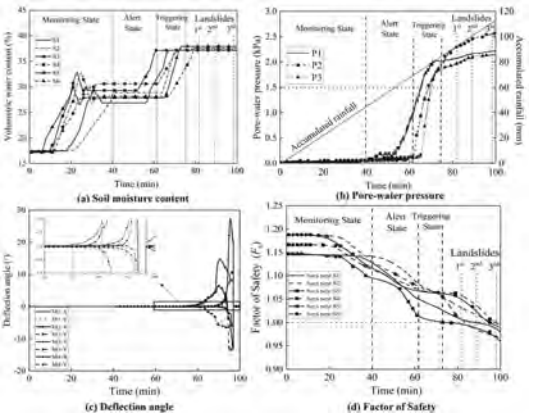

Figure 4. Monitoring results under rainfall intensity 70 mm/h.

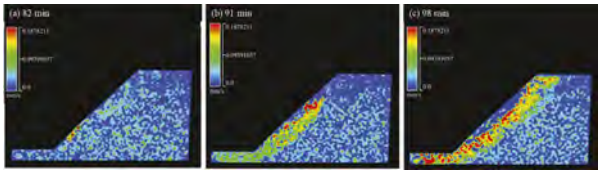

Figure 5. Result of PIV analysis under rainfall intensity 70 mm/h.

5 CONCLUSIONS

The architecture, operation and validation of the newly developed EWS are discussed in this paper. This EWS can monitor the soil moisture content and pore water pressure, track the ground deformation and provide real-time F_s during the rainfall. The application of IoT and solar battery systems enables the proposed EWS to operate cost-effectively and sustainably. Experimental validations prove that the EWS could effectively predict the risk and send warning notifications. The system can robustly predict the triggering of the landslide and provide warnings in advance at monitoring and alert state before the triggering state, thereby helping in saving numerous lives from rainfall-induced landslides disaster. This study also presents how IoT-based EWS can forge new paths for interdisciplinary study and generate a positive impact on disaster mitigation work.

Centrifuge modeling of failure of structured soil slope under water level fluctuation

Zhuona Ma & Ga Zhang
State Key Laboratory of Hydroscience and Engineering, Tsinghua University, China

ABSTRACT: Natural soil slopes have been caused to failure by water-level fluctuation. The structure of natural soil has a significant effect on the failure behavior of the slope. Therefore, centrifuge model tests were conducted to investigate the deformation and failure of structured soil slope under water-level fluctuation. The artificially structured soil is produced by adding cement into the silty clay and its strength behavior is determined by direct shear tests. The centrifuge model test results show that water-level fluctuation induces a shear failure in the structured soil slope with two deep slip surfaces that develops from the top to the bottom. The failure mechanism is revealed via the deformation localization analysis based on the measurement of full-field displacement of the slope. The water-level fluctuation is discovered to induce significant deformation localization and the localization develops into a local failure there.

1 INTRODUCTION

Natural soil slopes near reservoirs have always been caused to failure by water-level fluctuation. Most natural soils have structure in microscopic view, which refers to the arrangement and bonding of soil particles. Such a structure has a significant effect on the behavior of the natural soil and leads to deformation and failure of natural soil slopes different from remolded soil slopes. Reasonable safety assessment of natural soil slopes under water-level fluctuation is of great value.

Adding cement into silty clay to produce artificially structured soils is a common used method to simulate natural soils at present (Liu et al. 2018). Centrifuge model tests have been widely used to simulate the deformation and failure behavior of the slopes considering different conditions. (Zhang et al. 2011; Chen et al. 2018). Li et al.(2008) used centrifuge tests to analyze slope instability induced by water rise and fall, demonstrating that such water conditions gradually leads to strength reduction and therein induces large slope deformation. The centrifuge model test results revealed that the rise of the outside water level causes obvious collapse deformation inside the slope, and the drawdown of outside water level results in shallow multi-landslide(Yang et al. 2013). Miao et al.(2018) discovered through centrifuge model tests that the deformation and failure of the slope are mainly caused by the dynamic water pressure effect.

Most of centrifuge model tests were conducted on the remolded soil slopes under water-level fluctuation. However, natural slopes are often made of structured soil that exhibits different behavior from the remolded soil. Thus, in this paper, centrifuge model tests were conducted to observe the deformation and failure of the structured soil slope under water-level fluctuation. The deformation behavior and failure mechanism of the slope are investigated based on the full-field displacement measurement results.

2 TEST

2.1 *Devices*

The centrifuge model tests are carried out on the centrifuge at Tsinghua University with a maximum capacity of 50g-ton and acceleration of 250 g. The model container with

DOI: 10.1201/9781003299127-162

a length of 500 mm, a width of 200 mm, and a height of 350 mm is used in the test. It is equipped with transparent organic glass on the lateral side to observe the deformation and failure of the slope during the test.

A water simulator device is used to simulate water-level fluctuation during the centrifuge test (Luo and Zhang 2018). The device can be used to control water inflow and outflow and monitor water level change through pore water pressure sensors at the bottom of the container. In this way, the water level can be controlled and maintained during the test.

2.2 *Model*

A type of artificially structured soil with 1% cement content is used in the test. A type of silty clay, with a plastic limit of 18.5% and a liquid limit of 25%, is used for structured soil preparation. The specific gravity of the soil is 2.7.

The preparation process is to mix silty clay and cement after fully crushed and add water according to certain moisture content. The cement mass and water content account for 1% and 18% of the silty clay mass, respectively. The principle is that use the hydration reaction of cement and water to form the cementation between particles, so as to form a certain structural strength. According to the direct shear test results, the artificially structured soil shows strain-softening and strength due to the structure. The cohesion of the soil is 17 kPa and the friction angle is 17°.

In the model preparation, the structured soil is compacted to a dry density of 1.55g/cm^3 layer with an initial water content of 18% in the container. Each soil layer is 50 mm thick and 4 layers in total. After compaction, surplus soil is removed to achieve the predetermined dimensions of the slope with a height of 200 mm, a width of 100 mm, and a gradient of 1.5:1. White particles are embedded at random on one side of the slope model to reach higher grey differences for the convenience of image-based measurement (Figure 1).

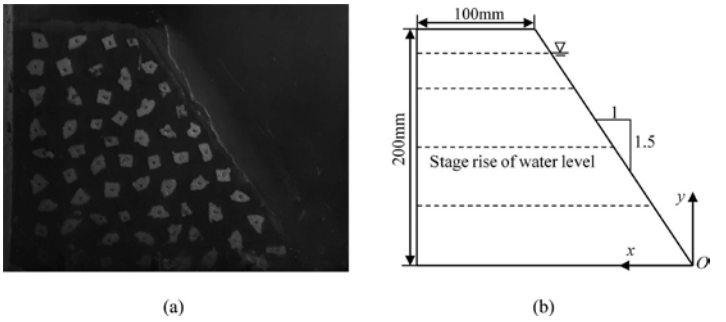

Figure 1. Photograph and schematic of test model. (a) photograph; (b) schematic view.

2.3 *Procedure*

The test process mainly includes three phases: (1) centrifugal acceleration: the acceleration level is raised from 1 g to 50 g with a 5g-step and pauses for 1 min every step, waiting for gravity-induced deformation of the slope to stabilize. (2) water level rising: the water level is raised from 0 mm to 50 mm, 100 mm, 150 mm, and 180 mm. Each level is maintained for 10 mins after the deformation induced by water inflow stabilizes. (3) water level falling: the water level decreases from 180 mm to 0 mm at one time. The process lasts for 79.8 s.

2.4 *Measurements*

Pictures and videos are captured using an image-capture and displacement-measurement system during the tests (Zhang et al 2009). These pictures and videos consist of image series that are used to determine full-field displacements of the slope.

To meet the needs of quantitative analysis, a Cartesian coordinate is set up with the origin at the toe of the model slope. The positive direction of the x-axis and y-axis is leftwards and upwards, respectively. All the dimensions referred to in this paper are in the dimension of the model. The prototype dimension is acquired by amplifying the dimension of the model with the g level, 50.

3 FAILURE PHENOMENON

3.1 *Slip surface*

Figure 3 shows the photograph and diagram of the structured soil slope at the end of the test. The structured soil slope exhibits two slip surfaces with a crack and the integral surface cuts deep into the slope body, dividing the slope into the base body and sliding body.

It can be observed from the test that the slope is stable during the water level rising while the failure happens and forms slip surfaces during the water level falling.

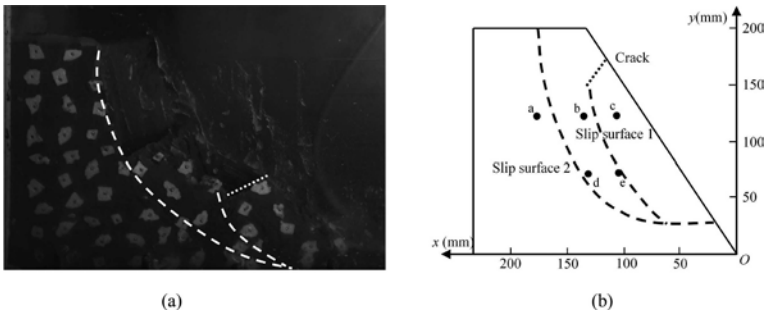

Figure 2. Photograph and schematic of the structured soil slope failure. (a) photograph; (b) schematic.

3.2 *Displacement distribution*

The displacement of the slope induced by the impoundment is so small that be neglected. Figure 3 shows the displacement distribution under water level falling to 70 mm. It can be seen from Figure 3(a) that each distribution curve of horizontal displacements has a significant displacement increase area and slip surfaces are in the area. This is also illustrated by Figure 3(b) and the remarkable displacements appear in a limited zone, which constitutes the sliding part. Meanwhile, the displacements of the base body are still about 1 mm and can be seen as a rigid body. This result indicates that water level fluctuation, especially drawdown, leads to more significant deformations of the slope.

Figure 4 shows histories of displacements of representative points during water level falling. Point a is on the base body, point c is on the sliding body 1 upon the slip surface 1 and point b, point d, point e is on the sliding body 2 upon the slip surface 2. By comparing the displacements of point a, point c and point e, it can be seen that the displacements of the structured soil slope are small before the failure while increasing a lot in a few seconds after the failure. Moreover, the displacements of the sliding body 1 are larger than the sliding body 2. This is due to that the sliding body 2 is affected by both the formation of the slip surface 1 and the slip surface 2 and produces new deformation after preliminary deformation. The horizontal and vertical displacements of both Point b and Point e were greater than those of Point d. This indicates that the deformation is more dramatic on the upper and exterior part of the slope.

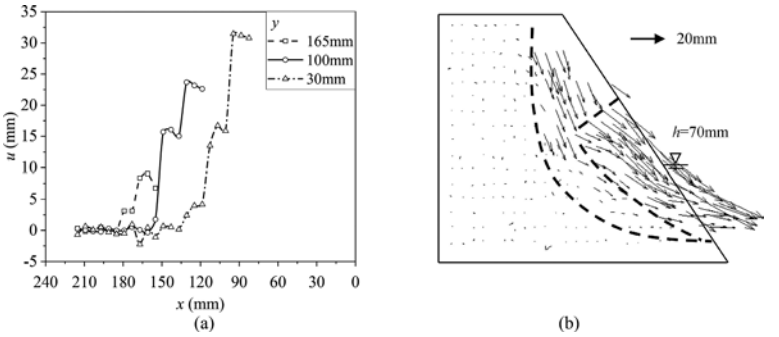

Figure 3. Displacement distribution under water level falling to 70 mm. (a) distributions of horizontal displacements; (b)distributions of displacement vectors. *u*, horizontal displacement; *h*, water level.

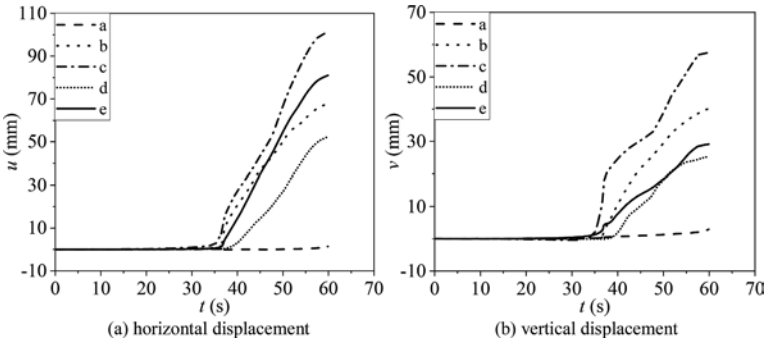

Figure 4. Histories of displacements of representative points during water level falling. (locations shown in Figure 2.) *u*, horizontal displacement; *v*, vertical displacement; *t*, time.

4 FAILURE PROCESS

The failure process of the slope under water-level fluctuation is analyzed using point couple analysis. The point couple is defined as two adjacent points with one on the base body and the other on the sliding body. The relative displacements of the point couple are decomposed to the tangential direction and the normal direction of the slip surface. Based on the observation and analysis of the slope failure, it can be determined that the main failure process happens during the period of water level falling from 150 mm to 50 mm. The process of water level falling from 150 mm to 50 mm lasts for 32.2 s, which is long enough to observe the failure.

Figure 6 shows histories of relative displacements of the point couple near the crack and can determine the property of the crack. The normal relative displacement increases slowly at first and then grows rapidly to 23.5mm at a certain moment. The turning point can be considered as the moment when a local failure occurs between the couple point. When the crack appears, the normal relative displacement is far more than the tangential relative displacement, so it could be concluded as a tension crack. As the water level falls, the slip surface 1 appears and the slope settles rapidly, and the tangential relative displacement is gradually greater than the normal relative displacement. It can be concluded that the generation and development of the crack are a combination of tension and shear.

Figure 7 shows histories of relative displacements of point couples (Point couple C and Point couple F) near slip surface 1 and slip surface 2. The tangential relative displacement is greater than the normal relative displacement for all the point couples near both slip surfaces during water level falling. This result means that the shear failure occurs in the slope. It also can be seen that the relative displacements increase rapidly at a certain moment and appear as a turning

point, which can be used as the moment when the slip surface develops here. The failure process of structured soil slope is sudden and fast, showing characteristics of brittle failure.

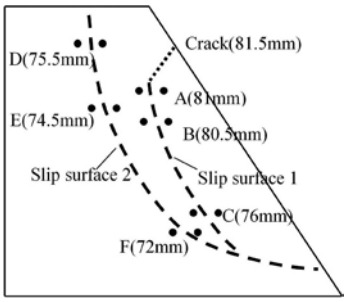

Figure 5. Locations of point couples and failure process.

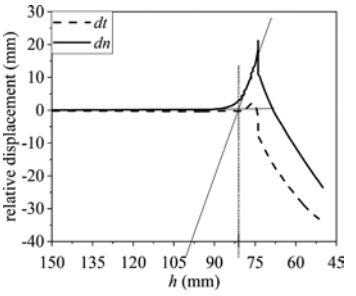

Figure 6. Histories of relative displacements of the point couple near the crack. *dt*, tangential relative displacement; *dn*, normal relative displacement; *h*, water level.

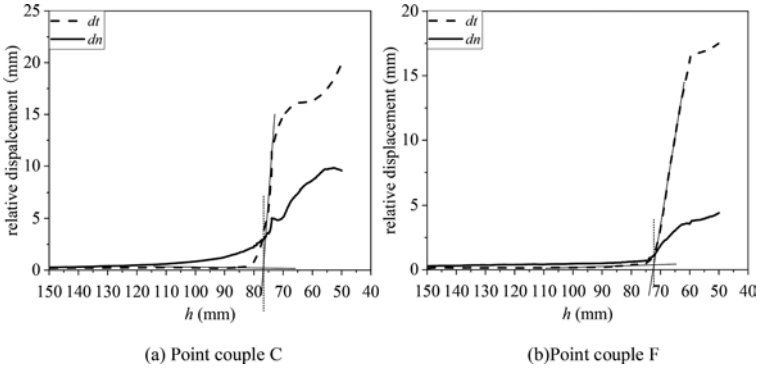

Figure 7. Histories of relative displacements of point couples. (locations shown in Figure 9). *dt*, tangential relative displacement; *dn*, normal relative displacement; *h*, water level.

Figure 5 marks the water levels at failure moments in brackets according to the turning points of histories of relative displacements of each point couple. It can be seen that the local failure in the structured soil slope induced by water fluctuation develops from the top to the bottom. The tension crack first occurs on the upper part of the slope and extends inward. The slip surface 1 starts at the crack extension and develops from top to bottom. The slip surface 2 appears after the formation of the slip surface 1 and develops from top to bottom and forms the integral slip surface with the slip surface 1 at the slope toe. Two slip surfaces are formed independently and the formation time difference is caused by the sequence of water levels falling in the slope.

A point couple can be seen as a soil unit in the shear test. According to the direct shear test results, the shear displacement is small before the shear failure. The shear stress decreases rapidly after the shear failure while the shear displacement starts to grow consistently. The reason why the structured soil slope failure is brittle is that the soil structure enhances the ability to resist external load damage. Once the structure is damaged, the strength will suddenly decrease, resulting in a rapid slip without signs of preliminary deformation.

5 FAILURE MECHANISM

Figure 8 shows the horizontal distributions of the horizontal strain at heights of 100 mm and 80 mm under four representative water levels, corresponding to the four moments before and after the slip surfaces formation. It also marks the locations of slip surfaces at different heights in the figure.

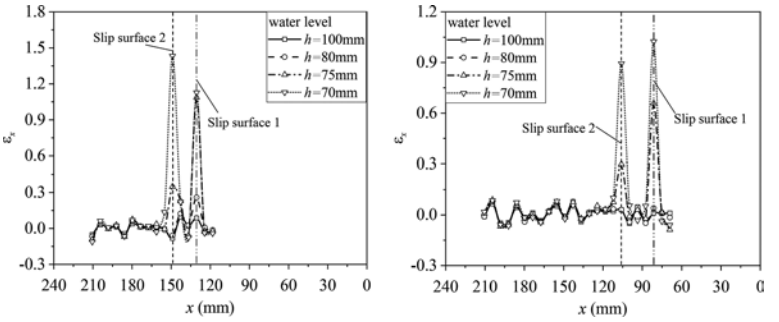

Figure 8. Distributions of horizontal strain at 100 mm and 50 mm height under four different water levels. ε_x, horizontal strain; x, x-coordinate; h, water level.

It can be seen that at the initial stage of water level falling (h=100mm), the horizontal strain is small at different heights. This result means the deformation in the slope is small and distributes evenly. As the water falls (h=80mm), there is a maximum value point on the distribution curve at the height of 100 mm, while the horizontal strain is still small and uniform on the other distribution curve. With the water level falling to 75 mm, there are two maximum value points on each curve. It can be noticed that the locations of two maximum points are near the slip surfaces and the maximum value near the slip surface 1 is much larger than the maximum value near the slip surface 2 and both maximum values on the curve at 100 mm height are larger than those at 50 mm height. This is because that the slip surface 1 is forms at both heights while the slip surface 2 develops to the height of 50 mm instead of 100 mm under the water level. When the water level falls to 70 mm, the maximum values has a significant increase and the slip surfaces are formed at both heights. Based on the analysis above, the slope occurs to progressive failure.

The horizontal strain values around maximum value points are much larger while in other areas horizontal strain is still maintained around zero. This implies deformation location occurs in the area. The locations of slip surfaces are around two maximum values and local failure occurs around here. This finding illustrates that the deformation localization occurs under water level fluctuation and induces local failure ultimately. It can be concluded that the integrated development of deformation localization and local failure under water level fluctuation causes the ultimate slope failure.

Furthermore, the changing patterns of two maximum values on the distribution curve of horizontal strain are different (Figure 8), which are related to the development of slip surfaces. Figure 9 shows the histories of the horizontal strain of two maximum values at the height of 100 mm during water level falling. There is a turning point on each curve and represents the moment that a local failure occurs. The turning point of the first maximum value point near slip surface 1 appears at 35 s, corresponding to the moment that slip surface 1 occurs at the height of 100 mm. After rapid growth, the horizontal strain stabilizes, and then after a fluctuation affected by the formation of the slip surface 2 stabilizes again. The turning point of the second maximum value point near slip surface 2 appears at 36.8 s and stabilizes after experiencing significant growth. This also illustrates that two slip surfaces occurs independently and the parts upon the earlier slip surface will be affected by the later slip surface and produce new deformation.

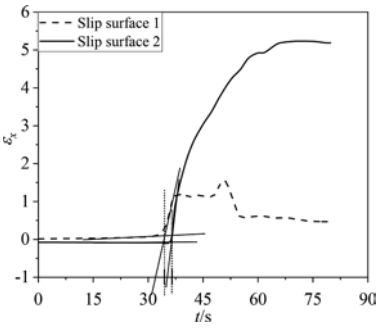

Figure 9. Histories of the horizontal strain of two maximum values during the water level falling. ε_x, horizontal strain.

6 CONCLUSION

The deformation and failure of the structured soil slope under water level fluctuation were investigated using centrifuge model tests. The failure mechanism was revealed via the deformation localization analysis based on the measurement of full-field displacement of the slope. The main conclusions are as follows:

1. The water level fluctuation causes two slip surfaces independently in the slope and the soil upon the earlier sliding body is caused new deformation by the later slip surface.
2. The structured soil slope exhibits progressive failure. The tension crack appears on the upper part of the slope at first, and the slip surface due to shear failure develops gradually from the top to the bottom of the slope.
3. Water level fluctuation leads to uneven deformation and is concentrated at a certain area in the soil slopes, indicating deformation localization there. The accumulation of deformation localization leads to local failure while local failure results in new deformation and enhancement of deformation localization. The coupling development of deformation localization and local failure leads to the ultimate slip surface.

ABSTRACT: The swelling characteristic is most important for expansive soil, and it is one of the main factors that cause the disaster of expansive soil slope. After mixing with cement, the engineering behaviours of the expansive soil get improved and, in particular, the swelling characteristic basically disappears. In this paper, Nanyang middle expansive soil, which is encountered in the Middle Route of South-North Water Transfer Project, was studied on the long-term effects. The optimum amount of cement content is determined according to the free swelling ratio. The long-term improvement of swelling potential, strength and modulus are studied by laboratory tests. Based on test results, numerical modelling was used to evaluate the plastic zone development and safety of the expansive soil slope. In addition, a method to determine the thickness of cement treatment was proposed.

1 INTRODUCTION

Expansive soil is a kind of clay which swells, collapses and softens when encountering water, and shrinks, cracks and hardens when losing water. There are two kinds of expansive soil slope instabilities, one happens under the swelling effect, and the other happens due to low fissure strength (Cheng et al., 2011). For the case of shallow instability the water content control method such as geomembrane treatment, or load method such as using unexpansive soil, cement modified, geogrid reinforced or lime modified expansive soil can be adopted to deal with the instability. The Middle Route of South-North Water Transfer Project is an important project in China. The canal passes through about 387 km of expansive soil in total. In order to avoid the problems such as water pollution, farmland destruction caused by soil replacement, and expansive soil disposal (Li et al., 2009), various treatments were compared in the field; at last, the cement modification method was selected to make sure the shallow stability.

This study carried out the laboratory swelling and triaxial tests of expansive soil and cement modified soil. The samples collected from Nanyang expansive soil field were used to demonstrate the long-term modification effect. The effect of treatments with different thicknesses was validated and a method of determining the treatment thickness of expansive soil slope was proposed.

DOI: 10.1201/9781003299127-163

2 THE OPTIMUM AMOUNT OF CEMENT FOR EXPANSIVE SOIL MODIFICATION

The free swelling ratio of Nanyang expansive soil is 77% and its colloidal particles content was 29.5%, which is mid-expansive clay and of high liquid limit. The modification to the mid-expansive soil was done with the composite Portland cement P.C 32.5.

The free swelling ratio test was conducted on cement modified mid-expansive soil (Huang et al., 2009). The modified soil samples were made of clay and cement, which were mixed together and compacted to a compaction degree of 93%, then ground down artificially after the curing time period. The relationship between the free swelling ratio and cement content for modified soil of 28 days old is shown in Figure 1.

It can be seen that the free swelling ratio reduced with the increase of cement content. When the cement content is less than 6%, the free swelling ratio varied greatly with the increase of cement content, and when the cement content was greater than 6%, the modification effect was much lower and the swelling ratio was close to the unexpansive limit of 40%. Therefore, 6% of cement content was recomended for Nanyang mid-expansive soil.

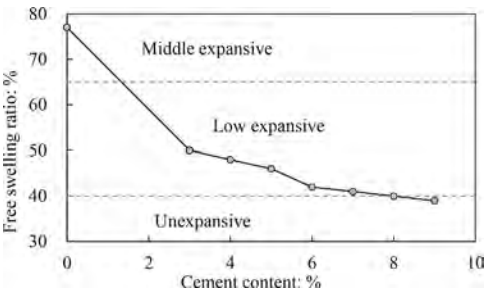

Figure 1. The relationship between the free swelling ratio and cement content for modified soil.

3 THE IMPACT OF CEMENT MODIFICATION ON SWELLING CHARACTERISTIC

Three kinds of soil samples were used in swelling ratio tests under load. One kind of samples were compacted virgin soil; the second kind of samples were modified soil mixing with expansive soil and cement in laboratory; The third kind of samples were field cement modified soil. All samples were of natural water content of 21.0% for virgin soil and compaction degree of 93%. The field sampling is shown in Figure 2. The swelling ratio results of the three kinds of soil samples are shown in Figure 3.

Figure 2. Field sampling of cement modified soil.

It can be seen from the Figure 3 that the swelling ratio of the virgin expansive soil has a steep drop when the vertical stress is between 0 and 12.5kPa, which indicates that the load method can be used to inhibit the swelling deformation of the expansive soil.

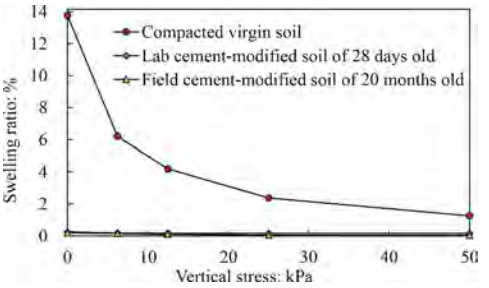

Figure 3. The relationship between swelling ratio and vertical stress.

The swelling ratio without load of the compacted virgin soil is 13.6%, and the swelling ratio of the intact soil is 9.9%. The swelling ratio of laboratory and field modified soils is less than 0.1%. The modification effect on swelling is remarkable when cement content is more than 6%.

4 THE IMPACT OF CEMENT MODIFICATION ON MECHANICAL PROPERTY

The triaxial test results of expansive and modified soil are shown in Table 1. The strength is increased obviously after cement modification. The strength of field modified soil is greater than that of laboratory modified soil. The reason for that, on one hand, is the impact of the age, and on the other hand, is the field modified soil containing more gravel which improve the fabric of the soil particles while it was removed from laboratory modified soil.

For the field modified soil, its strength and modulus are both high. The field modified soil had existed for 20 months, and had experienced water storage and recession process in the canal slope, thus, the cement modification is ideal for inhibiting the strength and modulus softening.

Table 1. Triaxial test results of expansive soil and cement modified soil.

Sample	Cement content: %	Compaction degree: %	Age	c: kPa	φ: °
Intact virgin soil	-	-	-	18.1	21.1
Lab modified soil	6	93	28 days	40.8	23.2
Field modified soil	6	93	20 months	91.2	35.9

5 THE IMPACT OF CEMENT MODIFICATION ON EXPANSIVE SOIL SLOPE

5.1 *The finite element method considering swelling effect*

The ideal elastic-plastic constitute model and Mohr-Coulomb failure criterion are adopted to calculate the swelling deformation of expansive soil after sufficient moisture absorption by taking the swelling strain as the initial strain, and the final stress and strain of the slope are calculated using the initial strain method (Xu et al., 2014).

The swelling strain of expansive soil in triaxial stress state can be expressed by the Equation (1) (Huang et al., 2015):

$$\varepsilon_v = a + b\ln(1 + \frac{\sigma_m}{p_a}) \tag{1}$$

Where ε_v is the swelling volume strain caused by sufficient moisture absorption in expansive soil (%); σ_m is the average principal stress; a and b are the parameters which are related to the

expansion class, initial water content and compaction degree. For Nanyang mid-expansive soil with the initial water content of 21%, a=22.7, b=-4.73.

5.2 *Calculation model*

The effect of cement modification on inhibiting swelling deformation was analysed with slope height of 9 m and slope gradient of 1:1.5, treatment thickness of 0, 1, 2, and 3 m. Based on practical experiences, it is assumed that the water content in slope surface varies from initial water content to saturated state within 2 m. The schematic diagram of calculation model is shown in Figure 4, and the geotechnical parameters obtained from triaxial test are shown in Table 2.

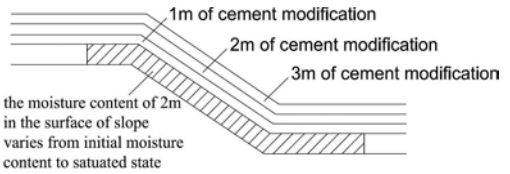

Figure 4. Schematic diagram of cement modification treatment with different thicknesses.

Table 2. Strength and deformation parameters.

Soil type	Density: g/cm^3	c: kPa	φ: °	E: MPa	μ
Cement modified soil	1.85	91.2	35.9	36	0.3
Virgin expansive soil	2.00	18.1	21.1	10	0.4

5.3 *Calculation result*

(1) Plastic zone development

Figure 5 is the distribution of the plastic zone when the water content of expansive soil in slope surface increasing to saturation. It indicates that, for the mid-expansive soil slope, there is no plastic zone for 2 m or more thickness of cement modification.

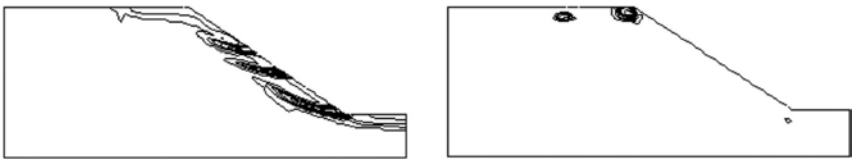

Figure 5. The plastic zones of expansive soil slope with different treatment thicknesses.

(2) Slope stability

For the treatment with different thicknesses, the finite element method considering expansion is used to analyse the stability. The slope safety factors of each treatment are shown in Table 3.

Table 3. Safety factors of slope stability with different treatment thickness.

		Treatment thickness		
Soil	Non-treatment	1m	2m	3m
Middle expansive soil	0.88	1.20	1.70	1.83

The stability of cement modified slope is obviously enhanced when the water content of expansive soil within 2 m changes from initial water content to saturated state. When the expansive soil slope is not treated, the safety factor is 0.88, and the safety factor of 1 m treatment reaches 1.20, which is less than the required value 1.35; the safety factor of 2 m treatment is up to 1.70, which meets the design requirement.

The cement modification treatment with thickness of 2 m was widely used in mid-expansive soil slope in the Middle Route of South-North Water Transfer Project.

6 CONCLUSION

(1) The swelling and mechanical properties of expansive soil can be remarkably improved by cement modification, which is a feasible method for shallow stability of expansive soil slope.
(2) According to the relationship between free swelling ratio and cement content, the optimum amount of cement can be determined.
(3) Using finite element method considering swelling effect, the sensitivity analysis can be conducted to determine the treatment thickness of expansive soil slope.

Comparison of soil water characteristic curves estimated using data assimilation and water retention tests

S. Ito, K. Sako & T. Morita
Kagoshima University, Kagoshima, Japan

ABSTRACT: The soil water characteristic curve (SWCC) is an important property for simulating infiltration behavior, and several methods exist for its estimation. This study aimed to investigate the relationship between the SWCC estimated by data assimilation based on field measurement data and that estimated using the pressure plate method (a water retention test). Simulations using the SWCC estimated by data assimilation reproduced 5 days of trained field measurement data and predicted 50 days of unlearned test data with sufficient accuracy. The SWCC estimated by data assimilation had a different shape than that of the SWCC estimated using the pressure plate method.

1 INTRODUCTION

Because soil moisture conditions affect the onset of slope failure during heavy rain, it is important to accurately evaluate the infiltration behavior of the soil. To simulate the infiltration behavior, we need to estimate the unsaturated soil hydraulic properties: the soil water characteristic curve (SWCC) and unsaturated hydraulic conductivity. The SWCC is an important property that indicates the relationship between water content and pore water pressure; it is generally estimated by conducting water retention tests. We studied the data assimilation of unsaturated soil hydraulic properties based on the field measurement data of volumetric water content (VWC) and found that numerical simulations using the parameters estimated by data assimilation could reproduce the field measurement data at various slopes with different types of soils (Ito et al., 2019). There are several methods for estimating the SWCC. The relationship between the SWCCs estimated using different methods has not yet been fully investigated. This study aimed to elucidate the relationship between the SWCC estimated by data assimilation based on field measurement data and that estimated using the pressure plate method (a water retention test). First, unsaturated soil hydraulic properties were estimated based on the field measurement data of the VWC at a site comprising pyroclastic flow deposits. We used the merging particle filter (MPF) (Nakano et al., 2007) as the data assimilation method. Next, the generalization performance of the estimated model was evaluated by conducting Monte Carlo simulations on 50 days of unlearned test data. Finally, herein, the relationship between the two SWCCs estimated using different methods (data assimilation and the pressure plate method) is discussed.

2 METHODS

2.1 *Unsaturated–saturated seepage analysis*

In this study, unsaturated–saturated seepage finite element analysis was used to reproduce soil moisture conditions. The Richards equation (Richards, 1931) was applied for numerical analysis, as follows:

DOI: 10.1201/9781003299127-164

$$C \cdot \frac{\partial \psi}{\partial t} = \frac{\partial}{\partial z}\left\{k(\psi)\left(\frac{\partial \psi}{\partial z} + 1\right)\right\} \tag{1}$$

where C (= $\partial\theta/\partial\psi$) is the hydraulic capacity function, θ is the VWC, ψ is the pressure head, and $k(\psi)$ is the unsaturated hydraulic conductivity. The van Genuchten model (van Genuchten, 1980) was adopted to express the SWCC, and the Mualem model (Mualem, 1976) was used to estimate the unsaturated hydraulic conductivity. The different models are calculated as follows:

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left\{\frac{1}{1 + (-\alpha \cdot \psi)^n}\right\}^{1-\frac{1}{n}} \tag{2-1}$$

$$k(\psi) = k_s \cdot S_e^{0.5}\left\{1 - \left(1 - S_e^{\frac{n}{n-1}}\right)^{1-\frac{1}{n}}\right\}^2 \tag{2-2}$$

where S_e is the effective soil water saturation, θ_r is the residual VWC, θ_s is the saturated VWC, α and n are material parameters, and k_s is the saturated hydraulic conductivity.

2.2 *Merging particle filter*

The MPF is a sequential data assimilation method wherein the probability distribution of a physical quantity is approximated using its realizations. Each realization is called a particle, and each set of particles is called an ensemble. The MPF evaluates particles at a discrete time using Bayes' theorem. Figure 1 illustrates the computational procedure for the MPF. First, several numerical simulations, wherein different sets of unknown parameters were applied to each particle, were conducted ((a) prediction in Figure 1). If the number of particles is N, then N Monte Carlo simulations are performed. Second, the likelihood was evaluated for each particle by comparing the measurement data and simulated results ((b) filtering in Figure 1). The particles were then resampled into samples (Figure 1(c)). If the number of particles is N, $l \times N$ samples are drawn based on the likelihood. The particles with a high likelihood were resampled more than l, and the samples of the particles with a low likelihood were decreased in number. Finally, the samples merged into new particles (Figure 1 (d)). By performing an iteration of these four steps (prediction, filtering, resampling, and merging) at each discrete time, the MPF modified the unsaturated soil hydraulic properties (θ_r, θ_s, α, n, and k_s) based on the measurement data.

2.3 *Pressure plate method*

Figure 2 shows the test setup for the pressure plate method. Air pressure was applied to the cell pressure chamber, where the soil specimen was installed, and the back pressure chamber, where the electronic balance was installed, to measure the amount of water drainage. The pressure difference causes soil water to drain. In this study, the SWCC of the wetting process was calculated from the relationship between the suction and water content under equilibrium conditions.

The soil specimen was prepared by compacting the disturbed soil sampled at the field measurement site and controlling the void ratio (e = 1.3) and the initial water content (w = 33%). The soils were pyroclastic flow deposits sampled at a site in Kagoshima City, Japan, and the density of the soil particles was ρ_s = 2.51 Mg/m^3. The specimen mold had an inner diameter of 60 mm and a height of 20 mm.

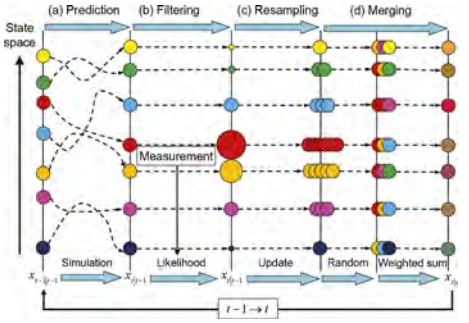

Figure 1. Computational procedure for the MPF.

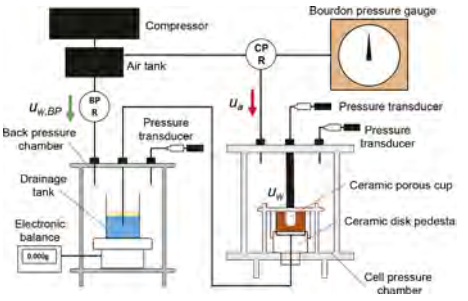

Figure 2. Test setup of the pressure plate method.

3 ESTIMATION OF THE SWCC BASED ON FIELD MEASUREMENT

3.1 *Field measurement data*

We installed a rain gauge and profile soil moisture sensor for the field measurement of precipitation and VWC. The profile soil moisture sensor measured the VWC at 10 cm intervals from a depth of 10 to 40 cm. The measurement intervals of precipitation and VWC were 10 min, and field measurements were performed from June 3 to July 28, 2021. Figure 3 shows the field measurement data. The VWC measured at a 40 cm depth was significantly lower than that measured at other depths and showed little variation in precipitation. It can be presumed that these data were measured because the profile soil moisture sensor was not in contact with the soil at a depth of approximately 40 cm. This study used the time variation of the VWC measured at depths of 10, 20, and 30 cm for data assimilation.

3.2 *Analytical results*

Figure 4 shows the one-dimensional seepage analysis model used to simulate the infiltration behavior. The model was divided into three layers (upper, middle, and bottom) corresponding to the depth of the soil profile moisture sensor. The model introduced a variable flux boundary at the top surface and a free drainage boundary at the bottom of the model. For data assimilation, 500 particles with different sets of unknown parameters were used. All particles were randomly generated within a certain range. The observation noise followed a three-dimensional normal distribution. Data assimilation was performed using 5 days of field measurement data from June 3 to June 8 as the training data to estimate unsaturated soil hydraulic properties. The remaining 50 days of data were used as test data to evaluate the general performance of the estimated model, and Monte Carlo simulations considering only precipitation were performed.

The analytical results are shown in Figure 5. The data assimilation and Monte Carlo simulation conducted 500 simulations such that the mean value, μ, and standard deviation, σ, of the simulations could be calculated. The solid lines indicate field measurement data, dashed lines indicate the mean value, μ, of the posterior distribution of VWC, and dotted lines show the range of $\pm\sigma$ from the mean value. The simulations reproduced 5 days of trained field measurement data used for data assimilation and also predicted 50 days of unlearned test data with sufficient accuracy. Thus, we concluded that data assimilation by the MPF could estimate unsaturated soil hydraulic properties that adequately represent the in-situ infiltration behavior.

4 DISCUSSION

The SWCCs estimated by data assimilation were compared with those estimated using the pressure plate method (a water retention test). Figure 6 shows the results of the comparison; clearly, the SWCCs estimated using the different methods have different shapes at all depths.

The interpretation of these differences is that the methods for the estimation of the SWCCs differed, and data assimilation was applied to undisturbed soils, while the soil specimen in the water retention test was disturbed. However, because this study was conducted at a single site, similar studies need to be conducted in future for other sites, in addition to investigating the effects of the differences in the SWCC on the results of seepage analysis.

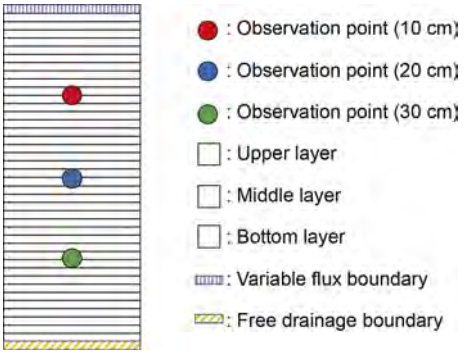

Figure 4. One-dimensional model.

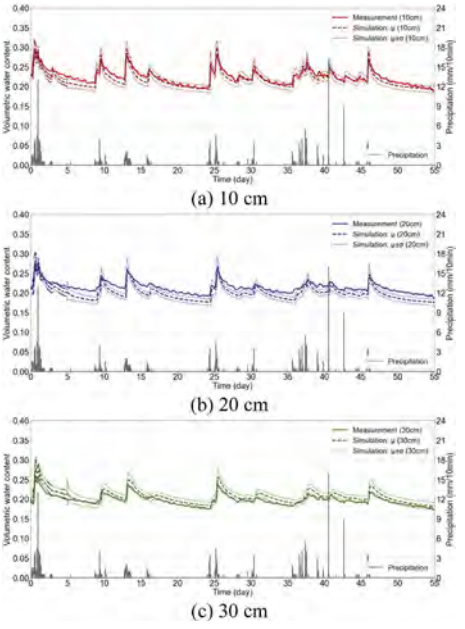

Figure 5. Analytical results.

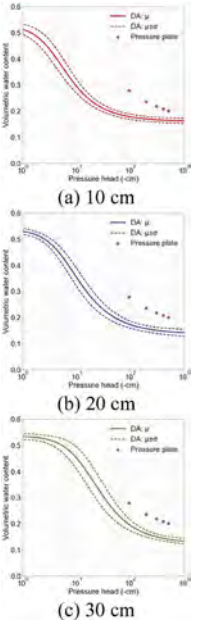

Figure 6. Comparison results of SWCCs.

5 CONCLUSIONS

This study aimed to investigate the relationship between the SWCC estimated by data assimilation and that estimated using the pressure plate method. The main conclusions of this study are as follows.

1. The simulation results reproduced 5 days of trained field measurement data used for data assimilation and predicted 50 days of unlearned test data with sufficient accuracy. This indicated that data assimilation by the MPF could estimate unsaturated soil hydraulic properties that adequately represent the in-situ infiltration behavior.
2. The SWCC estimated by data assimilation was compared with that estimated using the pressure plate method (a water retention test). The comparison showed that the SWCCs estimated using the different methods have different shapes at all depths. The interpretation of these differences is that the method for estimating the SWCCs differed. Data assimilation was applied to undisturbed soil, whereas the soil specimen in the water retention test was disturbed.

Suffusion experiments under condition of constant or fluctuating hydraulic gradient with focus on concentration-turbidity relationship of drainage

T. Ishimaru, M. Suzuki, S. Takano & A. Komori
Yamaguchi University, Ube, Yamaguchi, Japan

ABSTRACT: The phenomenon whereby only the fine soil particles flow out, while the skeleton of the coarse soil particles remains, is called "suffusion". It has been pointed out that the suffusion occurs in embankment structures affected by long-term seepage, such as river levees and reservoir dams, increasing the risk of collapse. However, the suffusion mechanisms in cases where the seepage force changes with time are often unclear. In this study, water-passing experiments with the suffusion were performed to clarify how the amount and the particle size of eroded soil change with changes in the seepage force. As a result, it was seen that the small soil particles with easy flowability had already eroded when the specimen was subjected to seepage force for the first time, and that the soil particles that flowed out due to changes in the hydraulic gradient were relatively large in diameter.

1 INTRODUCTION

In embankment structures affected by long-term seepage, such as river levees and reservoir dams, turbid water sometimes leaks from the ground surface. Embankment structures with leaking turbid water are at high risk of collapse. The phenomenon in which soil particles move inside open spaces in the ground, and eventually flow out of embankment structures along with water, is called "internal erosion". In particular, the phenomenon whereby only the fine soil particles flow out, while the skeleton of the coarse soil particles remains, is called "suffusion". It has been pointed out that suffusion progresses over a long period of time with repeated episodes of fines migration, pore clogging, and the removal of clogged pores (Luo et al., 2013). Although it has been noted that changes in seepage forces affect the progression of suffusion, the number of suffusion experiments that reproduce changes in the seepage force is still few.

In this study, water-passing experiments were performed assuming the case where the seepage force changes with time, such as river embankments and reservoir embankments, under the condition of constant or fluctuating water levels, to clarify how the amount and the particle size of eroded soil change with changes in the seepage force.

2 OVERVIEW OF WATER-PASSING EXPERIMENTS

2.1 *Outline of experimental apparatus*

Figure 1 shows a schematic diagram of the experimental column apparatus for the water-passing experiments. The specimens were cylindrical with a diameter of 10 cm and a height of 20 cm. At the bottom, where each specimen was located, an acrylic plate with 100 holes, each having a diameter of 5 mm, and mesh with a diameter of 425 μm, were installed. These parts allowed only fine particles, smaller than the size of the sieve, to flow out of the specimen under the application of downward seepage flow. The overburden load was applied by applying air

DOI: 10.1201/9781003299127-165

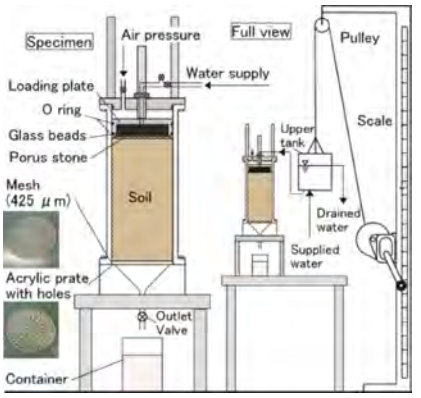

Figure 1. Schematic diagram of water-passing experiments apparatus.

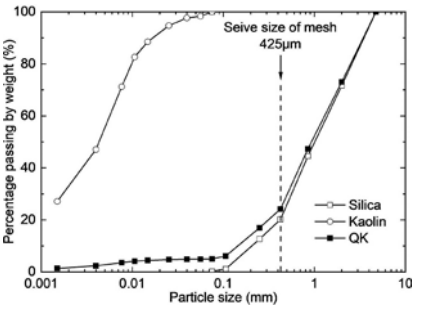

Figure 2. Particle size distribution of soil used in this study.

Table 1. Physical properties of soil used in this study.

Soil	Fines content %	Specific gravity G_s	Optimum water content w_{opt} %	Maximum dry density ρ_{dmax} g/cm^3
QK	5.0	2.651	11.5	1.935

pressure to the space above the loading plate. The hydraulic gradient was adjusted by changing the height of the upper tank, thereby subjecting the specimen to downward seepage flow. The hydraulic gradient is defined as the ratio of the water head difference (the height from the bottom of the specimen to the water surface of the upper tank) to the height of the specimen.

2.2 *Experimental samples used in this study*

Figure 2 and Table 1 show the particle size distribution and physical properties, respectively, of the soil samples used in this study. These soil samples comprise a mixture of sand and kaolin, and are named "QK". The samples were blended to have a particle size distribution resembling that of the decomposed granite soil collected in Ube, Yamaguchi Prefecture, Japan, which is often used as reservoir embankment soil.

2.3 *Experimental procedure*

The soil samples, adjusted to the optimum water content, were divided into five layers and compacted one layer at a time to achieve the pre-determined dry density. The interior of the specimens was replaced with carbon dioxide and infiltrated with de-aired water for 24 hours to achieve a saturation level of 95% or higher. After adjusting the hydraulic gradient to a pre-determined value, the outlet valve was opened to start the seepage process.

Table 2 shows the experimental conditions. In this study, water-passing experiments were performed under the condition of constant or fluctuating hydraulic gradients. C1.0 and C0.5 are the experimental cases performed under a constant hydraulic gradient. After the start of the seepage process, 20 containers were prepared, each with 100 ml of drainage, and the amount of drained water and eroded soil, and the turbidity of the drainage were measured. Cases 1 ~ 3 are the experimental cases performed under a fluctuating hydraulic gradient. In these cases, the hydraulic gradient was increased and decreased six or seven times. The containers for collecting the drainage were changed immediately before the hydraulic gradient was changed. Preliminary experiments showed that the discharge of soil particles almost stopped after about 1500 ml of water flow under the constant hydraulic gradient condition, so the hydraulic gradient was changed every 1500 ml of water flow. In all three cases, the range

in the variation of the hydraulic gradient was 0.5. The measurement items were the waterflow rate, water collecting time, amount of eroded soil, and turbidity of the drainage for each container. The turbidity of the drainage was measured by the transmitted and scattered light method, which has high sensitivity in the wide range of concentration. The polystyrene latex was used for calibration of the sensor.

Table 2. Experimental conditions.

ID	Void ratio	Initial hydraulic gradient	Fluctuating patten of hydraulic gradient	
C1.0	0.58	1.0	Constant	
C0.5	0.58	0.5	Constant	
Case 1	0.58	1.0	Fluctuating	(1.0 ⇔ 1.5)
Case 2	0.58	1.0	Fluctuating	(1.0 ⇔ 0.5)
Case 3	0.58	0.5	Fluctuating	(0.5 ⇔ 1.0)

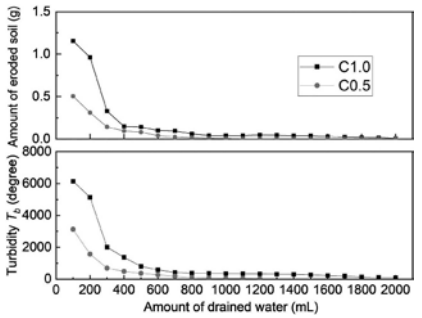

Figure 3. Changes in amount of eroded soil and turbidity.

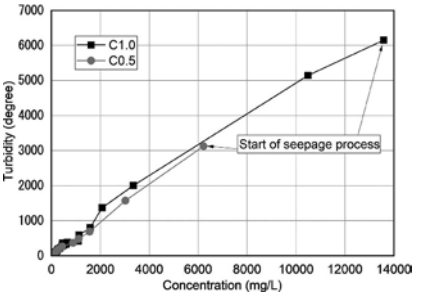

Figure 4. Relationship between concentration before dilution and converted turbidity.

3 RESULTS OF WATER-PASSING EXPERIMENTS

3.1 *Suffusion behavior under condition of constant hydraulic gradient*

Figure 3 shows the changes in the amount of eroded soil and the turbidity in C1.0 and C0.5. The amount of eroded soil gradually decreased when the amount of drained water increased. The larger the hydraulic gradient, the greater the amount of eroded soil and turbidity of the drainage. Figure 4 shows the relationship between the concentration and the turbidity for each container. After starting the seepage process, the concentration–turbidity behavior followed the pathway from the upper right to the origin. In the case of C1.0, the pathway was an upward convex arched pathway. In the case of C0.5, on the other hand, the pathway was nearly straight. It has been found that the turbidity is higher when the particle size of the suspended soil in the drainage is smaller, even when the concentration is the same (Ishimaru et al., 2022). Therefore, the upward convex arched pathway of C1.0 implies that the particle size of the eroded soil changed during the seepage process.

3.2 *Suffusion behavior under condition of fluctuating hydraulic gradient*

3.2.1 *Changes in flow rate*

Figure 5 shows the changes in the hydraulic gradient, the amount of drained water, and the flow rate during the water-passing experiments under the condition of the fluctuating hydraulic gradient. The flow rate was calculated for each section from the time the hydraulic gradient was raised or lowered until just before the next change in the hydraulic gradient. The flow rate fluctuated in conjunction with the change in the hydraulic gradient. As the hydraulic gradient was repeatedly changed, the flow rate became slightly lower at the same hydraulic gradient. The rearrangement of the soil particles may have reduced the hydraulic conductivity.

3.2.2 *Suffusion behavior*

Figure 6 shows the amount of eroded soil in each container of collected drainage. After the hydraulic gradient began to be changed, the amount of eroded soil was only slightly less than 0.5 g. However, as the hydraulic gradient was increased, the amount of eroded soil tended to increase. Figure 7 shows the relationship between the concentration and turbidity of the drainage. This figure also shows the relationship between the concentration and turbidity for suspensions made of kao-lin and the erodible components of QK (soil particles smaller than 425 μm). It can be inferred that many very small soil particles in the specimen were eroded since the data were plotted above the concentration-turbidity relationship of kaolin at the beginning of the seepage process. After the hydraulic gradient began to be changed, on the other hand, the data were plotted closer to the concentration-turbidity relationship of the erodible components of QK. This suggests that when a specimen was subjected to seepage force for the first time, the small soil particles with easy flowability had already eroded, and that the soil particles that flowed out due to the changes in the hydraulic gradient were relatively large in diameter.

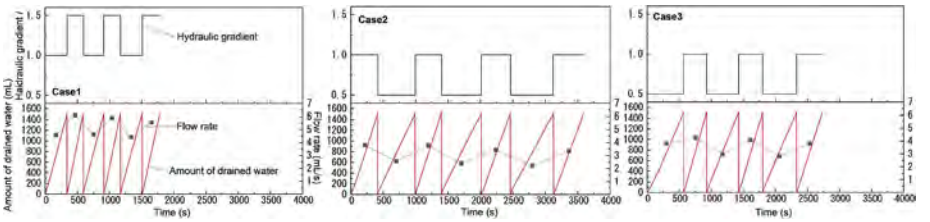

Figure 5. Changes in hydraulic gradient, amount of drained, water and flow rate.

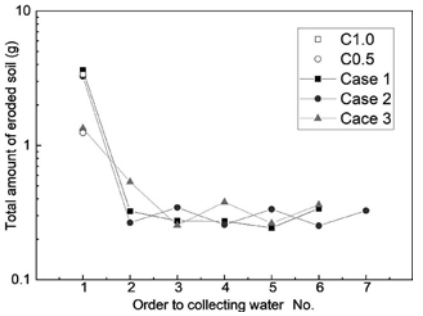

Figure 6. Amount of eroded soil in each collecting container.

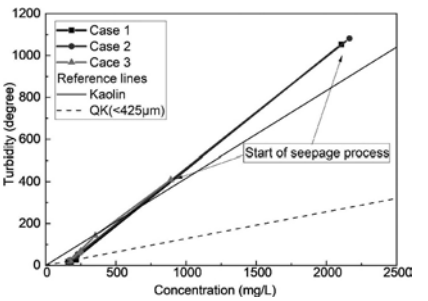

Figure 7. Relationship between concentration and turbidity of drainage.

4 CONCLUSION

Water-passing experiments were conducted to investigate the progression of suffusion under varying hydraulic gradients. The results showed that the discharge of fines continued to increase and decrease as the hydraulic gradient fluctuated repeatedly. The cases in which the soil particles were being discharged under the condition of a fluctuating hydraulic gradient were estimated to be relatively large in diameter among the erodible components.

Impact of internal erosion on soil fabric and mechanical behavior

C. Dong, A. Mehdizadeh & M.M. Disfani
The University of Melbourne, Australia

ABSTRACT: Internal erosion is responsible for an overwhelming proportion of dam failures. The microstructure of soil and its mechanical properties can be affected by particle migration, resulting in a decrease in soil stability. Using a modified erosion testing apparatus, this research examines the impact of internal erosion on the small strain shear modulus (G_0) of gap-graded granular soils. The moist tamping technique was used to prepare internally unstable gap-graded soils with varying fines content and relative densities. The specimens were subjected to a downward seepage flow, while the induced pore pressure and erosion progress both monitored continuously. Three sets of bender elements were mounted on the cell to track the variation in shear wave velocity throughout the sample height during erosion. The results indicate the negative correlation between fine particle content and G_0, while suggesting that the increment of soil compaction would potentially accelerate G_0 at transitionally unstable zone.

Keywords: soil fabric, mechanical property, fine particle content, relative density

1 INTRODUCTION

Subgrade filling materials are often composed of gap-graded soils from mountainous regions (Zhang et al., 2020). In an internally stable soil with a coarse-dominant structure, the coarse fraction acts as the matrix of soil structure to prevent non-plastic fine particles from migration under seepage force. In such a soil structure, fine particles may either provide lateral supports for coarse particles or may contribute directly to force chains within the soil fabric. According to Ke and Takahashi (2012), suffusion, a typical form of internal erosion, significantly decreases soil porosity, thereby reducing soil strength. It is consistent with the findings of (Mehdizadeh et al., 2018) and Tian et al., (2020) that the microstructure and shear strength of soils change with internal erosion. However, few research studies manage to monitor the decrease of shear strength due to soil migration (Kelly et al., 2012). This study investigates the impact of suffusion on the soil fabric and mechanical behaviour of an internally unstable soil through a series of permeameter erosion tests. During the erosion process, the bender element system was employed to monitor the shear wave velocity and G_0 in real-time and the erosion rate was correlated with G_0. A diagram of the shear waves of studied soils was summarised and compared to confirm the impact of fine particle content and relative density on soil structure and G_0.

2 EXPERIMENTAL SETUP AND MATERIAL PROPERTY

2.1 *Apparatus modification*

A rigid-wall permeameter, with dimensions of 211mm (H) x 90mm (D), was modified for erosion testing in this study. A pressure transducer installation hole was fabricated at the bottom

DOI: 10.1201/9781003299127-166

of the cell and three pairs of holes were drilled with a uniform spacing of 33mm to reduce the impact of electromagnetic interference between bender element transmitters. The permeameter pedestal was replaced with a funnel to facilitate the collecting of eroded fine particles. The overviews of the erosion and bender element systems shown in Figure 1(a) and (b) depict the side view of the Plexiglas cell with three pairs of holes along the side wall for modular anchoring of bender elements.

2.2 *Sample preparation*

The under-compaction moist tamping method was used to prepare the binary packing for this study (Frost and Park, 2003; Ladd, 1978). The soil mixture with the initial water content of 6% was evenly segmented into ten layers. Under compaction was intended for lower soil layers since compaction energy applied to upper layers would further compact underlying soil layers.

2.3 *Material property*

Bimodal mixtures of gap-graded cohesionless soils were sized as coarse fraction (1.18 - 2.36 mm) and a fine fraction (0.075 - 0.3 mm). This study applied the gap ratio of 5.2 with the addition of fine particle content (15, 25 and 35% by weight), which represented three fine particle activity states - inactive, semi-active and active (Shire et al., 2014). This research changed the relative density from 30, 60 to 90% to achieve a variety of specimen compactions. Figure 2 presents the particle size distribution diagram of tested soils.

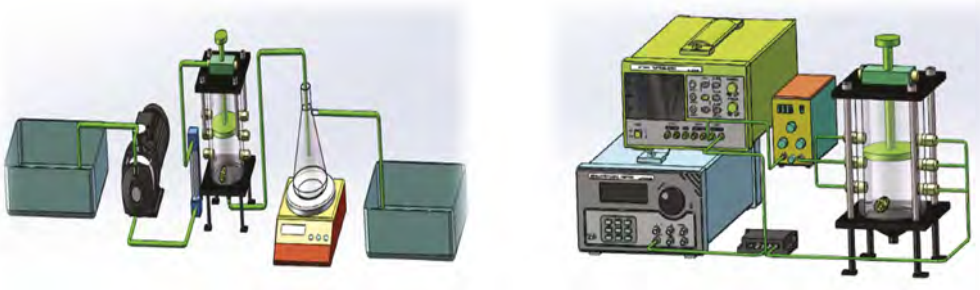

Figure 1. The overview schematics of (a) erosion test system and (b) bender element system.

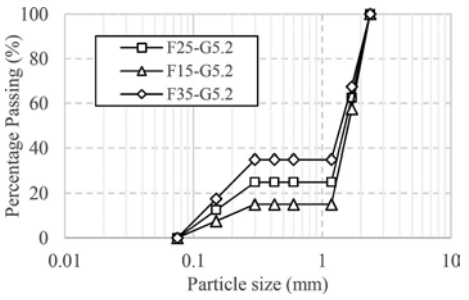

Figure 2. Particle size distribution of tested soils.

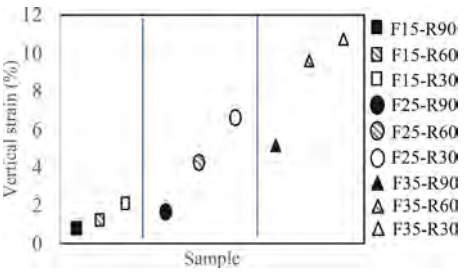

Figure 3. Post-erosion vertical strain of tested soils.

2.4 *Testing regime*

A 2-hour erosion test was conducted under the seepage velocity of 600 ml/min until no further erosion took place. A fixed vertical load of 27.56 kPa was applied to the top of the loading bar. Sine wave signals in a single waveform were generated at 5 kHz and transmitted across the soil

specimens. The transmitting signal amplitude was amplified ten times by a power amplifier, while the signal amplifier contributed 100 times to the receiving signal for signal accuracy improvement.

3 RESULTS AND ANALYSIS

3.1 *Impact of suffusion on soil matrix and G_0*

Vertical strain, the mass of fine particles eroded in real-time, and shear wave velocity of different soil layers were monitored. In this study, the internal soil erosion reduced specimen volume due to the re-adjusting of soil fabric and migration of fine particles. This is called suffusion, which is characterized by a decrease in soil volume due to the removal of fine particles (Richards and Reddy, 2007). It is consistent with the findings of Ke and Takahashi (2012) that with a constant relative density, the post-erosion vertical strain increases with the augment of fine particle content (Figure 3). The vertical strain, however, is negatively impacted by relative density, as higher compaction increases the contact force between particles in force chains, hence the soil skeleton remains unchanged despite the migration of fine particles, which loosely sit within the voids of coarse particles under seepage force (Figure 3).

Table 1. Geotechnical properties and geometrical parameters of studied soils.

Specimen Code	γ_{max} (KN/m^3)	γ_{min} (KN/m^3)	G_s	D_{15}/d_{85}	Sample Height (mm)	Duration (hr)
F15	18.44	15.60	2.65	5.2	137	2
F25	19.48	15.86	2.65	5.2	137	2
F35	19.22	16.40	2.65	5.2	137	2

As an example of how suffusion impacts the small strain shear modulus of soils, Figure 4 illustrates the erosion process of F25-R30 in real time. Particles were rapidly eroded from the cell within 40 minutes, followed by a steady plateau, indicating the end of erosion. The G_0 was measured at almost the same time at the top, middle and bottom of the sample at the beginning of the test. However, the corresponding G_0 measurements along the erosion path showed variations with the erosion progress, especially for the top layer of soil mixture with fine particles continuously migrating to layers below. It can be understood that almost for the first 40 mins, the G_0 increased by erosion of fine particles regardless of the location of measurement. The bender elements recorded minimal changes in G_0 for the middle sections, while a drop was recorded for the bottom section. It seems that the erosion of the middle layer was terminated after 40 mins and the soil structure finds a new stable status. However, the drop in G_0 for the bottom section might have been due to the accumulation of eroded particles from the upper layer at the bottom due to clogging.

3.2 *Impact of relative density and fines content*

Figure 5 presents the pre-erosion shear wave travel time results for the soils reported here. It suggests that the travel time decreased as relative density increased, i.e., denser compaction. The increase of G_0 can be explained by the fact that coarse particles and fine particles that actively take effective stress within the denser soil matrix provide higher resistance to seepage force. The reduced fine particle content (35% to 15%) negatively correlates with G_0. The results are consistent with the findings of Salgado et al. (2000), which suggest that fine particles lost during erosion probably cause soil fabric to be re-adjusted, thereby intensifying the soil structure.

4 CONCLUSION

This study investigated the effects of suffusion on the small strain shear modulus in internally unstable soils with various fine particle content and relative density using a modified rigid-

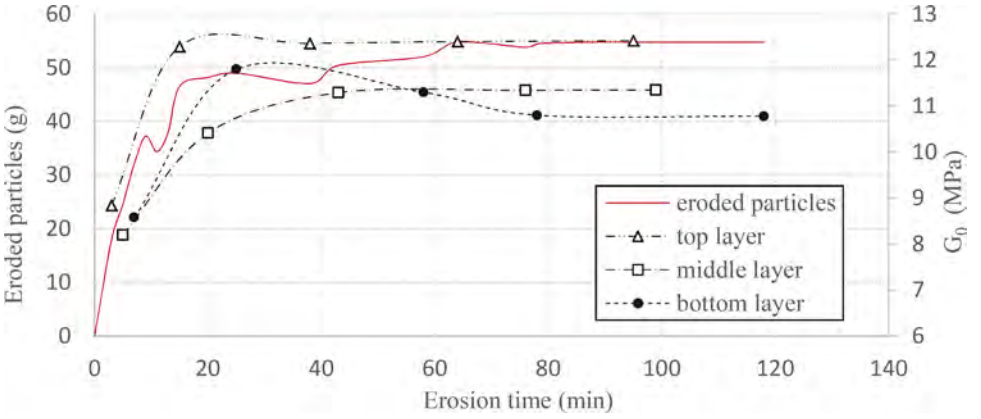

Figure 4. The erosion process and G_0 measurement for different layers of F25-R30.

wall permeameter and bender element technique. The results of erosion tests in this study suggest the following findings:

- Relative density is positively proportional to the small strain shear modulus for fine particle content at 15% to 35%. As a result of erosion of fine particle content at constant relative density, G_0 value is expected to increase.
- The bender element technique coupled with a rigid-wall permeameter has been confirmed as an efficient real-time method for monitoring small strain shear modulus.
- With the loss of fine particles through the voids of a soil skeleton, G_0 slightly increases with the progress of erosion, which probably puts the coarse particles in better contact.
- In contrast with the top and middle layers, G_0 value at the bottom layer is more prone to drop down, following the corresponding erosion progress due to the accumulation of eroded fine particles from the top layers.

ABSTRACT: Breaching of regulators results in potential threats like scouring, piping, and overtopping of the structures. An attempt has been made to assess the performance of a temporary barrage using boulders constructed on the breached portion of the brick masonry barrage during a heavy flood. The stability analysis was carried out on the temporary barrage using finite element code Plaxis 2D. It is revealed from the analysis that temporary barrage is inept to retain the water. Therefore, it is decided to strengthen the temporary barrage incorporating a row of geosynthetic sandbags concealing the temporary structure and providing sheet piles at upstream and/or downstream of the river to withstand the flood. The stability analysis performed for the strengthened barrage revealed that providing rows of geosynthetic sandbags in front of the temporary barrage and sheet piles both at upstream and downstream is effective in reducing uplift pressure and exit gradient, and thereby prevent any future scouring.

1 INTRODUCTION

Inundation risks can be alleviated by the construction of flood defense structures such as dams, embankments, levees and by creating flow diversions channels. But the durability and long-term performance of these structures depend on the magnitude and rate of recurrence of the flood as well as on the aging of the structure. Therefore, additional measures need to be adopted to improve the strength and reliability of the existing structure to overcome future floods. Numerous solutions for complex flow problems were studied by previous researchers to cut-off seepage and to reduce hydraulic uplift (Bligh 1915; Khosla et al. 1936; Terzhaghi & Peck.1967). The steady-state groundwater flow under the permeable foundation of earthen dam was studied for different permeability ratios and penetration depths (Kalkani et al. 1984). Sand- filled geosynthetic bags can be deployed successfully for the flood protection and stability improvement of dams (Saathoff et al. 2007). The possible failure mode and remedial measure to improve the factor of safety was evaluated by finite element method by Agustawijaya et al. 2015. Sheet pile wall behavior in seepage cut-off and stability improvement was studied by varying the length and position (Tung 2016). An iterative finite element procedure was adapted to various cases of groundwater flow in the short period of time compared to the conventional methods (Neuman & Paul 1970).

In the present study, the performance of a temporary barrage using boulders constructed in the breached portion of the brick masonry barrage during a heavy flood in the river of Cauvery in the Southern region of India was presented. Strengthening the temporary boulder

DOI: 10.1201/9781003299127-167

made barrage by providing rows of geosynthetic sandbags in front of the temporary barrage and sheet piles both at upstream and downstream was also presented. A 2D finite element analysis using Plaxis has been conducted to evaluate optimum number of rows of sandbags, length, and location of sheet pile to minimize the uplift pressure and exit gradient. The improvement of the stability of barrage with geosynthetic sandbag and sheet piles has also been studied.

2 BREACHING OF THE EXISTING MASONRY BARAGE AND CONSTRUCTION OF TEMPORARY BOULDER BARRAGE

The 182-year-old Upper Anicut, remains among the most important regulatory structures for irrigation in the delta region of the Cauvery River in India. During the heavy rain on August 24, 2018, 108 meters of the 685-metre-long brick masonry structure, had been washed away into the river as depicted in Figure 1. After the breach, about 90% (of about 38,262 cusecs) of the flow occurred through the breached section. The concentrated flow resulted in a deep scour. An emergency measure was taken to restore the supply immediately within a few hours by closing the breach to an appropriate height with available resources like sandbags and boulders. Additional casuarina and MS steel pipe piles have been driven and they were tied together to form a grid, to support the bags at a closer interval when the current was high. The effectiveness of the casuarina and MS pipe piles grid and the sandbag cofferdam system to perform its function in the years to come under heavy floods was being uncertain. Thus, it was decided further to strengthen the temporary barrage constructed on the breached portion on the brick masonry barrage.

A field investigation was carried out by drilling boreholes up to a depth of about 25 m. The soil profile obtained from the bore logs shows that the foundation soil comprises of a sand layer up to a depth of 10.5 m with SPT N value in the range of 10-40. Further below, a 2 m thick weathered rock followed by Granitic Gneiss lies up to borehole termination depth. The unconfined compressive strength of the rock layer varies from 40-110 kPa. The phreatic head in the upstream side was observed at a height of 5 m above the ground level.

Figure 1. Breached portion of the regulator at Upper Anicut (Image courtesy: The Hindu, 2018).

3 STRENGTHENING OF THE TEMPORARY BOULDER BARRAGE

An exemplary and cost-effective solution for the critical case of hydraulic failure was to erect sheet piles to divert the flow path and reduce the exit gradient. Further, the upstream apron was proposed to be sealed with geosynthetic sandbags to minimize seepage and subsequent piping failure due to scour. Influence of different lengths of sheet piles includes no socketing into the hard stratum - 8 m and 0.5 m above the hard stratum- 10 m are studied to control the seepage & uplift failures. Five different cases of study as shown in the Table 1 are considered. For all the cases, flow analysis is performed to study the seepage effects. The cross-section of the temporary boulder wall (case I) and sheet piles are installed at both U/s and D/s side with geosynthetic sandbags (case V) is presented in Figure 2 & 3 respectively.

– Case I: Temporary barrage without any strengthening measures
– Case II: Temporary barrage with geosynthetic sandbags as a cover
– Case III: Temporary barrage with geosynthetic sandbags and sheet pile wall on the U/s side
– Case IV: Temporary barrage with geosynthetic sandbags and sheet pile wall on the D/s side
– Case V: Temporary barrage with geosynthetic sandbags and sheet piles on the U/s & D/s side

4 NUMERICAL ANALYSIS

An idealized 2D plane strain model of the temporary barrage constructed on the breached potion of the brick masonry barrage with its dimensions is presented in Figure 4a. 15-noded triangular elements chosen to generate mesh and the meshed model is presented in Figure 4b. A Mohr-Coulomb constitutive relationship has been used for defining the elasto-plastic stress-strain behavior of different materials and the properties are provided in Table 2. The sheet pile is modelled as a plate element and the section details are given in Table 3. The sheet pile section chosen was JFESP-4 with intact interlock pattern which doesn't permit water or soil particles to pass through. A constant hydraulic head of 5 m is maintained throughout the analysis. Translations in all directions along the bottom boundary and translation in the

horizontal direction along the vertical boundaries are constrained in the analysis. Model boundaries are located away from the threshold boundary to avoid the boundary effect on the chosen area of interest.

Weight of the sheet pile, (kN)	1.9

5 RESULTS AND DISCUSSION

Because of high flood discharge, hydraulic failures such as piping, and uplift may arise and therefore it is essential to check for the satisfactory safety and stability of the structure. To predict the groundwater flow with the installation of a sheet pile wall, flow analysis has been carried out. Further separate safety analysis has been run to validate the adequate safety factor of the barrage against the piping failure.

5.1 *Seepage analysis*

The sheet pile wall is taken as an impermeable material in the analysis. The flow arrows signify the magnitude and direction of the water flow under the barrage. A steady-state two-dimensional groundwater flow vectors for case I without any strengthening measure is presented in Figure 5. This signifies that in the temporary barrage, a large quantity of flow is taking place through the barrage structure itself. On long-term, it may lead to a progressive increase in the scouring and internal erosion under the barrage. The groundwater flow vector for case II with geosynthetic sandbags is presented in Figure 6 represents that although the geosynthetic sandbags cannot completely mitigate the water seepage under the barrage, it can

protect the periphery to a great extent where the distress is high. The flow vectors presented in the Figure 7 for the case 5 of strengthened barrage with geosynthetic sandbag and sheet pile wall system evidently portray that the performance of combined sheet pile walls and geosynthetic sandbag system has a beneficial effect on seepage control.

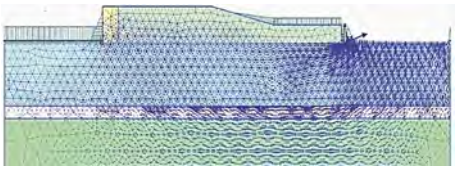

Figure 5. Groundwater flow vectors temporary boulder wall for the breached portion.

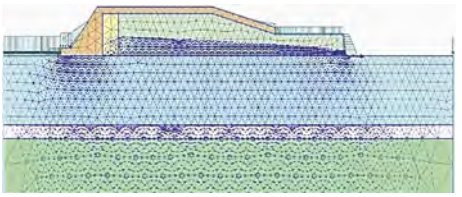

Figure 6. Groundwater flow vectors for strengthened barrage with geo-synthetic bags.

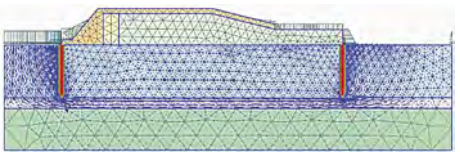

Figure 7. roundwater flow vectors for strengthened barrage with geo-synthetic bags and sheet pile walls installed at U/s and D/s side.

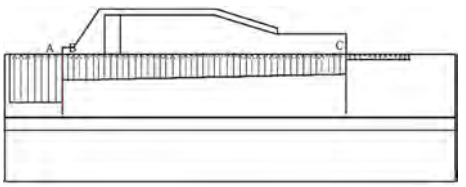

Figure 8. Typical sketch showing uplift pressure variation at the base of the footing.

5.2 *Effect of sheet pile on base heave*

The uplift pressure is measured at three locations, at a point before the sheet pile wall (A), after the U/s sheet pile wall (beginning of the barrage) (B) and before the D/s wall (toe of the barrage) (C) and for a typical case is presented in Figure 8. The base of the barrage structure must sustain the total pressure exerted by the hydraulic seepage beneath the structure. In other terms, if the structural weight is not sufficient to withstand the increased pressure exerted by the seeping water hydraulic heave may potentially occur. It shows that the uplift is reduced to a great extent by providing a sheet pile on the upstream side of the barrage. About 50% reduction in the uplift pressure is attained by providing a sheet pile at the upstream face of the barrage. Table 4 represents the reduction of the uplift pressure at the base of the structure with the installation of sheet pile wall at different locations and length. Nevertheless, the variation in the length of the sheet pile has minor influence in reducing the uplift pressure.

Table 4. Variation of pressure with length and location of sheet pile.

Different cases	Length of the sheet pile	Uplift pressure at the base of the footing (kPa)		
		A	B	C
III	8	50	25	6.5
	10	50	23	5
IV	8	50	45	30
	10	50	48	26
V	8	50	25	18
	10	50	23	17

5.3 *Effect of sheet pile on exit gradient*

One way to ensure the stability of a dam during the flood is to control the exit gradient. If the exit gradient exceeds the critical hydraulic gradient, it can lead to a failure mechanism called

piping. Since the exit gradient is inversely proportional to the path length, installation of sheet pile prominently increases the flow length and reduces hydraulic gradient therefore diminishes the piping failure especially at the toe. This can be seen in the results of a numerical analysis as shown in Figure 9, which illustrates the variation of exit gradient with location and length of sheet pile wall. It was observed that the exit gradient of the temporary boulder barrage was 1.05, but after the installation of sheet piles, it was reduced to 0.2. Additionally, it was found that the sheet pile wall installed at the downstream side was more effective in reducing the exit gradient than if it was only installed at the upstream side. Further with increase in the length of the sheet pile, exit gradient gradually decreases.

5.4 *Effect of sheet pile on factor of safety*

The overall safety factor of the barrage structure strengthened by geobags and sheet piles is calculated in Plaxis. As shown in Figure 10, the safety factor increased for all cases when sheet piles were installed. The safety factor of the temporary boulder barrage was only 1.05, which indicates that it was just safe. However, with the implementation of strengthening measure with sheet piles and geosynthetic sandbags, the FOS is increased to about 2.5. The undamaged section of the barrage has relatively higher FOS of about 1.9 but the long-term seepage may lead to reduce safety factor due to the piping action.

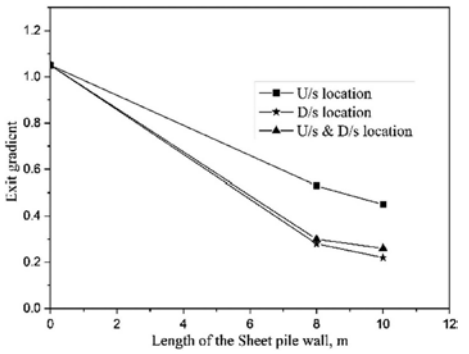

Figure 9. Variation of exit gradient.

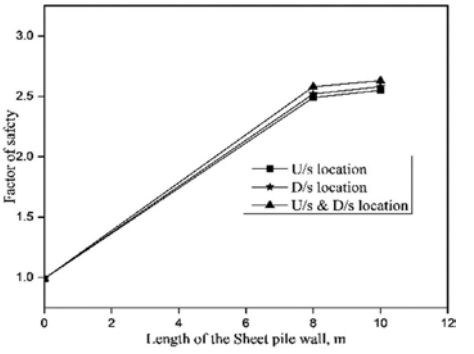

Figure 10. Variation of FOS.

6 CONCLUSIONS

Numerical analyses have been performed on the temporary boulder barrage strengthened with the different combinations of rows geosynthetic sandbags in front of the temporary boulder barrage and sheet pile wall in upstream and downstream of the river. The following are the conclusions drawn from the present study

- The installation of geosynthetic sandbags acts as a protective cover to control seepage and further the introduction of sheet piles acts as a seepage cutoff which improves the stability of the barrage structure.
- The inflowing water generates high porewater pressure that exerts great uplift force on the structure. The erection of the sheet pile wall at the upstream side tends to reduce the hydraulic heave of about 50% at the base of the structure.
- Increasing the sheet pile length favors the reduction of hydraulic exit gradient up to 70%. Thus, the exit gradient reduces with the sheet pile installed at the downstream side
- Along with geosynthetic sandbags provided in front of the temporary boulder barrage, sheet piles installed at both upstream and downstream side of the barrage, effectively arrests the heaving and piping respectively, and provides adequate stability to the hydraulic structure.

An extended mesh deformation algorithm for solving free surface problems

F.X. Liu & G.H. Lei
Key Laboratory of Geomechanics and Embankment Engineering of the Ministry of Education, Geotechnical Research Institute, Hohai University, Nanjing, China

H. Lin
School of Infrastructure Engineering, Nanchang University, Nanchang, China

ABSTRACT: The finite-element mesh deformation technique is one of the iterative solution methods used to locate the free surfaces in unconfined seepage flows through dams or levees. This technique involves adjusting the element heights and, hence, moving the top boundary of the mesh to the computed free surface as the iterations proceed. Smith et al. (2014) proposed an algorithm and program to adjust the element heights. In order to alleviate element distortion and improve numerical stability, Fenton & Griffiths (1997) proposed an additional algorithm and program to adjust the element widths. Nevertheless, these algorithms and programs have been specialized to the elements above the downstream water level. In this paper, the two algorithms are extended to the elements below the downstream water level. The validity of the extended algorithm is demonstrated by comparisons with results of an analytical solution, a closed-form approximate solution, and a numerical study with a commercial software.

1 INTRODUCTION

Deformed mesh, fixed mesh, and particle tracking techniques have been developed to locate the free surface. The mesh deformation technique was devised by Taylor & Brown (1967), Finn (1967), and Neuman & Witherspoon (1970). The free surface is located by iteratively adjusting the position of elements until the computed potentials along the top surface equal the elevation heads. It can be easily implemented in numerical computations because the hydraulic properties are held constant during the iteration process. Smith et al. (2014) provided a textbook algorithm and program to adjust the element heights and ultimately approach the free surface.

Excessive mesh deformation in the vertical direction can result in severe element distortion. Some elements may achieve an aspect ratio exceeding 5 and interior angles close to 180° as the free surface drops towards the downstream water level. This would lead to numerical instability or slow convergence (Cividini & Gioda, 1989). To overcome this drawback, Fenton & Griffiths (1997) proposed an additional algorithm and program to geometrically decrease the element widths in the downstream direction. Nevertheless, these algorithms and programs were specialized to the elements above the downstream water level. The heights and number of the elements below the downstream water level were not adjusted, as illustrated by Figures 7.14 and 7.19 of Smith et al. (2014). Distortions may occur in these elements. To prevent this from happening, this paper extends the two algorithms to the elements below the downstream water level.

2 INITIAL MESH

Only the lower part of a sloped earth dam or levee that is below the upstream water level is considered, as shown in Figure 1a. A Cartesian coordinate system xoy is defined with the origin at the downstream toe, the y axis positive upward, and the x axis coincident with the dam base. The reference datum for measuring the elevation head is placed at the x axis.

DOI: 10.1201/9781003299127-168

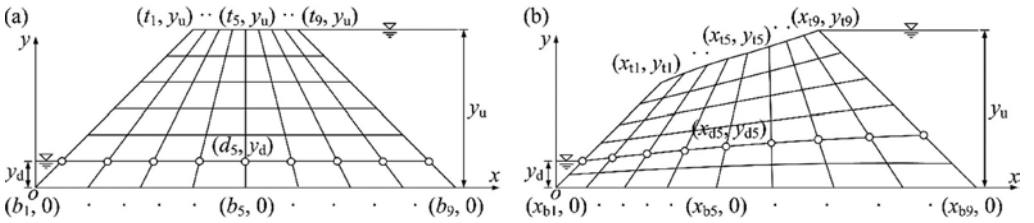

Figure 1. Mesh deformation by adjusting the heights and widths of the elements both above and below the downstream water level: (a) initial mesh; and (b) deformed mesh during the iterations.

The upstream and downstream water levels are denoted by y_u and y_d, respectively. The mesh below the upstream water level consisting of n_{xe} columns and n_{ye} rows of elements is initially generated as follows. The element nodes are evenly distributed along the top and bottom boundaries of the mesh. The x coordinates of the top and bottom nodes are denoted by t_i and b_i, respectively, where $i = 1, 2, \ldots, (n_{xe} + 1)$, increasing in the upstream direction. Each pair of the top and bottom nodes having coordinates (t_i, y_u) and $(b_i, 0)$ respectively is connected to form a straight line segment. These line segments are used to create the columns of the mesh.

A horizontal line at the downstream water level is used to divide the mesh into the upper and lower parts. The points of intersection between this division line and the straight line segments connecting (t_i, y_u) and $(b_i, 0)$ give the nodes on the division line, as shown by the open circles in Figure 1a. The coordinates of these nodes are denoted by (d_i, y_d), where $d_i = b_i + (t_i - b_i)y_d/y_u$.

A proportionality factor is defined to describe the proportion of the downstream water level y_d to the y coordinate of the topmost node on the downstream face, as given by

$$\lambda = \frac{y_d}{surf(1)} \tag{1}$$

where $surf(i)$ = a one-dimensional real array of length $(n_{xe} + 1)$, which is used to store the y coordinates of the nodes on the top boundary of the mesh. This proportionality factor is used to determine the numbers of rows of the elements below and above the division line as follows:

$$n_{ye\_d} = \mathrm{NINT}(\lambda n_{ye}) \text{ and } n_{ye\_s} = (n_{ye} - n_{ye\_d}) \tag{2}$$

where NINT = a function in FORTRAN, which returns the nearest integer to an argument.

The element nodes are evenly distributed along each straight line segment connecting (d_i, y_d) and $(b_i, 0)$ and each straight line segment connecting (t_i, y_u) and (d_i, y_d) according to the allocated numbers of rows of the elements below and above the division line, respectively. The coordinates of these nodes can be readily derived using analytic geometry formulas.

3 EXTENDED MESH DEFORMATION ALGORITHM

In each iterative computation, the free surface is assumed to be at the deformed top boundary of the mesh. The finite element computation is performed using program 7.3 of Smith et al. (2014). The hydraulic heads of the nodes on the top boundary of the mesh computed in the previous iteration are used to deform the mesh. Smith et al. (2014) proposed an algorithm and subroutine geom_freesurf (http://inside.mines.edu/~vgriffit/5th_ed/) to adjust the element heights. Fenton & Griffiths (1997) proposed a geometric spacing algorithm and subroutine mvmesh.f (http://random.engmath.dal.ca/rfem/) to adjust the element widths. By using these algorithms (for details, refer to the source references), the coordinates of the nodes on the top and bottom boundaries of the mesh are shifted to (x_{ti}, y_{ti}) and $(x_{bi}, 0)$, respectively, as shown in Figure 1b.

The array $surf(i)$ is updated using the values of y_{ti}, namely $surf(i) = y_{ti}$. The proportionality factor λ and the numbers of rows of the elements below and above the division line are recalculated using Equations 1 and 2, respectively. During the iteration process, the value of λ increases as the y coordinate of the topmost node on the downstream face, i.e., $surf(1)$,

decreases. This would possibly result in an increase and a decrease in the numbers of the elements below and above the division line, respectively, as illustrated in Figure 1.

The nodes constituting the deformed division line can be generated from the straight line segments connecting the top and bottom nodes, i.e., (x_{ti}, y_{ti}) and $(x_{bi}, 0)$. The y and x coordinates of these nodes are determined by $y_{di} = \lambda \times surf(i)$ and $x_{di} = x_{bi} + (x_{ti} - x_{bi})y_{di}/y_{ti}$, respectively.

The element nodes are evenly distributed along each straight line segment connecting (x_{di}, y_{di}) and (x_{bi}, y_{bi}) and each straight line segment connecting (x_{ti}, y_{ti}) and (x_{di}, y_{di}) according to the reallocated numbers of rows of the elements below and above the division line, respectively. The coordinates of these nodes can be readily derived using analytic geometry formulas.

The above procedure ensures that the total numbers of the elements and nodes are kept unchanged and the downstream water level intersects the downstream face at a node.

4 VALIDATION

To verify the validity of the extended mesh deformation algorithm, the free surfaces in steady-state seepage flows through a rectangular dam and an isosceles-trapezoidal dam were analyzed, as shown in Figures 2a-d and Figure 2e, respectively.

The rectangular dam has a width of 16 m. The upstream and downstream water levels are 24 m and 12 m, respectively. The saturated hydraulic conductivity (k_{sat}) was deliberately specified as 1 m/s because the free surface in a homogeneous isotropic dam is independent of k_{sat}. The initial mesh consisted of 16 columns and 24 rows of 1 m × 1 m square elements. The extended algorithm converged in 20 iterations. Figures 2a, b show the deformed mesh. The total number of the elements was kept unchanged. The elements both above and below the downstream water level were deformed. The elements widths were adjusted to be commensurate with their heights. The maximum aspect ratio of the elements is 1.55. Consider the elements along the downstream face. The numbers of the elements above and below the downstream water level were decreased from 12 to 4 and increased from 12 to 20, respectively. The common node of the elements adjacent to the downstream water level was exactly positioned at the water level. It is evident that the extended algorithm is effective in handling mesh deformation. The top boundary of the mesh represents the free surface obtained from the extended algorithm. The free surface in the rectangular dam was also computed by Liu et al. (2022) using Polubarinova-Kochina (1977)'s solution, as shown by the grey curve in Figure 2a. There is no discernible difference between the free surfaces obtained from the extended algorithm and the analytical solution. However, as shown by Figures 2c, d, the tail ends of the free surfaces obtained from the algorithms of Fenton & Griffiths (1997) and Smith et al. (2014) descend unevenly and exit somewhere below the free-surface exit points obtained from the extended algorithm and the analytical solution.

The trapezoidal dam has a bottom width of 150 m and a width of 30 m at the upstream water level. The upstream and downstream water levels are 37.5 m and 7.5 m, respectively. The k_{sat} value was assumed to be 10^{-7} m/s. The initial mesh consisted of 30 columns and 6 rows of trapezoidal elements. The extended algorithm converged in 11 iterations. Figure 2e shows the deformed mesh and the free surface. The maximum aspect ratio of the elements is 1.09. The free surface in the dam was also analyzed using SEEP/W (GEO-SLOPE International Ltd, 2015). In this analysis, the global element size was set as 2.0 m. The dam was discretized into 2625 four-node quadrilateral elements. The saturated–unsaturated soil model (Papagianakis & Fredlund, 1984) and the built-in volumetric water content function typical for clay were adopted. The saturated volumetric water content and the maximum matric suction were assumed to be 0.5 and 10 kPa, respectively. The Van Genuchten (1980) method was adopted to estimate the hydraulic conductivity function. The saturated hydraulic conductivity, the residual volumetric water content, and the maximum matric suction were set as 10^{-7} m/s, 0, and 10 kPa, respectively. These values made the hydraulic conductivity function steep enough to minimize water flow in the unsaturated zone and ensured that the resulting phreatic surface is close to the free surface (Lam et al., 1987). The free surface obtained from the analysis with SEEP/W is shown by the grey curve in Figure 2e. Additionally, the free surface in the trapezoidal dam was computed using Pavlovsky's method of fragments (Harr, 1962), as shown by the dotted curve in Figure 2e. These free surfaces are in good agreement with the free surface obtained from the extended algorithm.

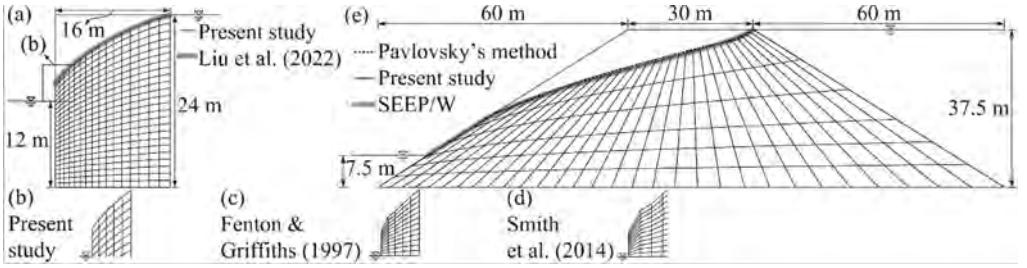

Figure 2. Deformed meshes and free-surface profiles in (a) a rectangular dam (insets b, c, and d: blow-up of the tail ends of the free surfaces obtained from different algorithms); and (e) a trapezoidal dam.

5 CONCLUSIONS

This paper extends the mesh deformation algorithms proposed by Smith et al. (2014) and Fenton & Griffiths (1997) to the elements below the downstream water level of a sloped dam or levee. The numbers of the elements above and below the downstream water level can be reallocated as the computed free surface drops towards the downstream water level. The heights and widths of all the elements are concurrently adjusted. The extended algorithm is shown to be effective in reducing element distortion and ensures that the downstream water level intersects the downstream face at a node throughout the iterations. The computed free surfaces from the extended algorithm are shown to be in good agreement with those from an exact analytical solution, a closed-form approximate solution and a finite-element analysis with SEEP/W.

ABSTRACT: An earthquake measuring 6.6 Mw struck southern Hokkaido, Japan, September 2018. Mizuho Dam and Azuma Dam were located near the epicenter of this earthquake and strongly shaken. The recorded base peak accelerations of Mizuho Dam in upstream and downstream directions was 491 gal and 937gal was recorded at dam crest. Maximum settlement of crest at upstream slope side was about 12cm and cracks attained about 2.0 m depth were observed around the crest. Azuma Dam's spillway was blocked by debris from landslides. Recorded base peak acceleration was 297 gal and 1293 gal was recorded at dam crest. A simple strain softening elasto-plastic constitutive model is applied to both dams with the features of non-associated flow characteristics, post-peak strain softening, and strain-localization into a shear band with a specific width. The dynamic response analyses of both dams and the computed settlements are compared to observed one.

1 INTRODUCTION

Mizuho Dam is a gravel-fill dam with central clay core zone shown in Figure 1 completed 1998. It is 25.9 m high and 427.05 m long, impounding up to 4,300,000 m^3 of water. Two seismometers were installed at the crest and the base ground as shown in Figure 1. An earthquake measuring 6.7 Mw on the moment magnitude scale struck Iburi Subprefecture in southern Hokkaido, Japan, on 6 September 2018. The earthquake's epicenter was near Azuma Town and occurred at a depth of around 33.0 km. Mizuho Dam located near the epicenter of this earthquake and strongly shaken. The recorded base peak acceleration of Mizuho Dam obtained by the seismometer in upstream and downstream direction was 491 Gal, and 937 Gal was recorded at the dam crest (Figure 2). Maximum settlement of the crest surface was about 8.0 cm (Figure 3), and main three cracks attained about 2.0 - 3.0 m depth were observed around the top edge of downstream slope (Figure 4).

Azuma Dam is a fill-type dam with mudstone and central clay core zone shown in Figure 11 completed 1971. It is 38.2 m high and 222.0 m long, impounding up to 10,080,000 m^3 of water. Two seismometers were installed at the crest and the base ground as shown in Figure 11. Azuma Dam also located around the epicenter of this earthquake and the recorded base peak acceleration obtained by the seismometer in upstream and downstream direction was 297 Gal, and 1293 Gal was recorded at the dam crest (Figure 12). The recorded

DOI: 10.1201/9781003299127-169

acceleration lasted only 30 seconds because the power supply was lost due to the slope failure on the right side downstream of the dam embankment. Maximum settlement of the crest surface was about 14.9 cm (Figure 13).

A simple strain softening elasto-plastic constitutive model is rather robust for application to a dynamic response analysis of fill-type dams. This strain softening material model was applied to Mizuho Dam and Azuma Dam with the features of non-associated flow characteristics, post-peak strain softening and strain-localization into a shear band with a specific width. In order to avoid the numerical instability due to the singularity of non-associated Mohr-Coulomb model, the constitutive model based on the yield function of Mohr-Coulomb type and the plastic potential function of Drucker-Prager type were used.

2 MATERIAL MODEL FOR BEHAXIOR OF GEOMATERIALS

The material model will be briefly described in this section (Tanaka 2002, 2015). The yield function (f) and the plastic potential function (Φ) are given by:

$$f = \alpha I_1 + \frac{\bar{\sigma}}{g(\theta_L)} - K = 0 \tag{1}$$

$$\Phi = \alpha' I_1 + \bar{\sigma} - K = 0 \tag{2}$$

where

$$\alpha = \frac{2\sin\phi}{\sqrt{3}(3-\sin\phi)} \tag{3}$$

$$K = \frac{6c\cos\phi}{\sqrt{3}(3-\sin\phi)} \tag{4}$$

$$\alpha' = \frac{2sin\psi}{\sqrt{3}(3-sin\psi)} \tag{5}$$

$$\sin\psi = \frac{\sin\phi - \sin\phi'_R}{1-\sin\phi\sin\phi'_R} \tag{6}$$

where I_1 is the first invariant (positive in tension) of deviatoric stresses and $\bar{\sigma}$ is the second invariant of deviatoric stress. With the Mohr-Coulomb model, $g(\theta_L)$ takes the following form;

$$g(\theta_L) = \frac{3-\sin\phi}{2\sqrt{3}\cos\theta_L - 2\sin\theta_L\sin\phi} \tag{7}$$

ϕ is the mobilized friction angle, c is the cohesion, ψ is the dilatancy angle and θ_L is the Lode angle.

In case of simple strain softening constitutive model, the frictional softening is given by next function.

$$\alpha(\kappa) = \alpha_p + \alpha_1\kappa/(B+\kappa) \;\; \alpha_1 = -(\alpha_p - \alpha_R) \tag{8}$$

and cohesion softening function is by next function.

$$\gamma(\kappa) = \gamma_p + \gamma_1\kappa/(C+\kappa) \;\; \gamma_1 = -(\gamma_p - \gamma_R) \tag{9}$$

The dilatancy is reduced by next function.

$$\alpha'(\kappa) = \alpha'_p(1 - \kappa/(C + \kappa)) \tag{10}$$

where κ is plastic parameter, B, C, D are constants for softening function. The suffices P, R represent the peak and residual state. Where γ is shear strain, γ_R is reference shear strain.

A more realistic frictional softening functions expressed as follows;

$$\alpha(\kappa) = \alpha_r + (\alpha_p - \alpha_r)\exp\left\{-\left(\frac{\kappa - \varepsilon_f}{\varepsilon_r}\right)^2\right\} \quad (\kappa \geq \varepsilon_f) \tag{11}$$

where ε_f and ε_r are the material constants and α_p and α_r are the values of α at the peak and residual states.

The residual friction angle (ϕ_r) and Poison's ratio (ν) were chosen based on the data from the triaxial compression test.

$$G_0 = G_E \frac{(2.17 - e)^2}{1 + e}\sigma_m^{0.4} \tag{12}$$

The elastic moduli are estimated using the following equations.

$$K = \frac{2(1 + \nu)}{3(1 - 2\nu)}G \tag{13}$$

The peak friction angle is a function of confining pressure, initial void ratio e and G_E is empirical constant.. The dilatancy angle (ψ) was estimated from Rowe's stress-dilatancy relation. The introduction of shear banding in the numerical analysis was achieved by introducing a strain localization parameter s in the following additive decomposition of total strain increment as follows.

$$d\varepsilon_{ij} = d\varepsilon^e_{ij} + sd\varepsilon^p_{ij} \quad s = F_b/F_e \tag{14}$$

where F_b is the area of a single shear band in each element and F_e is the area of the element.

An one-point integration method and an hourglass control scheme are used with 4-noded two-dimensional isoparametric element (Flanagan & Belytschko 1979). This element is effective and suited for collapse analysis of frictional material with shear banding. The most fully integrated continuum elements tend to lock especially for geomaterials, so the selection of element type is important for the collapse analyses of embankment dams. Simple shear strength is appropriate for earthquake response analysis of a fill-type dam and triaxial compression test results of layered soil sample are approximately equivalent to shear strength of horizontally anisotropic fill materials. We employed the triaxial compression test results for the two-dimentional dynamic analyses of fill-type dams.

3 DYNAMIC RESPONSE ANALYSIS OF MIZUHO DAM

The simple strain softening elasto-plastic constitutive equation was applied to the impounded Mizuho Dam. Figure 5 showed the finite element mesh used for dynamic response analysis. Before dynamic response analysis, build-up analysis was carried out.

Table 1 showed the material parameters for the dynamic analysis. The core materials (①, ②) were assumed undrained condition during the earthquake and elasto-plastic constitutive

model was applied. The strengths of core materials were obtained by isotropically consolidated undrained triaxial compression test. The internal friction angle was 25.3°. The cohesion was 32.3 kN/m^2. The constant (G_E) for elastic moduli was 40,000 kN/m^2. The assumed shear band thickness (*S.B.*) was 0.5 cm, taking into consideration that the thickness of shear band is 15~20 times of mean diameter of fill materials.

The strengths of semi-permeable materials were obtained by isotropically consolidated undrained triaxial compression test combined with cyclic loading and succeeding monotonic loading. The material constants of these zones used for the analyses were as follows: φ_{peak} = 32.0°, φ_{res} = 24.6°, c_{peak} = 53.0 kN/m^2, c_{res} = 38.8 kN/m^2, B = 0.5, C = 0.3, D = 0.7, G_E = 80,000 kN/m^2, *S.B.* = 3.0 cm (Case 1).

For semi-permeable zones (④, ⑥, ⑩) mainly at downstream slope side, drained condition were assumed. The strengths of semi-permeable materials were obtained by isotropically consolidated drained triaxial compression tests. The material constants of these zones were as follows: φ_{peak} = 39.2°, φ_{res} = 36.1°, c_{peak} = 22.0 kN/m^2, c_{res} = 19.0 kN/m^2, B = 0.5, C = 0.3, D = 0.7, G_E = 80,000 kN/m^2, *S.B.* = 3.0 cm (Case 2).

The filter zone (⑦) was assumed drained condition and the material constants of this zone are as follows: φ_{peak} = 42.9°, φ_{res} = 33.0°, c_{peak} = c_{res} = 0.0 kN/m^2, B = 0.5, C = 0.3, G_E = 100,000 kN/m^2, *S.B.* = 5.0 cm. The riprap (⑧, ⑨) zones were assumed drained conditions and the material constants of these zone were as follows: φ_{peak} = 44.0°, φ_{res} = 33.0°, c_{peak} = c_{res} = 0.0 kN/m^2, B = 0.5, C = 0.3, G_E = 120,000 kN/m^2, *S.B.* = 14.0 cm.

The Rayleigh damping was assumed 5.0%. The input acceleration was measured one at the base of dam as shown in Figure 2.

In Case 1, Figure 6 showed the computed response acceleration at the crest centre. Although the computed maximum response acceleration was larger than measured maximum response acceleration (937 Gal), the time of computed maximum response acceleration agreed at the time (12 second) of measured maximum response acceleration. Figure 7 showed the computed vertical displacements around crest. Maximum vertical displacements of No.2812 at the crest center and No.2785 around the top edge of upstream slope were about 5.0 cm, and maximum vertical displacements of No.2823 around the top edge of downstream slope was about 7.0 cm. As the measured crest settlements of this dam were within ranging from 5.3cm to 8.0cm, we could say that the comparable results were obtained.

In Case 2, Figure 8 showed the computed response acceleration at the crest center. The computed maximum response acceleration of Case 2 was smaller than that of Case 1, and the time of maximum acceleration agreed well as Case 1. Figure 9 showed the computed vertical displacement around crest. Although results of Case 2 tended to be larger than those of Case 1, the comparable result was obtained in Case 2, too.

Figure 10 showed the computed maximum shear strain distributions after 40 sec. by Case 1 and Case 2. The computed maximum shear strain (Case 1), was about 13% and concentrated around the top edge of downstream slope as shown in Figure 10, so we could say that the comparable results as observed were obtained.

4 DYNAMIC RESPONSE ANALYSIS OF AZUMA DAM

The simple strain softening elasto-plastic constitutive equation was also applied to the impounded Azuma Dam. Figure 14 showed the finite element mesh used for dynamic response analysis. Before dynamic response analysis, build-up analysis was carried out.

Table 2 shows material parameters for the dynamic analysis. The Core1 (①, ②) and Core2 (③) materials were assumed undrained condition during the earthquake. The total stress

strengths of core materials were obtained by isotropically consolidated undrained triaxial compression test. The Core1 internal friction angle was 15.0° and cohesion was 37 kN/m^2. The Core2 internal friction angle was 13.0° and cohesion was 51 kN/m^2. The elastic moduli (G_E) were 40,000 kN/m^2. The assumed shear band thickness (S.B.) was 0.2 cm.

The semi-permeable zones (④, ⑥) were assumed undrained condition during the earthquake. The total stress strengths of semi-permeable materials were obtained by isotropically consolidated undrained triaxial compression test. The material constants of saturated semi-permeable zones (④, ⑥) used for strain softening model were as follows: φ_{peak} = 15.0°, φ_{res} = 15.0°, c_{peak} = 81.5 kN/m^2, c_{res} = 81.5 kN/m^2, B = 0.5, C = 0.3, D = 0.7, G_E = 80,000 kN/m^2, S.B. = 4.0 cm. For unsaturated semi-permeable zones (⑤) at downstream slope side, the strengths of the material was obtained by isotropically consolidated undrained triaxial test on the in-situ density (density of 100% D-value). The material constants of this zone were as follows: φ_{peak} = 27.2°, φ_{res} = 27.2°, c_{peak} = 7.4 kN/m^2, c_{res} = 7.4 kN/m^2, B = 0.5, C = 0.3, D = 0.7, G_E = 80,000 kN/m^2, S.B. = 4.0 cm.

The filter zone (⑦, ⑧) was assumed drained condition and the material constants of this zone as follows: φ_{peak} = 40°, φ_{res} = 40°, c_{peak} = c_{res} = 0.0 kN/m^2, B = 0.5, C = 0.3, G_E = 100,000 kN/m^2, S.B. = 1.8 cm. The riprap (⑨, ⑩) zone was assumed drained condition and the material constants of this zone were as follows: φ_{peak} = 30°, φ_{res} = 30°, c_{peak} = c_{res} = 0.0 kN/m^2, B = 0.5, C = 0.3, G_E = 120,000 kN/m^2, S.B. = 20 cm.

The Rayleigh damping was assumed 5.0%. The input acceleration was measured one at the base of dam as shown in Figure 12. Figure 15 showed the computed response acceleration at the crest centre by simple strain softening elasto-plastic analysis. Although the computed maximum response acceleration (1090 Gal) was smaller than measured maximum response acceleration (1293 Gal), the time of computed maximum response acceleration agreed with the time (15.6 second) of measured maximum response acceleration. Figure 16 showed the computed vertical displacements the around crest by simple strain softening elasto-plastic analysis. The maximum vertical displacements of No.1809 at the crest center and No.1814 around the top edge of downstream slope were about 5.4 cm and 8.6 cm. Maximum vertical displacements of No.1805 around the top edge of upstream slope was about 18.1 cm. As the maximum measured crest settlement of this dam was within ranging from 14.9 cm, we could say that the comparable results were obtained.

5 CONCLUSIONS

A simple strain softening material model for geomaterial is used with the features of post-peak strain softening, and strain-localization into a shear band with a specific width. This material model is applied to the computation of real rock-fill dams. We obtained earthquake induced accelerations and displacements of Mizuho Dam which is 25.9 m high and Azuma Dam which is 38.2 m high. The computed accelerations at the crest of dams are compared to the observed ones and the computed displacements are also verified by the observed displacements. The simple strain softening constitutive model is applicable to the computation of a real fill-type dam.

ABSTRACT: The subgrade is an important part of the transportation system. Once it damaged in the earthquake, not only could create huge direct ecnomic loss, but also create difficulties to the rescue work. On 12 May 2008, a magnitude 8.0 earthquake occurred in WenChuan of Sichuan province, caused the destroy of many subgrade existed or in buliding such as overturn, remove and crack. Therefore, the research on emergency assessment of the subgrade damaged in earthquake has practical significance to the structure seismic performance evaluation and the earthquake emergency. In this paper, the key issues associated with post-earthquake emergency inspections of subgrades are presented, such as the forms of subgrade damage, the damage features under earthquake and the influence factors. Safety criteria are established and correlations of such criteria with various damage states are given. This paper presents the methods followed in the evaluation process, highlights the items for evaluation and intends to provide technical references for the post-earthquake disease prevention, diagnosis and disease treatment.

Keywords: subgrade, characteristics of seismic damage, safety assessment

1 INSTRUCTION

The safety of subgrade structure under earthquake action is one of the important problems in geotechnical seismic engineering and highway engineering. In the Wenchuan earthquake, the subgrade project once became the most critical lifeline project to be guaranteed, making the safety evaluation of the subgrade project after the earthquake a key issue to be solved.

In the process of earthquake, it is very common for highway subgrade structure to be damaged. Earthquakes with different intensities may cause subgrade structure deformation, local damage and even collapse. In history, it can be seen from many earthquake cases at home and abroad[1-3]. The damage of highway subgrade caused by earthquake is common, causing great economic losses to the society. Earthquake damage investigation is the most direct and reliable method to understand the working performance of subgrade structure after earthquake, and is also an important basis to verify theoretical analysis, model test methods and results[4]. Under different earthquake action, the earthquake damage characteristics of engineering structures with different site conditions are also different. Previously, the detailed earthquake damage investigation on the embankment was the 2004 Niigata Ken Chuetsu Earthquake[5] in Japan, with magnitude of 6.8. The recorded maximum acceleration exceeded is 1g, which

DOI: 10.1201/9781003299127-170

Figure 1. Direct damage.

Figure 2. Indirect damage.

caused damage to a large range of road embankments. The 2008 Wenchuan earthquake in China, with a magnitude of 8.0, recorded a maximum acceleration of 0.973 g and a duration of more than 80 s [6], was the most powerful earthquake in the western mountainous area of China in modern times. The road embankment in the earthquake area was damaged in various forms and seriously.

China is located in the two most active seismic zones in the world. It is an earthquake prone country. There are numerous highways in the strong earthquake zone. In the Tangshan earthquake in 1976, the highway subgrade structure in the earthquake area was seriously damaged. Among them, at k267 + 374 of Beijing Shanhaiguan railway line, one stone shoulder retaining wall on the side of Shanhaiguan was 3-4m high and 9m long. After the earthquake, the whole retaining wall overturned 20cm outward. In the 2008 Wenchuan earthquake, the highway subgrade was severely damaged. Among them, at k1030 + 400 of Dujiangyan Yingxiu highway of national highway 213, the subgrade subsided, the pavement cracked, the right retaining wall tilted outward and the foundation was empty, and half of the road passed. Therefore, it is of great significance to study the investigation and detection technology of post earthquake highway subgrade structure, conduct rapid evaluation and damage detection on the post earthquake safety of subgrade structure, and provide scientific basis for the seismic reinforcement of subgrade structure.

2 SEISMIC DAMAGE MANIFESTATION OF HIGHWAY SUBGRADE STRUCTURE

2.1 *Two main types of earthquake damage of subgrade structure*

1. Direct damage: the so-called direct damage refers to the rupture or instability of the subgrade structure itself caused by poor filling quality of the subgrade, insufficient retaining capacity of the wall, and excessive seismic load (Figure 1).
2. Indirect damage: refers to the compression deformation of subgrade caused by slope sliding induced by earthquake, which is easy to induce cracking, sliding and even collapse of subgrade, which is the most serious case of all subgrade structural accidents (Figure 2).

2.2 *Specific manifestations of subgrade earthquake damage* [7 ~ 9]

(1) Subgrade settlement, distortion and deformation: This is a common earthquake damage in the earthquake area, which is manifested in two aspects: 1) Subgrade settlement, deformation and damage; 2) The deformation and damage of subgrade surface are caused by the fault dislocation caused by the earthquake or the deformation of underground rock stratum caused by compression, distortion and tension.

(2) Subgrade cracking and sliding damage: it is mainly manifested in the half filled and half excavated subgrade on the slope. Because the compactness of the filled and excavated subgrade is inconsistent, and the base is soft and hard, it is easy to crack along the filling and excavation interface and form a penetrating soft surface with the rock and soil interface or the filling and undisturbed soil interface to cause sliding damage. In addition, when the subgrade filler is gravel soil, loose sliding occurs at the edge of the subgrade during the earthquake.
(3) Subgrade and pavement heave and extrusion damage: affected by seismic surface wave, the surface wave fluctuates, causing the subgrade to fluctuate and deform. In the bulged section, many transverse tensile cracks are generated, and the pavement is squeezed away in serious cases.
(4) Collapses, landslides and mudslides: collapses often occur in high slope sections with developed cracks and loose and broken rock masses. Collapses are mostly related to the presence of soft and broken rocks, groundwater activities, structural weak surfaces, etc., while mudslides often occur in steep valleys due to loose deposits formed by collapses and landslides under the action of rain. In addition, the loose and saturated gravel soil slope often suffers from shallow surface collapse.
(5) Damage of subgrade retaining and protection works: there are many phenomena of subgrade retaining walls in the earthquake area, such as collapse, outward inclination, lateral displacement, wall bulging and foundation void. These phenomena are related to factors such as the reduction of foundation bearing capacity, increase of earth pressure, uneven settlement of foundation, wall material and construction quality during the earthquake. In addition, pebbles are used as raw materials for some retaining walls in the survey area. After the earthquake, these retaining walls basically become loose.
(6) Secondary damage caused by the earthquake to the subgrade: for example, the river is blocked by the collapse, and the water level rises to submerge the highway; The river compression causes the rapid water flow to wash away the subgrade; The subgrade is damaged by collapse and rockfall; Landslide and debris flow buried the subgrade. Not only that, because the rock mass is loosened and the hillside cracks, secondary disasters such as landslides, collapses and mudslides will occur in succession for a long time after the earthquake, causing great harm to the highway.

2.3 *Main characteristics of earthquake damage of subgrade retaining structure*

(1) During the earthquake, the retaining wall will move together with its surrounding media. When the structure has obvious inertia or the stiffness mismatch between the surrounding media and the structure, it will be damaged due to excessive deformation.
(2) The earthquake damage of retaining wall mostly occurs in the area where the stratum conditions are greatly changed. In these areas, the changes of geological conditions or topography cause the stratum vibration and displacement response to be greatly different, thus generating large strain and causing the destruction of retaining wall structure.
(3) The parts with varying wall thickness and height are prone to disease. The corner of the retaining wall is also prone to damage, which is the weak link of anti-seismic.
(4) The retaining wall is easy to be damaged by earthquake when it is located in unfavorable geological conditions such as liquefiable strata and faults.

3 THEORETICAL STUDY ON SIMILARITY RELATION OF SUBGRADE SHAKING TABLE TEST MODEL

3.1 *General requirements for dynamic model tests*

Geometry Condition. Geometric similarity requires that the model and the prototype should remain similar in geometry and corresponding spatial location, so the length L, area A and the volume V should meet the following relationship:

$$A = L^2,\ V = L^3. \tag{1}$$

Movement Condition. The samilarity of the movement condition of the model and the prototype is that the corresponding velocity should in the same directionand proportion to the size, so the displacement, velocity and acceleration should satisfy the following relation equation respectively:

$$[\dot{u}] = \frac{d[u]}{dt},\ [\ddot{u}] = \frac{d[\dot{u}]}{dt} = \frac{d^2[u]}{dt^2},\ [u]^T = [u_x, u_y, u_z] \tag{2}$$

Where: T —— time; $[u]^T$—— soil displacement vector.

Physical Condition. For the physical condition similarity, mechanical properties and responses induced by the load must be similar, Prototype and model should satisfy the following equation:

Soil effective stress principle:

$$\begin{aligned} &[\sigma'] = [\sigma] - [m]p.\ \ [m]^T = (1,1,1,0,0,0) \\ &[\sigma]^T = [\sigma_x, \sigma_y, \sigma_z, \tau_{xy}, \tau_{yz}, \tau_{zx}]. \\ &[\sigma']^T = [\sigma'_x, \sigma'_y, \sigma'_z, \tau'_{xy}, \tau'_{yz}, \tau_{zx'}]. \end{aligned} \tag{3}$$

where $[\sigma]^T$—— total stress vector of soil unit; $[\sigma']$—— effective stress vector of soil unit; P —— pore water pressure.

Soil deformation geometry equations:

$$\begin{aligned} &[d\varepsilon] = [L][du]. \\ &[L]^T = \begin{bmatrix} \frac{\partial}{\partial x} & 0 & 0 & \frac{\partial}{\partial y} & 0 & \frac{\partial}{\partial z} \\ 0 & \frac{\partial}{\partial y} & 0 & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} & 0 \\ 0 & 0 & \frac{\partial}{\partial z} & 0 & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \end{bmatrix} \\ &[\varepsilon]^T = (\varepsilon_x, \varepsilon_y, \varepsilon_z, \gamma_{xy}, \gamma_{yz}, \gamma_{zx});\ \ [u]^T = (u_x, u_y, u_z). \end{aligned} \tag{4}$$

where $[\varepsilon]^T$—— strain vector of soil element; $[u]^T$—— soil displacement vector.

Constitutive law of soil: expressed by the tangent or secant modulus [D] of the stress-strain relationship and assume particle itself can not compressed, so obtain the following constitutive:

$$[d\sigma']^T = [D][d\varepsilon]. \tag{5}$$

where $[D]$—— tangent or secant modulus decided by the soil stress-strain constitutive;

Dynamic Equilibrium. Dynamic equilibrium equation of soil:

$$[L]^T[\sigma] + \rho[g] = \rho[\ddot{u}].\ \ [g]^T = (0, -g, 0). \tag{6}$$

where ρ—— natural density of soil; $[g]^T$—— acceleration of gravity.

Boundary Condition. The similar transformation of the boundary condition can be obtained by the following to satisfy the similarity.

$$[u]_s = [u]_r \tag{7}$$

where s —— represent the soil;

r —— represent the retaining wall.

The Design of Model Similar Ratio.

Similar Ratio Constant. Prototype and model meet the geometric similarity:

$$C_l = \frac{L_p}{L_m} = \frac{[x]_p}{[x]_m} \tag{8}$$

where p —— represent the prototype; m —— represent the model.

The physical meaning of other symbols is the same as the former.

Similar constant of the soil displacement C_u, the soil velocity $C_{\dot{u}}$, and the soil acceleration $C_{\ddot{u}}$can be expressed by the following equations:

$$C_u = \frac{[u]_p}{[u]_m}, \quad C_{\dot{u}} = \frac{[\dot{u}]_p}{[\dot{u}]_m}, \quad C_{\ddot{u}} = \frac{[\ddot{u}]_p}{[\ddot{u}]_m} \tag{9}$$

Similar constant of the soil stress C_σ, the soil strain C_ε, and the tangent or secant modulus can be expressed by the following equations:

$$C_\sigma = \frac{[\sigma]_p}{[\sigma]_m}, \quad C_\varepsilon = \frac{[\varepsilon]_p}{[\varepsilon]_m}, \quad C_G = \frac{[G]_p}{[G]_m} \tag{10}$$

$$C_D = \frac{[D]_p}{[D]_m}, \quad C_K = \frac{[K]_p}{[K]_m}, \quad C_\mu = \frac{[\mu]_p}{[\mu]_m} \tag{11}$$

Similar constant of the time C_t, the gravity acceleration C_g, and the density $C_{\ddot{u}}$ can be expressed by the following equations:

$$C_t = \frac{t_p}{t_m}, \quad C_g = \frac{[g]_p}{[g]_m}, \quad C_\rho = \frac{\rho_p}{\rho_m} \tag{12}$$

Similar Conditions. Through the similar transformation of the above conditions, we can get the similarity of the prototype and model.

Geometry similar condition: put formula (8) into (1) to conduct similarity transformation, then it comes to the available geometry similar conditions:

$$C_A = C_l^2, \quad C_V = C_l^3 \tag{13}$$

Movement similar condition: put formula (9) into (2) to conduct similarity transformation, we can obtain the movement similar conditions:

$$C_{\dot{u}} = \frac{C_u}{C_t}, \quad C_{\ddot{u}} = \frac{C_{\dot{u}}}{C_t} \tag{14}$$

Physical similar condition: by the similarity transformation of formula (10)~(11) and (3)~(5), it comes to the available physical similar conditions:

$$\begin{aligned} &C_\mu = 1 \\ &C_E = C_G = C_K = C_D \\ &C_u = C_l C_\varepsilon \\ &C_\sigma = C_D C_\varepsilon \end{aligned} \tag{15}$$

Dynamic similar condition: put formula (12) into (6) to conduct similarity transformation, then it comes to the available dynamic similar conditions:

$$C_\sigma C_l^{-1} = C_\rho C_g = C_\rho C_{\ddot{u}} \tag{16}$$

Boundary similar condition: through the similar transformation of the formula (7), we can get:

$$C_{us} = C_{ur} \tag{17}$$

3.2 *Experimental result analysis*

The primary goals of the shaking table model test are to reproduce the mechanical phenomena of the prototype under static and dynamic loading. The similarity relation is to deduce the responses of the prototype based on the monitor of the model responses. On the one hand, the similarity provides the rules of the model results projected to the prototype; the other hand, the similarity provides the similar conditions must be met.

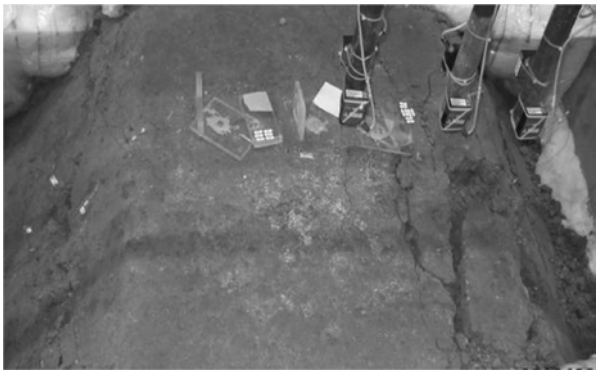

Figure 3. Fracture coalescence on the top of the subgrade model with retaining wall.

The modle test is realized smoothly considering the input earthquake wave type, intensity, frequency and multi-direction input. we use the finite difference program to simulate the shaking table test at the same time, so as to prove the rationality of the numerical analysis model. Based on the shaking table test results and the numerical analysis results, some knowledge of subgrade model dynamic response is achieved which including the acceleration magnification and displacement response and dynamic soil pressure on retaining wall and other aspecets of the analysis.

4 INFLUENCING FACTORS OF SUBGRADE STRUCTURE EARTHQUAKE DAMAGE

4.1 *Affecting factors of subgrade earthquake damage*

(1) The failure of subgrade slope is related to the lithology of rock mass, weathering and fragmentation degree and geological structure.
(2) The degree of subgrade damage is closely related to the distance from the epicenter and the seismogenic fault. According to the investigation, the closer the road subgrade is to the epicenter and the seismogenic fault, the greater the degree of subgrade damage is[10].
(3) The failure of the slope under the subgrade is related to the slope, protection type and height, treatment measures and other factors.

(4) The seismic damage of the upper slope of the subgrade is related to such factors as whether it is protected, whether the protection type is appropriate, the lithology of the rock mass and the degree of weathering and fragmentation.

4.2 *Factors affecting earthquake damage of subgrade retaining structure*

(1) Earthquake intensity. A large number of earthquake damage data show that when the earthquake intensity reaches 7 degrees, the retaining wall may be overturned, slid, cracked or even collapsed.
(2) Geological conditions. The geological conditions directly affect the magnitude and mode of the force exerted by the media around the retaining wall on the retaining wall during the earthquake, and the mode of the force acting on the retaining wall has a decisive effect on the failure mode of the retaining wall.
(3) Structure type of retaining wall. The seismic capacity of masonry retaining wall is weaker than that of reinforced concrete gravity retaining wall, and the seismic capacity of gravity retaining wall is weaker than that of reinforced soil and other flexible retaining walls.

5 SAFETY ASSESSMENT OF SUBGRADE WORKING CONDITION AFTER EARTHQUAKE

5.1 *Safety diagnosis items and evaluation of subgrade structure after earthquake*

After the earthquake, the subgrade shall be specially inspected immediately. The main purpose of the investigation and detection is to confirm the safety of the subgrade, master the status quo of the subgrade after the earthquake, and find out the adverse factors that have an impact on the safety and function of the subgrade structure. Countermeasures shall be taken as soon as possible according to the adverse degree, and timely treatment shall be carried out to ensure the safety of the subgrade and ensure smooth traffic. The inspection items of the subgrade after the earthquake mainly include slope, foundation, pavement, drainage system and retaining structure. Table 1 is the specific inspection contents. According to the inspection results, it is divided into three categories for evaluation.

5.2 *Diagnosis method of subgrade structure after earthquake*

After the earthquake, the main purpose of investigation and detection is to confirm the safety of subgrade structure. Therefore, the investigation and detection methods are required to be fast, convenient and targeted. The diagnostic methods adopted mainly include the following three types:

(1) Visual inspection method. At the construction site, walk for close inspection. In the process of investigation and detection, in addition to careful observation with the naked eye, advanced optical instruments, such as crack observation instrument, total station and digital camera, shall also be combined to provide accurate detection data for judging the safety of subgrade structure.
(2) Non destructive testing methods. According to the visual inspection results, the key inspection parts shall be identified for geological radar inspection to determine the crack development in the subgrade structure.
(3) Special investigation and testing. After the subgrade structure encounters an earthquake, in order to timely grasp the damage of the subgrade structure, judge whether it meets the use function and safety, and provide basis and suggestions for the design of subgrade maintenance and reinforcement, in addition to the above inspection and detection, special investigation and detection shall also be carried out. The main items of special investigation and detection include: surface condition, borehole coring, strength of retaining wall, buried depth of retaining wall toe, etc.

Table 1. Inspection contents of subgrade structure after earthquake.

respondents	Investigation contents
subgrade	Pit (depth, cause and area); Cracks (length, width, spacing, height of staggered sill); Overall settlement; The degree of perfection of drainage facilities and the degree of pavement wetting; Pavement deformation and damage; Deformation and failure of subgrade slope; Deformation of subgrade slope toe and foundation; Water content of slope; Operation of surface drainage system.
retaining wall structure	Apparent integrity; Deformation and movement characteristics (translation and rotation); Rock and soil deformation and failure related to retaining structure; Characteristic indexes of rock and soil mass; Environmental index of rock and soil mass.

Table 2. Evaluation of test results of subgrade structure after earthquake.

Safety grade	Evaluation classification	Damage degree	Damage condition	Traffic measures
No immediate danger	S	No abnormality	Through visual observation, no abnormality is found, the subgrade surface and retaining wall are not damaged obviously, and there is no need to repair after the earthquake.	Normal traffic
		Slight abnormality	Slight cracks on the retaining wall can be observed with the naked eye. There are slight cracks, slight depressions and bulges on the pavement, which do not affect the normal use and traffic. There is no need to repair after the earthquake.	
Danger	B	Abnormal	The subgrade surface is obviously damaged. The pavement is cracked, staggered, uneven and bulging. The crack width is less than 10cm. There is a small-scale collapse phenomenon at the embankment edge. The falling rocks of the cutting slope are peeled off to the pavement, causing inconvenience to the traffic. After simple treatment, the traffic can be smoothly opened; The retaining structure includes wall spalling, pointing dislocation, rebar exposure, expansion joint dislocation, etc., which has an impact on traffic.	Controlled traffic
	A	Significant abnormality	The subgrade surface is damaged obviously, the pavement is cracked obviously, the pavement is staggered seriously, the crack width is more than 10cm, the uneven and bulging of the pavement causes the pavement damage, the embankment collapses and moves sideways, the slope collapses and falling rocks fall on the pavement, the slope landslide buries the pavement, and the driving space is narrow or impassable; The side slope of the retaining wall collapses, the sliding or overturning of the retaining wall, and the foundation of the retaining wall is empty. The traffic can be restored after a certain period of time.	Closed to traffic

6 CONCLUSION

The phenomenon and characteristics of the damage caused by the Wenchuan earthquake to the roads deserve deep consideration, especially the damage to the low-grade roads, which is almost completely destroyed. Through this earthquake, we can see that the seismic capacity of highway engineering is still very weak. When the earthquake intensity reaches 7 degrees, the subgrade structure may crack or even collapse and overturn due to the earthquake damage, interrupt the traffic, and cause huge economic losses. It is very important to study the safety evaluation of the subgrade structure after the earthquake and determine the safety of the subgrade in time so as to take reasonable post earthquake repair measures and ensure the safe operation of the road.

Through earthquake disaster investigation and shaking table test this paper analyzes the general forms of earthquake damage to highway subgrade structures, the main characteristics of earthquake damage and the influencing factors of earthquake damage. On this basis, the contents and evaluation methods of post earthquake safety detection of subgrade structures are given, which can be used as reference for relevant professional and technical personnel in post earthquake investigation and diagnosis of highway subgrade structures.

ABSTRACT: Land subsidence, as a gradual settling of the ground surface, has become a threatening hazard to many infrastructures and lifelines. Among them, electricity dispatch centers (EDC) are considered the heart of a typical power transmission system, closely related to both domestic and industrial aspects of society. Therefore, this study aims to systematically explore early warnings and damages imposed on EDCs in Tehran. A combination of field reconnaissance and InSAR time series analyses are adopted to correlate subsidence-induced damages with several triggering mechanisms, such as the dynamic effects of subways and extra groundwater exploitation. Accordingly, spatially- and temporally-distributed deformation time series and velocities are produced between September 2019 to October 2021. To achieve that, the LiCSAR products are derived for all EDC locations using the LiCSBAS processing package. Eventually, the consequences of land subsidence for EDCs in terms of various types of damages and warnings are reported, classified, and discussed.

1 INTRODUCTION

Land subsidence (LS) caused by natural and human factors has become a growing threat infrastructures and a hence a global challenge (Bagheri-Gavkosh et al. 2021). LS occurs mainly in soil strata containing fine-grained plastic particles with evolving microstructures (Sadeghi, 2016; Sadeghi and Ng, 2018). Despite the minor influence of natural factors, human activities such as groundwater over-exploitation and urban infrastructure construction have been recognized as the most important factors affecting the occurrence and development of LS (Roccheggiani et al. 2019). Consequently, human activity mainly causes considerable subsidence-induced damage to many infrastructures and lifelines.

The electricity power distribution system is probably the most influential lifeline affecting a variety of industrial plants and household activities if a network instability and hence a sudden shutdown is enforced. Electricity dispatch centers (EDC) are considered as the central core of a general power transmission system. In other words, any malfunction caused to the electrical facilities installed in an EDC may cause significant property loss and operational delay (Jin et al. 2022). Iran is one of the countries that suffer from a high LS rate in many regions due to a major distribution of problematic soils and prolonged drought (Sadeghi and AliPanahi, 2020). For instance, the maximum cumulative displacements of about 40 cm with an average LS rate of more than 25 cm/yr give a serious warning for Tehran province (Haghighi & Motagh 2019).

DOI: 10.1201/9781003299127-171

Accordingly, several technics have been used to monitor the LS rate and developments. Among them, InSAR is the most well-known technique that can detect vaster spatial deformation of land surfaces and consequently measure the LS rate from small to large scales precisely (Ghorbani et al. 2022). Recently, Fadhillah et al. (2020) used InSAR time series data to detect the LS rate along the subway lines of the Seoul Metropolitan. The LS susceptibility maps were produced using Sentinel-1 data between 2017 and 2020. Similarly, Hu et al. (2019) applied the SBAS-InSAR technique to monitor the LS in downtown Fuzhou after the metro construction process. In addition, Jia et al. (2021) used the InSAR time series to monitor the photovoltaic system in the east of Shanxi province, China. Coal mining activities and the weight of power systems have been recognized as the leading causes of LS in these regions. Despite putting much effort into exploring the LS, there is no research that investigates the subsidence-induced damage to EDCs using InSAR time series analysis and validates with geotechnical reconnaissance.

Therefore, this study's main objective is to systematically explore warning signs and damages imposed on EDCs in Tehran. A mutual methodology of field reconnaissance and InSAR time series analysis is adopted to correlate subsidence-induced damages with several triggering mechanisms, such as the dynamic effects of subways and extra groundwater exploitation. Accordingly, spatially and temporally-distributed deformation time series and velocities during the period of 2019 to 2022 are determined. Then the LiCSAR (an automatic Sentinel-1 interferometric processing system) products using the LiCSBAS processing package are derived for each EDC location. Finally, key findings about the influences of LS on different types of damages are discussed.

2 METHODOLOGY

The LiCSBAS package is used in this study for the displacement time series analysis in Tehran. The LiCSBAS package uses data from the Sentinel-1 InSAR (COMET-LiCS) processor based on a modified small baseline NSBAS approach for the time-series analysis (López et al. 2009; Morishita 2020). In other words, it is possible to reduce gaps error in the sentinel-1 image network by using the NSBAS approach of the LiCSBAS package. This paper utilizes the 57 Sentinel-1 images from September 2019 to October 2021 in a time interval of 12 days. The generated interferograms were processed in a way that covers Tehran well in the ascending data over one frame (ID: 019A_05546_131313). It is worth noting that the GeoTIFF files of unwrapped phase and coherence have been published in a 250 km2 consistent geographic frame basis that is already available in the COMET-LiCS portal. Furthermore, bad interferograms were identified and discarded in the time-series analysis based on the coherence and unwrapped data, checking the loop closure (Morishita, 2020). In the following, to estimate the displacement value of each pixel, the whole interferometric networks were inverted for incremental displacements using the least-squares method. Eventually, using high and low-pass filtering in time and space, respectively, the noise sources from the displacement time series have been separated.

3 RESULTS AND DISCUSSION

Figure 1 shows the displacement map in the line of sight (LOS) direction of the Sentinel-1 satellite, derived from the LiCSBAS time series analysis. Negative and positive values show the ground surface displacement based on the satellite situation. In other words, the negative value reveals the LS, but the positive value indicates the Land uplift (LP). Regarding this figure, it is possible to find the highest LS rate in the southwest of Tehran as 90 mm/yr. This critical region comprises several EDCs, such as Azari and Yakhchi Abad, with an LS rate of 20 mm/yr. However, the other EDCs shown in this figure are in favorable condition from the LiCSBAS time series analysis. Despite the low LS rate (<10 mm/yr) in these regions, several damages have been reported for these EDCs. To find out the source of the damages, other GIS layers, i.e., the Tehran subway line system, have been used, as shown in Figure 1. Considering the distance between the EDCs and subway lines, the main source of EDC damage in the low LS rate region is revealed. Specifically, Khorasan Square EDC is located at the intersection station of subway lines # 6 and # 7, unlike the other EDCs like Railway Town, Shush, Beesat thermal, and Azadegan, which are somehow

far away from the subway lines. Therefore, field reconnaissance has been done in this study to better investigate the critical condition of the Khorasan Square EDC. Based on field monitoring and geotechnical assessments, several damages have been recognized, as shown in Figure 2. These damages can be listed as: 1) vertical cracks in masonry walls, 2) opening of fissure cracks on the ground surface, 3) sinking of the foundation pier into the ground, 4) uneven settling of equipment's foundation, and 5) dislocation of the concrete floor slab.

Considering the low LS rate in this area, the primary motivation for these damages is the tunneling effects. In other words, the settlement caused by the tunneling activities, on the one hand, and the dynamic loading and vibrations made by passaging of the train, on the other hand, have led to the continuous deformation of the ground and the subsequent side effects on the existing vital components of EDCs. It is worth noting that the LS time series drives from the remote sensing technique suffer from various errors. Subways dynamic effect is one of the main sources of errors contributing to the malfunctioning InSAR investigation of LS. Therefore, to better investigate the LS rate in the urban area, care about the source of errors should be considered. Specifically, for the regions exposed to dynamic effects of subways, it is recommended to utilize field monitoring and geotechnical assessments to verify the remote sensing analysis.

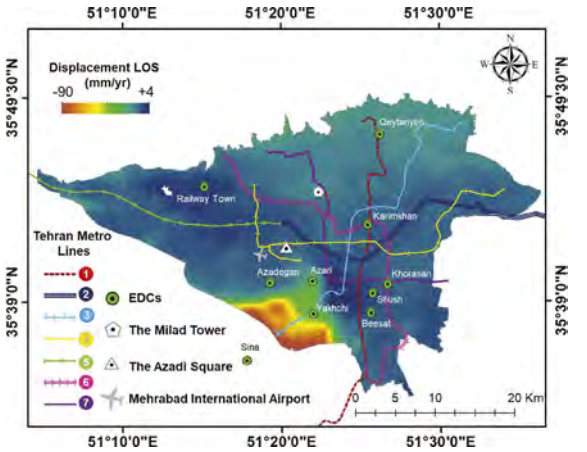

Figure 1. The displacement LOS obtained from the Sentinel-1 images processed by LiCSBAS during the time period of September 2019 to October 2021 for Tehran.

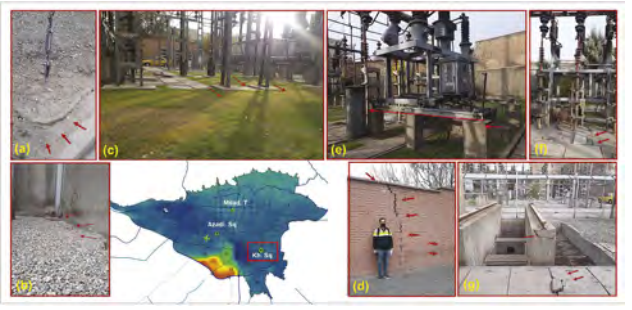

Figure 2. Typical damages observed in the EDC of Khorasan Square due to the interaction between the subway and superstructure: (a, b) opening of fissure cracks on ground surface, (c, e) sinking and the differential settlements of foundation pier, (d) cracking of the masonry walls, and (f, g) dislocation of the concrete floor slab.

4 CONCLUSIONS

In order to assess the EDCs prone to LS hazard, InSAR time series analysis was employed to generate the displacement LOS of Tehran for almost three and half years. The maximum LS rate was revealed as high as 90 mm/yr. Accordingly, the hazard level to EDCs was determined and a pilot EDC located in Khorasan Square was studied in further details. Although a relatively low rate of LS was determined for this area based on remote sensing, field reconnaissance indicated several warnings and damages imposed on the building and electrical facilities. Further investigation of other GIS layers including subway line system revealed the main cause of LS as the occurrence of the intersection station of subway lines # 6 and # 7. Consequently, severe damages were observed including: cracking of the masonry walls, opening of fissure cracks, sinking and the differential settlements of foundation pier. The results confirm that remote sensing can be enriched by complementary methodologies of field monitoring and geotechnical assessments.

A stratigraphic classification estimation method by Artificial Neural Networks for Geotechnical Information Database

S. Murakami
Fukuoka University, Fukuoka, Japan

ABSTRACT: The purpose of this study is to confirm the applicability of Artificial Neural Networks for stratigraphic classification estimation. The study proposes a machine learning procedure in consideration with ununiformity of spatial density of investigation locations, their depth and different appearance frequency of soils. The proposed method has been applied to Geotechnical Information Database in Fukuoka plain, Japan. The results have shown the proposed method is extremely effective for stratigraphic classification estimation by Artificial Neural Networks.

1 INTRODUCTION

Geotechnical Information Database (Geo-DB) can be used for local vulnerability assessment against geo-disaster. However, almost of geo-information of borehole logs in the Geo-DB have no information on stratigraphic classifications. Therefore, stratigraphic classification must first be performed for all geotechnical information if vulnerability assessment requires stratigraphic classification. So, the availability of a Geo-DB with pre-stratified stratigraphic classification would be extremely useful for the assessment.

The purpose of this study is to confirm the applicability of Artificial Neural Networks (NN) for stratigraphic classification estimation. The study proposes a machine learning procedure in consideration with ununiformity of spatial density of investigation locations, their depth and different appearance frequency of soils. The proposed method has been applied to Geo-DB in Fukuoka plain, Japan. The results have shown the proposed method is extremely effective for stratigraphic classification estimation by NN.

2 NEURAL NETWORKS FOR STRATOGRAPHIC CLASSIFICATION ESTIMATION

Using the geotechnical information (depth, soil type, N-value, etc.) in the BDs, we consider strata classification by Artificial Neural Network (NN). We focus on BD No. p shown in Figure 1. The number of input data corresponding to layer number k is denoted as $N_{p,k}$. This geotechnical information is used as the input value, and the output value is calculated from the input value through an intermediate layer.

In the ordinary NN (ONN), the sum of the error functions for all training data (referred to as the overall error function E in this study) is considered and the NN model that yields good estimation results is determined by minimizing it. E is defined as

$$E = \frac{1}{N} \sum_{p=1}^{P} \sum_{k=1}^{K} \sum_{n=1}^{N_{p,k}} E_{(p,k,n)} \tag{1}$$

The ONN method uses the data equally to make decisions during learning. However, in the case of BD, the survey depth is not uniform, and the number of data tends to become sparser as the depth increases. The engineer recognizes this bias in the data and understands the characteristics of each layer. The stratigraphic classification is then determined by looking at the

DOI: 10.1201/9781003299127-172

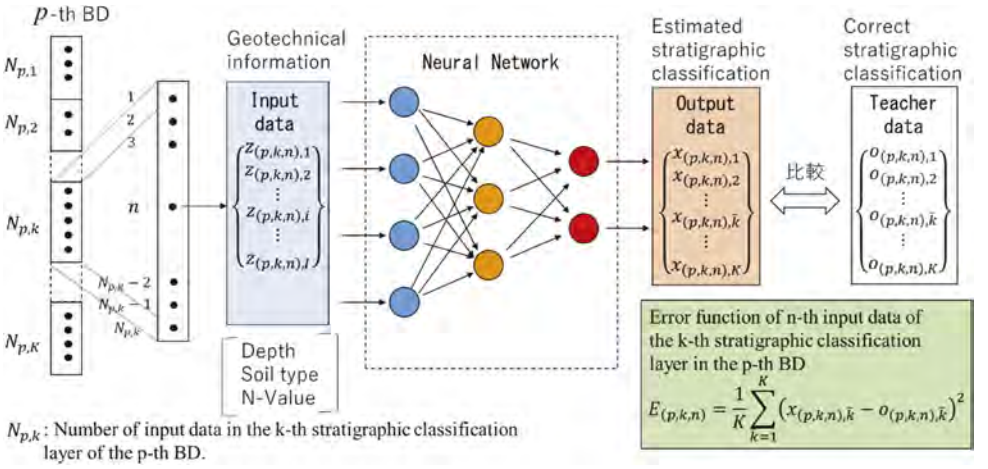

Figure 1. Machine learning of NN for p-th BD and its error function.

surrounding stratigraphic conditions. Therefore, this study considers incorporating the engineer's manner by redefining the overall error function, which is different from the ONN method.

The following overall error function E, which is calculated by averaging to eliminate bias in the data for each stratum in the BD, has been defined by introducing a weight coefficient $r_{p,k}$ with respect to the distance between the locations of BD.

$$E = \frac{1}{K}\sum_{k=1}^{K}\sum_{p=1}^{P}\frac{r_{p,k}}{N_{p,k}}\sum_{n=1}^{N_{p,k}}E_{(p,k,n)} \tag{2}$$

where $\sum_{p=1}^{P} r_{p,k} = 1$.

The method using weight coefficients that depend on the distance is called the Distance-Layer NN method (DLNN method), while the case with equal weight coefficients is called the Simple Layer NN method (SLNN method) (Murakami, 2020).

The SLNN method is a device to eliminate the bias by averaging the teacher data that differ in number per stratum, and the DLNN method further reduces the difference with the teacher data closer to the estimation location. By minimizing the overall error function in this way, we expect the NN model to average the data and reduce the bias, so that the information on BDs closer to the estimated location has smaller errors.

In this study, L2 regularization is applied in machine learning. The training data are first divided into teacher data and test data, and L2 regularization parameter λ is determined by contrasting the estimated value of the test data obtained from the machine learning results using the teacher data with the assumed λ with the measured value of the test data. Next, using the determined λ, the best IDW parameter used in the DLNN method is also selected by comparing the estimated value of the test data obtained from the machine learning results using the teacher data with several assumed IDW parameters and the actual measured value of the test data.

3 OVERVIEW OF THE OBJECTIVE REGION AND PREPARATION OF TRAINING AND VALIDATION DATA

The objective region is the Fukuoka Plain in Japan. The BDs were taken from the Kyushu Geotechnical Information Shared DB (2005, 2012, 2018), and the BDs along the Fukuoka Urban Expressway from Chidoribashi JCT (a) to Tsukiguma JCT (b), where continuous geotechnical information exists as shown in Figure 2.

For the 125 BDs extracted from the DB, stratigraphic classification in the area has been performed using the AIST-Borehole Log Analysis ver. 2.1 provided by the National Institute of Advanced Industrial Science and Technology (AIST) in Japan. The stratigraphic

classification results are shown in Figure-3. The 125 BDs were divided into five parts, four as training data (Dataset A, B, C, and D) and the remaining one as validation data (Dataset X).

The trends of the data for study and validation are shown that there is no difference in the percentage of data occupied by each layer, the Nakasu and Arae layers have a large number of data and account for the majority of the data, while the Kanatake gravel layer tends to be extremely small, about 10 to 15% of the total data (Murakami et. al., 2020).

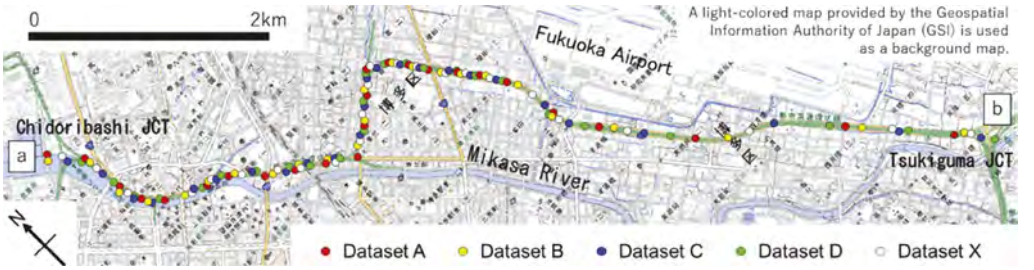

Figure 2. Cross-section line and BD locations in the objective region.

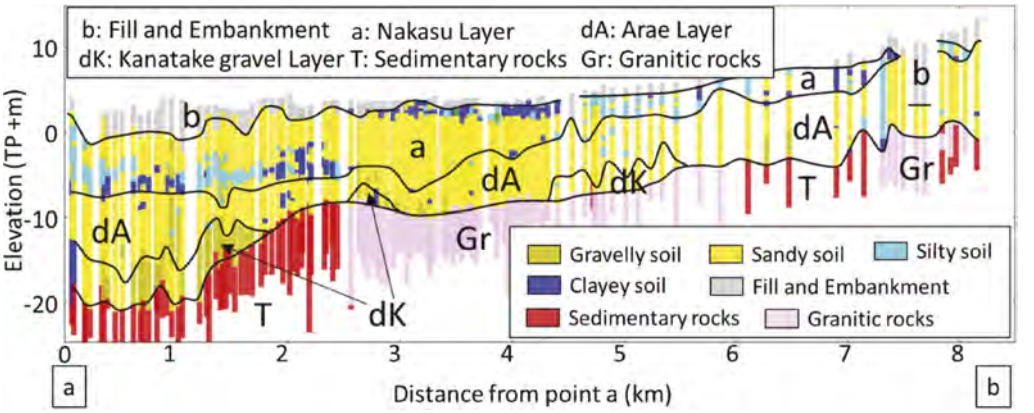

Figure 3. Geological cross section.

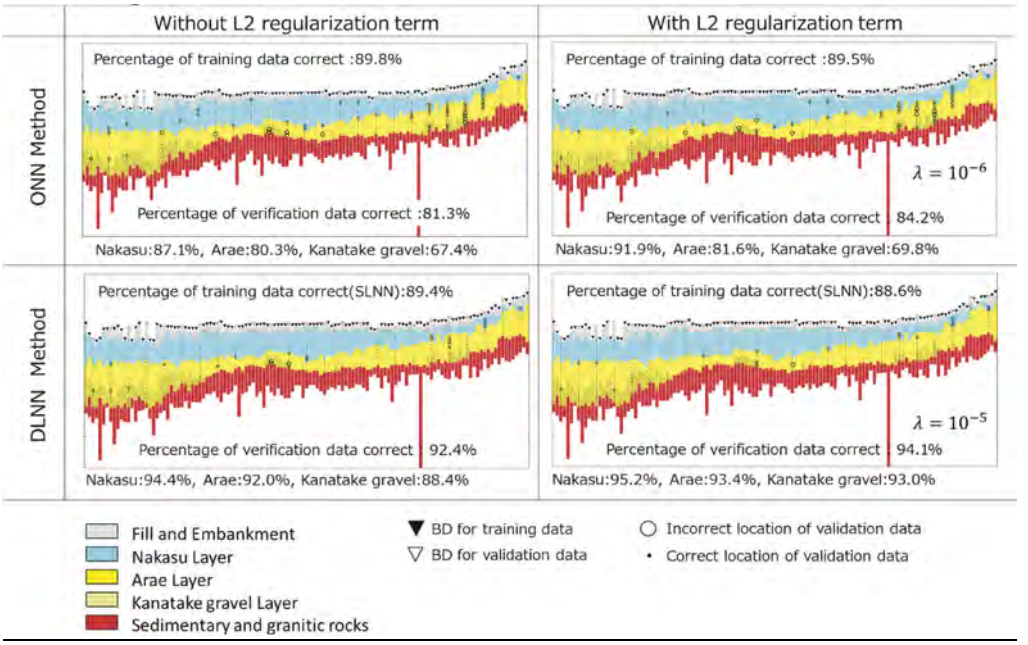
4 RESULTS AND DISCUSSIONS

Using four sets of training data (Dataset A, B, C, and D), three sets are used as learning training data and the remaining one set is used as test data for cross-validation, and λ has been determined by the ONN and SLNN methods. Given $\lambda = 10^{-3}$, 10^{-4}, 10^{-5}, and 10^{-6}, λ has been decided on 10^{-6} and 10^{-5}, which had the smallest difference between the percentage correct by the teacher data and the percentage correct by the data for testing, for the ONN and SLNN methods, respectively. Next, the IDW parameter m in the DLNN method has been determined using the results from the SLNN method. In the present study, the search radius R is fixed as 500 m. Based on the results of three comparisons with m=1.0, 2.0, and 4.0, m has been set as 2.0. Using the results of the above studies, the data for validation has been estimated. The number of intermediate layers in the NN model is set to 9, and 50 million machine learning cycles using ADADELTA (Zeiler, 2012) are used for the update calculation.

The results of the distribution of correct and incorrect answers and the percentage of correct answers for the data for validation by the ONN and DLNN methods are shown in Table 1. The table also shows the difference in results with and without the L2 regularization term. The results of the ONN and DLNN methods show that the correct answer rate for the training data slightly decreases with the addition of the L2 regularization term, but the correct answer rate for the verification data increases, confirming the effectiveness of L2 regularization.

The percentage of correct data for the validation of the ONN and DLNN methods is about 10% higher for the DLNN method, indicating that the strata classification estimation by the DLNN method, which attempted to incorporate engineers' methods, is superior to the ONN method.

Table 1. Comparison of ONN and DLNN Results.



5 CONCLUSION

The purpose of this study is to clarify the applicability of the NN method to stratigraphic classification estimation using BDs, and a cross-section of the Fukuoka Plain has been selected as the objective region. Although the ONN method, which uses all the data equally as a basis for decision making during training, gave a correct estimation rate of more than 80%, the DLNN method, which averages the data to reduce bias and expects the information from BDs closer to the estimated location to have a smaller error rate, gave a higher rate. This suggests that it is necessary to take into account the information bias of the geotechnical information in order to obtain better estimation results.

Model uncertainty in the random finite element analysis for an overall strength of a cement-treated soil column

T. Namikawa
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: The finite element method with the random field theory, the Random Finite Element Method (RFEM), has been adopted to evaluate the mechanical behavior of the cement-treated soil ground in which strength varies spatially. The spatial variability of the strength can be appropriately considered in the RFEM analysis. However, the model uncertainty might be included in the analysis result. This paper presents the evaluation of the model uncertainty in the RFEM analysis for an overall strength of a cement-treated soil column. The unconfined compression tests of a full-scale cement-treated soil column are simulated by the RFEM analysis. The statistical parameters of the analyzed overall strength are compared to those obtained from the full-scale test results. The comparison provides model correction factors representing the model uncertainty.

1 INTRODUCTION

The finite element method (FEM) with the random field theory, the random finite element method (RFEM), is a useful tool for evaluating the mechanical behavior of the cement-treated soil ground in which strength varies spatially. RFEM has been used to evaluate the mechanical behavior of cement-treated soil grounds in past studies (e.g. Namikawa & Koseki 2013). The RFEM analysis with a proper constitute model can simulate the ground behavior reasonably. However, it is not possible to correctly describe the ground behavior using the RFEM analysis. The discrepancy arising between the real and simulated behavior can be recognized as a model uncertainty. Such model uncertainty should be evaluated quantitatively in the reliability-based design procedure.

This paper presents the evaluation of the model uncertainty in the RFEM analysis for an overall strength of a cement-treated soil column. The unconfined compression tests of a full-scale cement-treated soil column were conducted in a past study. Those tests are simulated by the RFEM analysis. The statistical parameters of the analyzed overall strength are compared to those obtained from the full-scale test results. The comparison provides model correction factors representing the model uncertainty included in the RFEM analysis.

2 UNCONFINED COMPRESSION TESTS OF A CEMENT-TREATED SOIL COLUMN

The test results of the unconfined compression test conducted in the past study (Building Research Institute and Japan Institute of Country-ology and Engineering 1995) is simulated by the RFEM analysis. In that study, single cement-treated soil columns were constructed by wet method of deep mixing at 4 sites. Sand, silt, sirasu, and loamy layers are improved at these sites. The depth of improvement was around 4 m. The columns were excavated and the lower part of the columns were used for the full-scale column test. The size of the full scale columns used for the unconfined compressive tests was 1.0 m in diameter and 2.2 m in height. Core samples of 50 mm in diameter and 100 mm in height were retrieved from the upper part of the columns. Since it was reported that a loamy layer was to be difficulty mixed with cement homogeneously,

DOI: 10.1201/9781003299127-173

the test results of the columns at the loamy layer are excluded in this study. The test results of 11 columns at the sand, silt and sirusu layers are used for the RFEM simulation.

The unconfined compressive strength Q_u of the full-scale column are listed in Table 1. The unconfined compressive tests were carried out for 4 columns of the sand and silt layers and 3 columns of the sirasu layer. The mean μ_{qu} and standard deviation σ_{qu} of the unconfined compressive strength q_u of the core samples retrieved at each site are also listed in Table 1. When evaluating the model uncertainty, the data obtained at the three sites are handled together. The ratio of Q_u to μ_{qu}, Q_u/μ_{qu}, is adopted when comparing the simulation results to the test results. Q_u/μ_{qu} observed in the full scale tests ranges from 0.3 to 1.1.

Table 1. Full-scale cement-treated soil column test results.

				Core strength	
Soil type	Column No.	Overall strength Q_u	Q_u/μ_{qu}	Mean μ_{qu}	Standard deviation σ_{qu}
Sand	1	2.51 MPa	0.664	3.78 MPa	1.19 MPa
	2	3.60 MPa	0.951		
	3	2.94 MPa	0.778		
	4	4.01 MPa	1.06		
Silt	1	1.32 MPa	0.381	3.47 MPa	1.46 MPa
	2	1.64 MPa	0.472		
	3	1.72 MPa	0.494		
	4	2.24 MPa	0.647		
Sirusu	1	4.44 MPa	0.681	6.52 MPa	1.73 MPa
	2	4.12 MPa	0.631		
	3	6.33 MPa	0.971		

3 RANDOM FINITE ELEMENT ANALYSIS

3.1 *Analysis condition*

q_u of the elements composing the cement-treated soil column is assumed to follow the multivariate normal distribution in the analysis. A stationary random field with an exponential type autocorrelation function is assumed for the spatial variability of q_u. The realizations of the spatial distribution of q_u are generated using the covariance matrix decomposition method (Namikawa 2016). The mean μ_{qu}, standard deviation σ_{qu}, and autocorrelation distance θ_{qu} of q_u are required when generating the realizations. The sample μ_{qu} and σ_{qu} values of the core samples in the full-scale column tests are adopted as the μ_{qu} and σ_{qu} values when generating the realizations. The sample θ_{qu} value of the core samples was not obtained from the full-scale column test results. Assuming θ_{qu} following the log-normal distribution, the θ_{qu} values are generated from the log-normal distribution whose 95% confidence interval ranges from 0.1m to 4.0m. The q_u values of the generated realizations were assigned to elements composing the cement-treated soil column model.

Three dimensional finite element analysis are preformed using the FEM software DIANA. The finite element model of the full-scale column is shown in Figure 1. The full-scale column of 1 m in diameter and 2.2 m in height is modeled in the simulation. A mesh consists of eight-node isoparametric cubic elements with a length of 100 mm. The boundary conditions are smooth at the top and bottom of the model. Uniform vertical displacements are applied at the top boundary on the loading process.

An elasto-plastic model proposed by Namikawa & Mihira (2007) is used to simulate the unconfined compression behavior of the full-scale cement-treated soil column. The material parameters for q_u = 4 MPa are listed in Table 2. These values are determined from the results of the laboratory tests carried out in the past studies (Namikawa & Mihira 2007, Namikawa & Koseki 2006). The elastic modulus E, cohesion c, tensile strength T_f, and fracture energy G_f, are assumed to be stochastic parameters in the RFEM simulation. The stochastic parameters vary proportionally with q_u. Other material parameters, friction angle ϕ, Poisson's ratio v, hardening parameters α and e_y, softening parameter e_r, dilatancy coefficient D_c, localization size t_{s0}, and characteristic length l_c, are assumed to be maintained constant.

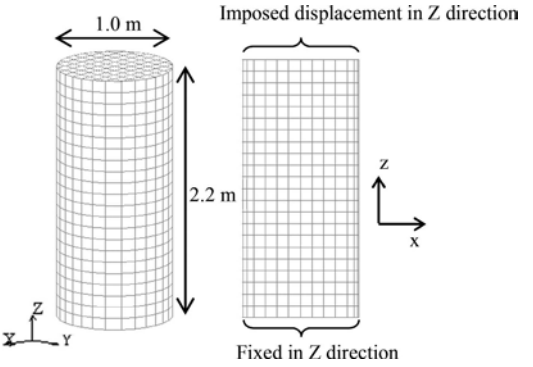

Figure 1. Finite element mesh.

Table 2. Material parameters for cement-treated soil with core strength q_u = 4.0 MPa.

E (MPa)	v	ϕ (degree)	c (MPa)	T_f (MPa)	α
Stoch. 7040	Deter. 0.167	Deter. 30	Stoch. 1.16	Stoch. 0.896	Deter. 1.05
e_y	G_f (N/m)	e_r	D_c	t_{s0} (mm)	l_c (mm)
Deter. 0.0002	Stoch. 21.2	Deter. 0.4	Deter. -0.4	Deter. 0.6	Deter. 100

Note: E = elastic modulus; v = Poisson's ratio; ϕ = friction angle; c = cohesion; T_f = tensile strength; α = hardening parameter; e_y = hardening parameter; G_f = fracture energy; e_r = softening parameter; D_c = dilatancy coefficient; t_{s0} = localization size; l_c = characteristics length; Stoch. = stochastic parameter; Deter. = deterministic parameter

3.2 *Analysis results*

Four hundred realizations are analyzed for the columns in the sand and silt layers and three hundred realizations are analyzed for the columns in the sirasu layers. The calculated Q_u values are shown in Figure 2. The variability of Q_u is large in all the cases. The full-scale test results are superimposed in Figure 2. The test results fall within the range of the values calculated in the RFEM analysis.

Q_u/μ_{qu} calculated in the simulation for the three layers is handled together. The empirical cumulative distribution function (ECDF) for the Q_u/μ_{qu} of 1100 realizations is shown in Figure 3. The cumulative distribution function (CDF) of the normal distribution is also shown in this figure. ECDF of the calculated Q_u/μ_{qu} values agree reasonably with CDF of the normal distribution. The mean and standard deviation of Q_u/μ_{qu} are 0.811 and 0.233.

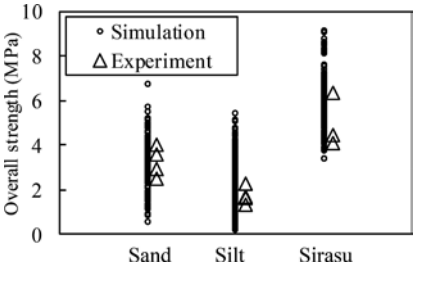

Figure 2. Calculated overall strength.

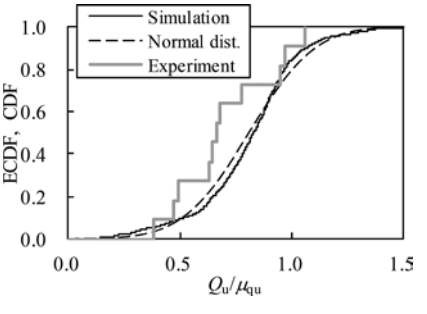

Figure 3. Cumulative distribution function.

4 MODEL UNCERTAINTY

ECDF for the Q_u/μ_{qu} observed in the full scale test is superimposed in Figure 3. The discrepancy in ECDF between the simulation and experimental results indicates the model uncertainty. The model uncertainty involved in the mean of Q_u/μ_{qu} is quantitatively evaluated by comparing the simulation results to the full scale test results. A model correction factor C_{fm} is adopted to represent the model uncertainty for the mean of Q_u/μ_{qu}. The relationship in mean between the full scale test and the simulation result is expressed as

$$M_R = C_{fm} M_S \tag{1}$$

where M_R and M_S are the mean of Q_u/μ_{qu} obtained from the test and simulation results.

The M_R and M_S values are 0.703 and 0.811. The C_{fm} value is 0.867. Since the number of the full scale tests is not large, the statistical uncertainty is involved in the M_R value. Assuming that Q_u/μ_{qu} follows the normal distribution, the expected population mean of Q_u/μ_{qu} follows a Student t distribution. Its standard deviation σ_{MR} can be expressed as

$$\sigma_{MR} = \sigma_{Qu}/\sqrt{n} \tag{2}$$

where σ_{Qu} is the standard deviation of Q_u/μ_{qu} and n is the number of Q_u/μ_{qu}. Assuming that the M_S represents the population mean, the probability distribution of C_{fm} follows the Student t distribution with the mean of M_R/M_S and the standard deviation of σ_{MR}/M_S.

The model uncertainty involved in the coefficient of variation of Q_u/μ_{qu} is examined. A model correction factor C_{fv} is adopted to represent the model uncertainty for the coefficient of variation of Q_u/μ_{qu}. The relationship in coefficient of variation between the full scale test results and the simulation result is expressed as

$$V_{cR} = C_{fs} V_{cS} \tag{3}$$

where V_{cR} is the coefficient of variation of Q_u/μ_{qu} obtained from the test results and V_{cS} is that calculated from the simulation results. The V_{cR} and V_{cS} values are 0.311 and 0.287. The C_{fs} value is 1.08. The evaluated C_{fs} value is not considerable large, indicating that the model uncertainty might be neglected for the coefficient of variation of Q_u.

5 CONCLUSIONS

This paper presented the evaluation of the model uncertainty in the RFEM analysis for an overall strength of a cement-treated soil column. The unconfined compression tests of a full-scale cement-treated soil column were simulated by the RFEM analysis. The mean and coefficient of variation of the analyzed overall strength were compared to those obtained from the full-scale test results. The model correction factors evaluated for the mean of the overall strength was 0.867, indicating that the overall strength is slightly overestimated in the RFEM simulation. The model correction factors evaluated for the coefficient of variation of the overall strength was 1.08. This indicates that there is no need to account for the model uncertainty on the variability of the overall strength in the RFEM analysis.

Seismic response analysis of an earth dam by using geostatistical methods and 3-D measurement

S. Nishimura, T. Shibata & T. Shuku
Graduate School of Environmental and Life Science, Okayama University, Okayama, Japan

ABSTRACT: Recently, a three-dimensional (3-D) survey has been developed, using an unmanned aerial vehicle (UAV), which has made the rebuilding of the 3-D topography of structures easier. In this study, for the purpose of incorporating the three-dimensional measurement technique into the design of geo-structures, an earth-fill dam is surveyed three-dimensionally by a drone, and its 3-D finite element model (FEM model) is made based on the measurement results. Finally, the FEM model is applied to a seismic response analysis, in which a search is made for the structurally weak locations inside the dam. The stiffness inside the earth-fill dam is interpolated based on the results of Screw Weight Sounding (SWS) tests. The 3-D kriging method, one of the geostatistical methods, is used as the interpolation method. According to the analytical results, the locations of high acceleration and high shear stress inside the earth-fill dam have been identified.

1 INTRODUCTION

There are many earth-fill dams in Japan, some of which have become old and weak. It is important, therefore, to diagnose the seismic resistance of such dams. The technique of a three-dimensional (3-D) finite element modeling is proposed for such a diagnosis here.

In recent years, due to advances in unmanned aerial vehicle (UAV) technology, the taking of 3-D measurements has become easier. In this study, a 3-D finite element model of an earth dam is created by 3-D measurement by a drone. In order to conduct 3-D FEM, the spatially sufficient information of the underground is required to model the 3-D underground model. In this study, SWS test is used as a method of obtaining 3-D ground stiffness. Because SWS tests can be conducted in narrow spaces or at sites that are difficult to access with large equipment, such as the cone penetration test (CPT) machine, it is advantageous for the earth-fill dam sites. Since these test results are point-estimated values, they need to be spatially interpolated. For this task, kriging, a geostatistical method, is adopted as the 3-D interpolation method.

Finally, to diagnose the seismic resistance, a seismic response analysis is performed on the created 3-D model, and the critical points due to earthquakes are identified. Thus, the novelty of this study is the packaging of the FEM modeling from the 3-D measurement technique, and 3-D underground modeling with the aid of the geostatistical interpolation technique.

2 SOUNDING TESTS AT STUDIED SITE

SWS tests were conducted at Site K, which was studied in this study. The sounding intervals were adjusted so that the parameters necessary for the application of geostatistical methods could be applied. The SWS test is a static test, which is very efficient and suitable for obtaining spatial information on geo-structures. In addition, since it is a very compact test, it can be applied to sites located in narrow spaces, such as the target site in this study.

DOI: 10.1201/9781003299127-174

Equation (1) is a regression equation between the N value, obtained from the standard penetration test for sandy soil, and the results of Swedish weight sounding (SWS) tests, presented by Inada (1960), from which the converted N value (N_{SWS}) is obtained.

$$N_{SWS} = 0.002 W_{SW} + 0.067 N_{SW} \quad (1)$$

where N_{SW} is the number of half rotations and W_{SW} (N) is the total weight of the loads. Figure 1 shows the locations (16 points) where the SWS tests were conducted along the x'-axis parallel to the embankment axis.

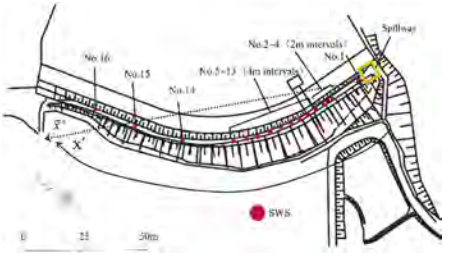

Figure 1. Planview of studied site and SWS test points.

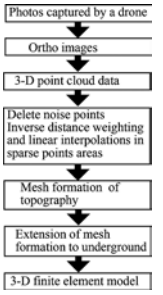

Figure 2. Algorithm of 3-D modeling.

3 THREE-DIMENSIONAL FINITE ELEMENT MODEL

A 3-D finite element model is created from aerial photographs taken by a drone. The procedure for the 3-D measurement by the drone is the same as that given in the authors' previous study (Kaneshige et al. 2021). The outline of the 3-D modeling is presented in Figure 2. LIQCA3D (Development Group of Liquefaction Analysis Code LIQCA, 2020) is used as the seismic response analysis program. The nodal coordinates of the finite elements are set to the x-axis for the east-west direction and to the y-axis for the north-south direction. Figure 3 presents an overall view of the model, and Figure 4 presents the cross section of the central part of the model. Nodes and elements were added to the sides of the model, and the analysis domain is extended to a square 50 times the width of the embankment to reduce the influence of the boundaries.

The boundary conditions are as follows: the bottom is a viscous boundary, the sides along the x-axis direction are fixed to y, the sides along the y-axis direction are fixed to x, and the nodes at the four corners are fixed to x-y and vertical rollers. The bottom and all the sides are set as undrained boundaries. The input seismic waveforms are selected from the Nankai Trough seismic waveform data published by the Cabinet Office. A linear elastic analysis is performed for all of the analyses in this study. In setting the elastic constants, Young's modulus E is set to 2800 N, which provides an empirical relationship (Japan Road Association 2012).

4 INTERPOLATION OF PARAMETERS BY GEOSTATISTICAL METHODS

A statistical model is used to represent the spatial distribution of the N values. Since the measured values obtained by the sounding tests is point-estimated values, it is necessary to interpolate the spatial information between the points by the statistical model. The statistical model allows for the estimation of the data for the points for which no data are available as a probability field. In this study, the procedure presented in Nishimura et al. (2016) is followed to determine the statistical model by MAICE. When the correlation length cannot be properly identified by MAICE, semi-variograms are adopted. The use of semi-variograms is one of the geostatistical methods for identifying the spatial correlation structure in each direction. The specific procedure is shown in Imaide et al. (2019).

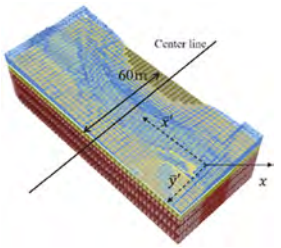

Figure 3. 3-D model of embankment area.

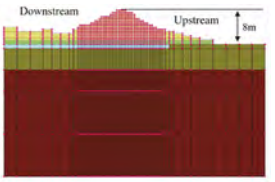

Figure 4. Cross section of center line of 3-D model.

For the estimation of the spatial distribution of $\log N_{SWS}$, the x' axis, which is set along the embankment with the origin at No. 1 (0 m) of the test site (see Figure 1), is converted into a linear $\bar{x}'$axis for simplicity. In the vertical direction, the z' axis is set in the depth direction with the origin at the ground surface. The mean function, and the covariance function determined by the method mentioned above, are shown in Equations (2) and (3), respectively. For simplicity, the correlation structure in the horizontal plane is assumed to be isotropic, namely, the horizontal correlation length of 15.7m in Equation (3), is same for the any horizontal directions.

$$m = 0.987 - 5.97 \times 10^{-3}\bar{x}' + 1.45 \times 10^{-3}z' + 3.91 \times 10^{-5}\bar{x}'^2 + 6.31 \times 10^{-3}z'^2 + 2.48 \times 10^{-3}\bar{x}'z' \tag{2}$$

$$C_{ij} = N_e \cdot 0.383^2 \exp\left(-\frac{\left|\bar{x}'_i - \bar{x}'_j\right|}{15.7} - \frac{\left|z'_i - z'_j\right|}{1.24}\right) \ (i \neq j) \tag{3}$$

$N_e = 0.409 \ \left(\left|\bar{x}'_i - \bar{x}'_j\right| \neq 0, \ \left|z'_i - z'_j\right| \neq 0\right)$ $\quad N_e = 0.593 \ \left(\left|\bar{x}'_i - \bar{x}'_j\right| \neq 0, \ \left|z'_i - z'_j\right| = 0\right)$
$N_e = 0.690 \ \left(\left|\bar{x}'_i - \bar{x}'_j\right| = 0, \ \left|z'_i - z'_j\right| \neq 0\right)$ $\quad N_e = 1.0 \ (i = j)$ $(i,j = 1, 2, 3, \ldots, M)$
N_e: Nugget effect parameter. $\quad M$: number of SWS test points.

In order to interpolate the stiffness values, 3-D kriging, which is one of the geostatistical methods, is employed. Figure 5 shows the inhomogeneous N value distribution of Site K obtained by the kriging.

5 SEISMIC RESPONSE ANALYSIS

A time series of the horizontal acceleration of the transversal direction to the embankment axis on the top of the embankment of the center cross section, is presented in Figure 6. The peak appears at 25 seconds after the start of the earthquake due to the input earthquake motion. A contour plot of the maximum acceleration at 25 seconds is shown in Figure 7. The figure presents a larger concentration of acceleration at the left side of the embankment near the spillway (see Figure 1). The reasons are that the embankment is divided by the spillway, and the stiffness of the ground around the spillway is relatively small (see Figure 5).

In addition, to evaluate the shear behavior, the $\sqrt{2J_2}$ distribution diagram obtained from the second invariant of the deviatoric stress (J_2) is given. The distribution of $\sqrt{2J_2}$ in the cross section, where the acceleration is concentrated (Figure 8), shows that the large $\sqrt{2J_2}$ is presented in the shape of an arc from the top of the embankment. On the other hand, in the central section of the embankment, there is no large $\sqrt{2J_2}$, according to the analytical result. This means that the weak point of the embankment against the shear behavior is assumed to be the left side of the embankment near the spillway. Although large value of $\sqrt{2J_2}$ is also depicted at the foundation ground, this is due to large initial stress.

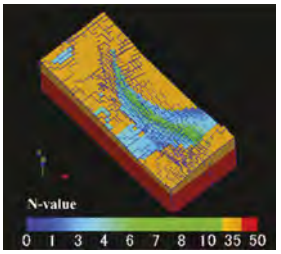

Figure 5. *N* value distribution.

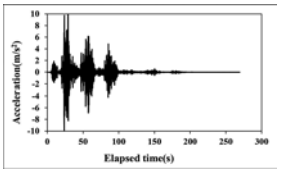

Figure 6. Acceleration of transversal direction at center point of embankment.

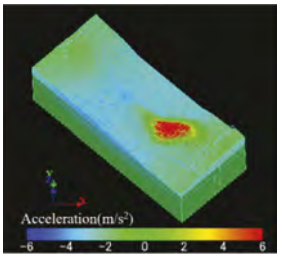

Figure 7. Distribution of acceleration.

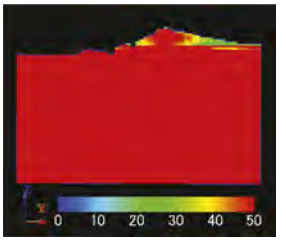

Figure 8. Distribution of deviatoric stress second invariant on concentration of acceleration.

6 CONCLUSIONS

(1) A three-dimensional finite element model has been created by extending the topographic measurement results to the underground using the 3-D measurement results obtained by a drone.
(2) The spatial distributions of the stiffness inside the embankment and the underground have been estimated. As a 3-D interpolation technique, kriging has been selected and it has been performed based on the statistical model derived from the SWS results.
(3) The seismic response analysis has been conducted for the created 3-D FEM model. The findings of the analysis are as follows.

    1) A concentration of local acceleration at the embankment of the earth-fill dam has been found, suggesting that spatial heterogeneity affects the seismic response.
    2) The distribution maps of $\sqrt{2J_2}$ has revealed the possible weak points of the embankment. In addition, detailed ground modeling identifies the location where the acceleration and shear forces of the embankment are concentrated (near the left bank spillway). In the vicinity of this location, the point where $\sqrt{2J_2}$ becomes large, appears in the form of a circular arc, which can be considered to be a structural weak point.

ABSTRACT: The article presents the results of investigation of soils in the base and reasons for the collapse of a reinforced concrete chimney. Based on the materials of the conducted studies, it was concluded that the main reason for the collapse of the reinforced concrete shaft of the chimney of coke oven batteries no. 5 and no. 6 of arcelormittal temirtau jsc (formerly karaganda metallurgical plant) is a decrease in the strength characteristics of concrete due to many years of constant moisture, freezing and thawing in the autumn winter-spring periods of time, and indirectly due to the lack of proper control over the technical condition of building structures of all areas of reinforcement of the reinforced concrete chimney shaft and assessment of their strength characteristics. The design of the reinforcement instead of its original purpose contributed to the development of negative consequences and the safe operation of the facility.

1 INTRODUCTION

As a result of an instrumental examination of slopes and retaining walls made of monolithic reinforced concrete and drainage systems, numerous defects were identified that were made during the design and construction process, which pose a threat to the safe operation of roads. Monolithic reinforced concrete retaining walls lined with natural stone with a height of 4.0-20.0 m, a width of 0.6 m rest on slabs measuring 1.2 x 2.40 m and do not have hard pinching.

Figure 1. Defective retaining wall design.

DOI: 10.1201/9781003299127-175

The slope of the slope is exposed to atmospheric and flood waters during the year. The identified defects indicate unacceptable cracks and inclination of retaining walls along the road (Figure 1).

The slope slopes along the highway are composed of loess subsidence soils. In subsiding loess soils, collapses of the slope slope massif occur with complete or partial water saturation of the soils due to a significant deterioration in the value of the design parameters (cohesion, angle of internal friction and deformation modulus). The relevance lies in the fact that it is necessary to analyze the stress-strain state of the slope of the slope with folded subsidence soils and evaluate the stability and strength of the retaining wall structure to ensure safety during the operation of the highway.

2 FEATURES OF THE CALCULATION OF RETAINING WALLS

According to the study of physical and geological phenomena in the foothill areas of the south of Kazakhstan, they are subject to planar washout, ravine formation, subsidence of slope soils. On the site, the slopes are composed of loamy soils of a brownish -gray color, from hard to hard- plastic consistency, carbonatize, to a depth of 15.5-21.0 m - subsidence. Physical and mechanical properties of loess-like loams: density - 1.50-1.60 g/cm^3**;** porosity coefficient - 0.84–1.1; degree of water saturation - 0.55-0.91; adhesion - 21-35 kPa; angle of internal friction - 16-22 degrees**;** total deformation modulus - 4.9 -15 MPa.

At the same time, the characteristics for loams according to the results of laboratory tests are: density - 15-16 kN/m^3; coefficient porosity - e > 0.9 with low values of mechanical properties. The pressure exerted by the backfill soil on the back face of the wall can be realized in different forms and values, depending on the design features of the wall, on the strength characteristics of the backfill soil and the base, on the magnitude and direction of wall movement.

In the absence of wall movement away from the backfill, the pressure is realized in the form of a rest pressure E_0 (in this case, the backfill soil is in a compressive stress state). The active soil pressure E_a (thrust) is realized when the wall moves away from the backfill and corresponds to the minimum value of the soil pressure. Passive pressure E_p (resistance of the wall) is realized when the wall moves towards the backfill and corresponds to the maximum value of the soil pressure.

The change in soil pressure depending on the displacement of the wall U is shown in Figure 2.

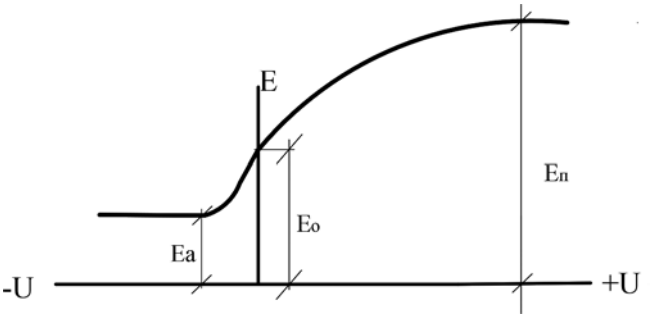

Figure 2. Change in backfill soil pressure E on a retaining wall depending on its displacement U.

Usually, in engineering calculations, the value of the active pressure E_a is used, which is realized at sufficiently small wall displacements. In this case, the wall structure is more economical than in calculations using the rest pressure E_0. Under the influence of active pressure E_a, the wall usually receives a small amount of displacement from the backfill, which, as a rule, cannot realize the full value of the rebuff E_p. To realize the full value of E_p, a displacement value will be required (due to soil compaction), which does not satisfy the conditions for normal operation of the wall. Therefore, when designing retaining walls, it is allowed to enter into the calculations

only a third of the realized resistance. Friction force Tacts on the wall sole. ε and for the angle of inclination of the backfill α, depending on the required calculation. The theoretical basis for calculating retaining walls is the Coulomb hypothesis, based on the following provisions:

1) in the soil of the backfill, upon the onset of the limit state, a collapse prism of the HPT is formed, limited from the rest of the soil, which is in the limit state, by a flat sliding (collapse) surface of the HP (Figure 3);

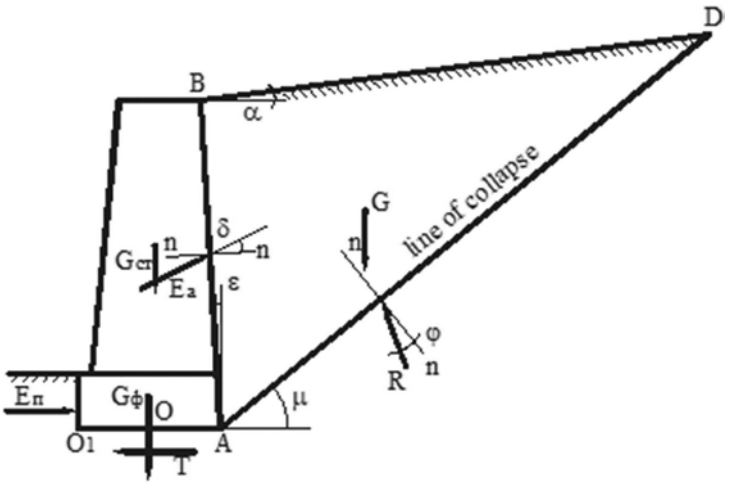

Figure 3. Scheme of the action of forces on the wall (Coulomb's Assumptions).

2) the angle of inclination of the collapse plane A D must be such that the value of the active pressure E a is maximum;
3) the reaction of the calculated resistance of the soil - R, which is in the limit state, is deviated from the normal to the collapse plane A, D by the angle of internal friction φ in the direction opposite to the movement of the collapse prism;
4) the active pressure force E_a (the active pressure reaction), acting on the back face of the wall AB, deviates from the normal to it by an angle δ. The angle δ is the angle of friction between the backfill soil and the wall material.

The collapse prism is in equilibrium under the action of forces G (dead weight) R and E_a

Determination of active and passive pressures acting on a retaining wall . Let us replace the uniformly distributed load - *q,* kPa with a layer of soil of reduced height/1 /:

$$h_{\pi p} = \frac{q}{\gamma_{3ac}}; \tag{1}$$

Calculate the active pressure coefficient:

$$\xi_a = \frac{1}{\left(1+\sqrt{Z_a}\right)^2} \cdot \frac{\cos^2(\varphi-\varepsilon)}{\cos^2\varepsilon \cdot \cos(\varepsilon+\delta)}; \tag{2}$$

$$z_a = \frac{\sin(\varphi+\delta)\cdot\sin(\varphi-\alpha)}{\cos(\varepsilon+\delta)\cdot\cos(\varepsilon-\alpha)}; \tag{3}$$

and ξ_a, special attention should be paid z_a to the signs α and ε.

Let's find the ordinates of the active pressure intensity diagram:

- at the top of the wall

$$e_{a1} = \gamma_{zas} \cdot h_{pr} \cdot \xi_a; \tag{4}$$

- at the level of the sole

$$e_{a2} = \gamma_{zas} \cdot (h_{pr} + H); \tag{5}$$

Then the active pressure

$$E_a = \frac{e_{a1} + e_{a2}}{2} \cdot H; \tag{6}$$

The horizontal and vertical components of the active pressure intensity are as follows:

$$e_{ag1} = e_{a1} \cdot \cos(\varepsilon + \delta); \tag{7}$$

$$e_{ag2} = e_{a2} \cdot \cos(\varepsilon + \delta); \tag{8}$$

$$e_{av1} = e_{a1} \cdot \sin(\varepsilon + \delta); \tag{9}$$

$$e_{av2} = e_{a2} \cdot \sin(\varepsilon + \delta); \tag{10}$$

Accordingly, the vertical and horizontal components of the active pressure

$$E_{ag} = \frac{e_{ar1} + e_{ar2}}{2} \cdot H; \tag{11}$$

$$E_{av} = \frac{e_{aB1} + e_{aB2}}{2} \cdot H; \tag{12}$$

The intensity of passive pressure at the level of the base of the foundation

$$E_p = \gamma_{zas} \cdot d \cdot tg^2(45 + \frac{\varphi}{2}); \tag{13}$$

Passive pressure acting on the front face of the wall,

$$E_p = \frac{\gamma_{3ac} \cdot d^2}{2} \cdot tg^2(45 + \frac{\varphi}{2}); \tag{14}$$

3 CALCULATION OF A RETAINING WALL USING NUMERICAL METHOD

We will calculate the retaining wall using the solutions of the theory of the limit state of a granular medium (numerical methods). When using the numerical method - the finite element method and using the Plaxis application program . When evaluating the stress-strain state of the slope during interactions on retaining walls, the behavior of subsiding soils was considered. At the same time, the subsidence soils of the slope are characterized by: a change in the stress state due to their redistribution after soaking; a change in the components of the strain tensor due to the development of elastic-plastic and viscoplastic deformations /2/. When water is saturated in subsiding soils, the desired stress state arises, which differs significantly from the initial one. A plane problem is considered in an elastic-plastic formulation using the Coulomb-Prandtl model for the medium, which assumes the elastic behavior of the medium at stresses below the yield strength and equal-volume (with zero dilatancy) plastic flow at stresses at the yield strength. The stresses at the yield point are described by the equation:

$$\sigma_{max} = S + \lambda \sigma_{min}; \tag{15}$$

where λ = ctg ^{2} $(\pi/4 - \phi/2)$ - coefficient of passive soil pressure; $S = 2C$ ctg $(\pi/4 - \phi/2)$ - ultimate strength in uniaxial compression; σ_{max}, σ_{min} - maximum and minimum principal stresses.

In the tensile region, the yield (rupture) criterion has the form:

$$\sigma\mu\tau v = -T; \tag{16}$$

where T is the tensile strength, taken in the Plaxis program, equal to C /5. After a rupture occurs at a voltage σ = - $C/5$ in the further analysis, the tensile strength of the element is assumed to be zero (T =*0*). The elastic-plastic solution is implemented by the finite element method and is achieved by the known method of "initial stresses" using the iterative Newton-Raphson procedure with a constant stiffness matrix, but with a variable load vector, replenished during the iterative process by "initial forces" in plastic elements. The error in the calculation of the FEM consisted of the discretization error due to the replacement of a body with an infinite number of degrees of freedom, a model with a finite number of degrees of freedom, and the rounding error of numbers when performing computational operations on a computer /4,5,6,7/. As a result of the numerical analysis of the tasks set and (Figure 4: Design scheme), the following were obtained: finite element mesh distortion (Figure 5), horizontal and general slope deformations when the calculated characteristics of subsidence soils change (Figure 6 and 7), as well as the isolines of the maximum horizontal (shear) stresses and general (full) stresses when changing the stress-strain state of the slope to the retaining wall.

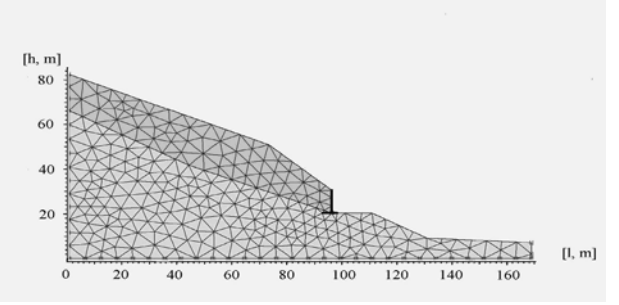

Figure 4. Calculation scheme.

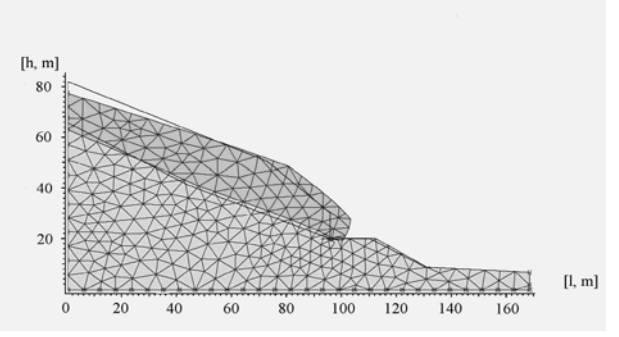

Figure 5. Mechanism deformation (extreme total displacement 162.42* 10^{-3} m).

An analysis of the results of a numerical solution when modeling the interaction of a slope and a retaining wall shows that the most dangerous are the development of maximum horizontal deformations near the retaining walls, due to shear deformations. The shear deformation propagation zone covers a large volume of slope soils. drawdown soils sagging from their own weight on a slope with water saturation worsens the initial value of adhesion, the angle of internal friction, the deformation modulus, completely changing the initial stress-strain state. Trajectories of movement of particles of subsidence soils when the stress-strain state of the slope changes to the retaining wall show that the movement of soil particles occurs at the boundary of subsidence and non- subsidence loams. Calculations for the numerical solution show that the retaining wall on the slope of the slope, composed of subsiding soils, is unstable and soil sliding occurs only in the volume subsiding soils of an elephant slope.

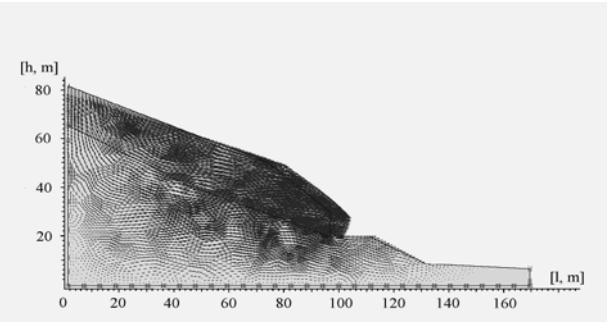

Figure 6. Total deformation (U_{tot}) (Extreme U_{tot} = 0.165m).

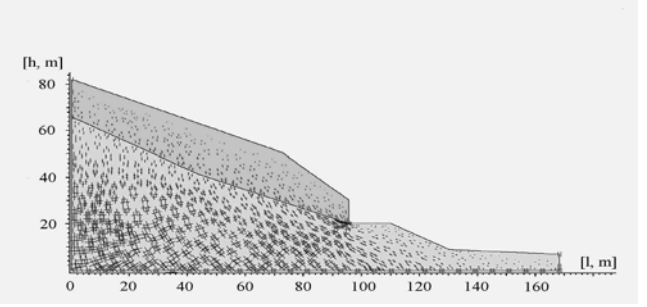

Figure 7. General stresses 483.25 * 10^3 Pa).

4 CONCLUSIONS

In the geological and lithological structure of the slope of the mountains, Lower Quaternary eolian deposits, represented by subsidence loess-like loams, take part.

As a result of instrumental inspection of slopes and measurements of protective retaining walls made of monolithic reinforced concrete and drainage systems, numerous defects and damages were identified during the design and construction process, which pose a threat to the safe operation of the road and the structure.

According to the results of compression tests, loams lying to a depth of 15.5-21.0 m exhibit subsidence properties when soaked. The initial settling pressure varies from 0.028 to 0.361 MPa (0.112). Calculations show that the total subsidence of soils with increasing humidity is 8.8-73.51 cm. Calculations of the stability of retaining walls along the highway located at the slope of the slope, carried out by numerical methods, showed that in the water- saturated state the slope is a landslide. An analysis of the results of a numerical solution when modeling the interaction of a slope and a retaining wall shows that the most dangerous are the development of maximum horizontal deformations near the retaining walls, due to shear deformations of the slope.

Features of the combined method of development of upland deposits of Kyrgyzstan

K.T. Tajibaev
Institute of Geomechanics and Development of Subsoil of the National Academy of Sciences of the Kyrgyz Republic, Bishkek, Kyrgyzstan

Ch.K. Sulaimanov
Kumtor Gold Company, Issykkul, Kyrgyzstan

ABSTRACT: Today, the mining industry is one of the priority sectors of the development of the Kyrgyzstan economy, of which the gold mining industry currently occupies a leading place. To date, more than 2,500 indigenous gold deposits have been explored on the territory of Kyrgyzstan, of which deposits with ore reserves of more than 30 tons have been identified according to gold reserves. As a rule, the gold deposits of Kyrgyzstan are mountainous, located in zones of tectonic disturbances and ore bodies, some of which come to the sur-face, and the lower part goes deep into the earth's crust, which predisposes a combined method of development. The combined method of field development is complicated by the tense state of the rock mass of the sub-quarry mine workings.

Kyrgyzstan is rich in minerals, has large deposits of gold, coal, antimony, mercury, uranium, zinc, rare earth metals and nepheline syenites, and the mining industry is one of the priority sectors of economic development.

The mining industry is one of the priority sectors of the development of the Kyrgyz economy. The gold mining industry currently occupies a leading position in the industry. Gold deposits, as a rule, are upland and are developed in a combined way. At the first stage, the work is carried out in an open way. (Table 1)

Both primary and placer deposits were developed on the territory of Kyrgyzstan. Traces of ancient developments are observed among the primary indigenous gold deposits such as Boz-Emchek, Kichi-Sandyk, Kuru-Tegerek, Ak-Tash, Kum-Bel, Kuran-Jailoo. To date, about 2,500 indigenous gold deposits have been explored on the territory of Kyrgyzstan. Of these, deposits with ore reserves of more than 30 tons have been allocated for industrial development according to gold reserves (Nikonorov V.V., Karaev Yu.V., Borisov F.I., 2004).

The largest, unique deposit on the territory of Kyrgyzstan is Kumtor, ore reserves exceed 400 tons. 70 tons of ore and more are contained in such deposits as Jeruy, Taldybulak Levoberezhny, Chaarat. At the Makmal, Bozymchak, Uncurtash, Ishtamberdy, Altyn-Zhylga, Nichkesu, Tokhtozan deposits, reserves range from 30 to 70 tons.

Gold deposits, as a rule, are upland and are developed in a combined way. Mining operations in upland quarries are complicated by the relief of the surface and are characterized by complex mining-geological, tectonic and hydrogeological conditions. The host rocks are, as a rule, intrusive and effusive rocks subjected to hydrothermal-metasomatic changes. Rocks are strongly fractured, and the intensity of fracturing increases at the contacts of rock varieties and tectonic disturbances. (Figure 1)

In the coal industry of the country, despite the significant resources and proven reserves of coal of all grades on the territory of Kyrgyzstan, the volume of their production remains insignificant,

DOI: 10.1201/9781003299127-176

Table 1. Licenses for prospecting and exploration of mineral resources of Kyrgyzstan.

Placer gold	20	3	23
Nonmetals	-	105	105
Underground water	-	-	109
Total	131	203	443

with a downward trend. As a result, Kyrgyzstan is forced to import coal from abroad, which, in turn, leads to a deterioration in the financial and economic condition of the republic.

At the same time, the prospects for an increase in energy prices and an increase in demand for them determine the need to revive domestic coal production by involving a large Kara-Keche deposit in the development.

The high-altitude Kumtor gold deposit

The high-altitude Jeruy gold deposit

Figure 1. The highest mountain gold deposits of Kyrgyzstan.

The main reasons for the decline in coal production can be attributed to the general decline in production in the republic and the deterioration of the financial condition of enterprises, which led to a decrease in coal consumption in the real sector of the economy. The transfer of a number of consumers to other types of energy carriers, the reduction of sales markets in the Central Asian region, high transportation costs reaching up to 300% of the cost of production, as well as large physical and moral wear of technological equipment at mining enterprises had a significant impact.

Having its own gas fields, Kyrgyzstan still remains practically a net consumer of imported gas. At the same time, the main role in the structure of natural gas consumption in the republic is played by the municipal and household sector, which accounted for 61.5% of the total volume in 2001. It should be noted that, as before, significant volumes of energy resources are supplied to the republic on a barter basis or are paid in freely convertible currency, which reduces the economic potential of the sector.

At the same time, the self-sufficiency of the republic with petroleum products is only 30%, while the data from the analysis of the possibilities of developing new oil and gas fields say that the use of modern technologies and methods of exploration and development will significantly increase production volumes.

The safety of the operation of upland quarries is determined by the properties of the geological environment. The geological environment is considered as a complex self-organizing nonlinear system in which physical processes in the Earth's crust are of decisive importance. The geological environment includes elements such as terrain, rock mass, rocks and their properties, groundwater, permafrost, natural gravitational processes, and during technogenic activity it experiences an impact that significantly changes the properties of its individual elements, the speed and direction of the processes occurring in it (Nikolskaya, O.V., Kadyralieva, G.A., 2013).

The main factors of the geological environment that significantly affect the stable condition of the sides of the quarry, the stability of the instrument array and the safety of mining operations include:

- Type of rocks, soils and soils, their structure, texture, physico-mechanical and geochemical properties;
- Tectonic disturbance and heterogeneity of the rock mass;
- Parameters of hydrogeological properties and processes;
- Endogenous and exogenous processes, thermal field;
- Features of geological structures;
- Relief of the Earth's surface;
- Geodynamic activity, seismicity;
- Geophysical fields.

Active structure-forming elements of the geological environment are tectonic faults and cracks, which represent a zone of disruption of the continuity of the Earth's crust, dividing the rock mass into two blocks and expressed in a complex and diverse deformation of the Earth's crust. Tectonic faults and cracks are present in any mountain range and in any territory (Sergeev, E.M., 1987).

As a result of discharges and large thrusts, rocks are subjected to prolonged displacement, overlapping of rocks of various origins and their structure, composition and physico-mechanical properties, which have a special effect on the geological environment, are thoroughly changed.

The modern needs of society for mineral raw materials require the development of mineral deposits located in climatically difficult, inaccessible conditions of the highlands. For states whose main territory is occupied by mountain ranges, the development of high-altitude deposits is an economic necessity. Such states, first of all, should include Kyrgyzstan, Tajikistan, Chile, Georgia, Armenia, Colombia and a number of others.

At the same time, the subsoil of the high-mountain countries is rich in mineral resources, the extraction of which makes it possible to effectively develop its own economy. The technology of open-pit mining of high-altitude deposits differs from the technology of lowland quarries in many ways. According to the definition of Russian scientists I.Z. Lysenko and S.A. Ilyin, "a mountain quarry is a quarry that develops a mineral deposit in a mountainous area.

Mining operations in upland quarries are complicated by the sloping terrain of the surface, the high-altitude location relative to sea level, the reduced partial pressure of oxygen in the atmosphere, increased solar radiation and wind activity, fogs, snow drifts and avalanche danger" (Nifadyev, V.I., Usmanov, S.F.).

As the surface mineral reserves are being worked out, many deposits in Kyrgyzstan are moving to the underground method of development.

A combined development system is, as is known, the development of a part of a mineral deposit prepared for excavation using various development systems or their elements. With the underground method, it is used on powerful ore deposits of various strengths, in cases when their effective development cannot be ensured using a single system. At the same time, the floor is divided into regularly alternating chambers close in width. (Figure 2)

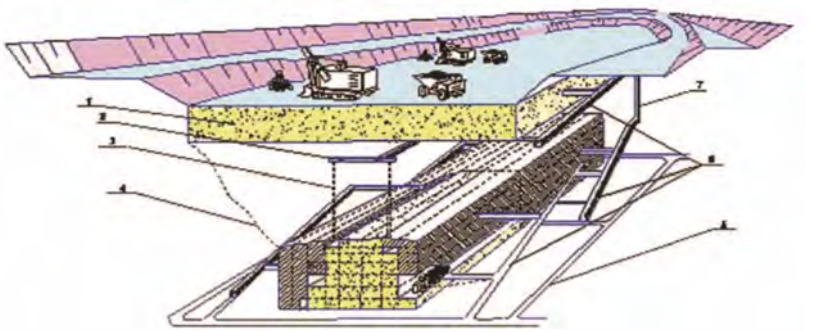

Figure 2. Combined development with horizontal layers with laying in the transition zone and an underground mine: 1 — artificial ceiling; 2 — ventilation-laying horizon; 3 — laying wells; 4 — contour of the ore body; 5 — pumping horizon; 6 — inclined exit.

The characteristic features of the complex open-underground method, which must be taken into account in the design justification of the parameters of the development of steep-falling deposits, are: the presence of a single worked-out space that ensures the placement of overburden rocks in internal dumps; working out the transition zone from open-pit to underground mining operations with one high-altitude ledge using quarry and underground drilling and transport equipment; rational interconnection technological schemes of open and underground mining methods in the process of field development.

Due to the specific conditions of the high-altitude deposits of Kyrgyzstan, with their combined development system, safety, equipment and labor productivity are usually 10-20% lower than at conventional deposits. Combined development of high-altitude deposits has a number of features that significantly complicate mining operations and lead to an increase in the cost of minerals:

- the difficult terrain complicates the location of transport communications, the placement of technological productions, leads to a limitation of the area of the mining enterprise and requires the concentration of all technological sites on a small territory;
- difficult climatic conditions imply low temperatures, high atmospheric pressure, lack of oxygen, which adversely affects the health of personnel and reduced productivity;
- the extremely heterogeneous geological structure of rocks, the presence of tectonic disturbances and structural weakening surfaces reduce the stability of the sides of quarries and underground mine workings
- large water inflow during the melting of glaciers, the presence of groundwater lead to the need for drainage of the quarry field;
- most of the high-altitude quarries are located in regions with high seismic activity, which requires taking into account the impact of natural earthquakes on the stability of mining structures;

– the costs of energy supply of the main technological processes are increasing, the use of mining equipment on diesel fuel is increasing;
– the influence of mass explosions on the stability of mining facilities is increasing;
– the irreversibility of combining combined geotechnology with a sequential transition to underground mining.

The peculiarities of the highlands have a significant impact on both the technology of field development and the safety of mining operations. An important point in the development of high-altitude deposits is to ensure the stability of the sides, ledges, underground mine workings and other geotechnical structures of the deposit.

The main factors contributing to the development of slope deformations in high–altitude and upland quarries are:

- the presence of weakening surfaces - tectonic disturbances, sliding surfaces of ancient landslides, weak contacts between layers;
- waterlogged rocks and their poor drainability due to melting glaciers;
- intense fracturing of individual sections;
- the presence of interlayers of weak clay rocks.

The conditions of such deposits impose their own characteristics on the methods of assessing stability, the choice of geomechanical models, the identification of the primary factors affecting the deformation of the mountain range. Most high-altitude quarries have a complex geological structure, tectonic disturbances, layers of weakened rocks, a significant flow of groundwater and groundwater.

Thus, the peculiarities of the highlands impose additional requirements for the application of new innovative methods for assessing the stability of the sides of quarries, underground mining workings and mining structures. The main condition for effective forecasting of the stability of rock slopes is the use of various techniques in a complex. A complex course will allow you to get a complete and adequate picture of deformation.

Synthesis of quality control procedures in the conduct of precision testing of standard soil mixes

J.A.R. Manaloto*, A.P.A. Acacio & M.A.H. Zarco
The University of the Philippines, Diliman, Quezon City, Philippines

ABSTRACT: Geotechnical index property test inputs are very important in foundation design in terms of soil classification and settlement calculations. It is therefore crucial to have accurate and reliable parameters for more reliable and safer foundation design.

In this research, Six Sigma and House of Quality were utilized and incorporated in the inter laboratory study (ILS) precision testing of standard soil mixes of Ottawa sand, Bentonite and manufactured sand. Specific Gravity tests, Sieve Analysis, Liquid Limit Test and Plastic Limit Test were conducted by Six (6) participating laboratories, including the Department of Public Works and Highways (DPWH), Bureau of Research and Standards laboratory.

The conduct of the ILS shows that for the soil tests, only sieve analysis produced good repeatability and reproducibility values. Both Specific Gravity Test and Liquid Limit and Plastic Limit Tests showed high r and R values. To rectify this, the observed probable sources of errors during the conduct of the ILS were identified and quality control measures were employed for a retest conducted in a single laboratory.

Retest results fell within the acceptable range of two results specifications of ASTM. Therefore, the quality control measures and procedures employed in the retest and ASTM precision statements were recommended to be followed for the proposed diagnostic testing for the DPWH Private Laboratory Accreditation and for the proposed accreditation of laboratory technicians.

1 INTRODUCTION

1.1 *Background of the study*

Geotechnical test parameters such as Specific Gravity, percentage passing different Sieve sizes, Liquid Limit and Plastic Limit are important inputs in geotechnical calculations and in determining the factors of safeties for slope or foundation design. A logical approach in determining the appropriate factor of safety for a given case is to consider the uncertainties in the quantities that would enter the calculations (Duncan, 2000).

Bias refers to various statistical issues that are classified as measurement, sampling and estimation. Measurement or sampling bias refers to "the difference between a population mean of the measurements or test results and an accepted reference or true value." Hence, bias causes an underestimation or overestimation of the reference/true value. Measurement bias is usually the result of defective measuring devices or procedures while sampling bias is caused by having an unrepresentative sampling of the target population. Both biases cannot be resolved by increasing sampling effort or the sampling size.

Precision, on the other hand, refers to the absence of random error or variability which is also described as the measure of the statistical variance of an estimation procedure. In contrast to bias, the magnitude of precision is dependent only on the estimated/observed values/measurements regardless of the true value. Thus, it can be described as the spread of the data which can be attributed to the statistical variability existing in the sample gathered. In measurements, precision can be determined from the variance caused by the measuring device or

*Corresponding author: jrmanaloto@up.edu.ph

DOI: 10.1201/9781003299127-177

methodology. This variability produced by the measurement error plus the sample variation and estimation variance contributes to the total variance.

1.2 *Significance of the study*

In the Philippines, there is no available data regarding the precision and reliability of sieve analysis, liquid limit, plastic limit and specific gravity data. These parameters are very important since they are used in the analysis and design of foundations and other earth structures. Therefore, it is very important to adopt a standard procedure in determining the precision statements of soil tests to be able to assess the reliability of soil laboratory tests in the Philippines.

1.3 *Statement of the problem*

There is no existing quality control program or standard/procedure to measure, control and improve precision and bias in soil classification laboratory tests in the geotechnical/soil testing facilities in the Philippines. The lack of such standard procedures puts into question the reliability and acceptability of the soil tests which includes specific gravity tests, sieve analysis, Liquid Limit test and Plastic Limit test which are conducted by the laboratories and also the foundation calculations and designs where these parameters were used.

1.4 *Objectives*

This study aims to establish a quality control procedure to measure, control and recommend improvements in the precision and reliability of geotechnical soil laboratory tests such as specific gravity test, sieve analysis, Liquid Limit test and Plastic Limit test in the Philippine testing laboratories for more accurate geotechnical parameter inputs that would lead to more reliable and safer foundation design.

1.5 *Scope and limitations*

Standard Testing Procedures. All of the tests that will be conducted in this research shall all be based and comply with the American Society for Testing and Materials (ASTM) international provisions. All variations from the ASTM procedures shall be recorded and explained. Moreover, for the purposes of this research, only the specific gravity test (ASTM D854), sieve analysis (ASTM D6913), Liquid Limit test and Plastic Limit test (ASTM D4318) shall be conducted as part of the soil classification routine laboratory tests. Other tests shall not be included and therefore not included in the analysis.

2 REVIEW OF RELATED LITERATURE

2.1 *Inter-Laboratory Study (ILS) to determine precision and bias*

ILS is composed of three basics steps which include planning the ILS, guiding the testing phase of the study and finally analyzing the test results as shown in Figure 1.

The final phase of the ILS is the analysis of test result data wherein "the ILS test results have three purposes, to determine whether the collected data are adequately consistent to form the basis for a test method precision statement, to investigate and act on any data considered to be inconsistent, and to obtain the precision statistics on which the precision statement can be based."

For the cell statistics, the cell average and cell standard deviation for each laboratory are given by Equations 1 and 2, respectively.

$$\overline{x} = \sum_1^n x/n \tag{1}$$

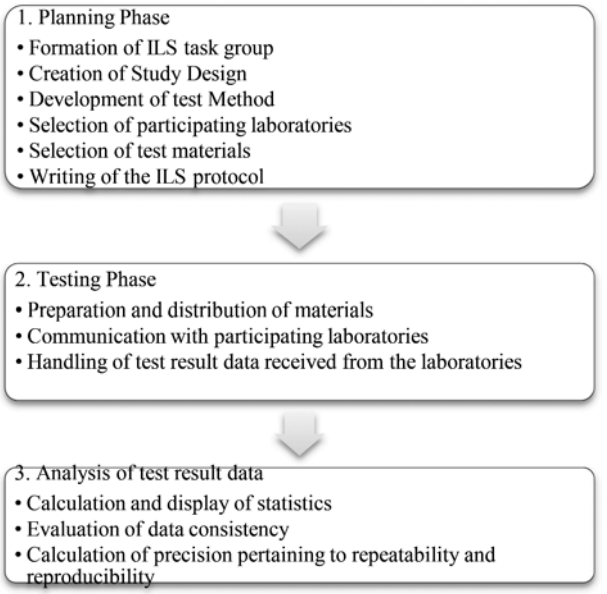

Figure 1. Flowchart of Inter-laboratory Study (ILS) Procedure based on ASTM E691.

where $\bar{x}$ = the average of the test results in one cell; x = the individual test results in once cell; n = the number of test results in one cell.

$$s = \sqrt{\sum_1^n (x - \bar{x})^2/(n-1)} \tag{2}$$

where s = the cell standard deviation.

For the intermediate statistical calculations, the average of the cell averages for each material and the cell deviation for each laboratory can be calculated using Equations 3 and 4, respectively. Furthermore, the standard deviation of the cell averages is given by Equation 5.

$$\bar{\bar{x}} = \sum_1^p \bar{x}/p \tag{3}$$

where $\bar{\bar{x}}$ = the average of the cell averages for one material; $\bar{x}$ = the individual cell averages; p = the number of laboratories in the ILS.

$$d = \bar{x} - \bar{\bar{x}} \tag{4}$$

where d = the cell deviation.

$$s_{\bar{x}} = \sqrt{\sum_1^p d^2/(p-1)} \tag{5}$$

where $s_{\bar{x}}$ = the standard deviation of the cell averages

The fundamental precision statistics for the ILS are the repeatability standard deviation and the reproducibility standard deviation. Equation 6 gives the repeatability standard deviation.

$$s_r = \sqrt{\sum_1^p s^2/p} \tag{6}$$

where s_r = the repeatability standard deviation; s = the cell standard deviation (p of them from Equation 2); p = the number of laboratories

Moreover, the between laboratory variance and between laboratory standard deviation can be calculated using Equations 7 and 8, respectively.

$$s_L^2 = s_{\bar{x}}^2 - s_r^2/n \tag{7}$$

where s_L^2 = the between laboratory variance.

$$s_L = \sqrt{s_L^2} \tag{8}$$

where s_L = the between laboratory standard deviation.

The reproducibility standard deviation, on the other hand, can be calculated using Equation 9.

$$s_R = \sqrt{s_L^2 + s_r^2} \tag{9}$$

where s_L = the between laboratory standard deviation.

For the consistency statistics, the between-laboratory consistency statistic and the within-laboratory consistency statistic can be calculated using Equations 10 and 11. Both computed statistic values should have two decimal places.

$$h = d/s_{\bar{x}} \tag{10}$$

where h = the between-laboratory consistency statistic.

$$k = s/s_r \tag{11}$$

where k = the within-laboratory consistency statistic.

For the precision statement information and using the corrected statistics, the 95% repeatability and reproducibility limits are calculated using Equations 12 and 13, respectively.

$$r = 2.8\ s_r \tag{12}$$

where r = the 95% repeatability limit

$$R = 2.8\ s_R \tag{13}$$

where R = the 95% reproducibility limit

2.2 *Quality management*

2.2.1 *Six Sigma principles*

Six Sigma is a methodology for improvement of processes and also a statistical concept to identify and define the inherent variation in any process. The principal premise of Six Sigma is that any variation in a process gives chances for errors that would then lead to risks for product defects, whether in a tangible process of a service. The yield, which can be used to determine the sigma level via a sigma table, can be calculated using Equation 13. The higher the sigma level, the more "perfect" the process is.

$$Yield = \left(\frac{No.\ of\ opportunities - No.\ of\ defects}{No.\ of\ opportunities}\right) \times 100 \tag{13}$$

2.2.2 *House of quality*
House of Quality (HOQ), which is a set of interrelated matrices, is the heart of QFD and is illustrated in Figure 2 (Goetsch & Davis, 2013).

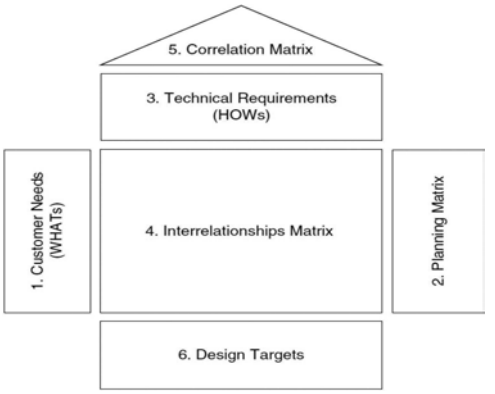

Figure 2. House of quality diagram.

As seen in Figure 2, the HOQ is composed of six sub-matrices. The goal of HOQ is to take input requirements from the customers and then translate them into a set of customer needs (VOC). Based on the VOC, bench-marking with competing shall be done prior the determination of prioritized features of a new or improved product/service that will best respond to the VOC.

3 METHODOLOGY

This chapter describes in detail the conduct of the Inter-laboratory Study (ILS) from the planning, testing, and data analysis phases for the soil classification test methods while applying quality control concepts and procedures all throughout the process.

3.1 *Planning phase*

3.1.1 *Formation of ILS task group*
For this ILS, the researcher shall be the overall ILS coordinator and laboratory supervisor. The statistical and data analyses shall also be done by the researcher with the assistance of the person in charge of the ILS of the Department of Public Works and Highways (DPWH), Bureau of Research and Standards (BRS).

3.2 *Analysis of test result data*

3.2.1 *Calculation and display of statistics*
For the basic statistics, Equations 1–8 shall be used to calculate the cell average, cell standard deviation, average of cell averages, cell deviation, standard deviation of the cell averages, repeatability standard deviation, between laboratory variance and between laboratory standard deviation.

3.2.2 *Calculation of precision pertaining to repeatability and reproducibility*
For the precision statement information and using the corrected statistics, the 95% repeatability and reproducibility limits are calculated using Equations 12 and 13, respectively.

3.3 *House of quality*

Based on the results of the ILS conducted, the House of Quality as discussed in Section 2.2.2 shall be established. This shall determine the needs, technical requirements and design targets of a high-precision proficiency testing system.

3.4 *The use of Six Sigma and house of quality in the soil testing interlaboratory study*

Generally, six sigma concepts and house of quality are used as quality control tools in the business sector wherein the processes are optimized to reduce errors in the procedures and reduce defects in the end products while at the same time increasing customer satisfaction. This research has explored the application of six sigma concepts and house of quality in the laboratory testing setting wherein the end products are the test results and the customers are the geotechnical engineers who require high precision with less errors for satisfaction. In order to fit this setting, some adjustments and simplifications were done in the six sigma processes and house of quality concept.

Table 1 shows the quality control concepts from six sigma and house of quality that were integrated in the conduct of the ILS.

Table 1. Quality concepts integrated within the ILS.

ILS Process	Quality Concept	Taken from
Planning phase	Define: Identify the business case, project scope, stakeholders, team member roles, milestones/timeline for the phases.	Six Sigma
	Measure: Using Failure Modes and Effects Analysis (FMEA), identify risks and errors within all steps of the tests	Six Sigma
Testing phase	Measure: Record/document all measurements and variations in time/measurements in each step process for all tests	Researcher
Data Analysis	Analyze: Using a Pareto Charts, identify the root causes of the variances of results	Six Sigma
	Analyze: Using Spearman Rho non-parametric Correlation, determine if there are relationships between the recorded data test variations and the ILS test results	Researcher
	Analyze: Create House of Quality diagram to serve as a guide to facilitate the design of other ILS tests for the same purpose and future studies.	House of Quality
	Improve: Recommend improvements in the conduct of ILS	Six Sigma
	Improve: Create a criteria for proficiency testing and DPWH accreditation	Researcher

4 RESULTS AND DISCUSSION

4.1 *Laboratory testing records*

The ILS coordinator required the participating laboratories to record testing data/details that may be used for analysis in identifying deviations and possible causes of errors in the tests.

4.2 *ILS test results*

Figures 3, Tables 2 and 3 show the ILS test results conducted on the three (3) soil mix proportions done by the six (6) participating laboratories for three (3) trials each of Sieve Analysis, Liquid Limit and Plastic Limit tests, and Specific Gravity Test, respectively.

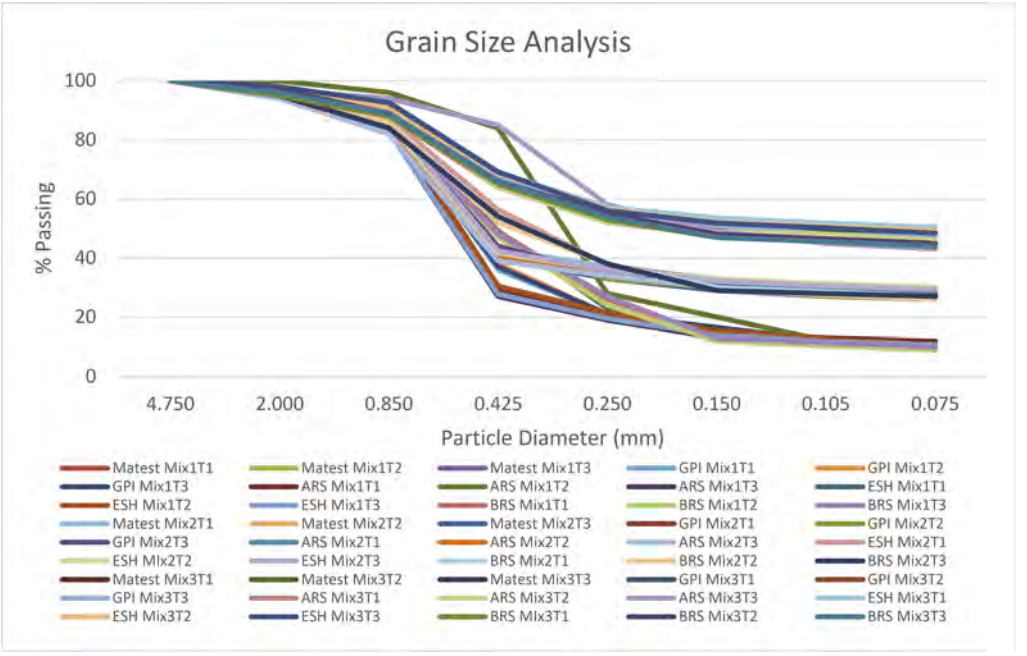

Figure 3. Sieve analysis ILS results.

4.3 *Data analysis*

4.3.1 *Comparison of precision statements with ASTM examples*

Table 4 shows the Comparison of ILS Precision Statements with Examples from ASTM.

It can be seen from Table 4 that only percent passing Sieve No. 10 for mixtures 2 and 3 have reproducibility limits less than the precision statement examples of ASTM. All the other repeatability and reproducibility values exceeds the said limits and are very much high in the liquid limit and plastic limit tests. Though the soil samples from ASTM and this ILS are different types, the precision statements in this ILS are very much higher than that of the ASTM examples.

4.3.2 *Retest*

Tables 5–7 show the results of the precision calculations for corresponding mixture.

From Tables 5–7, the acceptable range of two results (2ds) refers to the maximum difference any 2 trials for a given test in a laboratory can have and is determined by multiplying 1.960 $\sqrt{2}$ to the standard deviation. It can be seen that in this retest, all standard deviations and acceptable range of two results values fall within the ASTM specifications. This means that the correction/control of the probable sources of errors found during the ILS was effective.

4.3.3 *Precision testing criteria and checklists for quality control and procedures*

Since it was proven that the ASTM precision statements are achievable, then it shall be adopted as the precision testing criteria as shown in Table 8.

Table 4. Comparison of ILS precision statements with examples from ASTM.

5 CONCLUSIONS

In this research, quality control concepts from Six Sigma and House of Quality (HOQ) were used to identify the risk and sources of errors. From these analyzing tools and direct observations, deviations and possible sources of errors in the conduct of the soil laboratory tests were identified. Though the precision statements of the Inter-laboratory Study vary greatly from the ASTM requirements, it was found out that the control/corrective measures that were employed in the retest to rectify the errors as observed in the conduct of the inter-laboratory study were effective in bringing the precision statements to within the requirements of ASTM. In sieve analysis, thorough cleaning prior and after use of all sieves using standard sieve brush and giving after mechanical shaking of an average of 3-4 minutes for pure Ottawa and

Construction sands as well as an average of 6-7 minutes for Mixtures 1, 2 & 3 of manual shaking were effective measures in achieving the ASTM precision statements. Moreover, in the specific gravity test, the drying time shall be given more importance thus in the process of decantation the samples containing water in the pan must be immediately placed in a preheated oven to ensure that the weight of the samples will not be diminished during the taring. The transfer of soil slurry and use of dropper to remove/add water in the pycnometer were effective measures in achieving the ASTM precision statements. In the liquid limit test, using a motorized and level liquid limit device to ensure standard drop rate and ensuring that the technicians refrained from holding the base of the liquid limit device during the blowing procedure were effective measures in achieving the ASTM precision statements. Also, in the plastic limit test, use of a standard 3.2 mm diameter stick during the plastic limit test and placing the analytical balance on a level and permanent station were effective measures in achieving the ASTM precision statements. Further, the precision criteria and checklists that were established shall be useful in the accreditation criteria of Laboratories and also to geotechnical engineers to ensure reliable soil parameters for safe geotechnical design.

It is recommended to conduct another ILS employing the retest control measures and corrections to check whether it would be effective in another ILS setting. It is also recommended that since the primary sources of errors is the laboratory technicians' performance which is directly related to their training and experience in these soil tests, there must be an accreditation of laboratory technicians as well. Moreover, to improve this research, proficiency testing with an established reference laboratory is recommended. For future studies, the specific implications and quantified effects of the errors in the soil parameters and soil classification to the geotechnical design, calculations and decision-making must be explored and discussed.

Geotechnical risk assessment for construction of underground structures

Dmitry Chunyuk* & Serafima Selviyan*
National Research Moscow State University of Civil Engineering (NRU MGSU), Moscow, Russia

ABSTRACT: In underground construction, there is a high risk of emergency situations and accidents that can lead to death of people. Therefore, the article has developed methodology for calculating risks in underground construction, which provides for the allocation of individual components of the total damage (consequences) from risks and the determination of the price of each component from various causes. The proposed approach allows targeted implementation of risk mitigation measures. For example, protective actions are applicable to a specific, most significant consequence, while not addressing causes and events whose risk cost, except for the mitigated consequence, remains acceptable or negligible. The above methodology will later help to create a risk register for typical facilities, which will make it possible to determine the most appropriate protective measures necessary for the construction and operation of underground structures.

Keywords: risk analysis, geotechnical risks, source of risk, underground construction, monitoring

1 INTRODUCTION

The purpose of the study is to identify risks that can lead to an emergency event. The main reasons for the manifestation of risks are related to the engineering and geological conditions of construction. To minimize the risk, it is necessary at the initial stage to identify possible risk factors, analyze the possible impacts and the degree of danger from their manifestation.

Risks and manifestations of non-standard situations in underground construction in large metropolitan areas, primarily due to specific, complex engineering-geological, hydrogeological and urban planning conditions for laying objects, which include:

- the presence of a thick layer of technogenic soils, karst soils, high activity of groundwater and flooding of underground construction sites, etc.;
- significant technogenic loads on the engineering and geological environment of the city, which, by provoking negative fast-flowing geological processes, worsen the conditions for the construction and operation of underground facilities;
- the presence of dense urban development and the need to conduct underground construction work in cramped conditions, where, in addition to those under construction, many other buildings, structures and communications fall into the zone of influence.

2 MATERIALS AND METHODS

The listed risk factors and the possibility of their action in an unfavorable combination determine the need for their identification and accounting throughout the life cycle of the underground structure (during surveys, design, construction, operation and reconstruction), which is designed to optimize the choice of the location of the object (for example, the route

*Corresponding authors: Chunyuk@mail.ru and SelviyanSM@yandex.ru

DOI: 10.1201/9781003299127-178

of the tunnel) and the corresponding protective measures, the cost of which largely depends on the degree of danger for various conditions of laying the mine.

In the modern practice of construction and operation of critical underground facilities in large megacities, many tasks of prevention of non-standard situations, and in case of their manifestation – elimination of consequences, are solved by organizing scientific and technical support of works at all stages of the life cycle of the structure.

At the same time, the main importance is attached to solving geotechnical issues, for example, such as assessing the possible negative impact of new construction on the natural and urban environment, changing the conditions for the static operation of structures under construction over time, and determining the category of geotechnical complexity of construction. For such calculations, software systems PLAXIS, Z_Soil, MIDAS, etc. are used. The PC data are used to calculate the stress-strain state of the "soil mass-structure" system. Based on the results of these works, adjustments are made to design and technological solutions, to methods for ensuring the operational reliability of facilities under construction and in operation. However, the effectiveness of taking into account the peculiarities onto one or another geotechnical situation for risk assessment is still largely determined by the qualifications and experience of organizations performing the design, construction or operation of the facility. The regulatory and methodological framework available on this issue, including the Guidelines of the International Tunneling Association, is mostly of a general nature.

In the modern practice of designing complex and hazardous production processes, mainly a comprehensive assessment of the cumulative probability of the causes, risks and consequences of a possible non-standard situations (event) is used. In this case, the resulting damage (consequences) is not divided into components depending on the causes that caused them. Such an assessment does not allow optimizing the choice and evaluating the effectiveness of measures to reduce the risk from each of the possible types of danger.

The methodology proposed in this article, developed in the development of existing methods, provides for the allocation of individual components of the total damage (consequences) from risks and the determination of the price of each component from various reasons (dangerous engineering and geological processes, deviations from the project, technological failures, etc.). This approach allows you to "point" to carry out risk reduction measures. For example, protective actions are applicable to a specific, most significant consequence, while not addressing causes and events for which the cost of risk, with the exception of the mitigated consequence, remains acceptable or negligible.

3 RESULTS

3.1 *Risk assessment algorithm*

In the practice of underground construction, the implementation of such "point" measures is most relevant due to the ratio of the size of the zone of potential danger of the construction object and the zone of distribution of dangerous engineering and geological processes.

A risk in the described Methodology is an event that has its own cause and adverse consequences. Each event can be caused by several causes, and each effect can be the result of several events.

All objects have their own unique range of risks, which depends, among other things, on the parameters of the object (geometric, structural, functional, etc.) and its location. The cost of risks can be expressed both in shares (%) of the value, and in monetary or conventional units.

At the stage of substantiating investments in the construction of an object, the authors recommend the use of a point-based method for assessing risks, which allows determining the main risk factors and assessing them in an enlarged manner. The point-based method can also be used to narrow the list of considered risks, discarding insignificant risks (risks with low probability and/or magnitude of damage from the consequences).

Risk assessment in underground construction is presented as a process in which certain actions are performed according to the algorithm presented in the flowchart in Figure 1.

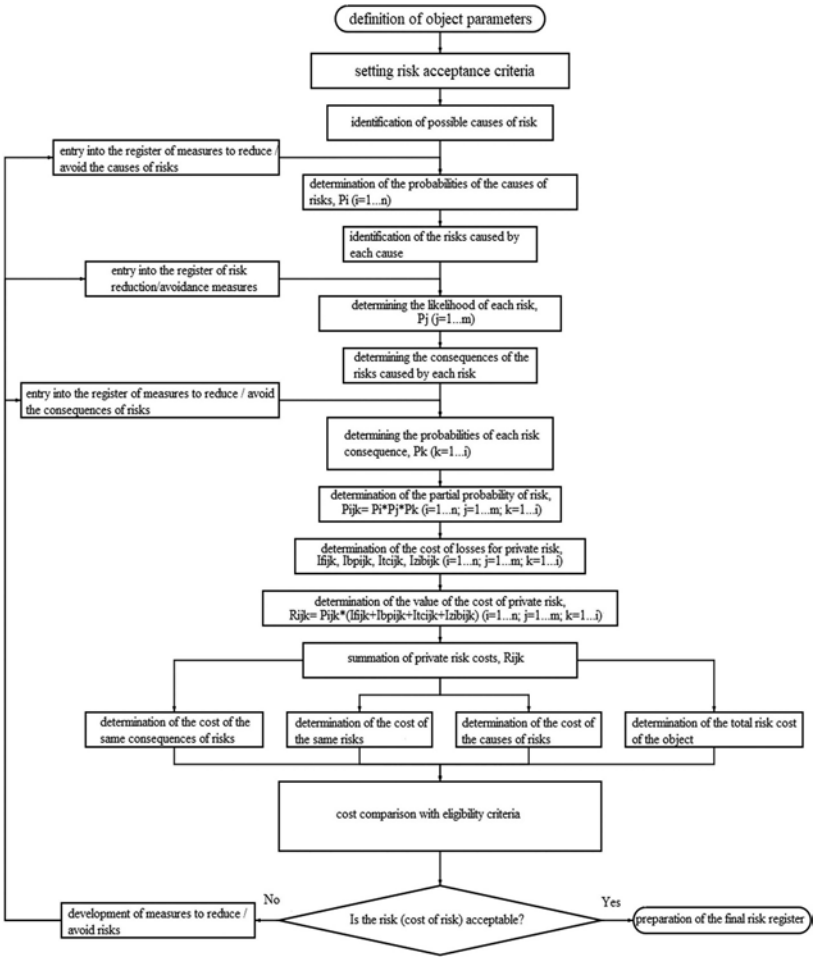

Figure 1. Algorithm of the risk assessment process during underground construction.

3.2 *Relationship between risks and their causes*

Guided by the proposed algorithm, it is possible to estimate the cost of risk (the cost of consequences, taking into account the probability of an non-standard from each of the possible causes) both for individual consequences and for individual events.

The interrelation between the final probability of the occurrence of the consequence with the probabilities of the presence of the cause of the risk and the manifestation of the event is schematically shown in Table 1.

The risk assessment process is a step-by-step process, with each step specifying what actions and by what methods they should be carried out. The risk assessment process (see the flow chart of the risk assessment algorithm in Figure 1.) is recommended to begin with the identification of the risk acceptability category for each object, bearing in mind the following definitions:

- negligible risk - a risk where the possible cost of losses has little effect on the cost of building an object;
- acceptable risk - a risk at which the possible cost of losses can be assumed by an investor, customer or designer;
- conditionally acceptable risk - the risk at which the possible cost of losses can be allowed by the investor if it is more expensive to prevent an non-standard situation;
- unacceptable risk - is a risk, the prevention of which is necessary regardless of the cost.

Table 1. The interrelation of risks with their causes and consequences.

Object parameters

$P_{ijk} = p_i * p_{1.1} * p_{1.1.1}$	$P_{ijk} = p_i * p_{1.1} * p_{1.1.2}$	$P_{ijk} = p_i * p_{1.1} * p_{1.1.1}$	$P_{ijk} = p_i * p_{1.2} * p_{1.2.1}$	$P_{ijk} = p_i * p_{1.2} * p_{1.2.2}$	$P_{ijk} = p_i * p_{1.2} * p_{1.2.1}$	$P_{ijk} = p_i * p_{1.m} * p_{1.m.1}$	$P_{ijk} = p_i * p_{1.m} * p_{1.m.2}$	$P_{ijk} = p_i * p_{1.m} * p_{1.m.1}$	$P_{ijk} = p_n * p_{n.1} * p_{n.1.1}$	$P_{ijk} = p_n * p_{n.1} * p_{n.1.2}$	$P_{ijk} = p_n * p_{n.1} * p_{n.1.1}$	$P_{ijk} = p_n * p_{n.2} * p_{n.2.1}$	$P_{ijk} = p_n * p_{n.2} * p_{n.2.2}$	$P_{ijk} = p_n * p_{n.2} * p_{n.2.1}$	$P_{ijk} = p_n * p_{n.m} * p_{n.m.1}$	$P_{ijk} = p_n * p_{n.m} * p_{n.m.2}$	$P_{ijk} = p_n * p_{n.m} * p_{n.m.1}$

Based on the results of the research and based on the principal design decisions, a list of potential causes of risks is compiled, which are entered in the risk register. The reasons for the risks may be due to engineering and geological conditions, adopted constructive decisions, construction methods, sequence of work, etc.

- Checklists;
- Scenario analysis;
- Structured analysis "What if?" (SWIFT), etc.

After identifying the causes of risks, the events themselves (risks, non-standard situations) and their consequences caused by the identified causes of risks are determined. At this stage, the following methods are recommended:

- checklists;
- analysis of the event tree;
- fault tree analysis;
- analysis of cause-and-effect relationships.

After compiling a list of considered causes, events and consequences, the probabilities of occurrence of each of the causes, events and consequences are determined. At the same time, for each risk (event), the probability of its manifestation is determined provided that the cause of the risk is present (the probability of the cause of the risk is 100%), and the probability of the manifestation of the consequences of the risk is determined, provided that the event has occurred (the probability of the event is 100%). The main methods for determining these probabilities are:

- Monte-Carlo simulation;
- method of expert assessments;
- statistical method;
- Bayesian analysis;
- Bayesian networks.

For each consequence, the probability of its manifestation is determined (let's call it the partial probability of risk) is determined by multiplying the probabilities of this consequence and

the probabilities of the cause and event that led to this particular consequence. Partial probabilities of risks from other causes or events are evaluated separately:

$$P_{ijk}=p_i \times p_j \times p_k \quad (1)$$

where P_{ijk} is the probability of a particular risk, taking into account the probability of the cause and the risk causing this consequence;

p_i is the probability of occurrence of the risk cause (event);

p_j is the probability of occurrence of a risk (event), while different causes of risk can be a source of the same risks;

p_k is the probability of occurrence of the consequences of a risk (event), while different risks (events) may have the same consequences.

Next, it is necessary to determine the cost of losses from a particular risk, i.e. the cost of eliminating the consequences or damage from the consequences of the risk in the event of its (consequence) occurrence. In most cases, losses can be divided into the following categories:

- financial losses for the facility, expressed in the cost of work to restore the destroyed part of the structure and additional work within the facility;
- increase in construction time, estimated in terms of the cost of downtime (can be expressed in terms of the cost of an object or a stage of an object and the refinancing rate of the Central Bank of the Russian Federation for each day of downtime);
- damage to a third party, expressed through the cost of restoration work on the structures of the surrounding buildings or material losses of vehicles, etc.;
- damage to health and safety (can be expressed in terms of compensation amounts).

The following methods are applicable to determine the cost of losses:

- expert method;
- statistical method;
- special methods for assessing damage from accidents.

At the next stage, the cost of private risk is determined by multiplying the private probability of risk by the cost of losses from private risk:

$$R_{ijk} = P_{ijk}\left(I_f + I_{bp} + I_{tc} + I_{zib}\right)_{ijk} \quad (2)$$

where R_{ijk} is the cost of private risk caused by certain causes and events (risks);

I_f - the amount of financial losses, expressed in monetary units or in shares (%) of the cost of construction;

I_{bp} - the amount of losses due to downtime in construction, expressed in monetary units or in shares (%) of the construction cost;

I_{tc} - the amount of damage to a third party, expressed in monetary units or in shares (%) of the cost of construction;

I_{zib} - the amount of damage to the health and safety of people, expressed in monetary units or in shares (%) of the cost of construction.

After determining the cost of losses from a private risk, the cost of private risks is summed up to obtain the following values:

- The cost of one consequence. In this methodology, it is defined as the sum of all private risk costs from the same consequences (and different causes of risks and/or risks).
- Cost of one risk. In this methodology, it is defined as the sum of all the costs of private risks from the same risks (and different causes).
- Cost of risk causes. In this methodology, it is defined as the sum of all the costs of private risks from one risk cause.
- The total risk cost of the facility. In this methodology, it is defined as the sum of all the costs of private risks.

The next step is to evaluate the acceptability of the risk, i.e. compare the cost of private risks and general risk with the categories of risks accepted for the object. To do this, it is convenient to use the ALARP or SFAIRP methods. These methods are used as criteria for determining the following indicators:

✓ ALARP - shows how much it is possible to reduce the risk to a minimum level;
✓ SFAIRP - serves to define security, showing the extent to which it is possible.

ALARP and SFAIRP are abbreviations for "As Low as Reasonable Practicable" and "So Far as Reasonable Practicable", which embody the principle of "reasonable execution". They are principles in which the condition for risk acceptability or tolerance for risk is how appropriate the costs are for risk reduction: ALARP is the principle of risk reduction to the lowest possible level; SFAIRP the principle of ensuring safety up to practically possible.

The SFAIRP and ALARP criteria are intended to achieve the same result, with ALARP providing security by making the risk as low as practicable and SFAIRP not referring to the level of risk. SFAIRP is usually interpreted as a criterion for evaluating risk management controls.

The ALARP model can be used to classify risks into one of three categories as follows (see diagram in Figure 2):

- unacceptable risk category, when the activity must be stopped in order to reduce it to an acceptable level;
- a broadly acceptable risk category, where the risk is so low that no further reduction needs to be considered (but it can be done if it is practicable and reasonable);
- the area between these boundaries (ALARP) where further risk mitigation should be implemented, if practicable.

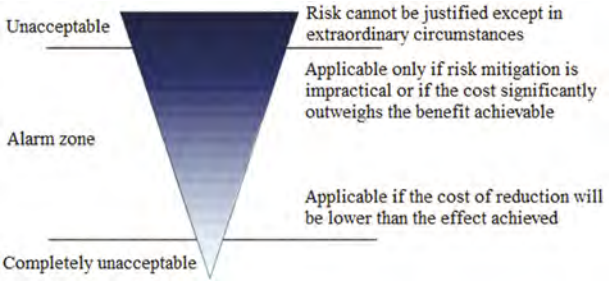

Figure 2. ALARP risk grading diagram.

The input data is information about the source of risk and the risk associated with it; on site controls and other possible control measures; about potential consequences; the likelihood that these consequences will occur; about the cost of possible measures to reduce the level of risk (risk treatment).

The result is a decision about whether risk treatment is necessary and how it should be performed.

After assessing the acceptability of risks, measures are developed and selected to reduce avoid risks defined as unacceptable and conditionally acceptable. In the process of searching for activities, the causes of risks caused by changes in design decisions (implementation of activities) are identified.

For each event, its effectiveness is evaluated by comparing the total risk cost of the object without the activity and with the activity, re-performing the assessment taking into account the implementation of the relevant activities. At the same time, it should be taken into account that risk reduction/prevention measures may lead to the emergence of new risks [6]. The impact (maximum 100%) of a reduction measure of a certain category (cause, event, consequence) is calculated by the formula

$$p_n = \frac{p_{st}}{100\%} \times \left(1 - \frac{p_m}{100\%}\right) \times 100\%, \quad (3)$$

where p_n is the probability of the realization (appearance) of the cause, event (risk) or consequences after the application of the measure,%;

p_{st} - the probability of the realization (appearance) of the cause, event (risk) or consequences before the event,%;

p_m is the effectiveness of risk reduction/avoidance measures, %.

4 DISCUSSIONS

The article presents a new methodology for calculating risks. This technique is a comprehensive risk assessment, which, if correctly identified, will reduce the risk of emergencies at various stages of the structure's life cycle. Subsequently, it is necessary to create a register of risks for the construction of underground structures in an open and closed way. Such a register will allow even before the design and construction stage to identify the most likely risks and their manifestations. It will allow even at the pre-project stage to minimize the possibility of their manifestation and select the necessary measures for further safe construction.

5 CONCLUSIONS

Based on the obtained cost of risks without and with measures, as well as the cost of carrying out the measure, the measures are finally selected according to their technical and financial efficiency.

Based on the results of the study, the following consequences and manifestations of risk were analyzed:a brief description of the risk (name, consequences and sequence of events);

- a statement about the likelihood of occurrence of consequences;
- sources or causes of risk;
- information on what is currently being done to manage the risk.

For the convenience of analyzing the risk register, it is recommended to include in it a list of causes, events and consequences, as well as a description of measures to reduce the likelihood of the corresponding risk occurring.

The initial data for compiling the risk register are the results of the risk assessment process described earlier, and the output is complete information about possible risks.

ABSTRACT: Local characterization of the geo-layer over a wide area is influenced by spatial uncertainties/differences in borehole data. In this study, the elevation and geo-layer thickness of borehole data in Seoul were standardized using outlier analysis with a 3-sigma model and cross-validation with the leave-one-out method. The borehole data, with or without elevation information, were categorized based on the accuracy of elevation by comparison with the digital elevation model (DEM). According to the errors with DEM, 3-sigma-based outliers were removed from the borehole data. Cross-validation-based mean errors resulting from the 3-sigma model were compared. The boundary elevation of the geo-layer in Seoul was applied based on the average ground conditions using optimum borehole data. The average ground condition method was applied to the boundary elevation of the geo-layer using optimum borehole data and compared with an ordinary kriging to evaluate for accuracy. As a result of comparing the two methodologies, the error tends to increase toward the lower layer. However, the average ground condition could not be applied to the entire area owing to the lack of current borehole data. Thus, additional geophysical data is required in addition to borehole data.

1 INTRODUCTION

As the demand for three-dimensional subsurface maps from the perspective of digital twins has grown, efforts have been made to improve the reliability of geotechnical information data. It is particularly necessary to improve reliability by defining and removing outliers in geotechnical information before applying the geospatial interpolation method.

Boring logs are frequently used to ascertain characteristics such as engineering strata, density, and resistance of the subsurface, by archiving samples and performing in-situ and laboratory tests. However, even borehole data have uncertainties owing to inherent soil variability and uncertainties in measurement and transformation. A reliable assessment of geomaterials requires the appropriate management of outliers (i.e., erratic information) of borehole data. Lee et al. (2017) proposed an improved method of verifying the precision of borehole data by removing outliers of errors in elevation.

In this study, borehole data were categorized and restored using principal attributes such as project location. After the detection of outliers and elimination using a statistical procedure, the borehole data were input into the database. The predicted area according to the distribution of

DOI: 10.1201/9781003299127-179

borehole data was identified for the entire city of Seoul, and the standardized subsurface condition was applied to the boundary elevation of the geo-layer based on the preprocessing of borehole data. The spatial interpolation accuracy according to the borehole density of the cell (250×250 m) was confirmed by comparing the standardized subsurface conditions with ordinary kriging results.

2 PREPROCESSING OF BOREHOLE DATA

2.1 *Classification of borehole data by attribute*

The public data portal (https://www.data.go.kr/) and geotechnical information portal system (https://www.geoinfo.or.kr/) provided data on 33,867 boreholes completed in Seoul (Figure 1). The data consisted of general boring, stratum, and standard penetration test information. Because the borehole data were mainly collected for urban development areas, there were borehole data from mountainous terrains. Consequently, the geo-knowledge-based data (e.g., location of the rock outcrop and shallow geo-layer from cut-slope) were supplemented and reviewed (Kim et al., 2019; Sun & Chung, 2006). The digital elevation model (DEM) was provided by the National Geographic Information Service in South Korea, and the cell size was 10×10 m. Since the surface elevation of the borehole was not provided in 14.27% of the borehole data, the general boring properties were categorized based on whether or not the surface elevation of the borehole was presented.

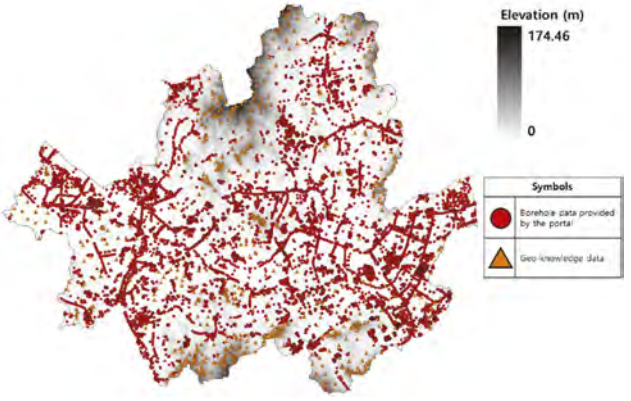

Figure 1. Distribution of borehole data and DEM.

When comparing the surface elevation of the borehole data and the DEM, the difference was mostly concentrated in the 100 m elevation zone. The purpose of the boring investigation was classified to configure the characteristics of the zone where the difference was biased. Borehole data for the railway project had an error of at least 100 m. In the case of the railroad project, the established standard for railroad design states, "the standard elevation is the value obtained by adding 100 m to the elevation announced by the national geographic information service." Conversely, surface elevation was restored by removing 100 m from the recorded surface elevation. As a result of the restoration as shown in Table 1, the mean absolute error (MAE) of the borehole data was 5.09 m, which was 65% lower than before the restoration. MAE is expressed as Eq. (1) by taking the average absolute error. This study used surface elevations from the DEM as observed values and surface elevations from borehole data as true values.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|\hat{Y}_i - Y_i\right| \tag{1}$$

where $\hat{Y}$ = observed value, Y_i = true value, and n = number of data points.

Table 1. Change of error as a result of classifying and restoring borehole.

State of the process	MAE (m)	Standard deviation (m)
Before restoration of borehole data	14.90	32.11
After restoration of borehole data	5.09	11.27

2.2 *Reliability verification through statistical processing techniques and outlier analysis*

The root mean square error (RMSE) was compared for reliability assessment using the cross-validation of the leave-one-out method. The RMSE is expressed by Eq. (2) by taking the square root of the squared errors.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(\hat{Y}_i - Y_i\right)^2} \tag{2}$$

where $\hat{Y}$ = observed value, Y_i = true value, and n = number of data points.

RMSE and standard deviation are similar concepts. The standard deviation is used to describe the variance of deviation for the population, whereas the RMSE is used to describe the variance of error for two or more unknowns.

The borehole data were restored, but a significant error remained. As shown in Figure 2, the 3-sigma rule (Bakar et al., 2006; Daw et al., 1972; Moivre, 2013) was used to calculate the standard deviation of the surface elevation at the boring location. Outliers were removed using an interval between 68.26% (±1 σ), 95.45% (±2 σ), and 99.73% (±3 σ).

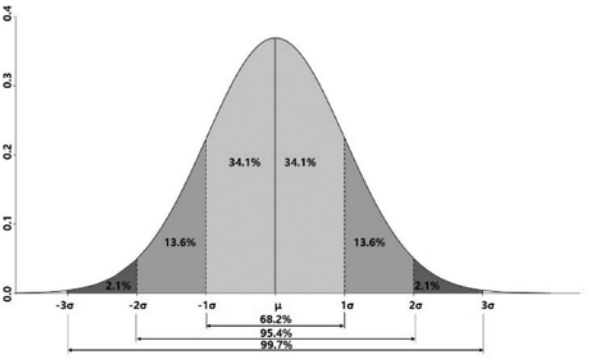

Figure 2. 3-sigma rule (Daw et al., 1972; Moivre, 2013).

Table 2. Attributes of borehole data for a total of 34,506 holes in Seoul.

State of the process	Data classification	Number of boreholes	Outlier removal rate (%)	MAE (m)	Standard deviation (m)	RMSE (m)
Before outlier removal	Data with surface elevation	25,201	0	5.09	11.27	8.75
	Railway project data	3,818				
	Geo-knowledge data	639				
	Data without surface elevation	4,848	–	–	–	
After outlier removal	68.26% (±1 σ	26,600	10.31	2.38	3.38	5.82
	95.45% (±2 σ)	28,075	5.34	3.09	4.97	6.16
	99.73% (±3 σ)	28,855	2.71	3.78	6.76	6.60

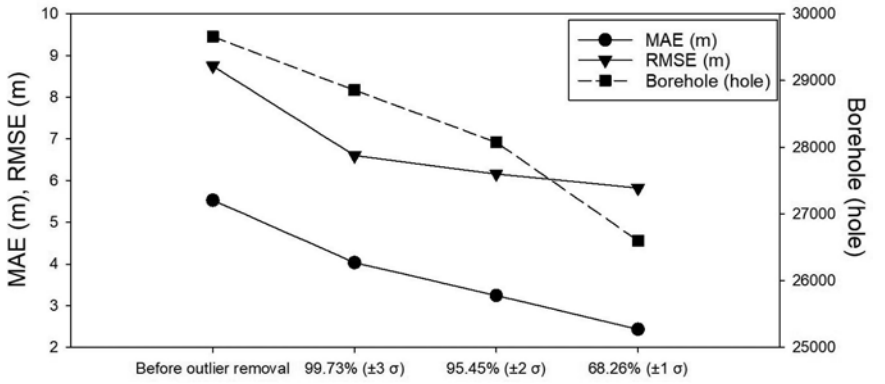

Figure 3. Rate of outlier removal and degree of error reduction.

A 68.26% (±1 σ) interval was used to preprocess the bore data in this study, as shown in Table 2 and Figure 3, taking into account the rate of outlier removal and the degree of error reduction, to increase the reliability of the estimated surface elevation for each borehole.

3 DISTRIBUTION OF GEOTECHNICAL CLASSIFICATION IN SEOUL THROUGH AVERAGE GROUND CONDITONS

3.1 *Distribution of borehole data in seoul*

The distribution of preprocessed borehole data for Seoul is shown in Figure 4. It depicts the distribution of borehole data in the soil and rock layers with and without the addition of geo-knowledge-based data. As the soil depth was directly measured using a hand auger during boring, it was impossible to investigate the rock layers due to equipment limitations. The target locations for the geo-knowledge-based data were concentrated on mountainous terrains (i.e., outside Seoul).

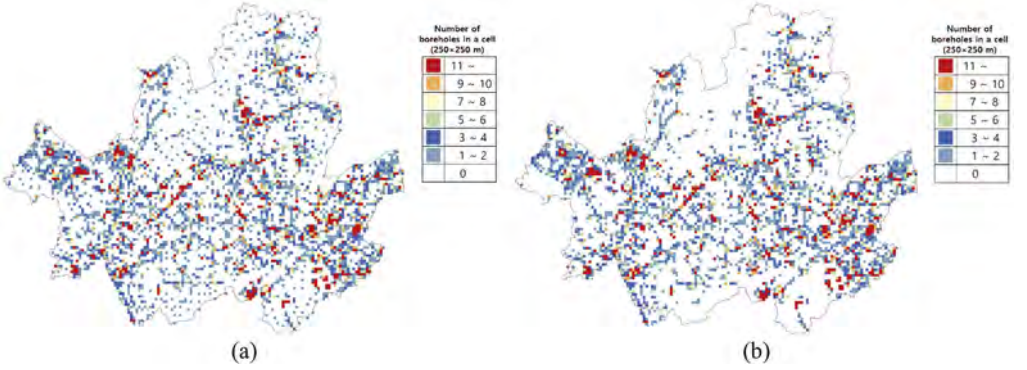

Figure 4. Borehole distribution in Seoul, South Korea: (a) soil layer (with geo-knowledge-based data) (b) rock layer (without geo-knowledge-based data).

3.2 *Application of standardized subsurface conditions*

According to Todo et al. (2013), the uneven distribution of borehole data can be overcome by using the average value within a cell size of 250×250 m considering the surrounding ground conditions in Japan's nationwide electronic geotechnical database systems (NEGDS). This facilitates a quick and intuitive understanding of the characteristic value of the borehole data

within the relevant area. In this study, the average ground condition was used to determine the boundary elevation of the geo-layer (i.e., fill, sedimentary, and weathered soils, and weathered, soft, moderate, and hard rocks), as shown in Figures 5–10, according to the distribution of the geotechnical stratum classification in Seoul. In the case of the soil layer with geo-knowledge-based data and the rock layer without geo-knowledge-based data, the average ground condition method was likewise possible for 38% of Seoul. The interpolated boundary elevation of geo-layers was compared with the results of ordinary kriging to validate the accuracy of the average ground condition. The cell resolution of ordinary kriging was set to 250×250 m, which corresponds to the size of an average ground condition cell.

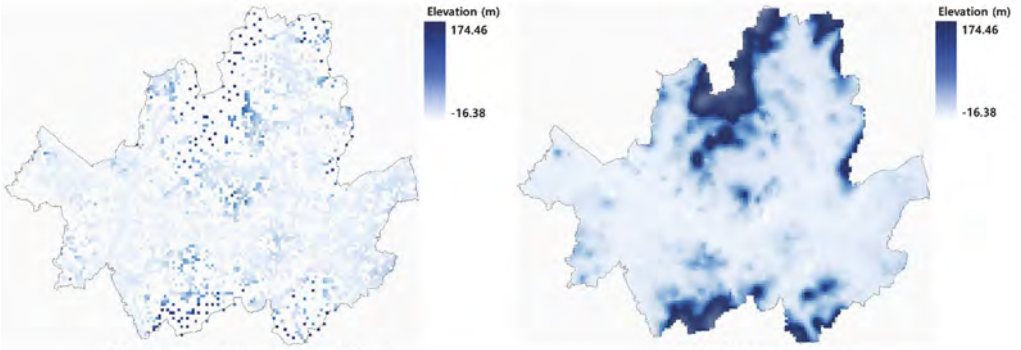

Figure 5. Spatial interpolation at the boundary elevation from the fill soil layer to the sedimentary soil layer.

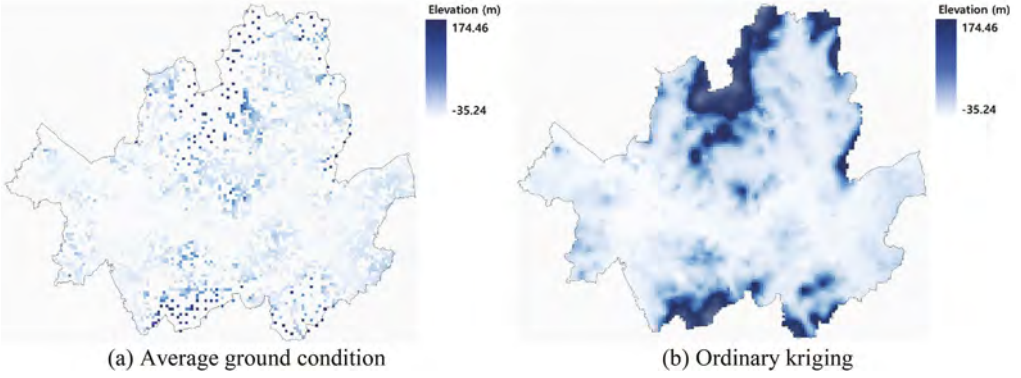

Figure 6. Spatial interpolation at the boundary elevation from the sedimentary soil layer to the weathered soil layer.

Table 3 shows a similar trend between the MAE and RMSE, and the RMSE was larger than the MAE. The average error increased as the elevation boundary of the geo-layer decreased. Geological uncertainty had a much greater influence in the lower layer, and errors in the upper layer accumulated in the lower layer. Moreover, the borehole data for the lower layer were smaller than those for the upper layer. Figure 11 shows substantial inaccuracy when there were primarily one or two boreholes in a cell (250×250 m). In addition, it was observed that the inaccuracy decreased if one cell had three or more boreholes.

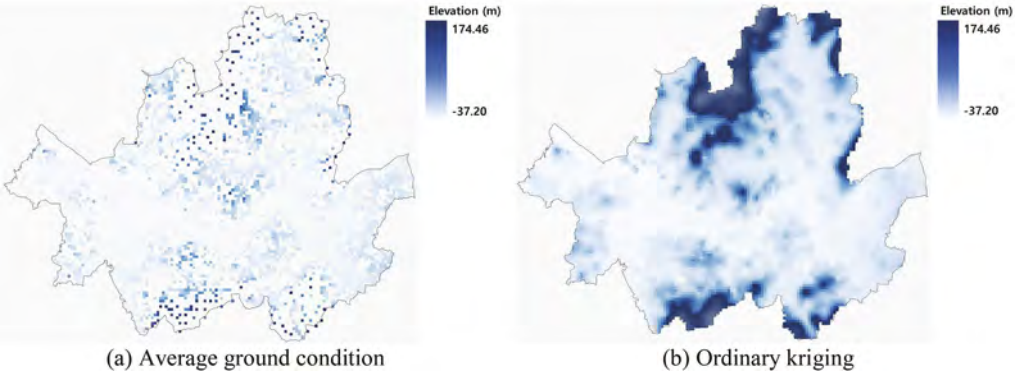

Figure 7. Spatial interpolation at the boundary elevation from the weathered soil layer to the weathered rock layer.

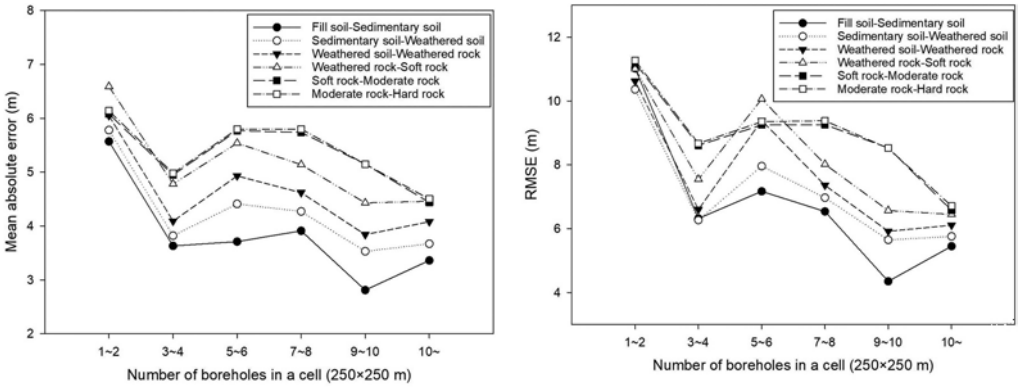
Table 3. Errors of boundary elevation of geo-layers by comparing methods of average ground condition and ordinary kriging.

Geo-layer boundary	MAE (m)	RMSE (m)
Fill soil-Sedimentary soil	3.80	6.70
Sedimentary soil-Weathered soil	4.23	7.07
Weathered soil-Weathered rock	4.57	7.53
Weathered rock-Soft rock	5.14	8.18
Soft rock-Moderate rock	5.37	8.89
Moderate rock-Hard rock	5.42	8.96



(a) MAE (b) RMSE

Figure 11. Errors according to borehole density in a cell.

4 CONCLUSIONS

Borehole data in Seoul were preprocessed using a statistical method to perform highly reliable spatial interpolation using the boundary elevation of the geo-layer. The borehole data were classified according to attributes and restored based on relevant project criteria. The reliability was then improved by removing outliers in the borehole data using a statistical method, and the database was standardized as a result. The distribution of the subsurface layered structure was obtained by applying spatial interpolation to the entire city of Seoul. Because the average

ground condition method cannot be evaluated for accuracy, it was compared with ordinary kriging. As a result of comparing the two methodologies, the error tends to increase toward the lower layer. Furthermore, the error was lower when the cell had more than three boreholes.

The average ground condition could not be applied to the entire area owing to the lack of current borehole data. Interpolation over a broader area is possible if additional geophysical data are used in addition to borehole data. As a result, further studies will apply the average ground condition to integrated analysis using geophysical data.

A study for correlation analysis between the density of under-ground utility structures and ground subsidence in urban areas

C. Choi*, J-Y. Kim, J.M. Kang & M. Chung
Korea Institute of Civil Engineering & Building Technology, Goyang-Si, South Korea

ABSTRACT: As many underground structures have been installed in urban areas, various types of ground subsidence have occurred around the world. In this paper, the correlation between the recorded ground subsidence and the density of underground structures in Seoul was studied. The relationship between the density of buried structures using GIS spatial digital data for 6 types of underground utilities (water, sewer, power, heat, communication, natural gas) and ground subsidence was optimized based on the concept of normalized line density. The effect of each buried utility on the recorded ground subsidence was optimized using weight factors generated from a random function. An algorithm was developed that can optimize the line density of buried utilities along with the 6 weight factors and the correlation between the normalized line density and the recorded ground subsidence. As a result of analyzing the normalized line density, it was found that more than 80% of recorded ground subsidence occurred in areas with higher normalized line density when the optimization algorithm was applied. It is concluded that the proposed optimization algorithm can be usefully applied to the analysis of the risk of ground subsidence using GIS digital data of buried utility structures.

1 INTRODUCTION

Various ground subsidence accidents have occurred in urban areas of S. Korea over the past several years, which has increased public anxiety about the safety. Federal and local government established the special Act for underground safety and comprehensive underground safety management system was carried out. Nevertheless, ground subsidence accidents continue to occur in urban areas, and it has been reported that a number of accidents have occurred, especially in areas where underground utilities are complexly buried (Kim 2022).

To prevent ground subsidence accidents, various studies have been conducted to predict the risk of ground subsidence and to use it for maintenance of buried utilities. Representatively, Choi et al. (2016) and Park et al. (2017) suggested a method to analyze the risk of ground subsidence by sensing the structural integrity of water and sewage pipelines and defects such as leakage. Choi et al. (2021) classified the spatial information on underground structures for certain urban areas, and analyzed the correlation between the line density of utilities and the occurrence of recorded ground subsidence. Through this, an optimization model that can predict the ground subsidence risk was presented.

In this paper, GIS-based spatial information data of 6 types of underground utilities (water, sewer, power, gas, heat and network) in an urban area is correlated to the recorded ground subsidence by evolving an optimization algorithm proposed by Choi et al. (2021). The risk prediction through optimizing the correlation conducted by Choi et al. (2021) are summarized and presented. The line density of underground utilities installed in the study area was analyzed, and the correlation of recorded ground subsidences that occurred between 2010 and 2015 were analyzed. Line density is a method used in spatial analysis, and defines the length

*Corresponding author: chchoi@kict.re.kr

DOI: 10.1201/9781003299127-180

of underground structures installed within an arbitrary radius around the cells of the interested region as the quantity per unit area (ArcGIS 2021). This paper presents an algorithm that calculates the line density of buried objects in the cell of interest and optimizes the correlation between the line density and the location of recorded ground subsidence. The accuracy of risk analysis by applying the proposed algorithm at 1km × 1km urban area of Seoul, Korea is verified and presented.

2 LINE DENSITY AND NORMALIZED LINE DENSITY FOR BURIED UTILITIES

The line density of the underground structures was analyzed using the spatial analysis function provided by ArcGIS (2021). Choi et al. (2021) introduced the concepts of line density and normalized line density. Line density indicates the density characteristics of structures installed around unit cells in space, and is an index that can indicate the spatial density of lines included in the area, and is calculated as the length per unit area. Figure 1 shows the concept of calculating the line density (ρ) for each grid cell. Conceptually, the sum of the lengths of lines located in a circle is calculated and the line density (ρ) is calculated by dividing this by the area of the circle. *L1* and *L2* represent the spatial lengths of two structures installed in a circle, and weight factors ω_1 and ω_2 can be assumed according to the characteristics of each structure.

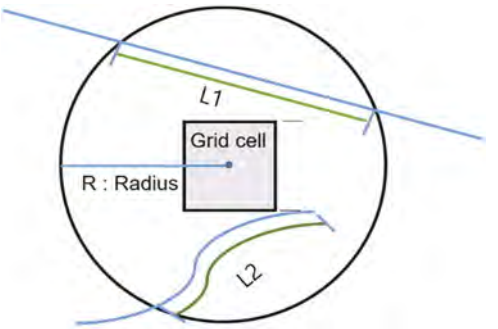

Figure 1. A raster cell and the circular neighborhood used to determine the length for the line density redrawn from ArcGIS(2021) (Choi et al.(2021)).

At this time, the line density (ρ) can be calculated through Equation (1).

$$\rho = \frac{\omega_1 L_1 + \omega_2 L_2}{A_R} \tag{1}$$

Here, A_R is the area of the circle obtained from the radius of the circle affecting the cell. Line density is calculated by determining the size of the grid cell, the radius R, and the weight factors ω_1 and ω_2 from Figure 1 and Equation (1). Choi et al. (2021) proposed the concept of normalized line density (ρ_n) of the interested area as shown in Equation (2).

$$\rho_n = \frac{\omega_1 L_1 + \omega_2 L_2 \ldots + \omega_n L_n}{n \cdot A_R} \tag{2}$$

where, $\omega_1 + \omega_2 \ldots + \omega_n$: weight factors
$L_1 + L_2 \ldots + L_n$: length of each buried structures
n: number of buried structure types
R: radius of affecting zone

$$\sum_{i=1}^{n} w_i = 1.0 \tag{3}$$

In Equation (2), ρ_n (normalized line density) can be defined as a line density normalized by the number of types of underground structures and the sum of the weight factors limited to 1.0 as shown in Equation (3).

3 OPTIMIZED NORMNILZIED LINE DENSITY ANALYSIS ALGORITHM WITH RECODED GROUND SUBSIDENCE

In this study, an optimization algorithm is proposed under the assumption that the normalized line density is largely distributed at the location where the ground subsidence occurs. Six weight factors $\omega_1, \omega_2, \ldots \omega_6$ of underground utilities (water, sewer, power, natural gas, heat, and network) were randomly generated to satisfy Equation (3) and to produce the higher the normalized line density at subsidence locations. Therefore, the core concept of the optimization algorithm is to calculate the weight factor set $(\omega_1, \omega_2, \ldots \omega_6)$ with the highest normalized line density at the location of the recorded ground subsidence by applying randomly generated weight factor sets (ω_i). Table 1 shows the pseudo-code of the algorithm proposed by Choi (2021) to optimize the correlation between the recorded ground subsidence and the normalized line density of underground structures.

Table 1. Pseudo-code to obtain optimal $\omega_i - set$ for finding higher correlation between normalized line density and ground subsidence.

Line No.	Pseudo-code	Description
1	for k=1: 100,000	
2	$\rho_n^k = \rho_{raw} \cdot \ \omega_i^k$	% ρ_n^k : normalized line density with $k^{th}\omega_i - set$ % ρ_{raw} : line density obtained from ArcGIS % ω_i^k : $k^{th}\omega_i - set$
3	$\rho_{n_{max}}^k = \max(\rho_n^k)$	% $\rho_{n_{max}}^k$: maximum scalar value of ρ_n^k
4	$\rho_{ns}^k = \rho_{sh} \cdot \ \omega_i^k$	% ρ_{ns}^k : normalized line density at the locations of ground subsidence % ρ_{sh} : line density at the locations of ground subsidence
5	$N_{ps}^k = \rho_{ns}^k / \rho_{n_{max}}^k$	% N_{ps}^k : normalized ρ_{ns}^k with respect to $\rho_{n_{max}}^k$
6	$Err^k = norm\left(1 - N_{ps}^k\right)$	% Err^k : error norm with $k^{th}\omega_i - set$
7	end	
8	$k_{opt} = find(Min(Err))$	
9	$\omega_{opt} = \omega_i^{k_{opt}}$	% ω_{opt}: $\omega_i - set$ at the index of k_{opt}

Line 6 in Table 1 shows the Error function for implementing the optimization algorithm. The Error function was proposed under the assumption that ρ_n where the subsidence occurred has a relatively higher value in interested area for analysis. Equation (4) is the Error function of the normalized linear density at the location of the recorded ground subsidence among random $\omega_i - set$.

$$Err^k = \left\| 1 - N_{ps}^k \right\| \tag{4}$$

$$\text{Where, } N_{ps}^k = \frac{\rho_{ns}^k}{Max(\rho_n^k)}$$

In Equation (4), Err^k represents the Norm of the error value at the location of the ground subsidence when the k^{th} random ω_i is applied. ρ_{ns}^k is the normalized line density when ω_i^k is applied at the location of the ground subsidence and ρ_n^k is the normalized linear density when ω_i^k is applied to the analysis area. The maximum value of is ρ_n^k defined as $\text{Max}(\rho_n^k)$. In other words, N_{ps}^k is defined as the scaled ratio (0~1.0) of normalized line density when applying ω_i^k at the location where the ground subsidence occurred.

4 NORMNILZIED LINE DENSITY AND CORRELATION ANALYSIS WITH RECORDED GROUND SUBSIDENCE

Figure 2 shows the map of the study area (1km × 1km), and the red circles on the map show the locations of 29 ground subsidence that occurred in the area during 2010-2015. The optimal set of 6 weight factors was obtained by applying the algorithm (Table 1) to the 29 recorded ground subsidences presented in Figure 1. In this study, R (100m) and cell size (10m) were applied to Equation (2) to calculate the normalized line density (ρ_n) of 6 types of underground utilities.

Figure 2. The 1km × 1km Map of analysis area and 29 ground subsidence locations with magenta circle symbol (Choi et al. 2021).

4.1 *Correlation analysis result between normalized line density and recorded ground subsidence with* $\omega_1, \omega_2, \ldots \omega_6 = 1/6$

Figure 3(a) is the normalized line density (ρ_n) of 6 underground utilities subjected to $\omega_1, \omega_2, \ldots \omega_6 = 1/6$. In the figure, the red circle symbol indicates the location where 29 ground subsidence occurred. From visual observation, it can be seen that the ground subsidence occurred relatively frequently in the area with higher normalized line density.

4.2 *Correlation analysis result between normalized line density and recorded ground subsidence when* ω_{opt} *applied*

Randomly generated 100,000 $\omega_i - set$ were applied to the optimization algorithm in Table 1 to analyze the values that minimize Error Norm at 29 ground subsidence locations. Figure 3(b) shows the normalized line density (ρ_n) of 6 underground utilities by applying Equation (2) to minimize Error Norm of the line 6 in Table 1. In the figure, the red circle is the location where 29 ground subsidence occurred. Comparing with the analysis results for $\omega_1, \omega_2, \ldots \omega_6 = 1/6$ case, it can be seen that the normalized line density where the ground subsidence occurs is relatively higher in the analysis area.

4.3 *Analysis of recorded ground subsidence classified with 5 grades*

Based on the maximum normalized linear density, the density was classified into 5 grades. The 5 grades are divided into G1 (lowest), G2, G3, G4, and G5 (highest). The higher the grade, the higher the line density of underground utilities and the higher the risk of ground subsidence.

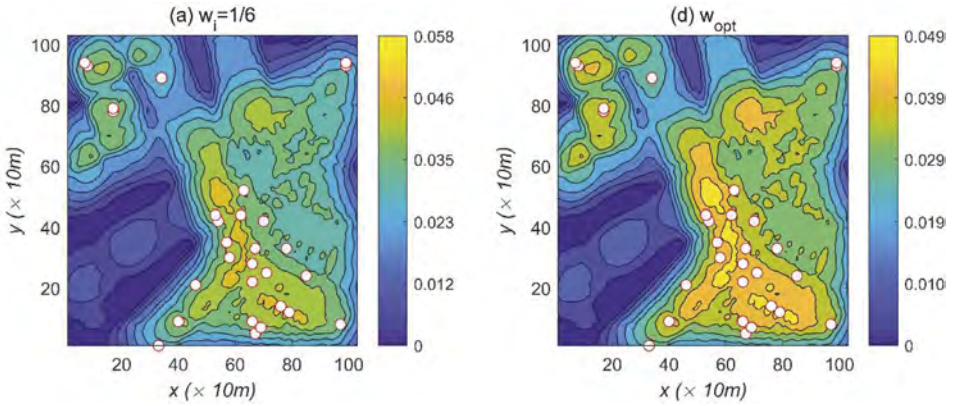

Figure 3. Comparison of ρ_n (normalized line density, m/m^2) analysis results subjected to (a) $\omega_1, \omega_2, \ldots \omega_6 = 1/6$ and (b) ω_{opt} (color bar in right represents 5 degrees of normalized line density).

Figure 4 shows the grades of normalized line density at 29 ground subsidence locations. Figure 4(a) and (b) show the results of $\omega_i = 1/6$ and ω_{opt}, respectively. From the comparison, it can be seen that the grade of normalized line density rises at the location where the ground subsidence occurred when ω_{opt} is applied to the analysis. That is, it means that the relative ground subsidence risk is high at the location where the recorded ground subsidence occurs.

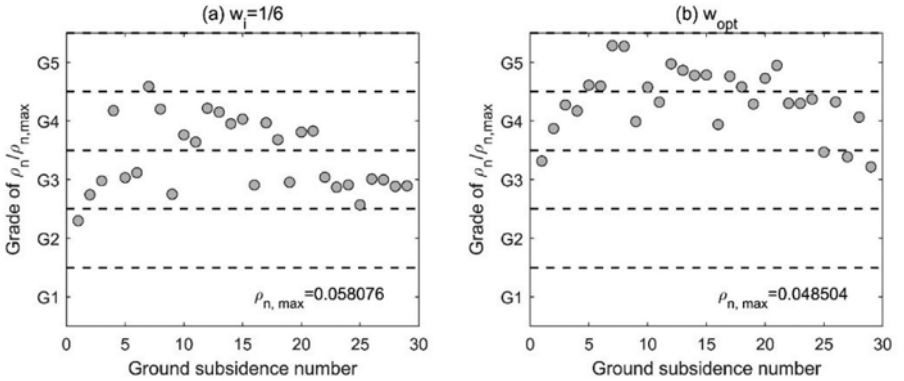

Figure 4. Comparison of 5 grades for $\rho_n/\rho_{n,\,max}$ at 29 sinkhole locations: (a)$\omega_i = 1/6$ and (b)ω_{opt}.

Table 2 summarizes the number of subsidence included in each of the five grades by analyzing the normalized line density at 29 recorded ground subsidence locations. When analyzing

Table 2. Number of ground subsidences corresponding to 5 grades at 29 sinkhole locations with $\omega_i = 1/6$ and ω_{opt}.

Grade	$\omega_i = 1/6$	ω_{opt}
G1	0	0
G2	1	0
G3	15	4
G4	12	12
G5	1	13
% (≥G4)	45	86

the normalized line density by applying ω_{opt}, it was found that 29 ground subsidences occurred at grade 3 (G3) or higher area. In case of applying $\omega_i = 1/6$, the most of ground subsidence occurred even in grade 2 & 3 (G3&G4).

From Table 2, it is denoted that if ω_{opt} obtained by applying the optimization algorithm is applied to the line density analysis of underground utilities in the area of interest, the risk of ground subsidence can be analyzed more accurately.

5 CONCLUSION

In this paper, a method for optimizing the correlation between the line density of underground structures and recorded ground subsidence was presented. A study was conducted to link the density of underground utilities and the risk of ground subsidence. The optimization algorithm was applied to analyze the normalized line density for 1km × 1km area, and the spatial correlation analysis with the 29 recorded ground subsidence data previously occurred in the area (the location data was obtained from the infrastructure management Dept. of Seoul). It was verified that the risk grades of ground subsidence correspond to the normalized line density. The main finding and conclusion for this study are as below.

(1) A study was conducted to maximize the correlation between recorded ground subsidence and the line density of 6 types of underground utilities. When the optimization algorithm using the normalized line density was applied, the case where the normalized line density was grade 4 (G4) or higher at the recorded ground subsidence location was about 80% or more, and the applicability of the algorithm was verified.
(2) If the analysis result is expanded and verified to a wider area, it is thought that the proposed optimization algorithm can be used for basic decision-making analysis tool for facility maintenance and constructing a ground subsidence risk map in urban areas.

Vertical scale of fluctuation for spatially varying soil: A case study in Taiwan Using iPDC Data

Ying Zheng, Yu-Syuan Jhuo & Louis Ge
Department of Civil Engineering, National Taiwan University, Taipei, ROC

ABSTRACT: Data collected from soil investigation techniques, including standard penetration test, cone penetration test, and shear wave velocity measurement, are often used for liquefaction potential assessment. The spatial variation of soil properties is challenging to be quantified through limited data collected from standard penetration test. The data collected from a newly developed in-situ investigation technique, namely intelligent piezo drive cone, was adopted to determine their scale of fluctuation in this study. They were calculated by the method of moments and the Bayesian method with various autocorrelation models. The results show that the Bayesian method with the Whittle-Matérn model can effectively reduce the uncertainty of soil spatial variability. It also improves the accuracy of the scale of fluctuation to reflect the actual state of the data.

1 INTRODUCTION

Soil properties are influenced by the geological formation process, which changes with area and depth, and causes spatial variability. The scale of fluctuation (SOF) is a parameter for describing spatial variability. SOF can be used to illustrate the vertical and horizontal variety of soil layers, presenting by probability. Blow count (N) value is an index reflecting soil strength and an vital parameter for soil liquefaction potential analysis, which usually obtain by standard penetration test (SPT). The SPT-N value is recorded every 1.5 m and soil samples are taken. It is possible to misjudge the actual soil layer distribution and the spatial variability at a site when analyzing the SOF using the SPT-N value. The intelligent Piezo Drive Cone (iPDC) developed by OYO Corporation in Japan provides continuous depth-dependent data for site investigation, which is used for evaluating the soil liquefaction potential without sampling (Yoshizawa et al., 2016; Sawada et al., 2019). IPDC is a device whose concept is similar to SPT (Figure 1). On the tip of the rod, a transducer and load cell are mounted, allowing the excess pore water pressure and the loading to be recorded at every penetration. It is possible to determine the fines content and the transmission loss of energy. IPDC displays the calculated N value that is similar to SPT-N at the same depth. The continuous depth-dependent N value would be obtained by every penetration. This study attempts to utilize iPDC data to analyze the SOF, and figure out a proper method to process the unequal-spacing data.

2 SOF AND ACFM

In the past decades, it is necessary to consider spatial variability into practical engineering design (Ching and Phoon, 2017), which is described by scale of fluctuation (SOF, θ). The analysis of spatial variability can be traced back to the time series method of statistics. Similarly, it can be expressed as the spatial properties of soil particles at a given location under the

DOI: 10.1201/9781003299127-181

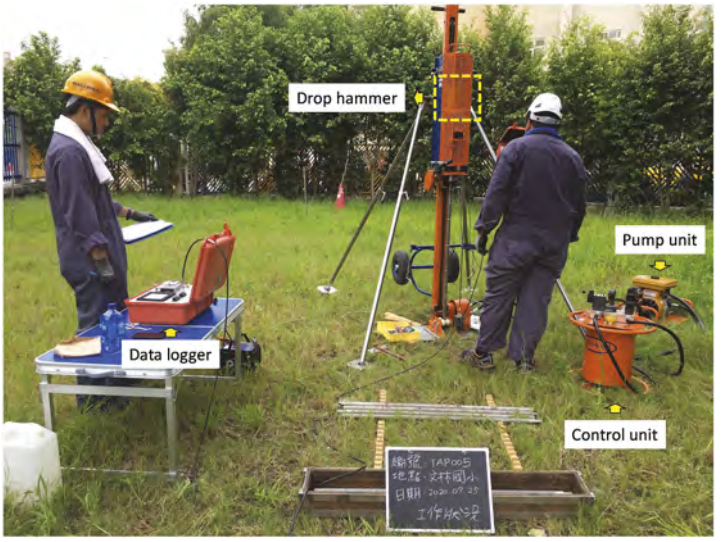

Figure 1. Device set-up of iPDC.

background as the sum of the trend function t(z) and the residual ε(z) in the geotechnical application (Vanmarcke, 1977).

$$X_i = t(z) + \varepsilon(z) \tag{1}$$

where X_i = value of soil property at location i; z = soil vertical depth, unit is meter (m); and i = vertical depth below the ground surface; i.e. takes the total measure data points i =1,2,. . .,k.

It is the SOF that depicts the relationship between a simulated random field and a geotechnical site, which uses the known variety of ACFM as an input. The SOF of soil refers to the continuous relationship or correlation of the parameters within a certain distance (which is lag, τ). In the soil profile, adjacent soil properties usually have the similar SOF, and as the distance between them increases, the correlation decreases. That is, SOF is the integral of the area under the empirical formula of ACFM.

$$\theta = 2\int_0^{\infty} \rho(\tau)d\tau \tag{2}$$

Where ρ = the autocorrelation coefficient of variables.

From the Equation (2), ρ also can be indicated as the formula below:

$$\rho(\Delta z) = \rho[\varepsilon(z), \varepsilon(z+\Delta z)] = \frac{CV[\varepsilon(z), \varepsilon(z+\Delta z)]}{\sqrt{Var[\varepsilon(z)]}\sqrt{Var[\varepsilon(z+\Delta z)]}} \tag{3}$$

Where CV[.] = the covariance, i.e. the covariance between two points; Var[.] = the covariance, i.e. the idle variance between two points; Δz = the soil data interval, i.e. τ.

Recent studies have identified some typical ACFMs frequently used in geotechnical applications. There are two kinds of ACFM. One is the single-parameter model, known as classical ACFMs, and the other is the double-parameter model. Among the single-parameter models, the Markovian (single exponential, M1) model, the second-order Markov (M2) model, the third-order Markov (M3) model, the Gaussian model, and the Cosine exponential model were used in this study. The empirical functions about θ are shown as follows Equations (4)–(8). The Whittle-Matérn model (WM) is selected for the double-parameter model in this study.

Also, Equation (9) shows its empirical function about θ, where the smoothness parameter, the scale parameter, the Gamma function, and the modified Bessel function of the second kind with order v are denoted by v, s, $\Gamma(.)$ and K_v respectively (Cami et al., 2020).

$$\rho(\tau) = \exp\left(\frac{-2|\tau|}{\theta}\right) \tag{4}$$

$$\rho(\tau) = \left(1 + \frac{4|\tau|}{\theta}\right)\exp\left(\frac{-4|\tau|}{\theta}\right) \tag{5}$$

$$\rho(\tau) = \left[1 + \frac{16}{3}\left(\frac{|\tau|}{\theta}\right) + \frac{256}{27}\left(\frac{|\tau|}{\theta}\right)\right]^2 \exp\left[\frac{-16}{3}\left(\frac{|\tau|}{\theta}\right)\right] \tag{6}$$

$$\rho(\tau) = \exp\left(\pi\frac{|\tau|^2}{\theta}\right) \tag{7}$$

$$\rho(\tau) = \exp\left(\frac{-|\tau|}{\theta}\right)\cos\left(\frac{-|\tau|}{\theta}\right) \tag{8}$$

$$\rho(\tau)^* = \frac{2^{1-\nu}}{\Gamma(\nu)}\left(\frac{|\tau|\sqrt{2\nu}}{s}\right)^2 K_\nu\left(\frac{|\tau|\sqrt{2\nu}}{s}\right) \tag{9}$$

3 METHODS OF CASE STUDYAND RESULTS

3.1 *Database*

The iPDC database is from Chen (2021) in Taiwan. The location of the iPDC boreholes was determined by referring to the previous SPT report. They should be within 10 m of the SPT boreholes to reduce spatial variability. Total 25 sites, including 17 in Taipei and 4 each in Changhua and Kaohsiung. The target penetration depth was 20 m on each site. This study illustrated the methodology using the site TAP007 in northern Taiwan as a case study, where the range of vertical depth is 0.901 m - 20.000 m. The SPT report indicates that the technique was applied at TAP031 (depths of 1.05m-37.05m). The soil distribution is as follows: CL from 1.05m-4.29m, SM from 4.3m-25.24m, CL from 25.25m-34.19m, and SM from 34.2m-37.05m. The following SOF analysis will be carried out at a soil depth of 4.3m-20m, considering the depth of application of the iPDC and the fact that it is mostly backfilled before 4.3m. The comparison of the SPT and iPDC reports is shown in Figure 2.

3.2 *Method of moments (MM)*

Statistics use the MM to estimate parameters. By applying the MM, the empirical moments are set equal to the theoretical moments, and the parameters of interest are solved to minimize the error between them. The depth corresponding to each iPDC data is unequally spaced, which is related to the soil strength at the time of penetration, roughly in the range of 0.01 m-0.2 m. Hence, Δz could be set at 0.05 m, 0.1 m, 0.5 m, and 1.0 m before detrending data to determine the appropriate sampling interval required to run a steady random field.

It is noted that the lag term should be considered during MM analysis. The maximum lags were suggested by Box-Jenkins (1970) and adopted as D = n/4 for estimation. The coefficient of determination (R^2) is used to determine the best fitting ACFM with SOF values. With the SOF of the different ACFMs and their R^2 at the interval 0.05 m, the best single parameter ACFM is M3, where the SOF is smallest and R^2 is largest, the values are 0.4497 and 0.8864 respectively. The SOF and R^2 of WM model are 0.4456 and 0.9859.

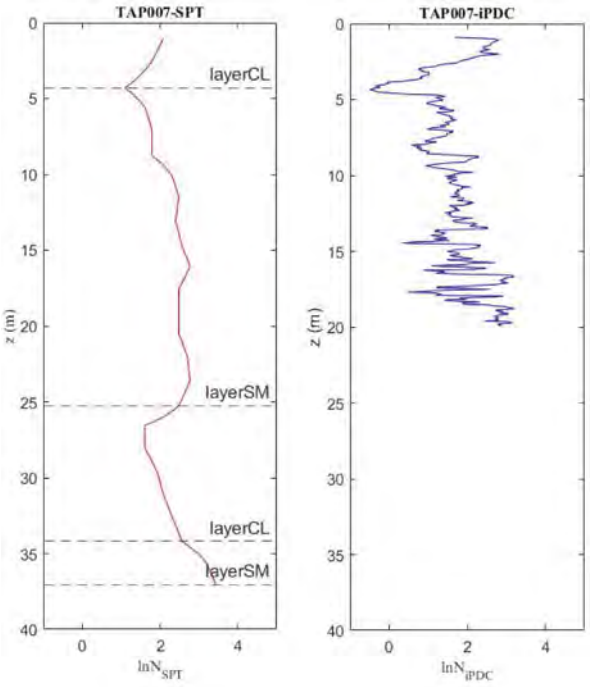

Figure 2. The relationship between N value and depth for SPT data and iPDC data.

When using the method of moment, the reason why the SOFs analyzed by different models are very similar is that the theoretical autocorrelation model is set equal to the sample auto-correlation function. Furthermore, the characteristic of the approach is using a fitting method such as least squares, which reduce the sum of squares of the relevant errors and make the fitting curve close to the sample trace, as Figure 3. It indicates that no matter which ACFMs

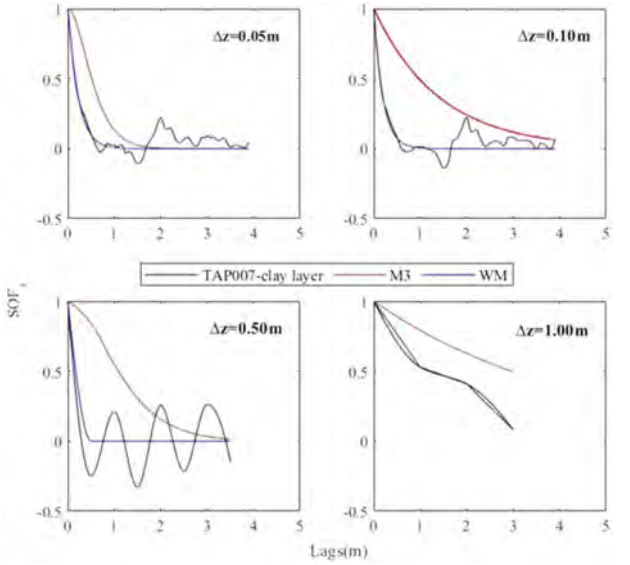

Figure 3. SOF_v of selected ACFMs at different Δz (MM).

is chosen, the SOFs are usually the same. In this study, the large amount of data and the more parameters controlled by the WM model resulted in an increase in the certainty of SOF when using Δz = 0.05 m as the measurement interval.

3.3 *Bayesian method (BM)*

Method of moments follows frequentist analysis methods which means using the known data to calculate the SOF. Bayesian method requires the parameters of probabilistic model for the location (e.g. the mean, the variance, coefficient of variation, and the weights under each parameter). Bayesian method uses these parameters to express the 95% confidence interval of the sample. That is, the defined prior distribution can be defined first then the posterior distribution is determined and updated according to its analytical rules, which benefits geotechnical applications for considering inherent statistical uncertainty.

Using the WM model and sparse Bayesian learning framework (SBL), then sampling randomly under the transitional Markov chain monte Carlo method (TMCMC) around 1000 times can obtain a more accurate value of the SOF (Ching and Phoon, 2017). Take TAP007 as an example. Using the BM to all unknown parameters, such as the trend, the SOF, and standard deviation, gives excellent and reliable results. That is, soil parameters samples are all in their 95 % confidence interval, as shown in Figure 4(a)-(c), respectively: the red line trend sample is in its 95 % confidence interval; the blue fork marker, estimated SOF, with value 0.3727, is also in its 95 % confidence interval; the blue hist, standard deviation of TMCMC sampling, is identical to the above results.

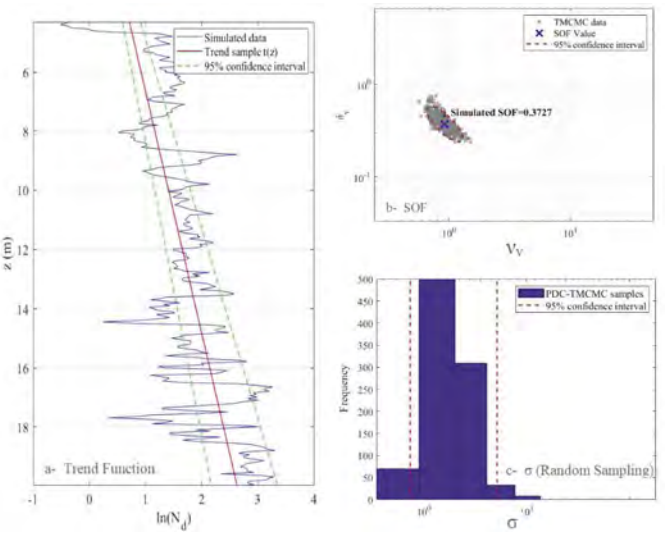

Figure 4. Results of the BM: (a) trend function; (b) SOF; (c) σ (site: TAP007).

4 DISSCATION AND CONCLUSION

This study compares two different approaches to handling in situ borehole data. One is the classical statistical analysis method, the method of moments (MM), and the other is the bayesian method (BM). The result of this study shows that the SOF = 0.3727 for the BM and 0.4456 for the MM. The BM gets a smaller SOF than the MM, which indicates the BM can more fully show the spatial variability of soil properties.

In terms of methodology, the use of MM requires the construction of a smooth random field to comply with the time series analysis method; therefore, the data is interpolated,

diluting the actual soil's spatial variability to some extent. The use of the SBL objectively characterizes the trend function, thus eliminating the need to process the data itself and allowing an objective representation of the spatial variability of the soil (Ching et al., 2017). Consequently, the BM with the WM model is recommended for the analysis of non-equally spaced data such as iPDC to reflect the actual situation of the soil better.

ABSTRACT: The Seismic Safety and Resilience of Schools (SAFER) project aimed to improve seismic hazard assessments in the Kathmandu Valley, Nepal. There remains scarce geotechnical data in this region. Therefore, the SAFER project team collected and sourced new geotechnical and geophysical data to allow for the development of improved maps showing the distribution of shear wave velocity measurements in the study region. This paper summarises geotechnical and geophysical investigations conducted in the valley and outlines the building of SAFER/GEO-591, which contains data from different sources such as previously drilled boreholes in the Kathmandu Valley. A methodology is proposed for geotechnical engineers and engineering geologists wishing to develop geodatabases in data-scarce regions.

1 INTRODUCTION

1.1 *Background*

In 2015, the M_w 7.8 Gorkha earthquake struck the Himalayan region affecting many communities, including the highly populated Kathmandu Valley in Nepal (Goda *et al.* 2015). Significant ground motion and many instances of damage were observed (e.g. Ohsumi *et al.* 2016). There was considerable investment in new seismic engineering research efforts from various agencies and organisations post-earthquake. This paper reports on some key outputs from the Engineering and Physical Sciences Research Council (EPSRC) funded project 'Seismic Safety and Resilience of Schools in Nepal' (EP/P028926/1), hereafter referred to as the 'SAFER project' (https://www.safernepal.net/). This paper primarily focuses on outputs related to geotechnical earthquake engineering from the 'New generation seismic hazard for Nepal' work package, hereafter referred to as 'WP1'.

1.2 *Study aims*

The SAFER project was comprised of five work packages (https://www.safernepal.net/) and ran from 2017 to 2021. A major focus of WP1 was on the compilation and curation of new geo-data sets for use in the development of new tools, such as new and updated maps for seismic hazard assessments in the Kathmandu Valley. This paper has two objectives: (i) it summarises the key deliverables from WP1 elaborating on how the outputs have contributed to improving seismic hazard assessments; and (ii) it offers a general methodology for geodatabase building for geotechnical engineers and engineering geologists working in data-scarce regions.

DOI: 10.1201/9781003299127-182

2 PROJECT OUTPUTS

This section focuses on the first objective of the paper. Sections 2.1 to 2.3 summarise the main deliverables from WP1 across three broad themes: (i) New geotechnical field testing in the Kathmandu Valley; (ii) Development of an open-source geodatabase for Kathmandu Valley soils and (iii) Updated maps for hazard assessments for the Kathmandu Valley.

2.1 *New geotechnical field testing in the Kathmandu Valley*

The field investigation included two new boreholes (progressed with rotary open hole drilling and sample recovery using the Standard Penetration Test (SPT) split spoon sampler), referred to as BH-1 and BH-2 (Gilder *et al.* 2019a). BH-1 was located at Dillibazar on the Padmakanya school premises at a ground elevation of 1309m. BH-2 was located on a site in Bijeshowari at a ground elevation of 1286m (see Gilder *et al.* 2019a for details on the testing). Seismic downhole testing was used to determine shear wave velocities at BH-1 (Gilder *et al.* 2019a), and Horizontal to Vertical Spectral Ratio (HVSR) testing was used for the same purpose at BH-2 (Pokhrel *et al.* 2019).

On a separate trip, Cone Penetration Testing (CPT) (to the authors' knowledge the first undertaken in the area) was carried out on seven sites to obtain measurements of shear wave velocity (*Vs*) using the seismic cone and also acquire continuous ground profile records with depth for the soils in the study region (see Gilder *et al.* 2021a and Gilder 2022 for further details on the CPT work). Figure 1 shows the locations of the new CPT readings (along with the location of the SPT readings from the SAFER/GEO-591 database) in the Kathmandu Valley.

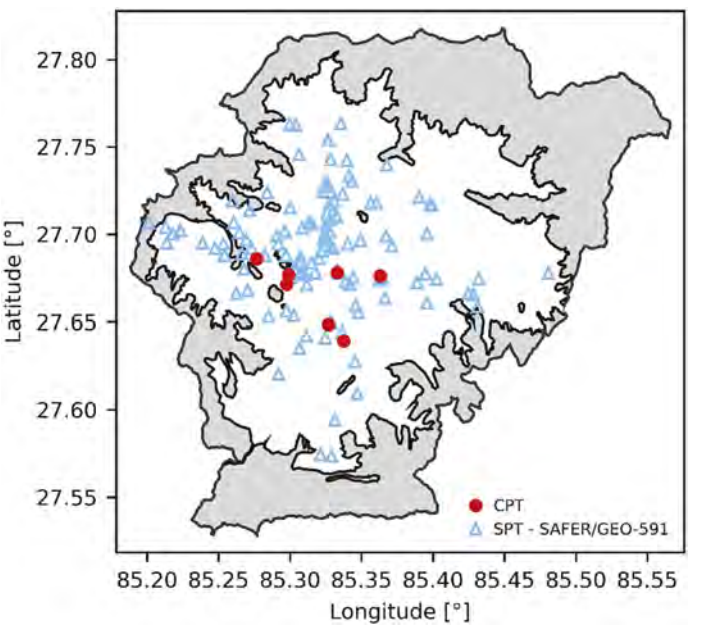

Figure 1. Location of the CPT sites outlined in Gilder *et al.* (2021a) compared with SPT locations from SAFER/GEO-591 (data from Gilder *et al.* 2019b) (figure adapted from Gilder *et al.* 2021a under the terms of the CC BY 4.0 license).

2.2 *Development of an open-source geodatabase for Kathmandu Valley soils*

The construction and data files of the SAFER/GEO-591 database is described in detail in Gilder *et al.* (2020) and the accompanying data record (Gilder *et al.* 2019b). SAFER/GEO-591 is available open-access from the University of Bristol Research Data Repository. While the database

contains almost 600 borehole records collected by the project team from the literature, published reports and industry files, an extensive 'data-cleaning' process was necessary in order for the data to be sensibly put into the database structure (Gilder *et al.* 2021b gives an example of this process). As explained in Section 3, adopting a standard format for a geodatabase is essential for effective data transfer but requires considerable time investment and prior geotechnical knowledge. Figure 2 shows an example borehole log from SAFER/GEO-591 (Gilder *et al.* 2019b, 2020). The log shown in Figure 2 is for a site in the Gokarna formation.

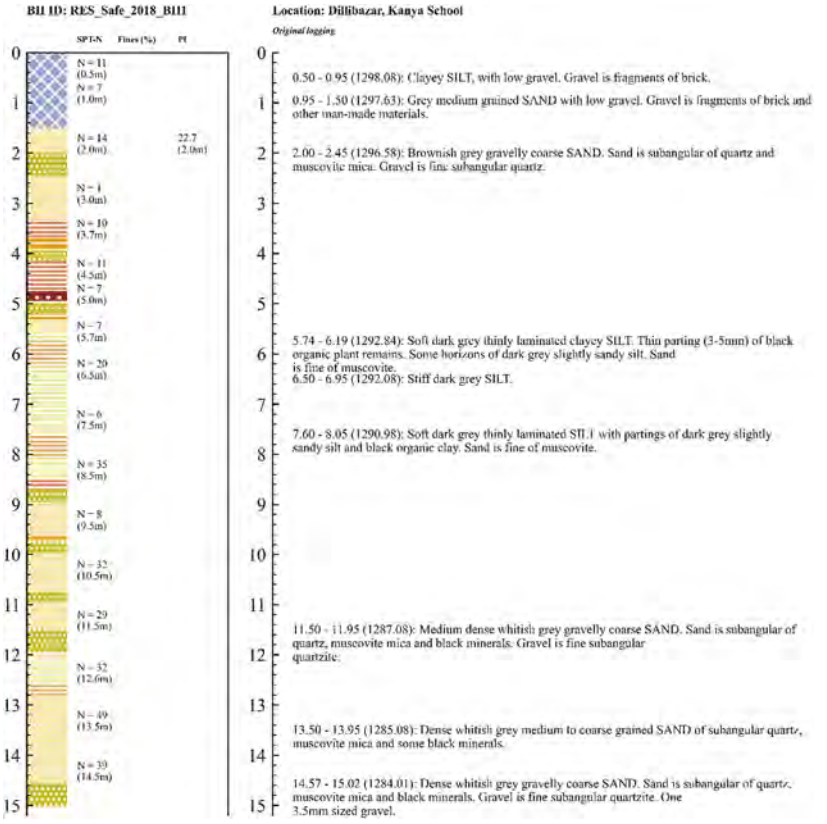

Figure 2. Example SAFER/GEO-591 borehole log from the Gokarna formation: upper 15m of the log shown (data from Gilder *et al.* 2019b).

2.3 *Updated maps for hazard assessments for the Kathmandu Valley*

Shrestha *et al.* (1998) produced a key engineering and environmental geological map for the Kathmandu Valley. During the SAFER project, data digitised from this map was often used as a base for the presentation of new analysis results and as a source of comparison for further findings. An important proxy for site amplification studies is the soil *Vs* averaged across the top 30m depth of ground ($V_{S,30}$), (e.g. Stewart *et al.* 2003). Kriging analysis is often used to estimate $V_{S,30}$ across geographical regions. De Risi *et al.* (2021) presented the results of a newly developed Bayesian-Kriging study making use of the V_{s30} measurements available (not including the new CPT data from Gilder *et al.* 2021a). Then the new V_{s30} measurements from the CPT work as well as those from the original database, were combined and analysed using the further enhanced multi-Gaussian Bayesian updating framework, showing how different kinds of V_{s30} proxies can be used to supplement local data and capture key geological features of the basin (see Gilder 2022 and Gilder *et al.* 2022).

3 DATA COLLECTION & CURATION IN DATA-SCARCE REGIONS

Geodatabases are vital for geotechnical engineers to benchmark results and make a-priori predictions of key design parameters. Thompson (2016) presented a case for public databases and described examples of such databases from various jurisdictions around the world. Open geodatabases allow the technical community to add new data to existing datasets and avoid duplicating digitisation and curation work. Phoon (2019, p.187) explained the 'MUSIC' concept i.e. that geotechnical data is often 'Multivariate, Uncertain and Unique, Sparse, Incomplete, and potentially Corrupted (MUSIC)'.

While the case for open geodatabases can be easily made in the authors' view, there are barriers to their creation and curation. Gilder *et al.* (2021c) presented a detailed review of the current barriers to geotechnical and geological data-sharing, with time and resources often cited as key constraints (as well as incentive) (see also the discussion in Thompson 2016). Based on the learnings from the SAFER project, a general methodology is proposed for those professionals starting work in data-scarce regions (see also Shepheard *et al.* (2019), where similar efforts have been made to develop new databases using a similar methodology, as well as efforts to build a pile load test database for the UK (Vardanega *et al.* 2021) and Thompson (2016) who also articulated many pertinent issues with developing public geodatabases). Phoon (2018) outlines some key challenges and important aspects of 'probablisitic site characterization' an activity for which geodatabases are useful (cf. Phoon 2018).

3.1 *Assess the geo-data landscape*

As with desk studies during site investigation projects, historical soil maps, hazard maps, and other geo-resources should be sourced by the project team. These resources (if available) can serve as useful benchmarks against future analyses (see Section 3.5). During this phase, the literature should be consulted to see if other databases have been compiled for the region of study.

3.2 *Local knowledge*

Liaise with local practitioners to determine who the main 'data owners' are. If they easily identifiable, approach these individuals/entities to determine if contributions to the new database are possible. Discuss at the outset how data records may need to be anonymised, e.g. exact locations removed, project names redacted etc. During this phase, agree the license and terms of use for the compiled database and ensure that those donating data aware of these conditions related to future data release.

3.3 *Local practice*

Unless the project team is familiar with site investigation practices in the area and, if budget permits, arrange to visit local projects or laboratories to determine which testing standards are used and which testing equipment is commonly utilised for laboratory and field studies conducted in the study region.

3.4 *Data harmonization and cleaning*

If data from multiple laboratories or site investigation companies will comprise the database, ensure that a 'data harmonisation' and 'cleaning' process is carried out by an experienced project team member. During this time, determine the data format to be used (see the discussions in Thompson (2016) and Gilder *et al.* (2021c) regarding file formats and workflow) and prepare a database manual with the data sources and notes from the cleaning and harmonisation process.

3.5 *Benchmarking analysis*

The new database should be checked against existing resources (if available), e.g. soil maps, local 'transformation models' (cf. Phoon & Kulhawy 1999a, b) or previously published parameter distributions, to determine if the new database is sufficiently representative of the study area. Also ascertain if the database contains sufficient data for meaningful statistical analyses. Some engineering judgement will be needed to determine if this is the case and during this step, potential outliers may be identified and noted in the database manual. It may be that the database will need further expansion as new data becomes available after the initial data release. This stage is also where major gaps in the database can be identified (cf. Phoon 2019: MUSIC) and these should be noted in the database manual.

3.6 *Data release*

While there are barriers to this stage (e.g. commercial interests), if possible, the database should be released open-access with appropriate disclaimers. Later corrections and clarifications may be needed as practitioners and researchers start using the database, which can be incorporated in future versions. 'Living databases' may, become a useful technical resource for the local and international geotechnical communities, allowing for improved design and model calibration efforts.

4 SUMMARY AND CONCLUSIONS

This paper has presented some of the key outputs from WP1 from the SAFER project. The outputs discussed covered three broad themes: (i) New geotechnical field testing in the Kathmandu Valley; (ii) Development of an open-source geodatabase for Kathmandu Valley soils and (iii) Updated maps for hazard assessments for the Kathmandu Valley. The focus of the SAFER project was on improving the safety and resilience of school buildings in Nepal; however, many of the project findings should be useful for other infrastructure classes. The paper proposed a 'step-by-step' methodology for those developing open-access databases in data-scarce regions.

In conclusion, the lessons from WP1 of the SAFER project have revealed many challenges in building and releasing open-access geodatabases, however such resources are essential for regional statistical analyses (e.g. using Kriging-based methodologies), to produce new maps and information for improved hazard assessments.

ABSTRACT: The 'hybrid method', a simplified prediction technique for foundation settlement in which piles are modeled using finite elements, springs representing the non-linear properties of the soil around the piles are attached to the nodes, and elastic interactions through the soil between each element are considered, has been used to predict the settlement of several large-scale buildings with bell piles or diaphragm walls. However, the accuracy of settlement behavior predictions for multi-belled cast-in-place piles has not been sufficiently clarified. In this paper, a soil spring is proposed for an intermediate bell as a modification of the spring recommended for a pile tip. The results of simulating three full-scale load tests using the modified spring, which closely match the actual measurements, demonstrate the validity of the proposed spring.

1 INTRODUCTION

The multi-belled cast-in-place piling method has been developed to meet the high demand for supporting a large load of high-rise or long-span structures in Japan. These are piles that have enlargements (called 'bells') at some intermediate point as well as at the pile tip (Hama et al. 2019; see Figure 1). It is significant for the construction plan and structural design of such piles to understand settlement behavior under vertical loading, but this has not been sufficiently clarified for multi-belled piles. The finite element method (FEM) with solid elements is useful for analyzing behavior, including settlement behavior, in detail, but modeling and calculation are time-consuming. On the other hand, the 'hybrid method' (Clancy & Randolph 1993 and Nagao et al. 1998) is often used in practical design, offering the advantage of flexibility in modeling as design requirements change. There are several examples of this method being used for large-scale buildings with bell piles or diaphragm walls (Sugimura et al. 2017). In this paper, as a basic study on evaluating the settlement behavior of multi-belled piles by the hybrid method, a modified spring is assumed for the intermediate bell, obtained by correcting the equation recommended by the Architectural Institute of Japan (AIJ 2019) for a pile tip according to logical consideration related to the shape of the bell. The validity of the new spring is discussed by simulating full-scale load tests reported in the published literature (Muramatsu et al. 2020, Watanabe et al. 2012 and Sano et al. 2013).

2 SETTLEMENT PREDICTION METHOD

2.1 *Analysis method*

The hybrid method is a means for predicting the settlement of building foundations in which elastic theories and FEM are combined and integrated with non-linear springs for the soil

DOI: 10.1201/9781003299127-183

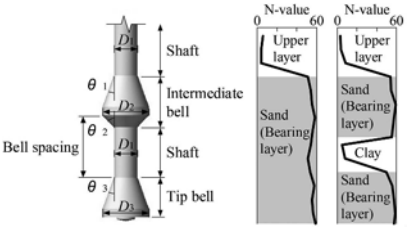

Figure 1. Multi-belled pile and applicable ground conditions.

around the piles (see Figure 2a). It is capable of evaluating complex settlement behavior of piles in a group by modeling interactions between different piles and with the soil. The outline of the hybrid method is summarized as follows. a) Piles and foundation structures are modeled with three-dimensional (3-D) finite beam elements. b) Soil stratums are assumed to be horizontally separated semi-infinite elastic bodies and modeled by equivalent linear springs, of which the deformation moduli are determined in consideration of the non-linear properties of soils. c) Elastic interactions through the soil between each element are computed using Steinbrenner's solution and from the integral of the first Mindlin's solution. d) Springs representing the non-linear properties of the soil around the piles are connected at the piles' nodes. A 3-D hybrid model based on the method outlined in a) – d) is integrally analyzed with building loads. In this paper, since the targets of analysis are single piles, the analysis method is almost equivalent to load transfer analysis (Coyle & Reese 1966).

2.2 *Non-linear spring of intermediate bell*

In this study, non-linear springs for the soil around a pile were defined as the following functions: a hyperbolic function for shaft friction and an exponential function for pile base stress (AIJ 2019; see Figure 2a). The initial stiffnesses K_0 of the hyperbolic springs were set according to Mindlin's solution using the soil deformation moduli, while the ultimate values were defined as ultimate shaft frictional unit stress τ_{max}. The exponential springs were evaluated using Equation 1 (AIJ 2019), in which the coefficients, α and n, were set according to soil type:

$$\frac{S_p/d_p}{0.1} = \alpha \frac{R_p/A_p}{(R_p/A_p)_u} + (1-\alpha)\left\{\frac{R_p/A_p}{(R_p/A_p)_u}\right\}^n \tag{1}$$

where S_p = settlement of pile tip; d_p = diameter of pile tip; R_p/A_p = base unit stress; $(R_p/A_p)_u$ = ultimate base unit stress; α = initial tangential gradient of curve; and n = degree on curve shape.

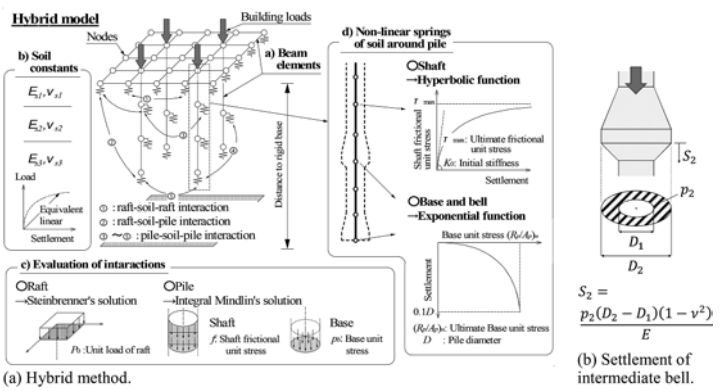

Figure 2. Overview of hybrid method and assumption of intermediate bell settlement.

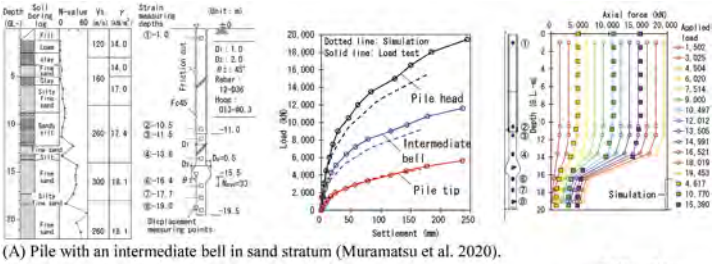
For an intermediate bell, the non-linear spring was modified as follows (and see Figure 2b). First, the settlement of an intermediate bell was assumed as the settlement of a semi-infinite elastic body with the shape of a projected area of the bell under uniform loading (p_2). This projected shape should be a ring due to the presence of the shaft below the bell. Thus, the bell's settlement S_2 can be calculated using the equation in Figure 2b (AIJ 2019), while settlement stiffness should be $D_2/(D_2 - D_1)$ times as much as the case without a shaft under the bell. Based on this consideration, a modification of Equation 1 was defined as the evaluation equation for the spring of an intermediate bell, in which α is multiplied by the ratio $(D_2 - D_1)/D_2$. It was confirmed that the shape of the curve of this modified spring corresponded to the load versus settlement relation of the intermediate bell in full-scale load test A (described in the next section).

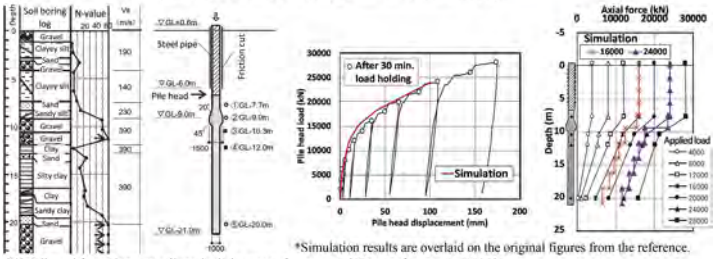
3 SIMULATION OF FULL-SCALE LOAD TESTS

Here, simulation analyses of three full-scale load tests are conducted using the hybrid method and the validity of the modified springs is discussed. In preparation for the analyses, the piles were modeled by the plurality of beam elements and then non-linear springs including the modified springs for intermediate bells were connected at their nodes. The other requirements were set as described below. Figure 3 and 4 outlines the configuration and the results for each test pile, allowing the results of the simulation to be compared. The simulation of each pile is outlined below.

(A) Pile with an intermediate bell in sand stratum and without tip bell (Muramatsu et al. 2020). For the spring of the bell, coefficients α and n in the modified Equation 1 were set to 0.23 and 2.7, respectively (further multiplying α by the ratio $(D_2 - D_1)/D_2 = 0.5$); these are values proposed as the properties of sandy soil (AIJ 2019). The value of $(R_p/A_p)_u$ was calculated as $120*\bar{N}$ (AIJ 2019), where $\bar{N}$ denotes the average N-value near the pile tip as obtained by the standard penetration test (SPT). Soil constants were determined from the results of PS logging. Although load levels in the simulated load–settlement relation of the bell are slightly lower than those in the actual load test, the shape of the curve matches that of the test quite well. The analysis could simulate well the test results in the depth distributions of axial force as the bearing forces at the bell were larger than elsewhere on the pile.



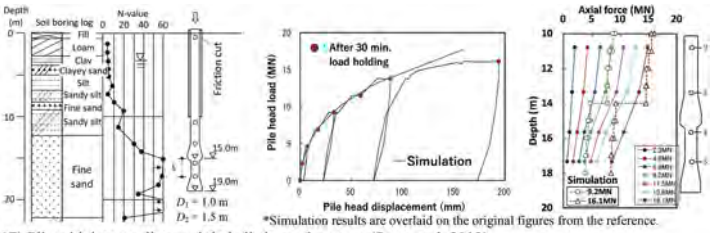
(A) Pile with an intermediate bell in sand stratum (Muramatsu et al. 2020).



*Simulation results are overlaid on the original figures from the reference.

(B) Pile with an intermediate bell in gravel stratum (Watanabe et al. 2012).

Figure 3. Results of simulations of full-scale load tests (part 1).



*Simulation results are overlaid on the original figures from the reference.

(C) Pile with intermediate and tip bells in sand stratum (Sano et al. 2013).

Figure 4. Results of simulations of full-scale load tests (part 2).

(B) Pile with an intermediate bell in gravel stratum and without tip bell (Watanabe et al. 2012). Coefficients α and n were set to 0.12 and 3.3, respectively (applied the ratio $(D_2 - D_1)/D_2$ = 0.33 as above), to simulate the properties of gravel (AIJ 2019). The values of $(R_p/A_p)_u$ and the soil constants were set as described above. The simulated load–settlement relation at the pile head and the depth distributions of axial force correspond well to the results of the actual test.

(C) Pile with intermediate and pile-tip bells in sand stratum (Sano et al. 2013). Coefficients α and n were set to 0.23 and 2.7 as above, and $(R_p/A_p)_u$ was calculated as $120^*\bar{N}$. Soil constants were determined from the results of SPT. The simulated load–settlement relation at the pile head corresponds well to the results of the actual test.

Considering that the simulated values approximately corresponded to the test results, the assumption of the modified spring for intermediate bells was regarded as valid.

4 CONCLUSIONS

The following conclusions were obtained from evaluating settlement of multi-belled piles by the hybrid method.

- A suitable non-linear spring for the settlement behavior of an intermediate bell can be defined by modifying the initial stiffness of the non-linear spring proposed to model the behavior of the pile tip while taking into consideration of the bell's shape.
- The results of simulating actual full-scale load tests indicate that the application of the modified spring to intermediate bells is valid.

ABSTRACT: Static centrifuge tests of piled rafts subjected to vertical load were performed in order to examine the interaction of piles-ground-raft. Piles were instrumented with continuous Rayleigh-based optical fiber sensors to measure deformation occurring in the piles. Optical fiber was also set up in the soil to measure deformation of the ground around the foundation. Two types of piled rafts foundation were tested: a rigid raft (1.5cm thick) and a flexible raft (0.2cm thick). A pile group (without raft touching the ground) was also tested in centrifuge to compare the performance. The optical fiber in the soil showed the extent of the deformation resulting from the loading in the container.

1 INTRODUCTION

As high-rise buildings are becoming more common and the concept of environmental cost is now central to the construction sector, piled raft foundations combining deep and shallow foundations will be used more and more frequently. Piled raft foundations consist of a surface foundation that is in contact with the ground and a group of piles connected to the shallow foundation. There are two possible design strategies for mixed foundations:

- reducing settlements by adding piles when the bearing capacity is provided by the shallow foundation but settlements are excessive for the proposed structure (Burland et al. 1977),
- increasing the bearing capacity of the deep foundations by taking into account the additional bearing capacity provided by the surface foundation, with a view to limiting costs and the use of raw materials. Up to now, various studies have been reported on the application of settlement-reducer piles (Hansbo, 1984, Hirokoshi and Randolph, 1998, Viggiani, 2001, Poulos, 2001, Mandolini 2003). In both cases, the combination of these two types of foundations implies that the behavior of the piled raft foundation is different from the foundations taken separately. Indeed, the addition of a footing in contact with the ground on a pile group implies additional interactions.

Experimentation on this type of foundation at real scale is not very common due to their size and cost. 1g models in the laboratory can provide qualitative results whereas centrifuge models can represent the reality with a small scale model. In this study, a series of vertical loading tests was conducted for three type of foundation model. These three types of foundations have 9 piles respectively embedded in rigid raft, flexible raft and free headed.

Many researchers have reported the results of piled raft loading using centrifuge modeling. Among them, Fioravante and Giretti (2010), studied the load transition mechanism in piled raft systems. They studied the effect on the stiffness of the foundation in dense dry sand. The

DOI: 10.1201/9781003299127-184

results showed that the load distribution mechanism in the piled raft foundation depend on the relative stiffness of the pile and soil.

Nguyen et al. (2013), studied the settlement controlling of piled raft foundation in high-rise building by using a centrifuge model. They made two types of foundation with concentrated piles and uniformly distributed piles. The results showed that a foundation with concentrated pile can effectively decrease the total and differential settlements in comparison with a foundation having uniform pile arrangement.

The following study enables us to understand the effect on total load of different rafts.

2 MODEL FOUNDATION AND TEST PROCEDURES

2.1 *Loading devices and instrumentation*

The centrifugal acceleration chosen in the present study was 50g. Figure 1 shows a schematic illustration of the model setup for this study. The model container used for the test is a rigid box with inner dimensions of 120cm in length, 80cm in width and 72cm in depth. Vertical loading test is carried out by displacement control with constant loading rates of 0.01mm/s. The hydraulic jack is used to apply the vertical load respectively for the installation and loading phases. A force sensor with a range of 2200daN (550MN at 50g) was used and four displacement potentiometers were placed at the four corners of the raft. All foundations models were placed as shown in Figure 2 in the same container.

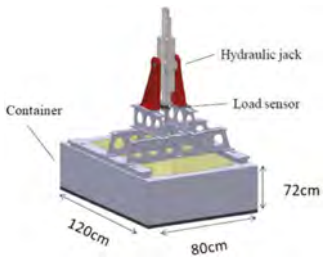

Figure 1. Model setup.

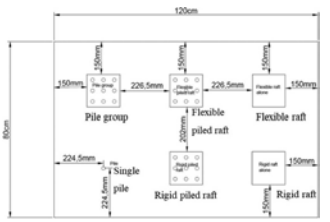

Figure 2. Model foundation position in container.

2.2 *Model foundations*

In the present study static vertical loading tests were conducted on the pile group and two piled rafts. Figure 3 shows the raft and the pile models used in the centrifuge tests.

The model pile was a treaded rod made from brass with an 17mm outer diameter and a 0.72mm thickness. A plastic cap was inserted at the pile base to close the pile. An optical fiber was glued on both sides of the pile to measure the strain. The optical fiber forms a loop at the base of the pile to measure the pile base resistance. To attach the optical fiber to the side of the pile, a very narrow and shallow groove was machine in the pile. After this, a two-component adhesive was used to implement the fiber inside the groove. The glue creates a relatively smooth and uniform pile surface. In the present paper, the results of the optical fiber located in pile will not be shown because of lack of place in this paper.

The piles were rigidly fixed to a steel raft with 150 x 150mm. There is two types of raft model. A flexible raft model with a thickness of 2mm and a rigid raft model with a 15mm thickness. The raft was composed of 9 holes allow the 9 piles heads to fit through, with pile spacing of 3 diameters as shown in Figure 3.

The raft model and the piles were used for the test of piled raft, pile group, raft alone and single pile. For the pile group, the rigid raft was used and a gap between the ground surface and the raft base was maintained. The piles in the pile group were embedded into the ground at 24cm and

were the same in every tests. Table 1 summarize the specifications of the pile and raft both in model scales.

The soil was instrumented with an optical fiber to measure the strain of the ground under the raft base and between the piles. The optical fiber was set up just before the end of the sand pouring with different spaces between each line of the fiber. It was placed taken into account the position of each foundationso as not to damage the optical fiber during the installation of the foundations as shown in Figure 4.

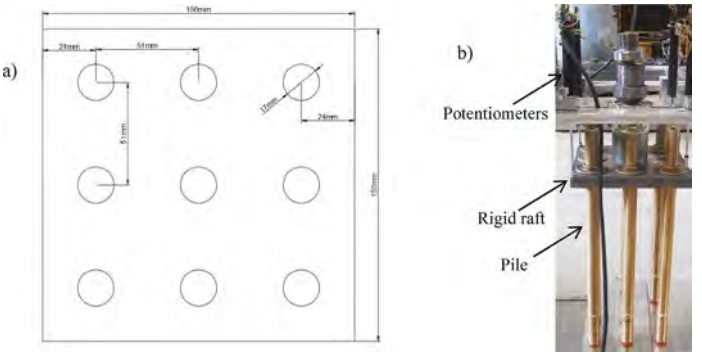

Figure 3. a) Raft model; b) Piled raft model.

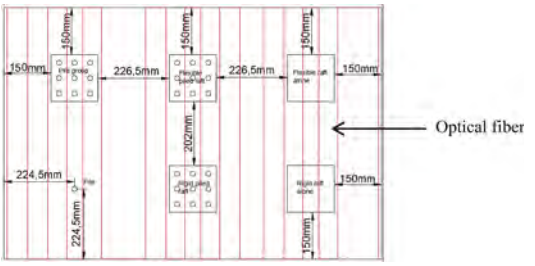

Figure 4. Optical fiber implementation plan.

Table 1. Specification of models foundations.

Properties	Flexible raft	Rigid raft	Pile
Thickness (cm)	0.2	1.5	
Length (cm)	15	15	
Width (cm)	15	15	
Diameter (cm)			0.17
Embedment depth (cm)			24
Materials	steel	steel	brass
Young modulus (GPa)	210	210	105

2.3 *Soil and model preparation*

The reference sand Hostun (HN31) was used during these experiments. The characteristics of the sand and the grain size are presented in Table 2. The sand mass was reconstituted at the required density using dry pluviation. This method produces homogeneous samples and reproduces the natural deposition process of sands (Le Kouby, 2003).

Table 2. Physical properties of Hostun (HN31) sand.

Properties	
Mean particle diameter, D_{50} (μm)	341
Maximum void ratio, e_{max}	0.961
Minimum void ratio, e_{min}	0.624
Solid particle density, ρ_s (g/cm^3)	2.65
Maximum particle density, ρ_{min} (g/cm^3)	1.59
Minimum particle density, ρ_{max} (g/cm^3)	1.32

Densification by sand pouring is effective for drop heights between 0 and 50cm (Vaid and Negussey (1984), Levacher et al. (1994)). For the sand used during these tests, a logbook of the different heights and rates allowed the determination of the parameters required to obtain a relative density of 80%. After the sand pouring of the model ground, the piled raft foundation was jacked in the soil at 1g with a rate of 0.1mm/s. The piles attached to the raft were penetrating into the ground vertically. During the process of jacking, the force and the displacement were monitored to determine the contact of the raft base with the ground surface for each piled raft model. After the installation phase of the foundation, potentiometers were set up to measure the settlements and then the centrifuge acceleration was increased up to 50g.

3 RESULTS AND DISCUSSIONS

3.1 *Load-displacement*

The foundations were jacked in the soil at 1g as explained in section 2.3. Figure 5 shows the load-displacement curve of different foundations during the installation. The load-displacement curve of the pile group is continuous and stopped when the embedded depth of the pile reach 24cm. The load-displacement curve show a displacement of 21cm because of the pile group weight when it was placed on the ground and the piles settle a few centimeters. The rigid piled raft and the flexible piled raft present a slope discontinuity at the end of the loading. As the base of the raft reaches the surface of the ground, the load increases substantially, but the displacement increases slightly. This variation of the load is caused by the raft base pressure. When the contact between the raft and the soil is made, the rotation of the centrifuge starts to reach 50g.

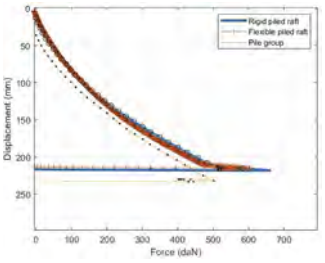

Figure 5. Load displacement curve of a jacked piles group, rigid piled raft and flexible piled raft.

The test experiment could only reach small displacement because of the force sensor capacity (2200daN). The load of the pile group, rigid piled raft and flexible piled raft is shown in the same figure. Figure 6 shows that the total load taken by the flexible piled raft is higher than rigid piled raft. The pile group is less resistant than the others. The flexible piled raft had settled by 1mm for 2200daN, 1.5mm for rigid piled raft and 1.95mm for pile group. However, the Figure 7 shows the displacement of the piled raft and group with the displacement sensor of the hydraulic jack. The flexible piled raft had settled more than the other foundation, with

a settlement of 9mm. The difference between the Figures 6 and 7 is that the rafts are loaded at the center of the raft. This creates a stress concentration on the flexible raft resulting in a bending of the foundation. The potentiometers placed at the corner of the raft are therefore not moving during the test. The piles have undergone a bending moment and were no longer taking the vertical load. The entire load was concentrated on the center of the raft.

The Figure 8 shows the load-displacement between the rigid piled raft and the pile group. The variation of the resistance is due to the contact of the raft on the ground. The higher the load, the bigger the gap between pile group and piled raft. The raft is an immediate asset and transfers a small part of the load to the ground. This variation is linear for the most part of the reloading until 1500daN and reached a level of 2.25mm for the rest of the loading process. This level of settlement means that the raft is providing the same resistance between 1500 and 2200daN. To better understand the behavior of the raft, further tests are required. The tests carried out did not reach a high load value. The tests carried out by Nguyen et al. (2013), showed that if higher loading values are reached, the loading gradient of the load curve is higher. The Figure 7 shows that the piled raft and the pile group curves are very close. This indicates that the piled raft works as a pile group. It may be assumed that 50g creates a loose of contact of the raft by a compaction of the soil. This piled raft model act like a group of piles.

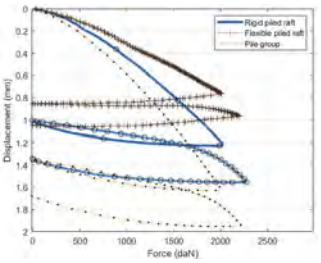

Figure 6. Load displacement curve at 50G (average of four displacement sensor).

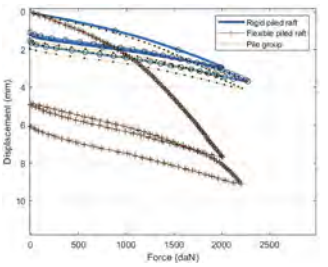

Figure 7. Load displacement curve at 50G (hydraulic jack displacement sensor).

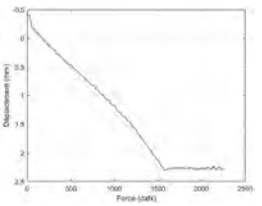

Figure 8. Difference of settlement between pile group and rigid piled raft.

3.2 *Strain in ground*

In this section, the results of the strain measured in the ground with the optical fiber will be discussed for the rigid piled raft at 2200daN. The variation of the strain in the ground between the piles for a load at 2200daN is shown in Figure 9. The strain is increasing at the center of the raft and decreases as you get closer to the ends of the raft. For the optical fiber, positive strain means an extension deformation. Figure 10 shows the extent of the deformation in the container at 2200daN. The deformation decreases with a nonlinear curve and tends toward zero closer to the edge of the container. It means that settlement of sand mass at 50g is observed by optical fiber on all container surfaces. The strain stabilizes from 2B, that means, there is no border effect.

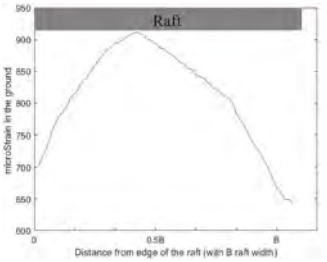

Figure 9. Deformation measured under the raft base.

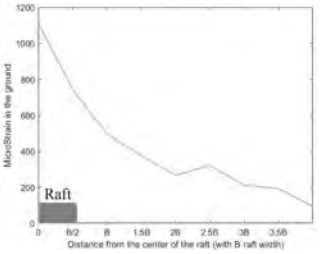

Figure 10. Development of the deformation between the center raft and the wall of container.

4 CONCLUSION AND PERSPECTIVES

To conclude, models of three type of foundation were tested in centrifuge at 50g. Rigid piled raft foundation, flexible piled raft foundation and pile group were loaded vertically. The results shows that the flexible piled raft has a very low stiffness and bended in the center of the raft. The rigid piled raft shows higher stiffness and resistance than the pile group. The results validate our testing procedure as a difference was shown between the pile group and the rigid piled raft foundation. The system will be adapted to allow either higher maximum load or smaller centrifuge acceleration g values or reducing the number of piles. Furthermore increasing the g value creates a compaction of the soil that can provoke a settlement of the soil higher than the rigid piled raft therefore a loose of the contact of the raft from the soil. The results of the optical fiber in the ground has made possible to observe the development of the strain in the soil mass. Using optical fiber made possible to evaluate the effect of loading a foundation on the soil mass.

Challenges executing deep foundations in metros and hydro power projects

B. Vidyaranya & A.K. Mishra
Bauer Engineering India Pvt. Ltd., India

O. Eswar Reddy
Sree Vidyanikethan Engineering College, India

ABSTRACT: The construction requirements of the deep foundations for the Urban Infrastructure and Hydro power projects in terms of the equipment, manpower and other resources planning are similar in nature. However, the construction and sequencing are the challenging issues for each activity. The paper tries to bring all the construction challenges in executing the deep foundations starting from the equipment planning, logistics, execution, geographical constrains, work front availability and uncertainties in the geological conditions. Maneuvering of the key construction equipment's like the trench cutters, hydraulic piling rigs and cranes movement in the metros is limited by the working space while on the contrary its limited spaces within the mountains. In terms of the geological constrains metros have the utility diversions and underground debris to be cleared before start of the works, while the fresh and completely weathered rock with shear zones and cavities pose challenges during the construction. In this paper, authors tries to bring in case studies of the projects executed in metros and hydro power project with the same equipment highlighting the insights for better planning and scheduling of the activities.

1 INTRODUCTION

This paper discusses deep foundation works of wtypical projects executed in the urban and hilly terrain for the construction of Metro and Hydro power projects. The challenges encountered during the execution of foundation works for Cairo Metro, Mangdechhu Hydroelectric Project and Jannah Dam projects are described in detail in this paper. This paper makes an effort to detail the equipment's used for construction and other challenges encountered during the execution. The equipment used for the both the projects are the same whose details are shared in below section.

2 MAIN EQUIPMENT FOR DIAPHRAGM WALL (D-WALL) OR CUT-OFF WALL (COW)

For the execution of the Diaphragm Wall or Cut-Off Wall trench cutter systems are used. The trench cutters have cross-sectional area of 2.80 m x 1.20 m. These trench cutters are mounted on base carriers equipped with Hose Drum System (HDS) or Hose Tension System (HTS). To ensure the high-quality standards. During cutting operation bentonite slurry circulation ensures the continuous working process of the D-wall construction by stabilizing the trench and removal of the excavated spoil. The polluted slurry from the trench are sent to the centralized desanding units/ slurry treatment plant to separating the excavated material from the slurry fluid. After the

DOI: 10.1201/9781003299127-185

separation the slurry is available for reuse within the system. Up to 1000 m3 of working slurry is processed every hour by the installed Bauer BE500 and BE550 desanding plants.

3 MANGDECHHU HYDROELECTRIC PROJECT, BHUTAN

Concrete Cut-off Wall in place of permeation grouting was executed in the upstream coffer Dam of Mangdechhu Project (Mishra et al. 2019). The work was carried out by the Bauer, Germany. The induction of Concrete Cut-off Wall was done primarily because the River Borne Material (RBM) had the silt content more than 18%. As per the research carried out worldwide, it is established that the permeation grouting is effective only when the silt content in the RBM is less than 18%. Henceforth, profession Engineers on ground shall appreciate that Concrete Cut-off Wall is the best solution for controlling the river side seepage in the RBM as the same has been seen on ground in Mangdechhu Project, Bhutan. As far as the cost per sq meter of the cross-sectional area of the river is concerned, the Concrete Cut-off Wall is slightly costlier than permeation grouting but 100% effective in controlling the seepage.

Underground Powerhouse (UGPH) of Mangdechhu HE Project had the low dipping shear zones on both the long walls of the UGPH and the consultant advised for shifting the Underground Powerhouse as above along the longitudinal axis by 40m. However, the UGPH as above was not shifted by the MHPA and the 3 DEC software was used for Numerical Modelling by the NIRM to find out the deformations in the Crown and the Sides of the UGPH. Based on the results of the analysis as above, the rock supports were modified, and intensive grouting was carried out by deploying Mahi Pumps. With the above, MHPA saved one year construction time for the Project.

4 CAIRO METRO

Cairo, the capital of Egypt, is the biggest city of the Islamic hemisphere, with approximately 21 million inhabitants in Greater Cairo. The first tram opened in 1896 and this tram system formed an important part of public transportation. But sharing the streets, additionally with busses transporting approximately two billion passengers per year, called for the establishment of an underground infrastructure as being the efficient solution. Consequently, the Cairo Metro has become the most important public transport system. Two lines with a total length of 61.5 km are in operation and transporting approximately 950 million passengers a year by 2004. The National Authority for Tunnels (NAT), a department of the Ministry of Transport, Arab Republic of Egypt, is the owner and in charge of all constructions. When Metro Line 1 was opened in 1987, it consisted of 4.7km long tunnel section. In 1990's, the first tunnel under the river Nile was constructed for Metro Line 2. The works for Line 3 started in 2008. The total lengths are divided into four phases of which phases 2 & 3 with a length of 12 km are already in operation. The works executed by Bauer shown in Figure 1.

4.1 *Geotechnical works for metro line 3*

Bauer commissioned the specialist civil engineering works i.e. 18 of the 22 underground stations on Line 3 and constructed approximately 600,000m² of diaphragm walls and 58,000m² of silicate gel grout plugs (Mostafa et al. 2022) . BAUER executed open excavation pits, for the start shaft of TBM, several Metro stations and ventilation shafts. Excavation and foundation levels for stations planned up to 32m below ground water level requiring retaining walls (Diaphragm walls) with connection to deep-lying silicate gel grout plugs down to a maximum depth of 86m, allowing for the excavation of the construction pit in dry conditions controlled by dewatering of limited seepage. Mostly, the stations are located under existing roads. Depending on traffic, the concerning road was closed partly or completely by temporary traffic diversions. After the completion of D-Walls and silicate gel grout plug, the main contractor shall start excavation and construction using the top-down method with temporary struts.

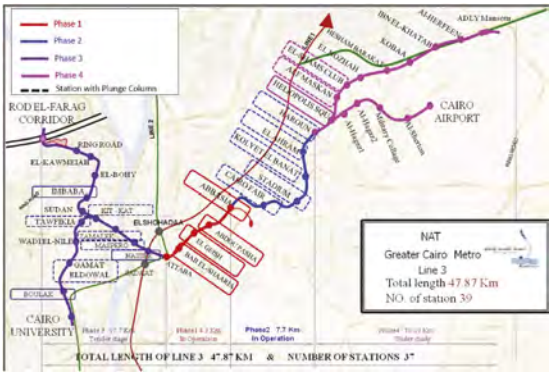

Figure 1. Cairo Metro, Line 3 - Stations awarded to Bauer are surrounded by a rectangle with the same color as the phase. Plunge columns were used in station where the boxes are dotted.

The execution was based on the following general construction sequence:

- Construction of the vertical retaining walls by means of diaphragm wall technique
- Installation of Plunge Columns
- Construction of cut-off walls to divide a station box into smaller boxes
- Construction of the sealing base as a silicate gel grout plug

The general soil profile at awarded sites are investigated had cultural fill, clay, silt, and sand profile. There was no presence of natural impervious soil layer within acceptable depth in typical Cairo soil conditions for Line 3, construction pits usually also needed cut-off from ground water at the bottom by a horizontal grout plug in form of soft gel. The grouting activities for the horizontal sealing of the excavation pits started after completion of the reinforced diaphragm walls in two main phases. Preparation of actual permeation grouting by drilling vertical holes in a defined grid and installation of grouting tubes into the holes supported by a self-hardening bentonite-cement-slurry. When this slurry gained sufficient strength, the actual grouting with soft silicate gel was commenced valve by valve and layer by layer. The silicate gel grout plugs for Cairo Metro Line 3 had thicknesses varying from 4.5-12 m, complying with the individual specifications of site. To allow for grouting up to five layers, the same number of tubes with one valve each per hole were installed at the various layer's elevations accordingly. For mixing the silicate gel, sodium silicate and reactant are required so that the water becomes a gel. Grout by Silicate gel is highly sustainable, as it requires less transportation produce silicate gel on site with less material consumption thus reducing carbon footprint. Before excavation, the water level is lowered inside by internal wells. By means of residual dewatering, the water level is kept at the required level below the bottom of the excavation pit.

4.2 *Diaphragm wall*

The underground retaining structure/ wall is constructed by means of the diaphragm wall technique formed of individual panels, each of panel length varying between 2.80 m to 6.80 m having nominal thickness of 1.20 m. To create a structural and watertight bond between the respective adjacent panels, primary panels are overcut during the excavation of the secondary panels depending on the required depth. Static calculation of the walls require reinforcement in all panels, so prefabricated reinforcement cages are installed in the primary panels in an exact position, to avoid any subsequent contact between the cutter and the reinforcement during the trenching of the secondary panels. The construction sequence is shown in Figure 2.

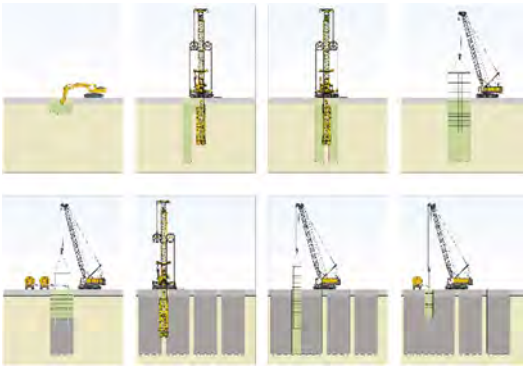

Figure. 2. Schematic Construction sequence of Diaphragm wall using cutter.

4.3 *Trench stability*

Technically and economically appropriate option for the construction of diaphragm wall is the use of supporting bentonite slurry to stabilize the open trench. However, considering the conditions (e.g., the price & availability of bentonite, properties of the subsoil, storage, disposal, etc.) there may be reasons to consider alternatives. Polymers are used in diaphragm wall construction sites.

4.4 *Permeation grouting*

Permeation grouting by means of silicate gel is used in the excavation pits at Cairo Metro project in appropriate depth regarding safety against uplift, and because the subsoils in these depth mostly consists of sand. Grouted horizontal cut-offs for which the safety against hydraulic uplift is to be verified are assumed to be totally impervious with an imaginary membrane located at the proposed underside of the horizontal cut-off. In the analysis the uplift pressure acting on the underside of the grouted horizontal cut-off is balanced against the total weight of all soil layers above the imaginary membrane. Bauer BG 28 piling rigs with extended mast along with grout or soft gel containers with grout pumps are used on site along with several mixing plants.

4.5 *Jet grouting*

The objective of the jet grouting between the existing Sewer and the CML3 tunnel is to allow the TBM to bore the tunnel in a safe way that there is no filling of the sewer with the slurry. In addition, the settlement and the differential settlements of the sewer tunnel should be limited to the minimum possible while the TBM is crossing below the Sewer. The jet grouting soil treatment zone is extended to 20 m along the sewer on each side of the crossing. As per the geometry and design of the treatment zone, a network of Jet Grouting points had to be installed with different inclinations in both directions and different depths. The design Jet Grout column was 2 m. In reality the actual diameters reached up to 2.20m to 2.30 m. The main advantage of Jet grouting is that large solidified elements can be executed in the ground using a relatively small drill rod of approximately 150mm and the method is applicable within limited working space. Bauer BG 28 piling rig, Jet grouting pump and a complete mixing plant for the Jet Grouting Works.

4.6 *Soil freezing*

During the tunnel boring works for Cairo underground metro line 3, a collapse caused by one of the segmental liners having failed during tunnel construction. Inflow of water and soil flooded the tunnel boring machine (TBM) resulting in a sink hole at the ground surface. The TBM was buried at a depth of about 30m under the street level. After evaluation of different

options considering jet grouting, ground freezing and mixed solutions using both techniques, finally the construction of a shaft directly in front of the TBM and horizontal ground freezing was chosen to rescue the TBM. Two rings of bore holes, with the holes tapering towards each other, were necessary for this. These holes were drilled from a previously constructed rescue shaft. The frozen soil body to be produced to act as sealing and structural member. In general, ground freezing technology was used for temporary groundwater control and excavation support in shaft construction and tunnelling projects. The main application is, however, the creation of a water cut off (groundwater control) with a certain aspect of ground stabilization. Therefore, the methodology depends in general on soil material in conjunction with adequate volumes of natural water. The technology is environmentally friendly as it takes temporarily advantage of the physical properties of the soil and water without changing their quality and natural condition permanently. There are two principal artificial ground freezing procedures that are used to convert groundwater to ice, creating a strong watertight soil body in the ground: ground freezing with brine or with liquid nitrogen (Figure 3).

This method utilizes large portable freezing /refrigeration plants where the refrigerant solution is passing through the following circular process. The basic principle involves:

- Compression of gaseous ammonia; this increases the temperature of the gas to approximately 70°C and a pressure of 12 bar.
- Cooling down of the gas to 35°C with the pressure remaining at 12 bar, thereby liquefaction.
- Decompression of the liquid ammonia (evaporation), thereby lowering of the temperature to approximately -35°C.

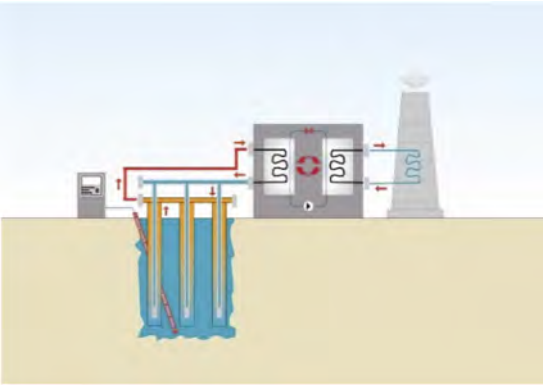

Figure 3. Soil freezing with brine (schematically only).

5 JANNAH DAM, LEBANON

The water shortage in the Mount Lebanon and Greater Beirut area in the year 2035 is estimated by the World Bank at more than 350 million cubic meters. Jannah Dam, with a design capacity of up to 38 million cubic meters, along with other envisaged dams, is expected to help alleviate the problem of water scarcity. The planning study, as well as the dam design, was carried out by the engineering firm Khatib & Alami and Artelia Group respectively. The construction was entrusted to Andrade Gutierrez Group, as the main contractor. The project site extends over a length of 500 m in a relatively narrow, steep and rocky section of the Jannah Valley. The soil conditions are characterized by Quaternary alluvial deposits with a thickness of up to 53 m and underlying limestone and dolomite. Several tectonic folds do exist adjacent to or across the project area.

The alluvial deposits consist mainly of the following:

- Gravels, cobbles and blocks of limestone and dolomite in fine- to coarse-grained sandy-clayey matrix

- Medium-dense to dense, slightly loamy to clayey sand, partly with gravel inclusions. Intermittent areas of loosely bedded sand were also recorded
- Soft to very stiff clay with intercalated bands of sand

5.1 *Main works*

The major deep foundation works executed on this project included:

- Cut-off wall at Upstream cofferdam
- Cut-off wall at Downstream cofferdam
- Diaphragm walls to create a bulkhead
- Consolidation and curtain grouting
- Ground improvement by means of piles

A major challenge of the project was the required deep excavation below the river level. Special concepts to control the water ingress and ensure the stability of the excavation and the footing had to be implemented (Adnan et al. 2022).

5.2 *Cut-off walls at cofferdam*

The cut-off wall at the upstream cofferdam extended to a depth of 42 m and stretched to about 128 m. The excavation was predominantly in alluvial deposits. On the slopes, the cut-off walls are keying into the bedrock. The cut-off wall at the downstream cofferdam extended over 161 m, and the maximum depth reached 50 m. Bauer proposed the utilization of the cutter technique. In addition to the reliable verticality control and higher performance, this technology mitigates the so-called hydraulic windows at the connection to the bedrock.

5.3 *Bullhead – as a block of diaphragm walls*

One of the remarkable challenges on this project was the execution of the bulkhead required for the excavation down to the foundation depth of the dam main body in the non-rocky soil. The relatively limited dimensions of the stretch available for the construction and the related hydraulic conditions prohibited an open excavation. The arch-shaped bulkhead was designed with a thickness of 4 m, supported in the bottom part with tie-back rods. The compressive strength of the bulkhead was specified with 7 MPa, a fully realistic strength magnitude for jet grouting columns executed in non-cohesive soil layers. The consideration of a different version of the jet grouting technique, besides the much longer retrieval rate, associated with almost total replacement of eroded soil by a viscous and solid-rich grout filling, results in much higher quantities of back-flow sludge. The construction of the diaphragm walls had to be associated with preliminary grouting measures. Some zones, with boulders and bedrock fragments adjacent to the trenches, had to be pre-treated to prevent them from falling onto the cutter during the excavation. The statically required use of structural concrete presupposed that the cutting of the already concreted panels was carried out as symmetrically as possible. For this reason, the two outer diaphragm wall rows were constructed first, followed by the middle row of the bulkhead structure. The coarse-grained soil between the two outer diaphragm wall rows therefore had to be pre-treated as well. Otherwise, during the construction of the second external row, the slurry would penetrate into this zone and lean against the previously produced first external row. The supporting effect would be lost, and the entire soil package located between the external rows could fall into the open trench. Apart from the acute risk for the cutter in the open panel, such a situation would require full-scale concrete cutting, together with the associated considerable wear and loss of performance.

5.4 *Grouting*

The grouting works on the project consisted of consolidation grouting under the footprint of the dam and three rows of grouting curtains extended into the abutments through several

layers of galleries, with the related QA/QC measures, such as coring and water pressure tests. The maximum depth reached some 80m in the foundation section and extended down to 100 m at the abutments. The co-existence of cavities on one side and relatively tight joints in the rock stratum on the other side impaired the suitability of the GIN method on the given project. Possibly, the rock properties in the sense of the pattern of the discontinuities at the dam location, have been particularly affected by the tectonic movements manifested by the encountered faults.

6 CONCLUDING REMARKS

The paper makes an attempt to highlight the challenges in executing the Deep foundations in Metro and Hydro Power Projects. Risks due to subsoil profile and working conditions. At Mangdechhu HEP in addition to the challenging mountainous terrain for the execution of works with fractured rock profiles, the reassessment of the shear zone has saved the construction schedule of the project by nearly 1 year. The successful implementation of the single-valve method for the execution of silicate gel grout plugs, and completion of several excavation pits for Metro Line 3, increased the confidence of client and contracted Bauer for six more stations for new Line 4 in Cairo Metro. The conditions at Jannah Dam required a flexible adaptation of the design and execution. The thickness of the clay layers, the diversity of the ground properties and the high static and hydraulic demands on the bulkhead imposed the use of a soil replacement method instead of a soil improvement method for its construction. The frequent and extensive fault zones in the rock called for a flexible adaptation of the originally specified GIN injection method. The case histories of projects executed in metros and hydro power at Mangdechhu HEP, Cairo Metro and Jannah Dam project with the same equipment mandate extensive planning, review of ground profiles and scheduling of the activities for successful completion of projects.

ACKNOWLEDGEMENT

We thank Mr. Mishra and his colleagues (Mishra et al. 2019) for their support in understanding the identification of the shear zone and mitigation measures in Dam structures in Himalayan mountains. We thank our colleagues Mostafa and team (Mostafa et al. 2022) for sharing the learning from the Cairo Metro operating in middle of Urban Infrastructure. Use of soil freezing in retrieving TBM is highly commendable. We thank Adan and other colleagues (Adnan et al. 2022) for the information on the construction of Bulkhead and Grouting works at Jannah Dam.

ABSTRACT: Caisson (Well) foundation has been widely used in South Asian countries like Nepal, India for construction of bridge piers and abutments. Generally, the caisson is cast in the ground and slowly sunk to the desired depth by gravity. But, due to sinking difficulties, designers are discarding it despite its several advantages. To overcome such a peculiar situation by taking advantage of caisson foundation, a composite caisson-pile foundation (CCPF) has been recently proposed and used to construct a bridge foundation in Nepal. This study aims to investigate the load-settlement behaviour of CCPFs resting on sand subjected to vertical load using three-dimensional finite element analyses. Through other numerical and experimental studies, the accuracy of the finite element analysis was proven to be correct and valid. A detailed parametric study is conducted, which includes the influence of pile length, number of piles and friction angle on the performance of CCPF embedded in sand.

Keywords: Load settlement, Pile foundation, Caisson foundation, Composite foundation, CCPF, FEM

1 INTRODUCTION

Caissons and piles are the two most popular deep-water foundation types for bridges spanning rivers and seas. For long-span bridges (Chowdhury et al. 2017; Bag et al. 2021) and in rivers where the depth of alluvial deposits and scour at the base of pier foundations might be rather significant (Kothyari 2007; Mukherjee et al. 2015), a caisson foundation—also known as a well foundation—is acceptable to meet the criteria for stability and serviceability. Caissons work well in liquefiable soils but are susceptible to strong seismic motion, as shown by recent incidents like the 1995 Kobe Earthquake (Liang et al. 2018). However, its construction has been plagued by recurrent obstacles due to difficulties in sinking to the desired depth. For instance, it took more than 10 years to finish the caisson foundations for a five-span, 175 m long bridge in Lumbini, Nepal's strategic road network because there were unanticipated hard strata within the foundation's design depth. Numerous bridge projects in Nepal, India, and China had similar issues (Bag et al. 2021; Tu et al. 2021; Misra et al. 2022).

DOI: 10.1201/9781003299127-186

Contrarily, pile foundations are more adaptable and favoured in situations when the ground's hard strata are significantly deeper and have a much lower bearing capacity than caissons. However, due to its limited ability to withstand vessel impact and difficulty in construction as a result of its extensive length and reduced rigidity, it might not be the best option to use in deep water. To address these issues, the caisson and piles may be combined to create the cutting-edge Composite Caisson-Pile Foundation (CCPF), a hybrid foundation that utilizes the best aspects of both types of foundations while minimising their drawbacks. Figure 1a and 1b show the schematic diagram of section and plan view of CCPF system.

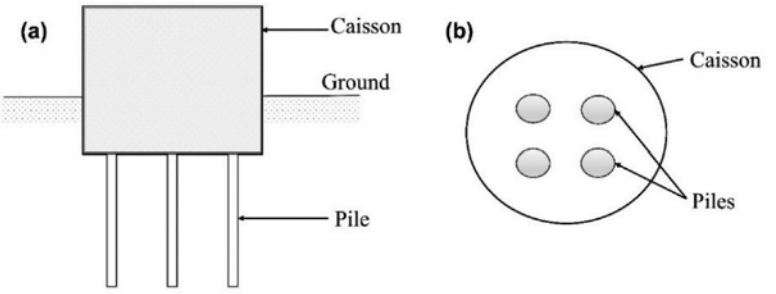

Figure 1. Composite Caisson-Pile Foundation (CCPF): a schematic diagram.

CCPF provides innovative solutions to complex site conditions in deep-water and reduces construction time and cost. Compared to conventional foundations, the CCPF may effectively minimize the length and embedment depth of the caisson and pile foundation, reducing construction complexity and risk (Huang et al. 2018). However, the research on CCPF is still scanty (Tu et al. 2020). Moreover, performance evaluation study of CCPF is still lacking. Due to which, the application of CCPF has been minimal. More research and development initiatives are desperately needed to give designers more confidence in adopting such innovative foundation systems. Thus, in this study, a 3-D finite element model (FEM) of CCPF is developed and parametric study has been conducted based on vertical load-settlement response of the foundation.

2 FEM AND ITS VALIDATION

Plaxis 3D was used to develop 3-D model of the CCPF (Figure 2). The PLAXIS 3D library's 10-node tetrahedral components are used to simulate the soil volume with medium meshing. A linear elastic-perfectly plastic Mohr-Coulomb failure criteria is used to represent the behaviour of sand. Modeling of the caisson and piles is done using plate and embedded beam element with a special interface. The soil and structural elements are assumed to have a smooth interfacial contact by setting 'R_{int}' to 0.67.

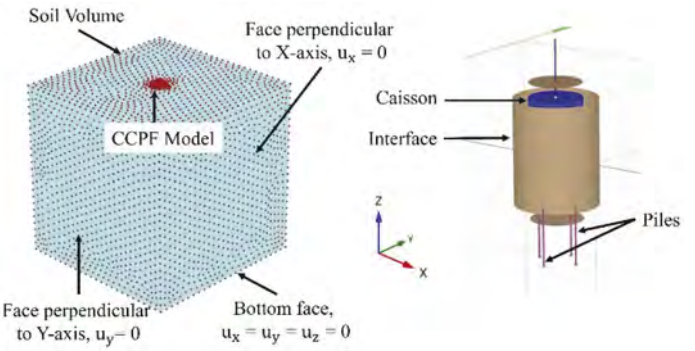

Figure 2. Meshing and boundary conditions of Finite element model of CCPF.

The validation of the model was done with the static CCPF load test conducted in the field by Wang et al. (2015) in China. Two tests are chosen for validation. The first test was performed on a caisson of size 0.6 x 0.6 x 0.8 m and thickness of 20 mm without considering any pile. The second test was performed on a same-size caisson with 3 x 3 piles of 40 mm diameter and 2 mm thickness located under the caisson with 15 mm in thickness. Each pile was 0.5 m in length. Pile and caisson were simulated by steel plate of elastic shear modulus of 216 GPa. The subsoil comprised dry sand. The results of the vertical field test and finite element analyses are presented in the form of load-settlement curves in Figure 3 for caisson alone case and caisson with 3 × 3 piles. Overall, it can be noted that the calculated load-settlement responses of the foundations show a close match with the field test results in terms of both trend and magnitude.

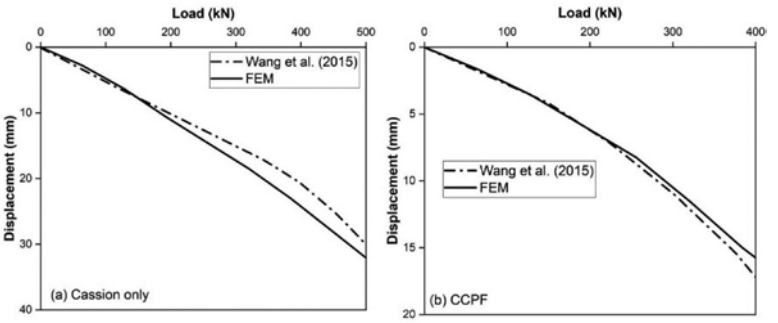

Figure 3. Validation of the finite element model with the vertical load test results of Wang et al. (2015): (a) caisson only (b) CCPF with 50cm long 3 × 3 piles.

3 RESULT AND DISCUSSION

3.1 *Effect of length of piles*

Four pile lengths (10m, 12m, 14m and 16m) were considered for the study to assess the effects of pile length on performance of CCPF. Figure 4 shows the load-settlement response of CCPF for these pile lengths. It can be seen that the settlement has been significantly reduced with increase of pile length from 10m to 14m. However, after reaching 14m, the settlement for 16m long piles found to be increased again. At any settlement level, it is found that the increase in CCPF's load-carrying capability increases with the length of the pile. For instance, load improvement ratios (LIR) for pile lengths 10, 12, 14, and 16 m are calculated as 1.13, 1.32, 1.53, and 1.54 accordingly at 0.1 m settlement level. Another significant finding is that lower settlement levels have a bigger boost in CCPF capacity. For instance, the estimated LIRs for 0.1m to 0.5m settlements at a 14m pile length are determined to be 1.53, 1.41, 1.29, 1.26, and 1.24, respectively. Such a situation can be explained by the fact that the CCPF's rigidity reduces as load level, or greater settlements, increases. In comparison to situations where pile length increases from 14m to higher values at any settlement level, the increment rate of LIR is higher when the pile length goes from 10m to 14m.

3.2 *Effect of pile number*

To assess the effects of number of piles in performance of CCPF, various numbers (0, 1, 2, 4 and 5) of piles were utilized in the 3D model. Figure 5 shows the load settlement response of CCPF for various number of piles. It is worth mentioning that the settlement is reduced with increase in number of piles from 0 to 4, however, it has been found increased in 5 piles condition; which indicates that the sole increase in number of piles beyond a limit cannot decrease the settlement of CCPF.

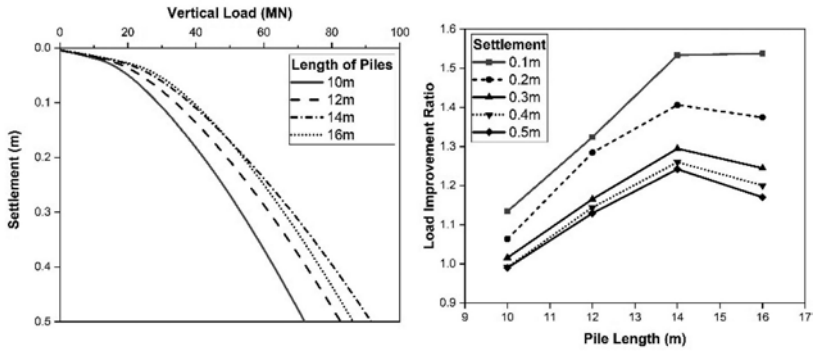

Figure 4. Load-settlement response and LIR ratios of CCPF for various pile lengths.

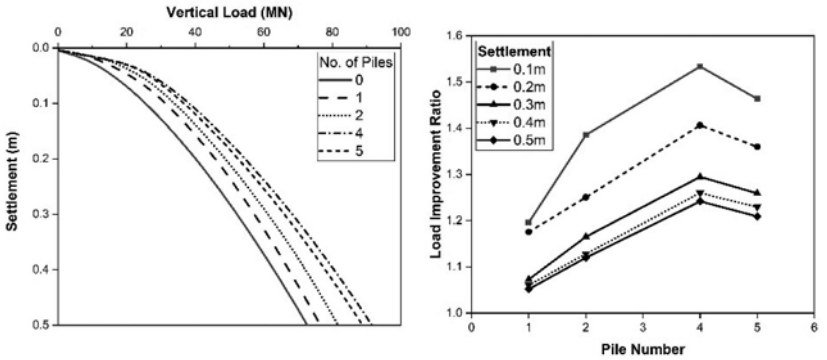

Figure 5. Load-settlement response and LIR ratios of CCPF for various pile number.

3.3 *Effect of friction angle*

In this series, tests were conducted on CCPF foundations in soils having angle of internal friction (ϕ) of 20°, 25°, 30°, and 35°. The remaining parameters and geometry remained the same as described in the previous section. Figure 6 presents the results of this series in the form of load-settlement curves for different angles of internal friction (ϕ). It can be noted that the settlement decreased rapidly with an increase in the angle of shearing resistance from 20 to 35°.

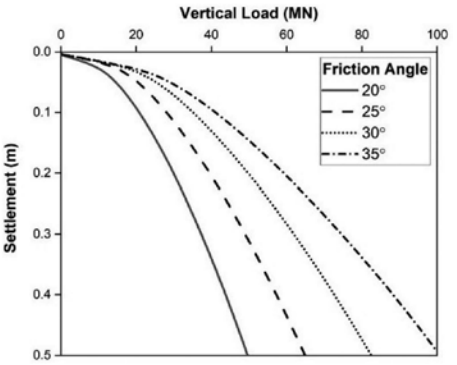

Figure 6. Load-settlement response of CCPF for various angle of friction of sand.

4 CONCLUSIONS

Following are the conclusions of the numerical study on CCPF:

- The CCPF maximizes the vertical load carrying capacity of the soil while successfully controlling the settlement. Generally, the caisson could support the top weight and be utilized as a platform for bridge construction. After bridges are erected, the piles beneath the caisson may be used to regulate the settlement.
- It can be seen that the settlement has been significantly reduced with an increase in pile length from 10m to 14m. However, after reaching 14m, the settlement for 16m long piles was found to be increased again.
- At any settlement level, it is discovered that the increase in CCPF's loadcarrying capability increases with the length of the pile. Another significant finding is that lower settlement levels have a bigger boost in CCPF capacity.
- In comparison to situations where pile length increases from 14m to higher values at any settlement level, the increment rate of LIR is higher when the pile length goes from 10m to 14m. The settlement is reduced with an increase in the number of piles from 0 to 4, however, it has been found to increase in 5 piles condition; which indicates that the sole increase in the number of piles beyond a limit cannot decrease the settlement of CCPF.
- It can be noted that the settlement decreased rapidly with an increase in the angle of shearing resistance from 20 to 35°.

Negative skin friction effect on pile group due to an adjacent excavation

Paromeeta Bandyopadhyay & Fuchen Teng
Department of Civil and Construction Engineering, National Taiwan University of Science and Technology, Taipei, Taiwan

ABSTRACT: Due to rapid infrastructure development in urban areas, is a common practice to excavate near an existing pile foundation which changes the state of stress of the existing surrounding soil. The unloading due to excavation, changes the behavior of pile as compared to pile subjected to only vertical loading. If the excavation is near to a group pile, the group effect also tends to change the behavior of each pile in the group along with the unloading effect due to excavation. In this study, numerical simulation is done using commercially available software PLAXIS 3D to analyze the change in behavior of group pile due to adjacent excavation in commonly occurring multi-layered soil along the pile shaft. The analysis is done with Hardening soil constitutive model to simulate the naturally existing soil strata. The results from this study can be used for similar type of soil to predict the change in behavior of group pile subjected to deep excavations.

1 INTRODUCTION

Underground construction is often a necessity to improve the infrastructure in urban areas. Such underground constructions lead to deep excavations and tunnel construction which invariably affect the surrounding existing structures. Mostly the existing structures like buildings, bridge piers, and metro corridors are supported by pile foundation. As compared to a single pile, a pile group connected by a pile cap is more common as a foundation system. Hence, how an excavation affects a nearby pile group is a topic of interest for engineers to ensure the safety and serviceability of the existing structures. Most of the previous studies consider only one type of soil, either clay or sand to analyze the change in behavior of an existing pile foundation when it is subjected to a nearby excavation.

Liyanapathirana and Nishanthan (2016) and Ong et al. (2009) numerically analyzed the additional deflection and bending due to excavation caused in a single pile and pile group respectively in clay. Ong et al. (2006) used centrifuge test to predict the post-excavation soil settlement, wall deflection and pile movement for a single pile in clay. Korff et al. (2016) proposed analytical method to determine the vertical movement of pile in soft soil with the assumption that horizontal stress remains same during the excavation. Shi et al. (2019) performed three dimensional numerical analyses to predict the settlement and stress transfer mechanism due to excavation in dry sand.

It is most unlikely that any naturally occurring soil profile will consist of only clay or only sand. Generally, a soil profile is a combination of multiple layers of sand and clay with different properties for every layer of soil. This study tries to focus on the behavior of a pile group with three piles connected by a pile cap placed near to an excavation in the naturally occurring multi-layered soil. The soil excavation analyzed here is part of a metro railway project in Taipei city in Taiwan. Hardening soil model is used to simulate the behavior of soil in Plaxis 3D for this analysis. A typical naturally occurring soil profile in Taipei and the calibrated soil parameters for the Hardening soil model used in the analysis are shown in Table 1.

2 NUMERICAL ANALYSIS

The group pile is located 5 m away from the face of the excavation. The final depth of excavation is 24 m with a 1.2 m thick diaphragm wall. To keep the excavation stable, buttress walls are used at 7.5 m spacing and struts are positioned 5 m center to center distance horizontally. Commercially available finite element software Plaxis 3D is applied for the numerical analysis. Bottom up method of excavation is adopted a struts are placed 70 cm above the excavation level in each phase. The excavation geometry along with the pile group is shown in Figure 1, with the three piles in the group marked as PG1, PG2 and PG3.

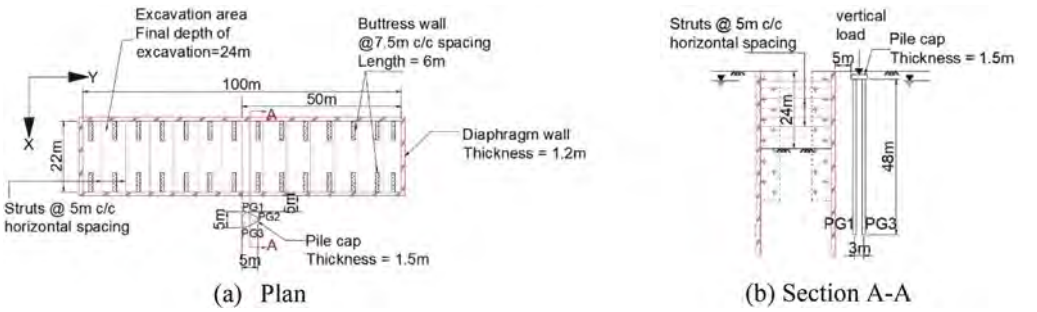

Figure 1. Excavation geometry with pile group.

To study the difference in effect on a single pile as compared to a group pile in the same soil profile, a single pile P1 of same dimension is placed at the location of PG1. The excavation geometry with the single pile P1 is shown in Figure 2. The geometry remains the same; only change is the group of three piles is replaced by a single pile P1 in the position of PG1. The intensity of load is kept same in both the cases.

2.1 *Pile properties*

The piles are 1 m in diameter, 48 m in length and connected by a pile cap of 1.5 m thickness placed 1 m below the ground surface. Embedded beam element is used in Plaxis 3D to simulate the pile. The connection between the pile and the pile cap is considered to be rigid. The pile properties as shown in Table 2.

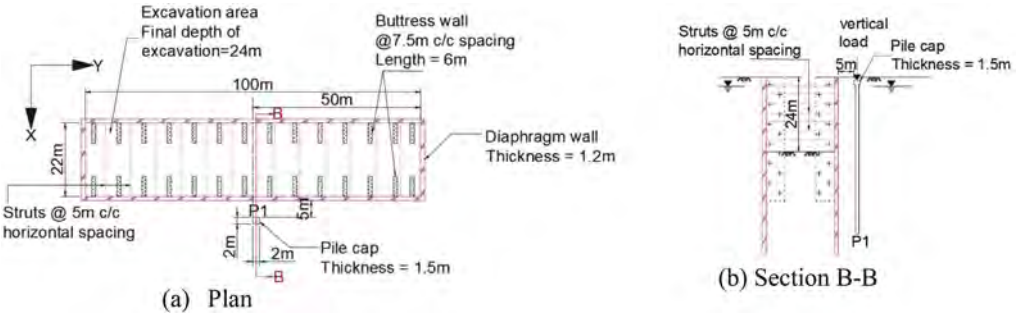

Figure 2. Excavation geometry with single pile.

Table 2. Pile parameters used in Plaxis 3D analysis.

Parameter	Value
Unit weight, ɣ (kN/m^3)	25
Young's modulus, E (kPa)	13*10^6
Pile diameter, d_p (m)	1
Pile length, L_p (m)	48
Maximum skin resistance, T_{max} (kN/m)	1*10^{12}
Maximum base resistance, B_{max} (kN)	1000

2.2 *Boundary conditions*

The vertical sides are fixed normally, base is fully fixed and the top is free to move in any direction. Hydraulically, there is no flow through bottom surface. All the vertical sides and top are open to allow flow of water.

2.3 *Phases in numerical modelling*

"Wished-in-place" piles are activated followed by the working load. The diaphragm wall along with the buttress wall are activated. Excavation is done up to -3.7 m first and first level of strut is installed 70 cm above the excavation level in each phase. This process is continued until the final formation level of 24 m is reached.

3 RESULTS AND CONCLUSION

3.1 *Interpretation of obtained results*

Figure 3 shows the lateral deflection of pile PG1 and P1. The lateral deflection towards the excavation is considered to be positive. The comparison shows that due to the same excavation dimension located at same distance away from the pile, there is no difference in lateral deflection between the pile in the group (PG1) and the single pile (P1). Figure 4 shows the comparison of bending moment between pile PG1 and P1 prior to excavation with only working load on pile (marked as 'WL only' in graphs) and at the completion of excavation (marked as 'final excavation' in graphs). The magnitude of maximum bending moment of PG1 and P1 is almost the same. The lateral behavior of the pile thus remains same for both group pile and single pile provided it is in same position with respect to the excavation.

The vertical settlement of piles PG1 and P1 are shown in Figure 5. Under the same intensity of load prior to excavation, the pile top for PG1 settles by 14.48 mm whereas for P1 it is 9.66 mm. Thus, PG1 settles more than P1 by 49.85%. But when excavation reaches the formation level. The pile top settlement of PG1 is 42.24 mm and that of P1 is 40.79 mm; PG1 settles only 3.54% more than P1. The axial forces of PG1 and P1 prior to and on completion of

excavation are compared in Figure 6. Due to the excavation, a drag down generates in the upper part of both PG1 and P1. The absolute maximum axial force in P1 is 3833 kN and that in PG1 is 3257 kN. Thus the axial force generated in single pile is more than that in the group.

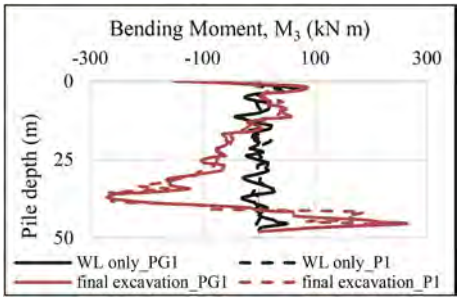

Figure 3. Lateral displacement of pile with depth.

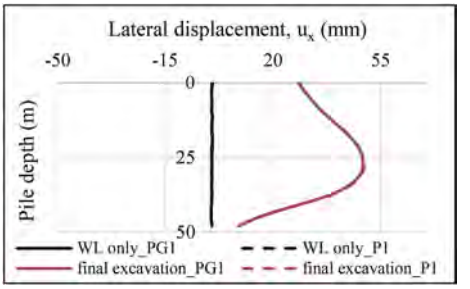

Figure 4. Bending moment of pile with depth.

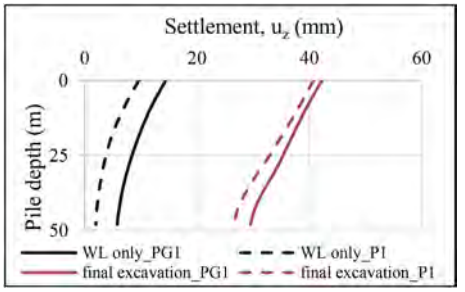

Figure 5. Settlement of pile with depth.

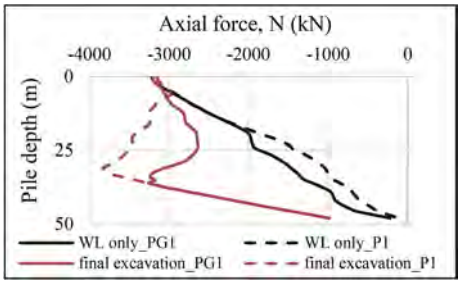

Figure 6. Axial force in pile with depth.

3.2 *Conclusion*

The study analyzed two piles of same dimension located in same position with respect to an excavation in a naturally occurring multi-layered soil. The lateral behavior of the pile, whether placed in a group or single remains same. The axial settlement of the group pile is more as compared to single pile. The axial force after the final phase of excavation, is more for the single pile. This behavior can be attributed to the pile group effect.

P-Y curves from the SPT test for laterally loaded single piles in sand

A. Laouedj
National Marine Science and Coastal Planning School University, Algeria

A. Bouafia
University Saâd Dahleb of Blida, Algeria

ABSTRACT: P-Y curves-based design methods offer a powerful framework of analysis of laterally loaded piles. This paper aims at presenting a practical method of direct construction of the P-Y curves for piles in sand on the basis of the number of blows N_{SPT} measured during the SPT test. This method was developed from a detailed interpretation of full-scale lateral loading tests on single piles carried out in sandy soils. The two main parameters of the P-Y curve, namely the lateral reaction modulus and the lateral soil resistance, were directly correlated to N_{SPT}. The methodology of construction of the P-Y curve from the SPT data is presented and the validation of the proposed method by testing it in a small sized database of full-scale loading tests showed a very good predictive capability.

1 INTRODUCTION

The non-linear subgrade reaction method also called P-Y curve is widely used for the design of laterally-loaded piles. As shown in Figure 1, the P-Y curve has a non-linear shape and is characterized by an initial slope denoted E_{ti} and called the lateral reaction modulus, and a horizontal asymptote P_u corresponding to the lateral soil resistance (Bouafia 2013-2017).

In spite of the large number of applications of the Standard Penetration Test (SPT) in foundation engineering and the important case histories of full-scale lateral load tests of single piles, it has not yet been published an original work dealing with a direct derivation of the lateral reaction P-Y curves on the basis of the Standard Penetration Test (SPT) (Laouedj & Bouafia 2017).

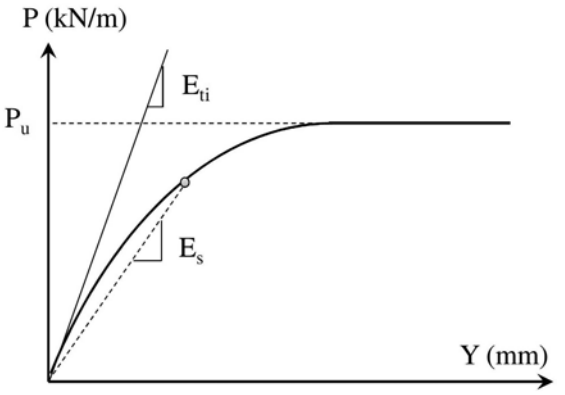

Figure 1. Schematic shape of the P-Y curve (Bouafia 2013-2017).

DOI: 10.1201/9781003299127-188

This paper is aimed at presenting a practical method of constructing the P-Y curves on the basis of a direct correlation of the two main parameters of the P-Y curve with the blow counts N_{spt} of the SPT test, derived from an extensive analysis of several full-scale lateral loading tests on fully instrumented single piles carried out in sandy soils. Subsequent validation of the proposed P-Y curves method was undertaken by predicting the behavior of many test piles reported in the literature.

2 METHODOLOGY TO CONSTRUCT P-Y CURVES

Hereafter is presented a step-by-step procedure to compute the parameters of the P-Y curves:

1. Along the pile, subdivide the soil into N horizontal slides thin so that the N_{spt} value may be considered varying linearly within any slide.
2. Assume the "*effective embedded length of the pile*" D_e equal the pile embedded length D.
3. Along the pile, compute the "*characteristic soil modulus*" E_C along the effective embedded length of the pile D_e as follows:

$$E_C = \frac{1}{D_e}\int_0^{D_e} N_{SPT}(z)\sigma_{v0}(z)dz \tag{1}$$

For practical purposes, the calculation of the integral can be replaced by the summation of the trapezes method.

4. Compute the "*lateral pile/soil stiffness ratio*" K_R defined as follows:

$$K_R = \frac{E_p I_p}{E_c D^4} \tag{2}$$

5. Determine the "*modulus number*" K_E^i of each slide i, from Table 1, depending on the position of the slide with respect to GWT (Ground Water Level) level, and compute the "*characteristic initial lateral modulus*" E_{ti}^C by the following equation:

$$E_{ti}^C = \frac{1}{D_e}\int_0^{D_e} E_{ti}(z)dz = \frac{1}{D_e}\int_0^{D_e} K_E N_{SPT}\sigma_{v0}(z)dz \tag{3}$$

6. Compute the "*elastic pile length*" (or the "*transfer length*") L_0 defined by:

$$L_0 = \sqrt[4]{\frac{4E_p I_p}{E_{ti}^c}} \tag{4}$$

Where E_pI_p is the pile flexural stiffness.

7. Compute the effective embedded length D_e of the pile defined as the smaller of the two following quantities:

$$D_e = min\ \{D, 3L_0\} \tag{5}$$

If $D > 3L_0$ (flexible pile), then repeat steps 3 to 7 according to an iterative process and introducing at each iteration step the value of D_e until the convergence. Otherwise, $D < 3L_0$ the pile is rather semi-rigid or rigid and the method is not applicable.

8. Compute the initial lateral reaction modulus E_{ti} and the lateral soil resistance P_u, K_N being the *"lateral resistance factor"*, for each slide as follows

$$E_{ti} = K_E N_{SPT}\sigma_v' \tag{6}$$

$$P_u = K_N \sigma_v' B \tag{7}$$

It was found that the modulus number K_E and the lateral resistance factor K_N depend on the position of the pile slide with respect to the groundwater table level as summarized in Table 1.

9. Construct the P-Y curve for each segment along the pile by using the hyperbolic function as follows:

$$P(z) = \frac{Y(z)}{\frac{1}{E_{ti}(z)} + \frac{|Y(z)|}{P_u(z)}} \tag{8}$$

10. To analyze the load-deflection response of a single pile under lateral forces, input the P-Y curves constructed according to this step-by-step procedure into any software based on the P-Y curves method, like SPULL (Single Pile Under Lateral Loads) developed at the University of Blida.

Table 1. Values of K_E and K_N for flexible piles.

Above water table	Below water table
$K_E = 207$	$K_E = 156$
$K_N = 21$	$K_N = 17$

3 VALIDATION OF THE PROPOSED METHOD

In order to demonstrate the predictive capability of the proposed method, the lateral load-deflection response of single piles was predicted. 21 full-scale lateral loading tests in 7 sandy soils were collected from the case studies reported in geotechnical literature, and studied according to the proposed method.

The seven test sites are: Chaiyi County, Taiwan (2 tests – Site 1), City of Natal, Brazil (6 tests – Site 2), Algiers Mosque, Algeria (3 tests – Site 3), Calgary, Canada (5 tests – Site 4), Opelika, Alabama, U.S.A. (1 test – Site 5), North Carolina, U.S.A. (2 tests – Site 6), and Solar farm projects (2 tests – Site 7).

The P-Y curves parameters were computed in correlation with the N_{spt} values, and the pile geometry, boundary conditions and P-Y curves were input into SPULL software. For each test pile, the P-Y curves parameters were defined according to the methodology described above. The load-deflection curve was simulated by computation using SPULL. The top lateral deflections calculated for each test pile were compared to measured top lateral deflections.

As shown by the Figure 2, very good agreement between the predicted pile deflections on the basis of the proposed method of P-Y curves and the measured ones is to be noticed. It can also be seen that the best prediction is for small and medium pile deflections.

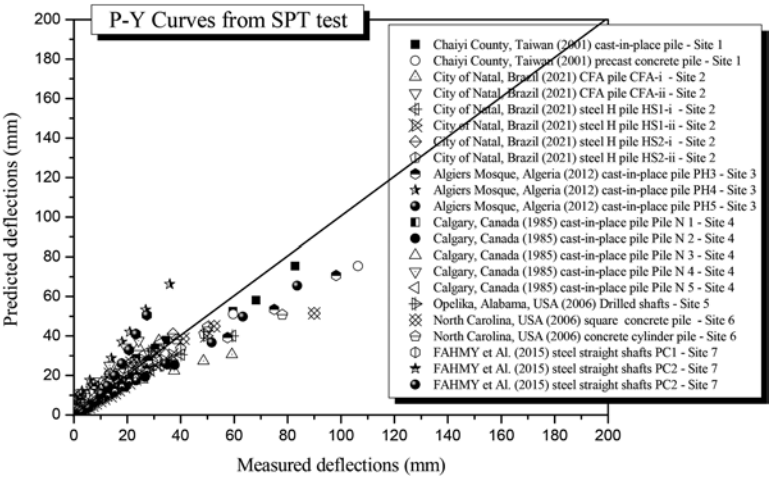

Figure 2. Comparison of predicted to measured pile deflections.

4 CONCLUSION

This paper presents a practical method of construction of the P-Y curves whose parameters, namely the initial reaction modulus and the lateral soil resistance, are directly correlated to the N_{SPT} value of the standard penetration test SPT.

A step-by-step procedure to define the parameters of P-Y curves for a single pile under lateral loads in sandy soils was suggested.

A small sized database of 21 full-scale horizontal pile loading tests carried out in 7 sandy sites worldwide are used to validate the proposed method. The comparison of the predicted pile deflections to the measured ones showed very good predictive capability. This finding is encouraging seeing the multitude of uncertainties affecting the data analysis during the process of development of this empirical method.

Estimation of stiffness of disconnected piled raft foundation system with pile contribution factors

B. Yoon & W. Lee
Korea University, Seoul, South Korea

H. Choo
Hanyang University, Seoul, South Korea

C. Lee
Chonnam National University, Gwangju, South Korea

ABSTRACT: Behavioral analysis of the disconnected piled raft foundation (DPRF) is more complicated than the conventional piled raft foundation owing to the complex interactions between piles, subsoil, and load transfer platform (LTP). The effect of pile-related parameters and LTP-related parameters on load-settlement behavior of DPRF has been compared by 3-dimentional numerical work. The result of this study shows that both pile-related factors and LTP-related factors affect the load-settlement of DPRF. The simple equation to estimate the load-settlement behavior of DPRF system has been suggested in terms of pile-contribution factors. The results of previous studies were also analyzed to verify the validity of suggested equation. A good agreement between the measured and estimated values were obtained, indicating the potential to apply in practical field.

1 INTRODUCTION

For several years, piled raft foundation (PRF) has been adopted for intermediate situations where shallow foundation is not acceptable for large settlements while the pile foundation is overdesigned (Burland, 1995). However, the structural connection between piles and raft in PRF produces high bending moments in raft and concentrated stress in the pile heads which causes cracking in the raft. To overcome these limitations, disconnected piled raft foundation (DPRF) has been suggested as an alternative. Load transfer platform (LTP) layer, generally composed of granular soils are imposed between the raft and piles to produce physical disconnection between the piles and raft (Wong et al., 2000, Mali and Singh, 2018).

Many researchers studied the mechanical behavior of DPRF by numerical simulations (Zheng et al., 2008, Eslami and Malekshah, 2011, Azizkandi et al., 2019) and physical modeling test (Fioravante and Giretti, 2010, Malekkhani and Bazaz, 2021), however, the analysis and the interpretation method of mechanical behavior of DPRF is still under discussion owing to the complex interaction between piles, raft and subsoil.

This study aims to suggest a simple equation to estimate the stiffness of DPRF within the serviceability range of the raft settlement (i.e., $w_r/B_r < 0.5\%$, where w_r = raft settlement and B_r = width of the raft) (O'Neil, 1996) by 3-dimentional numerical work by ABAQUS. Both the pile design parameters and LTP design parameters were considered as variables.

DOI: 10.1201/9781003299127-189

2 FINITE ELEMENT MODELING

2.1 *Material modeling*

Piles and raft were modeled as a linear elastic material, while subsoil and LTP layers were modeled as a linear elastic-perfect plasticity material using the Mohr-Coulomb yield criterion. The subsoil was modeled to have a linear depth-variation of elastic modulus to simulate the soil stiffening with increment of confinement with depth (Tradigo et al., 2015) (Equation 1). Furthermore, to observe the effect of E_{LTP} (elastic modulus of LTP layer) on DPRF behavior, E_{LTP} was varied to have 30-125 MPa. Table 1 summarizes the mechanical properties applied in this study.

$$E_{sub}(z) = E_0 + E_{inc} \cdot z \tag{1}$$

where E_{sub}=elastic modulus of subsoil, E_0=elastic modulus at the ground level, and E_{inc} = gradient of the elastic modulus

Table 1. Material properties used in FE analysis.

Parameters	Subsoil	LTP layer	Pile	Raft
Unit weight, γ (kN/m^3)	15.3	15.3	24	24
Elastic modulus, E (MPa)	10+2z	30-125	30,000	120,000
Poisson ratio, ν	0.25	0.25	0.15	0.15
Friction angle, φ (°)	35	35	-	-
Cohesion, c (kPa)	<1	<1	-	-
Dilatancy angle, ψ (°)	5	5	-	-

2.2 *Geometrical configuration*

This study modeled a quarter of a whole model as symmetric boundary condition is satisfied (Zheng et al., 2008). The pile was designed to have diameter (D) 0.5m and varied length ratio (L/B_r, where L=pile length and B_r=width of raft) 0.18−0.91, less than 1 to satisfy large piled raft criteria (Sanctis and Mandolini, 2006). Different arrangements of piles were modeled with pile number (N) = 0, 4−64, and spacing ratio (S/D, where S=pile spacing) =2−8. DPRF with N=64 and S/D=8 was excluded owing to the limited geometrical configuration. The LTP layer was designed to have thickness ratio (H_{LTP}/D, H_{LTP}=thickness of LTP layer) =0−3. The rigid raft width was designed to have constant value 22m. The total width and depth of the whole model was 110m and 95m, respectively, to satisfy the wide boundary conditions where they do not affect the results (Azizkandi et al., 2019).

After geostatic condition is satisfied at soil deposit, the weight of structural elements were activated (Richter et al., 2011, Tradigo et al., 2015). Then, a uniform stress (q_0) =500kPa was applied on top of the raft.

3 RESULTS

The stiffness of the foundation (k) was defined as the load applied on the raft divided by the raft settlement at w_r/B_r=0.5%.

3.1 *Stiffness of raft foundation with LTP layer (RL foundation, N=0)*

The effect of E_{LTP} on the stiffness of RL foundation (k_{RL}) shows different trends according to H_{LTP}/D as shown in Figure 1 (a). Behaviors of RL foundation shows very similar to that of shallow foundation on layered soil, where the behavior of shallow foundation is determined by the relative difference in the bearing capacity of layered soils (Das, 2016). In other words, when LTP layer categorized to be 'stronger' than subsoil, increment of H_{LTP}/D increases k_{RL}. On the contrary, increment of H_{LTP}/D decreases k_{RL} when LTP layer is categorized to

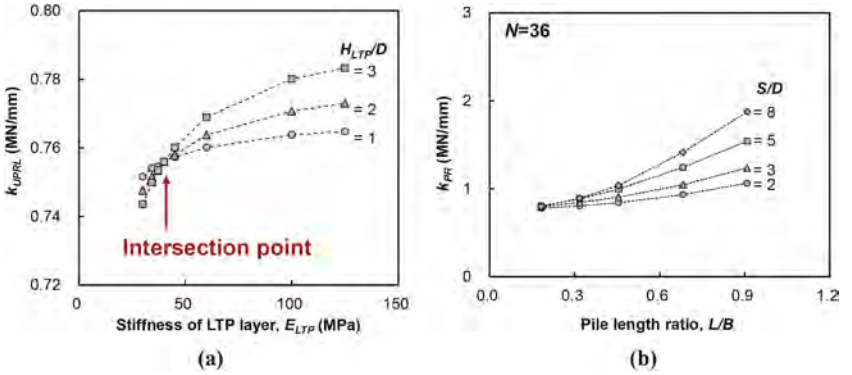

Figure 1. (a) Variation of k_{RL} with E_{LTP} according to H_{LTP}/D and (b) Variation of k_{PR} with L/B according to S/D (PRF with N=36 is only shown).

'weaker' than subsoil. At state where subsoil and LTP layer have similar bearing capacity, k_{RL} will not be affected by H_{LTP}/D. The intersection point at Figure 1(a) may indicate the mentioned situation, where similar bearing capacity of LTP layer and subsoil is satisfied.

3.2 *Stiffness of piled raft foundation (PRF, H_{LTP}=0)*

As identical effect of L/B and S/D was observed at various N, only case of PRF with N=36 is shown in Figure 1 (b). Consistent to previous research, as increment of L/B increases the pile capacity along pile length (Nguyen et al., 2014) and increment of S/D decreases the interaction between the piles (Cao et al., 2004, Rasouli et al., 2015), the stiffness of piled raft foundation (k_{PR}) increased with increment of L/B and S/D.

3.3 *Stiffness of disconnected piled raft foundation (DRPF)*

The effect of LTP-related and pile-related parameters on k_{DPR} showed similar effects on k_{DPR}, that includes the concept of layered soil having LTP layer above and bottom layer with pile reinforced subsoil where the pile reinforcement increases with increment of N, L/B and S/D (Cao et al., 2004, Nguyen et al., 2014, Rasouli et al., 2015). Consequently, the effect of LTP thickness on k_{DPR} varied according to the relative stiffness between LTP layer and pile reinforced subsoil (=E_{LTP}/E_{sub}^*, E_{sub}^* = Equivalent elastic modulus of pile reinforced subsoil) that can be summarized in Figure 2 (a). Since E_{sub}^* varies at given pile configurations, the variation trends of k_{DPR} with H_{LTP} showed inconsistent trends that may depends on pile configurations as shown in Figure 2 (b) and (c), at constant E_{LTP}=125MPa and N=36 for instance.

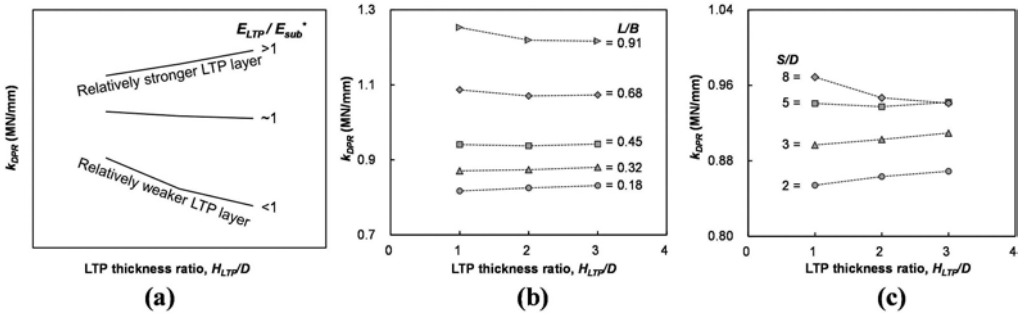

Figure 2. (a) Variation of k_{DPR} with H_{LTP}/D at various E_{LTP}/E_{sub}^*, and inconsistent effect of H_{LTP}/D on k_{DPR} at constant E_{LTP}=125MPa and N=36, shown for instance, according to (b) L/B and (c) S/D.

4 ANALYSIS AND DISCUSSION

4.1 k_{DPR} estimation formula

As both pile-related and LTP-related parameters affect k_{DPR}. To estimate the k_{DPR} simply, this study attempted to represent k_{DPR} with k_{RL} and k_{PR} since they include the effect of LTP-related and pile-related parameters, respectively. While this process, some cases of DPRF were also excluded for further verification process. The overall relationship between k_{DPR}/k_{RL}-k_{PR}/k_{RL} can be summarized as power function with fitting parameters of A and b (Equation 2).

$$\frac{k_{DPR}}{k_{RL}} = A\left(\frac{k_{PR}}{k_{RL}}\right)^{b} \tag{2a}$$

$$k_{DPR} = A \times (k_{PR})^{b} \times (k_{RL})^{1-b} \tag{2b}$$

In this study, the fitting parameter b was defined as 'contribution' factor and it represents the contribution of pile-reinforcement effect to mechanical behavior of DPRF, with ranged values of 0 – no contribution to foundation system, indicating RL foundation; and 1 – full contribution to foundation system where $k_{DPR} \approx k_{PR}$.

4.2 *Contribution factor, b*

Contribution factor b was first calculated at DPRF with constant k_{RL} and k_{PR}. Figure 3 compares the measured b at constant N=36 according to pile-related parameters of H_{LTP}/D and E_{LTP}, at various S/D. As expected, increment of E_{LTP}, and decrement of H_{LTP}/D increased b. The negative effect of S/D on b indicates that the summation of each single pile effect on DPRF is larger than that of group pile.

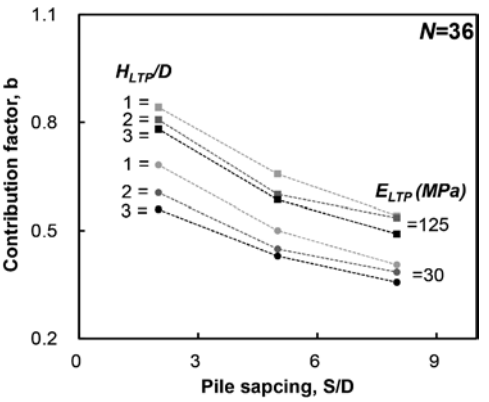

Figure 3. Variation of b according to LTP-related parameters (H_{LTP}/D and E_{LTP}) according to S/D.

Multiple regressions analysis was progressed with the measured b at constant N through statistical software SPSS, and linear correlation of design parameters were obtained (Equation 3). Since there exist upper limit of N, beyond which insignificant effects were expected (Poulos, 2001), the regression factors of a', α, β, and λ were estimated by hyperbolic model (Duncan and Chang, 1970) (Equation 4). Table 2 summarizes the hyperbolic parameters of c_1 and c_2 calculated at each N. Note that E_{LTP} was replaced by $E_{ratio} = E_{LTP}/E_{sub}$ to make the dimensionless factor, where E_{sub}=elastic modulus of subsoil layer.

$$b = a' + \alpha(S/D) + \beta E_{ratio} + \lambda(H_{LTP}/D) \tag{3}$$

$$Regression\ Factor = \frac{N}{c_1 + c_2 N} \tag{4}$$

Where c_1, c_2 = hyperbolic parameters determined as the intercept and slope of linear relationship between N/regression factor – N.

Table 2. Calculated hyperbolic parameters of regression factors.

Hyperbolic parameters	Constant, a'	α	β	λ
c_1	7.32	-278.88	3.50	67.39
c_2	1.12	-14.88	14.74	-30.48

4.3 *Constant factor, A*

Based on Equation 2a, the constant factor A represents k_{DPR}/k_{RL} at k_{PR}/k_{RL}=1 or k_{DPR}/k_{RL} at zero-pile contribution to DPRF. For the former case, the constant factor A was calculated in case of DPRF where $k_{DPR} \approx k_{RL} \approx k_{PR}$ is satisfied. It was calculated to have values of A ranged 1.01–1.03. In the latter case, A has value of 1 since zero-pile contribution implies RL foundation. Finally, the averaged value of A=1.02 was applied.

4.4 *Validation*

Figure 4 compares the measured k_{DPR} and estimated k_{DPR} via Equation 2-4. Good agreement between the measured and estimated values of k_{DPR} was obtained for both cases of included and excluded cases of DPRF while simple formula development process.

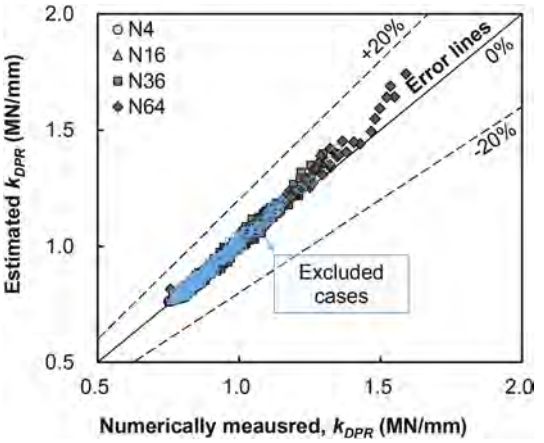

Figure 4. Comparison between the measured and estimated k_{DPR}.

Furthermore, centrifugal testing data of Fioravante and Giretti (2010) and Rasouli et al. (2015) was applied to Equation 2-4 to evaluate the validity of suggested equation in practical field. Since neither of these studies provide the information of E_{ratio} (=i.e., E_{LTP} and E_{sub}), reasonable assumption of this value was made based on the typical correlation of relative density and normalized elastic modulus (E/P_a, where P_a=atmospheric pressure) suggested by Kulhawy and Mayne (1990). As Table 3, it can be concluded that the simple k_{DPR} estimation formula in this study provides reasonable value of k_{DPR} when sufficient information is given.

5 CONCLUSIONS

This study analyzed the effect of both pile-related parameters and load transfer platform (LTP) related parameters on the mechanical behavior of disconnected piled raft foundation (DPRF). Consistent to conventional piled raft foundation, increment of pile length, pile spacing and pile number increased stiffness of DPRF. Increment of stiffness of LTP layer increased stiffness of DPRF while increment of thickness of LTP layer decreased stiffness of DPRF. Furthermore, this study suggests a simple formula to estimate the stiffness of DPRF by considering contribution of piles to the behavior of DPRF that depends on given design parameters. The validity of

Table 3. Validation process of suggested formula with physical testing data.

ABSTRACT: The work is devoted to a comprehensive study of the bases and foundations of electric furnaces No. 61 and 63 of the melting shop of the Aksu ferroalloy plant. Engineering-geological and hydrogeological surveys of souls, geophysical work, as well as studies of the technical condition of existing foundations were carried out.

Based on the conducted comprehensive scientific and technical studies of the mechanism of interaction of the foundation with the ground foundation, a fundamentally new calculation model has been developed that allows calculating the precipitation of buildings taking into account the long-term water saturation of the foundation soils and an assessment of the reliability of the existing foundations of electric furnaces No. 61 and 63 of smelting shop No. 6 with the possibility of their reconstruction in connection with the upcoming renovation.

1 INTRODUCTION

Aksu Ferroalloy Plant is located on the territory of Pavlodar region, 20 km southwest of Pavlodar and 2.5 km north of Aksu, on the left bank of the Irtysh river. The production infrastructure of the city is represented by two city-forming enterprises: the Aksu Ferroalloy Plant and the electric station of JSC "EEC". The object is connected by asphalt and railways with the cities of Nur-Sultan, Pavlodar, Ekibastuz, Semipalatinsk. Aksu Ferroalloy Plant is a ferrous metallurgy enterprise for the production of high-carbon ferrochrome, manganese and siliceous alloys.

The smelting building of shop No. 6 of the Aksu Ferroalloy Plant is designed for the production of high-carbon ferrochrome. Aksu Ferroalloy Plant is a two-span industrial building of complex shape in plan. This object has overall dimensions in plan in the axes "1-24, A-B" – 276x24 m, in the axes "1-20, B-C" – 228x24 m and one deformation seam in the axes "21, A-B". Gas treatment facilities are adjacent to the building of the smelting building in the axes "1-4, A". The rigidity of the building is ensured jointly by the work of foundations, metal frame elements, vertical and horizontal stiffness connections, coating and floor slabs.

Engineering and geological surveys revealed that clay serves as the bearing base for the foundations of electric furnaces No. 61 and No. 63 (CLAY N1 1-2 ar is opened everywhere at depths of 0.1–4.8 m). The exposed thickness of the clay thickness varies from 3.2 m to 26.7 m . With a relative swelling value of 0.005, the calculated swelling pressure is 3.0 kgf/cm2. The exposed

DOI: 10.1201/9781003299127-190

thickness of the Neogene clays of the Aral formation is considered to be strongly swelling, according to the complexity of engineering and geological conditions according to the Joint Venture of the Republic of Kazakhstan 1.02-102-2014 the survey site belongs to the III category.

According to the field description, the clays are greenish-gray, light gray, dark gray, with the inclusion of gypsum, dense, having the following characteristics:

γ = 18, 1 kN/m^3; γ_s = 25,2 kN/m^3; γ_d = 13,9 kN/m^3; $\varphi_{II} = 7^0$; c_{II} = 10,8 kPa; E_0 = 10 MPa; S_r = 0,95; e = 0,816.

The foundation of Fo-37 for the electric furnace RKZ-63-I1 No. 61 is monolithic reinforced concrete, filled in the form of a disk with a diameter of 12.00 m and a depth of laying – 3.0 m from the level of the clean floor of the first floor of the melting shop No. 6. The foundation of Fo-1 for the electric furnace RKZ-63-I1 No. 63 is monolithic reinforced concrete, made in the form of a disk with a diameter of 14.26 m with rectangular protrusions, a depth of laying -2.30 m from the level of the clean floor of the first floor of the melting shop No. 6.

Based on the field visual description of engineering and geological workings, confirmed by the results of laboratory tests of soils, it was found that up to a depth of 8.0-30.0 m in the geological structure of the survey site, the following take part (up-down): • quaternary deposits, represented by large sands and coarse sands; Neogene clays Pavlodar suite. From the surface, these formations are covered with a layer of bulk soils.

Control calculations of the soil sediment of the foundations were carried out in accordance with the requirements of the current building regulations - SP RK 5.01-102-2013 The basis of buildings and structures [1, 2].

According to the requirements of the norms, the calculation of the sediment of the flooded bases is carried out taking into account the decrease in the modulus of deformation of the soils during their soaking and the change in the stress state of the compressible zone of the foundation base following hydrostatic and hydrodynamic weighing. At the same time, the main reason for the decrease in the modulus of deformation of soils subject to flooding is mainly due to the weakening of their structure due to water saturation. In this regard, when geotechnical design of buildings and structures in conditions of flooded soil bases, it will be advisable to adhere to the basic principles applied to subsidence soils based on the use of the results of compression tests [3, 4].

Construction practice shows that the operational reliability and durability of buildings and structures under construction mainly depend on the reliability of the results of engineering and geological surveys used as input data in geotechnical design. In particular, the calculation of foundation bases according to the second limit state imposes high requirements on the accuracy of determining the values of the soil deformation modulus, on which the risk of accidents of constructed objects directly depends. However, there is still uncertainty in the choice of this important characteristic of soil compressibility, which is due to a significant discrepancy between its values determined by laboratory (compression) and field (stamp) methods.

As is known, compression tests have found wide application in the practice of engineering and geological surveys as one of the main methods for determining the deformation characteristics of the soils of the bases of the projected foundations (GOST 12248-2010). Such tests are characterized by simplicity, low labor intensity and cost.

The compression dependence reflects one of the laws of porosity of dispersed bodies – the law of compaction and is used to solve the main problem of soil mechanics, determining the precipitation of the soil layer under continuous load.

However, at present, according to the current norms (SP 22.13330, 2016), the results of compression experiments are used in the design of foundations on structurally unstable soils and are not directly used in the calculations of deformations of foundations composed of ordinary soils. In accordance with the requirements of standards for buildings and structures of geotechnical category 2 and 3, the value of E according to compression tests for each soil layer should be adjusted based on their comparison with the results of parallel stamp, pressiometric tests, which have a high cost and high labor intensity.

To determine the precipitation of the flooded foundations of newly erected and existing buildings, it is necessary to have the actual dimensions of local sections of water-saturated soil within the active area of the foundation of the foundation under construction and inhomogeneously compacted zones of the foundation of existing foundations. However, the methods of

the current norms based on the theory of linearly deformable bodies, the object of study of which, according to its basic prerequisites, is a conditional, idealized foundation soil as an isotropic solid, are not acceptable for solving such a complex geotech problem. Because this theory does not allow us to predict the actual dimensions of the parameters of the deformed zone of the base, allowing errors of more than 100%, but, as experiments show, its application to calculate stresses in real soils gives quite satisfactory results with an accuracy of 20% [5, 6].

2 METHODOLOGY

Calculation of the sediment of the existing foundations of furnaces No. 61 and No. 63 of the Aksu Ferroalloy Plant, taking into account the flooding of the foundation soils in the operational period by the modulless method.

The forecast of the development of foundation precipitation caused by flooding of previously compacted soils of its base during the operational period is an insufficiently studied complex task. To solve it, we will make assumptions, according to which we will assume that "the precipitation of the base from the prolonged action of loads is stabilized, and the soils are compacted inhomogeneously within the compressed zone in accordance with its stressed state, therefore, additional precipitation of the existing foundation in the process of flooding its base occurs by analogy with the phenomenon of subsidence due to weakening soil structures in the process of soaking".

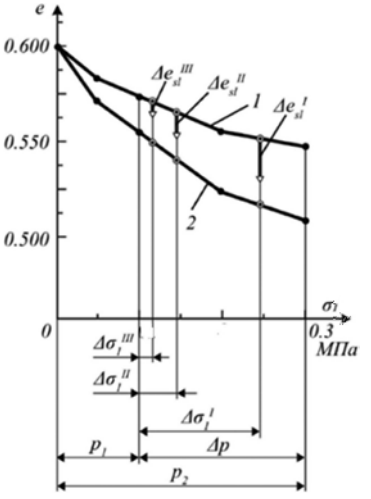

Figure 1. Compression curves of the soil of the foundation base: 1 и 2 – experimental soil compression curves with natural humidity and in a water-saturated state; ● - experimental points; ⊙ - points on the experimental curves used in the calculation of precipitation by the non-modular method; ▽ - prospective test points obtained as a result of soaking of long-compacted soils of the base of the existing foundation.

The following formula is used to determine precipitation without a modular method:

$$S = \frac{1}{A_\Phi} \cdot \sum_{i=1}^{i=n} \left[V_{i3} \cdot \left(1 - \frac{1 + e_2^{i3}}{1 + e_1} \right) \right], \quad (1)$$

where i and n – number and number of dedicated compacted base zones;

$A_ф$ – the area of the sole of the foundation;

Viз – volume of the i – th compacted zone of the base;

e_1 – the porosity coefficient of the soil of natural composition;

$e_2^{iз}$ - porosity coefficient of soil compacted under compressive stress $\Delta\sigma_1^{iз}$, arising in the i – th zone from an external load.

3 RESULTS

The proposed model-free method can also be used to calculate the sediment of foundations having the shape of a sole in the form of a circle, a square and a straight square.

As a result of modeling the behavior of the existing foundation during flooding of its base by conducting three parallel compression tests with soil samples pre-compacted under loads $\Delta\sigma_1^{I}$, $\Delta\sigma_1^{II}$ and $\Delta\sigma_1^{III}$ and subjected to soaking under the same loads, the corresponding values of reducing the porosity coefficient of the soil were obtained $\Delta e_{sl}^{I} = 0{,}024$; $\Delta e_{sl}^{II} = 0{,}018$; $\Delta e_{sl}^{III} = 0{,}012$.

At the same time, additional precipitation of the foundation of the existing building, taking into account the factors of soil compaction and subsequent flooding, amounted to: for position 2 (WL_1) $s_{sat.ex} = 1{,}40$ cm; for position 3 (WL_2) $s_{sat.ex} = 4{,}6$ cm; for position 4 (WL_3) $s_{sat.ex} = 7{,}5$ cm.

Thus, the proposed method, in comparison with the recommendations of the norms, makes it possible to more accurately and reliably predict the nature of the development of additional sediments of the flooded foundations of existing buildings, establish the permissible amount of groundwater level rise and determine the optimal depth of water reduction.

4 DISCUSSIONS

According to engineering and geological surveys, an uneven increase in the groundwater level was noted at the site, which indicates that water saturation of the foundation soils, including swelling clay, occurred for a long time, which usually leads to the development of unacceptable deformations of the foundation and reduces its operational reliability. In addition, with the continuous annual seasonal flooding of the territory (min to the level of 127.30 and max. up to the level of 128.00), the compressibility characteristics (modulus of deformation E_0) and strength (c, φ) of the soils of the base layers undergo significant changes, as a rule, a decrease of 2 or more times, and these changes in space are also uneven in the supporting area of the foundation and in the depth of the base.

Thus, loading of the flooded foundation, composed of swelling soils, in conditions of poor drainability can lead to a dangerous unstable condition of the foundations. In such a situation, as a result of the lag of the "water filtration process" from the "soil compaction process (pore reduction)", the excess pressure in the pore water sharply increases, which leads the foundation to an unstable state or is the cause of the development of excessive plastic deformations of the soil.

5 CONCLUSIONS

The periodically recurring (cyclically) process of flooding of the foundation soils does not favorably affect the nature of the development of foundation sediments, namely, it causes their unevenness, which can be seen from the following analysis of the results of control calculations:

a) when calculating by the method of layer-by-layer summation, an increase in foundation sediment due to the influence of the weighing action of ground water, as can be seen from the following comparison: 5.85 cm < 6.84 cm;
b) when calculating by the non-modular method, the additional precipitation of the foundation of the existing building, taking into account the factors of soil compaction and subsequent flooding, amounted to: 1.40 cm<4.6 cm<7.5 cm. What shows the real values of the precipitation of foundations caused by the flooding of the foundation soils, taking into account the additional change in the compressibility of soils: an increase during watering or a decrease during drying.

Performance of sheet piles subjected to vertical loadings in saturated clay ground

X. Xiong
Kanazawa University, Ishikawa, Japan

L.T. Hoang
Thuyloi University, Hanoi, Vietnam

ABSTRACT: Recently, with the development of new piling methods, steel sheet piles can be penetrated into various grounds with high quality and precision. Though the piles for deep foundations are usually pipe piles, sheet piles could become an alternative. However, the bearing capacities of sheet piles have not been clarified fully yet. In this research, a series of monotonic and quasi-static cyclic load tests on model steel sheet piles in a saturated clay ground have been conducted. The test results show that excess pore water pressures generated during the pile installation and loading, as well as cyclic loading significantly influenced the bearing capacities. Moreover, compared with pile tip resistance, shaft resistance was more influenced by the excess pore water pressures generated and the effect of consolidation. Therefore, the bearing capacity of sheet piles immediately after pile penetration could be used as an index for conservative design.

1 INTRODUCTION

Generally, the piles for deep foundations are concrete piles or steel pipe piles. In recent years, piling methods, such as the Silent Piler and Gyro Piler, have been developed. Using these technologies, steel sheet piles, structures with sheet sections and interlocking edges, can be penetrated into grounds with high quality and precision under various geological conditions (Otani, 2021). Considering that the construction time and cost of sheet piles could be lower than those of pipe piles, therefore, sheet piles could become an alternative to pipe piles for deep foundations.

Considering the space constraints of construction in urban areas, Koda et al. (2003) first proposed a sheet pile foundation by installing sheet pile walls around an existing footing. Recently, a few studies have been conducted to investigate the bearing capacity of sheet piles as foundations to support superstructure. Guo et al. (2021) conducted a series of static load tests on various model pile foundations to investigate the performances of different pile types on dry sand and found that sheet pile foundations would be a promising alternative to conventional pipe pile foundations. However, the performance of sheet piles in clay ground, with high degree of saturation, has not been clarified fully yet.

Therefore, in this paper, a series of monotonic and quasi-static cyclic load tests on model sheet piles in a saturated clay ground have been conducted. Excessive pore water pressures (EPWPs) around the model piles were carefully measured during the load tests to investigate the interaction between the piles and the ground.

2 EXPERIMENTAL DESCRIPTION

2.1 *Model grounds*

Clay ground was prepared in a cylindrical chamber of height 420 mm and diameter 420 mm. The soil used for the model ground was a mixture of Kasaoka clay and Silica sand #6. The model ground was prepared following the procedure reported by Hoang & Matsumoto (2020).

DOI: 10.1201/9781003299127-191

Dry Kasaoka clay powder and Silica sand #6 were mixed at a mass ratio of 1:1 (called K50S50), and water was then added to the mixture to obtain a soil slurry with a water content of 1.3 *LL* (*LL*: liquid limit). This soil slurry was poured into the soil chamber and a vertical load was applied to the soil to consolidate the soil one-dimensionally in several steps up to vertical stress of 100 kPa. Table 1 shows the properties of the model grounds.

2.2 *Model piles*

The model pile used in experiments is shown in Figure 1. Two acrylic plates were used to represent sheet pile walls, which have a width of 40 mm, a length of 195 mm and a thickness of 2 mm. The Young's modulus of the model pile is 3.57 GPa, and the Poisson's ratio is 0.35. To obtain the axial force in the pile, twelve strain gauges were attached on opposite sides of each model pile.

2.3 *Test instrumentation and procedure*

Figure 2 shows test devices and instrumentation used in model tests. During the load tests, the vertical load was applied by a screw jack and was measured utilizing a load cell. Pore water pressure sensors were set 20 mm below the ground surface, and their locations are shown in Figure 3. During the experiments, pile penetration tests (PPTs) were first conducted, and the two model piles (SP1 and SP2) were penetrated into the model ground one by one (Figure 3). Then, monotonic vertical load test (VLT) was conducted on SP1 immediately and on SP2 24 hrs after the installation process to investigate the consolidation effect on the pile capacity. After the dissipation of EPWPs, quasi-static cyclic load tests (CLTs) were conducted on the two piles. And again, VLT was conducted on SP1 immediately and on SP2 24 hrs after CLT to investigate the influence of earthquake.

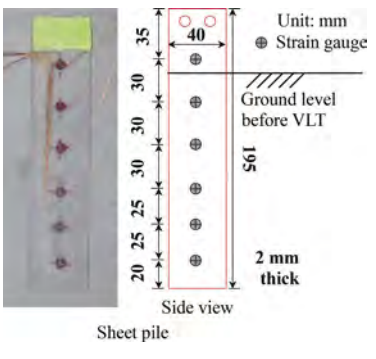

Figure 1. Model sheet pile.

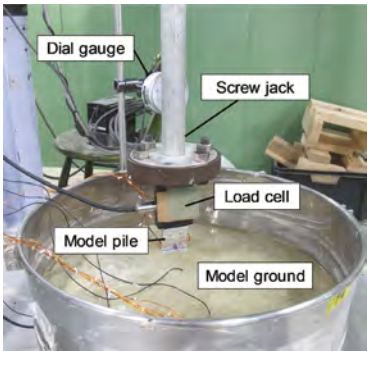

Figure 2. Test devices and instrumentation.

3 EXPERIMENT RESULTS

3.1 *Results of PPTs*

Figures 4 and 5 show the results of PPT on SP1 and SP2. It can be found from Figure 4 that the vertical load applied to the pile head, P_v, increased with the increase in settlement, w. Notably, there was no significant difference in the load-settlement behaviors of the two model piles. EPWPs were generated around the piles during PPTs, as shown in Figure 5. Except EPWP at PWP3, EPWP at other locations increased sharply at first and then turned to decrease gradually. The peak EPWP occurred at w reaching around 25 mm when the pile heads just passed through the level of pore water pressure sensors. This means that the largest EPWP occurred around the pile heads during PPTs. Furthermore, it is clear that EPWP still remained at the end of PPT.

3.2 *Results of VLTs*

The monotonic VLT was conducted on SP1 immediately and on SP2 24 hrs after PPTs. According to Hoang & Matsumoto (2020), the period of 24 hrs is the necessary for the EPWP generated

during the installation process to completely dissipate. As shown in Figure 6, after 24 hrs of consolidation, the yield P_v of SP increased significantly from 93 N to 139 N (increased around 50%). Comparing with PPTs, the measured EPWP during VLTs was very small (Figure 7). It seems reasonable to assume that lager EPWP was also generated around the pile head at a depth of about 150 mm, which is quite far from the locations of PWP sensors, during VLTs.

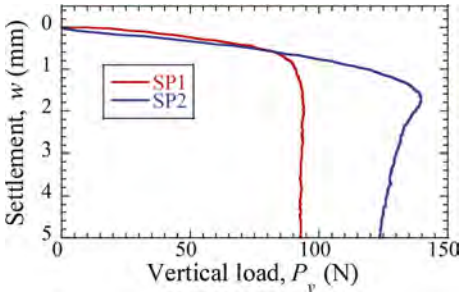

Figure 6. Load-settlement behavior during VLT.

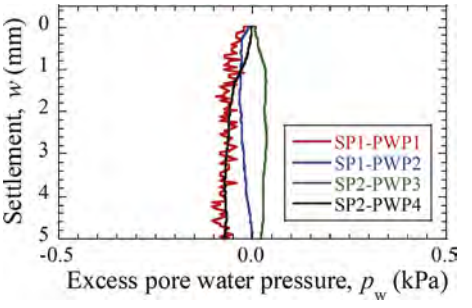

Figure 7. EPWP-settlement behavior during VLT.

3.3 *Results of CLTs*

CLTs were conducted on the two model piles 24 hrs after VLTs. During CLTs, the screw jack pushed and pulled the model piles within 1 mm penetration at a speed of 0.2 mm/s for a total of 50 times to simulate the vertical component of external load from an earthquake. Figure 8 shows the EPWPs generated during CLTs. It can be found that EPWPs accumulated with the increase in cyclic loading times. The signs of EPWPs on both sides of the pile were opposite, indicating that the pile was bent during the CLTs.

Figures 9 and 10 show the results of VLTs conducted on SP1 immediately and on SP2 24 hrs after CLTs. Pile tip resistance, P_t, was calculated from the axial strain near the pile tip, and pile shaft resistance, P_f, was obtained by subtracting P_t from P_v. Regarding P_v, the bearing capacity of SP significantly reduced subjected to cyclic loading. Though the yield P_v recovered a lot 24 hrs after CLT (Figure10), it was much smaller than the yield P_v before CLT (Figure 6, SP2). Moreover, though P_f carried almost the same load with P_t in the case of SP1, it carried a much greater load than P_t in the case of SP2. Compared with P_t, P_f was more influenced by the EPWPs generated during CLTs and the effect of consolidation.

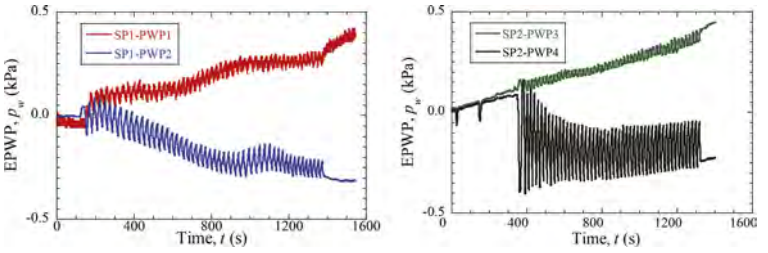

Figure 8. Time-EPWP behavior during CLT.

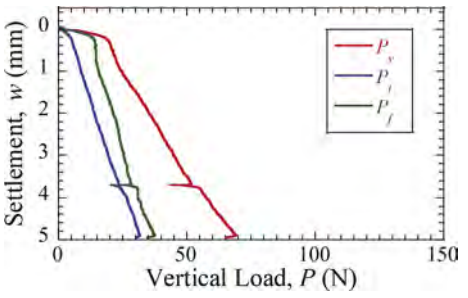

Figure 9. Load-settlement behaviour of SP1.

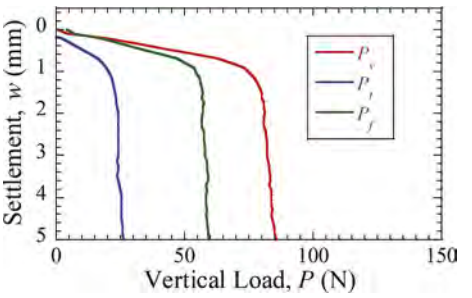

Figure 10. Load-settlement behaviour of SP2.

4 CONCLUSIONS

To investigate the performance of sheet piles in saturated clay ground, a series of monotonic and quasi-static cyclic load tests on model sheet piles have been conducted in this paper. The experimental results show that EPWPs generated during the pile installation and cyclic loading significantly influenced the pile bearing capacities. Moreover, compared with P_t, P_f was more influenced by the EPWPs and the effect of consolidation. Therefore, the bearing capacities of sheet piles immediately after pile penetration could be used as an index for conservative design.

Examination of the ultimate bearing capacity formula regarding size effect and relative density for sandy soils

T. Iqbal, S. Ohtsuka & Y. Fukumoto
Nagaoka University of Technology, Nagaoka, Japan

K. Isobe
Hokkaido University, Hokkaido, Japan

ABSTRACT: It is proven that the sandy soils exhibit the non-linear trend in the shear stress-normal stress space. This study discusses the assessment of the UBC of surface strip footing on sandy soils concerning size effect and relative density subjected to centric vertical and uniform surcharge loads. The RPFEM, based on the shear strength property of Toyoura sand, is employed in analyses. The findings are consonant with the centrifuge tests in the published references. The results are compared with the existing guidelines, and the modified UBC formula is proposed.

1 INTRODUCTION

The ultimate bearing capacity (UBC) formulas being widely used in Japan are those recommended by the Architectural Institute of Japan's guidelines (AIJ 1988, 2001, 2019) and the Japan Road Association's specifications (JRA 2017). The simplified JRA bearing capacity formula for sandy soils is expressed as Equation 1 in the case of surface strip footing, while the AIJ guidelines do not consider the modification factor for the surcharge term.

$$q_u = \frac{1}{2}\gamma B N_\gamma S_\gamma + q N_q S_q \quad \text{where} \quad S_\gamma = (B)^{\frac{-1}{3}} \;\&\; S_q = \left(\frac{q}{q_o}\right)^{\frac{-1}{3}}, 1 \le \frac{q}{q_o} \le 10 \tag{1}$$

In the above equation, N_γ and N_q depict the well-known bearing capacity factors, γ denotes the soil unit weight underneath the footing, B accounts for the footing size, S_γ and S_q symbolize the size effect modification factors for N_γ and N_q, respectively, and q describes the surcharge load. Besides, q_o=10 kPa is taken as a reference value in the surcharge load.

In both AIJ and JRA formulas, the size effect factor for N_γ only considers the effect of footing size. However, notable experimental studies have underscored the importance of soil unit weight (γ) in estimating the stress level effect on UBC through the term γB (Okahara et al. 1988). Likewise, the effect of relative density (D_r) on UBC through internal friction angle ϕ has been highlighted through numerous experimental investigations (Tatsuoka et al. 1986). Therefore, this study estimates the size effect of footing on UBC under centric vertical and uniform surcharge loads in case of total and effective stress analysis conditions. The rigid plastic finite element method (RPFEM), by using the non-linear yielding characteristics of Toyoura sand, is used in numerical computations. A modified UBC formula is proposed, and its performance is assessed in the case of various relative densities of Toyoura sand.

2 RIGID PLASTIC FINITE ELEMENT ANALYSIS FOR SANDY SOILS

2.1 *Yield function*

The non-linear yield function employed in this study is expressed through Equation 2:

DOI: 10.1201/9781003299127-192

$$f(\boldsymbol{\sigma}) = aI_1 + (J_2)^n = b \tag{2}$$

In the above equation, a and b account for the material shear strength characteristics, i.e. internal friction and cohesion, respectively, while n denotes the non-linearity of the failure envelope in relation to the first stress invariant, I_1, and the second invariant of deviator stress, J_2. The non-linear rigid plastic constitutive equation is used for the numerical analysis (Nguyen et al. 2016).

2.2 *Non-linear shear strength property of sandy soil*

Physical properties of Toyoura sand were utilized, having specific gravity; G_s=2.64, maximum and minimum void ratios; e_{max}=0.977 and e_{min}=0.605, respectively (Tatsuoka et al. 1986). The experimental data of Tatsuoka et al. (1986) are extrapolated to estimate the y-intercept, i.e. initial internal friction angle (ϕ_0) against each void ratio (e) as depicted in Figure 1, to develop a normalized relationship of internal friction angle corresponding to various stress levels (Figure 2). In Figure 2, the relationships are drawn for each void ratio as well as the mean trendline by using the least squares method. Based on relationships pertaining to the various void ratios and mean trendline, the non-linear shear strength parameters are set in Tables 1 & 2, respectively.

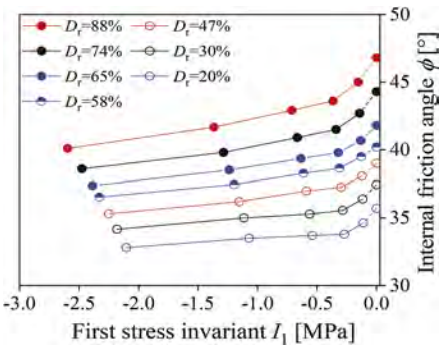

Figure 1. Relationship between ϕ and I_1 for Toyoura sand (after Tatsuoka et al. (1986)).

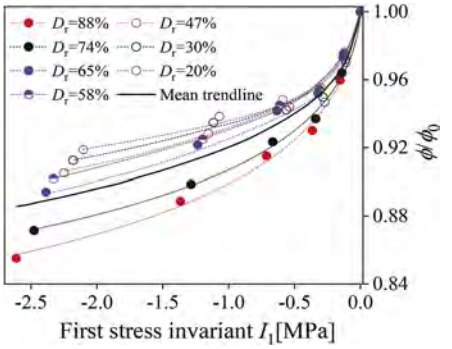

Figure 2. Normalized relationship between ϕ/ϕ_0 and I_1 for Toyoura sand.

3 EXAMINATION OF UBC FORMULA FOR SANDY SOILS

3.1 *Ultimate bearing capacity analysis under centric vertical load*

The analysis method is validated against the centrifuge experiments in the published references (Figure 3). Figure 4 indicates good agreement of analysis results by RPFEM with those from the AIJ and JRA formulas in the case of γ=18 kN/m^3 for centric vertical load without surcharge. Figure 5 investigates the normalized UBC against $\gamma B/p_a$ for varying γ and B. The term γB is normalized with respect to normalization factor p_a, i.e. standard atmospheric pressure, p_a=101.325 kPa. The trendline evinces diminution in normalized UBC with increased stress

levels by stepping up both γ and B (Figure 5). Apropos, modification factor η_γ is inevitable, as the effect of γ is not well conceived in the AIJ and JRA formulas (Figure 5). The size effect modification coefficientη_γ is described as ($2q_u/\gamma BN_\gamma$) and graphically illustrated in Figure 6. The data plotted in Figure 6 is fitted with the mean trendline using the least squares method. The mean relationship for η_γ can be closely approximated as given in Equation 3.

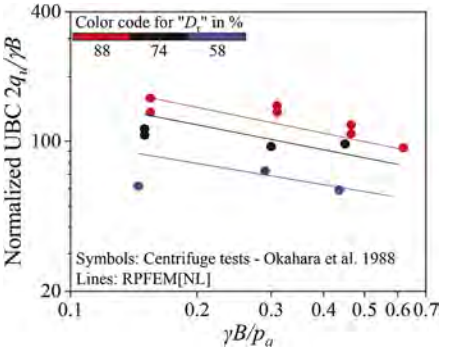

Figure 3. Validation of the analysis method in comparison with the centrifuge tests on Toyoura sand.

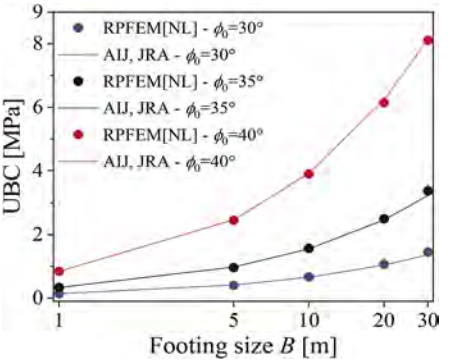

Figure 4. Comparison of ultimate bearing capacity results in case of γ=18 kN/m^3.

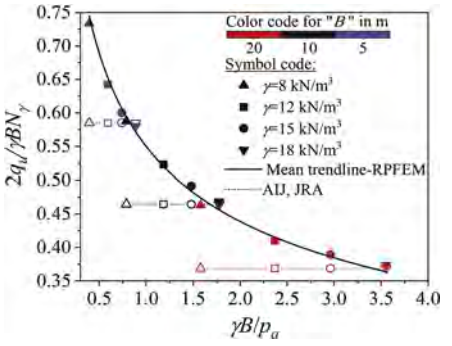

Figure 5. Effect of γ on normalized UBC ($2q_u/\gamma BN_\gamma$) in case of ϕ_0=35°.

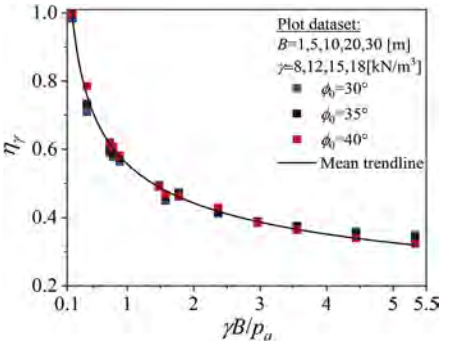

Figure 6. Relationship between modification coefficient η_γ and $\gamma B/p_a$ in case of Toyoura sand.

Hence, the modified UBC formula for the sandy soils, based on the analysis results, is as follows:

$$q_u = \frac{1}{2}\gamma BN_\gamma\eta_\gamma \quad \text{where} \quad \eta_\gamma = 0.55\left(\frac{\gamma B}{p_a}\right)^{\frac{-1}{3}} \; 0 \le \eta_\gamma \le 1 \tag{3}$$

3.2 *Discussion on UBC formula for surcharge loading*

Figure 7 elucidates the trend in UBC against surcharge load amidst RPFEM and other guidelines under the effective stress condition, i.e. γ=8 kN/m^3. The numerical outcomes in Figure 7 exhibit a substantial difference from the AIJ and JRA formulas, therefore, a modification coefficient η_q is necessary to be proposed for N_q. η_q is equal to $\{(q_u\text{-}0.5\gamma BN_\gamma\eta_\gamma)/qN_q\}$ and plotted in Figure 8 against q/p_a for various footing sizes and shear strength characteristics. Here, q denotes the uniform surcharge load. The decrementing trend in η_q is primarily associated with the reduced peak friction angle due to the augmented stress at higher surcharges. The best fit relationship of η_q based on Figure 8, and the modified UBC formula, are proposed as Equation 4. Here, N_γ and N_q

correspond to the Meyerhof bearing capacity factors. Like AIJ recommendations, this study also recommends cutting off the bearing capacity factors at and beyond ϕ=40°. The performance of the proposed formula is surveyed against RPFEM results for various D_r in the case of Toyoura sand (Figure 9). In comparison to the other prevailing guidelines, the proposed UBC formula (Eq. 4) well estimates the size effect concerning γ, B and q (Figure 10).

$$q_u = \left(\frac{1}{2}\gamma B N_\gamma \eta_\gamma\right) + \left(qN_q\eta_q\right) \quad \text{where} \quad \eta_q = 0.55\left(\frac{q}{p_a}\right)^{\frac{-1}{8}} \quad 0 \le \eta_q \le 1 \tag{4}$$

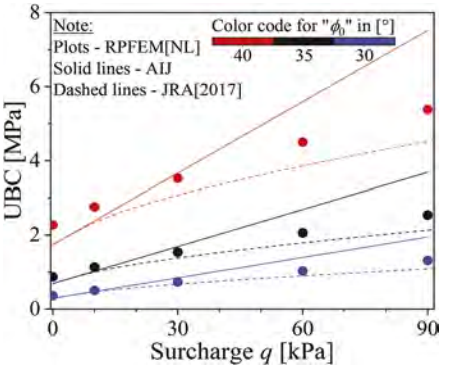

Figure 7. Comparison of ultimate bearing capacity in case of B=10 m and γ=8 kN/m^3.

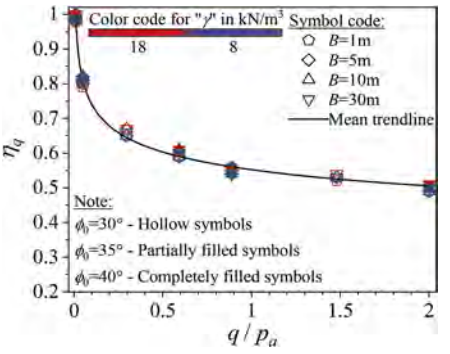

Figure 8. Relationship between modification factor η_q and (q/p_a).

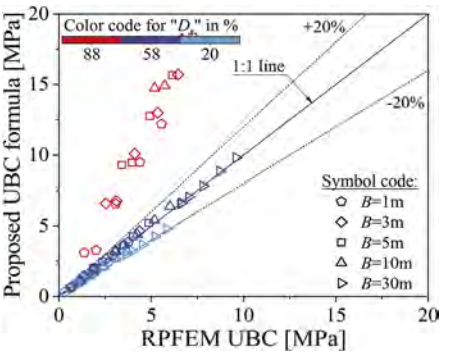

Figure 9. Performance of proposed UBC formula in case of Toyoura sand (q=0-90 kPa).

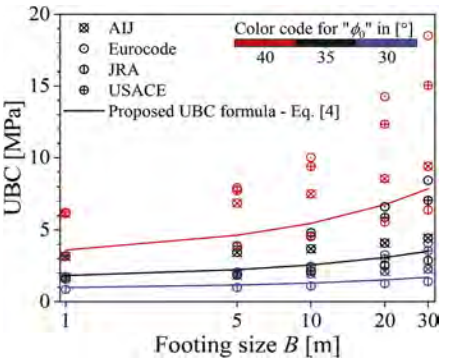

Figure 10. Performance of proposed UBC formula in case of γ=8 kN/m^3, q=90 kPa.

4 CONCLUSIONS

A UBC formula was examined and improved based on the mechanical property of Toyoura sand. The numerical method was validated through centrifuge tests in the published references. The effect of γ was clarified to be well indicated by normalized variable ($\gamma B/p_a$) regarding size effect and the correction factor for N_γ was newly proposed. Furthermore, a correction factor for N_q was proposed, owing to the contradiction amid AIJ and JRA formulas regarding size effect due to the surcharge load. The proposed formula estimates the size effect within ≈±20% for loose to medium dense Toyoura sand. However, the proposed UBC formula can be widely used for UBC estimation by cutting off the bearing capacity factors at and beyond ϕ=40°. Moreover, the international guidelines such as U.S. Army Corps of Engineers (USACE) and Eurocode are also found to have limited applicability concerning the size effect. The aptness of JRA specifications was found to be applicable from an engineering viewpoint.

Ultimate bearing capacity of a shallow foundation on unsaturated sandy soil with cavity

E.L. Keba
Hokkaido University, Graduate School of Engineering, Sapporo, Japan

K. Isobe
Hokkaido University, Faculty of Engineering, Sapporo, Japan

ABSTRACT: A series of model footings tests were conducted on unsaturated sand with cavity. The cavity was created using an easily found commercial balloon, placed, and expanded within the model soil. The unsaturated soil was vertically loaded using a circular model footing of diameter $B = 30$ mm after the balloon was deflated. The load versus displacement curves reveal the increase of the ultimate bearing capacity of footing on sand with cavities in deeper layers. The Rigid Plastic Finite Element analysis results are introduced to apprehend the variation of bearing capacity of a footing resting on ground with cavity and confirm the experimental results. As a result, the trade-off relationship between matric suction and effective stress, from the fact that giving higher values of ultimate bearing capacity in deeper cavity cases and lower ultimate bearing capacity in shallower cavity cases, comparing to the cases without consideration of the ground water table.

1 INTRODUCTION

Underground cavity can occur in the ground due to both natural causes (karst dissolution), and manmade causes (tunneling, mining, quarry, defective sewage pipes, etc.). The karst environment occurs in over 20% of the earth's ice-free continental area and 25% of the global population depends on the karst water supply (Ford & Williams, 2007). On the other hand, as the demand for land grows and humans increasingly modify their environment, more and more people might be exposed to the instabilities caused by underground cavities (Holzer, 2009). Researchers analyzed the behavior of ground with cavity and the bearing capacity of the shallow foundation above the ground with cavity (Baus & Wang, 1983; Augarde C.E. et al, 2003). Progress in unsaturated soil mechanics revealed the contribution of the matric suction toward the increase of the shear strength of unsaturated soils (Fredlund & Rahardjo, 1993; Costa, 2003). Oh & Vanapalli (2013) modified the total stress approach and the effective stress approach for the saturated soils to unsaturated soils considering the influence of matric suction.

Previous conventional saturated soil mechanics applications to unsaturated soil might lead to underestimate the ultimate bearing capacity in the design and construction processes. In the semi-arid area, shallow foundations are found in an unsaturated state during their life cycle. Thus, no investigation addressing the issue of ground with a cavity under unsaturated conditions has been found in the literature. This paper introduces an experimental analysis of the ultimate bearing capacity of a footing above an unsaturated sandy soil with a cavity. Results are compared with numerical analysis conducted with the Rigid Plastic Finite Element Method (RPFEM), whose detail is referred in the literature (Du, N.L. et al., 2016), to obtain the influence zone of a cavity within the ground against the bearing capacity. The sandy soil (silica sand No.7) in the model tests was prepared in layers at a relative density of $D_r = 70\%$. The results and different observations are summarized and presented in the following lines.

DOI: 10.1201/9781003299127-193

2 TEST EQUIPMENT AND PROCEDURES

Several model footing tests were conducted considering the different depths of the cavity and saturation degrees. Figure 1 illustrates the equipment used in this study.

The acrylic experimental soil tank has an inner diameter of 300 mm. Valves are connected at the bottom for water supply and soil saturation is realized from the lower part of the model soil to the surface. Air pressure can be supplied from valves on the top metallic plate. A loading device is installed on the top plate of the model soil tank and can be actuated by a motor at a speed of 0.5 mm per minute. The loading device uses a load cell to measure the resistance load received by the footing. The soil (silica sand No.7) sample is dropped into the tank from a certain height and prepared in 10 layers of 30 mm thick each. Table 1 summarizes the soil properties.

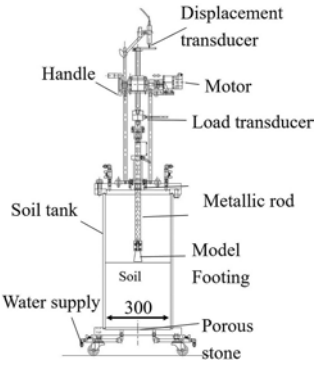

Figure 1. Schematic view of the equipment.

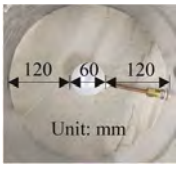

Figure 2. Balloon inserted within the tank.

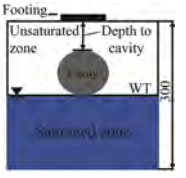

Figure 3. Illustration of unsaturated soil model with cavity.

Table 1. Soil properties.

Soil type	Dry unit weight γ_d (kN/m^3)	Relative density D_r (%)
Silica sand No. 7	14.8	70

After saturation, the water is drained by applying air pressure on the top of the soil out to the desired depth (preferably below the cavity as illustrated in Figure 3 where we assume that the water table is at the limit of the lower part of the cavity). The load and displacement transducers are connected to the computer for recording. The technique used to create the cavity consists of a balloon attached to a tube within the tank, expanded with air, and, its size adjusted to the desired size of the cavity (Figures 2 and 3). This creates a cavity with unsupported walls within the model soil, which is stable enough before the loading process is started. The horizontal and vertical dimensions of the cavity were kept constant (60 mm) before the loading test.

3 RESULTS AND DISCUSSION

The test results on the ground with cavity are presented in form of load-displacement curves under dry and unsaturated conditions (Figure 4). The ultimate bearing capacity for the unsaturated condition cases is summarized in Table 2. Note that their curves for the cases with the cavity depth H = 60 mm in unsaturated and 90 mm in dry conditions clearly reach a peak load considered as the ultimate load. On the other hand, the displacement curves at the cavity depth H = 100, 120, and 150 mm in unsaturated conditions show a linear increase with the load applied. Thus, observe that the ultimate load was defined as the applied load at the displacement corresponding to 10% of the footing diameter B for the cases with the cavity depth H = 100, 120 and 150 mm in unsaturated conditions.

The ultimate load for the cavity at depth H = 150 mm is the largest among all cases. As the cavity (water table) is deeper, the saturation degree is lower. It is, therefore, because matric suction increases the shear strength of the unsaturated sand.

Figure 5 shows RPFEM results that the bearing capacity normalized by the bearing capacity of ground without cavity (BC/BC_{NC}) varies with the normalized horizontal distance from the centerline of the footing (r/D). The ultimate bearing capacity variation in Table 2 can be quantitatively confirmed comparing with the cases beneath the footing at r/D = 0 in Figure 5. The BC/BC_{NC} of the deeper cavity cases tends to be higher along r/D and reach the constant value within a small value of r/D.

For the reference, Table 3 shows a comparison of the ultimate bearing capacity (UBC) obtained in dry conditions and saturated conditions for soil without a cavity. A noticeable decrease in the UBC from dry conditions to saturated conditions is observed.

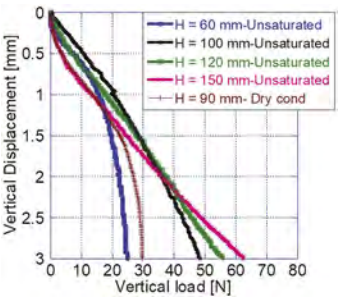

Figure 4. Vertical load vs vertical displacement.

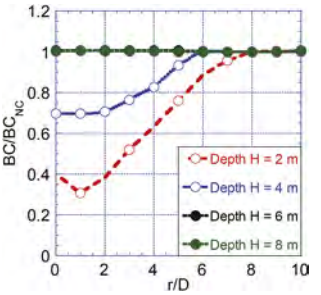

Figure 5. RPFEM results of bearing capacity variation with normalized horizontal distance by cavity diameter r/D.

Table 2. Ultimate bearing capacity obtained in unsaturated conditions.

Depth of cavity H (mm)	Ultimate bearing capacity (kN /m^2)	BC/BC_{NC}	Saturation degree Sr (%)
60	31.2	0.309	47.9
100	65.2	0.645	Unmeasured
120	76.5	0.757	32.3
150	87.7	0.868	29.8

Table 3. Ultimate bearing capacity obtained in dry and saturated conditions without cavity.

Relatively Density Dr (%)	UBC in Dry conditions (kN /m^2)	UBC in Saturated conditions (kN /m^2)
60.0	32.55	3.53
70.0	72.27	2.24

The tables above show an increase in the UBC under unsaturated conditions. The increase of the UBC is even greater for some cases in unsaturated conditions with cavities compared to the cases without cavities in dry and saturated conditions.

Furthermore, the distribution of the porewater pressure in the ground obtained with the RPFEM in Figure 6 shows a zone of negative porewater pressure above the cavity. This confirms the assumption in Figure 3 although the difference in water table shapes around the cavity. The influence of matric suction is revealed by the strain rates distribution around cavities under unsaturated conditions in Figure 7 with the shear bands reaching the cavity. Under the unsaturated condition, the failure mode reveals that the strain rates are concentrated on the edges of the cavity. However, under dry conditions, it should, considering the cavity depth, tend to a general failure mode despite the influence of the cavity. In fact, in the unsaturated cases, the bottom of the cavity is at the boundary of the water table i.e., in the capillary zone where water fills most of the pores and consequently,

a decrease in effective stress occurs. On the contrary, in the upper layers, the generated matric suction increases the soil shear strength as Equation (1) by Karube et al. (1996).

$$C = Se\,(\theta)\tan\phi^{'}.s \tag{1}$$

where C: cohesion under unsaturated condition; $Se\ (\theta)$: effective saturation degree, the function of moisture θ; s: suction; ϕ': effective shear resistance angle.

This study has the merit to embrace a neglected approach up to now regarding the behavior of the shallow foundation above the ground with a cavity. Although the matric suction increases the shear strength of the soil, we need to think about the 'apparent stability' provided by the unsaturated condition in the long term. The collapse of underground cavities is usually sudden, and the water table fluctuates during the life cycle of the foundation. This approach with the revealed trade-off relationship of matric suction and effective stress might be a key to solving the problem.

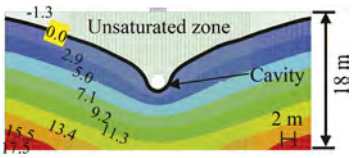

Figure 6. Pore water pressure (kPa) distribution within a ground with a cavity at Depth H = 8 m.

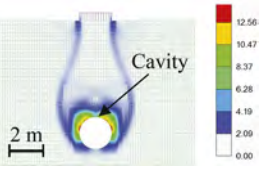

Figure 7. Norm distribution of the strain rate within the ground under unsaturated conditions.

4 CONCLUSION

Several model tests, introducing an easy and cost-effective technique to simulate the cavity in the ground with easily found commercial balloons, were conducted on the ground with a cavity under unsaturated conditions. The trade-off relationship was observed between matric suction and effective stress; giving higher values of ultimate bearing capacity in deeper layers and lower ultimate bearing capacity at a shallow depth of the cavity, compared to the cases without consideration of the groundwater table. The RPFEM results in the cases with the cavity beneath the footing (r/D = 0) qualitatively reproduced the trend of ultimate bearing capacity observed in the model tests. The results can help in understanding the sudden collapse of cavities in the long term as the water table fluctuates within the ground as well as the expansion of the influence zone of a cavity under the observed conditions. Although the measurement of matric suction and saturation degree was not done directly in the present experiments (planned in the future), the designed process proved to be reliable in modeling the ground with a cavity.

Numerical study of lateral resistance of rectangular piles with various pile widths

M. Odagiri, T. Kiriyama & Y. Asaka
Institute of Technology, Shimizu Corporation, Tokyo, Japan

ABSTRACT: The coefficient of lateral subgrade reaction is smaller for piles with wide width. However, applicability for wide piles of reduction factor for lateral reaction with respect to the pile width in pile structural design is unclear. In this study, a 3D FEM model is used to replicate previously reported lateral loading tests on rectangular piles with different widths. A good correspondence between experiment and analysis is achieved. The size of the soil displacement zone during lateral loading of the piles is examined. Pile width is found to affect the lateral subgrade reaction and the extent of the soil deformation area in all three dimensions.

1 INTRODUCTION

It is generally known that the larger the pile width, the smaller the lateral subgrade reaction per width. The design guidelines provide a reduction factor for the coefficient of lateral subgrade reaction with respect to the pile width. However, its applicability to wide piles such as wall-type piles is unclear, and the lateral resistance mechanism of piles is needed to ascertain. In this study, 3D FEM analysis is used to simulate published lateral loading tests of rectangular piles with different pile widths in a centrifuge (Mano et al. 2021) and discuss the effect of pile width on pile lateral resistance based on the size of the soil deformation zone.

2 METHODOLOGY OF 3D-FEM ANALYSIS

2.1 *Outline of experiments and analysis*

The experiments were performed at a centrifugal acceleration of 40g. The model ground was dry Toyoura sand and the relative density *Dr* of the experimental layer exceeded 90%. The rectangular cross-section piles were made of stainless steel. In this study, experimental specimens with equal pile thickness (160mm in prototype scale) and different pile widths (seven cases ranging from 0.4m to 20.4m (the width of the container)) were subject to simulation.

Analyses were implemented using the software SoilPlus. As shown in Table 1, each analysis case (B0.4-B20.4) corresponded to one experimental specimen. Analyses were first performed for initial stress in the gravity field, and then horizontal displacement was applied to the pile head elements (at 0.8 m from the ground surface).

Table 1. Analysis case list.

Case identifier	B0.4	B0.8	B1.2	B2.0	B4.0	B8.0	B20.4
Pile width (m)	0.4	0.8	1.2	2.0	4.0	8.0	20.4
Pile thickness (mm)	160	160	160	160	160	160	160

DOI: 10.1201/9781003299127-194

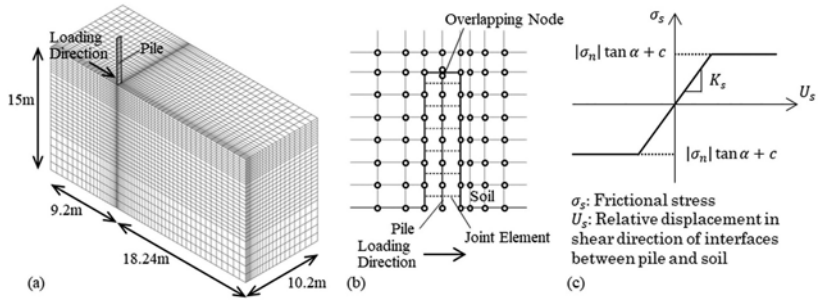

Figure 1. 3D FEM model: (a) entire model (B1.2); (b) plan view of pile region; (c) frictional stress characteristic of joint element.

2.2 *Finite element meshing and material properties*

The finite element mesh for case B1.2 is shown in Figure 1(a). As seen in this figure, half of the domain was modeled by taking advantage of the symmetry in the loading direction. The ground volume is the size of the experimental soil container and is constant regardless of pile width. Soil was modeled with solid elements, while the pile itself was modeled using two-dimensional shell elements. As shown in Figure 1(b), the space representing pile in the soil was void and the interfaces between pile and soil were connected by joint elements. Pile and soil did not have common nodes. The bottom boundary was fixed in all directions. The sides was free to move vertically. In cases B8.0 and B20.4 only, the side parallel to the loading direction was free to move vertically and in the loading direction, because the side walls of the soil container used in experiments were lined with Teflon sheet to remove the effect of friction at the walls.

The material properties are summarized in Table 2. The pile was modeled as a linear elastic perfectly plastic material with a von Mises yield condition. The yield stress was assumed to be 255MN/m^2. The sand was modeled as a linear elastic perfectly plastic material with a Mohr-Coulomb yield condition. The internal friction angle φ of the sand was assumed to be 43° with reference to Hatanaka 1977. Dilatancy angle ψ was 13° ($\psi = \varphi$-30). Cohesion c was 0kPa. The soil was divided into five layers of 3m thickness each in the vertical direction. Shear modulus G was calculated from shear wave velocity Vs obtained in experiments at the center depth of each layer as $0.2 \cdot \rho \cdot Vs^2$ (ρ: density). Taking G as $\rho \cdot Vs^2$ would give a large value, when the constitutive equation of soil is a linear elastic perfectly plastic.

Table 2. Material parameters used in analysis.

Material	Shear modulus G (MPa)	Poisson's ratio ν	Unit weight γ (kN/m^3)	Friction angle φ (deg)	Dilatancy angle ψ (deg)
Pile	7.4×10^4	0.3	77.7	-	-
Soil	$0.2 \cdot \rho \cdot Vs^2$	0.3	16.3	43	13

Joint elements were inserted to model the frictional force, and exfoliation between pile and soil. As shown in Figure 1(c), the frictional stress modeled as a linear elastic perfectly plastic. The maximum frictional force σ_{s_max} was determined by the following equation.

$$\sigma_{s\_max} = |\sigma_n| \tan \alpha + c \tag{1}$$

Where σ_n: normal stresses acting on joint elements; frictional angle α = 26° (coefficient of friction was 0.5); and cohesion c = 0.001 kPa. Shear stiffness K_s was calculated using the following equation.

$$K_s = \tau_{max}/0.02 \tag{2}$$

$$\tau_{max} = K_p \sigma_v \tan \alpha \tag{3}$$

$$K_p = \tan^2\left(45 + \frac{\phi}{2}\right) \tag{4}$$

where σ_v: confining pressure; α: friction angle between pile and soil (26°); and φ: internal friction angle of soil (43°). It is difficult to model the circumferential frictional resistance of a pile under lateral loading correctly. Therefore, in this study, the maximum frictional force acting on the pile is assumed from the Rankine's passive earth pressure, and stiffness K_s was calculated assuming that the frictional force increases linearly until the relative displacement reaches 20 mm.

3 LATERAL SOIL REACTION BY FEM SIMULATION

Figure 2(a)-(c) show the analytical and experimental relationships between load per unit width and horizontal displacement at the loading point for all cases. The experimental and analytical results correspond well, with the load decreasing as the pile width increases. The loads in the analysis are slightly larger than the experimental results. Figure 2(d)-(e) show the distribution of bending moment per unit width in the depth direction when the lateral load per unit width applied to the pile was about 250kN/m (for cases B0.4 and B20.4, respectively). Here, the analysis reproduces the phenomenon by which maximum bending moment value increases as the pile width increases and the depth at which it develops increases.

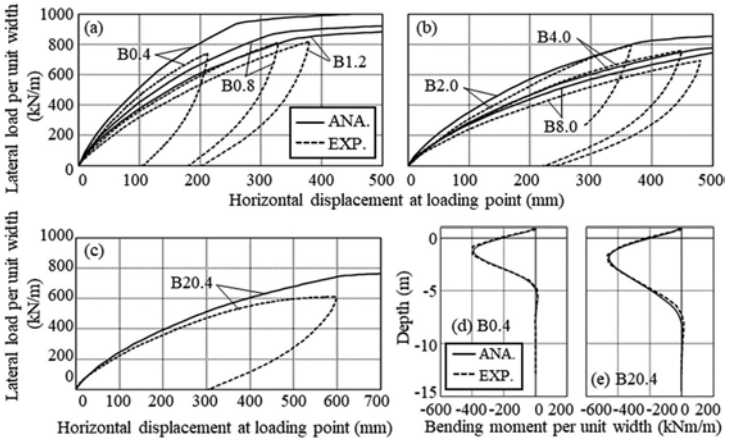

Figure 2. Analytical results vs experimental results: (a)-(c) load per unit width vs displacement; (d), (e) bending moment distribution of piles (B0.4 and B20.4).

The following discuss the results of the analyses. Figure 3 shows lateral subgrade reaction at a depth of 1.5m. Lateral subgrade reaction was calculated by differentiating the shear force of the pile in the direction of depth. Figure 3(a) shows pile displacement versus lateral subgrade reaction (for cases B0.4, B1.2, B8.0, B20.4). The larger the pile width, the smaller the lateral subgrade reaction per unit width. Figure 3(b) shows the relationship between pile width and ratio of lateral subgrade reaction based on case B0.4. Here, lateral subgrade reaction means the value when the pile displacement at 1.5m depth was 10mm. Also plotted on the figure are lines indicating where the lateral subgrade reaction is proportional to the -3/4 to -1/4 power of pile width B. The calculated lateral subgrade reaction is approximately proportional to the -1/2 power of pile width.

Figure 4(a) shows the total displacement contour at the ground surface and for the vertical section through the center of the pile for case B1.2 when pile head displacement was 100 mm. Here, W_x is the extent in the loading direction of the area of soil with a displacement of 20 mm or more. Then, the extent of the deformation area in the direction orthogonal to loading is W_y, and the extent in the depth direction is W_z. The displacement contour at the ground surface shows that W_y exceeds the width of the pile. Figure 4(b)-(d) show the relationships between the extent of the

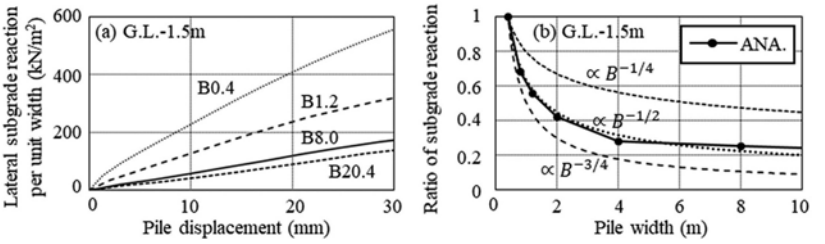

Figure 3. Relationships between pile width and lateral subgrade reaction: (a) pile displacement vs lateral subgrade reaction; (b) pile width vs ratio of subgrade reaction (pile displacement was 10mm).

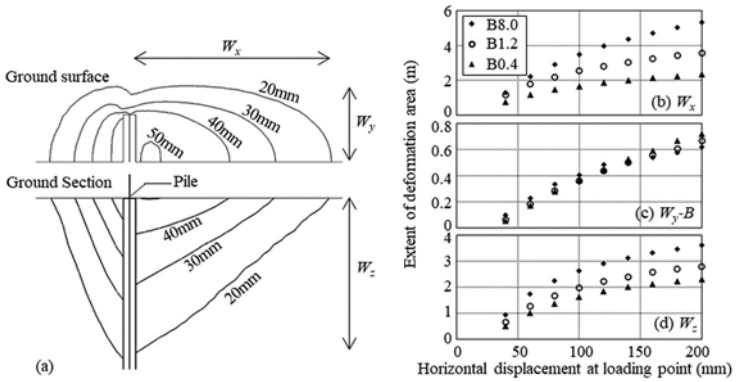

Figure 4. Size of the soil deformation area: (a) contours of total displacement (for case B1.2 when pile head displacement was 100 mm); (b)-(d) horizontal displacement vs extent of deformation area.

deformation area in each direction and pile head displacement for cases B0.4, B1.2, and B8.0. In the direction orthogonal to loading, the value is given as W_y-B to take into account the pile width.

Figure 4(c), the amount by which the deformation area extends beyond the pile was almost constant regardless of pile width. That is, the size of the soil resistance zone beyond the pile does not change with pile width, and the lateral subgrade reaction decreases with increasing pile width. As the lateral subgrade reaction decreases, stresses are transmitted to deeper parts of the pile. Therefore, W_z increase as pile width increases. Since passive soil is pushed up by the pile, deformation at greater depths will result in deformation at locations farther from the pile in the loading direction. This is why W_x was seen to increase with pile width B and W_z.

4 CONCLUSIONS

In this study, lateral loading tests on rectangular piles with various widths in a centrifuge were replicated using a 3D FEM model. The analytical results corresponded well with the experimental observations, confirming the validity of the analytical model. The analytical results showed that the lateral subgrade reaction per unit width was proportional to approximately -1/2 power of the pile width. The extent of the soil deformation area outside the pile caused by a lateral loaded pile almost constant regardless of the pile width. Therefore, it is considered that the resistance zone beyond the pile does not change with pile width, and the lateral subgrade reaction decreases with increasing pile width.

Bearing pressure of granular bed overlying desiccated normally consolidated ground

J.Y.V. Shiva Bhushan, G.V. Narasimha Reddy & M.R. Madhav
JNT University, Hyderabad, India

ABSTRACT: Bearing capacity of footings, the most important design aspect for structures, is calculated most commonly considering the soil as homogenous and semi-infinite. Naturally deposited clay exhibits a complex variation of undrained shear strength with depth, depending upon the stress history, climatic and environmental exposure, etc. Many studies assume the soil as rigid plastic but in practice soft soil shows non-linear response. In the present study, footings resting on a two-layered soil consisting of dense granular fill over desiccated normally consolidated deposit (DNC) are analyzed considering the non-homogeneity and compressibility of the soils. The analysis is performed for circular footing using PLAXIS software. Bearing pressure – settlement responses are obtained for different thicknesses of sand bed. Effect of depth of footing on the bearing pressure – settlement response of granular bed overlying DNC is also studied.

1 INTRODUCTION

Most of the bearing capacity theories consider the soil to be homogeneous and incompressible. Ultimate bearing capacity of circular footing resting on homogeneous clays was estimated by considering the average undrained strength till 0.67 times the diameter of the footing (Skempton 1951) and average shear strength over depth of soil (Meyerhof 1951). Ultimate bearing capacity, q_u, of shallow footings on homogeneous compressible soils is obtained by Vesic (1973) using cavity expansion theory as

$$q_u = c_u N_c F_{cc} \tag{1}$$

where N_c (= 5.14) is bearing capacity factor, c_u- undrained strength of soil, and F_{cc} - compressibility factor as a function of rigidity index, I_r (= G/c_u) and G is shear modulus of soil. Shiva Bhushan *et al*. (2022) studied the effect of compressibility on undrained bearing pressure of homogeneous soft ground and bearing pressure factors are proposed as functions of rigidity index for specific settlements.

Normally consolidated soil (*NC*) have strength increasing with depth and with a desiccated layer near the top due to diurnal variations of temperature and weathering effects (Day 1996). Top layer of NC soils may loses its moisture due to atmospheric evaporation and lowering of water table which results in desiccation. Desiccated soft deposits with decrease in strength in top portion of NC soil were reported by several researchers (Bozozuk 1972; Almeida and Ferreira 1993; Bergado et al. 2002; Balasubramaniam et al. 2005). Shear strength profiles of DNC soils from various locations are shown in Figure 1. Variability in these soil profiles are evident in the thickness of the desiccated layer which varies from 1.5 to 3.5 m, the rate of increase of undrained strength in NC layer from 1.0 to 4.5 kPa/m, the rate of decrease of undrained strength in the desiccated zone varies from 25 to 0 (crust), and the undrained strength at the interface of desiccated and NC layer from 8 to 20 kPa.

DOI: 10.1201/9781003299127-195

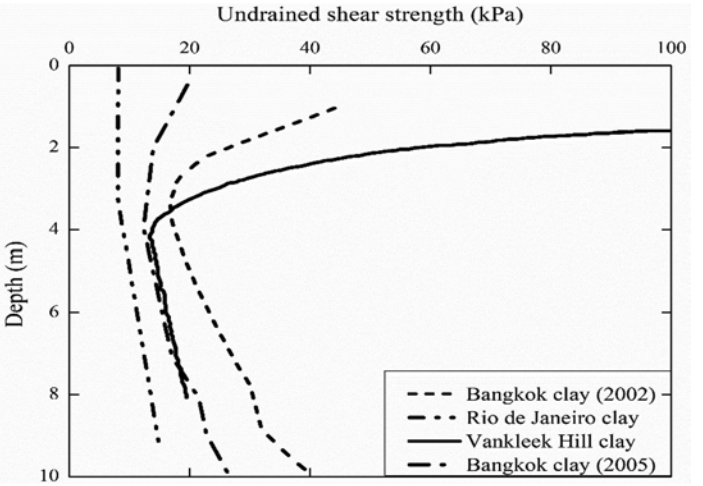

Figure 1. Shear strength profiles of desiccated normally consolidated soil. (Bozozuk 1972; Almeida and Ferreira 1973; Bergado et al. 2002; Balasubramaniam et al. 2007).

Many sites have nonhomogeneous, layered or stratified soils. Few studies (Button 1953; Siva Reddy and Srinivasan 1971; Michalowski 1992; Tani and Craig 1995; Merifield and Nguyen 2006) consider the effect of layering of soils on the bearing capacity of footings. Davis and Booker (1973) based on plasticity theory gave solution for the bearing capacity of strip footing on non-homogenous soil considering the roughness of the footing.

Dense granular bed is placed over the existing desiccated normally consolidated deposits as a part of ground improvement technique. This bed provides a good platform to dissipate the load transferred from foundations. Meyerhof and Hanna (1974) considered the punching mechanism of strong top layer over weak bottom layer and proposed bearing capacity equation. The ultimate bearing capacity of circular footing on dense sand overlying soft soil is given in Equation (2), with a maximum of $q_u = q_{top\ layer} = 0.3\gamma D_f N_\gamma + \gamma D N_q$, where N_γ and N_q are the bearing capacity factors, γ is the unit weight of soil, D and D_f are the diameter and depth of circular footing.

$$q_u = 1.2\,cN_c + 2\gamma H^2\left(1 + \frac{2D}{H}\right)\frac{s}{B}k_s tan\,\phi + \gamma D \tag{2}$$

where s is the shape factor for circular footing, k_s is the coefficient of punching shear resistance, and δ is the angle of mobilized interface friction and its variation with bearing capacity ratio (q_2/q_1) is given in Figure 2(a). It was shown to be dependent on the ratio of bearing capacities of individual layers of sand, q_2 and clay layers, q_1. Variation of coefficient of punching shear resistance, k_s and its variation with angle of shearing resistance, ϕ is given in Figure 2(b) (Meyerhof and Hanna 1978).

Michalowski (2002) considered the rigid block mechanism of failure for semi-infinite soils (depth is very large) and reported that bearing capacity of footings on two-layered clay is unaffected by shear strength of second layer. Load spread mechanism for sand overlying clay is another method of computing ultimate bearing capacity of footings on sand over clays (Terzaghi and Peck 1948; Jacobsen 1977). Rajyalakshmi *et al.* (2015) quantified the effect of non-homogeneity on ultimate bearing capacity of footings on granular bed over soft ground.

The present numerical study accounts for the non-homogeneity of both the desiccation and NC layers of strength profiles over the bearing pressure of dense granular bed overlying DNC

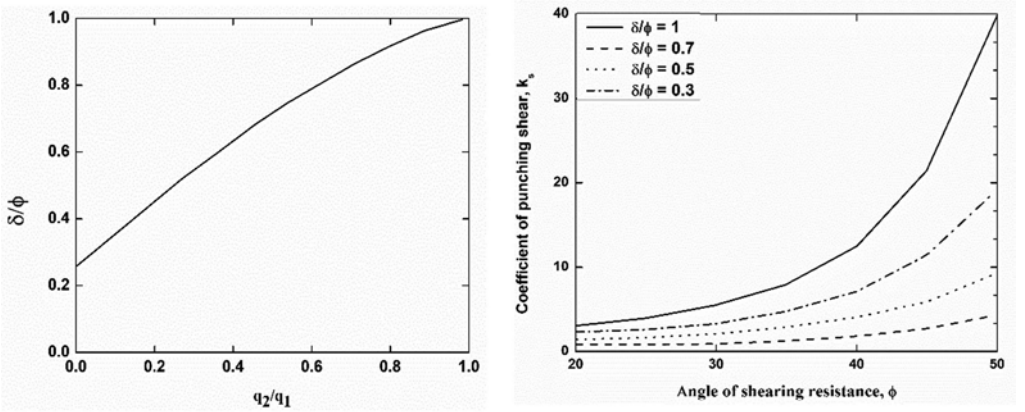

Figure 2. Variation of (a) δ/φ with q_2/q_1 (b) k_s with φ for different δ/ϕ (Meyerhof and Hanna 1978).

ground. This parametric study also quantifies the individual effects of compressibility of NC soil, non-homogeneity of desiccation zone, thickness of granular bed and embedment depth of footing on bearing pressure-settlement responses.

2 PROBLEM DESCRIPTION

Rigid circular footing (diameter, D) located in a dense granular bed overlying desiccated normally consolidated soil is considered (Figure 3). Desiccated normally consolidated (DNC) ground is considered as a two-layer soil whose undrained shear strength varies linearly with depth. The rate of decreasing and increasing of shear strength with depth is denoted by κ and ρ in the top desiccated layer and bottom NC soil respectively. The shear strength of the soil at the interface of the desiccation zone and NC soil is c_{u0}. Desiccation strength ratio, μ ($=c_{uT}/c_{u0}$) is defined as the ratio of undrained strength at the top, c_{uT}, to that at the bottom, c_{u0}, of the weathered soil of thickness, z_0.

Two-meter thick desiccated layer with undrained strength of 30 kPa at the top of desiccated surface and 10 kPa at the interface with NC soil is considered. Poisson's ratio of desiccated normally consolidated ground is taken as 0.495 to simulate the undrained behavior. Unit weight of DNC is taken as 15 kN/m^3 whereas that of granular layer is 20 kN/m^3. Rigidity indices of NC and desiccated layers are assumed as 200 with the strengths of the former increasing and that of the latter decreasing with depth. The angle of shearing resistance of sand, ϕ is taken as 35°. This study considers granular fill over *DNC* soil as a two-layered system that includes the non-homogeneity and compressibility of the ground, in addition to the effect of desiccation on the strength profile.

3 METHODOLOGY

Axisymmetric finite element analysis was carried out using PLAXIS 2D software to simulate the two-layered soil system. A prescribed vertical displacement was applied and stress – settlement responses were analyzed. 15-noded triangular elements were used to discretize the geometry. Mesh convergence was checked and the mesh size was fixed as very fine. The bottom boundary was fixed in both radial and vertical directions, while the side boundaries were fixed in the radial direction and the top boundary was free. The boundaries were fixed at 6 times the diameter in vertical and horizontal directions.

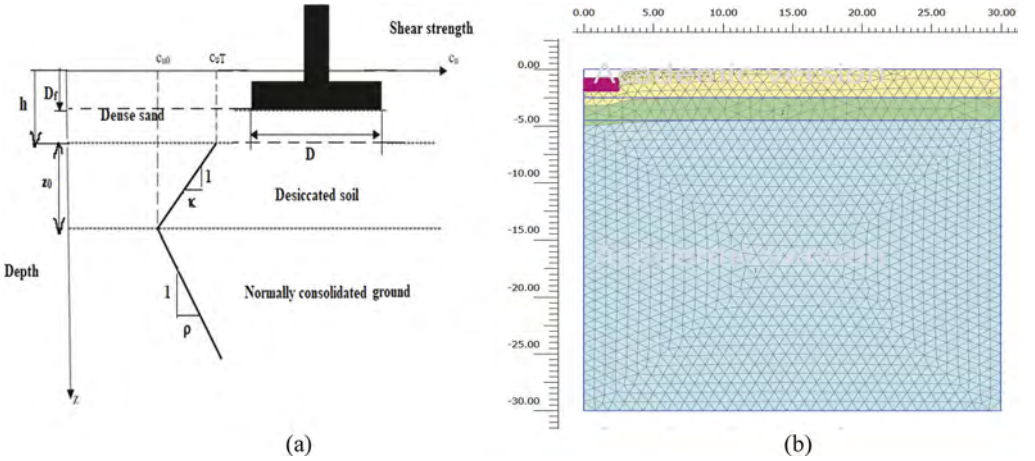

Figure 3. Problem statement showing (a) Strength profile with parameters (b) Deformed finite element mesh of sand overlying DNC (h = 2.5 m).

The analysis is carried out in two stages – initially, the effect of desiccation on NC soil is studied considering the compressibility and heterogeneity of the ground without the granular layer on top. Subsequently, a dense granular bed of thickness, h, laid over the two-layered DNC soil is considered (Figure 3(a)). Figure 3(b) shows the deformed finite element mesh for thickness of sand bed of 2.5 m. The study is limited to a vertical displacement of 10 cm. Numerical model is validated with available literature for incompressible homogeneous ground. Parametric study is carried out and the results obtained based on numerical modeling.

4 RESULTS AND DISCUSSION

A circular footing of 5 m diameter resting in granular bed overlying DNC soil is assumed for the analysis. The non-homogeneity (strength variation with depth) of DNC soil is considered alongside the desiccation effect in the top portion of the clay (Figure 3). Obtained bearing pressure for various prescribed settlements is normalized by unit weight of sand times the diameter of the footing as N_{cf} (= $q/\gamma D$).

a. *Effect of compressibility on bearing pressure*

A dense granular layer 2 m thick and of unit weight, γ of 20 kN/m^3 is considered on top of desiccated NC ground. Rigidity index of desiccated zone, I_r' is taken as 200. Desiccation strength ratio, μ value is 3 and unit weight of DNC is 15 kN/m^3. The cohesion and angle of shearing resistance of sand are taken as 1 kPa and 35° respectively. Rigidity index, I_r of NC soil, is varied from 50 to 1000.

Variations of normalized bearing pressure of granular bed overlying DNC ground for different rigidity indices of NC ground with settlement ratio are presented in Figure 4(a). N_{cf} increases with rigidity of NC ground. N_{cf} increases by 60% as I_r increases 20 fold from 50 to 1000, at SR = 2%. Figure 4(b) shows the effect of compressibility of *NC* soil on normalized bearing pressure for different settlement ratios. For SR = 1%, N_{cf} value increases from 0.9 to 1.72 for I_r increasing by 20 times. Increments in bearing pressure are higher at smaller settlements i.e. for SR = 0.5% and 2%, N_{cf} increased by 1.46 and 0.61 times respectively when I_r increases from 50 to 1000.

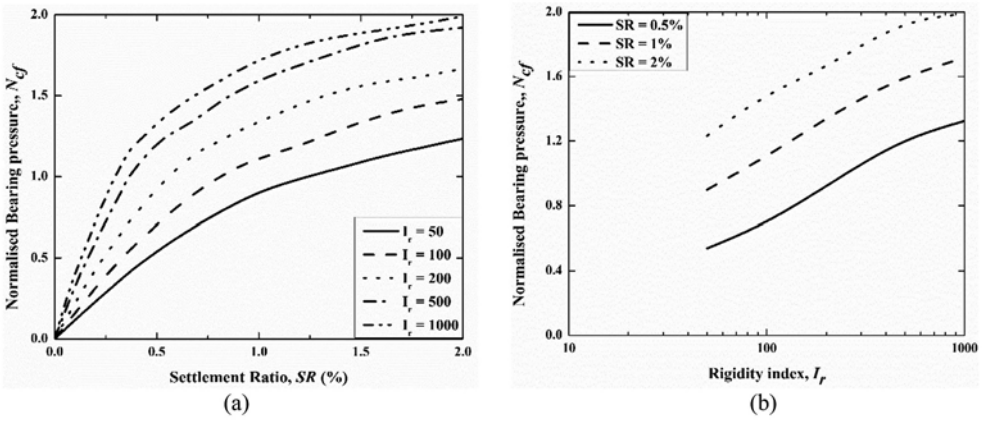

Figure 4. Effect of compressibility of NC soil a) N_{cf} versus SR (%) b) N_{cf} versus I_r at different SR.

b. *Effect of non-homogeneity of desiccation*

Bearing pressure-settlement responses of circular footing resting on sand overlying DNC ground for varying degree of non-homogeneity in desiccation layer is studied in this section. Two meter dense granular bed of unit weight of 20 kN/m^3 and angle of shearing resistance of 35° is considered over DNC ground. Degree of non-homogeneity of NC ground, $\rho D/c_{u0}$ was kept constant at 2.5. Thickness of desiccation layer, z_0 was taken as 2 m. The rate of decrease in strength, κ in the desiccated layer is varied from 2 through 10 kPa/m. Rigidity indices of desiccation and normally consolidated layers are 200. Strength and stiffness decrease gradually with a rate of κ till the interface of desiccated and NC layers.

Figure 5(a) show the normalized bearing pressure - settlement ratio curve obtained for granular bed overlying DNC ground for various degree of non-homogeneity of desiccation for z_0 = 2.0 m. Higher rates of decrease in strength in the desiccation zone results in higher bearing magnitude. N_{cf} increases by 21% for 5 fold increase in rate of decrease of strength in the desiccated zone, κ at SR = 2%.

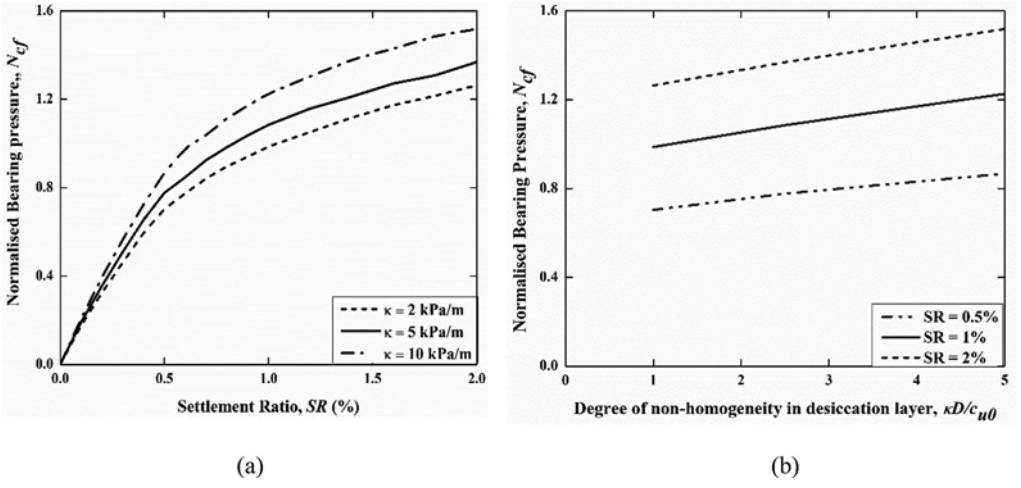

Figure 5. Effect of non-homogeneity of desiccation a) N_{cf} versus SR curves b) N_{cf} versus $\kappa D/c_{u0}$ at different SR.

Normalized bearing pressure of footing, N_{cf} (=$q/\gamma D$) on granular layer overlying DNC ground is plotted against the degree of non-homogeneity of desiccation layer, $\kappa D/c_{u0}$ for different settlement ratios and is depicted in Figure 5(b). As since the degree of non-homogeneity of the desiccated layer correspond to the layer's strength in magnitude, N_{cf} increases linearly with increase in $\kappa D/c_{u0}$ for a given foundation settlement. At SR =1 and 2%, N_{cf} increases by 24% and 20% respectively for 5 times increment in degree of non-homogeneity of desiccation layer.

c. *Effect of thickness of granular layer (Surface footing)*

Bearing pressure-settlement responses of footing resting on sand of varying thickness overlying DNC ground is studied in this section. Desiccation strength ratio, μ value is 3 and DNC soil has ρ and κ values of 5 kPa/m and –10 kPa/m respectively. The thickness of granular bed, H is increased from 1.25 m through 5 m and bearing pressure versus settlement responses are obtained. Figure 6(a) gives variations of N_{cf} of footing on granular layer overlying DNC with SR for different thicknesses of granular bed. N_{cf} increases by 85% at a settlement of 10 cm for four fold increase in thickness of granular bed.

Variations of normalized bearing pressure of two-layered soil with the thickness of granular bed for different settlement ratios are shown in Figure 6(b). N_{cf} increases with thickness ratio, H/D for a specific settlement. For SR = 1%, N_{cf} value increases from 1.07 to 1.98 for H/D increasing by 4 times. Increments in bearing pressure are higher at higher settlements i.e. for SR = 0.5% and 2%, N_{cf} increased by 0.60 and 1.06 times respectively when thickness of sand bed increased from 1.25 to 5.0 m.

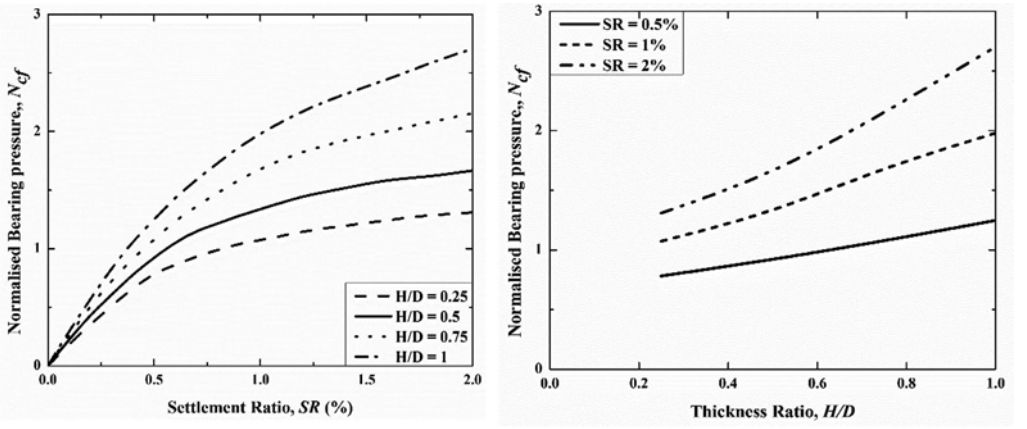

Figure 6. Effect of thickness of granular bed (a) N_{cf} versus SR curves b) N_{cf} versus Thickness ratio (H/D) curves at different SR.

d. *Effect of depth of embedment of footings in the granular layer*

Footing placed at the middle of dense granular layer, i.e. $D_f = 0.5H$ for granular beds of different thicknesses, H, (= 1.25, 2.5, 3.75 and 5 m) are analyzed. All the parameters of DNC and granular bed are the same as those of the previous case. Figure 7(a) gives variations of N_{cf} of footing in granular bed overlying DNC with SR for varying thicknesses of the dense granular bed. N_{cf} increases by 70% at a settlement of 5 cm for four fold increase in the thickness of granular bed.

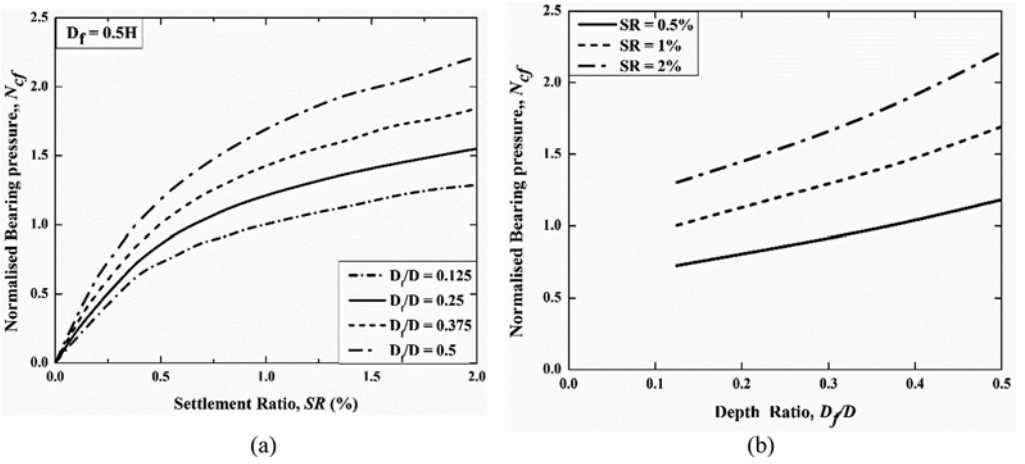

Figure 7. Effect of depth of embedment a) N_{cf} versus SR (%) b) N_{cf} versus Depth ratio (D_f/D) for D_f = 0.5H.

Figure 7(b) illustrates the effect of embedment depth of circular footing on bearing pressure for different sand bed thicknesses. For SR = 1%, N_{cf} value increases from 1.0 to 1.7 for depth ratio, D_f/D increasing by 4 times. Similar to the previous case, increments in normalized bearing pressure are larger at higher settlement ratios i.e. for SR = 0.5% and 2%, N_{cf} increased by 0.63 and 0.70 times respectively when the embedded depth ratio increased from 0.125 to 0.5. N_{cf} values for embedded footing are less than those for surface footing since the contribution of the granular bed gets reduced by half.

5 CONCLUSIONS

The present study analyzed the footing on dense granular bed over soft normally consolidated soil incorporating desiccation into consideration. Variation of undrained shear strength with depth in desiccated layer over an increase in strength in non-homogeneous soil is considered. Bearing pressure-settlement responses obtained from this numerical study are analyzed for various parameters of layered soil. Individual effects of compressibility of NC soil, strength variation in the desiccated layer, thickness of granular bed and embedded depth of footing on bearing pressure are quantified as a function of settlement. Bearing pressure of two-layered sand overlying DNC ground increases with the rigidity index of NC soil and with degree of non-homogeneity parameter in desiccation layer for a specific settlement. The effect of thickness of granular bed and embedment depth on bearing pressure is significant at higher settlements.

Use of geophysical investigation in assessing the differential settlement of shallow foundations

A.K. Dey & A. Saha
National Institute of Technology Silchar, Assam, India

ABSTRACT: Consolidation settlement is a major concern in designing foundations resting on clayey soil. Under a given load its value may vary from place to place depending on different parameters like loading history, in-situ water content, clay content, plasticity, etc. Again for the same site if the depth of compressible layer below the foundation is different, the expected settlement will also be different. In such a situation, geophysical tests are proven to be more reliable, easy and quick than the conventional borelog survey. The bore log survey at one site at Silchar showed possibility of differential settlement if the depth of foundation is kept constant for all the footings. The MASW test clearly supported the apprehension

1 INTRODUCTION

Settlement calculation is an integral part for obtaining the allowable bearing capacity of soil in a subsoil investigation. In the usual practice, a requisite number of boreholes upto a specified depth is made, and the soil samples are collected at regular intervals. Settlement is then calculated from the relevant soil properties. For clayey soil, the total settlement is not immediate but time-dependent. The time-dependent settlement is called consolidation settlement, and the procedure to obtain the consolidation settlement is prescribed in relevant geotechnical codes. However, it is not sure how much accurate will be the prediction of settlement because of compromise in sample preparation, personal errors and restriction in number of boreholes. The spatial variability of a plot cannot be incorporated in the borelog survey. As a result, the possibility of differential settlement cannot be overlooked. The problem is more acute if a small pocket of very poor soil exists within two boreholes. Geophysical methods of soil survey can be adopted to overcome the limitations of the borelog survey. Geophysical methods give a continuous record of subsurface soil stratification. Geophysical methods are non-invasive, rapid, and mostly accurate depending on the expertise of the investigator (Pazzi et.al.2019).Over the years, researchers have tried to investigate soil's continuous and spatially varying physical and chemical properties through different geophysical testing methods (Ullah and Prado, 2017) which include seismic (Donohue et. al., 2013, Hugenschimdt, 2000), electromagnetic (Atef et. al. 2016, Chambers et al 2011), electrical (Saad et al., 2012), gravitational (Loz & Porzucek, 2019), etc. Each method has its own advantages and disadvantages. In the present work, the seismic survey is adopted considering the potential of shear wave data for predicting static deformation, subsoil conditions and soil stiffness. Different seismic survey methods like Spectral Analysis of Surface Waves (SASW), Continuous Analysis of Surface Waves (CASW), and Multichannel Analysis of Surface Waves (MASW) are in practice. Out of these, MASW is considered to be the most suitable and reliable method for predicting soil stiffness in the urban areas (Donohue et. al., 2011). Shear wave velocity has been rigorously used for site characterization and assessment of soil properties.

DOI: 10.1201/9781003299127-196

In the present study, a city, namely Silchar is chosen for prediction of consolidation settlement using MASW. Silchar is the second-largest city in Assam, a northeastern state in India with a population of around 4,00,000 covering an area of 26.88 km^2. A significant part of the city contains clayey soil upto a considerable depth where consolidation settlement is of prime concern. The usual practice of subsoil investigation is to obtain the allowable bearing capacity for different shapes and sizes of footings founded at different depths based on the borelog survey. The possibility of differential settlement due to spatial variability has never been considered. The secondary stresses developed in the column beam joints due to this differential settlement are totally overlooked. These secondary stresses may govern the failure criteria of a building during seismic vibrations. In the present study it is tried to show the effectiveness of an MASW survey to represent the spatial variation of soil strata and also to obtain settlement of columns along the survey line through correlation ship between shear wave velocity and the geotechnical properties.

2 SITE LOCATION AND GEOMORPHOLOGY OF THE STUDY AREA

Silchar is the second-largest city in Assam, India and is situated between longitudes and latitudes 92°24′ E & 93°15′ E and 24°22′N & 25°8′N respectively in Cachar district.The town area of Silchar is located in an alluvial flat plain, spotted with swamps and bisected by stream and surrounded by isolated small hills (*tillas*).The area experiences a very high rainfall, almost seven to eight months in a year and about 379 cm in average in the monsoon month of July with a moderate climate and an annual temperature variation of 10° to 35° C. The groundwater table is located within 1 m from the ground level in most of the part of the city. So the top soil, which is predominantly clay, is in saturated form in most of the time. The Barak river, which runs through three sides of the city, is the main river in this region. The region also falls in zone V, the highest seismic zone in the seismicity map of India. Earthquakes of magnitude 5 to 5.5 are very common due to presence of an active Indo-Myanmer subduction zone, around 350 km on the eastern side of the city.

Geomorphologically, the area of Cachar district forms a part of north – south trending compressed thrust fold belt of Assam - Arakan basin. The structural style of the sedimentary cover in this area is depicted by a series of NNE – SSW trending, doubly plunging, elongated narrow, and highly faulted anticlines. These anticlines are en-echelon to each other. The anticlines are asymmetrical & are separated by the synclines. A very thick sedimentary cover consisting of alternate layers of shale, claystone, sandstone and siltstone with age from Eocene to Recent exists in this area[28].

Before the birth of the city in 1832 (https://en.wikipedia.org› wiki › Silchar), the area was mainly marshy which was subsequently filled up to promote human habitation. As a result, the major part of the city is prone to consolidation settlement. For construction of multistoreyed structures, people conduct one or two boreholes in a plot and obtain the safe bearing capacity which is considered to be constant for the entire plot. Except a few cases, differential settlement has not yet posed any major problem in the city. However, with rise in population and increase in housing demand, the city may face a threat due to occurrence of differential settlement in the coming days.

3 BORELOG SURVEY

Two boreholes of 15.0 m depth were dug in the proposed site, the locations and the soil profile are shown in Figure 1. It is observed that the site consists of five layers of clayey soil of different consistencies upto 15.0 m depth. Properties of the soil were obtained in the laboratory from undisturbed soil samples and are shown in the figure. From the general observation of the soil profile it is understood that there will be a differential settlement in case the footings

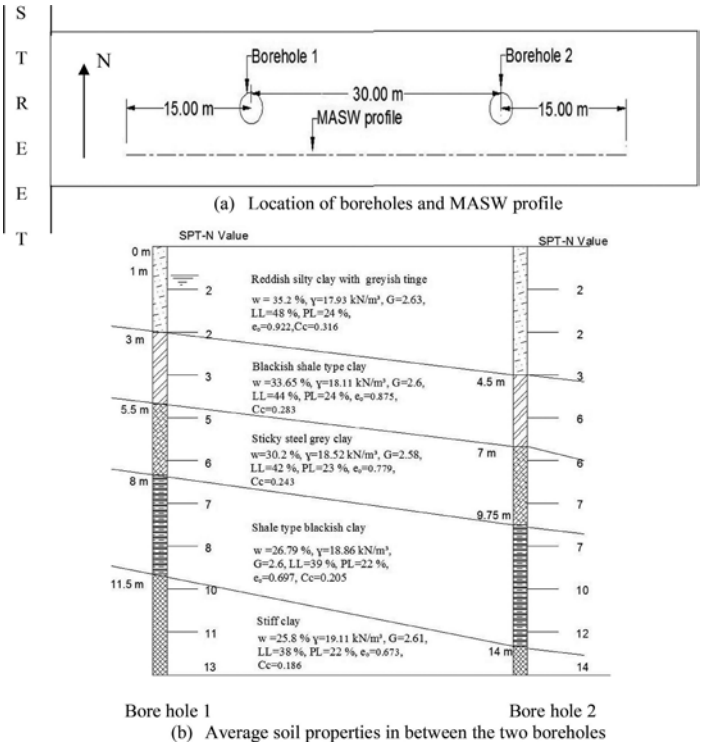

Figure 1. Borehole locations and average soil profile in Plot A (refer Figure 3).

are constructed at the same depth with the same pressure intensity. The probable consolidation settlement near the two bore holes is obtained as follows.

3.1 *Settlement calculation*

The primary settlement due to external loading is calculated using the following equation

$$S = \sum_{i=1}^{n} \left(\frac{(C_c)}{1+e_0} H \log\left(\frac{\sigma' + \Delta\sigma}{\sigma'}\right)\right)_i \quad (1)$$

Where
S=the amount of settlement caused by the load applied
H = thickness of the soil layer within the influence zone
e_0= the soil layer initial void ratio.
σ' = initial effective vertical stress at the mid-height of each soil layer
Δσ= the change in vertical stress caused by loading.
n = number of layers upto the influence zone, taken to be two times the width of footing
i = layer under consideration varying from 1 to n

Considering a square footing of size 2.5 m x 2.5 m founded at a depth of 2.5 m and bearing a loading intensity of 100 kPa, the primary consolidation settlement using Equation 1 is obtained as 164.23 mm near bore hole 1 and 172.8 mm near bore hole 2 with influence zone extending upto two times the width of the foundation i.e. 5.0 m. The soil profile upto the influence zone below the footings near the boreholes is shown in Figure 2. This figure is drawn to show the number of layers fall within the compressible zone i.e. two times the width of the footing.

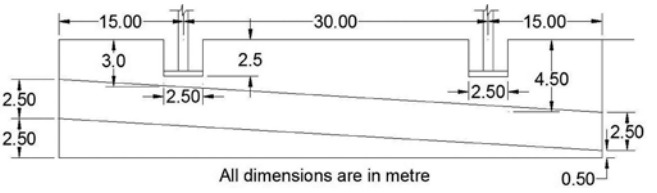

Figure 2. Soil profile upto the influence zone below the depth of footing.

4 GEOPHYSICAL TEST – MULTICHANNEL ANALYSIS OF SURFACE WAVES (MASW)

Multichannel Analysis of Surface Waves (MASW) is a non-invasive method that utilizes the dispersive nature of the surface waves to obtain the subsurface stratification through variation of shear waves with depth. The overall procedure consists of three steps, data acquisition, dispersion analysis, and inversion of dispersion curve. The maximum depth of investigation in an MASW survey varies depending on the length of the site, measurement profile configuration, natural receiver frequency, and type of seismic source employed (Park et al., 2002). In the present study, an 8 kg sledge hammer was used. For data collection, field measurements were undertaken with 24 numbers 4.5 Hz frequency geophones spaced at 2.0 m interval. Total 25 shot points were undertaken, one in the middle of two consecutive geophones and two at the ends. To eliminate the uncertainty/error associated with the actual energy provided in the test sample, 10 shots were applied one after the other sequentially to build a mean shot collect file.

The dispersive nature of the soil is used to obtain a relationship between wavelength and phase velocity. Longer wavelengths reflect properties of soil at larger depth and shorter wavelengths reflect properties at shallower depth. Dispersion curves are derived from this recorded surface wave data as a plot between phase velocity and frequency. Obtaining a high quality dispersion curve is essential for obtaining accurate shear wave velocity (V_s), which is one of the most critical steps encountered during surface wave data processing. The variation of shear wave velocity in a layered medium is obtained by inversion of the dispersion curve. Number of layers is assumed and density, Vs and Poisson ratio of each layer are to be added to software. The software then iterates the data so that the root-mean-square (RMS) error between the theoretical and experimental dispersion curves is reduced to a tolerance limit. 1-Dimensional V_s profile (V_s versus depth) is then obtained. Finally the software gives a 2-dimensional result combining all the shot point results. In the present study 10 layers of soil were assumed and SeisImager/SW software consisting of three individual programmes: PickWin95, WaveEq, and GeoPlot were used. The MASW test was carried out in 24 locations at Silchar city as shown in Figure 3. The plot A is also shown in the drawing where the two bore holes were made. The variation of V_s with depth from all these sites are shown in Figure 4. The bore log data of these 23 sites were collected and correlations between e_0, γ and C_c with V_s are obtained as shown in Figure 5. The best fit curves show the following relations

$$e_0 = 23.982\ V_s^{-0.659} \tag{2}$$

$$\gamma = 9.3322\ V_s^{0.1325} \tag{3}$$

$$C_c = 29.05\ V_s^{-0.928} \tag{4}$$

The MASW test result from plot A is shown in Figure 6. Using the above correlations, the expected settlement is obtained along the length of the plot considering the column spacing at 5.0 m and the pressure intensity as 100 kPa and depth of foundation 2.5 m (Figure 7). The theoretical values from the standard settlement Equation (1) are also shown. The MASW results give a lower value.

5 CONCLUSIONS

Following conclusions are drawn from the present study:

1. Geophysical methods give a continuous prediction of settlement
2. Any soft pocket within a plot can be easily identified with the geophysical method

3. The correlations obtained between geotechnical properties and V_s for the Silchar soil hold good
4. It is possible to fix the depth of foundation for a constant settlement.
5. The long procedure for calculation of C_c can be avoided without compromising the settlement value.
6. The tedious method of collection of undisturbed samples can be avoided

Bearing capacity and settlement of foundations on clayey soils under regime block cyclic loading

I.T. Mirsayapov & H.M.A. Sharaf
Kazan State of Architecture and Engineering University, Kazan, Russia

ABSTRACT: In modern conditions the soils base of buildings and structures are exposed to various types of regime cyclic loading. Existing calculation methods for foundations bearing capacity and deformations are developed mainly for the case of short-term single static load or cyclic loading with constant parameters during the whole period of exploitation. Buildings and structures for various purposes and their soil bases, along with cyclic loading with constant parameters, are subjected to cyclic loading of non-stationary regimes which are usually reduced to block loading for calculations and in some cases these loads are the main ones determining the safety of buildings and structures as a whole. Influence of cyclic loading of non-stationary regimes on the behavior of soil foundations is practically unstudied. In this connection researches have been conducted and methods of calculation of bearing capacity and settlement of foundations on clayey soils at regime block cyclic loading have been developed.

Keywords: bearing capacity, settlement, block cyclic loading, clay soil, stress-strain state

1 INTRODUCTION

In fact, most structures are exposed to cyclical loads due to changes in the intensity of the amount of applied load over time, such as wind load, tractor-driven load or load caused by operation. The phenomenon is that small load fluctuations affecting structures can be ignored. However, in some cases, it is impossible to neglect the presence of cyclic loading, in particular, wave load on offshore structures, wind load on structures with high flexibility, transport loads on roads and vibrations on the foundations of heavy machinery [4]. The impact of cyclic loading on structural elements can lead to cyclic loading on soils. To solve the above problems, engineers must offer the best solution in a safe, efficient and cost-effective way. Static analysis may be suitable for cases with very low applied load rates. When changes in the magnitude of stress or strain and the frequency of loading are not ignored, static analysis may give underestimated forecasts, which will lead to unsafe and inefficient designations due to their inaccurate results [6]. Consequently, in geotechnical projects, an extremely important role is played by taking into account the effects of the block cyclic loading regime and its influences, in which the behavior of the soil under cyclic loading should be considered as the root of the problem [7].

2 LABORATORY TESTING OF CLAY SOIL UNDER LOADING MODE

To determine the effect of loading mode and stress state on the strength and deformability of clayey soil, experimental studies of clayey soils under three-axis mode block cyclic loading using 2 types of devices, namely prismatic shape with dimensions 100×100×200 mm and cubic shape with dimensions 100×100×100 mm were given Figure 2a. Characteristic signs of destruction of the samples were obtained. The observed soil sampling zones of different

DOI: 10.1201/9781003299127-197

densities differ from the initial values. This fact indicates a difference in the level of soil damage in these zones. Thus, under mode block cyclic loading Figure 1, the clayey soil density in the upper zones increased by 6-10%, in the middle zones by 1-3% and in the lower zones by 3-5 It was found that the average density of the sample after the tests increased by 3-6% compared with the initial. In addition, it was found that the moisture content under the mode block cyclic loading decreased to 7% Figure 2b.

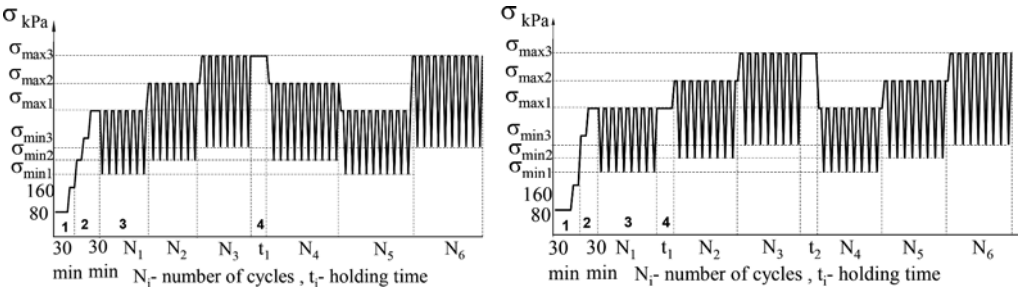

Figure 1. Loading modes under block cyclic loading; 1 – stage of comprehensive compression; 2 – stage of deviatory loading; 3 – stage of cyclic loading; 4 – holding time under static loading.

To determine the change in the values of specific cohesion *C* and the angle of internal friction *φ*, soil samples were taken from characteristic hardened and softened zones and examined using a single-plane slice device. It was found that the specific cohesion in the upper zone increased by 24-50%, and in the middle zone decreased by (30-50%) and in the lower zone increased by (15-30%). The angle of internal friction φ of the soil in the upper zone from the initial values increased by (5-8%), and in the middle zone decreased by 20-30 and in the lower zone increased by (3-4,3%) [3]. With increasing and decreasing the load value, increasing the number of loading cycles and holding time, densified pyramid-shaped zones are formed: in the upper, in the lower part of the sample and on its side surfaces Figure 2b. The geometrical dimensions of these compacted pyramids may be different and depend on the loading mode. Since these pyramids are displaced as solids, the specimen is deformed. The pyramids of solids form the ground with a denser structure; in the areas between the pyramids, shear and tearing occurs, which is accompanied by the appearance of small cracks. At the same time, it should be noted that deterioration of physical and mechanical properties of clayey soils in three-axial compression is fixed in the zone of loosening 2. This is due to the existence of two mutually compensating processes of cracking (destruction) and self-repair in the mode of block cyclic loading Figure 2c. What happens in these zones was described in more detail in the work of Mirsayapov I.T. and Koroleva I.V. [2].

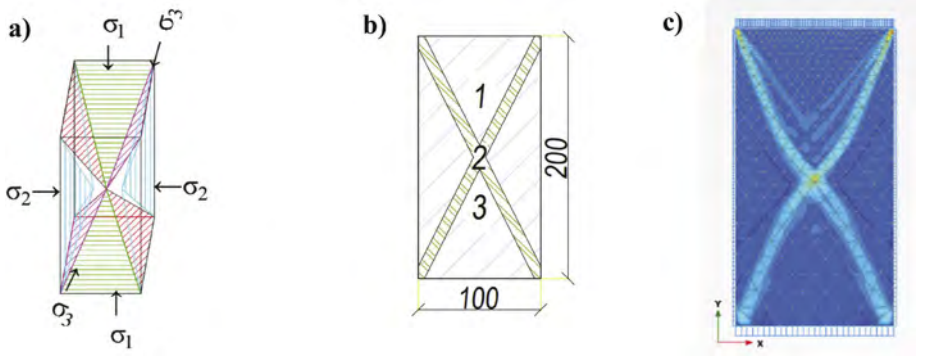

Figure 2. Appearance and fracture diagrams of a clay soil sample in triaxial compression devices. a-diagram of soil loading, b-diagram of local zones in the sample, c-diagram of sample fracture in the program Plaxis.

When describing the deformation of cyclic creep and soil strength under regime cyclic loading, it is necessary to take into account the influence of the vertical pressure of the previous block (σ1) on strength, deformation modulus, shear modulus and relative vertical deformations during subsequent loading after transition to another mode Figure 3.

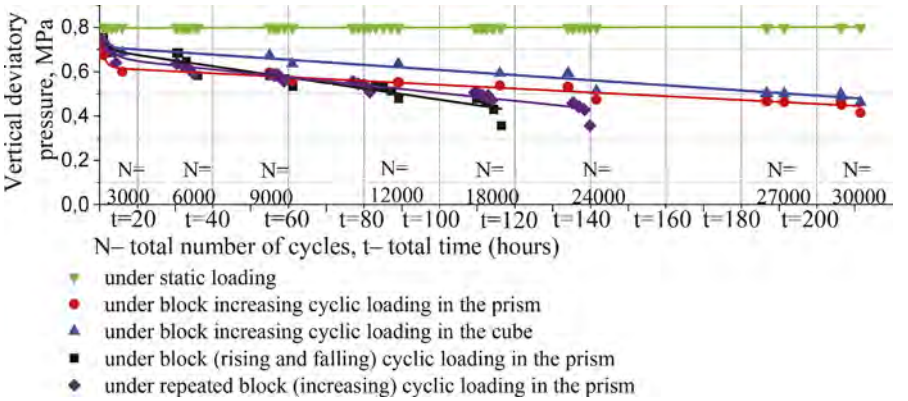

Figure 3. Change in the maximum permissible vertical deviatory pressure of the soil under regime block cyclic loading.

3 BEARING CAPACITY OF CLAY SOIL UNDER BLOCK CYCLIC LOADING

In accordance with the standards of the design of foundations when assessing the bearing capacity of the foundation, the calculated resistance of the soil under the sole of the foundation is determined SP 22.13330.2016 by the equation [1]:

$$N_u = b' \cdot l' \cdot \left(N_\gamma \xi_\gamma b' \gamma_1 + N_q \xi_q \gamma'_1 + N_c \xi_c C_1\right) \tag{1}$$

Where b', l' = Length and width of foundation; $N\gamma$, Nq and Nc = dimensionless coefficients of soil bearing capacity under the base of the foundation depending on the angle of internal friction φi; γ_1, γ'_1 = Specific weight of soil above and below the base of the foundation; ξ_γ, ξ_q, ξ_c = depending on the angle of internal friction φi. When determined analytically, the strength characteristics $C\ (N,\ t,\ \tau)$ and $\varphi\ (N,\ t,\ \tau)$ = determined by equations 2 and 3 for stationary and non-stationary cyclic loading. The specific cohesion under regime block cyclic loading is represented in the following form:

$$C(N, t, \tau) = C_0 + \sum_{i=1}^{n} \Delta C_{dpl}(t, \tau) - \sum_{i=1}^{n} \Delta C(N, t) \tag{2}$$

where C_0 = the initial value of the specific cohesion of the soil; $\Delta C_{dpl}\ (t,\ \tau)$ = the change in specific adhesion in the stages of comprehensive and deviatory loading; $\Delta C\ (N,\ t)$ = the change in specific cohesion during exposure under the action of block cyclic loading.

Then the specific cohesion equation under mode block cyclic loading is presented in the following form:

$$\begin{aligned} \mathrm{C}(N,\ t,\ \tau) = C_0 + \textstyle\sum_{i=1}^{n} \Delta C_{dpl}(t,\ \tau) - \sum_{j=1}^{m} \Delta C(N, t) = \Bigg[\Bigg(C_0 + \Bigg[C_0 . \textstyle\sum_{i=1}^{n} (2. \\ \cdot \left(\Delta \varepsilon_{ij}^{pl}(t, \tau) - \tfrac{1}{3} \Delta \varepsilon_{vi}^{pl}(t, \tau) \cdot \delta_{ij}\right) \cdot \Delta \varepsilon_{vi}^{pl}(t, \tau)\Big)^{1/2}\Bigg]\Bigg) - \textstyle\sum_{j=1}^{m} \left(K_{\varepsilon pli}^{v}(N,\ t,\ t_0) \cdot \right. \\ \left. \Delta \varepsilon_{pli}^{v}(N,\ t,\ t_0) + + K_{\gamma pli}^{v}(N,\ t,\ t_0) \cdot \Delta \gamma_{pli}^{v}(N,\ t,\ t_0)\right)\Bigg] \end{aligned} \tag{3}$$

where $\Delta\varepsilon^{pli}{}_{v}$ (N, t, t_o) and $\Delta\gamma^{pli}{}_{v}$ (N, t, t_o) = increments of vertical and shear strain of cyclic creep in increasing and decreasing blocks of cyclic loading; $K_{\varepsilon pli}{}^{v}$ (N, t, $_{to}$) and $K_{\gamma pli}{}^{v}$ (N, t, t_o) - parameters of proportional relationship between ΔC (N, t, t_o) and $\Delta\varepsilon_{pli}{}^{v}$ (N, t, t_o) and $\Delta\gamma_{pli}{}^{v}$ (N, t, to) determined from experimental studies; $\Delta\varepsilon_{ij}^{pl}(t,\tau)$ = the creep strain tensor increment in the considered loading stages; $\Delta\varepsilon_{vi}^{pl}(t,\tau)$ = the volume creep strain increment in the considered loading stages; δij = Kronecker delta.

The change in the angle of internal friction φ of the soil is determined by the following equation:

$$\varphi(N,t,\tau) = tan^{-1}\left(\frac{\tau_{ultgrt}(N,t) - C(N,t,\tau)}{\sigma(N,t)}\right) \tag{4}$$

where τ_{ultgrt} (N, t) =σ (N, t) tgφ (N, t, τ) +C (N, t, τ) = strength condition by Coulomb-More equation under mode block cyclic loading; φ (N, t, τ) and C (N, t, τ)- strength characteristics of soil under mode block cyclic loading; σ (N, t) = normal maximum stress.

The equation of the ultimate bearing capacity of the base after the transformation is written as following:

$$\begin{gathered} N_u = b'\cdot l'\cdot\left[\left(N_\gamma\xi_\gamma b'\gamma_1 + N_q\xi_q\gamma'_1 + \right.\right. \\ +N_c\xi_c\cdot\left(\left[C_0 + C_0\cdot\sum_{i=1}^{n}\left(2\cdot\left(\Delta\varepsilon_{ij}^{pl}(t,\tau) - \tfrac{1}{3}\Delta\varepsilon_{vi}^{pl}(t,\tau)\cdot\delta_{ij}\right)\cdot\Delta\varepsilon_{vi}^{pl}(t,\tau)\right)^{1/2}\right] - \\ \left.\left.\sum_{j=1}^{m}K_{\varepsilon pli}^{v}(N,\ t,\ t_0)\ .\ \Delta\varepsilon_{pli}^{v}(N,\ t,\ t_0) + K_{\gamma pli}^{v}(N,\ t,\ t_0)\cdot\Delta\gamma_{pli}^{v}(N,\ t,\ t_0)\right)\right) \end{gathered} \tag{5}$$

The functions of the bearing capacity of the soil under stationary and non-stationary cyclic loading after the transformation take the form:

$$N_\gamma = (N_q - 1)\cdot\left(arc\left(\frac{\tau_{ultgrt}(N,t) - C(N,t,\tau)}{\sigma(N,t)}\right)\right); \tag{6}$$

$$N_q = tg^2\left(45^0 + \frac{\varphi_1}{2}\right)\cdot e^{\pi\cdot arctan\left(\frac{\tau_{ultgrt}(N,\,t)-C(N,\,t,\,\tau)}{\sigma(N,\,t)}\right)};\ N_c = \frac{N_q - 1}{arctan\left(\frac{\tau_{ultgrt}(N,\,t)-C(N,\,t,\,\tau)}{\sigma(N,\,t)}\right)} \tag{7}$$

4 SETELLMENT CAPACITY OF CLAY SOIL UNDER BLOCK CYCLIC LOADING

To calculate the settlement of the bases under real regime loading, a calculation method is proposed, which is based on the method of layer-by-layer summation, taking into account the spatial stress state of the soil mass and changes in the mechanical state of soils during regime loading. The volumetric stress is taken, the state of the soil of the base foundation compressible thickness of the base into layers, for each layer, based on the stress deviator, we determine the deformations corresponding to the vertical pressure value, and then the deformation values, within the compressible thickness, the increment of the axial deformation of the i–th layer is summed up at the time of loading is determined by the equation [1, 2]:

$$\Delta_{zi} = \frac{\Delta\sigma_z}{G_v} - \Delta G\cdot\frac{3k_v - G_v}{3k_v\cdot G_v} \tag{8}$$

where $\Delta\sigma z$ = the vertical stress at the moment of loading; Gv = the shear modulus at the moment of loading; kv = the volumetric modulus at the moment of loading.

The increment of axial strain under cyclic loading is determined by the equation:

$$\varepsilon_{pli}^{v}(N,t,t_0) = \sum_{i=1}^{n}\left[\sigma_i^{max}(N,t,t_0)\cdot k_R\left\{\left[\frac{f_{UP}(N)}{\sigma(N,t,t_0)}\right]\cdot f_{UP}(N)\cdot\rho_{cyc}\cdot+\left[\frac{f_{dow}(N)}{\sigma(N,t,t_0)}\right]\cdot f_{dow}(N)\cdot\rho_{cyc}\cdot+\left[\frac{f(t)}{\sigma(N,t,t_0)}\right]\cdot f(t)+\left[\frac{f_{UP}(t_0)}{\sigma(N,t,t_0)}\right]\cdot f_{UP}(t_0)+\left[\frac{f_{dow}(t_0)}{\sigma(N,t,t_0)}\right]\cdot f_{dow}(t_0)\right\}\cdot\right] \quad (9)$$

where σ_i^{max} (N, t, t_0) is the maximum vertical stress in step-down loading blocks, dwell block and at the moment of load change; σ (N, t)- allowable vertical stress in block cyclic loading; k_R - coefficient depending on correlation of parameters of creep and cyclic creep of soil, strength of soil and vertical stress in the considered block of loading; ρ_{cyc} - asymmetry of vertical stress cycle of soil; f_{UP} (N), f_{dow} (N), f(t), f_{UP} (t_0), f_{dow} (t_0) - cyclic creep deformation growth functions of soil in increasing and decreasing blocks of cyclic loading, holding time and at the moment of load change.

Then the foundation settlement under mode block cyclic loading according to the following equation:

$$S(N,t,t_o) = \sum_{i}^{n}\left[\Delta\varepsilon_{zi} + \varepsilon_{pli}^{v}(N,t,t_o)\right]\cdot h_i \quad (10)$$

where ε_{pli}^{v} (N, t, t_0) = the increment of axial deformation under cyclic loading; $\Delta\varepsilon_{zi}$- is the increment of axial deformation of the i–th layer at the time of load application; $\Delta\,\varepsilon_{pli}^{v}$ (N, t, $t_{o)}$ = the increment of axial deformation of the i-th layer under cyclic loading; *hi* = the thickness i-th layer; n – the number of layers.

To test the obtained equations for calculating the settlement of foundation, stamp tests (models of the slab foundation in tray) of clayey soil were carried out Figure4. The results of experimental studies in a volumetric tray Figure 4. show that the development of the base settlement occurs in three stages. At the first stage, the settlement of the base develops with an increase in maximum loads and the number of cyclic loadings, while the settlement values were 50-54% of the maximum settlement value. At the second stage, from the second to the penultimate block, it is seen that the rate of development of the base settlement decreases or their complete stabilization occurs with increasing block cyclic loading, and a decrease in the base settlement with decreasing block cyclic loading. At the third stage (the penultimate and last block), there is an increase in the development of the base settlement as the number of loading cycles increases compared to the previous loading stages. The rate of settlement development increases without stabilization until the limit value for the slab foundation model is reached Figure 4.

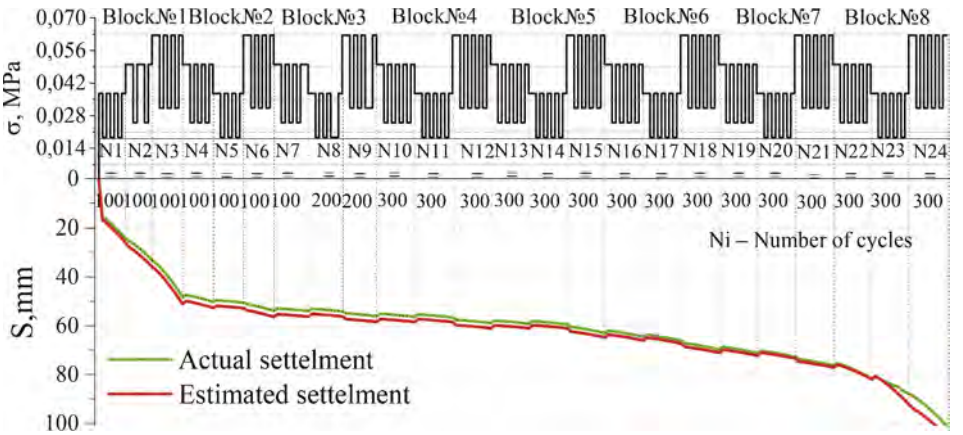

Figure 4. Comparison graph of slab foundation settlement under regime block cyclic loading.

5 CONCLUSION

1) The equation of the ultimate bearing capacity of the soil base under regime block cyclic loading has been developed, taking into account the simultaneous change in rheological and strength characteristics of soils, hardening processes, as well as loading mode;
2) An engineering method for calculating the settlement of the bases has been developed, which is based on the method of layer-by-layer summation, taking into account the simultaneous change in the spatial stress-strain state and mechanical characteristics of soils in the process of regime block cyclic loading.
3) A comparison of the measurement results on the development of the settlement of the slab foundation model in tray under mode block cyclic loading indicates that the obtained dependence of the change in the amount of settlement with a mode block cyclic loading coincides fairly well with the results of tray laboratory tests. The discrepancies between the calculated and experimental values are in the range of 10-20%.

Ultimate bearing capacity of a raft-pile foundation under cyclic loading

I.T. Mirsayapov
Kazan State of Architecture and Engineering university, Kazan, Russia

ABSTRACT: The bearing capacity of a raft-pile foundation under cyclic loading depends on the conditions of joint deformation of the soil, piles and pile cap, their strength and deformation properties and corresponds to the maximum cycle load that a raft-pile foundation can perceive with a given number of loading cycles and a predetermined maximum settlement. The maximum bearing capacity under cyclic loading is determined for the stage when tangential stresses along the lateral surface are absent in the upper and middle parts of the piles due to the achievement of the maximum shear resistance. It is assumed that a spatial stress-stain state is realized in the soil under the raft and under the pile toe. The bearing capacity of the raft-pile foundation is reached when the stresses under the pile toe and under the raft exceed the fatigue strength and the ultimate deformations of the soil under triaxial cyclic compression. The objective of study is to determine ultimate bearing capacity of the raft-pile foundation under cyclic loading. Theoretical studies have been carried out, the redistribution of efforts between the main elements of the raft-pile foundation has been considered. The change in the stress-strain state of the base of the raft-pile foundation under cyclic loading is considered. The significance of the obtained results for the construction industry lies in the fact that the proposed method for the first time allows us to evaluate the bearing capacity of a raft-pile foundation. Comparison of the calculation results for the proposed model with experimental studies showed good convergence.

Keywords: Deep foundations, Piles, Raft-pile foundation, Cyclic loading, Bearing capacity

1 INTRODUCTION

The limit value of the cyclic load (ultimate bearing capacity) taken by the raft-pile foundation depends on the conditions of joint deformation of the soil, piles and plate grate, and their strength and deformation properties and corresponds to the maximum cycle load that the raft-pile foundation can take at a given number of load cycles and a predetermined ultimate settlement (Indraratna. et al. 2015). The ultimate bearing capacity of the raft-pile foundation under cyclic loading is calculated at design values (γ_f>1) for the first group of the load limiting states and design values of strength and strain characteristics of soil, taking into account the decrease of fatigue strength and increase of cyclic creep deformation by the value of the ultimate resistance of soil base under the condition of limitation of development of vertical deformations in it according to predetermined conditions. In determining the ultimate bearing capacity of the raft-pile foundation under cyclic loading, we consider the ultimate stress-strain state of the system "raft-pile-pile-space-soil below the pile toe" under the bottom end of the pile and under the raft. When the pile is rigidly connected to the raft pile, all elements of the system are deformed together during cyclic loading and forces are redistributed between them (Katzenbach, R. & Leppla, S. 2011, Bokov, I.A & Fedorovski, V.G. 2018, 2019).

The behavior of the components of a raft-pile foundation with the surrounding soil mass in determining the stress-strain state of a raft-pile foundation has been considered by many

DOI: 10.1201/9781003299127-198

authors (Harichkin, A.I. et al. 2018, Shulyatev Q.A. 2016). So, for example, when determining the settlement of a raft-pile foundation, various factors and features are taken into account, one of such features is the additional settlement of a raft-pile foundation due to deformation of the pile shaft (Ter-Martirosyan Z.G. & Chin T.V. 2012).

Gotman, A.L. et al. (2021) describes a method for finding the bearing capacity of the soil under the pile foot as part of a group of piles. The method for determining the stress-strain state is based on the results of tests carried out for a pile as part of a group of piles and for one pile.

2 MATERIALS AND METHODS

The ultimate bearing capacity under cyclic loading of the raft-pile foundation is determined for the stage when tangential stresses along the lateral surface are absent in the upper and middle parts of the piles due to reaching the ultimate shear resistance (Mirsayapov, I.T. & Koroleva, I.V. 2016).

It is assumed that the spatial stress state is realized in the soil at the bottom of the raft cage and under the pile toe. The bearing capacity of the raft-pile foundation is reached when the stresses under the pile toe and under the raft exceed the fatigue strength and ultimate strain of the soil in three-axial cyclic compression. A model consisting of a raft rigidly connected to piles and a soil mass surrounding was taken as a design scheme. The bearing capacity of the raft-pile foundation was determined based on the conditions that the stresses under the pile toe and the stresses at the level of the pile head do not exceed the limiting stresses in the soil.

Calculation of ultimate bearing capacity is performed according to the value of stresses under the pile toe $P_3(N)^{max}$ and stresses under the raft superstructure $P_1(N)^{max}$ which value is determined for any considered loading cycle from solution of equation system (1) considering redistribution of forces between the system elements and their change in the process of cyclic loading.

$$\begin{cases} p \cdot AB = p_2(N) \cdot ab + p_1(N)(AB - ab) \\ p_2(N) \cdot ab = p_3(N) \cdot ab - 4(a+b) \cdot l \cdot \frac{\tau_0(N)}{\alpha} \cdot e^{-\alpha l} + (a+b) \cdot l \cdot \frac{\tau_0(N)}{\alpha} \\ \frac{p_1(N) \cdot \beta_{gr} \cdot L}{E_{gr}(N)} \left(1 - \frac{1}{L}\right) + \frac{k_1 \cdot \tau_0(N) \cdot (A-a)}{3G_{gr}(N)} + \frac{k_2 \cdot \tau_0(N) \cdot (B-b)}{3G_{gr}(N)} = \frac{\omega \cdot a \cdot p_3(N) \cdot (1-v_{gr}) \cdot k(l)}{G_{gr}(N)} \\ \frac{p_1(N) \cdot \beta_{gr} \cdot L}{E_{gr}(N)} + \frac{k_1 \cdot \tau_0(N) \cdot e^{-\alpha l}(A-a)}{3G_{gr}(N)} + \frac{k_2 \cdot \tau_0(N) \cdot e^{-\alpha l}(B-b)}{3G_{gr}(N)} = \frac{\tau_0(N)(a+b)l}{ab\alpha \cdot E_p} + \frac{\tau_0(N)(a+b)e^{-\alpha l}}{ab\alpha^2 \cdot E_p} + \\ + \frac{p_3(N) \cdot l}{E_p} + \frac{\omega \cdot a \cdot p_3(N) \cdot (1-v_{gr}) \cdot k(l)}{G_{gr}(N)} - \frac{\tau_0(N)(a+b)}{ab\alpha^2 \cdot E_p} \end{cases} \quad (1)$$

After definite number of loading cycles, the stresses in the soil reach the endurance limit in some of the elements:

under the raft, and then after a given number of cycles under the pile toe;

under the pile toe;

the simultaneous achievement under the raft and under the pile toe, i.e., in the soil under the raft $P_1(N)^{max} \le \sigma_{1v}(N)$, in the soil under the pile toe $P_3(N)^{max} \le \sigma_{1v}(N)$. Then a thin layer of soil under the pile toe and under the raft is pressed through and, consequently, an increase in displacement (settlement) of the raft pile foundation occurs and this process is periodically repeated until the total cumulative settlement of the pile foundation reaches the limit value for a particular building or structure (Figure 1).

3 RESULTS

The bearing capacity of the slab pile foundation soil under cyclic loading at the calculated moment of time (t = N) depending on the ratio $\tau_0(N) \le \tau^*(N)$ is estimated for two zones (Figure 2) based on the conditions:

In the soil under the raft:

$$p_1^{max}(N) = \sigma_{gr1}^{\max(N)_{gr}(N)} \le \sigma_{1u}(N) \quad (2)$$

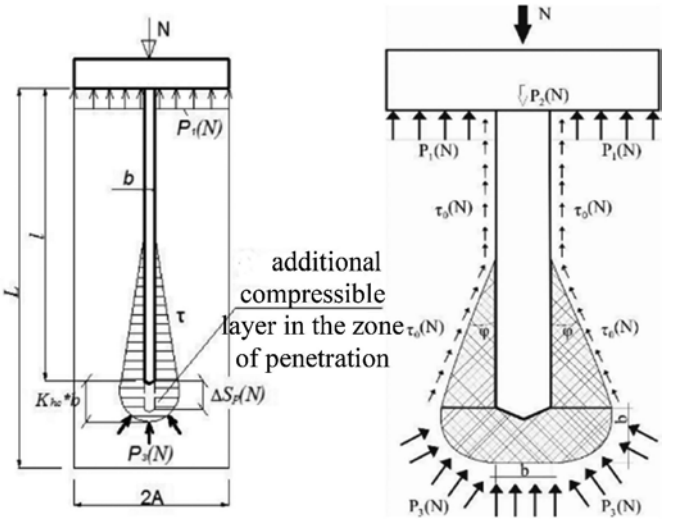

Figure 1. Scheme of the stressed state of the element of a raft-pile foundation according to the ultimate bearing capacity assessment.

In the soil under the bottom end of the pile:

$$p_3^{max}(N) = \sigma_{gr3}^{\max(N)_{gr}(N)} \leq \sigma_{1u}(N) \tag{3}$$

where $\sigma_{1u}(N)$ is the ultimate compression stress in of the soil under triaxial cyclic loading.

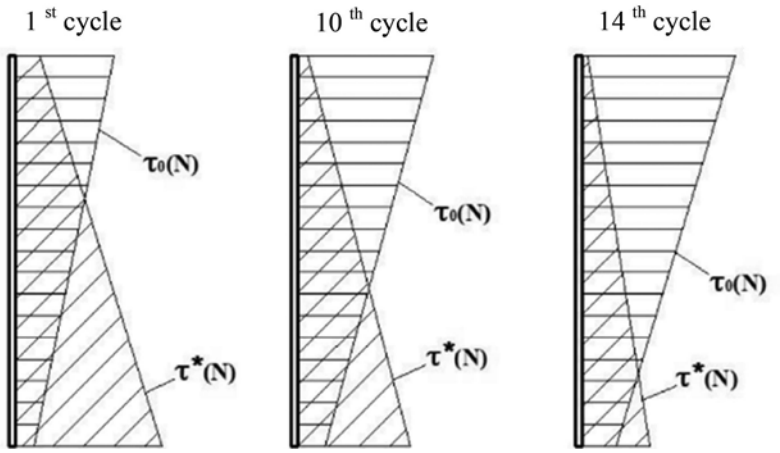

Figure 2. Diagrams of mobilized shear stress and ultimate shear stress by experimental study.

The ultimate stresses in the soil under the raft-pile foundation under triaxial cyclic loading are determined from the calculation model of soil under spatial mode loading developed by Ilizar T. Mirsayapov & I.V. Koroleva (2019) and are represented in the form:

$$\sigma_{1u}(N) = \frac{4}{A_1} \cdot [\sigma_v(t, t_1, N) \cdot A_{sh} \cdot \cos\alpha_1(t, t_1, N) + \tau_V(t, t_1, N) \cdot A_{sh} \cdot \sin\alpha_1(t, t_1, N)] \tag{4}$$

Normal stress to the surface of limiting equilibrium:

$$\sigma_v(t,t_1,N) = \sigma_1 \cdot l(t,t_1,N) \cdot l'(t,t_1,N) + \sigma_2 \cdot m(t,t_1,N) \cdot m'(t,t_1,N) + \sigma_3 \cdot (t,t_1,N) \cdot n(t,t_1,N) \cdot n'(t,t_1,N) + \sigma_d(t,t_1,N) \quad (5)$$

Dilatant stresses:

$$\sigma_d(t,t_1,N) = \frac{E \cdot \Delta\delta d}{(1+v) \cdot r} \quad (6)$$

where E – soil deformation modulus.

Shear stresses at the limiting equilibrium surface:

$$\tau_v(t,t_1,N) = \sigma_v(t,t_1,N) \cdot tg(t,t_1,N) + c(t,t_1,N) \quad (7)$$

where, σ_v (t,t_1,N) – normal stress to the surface of limiting equilibrium;φ (t,t_1,N) - angle of internal friction of soil under cyclic loading;

c (t,t_1,N) – specific cohesion of soil particles under cyclic loading.

Parametres of calculating model for bearing capacity taken according to work of I.T. Mirsayapov & M.A. Sharaf Hani (2020, 2021).

4 DISCUSSION

The bearing capacity of a slab-pile foundation under cyclic loading is determined at the design values of the load, strength and deformation characteristics of the soil, taking into account the decrease in fatigue strength and the increase in cyclic creep deformation by the value of the ultimate resistance of the soil base under the condition of limiting the development of vertical deformations in it. If conditions (2) and (3) are simultaneously fulfilled, the bearing capacity of the raft-pile foundation is ensured.

If the conditions are not fulfilled, the bearing capacity of the foundation is not ensured and there are three possible ways of reaching the bearing capacity ultimate condition of the raft-pile foundation:

1. Condition (2) is not fulfilled, i.e., the stress in the soil under the raft becomes greater than the ultimate stress in the soil. In this case, the part of the load absorbed by the soil is transferred to the pile by loading the pile. The raft-pile foundation absorbs the load as long as the condition (3) is fulfilled. When condition (3) is violated, the soil beneath the bottom end of the pile will be pressed through, and the raft-pile foundation will sink;
2. Condition (3) is violated first, but there is no sharp movement of the foundation, because the pile rests on the raft-suspended buttress, which loads the soil under the raft-suspended buttress.
3. The foundation takes the load until the first condition (2) is violated. At this point, rapid settlement of the raft-pile foundation occurs. Both first and second conditions are not fulfilled at the same time, and rapid subsidence of the raft-pile foundation occurs. This process is periodically repeated in the process of cyclic loading until the foundation's settlement becomes greater than the maximum allowable settlement.

5 CONCLUSION

Equations for the bearing capacity of a raft-pile foundation under cyclic loading have been developed. The resulting equation of the mechanical state of the raft-pile foundation describes the main patterns of behavior of such foundations, observed in experiments at various stages

of loading, make it possible to reliably assess the bearing capacity of raft-pile foundations under cyclic loading. Thus, the limiting value of the bearing capacity of a raft-pile foundation under cyclic loading corresponds to the maximum value of the cycle load, at which the ultimate given value of foundation settlement is achieved for the number of load cycles established by the operating conditions of a particular building or structure at the value of the loads, strength and strain properties of soils accepted. Comparison of the calculation results with the data of experimental studies of pile foundations showed good convergence between the calculated and experimental values (deviation no more than 15%).

ABSTRACT: India's longest river bridge (Dhubri-Phulbari Bridge) will be constructed over the river Brahmaputra in the state of Assam/Meghalaya in northeast India. Based on the geotechnical investigations at the site, the entire bridge is proposed to be constructed on pile foundations. The integrity of the piles was verified through the assessment of Cross Hole Sonic Logging (CHSL) tests at the site. The arrival time and signal energy of the stress pulses were used to inspect the pile integrity, and the position and extent of defects, if any. The tests were conducted while maintaining pulse wave speed (>4000 m/s) and recommended signal strengths. Usually, a pile is classified as acceptable if the first arrival time increases up to 20% and the energy reduction is <9 dB. The interpretation of CHSL test data identified a few defective piles attributing cross-sectional changes, honeycombing, and poor concrete quality. This paper presents a detailed case study to handle such an important mega project showing the effective use of the CHSL test.

Keywords: Bridge, CHSL, North-East India, Pile Integrity, Pile Foundation

1 INTRODUCTION

The Dhubri-Phulbari 4-lane road bridge will be constructed over the river Brahmaputra and will connect Dhubri (in North Bank) with Phulbari (in South Bank) in the state of Assam/Meghalaya on National Highway (NH-127B). The total length of the bridge from Dhubri to Phulbari end is approximately 18.36 km. Out of the total length, 12.625 km is navigational span, and the remaining portion is the approach viaduct. This will culminate in establishing the shortest access to Meghalaya from Assam and will serve as a main commercial and strategic link route. The construction of this bridge will reduce the travel time to twenty-three minutes from Dhubri to Phulbari, which presently takes more than eight hours by land route and about two and a half hours by ferry.

The bridge will further provide a stable flood-free route and become an effective alternative to the existing ferry route during monsoon season. Figure 1 (a) presents the geographical location of this proposed bridge on the world map. Based on the geotechnical investigation and subsoil condition, the entire bridge is proposed to be constructed on pile foundations. Quality Assessment

DOI: 10.1201/9781003299127-199

(QA) of these piles is a prime concern as this may eventually affect the pile capacity and ability to resist the desired lateral and vertical loads. For example, Camp et al. (2007) performed pile integrity tests on different projects in southern California and found that 70% of the projects had at least one defective pile. Non-Destructive Testing (NDT) methods are commonly used for quality assessment integrity tests of cast in-drilled-hole piles, bored piles, or other concrete structures, such as the drilled pier, caissons, diaphragm slurry walls, dams, etc. Several methods such as Cross Hole Sonic Logging (CHSL), High Strain Dynamic Pile Test (HSDPT), Pile integrity test (PIT), etc., are presently utilized to perform NDT of pile foundations.

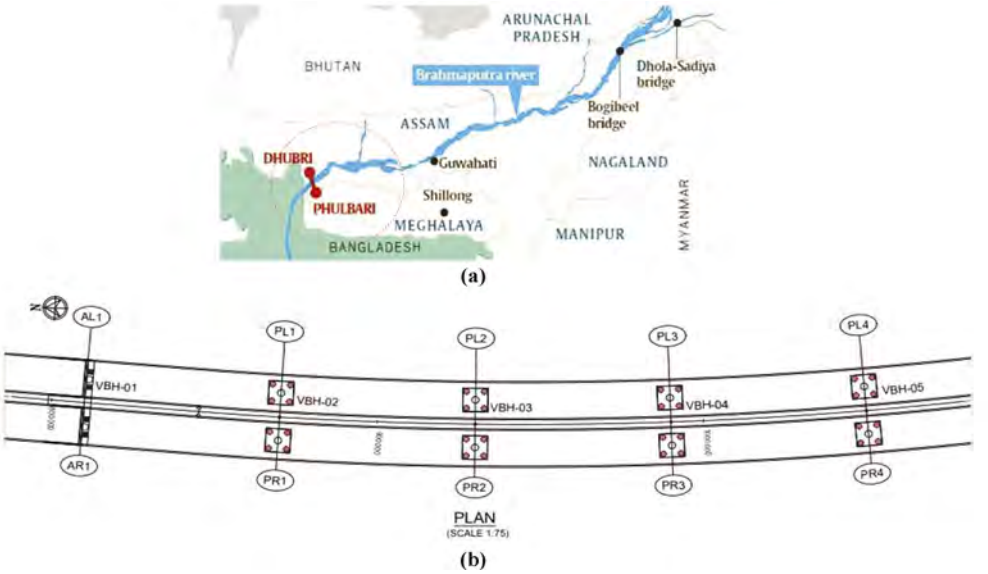

Figure 1. (a) Geographical location of Dhubri-Phulbari Bridge, and (b) Plan view of a small section of the proposed bridge indicating the location of the piers and the piles.

Among these, CHSL is a well-established technique to inspect the soundness of concrete for deep piles and recognizes the defect/flaw position based on the velocity of ultrasonic pulses (Bagui et al., 2020). The test offers several advantages such as (a) precise determination of soil incursion or other irregularities throughout the shaft inside the rebar cage, (b) defects at various depths of the pile can be recognized with high accuracy, (c) uncured concrete in chemically retarded mixes can be identified, and (d) exceptional care in handling is not necessary at the time of the use of radioactive sources. The present study, therefore, preferred to undergo CHSL tests to determine the soundness of concrete for piles at the Dhubri-Phulbari project location and discusses the effectiveness of this test in handling such an important mega project. The discussion is limited to the CHSL test results of four defective bored piles identified as PR1-C1, PL2-C2, PR3-C1, and PR5-C1 under different piers P01, P02, P03, and P05, respectively, as designed for this project. This limitation is for the sake of the brevity of the paper. Figure 1(b) presents a plan view of a small section of the proposed bridge indicating the location of the piers and the piles.

2 METHODOLOGY ADOPTED FOR CHSL TEST

The Cross Hole Sonic Logging tests were performed following ASTM D6760 (2014). The test initially applied drill shafts and six mild steel tubes were installed in a drilled shaft before pouring the concrete. Figure 2 (a) presents a schematic representation of the tubes installed in PR1-C1. A similar arrangement of tubes was followed for the other piles. The installation of tubes was followed by the pouring of water into the tubes and the top and bottom of the tubes were sealed before concreting. The reason behind pouring water into the tubes was to control the differential

temperature during concreting and curing. The CHSL test was conducted after a week of concreting the pile. At first, the ultrasonic transmitter and receiver probes were dropped down to the base of the access tubes. These probes were then pulled off concurrently at the same time to maintain near-horizontal ray paths between them (i.e., zero offset logging). Both transmitter and receiver probes were connected by cables to the Cross Hole Analyzer (CHA) and high-frequency stress pulses were sent from one tube to the other at 50 mm vertical intervals. The CHA recorded the arrival time as well as the signal energy of the pulse at the receiver tube. Figure 2 (b) presents a schematic representation of the CHSL test setup. These recorded data were used to interpret the quality and integrity of the concrete between the tubes. The entire shaft length was scanned in this fashion by repeating the test across diagonals & adjacent perimeters as presented in Figure 2 (a). The tube corridor considered for each pile is represented as 1-2, 2-3, 3-4, 4-5, 5-6, 6-1, 1-4, 2-5 (refer to Figure 2 (a)).

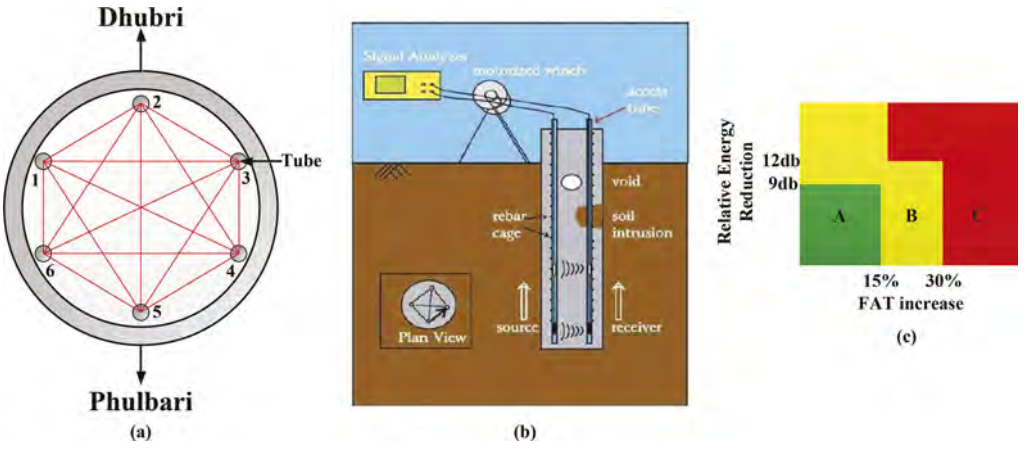

Figure 2. Schematic representation of (a) the tubes used in the CHSL test for PR1-C1, (b) CHSL test setup, and (c) Graphical interpretation of proposed CSHL rating criteria by DFI (2019).

2.1 *Interpretation of the CHSL test results*

The arrival time and signal energy of the stress pulses recorded using CHA were used to inspect drilled shaft's integrity, and the position and extent of defects in the piles. Uniform concrete will result in a near-continuous vertical profile of the waterfall-displayed data and yield consistent first arrival times (FAT) with reasonable pulse wave speed and signal strengths. Non-uniformities in concrete such as honeycombing, formation of voids in concrete, contaminated concrete, or soft concrete exhibit delayed FAT with lower signal amplitudes. The wave speed is affected if the tubes installed are not perfectly straight and parallel and depend on the age of the concrete. DFI (2019) recommended that CHSL results for each profile should be categorized into either of the following three classes based on FAT and signal energy received at the receiver tube relative to FAT and signal energy received in a nearby zone of good concrete: Class A: It represents acceptable test results where percentage increase in FAT value and the reduction in relative energy value is not more than 15% and 9 dB of their local average values, respectively. Class B: It represents conditionally acceptable CSHL test results where the percentage increase in FAT value lies within a range of 15% to 30% of the local average FAT value, and relative energy reduction is less than 12 dB. Further, Class B can be also represented as the percentage increase in FAT value less than 15 % and the reduction in relative energy value higher than 9 dB of their local average values, respectively. Class C: It represents highly abnormal CSHL test results with FAT increasing more than 30% of the local average values. Further, it may also be represented as the percentage increase in FAT value and the reduction in relative energy value greater than 15% and 12 dB of their local average values, respectively. Figure 2 (c) presents a graphical interpretation of the proposed CSHL rating criteria by DFI (2019). The present study followed the classification system

Table 1. Interpretation of defects in the pile shaft based on FAT and signal energy.

S. No.	Pile Classification	% Increase in FAT relative to good concrete	Energy reduction relative to good concrete	DFI (2019) classification guideline
1.	Satisfactory/good	0-10	< 6 dB	Class A
2.	Minor/flaw	11-15	<9dB	
3.	Poor/flaw	15-30 or < 15	9 dB to 12 dB	Class B
4.	Poor/defect	> 30	> 12 dB	Class C

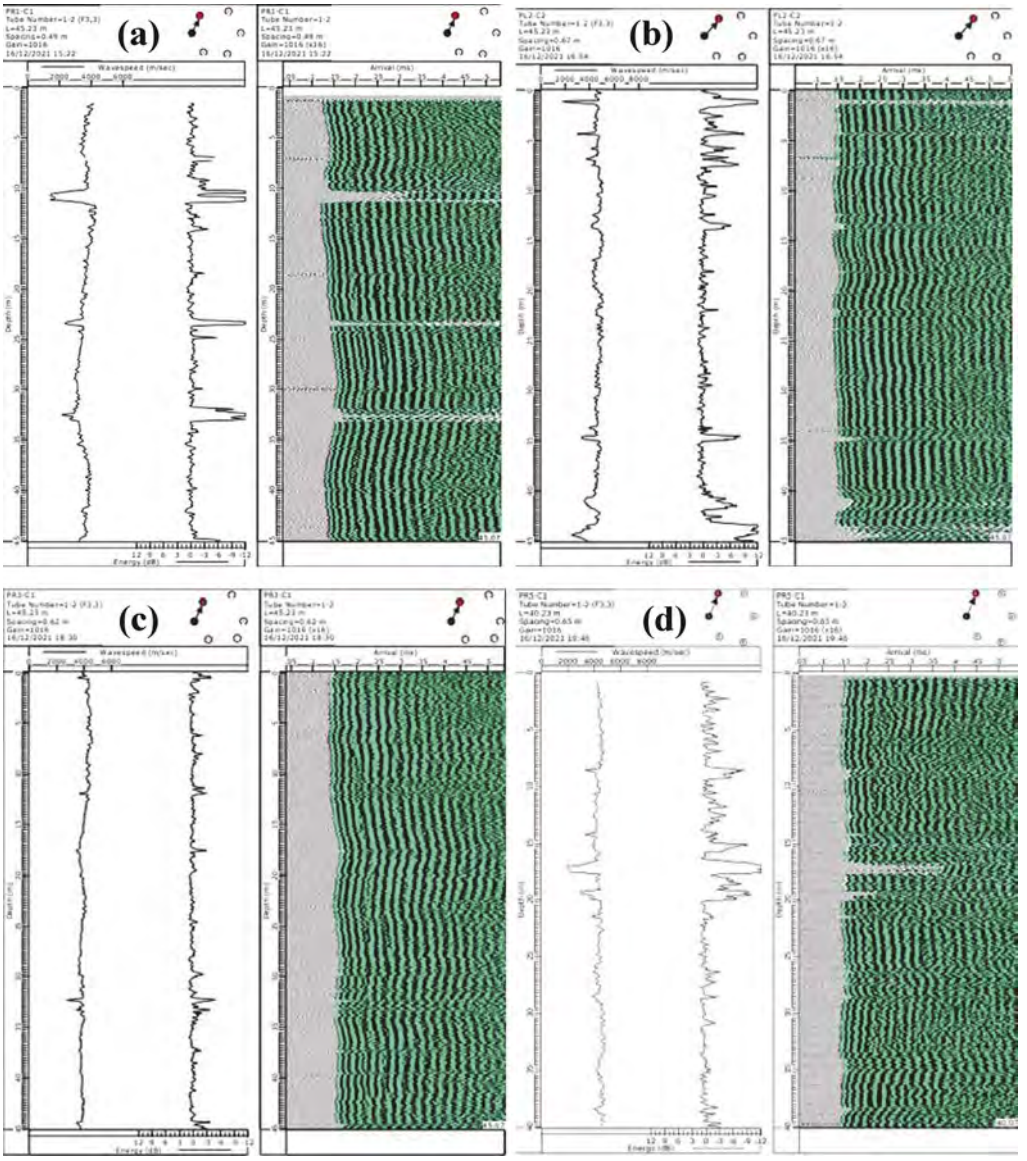

Figure 3. CHSL result of tube corridor 1-2 for (a) PR1-C1, (b) PL2-C2, (c) PR3-C1, and (d) PR5-C1, respectively.

proposed by DFI (2019) to predict the defects and flaws in the pile shaft at the project location. Table 1 typically presents the classification details for the interpretation of defects in the pile shaft.

3 OBSERVATIONS FROM CHSL TEST RESULTS

This section is focused to comment on the critical observations made from the CHSL test results.

Figure 3 presents a sample result for the tube corridor 1-2 (refer to Figure 2 (a)) for PR1-C1, PL2-C2, PR3-C1, and PR5-C1, respectively. The curves indicate the average wave speed, energy reduction values, and FAT values which are used to identify the defects and flaws at different pile locations. Similar types of curves were also generated for all other tube corridors (i.e., 1-2, 2-3, 3-4, 4-5, 5-6, 6-1, 1-4, 2-5) across diagonals & adjacent perimeters for all piles. Further, DFI (2019) guideline is used to categorize the defects in the piles in different classes (i.e., Class A, B, and C). It may be observed from Figure 3 (a) that the energy reduction and percentage increase in the FAT value are greater than 12 and 30, respectively, for PR1-C1 and as a result, indicated poor/defect and can be classified in the Class C category as per DFI (2019) guideline.

Further, it is noticed that PL2-C2 shows poor/defects and poor/flaws (i.e., Class C and B) at around 1 m to 5 m, 6 m to 7 m, and 41 m to 44 m depths, respectively. Apart from these, PR3-C1 test results indicate a uniform pile shaft throughout the depth with minor/flaws (i.e., Class A) at a few locations. Lastly, PR5-C1 shows poor/defect (i.e., Class C) between 16.5 m to 17.5 m depth and poor/flaw (i.e., Class B) at a depth between 19 m to 19.5 m. Further, the detailed review of the defects and flaws for the four piles considering all the tube corridors and attributing the location of defects in the piles are summarized in Table 2.

Table 2. Poor defects and flaws observed at different pile locations.

S. No.	Pile Number	Pile Length (m)	Pile Diameter (m)	Comments
1.	PR1-C1	45.07	1.65	Poor/ defect at • 8.8 m to 11.5 m • 22.3 m to 23.5 m • 31.7 m to 33.1 m
2.	PL2-C2	45.07	1.65	Poor/ defect and Poor /Flaw at • 0.8 m to 1.8 m • 3.0 m to 4.8 m • 6.7 m to 7.7 m • 40.7 m to 45.07m
3.	PR3-C1	45.07	1.65	Poor/ defect at • 29.3 m to 33.3 m
4.	PR5-C1	45.07	1.65	Poor/ defect at • 16.4 to 20 m

Note: Minor defects and flaws are not mentioned in this table.

4 SUMMARY AND CONCLUSIONS

The present study discusses the outcome of the Cross Hole Sonic Logging (CHSL) test results conducted on test piles at the Dhubri-Phulbari Bridge site in Assam, India. The discussion of this study is limited to the CHSL test results of four defective RC bored piles identified as PR1-C1, PL2-C2, PR3-C1, and PR5-C1. The test results are presented across diagonals & adjacent perimeters for each pile and interpretation of the defects in the piles is made based on energy reduction value, FAT, and average wave speed of the signal, respectively. Poor defects and flaws (i.e., Class C and B) are noticed at several pile depths. Apart from this, minor/flaws

are also observed. The details of the defects and flaws observed in this test for all the piles considered are summarized in Table 2. Further, it may be concluded that the CHSL test may be considered appropriate for the initial inspection of the defects/flaws at different pile locations. However, a single CHSL test may not be sufficient to accurately evaluate the integrity of the pile for potential problems like cross-sectional changes, honeycombing, etc. Hence, other low-cost NDT tests such as HSDT and PIT may help in ensuring the discrepancies occurred in the pile. These tests were performed at the Dhubri-Phulbari project site for a re-assurance of the defects in the piles identified in the present study, however, not presented here for the sake of brevity.

Analysis of the interaction of the massive shell with the ground

N.A. Perminov
Emperor Alexander I St. Petersburg State Transport University, St. Petersburg, Russia

ABSTRACT: Analysis of interaction regularities of large-size reinforced concrete shells at the erection stages in heterogeneous soil mediums allowed to significantly expand the field of their rational use in underground construction parameters and indicators. Strength and deforativeness of a large-size massive structure, its geometrical variability should be calculated not only for the final stage of construction but also for a whole history of driving considering a history of caisson-soil bulk interaction at driving, and, consequently the effect of gradual inheritance of stress-strain state. The methodological approach proposed in the paper allows transferring from the earlier accepted methods of calculation of underground caisson structures to the concept of simulation and prediction of defectless lifecycle at the stage of construction. Modeling and calculative substantiation of schemes and parameters of preventive protection of an underground structure at the stage of its construction using geotechnical methods provides its safety and resistance against technically generated impacts.

1 FEATURES OF INTERACTION OF A LARGE SHELL WITH HETEROGENEOUS SOIL MILIEU AT THE STAGE OF ITS LOWERING

In order to provide stable and safe operation of large caisson structures there is a need to ensure internal integrity of fencing structures with high degree of waterproofness at all stages of their life cycle.

The existing standards (Ilichev & Mangushev. 2016) and regulations (The set of regulations. 2012) envisage checking calculations of underground structures to be lowered for the stages of their construction and operation. However, based on the experience one can say that in case of large caisson structures it is not enough due to specific conditions of their interaction with a soil bulk and inclusion the effect (factor) of a large scale: hyper sizes of an area of lateral surface of the shell, which interacts with heterogeneous soil, and its super large weight, which creates a powerful kinetic impulse during instant, often sudden subsidence, cause a beyond-design situation for a caisson structure. Joint actions of these factors stipulate specific non-linear behavior of the structure at lowering as well as the host soil bulk. Due to strength and deformability of the large massive structure, its geometric changeability it is necessary to calculate not only the final stage of construction but also the whole history of lowering taking into account a history of the process of shell-soil bulk interaction during caisson lowering and, consequently, the effect of gradual inheritance of stress-strain behavior. These problems could be solved only by tackling non-linear problems, non-linear models and computer non-linear simulation (Perminov, Zencov & Perminov. 2013), (Barabash. 2012), (Ilichev. 2008).

The analysis of the results of in situ and calculation-experimental works and the data of the comprehensive system of geotechnical monitoring (Figure 1) of lowering large shells showed the features of their interaction with heterogeneous soil milieu (Perelmuter & Kazantsev. 2015). The geotechnical profile for the monitored facilities is characterized as follows: the upper layer is represented by Quaternary strata down to the depth of 14.0–25.0 m. (Table 1).

The monitoring identified a very important phenomenon: the peak values of horizontal stresses exceed the calculation values 2.3–2.5 times, and it is observed at deviation of the shell from the vertical axis and changes of its geometry (Figure 1). It can be the reason of

DOI: 10.1201/9781003299127-200

Table 1. Characteristics of the geotechnical profile of the monitoring object.

Layer	Deformation model (E)	Specific coupling (C)	Internal friction angle (φ)

suspension of the process of lowering the massive shell with a subsequent sudden, conditionally instant drop. Based on the analysis of the graph of lowering (Figure 2a) it can be seen that a value of drop reaches 1.5 m and more. The shell structure takes impact beyond-design loads by creating a powerful kinetic impulse by its drop to the soil bulk of a pit bottom (Perminov. 1997), that can cause occurrence of microcracks in concrete of the structure and inevitably leads to violation of the structural hydro insolation. This phenomenon has been identified after 10–15-year-long operation of the gas and pumping station complex of the water treatment facilities of St. Petersburg (Perminov & Perminov. 2014).

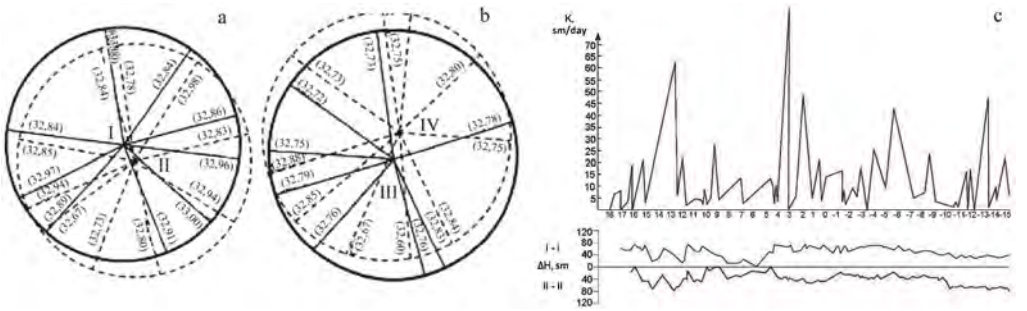

Figure 1. Displacement of the center of circle O during its lowering to a depth: a, b, c– H = 17 m; H =29 m; H = 25m; H = 29m.

Geomonitoring showed unsteadiness of the processes of interaction of the external contour of the massive structure (Perelmuter & Slivker. 2011). Complex and, as a rule, uncontrolled character of the processes during conditionally instant embedment of the shell into the host heterogeneous milieu as well as the environment, that has physical and genetic non-linearity (The set of regulations. 2016), demonstrate that the study of stain-stress behavior of the shell and soil bulk can be carried out only on the basis of computer modeling of this process using geotechnical and structural software complexes.

2 THE SIMULATION OF CONTROLLED REGIMES OF LOWERING THE MASSIVE SHELL INTO A SOIL OF DIFFERENT STRENGTHS USING THE METHODS OF GEOTECHNOLOGY

The analysis of behavior of the caisson structure during its sudden uncontrolled sliding (drop) to the bottom of an open soil cavern from the height 1.3 – 1.5 m with the angles of deviation from the vertical axis 0.5°-5°C was conducted with a help of the software complex Autodesk Robot Structural Analysis Professional (Carmody & Sterling. 1993).

While developing the calculation model (Figure 2) it was considered that the shell structure consists of two cylinders, one stands on the other: the upper cylinder: the external radius R = 36 m, the internal radius R = 30.5 m, the height H1 = 46 m; the lower cylinder: the external radius R = 36 m, the internal radius R = 30 m, the height

H2 = 25 m. Therefore, the external diameter of the shell was D = 72 m, the height of the shell was H = 71 m. Concrete grade - B30.

In order to simulate a value of impact force at dropping the shell in the model the cylinder fell from the height H = 150-250 cm under the action of its own weight with the tilt angle 0.5°-5° to a flexible soil (green-gray clay: φ = 21°, C = 0.04 MPa, E = 19 MPa). A spatial calculation scheme of the shell was modelled: the weight G = 210000 tons; the amount of nodes 16944; the amount of volumetric finite elements 12496; the amount of static degrees of freedom 50828; the amount of loadings 27; the acceleration of gravity g = 9.81 m/kV.s; the time of drop $t=\sqrt{(2*H/g)}$; Δt=0.30-0.54 s. Due to the tilt angle friction forces were applied in the upper part of the caisson from one side and in the lower part – from the opposite one.

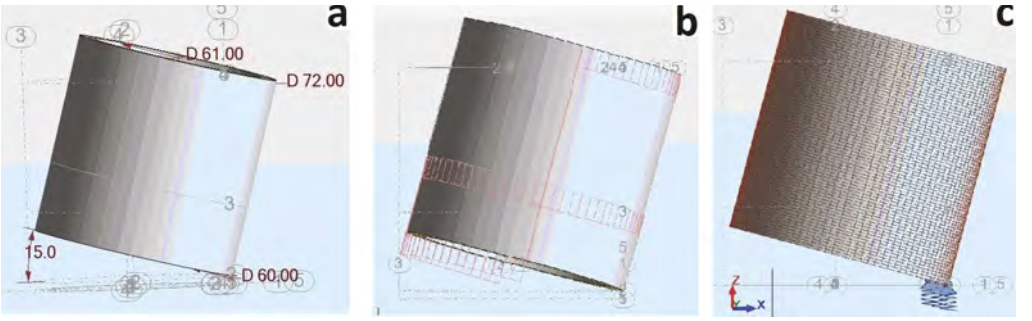

Figure 2. The schemes of calculation models of the lowered shell at different angles of its deviation from the vertical axis: a- static support at tilt; b,c — drop and sliding at tilt (deviation from the vertical axis).

As the simulation of the processes of drop at different angles of deviation of the shell from the axis -α and falling heights –ΔH was made in quite a large range, Figure 3 gives only the most typical results, which were taken for the analysis. The total calculation table of the results of integration of motion equation for the shell during the drop (falling) at speeds VZ, VX, VY (cm/s), acceleration AZ, AX, AY(cm/s^2) and displacements UZ, UX, UY (cm) included 186385 lines.

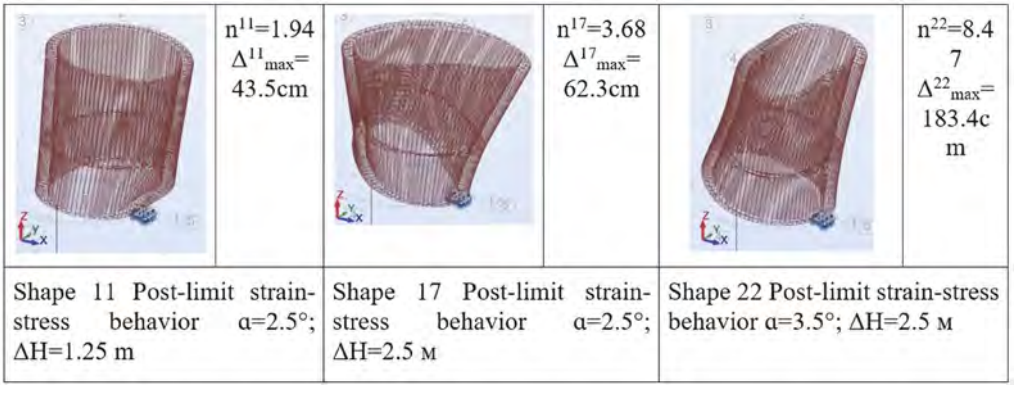

Figure 3. The simulation results.

Based on the simulation results (Figure 4) there were set admissible parameters of spatial location of the shell and the ranges of its conditionally instant drops, which provide pre-limit strain-stress behavior of the shell.

The simulation results show that for the large shell the recommendations of regulatory documents (Ponomaryov, Kaloshina, Zakharov, Bezgodov, Shenkman & Zolotozubov. 2015) have limited application and are needed to be confirmed via calculative modeling.

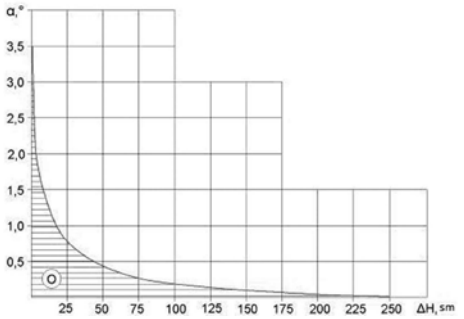

Figure 4. The area of limit admissible values of conditionally instant drops ΔH of the shell, D=61m, height H=71m, weight G=210000 tons, at different angles of deviation of the structure from the vertical axis α°(Concrete B30; φ = 21°, C = 0.04 MPa, E = 19 MPa).

Taking into account the results of the previous steps of modeling, at this stage the problem of geotechnical simulation of the process of lowering the shell into the soil bulk in a controlled mode was solved. The geotechnical methods (Nikiforova, Konnov, Nguyen Van Hoa, Prostotina. 2019) served as external impacts on the "shell-soil bulk" system.

An incremental model of deformation type was used as the calculation soil model for solving the non-linear problem. A stress-strain connection in the model was taken separately for volumetric and shear components of a stress tensor

$$\left.\begin{aligned} dS_{ij} &= 2G^T \cdot de_{ij} \\ d\delta_{cp} &= 3K^T \cdot d\xi_{cp} \end{aligned}\right\} \tag{1}$$

where: dS_{ij} and de_{ij} are increments of deviatoric components of stress and strain tensors, respectively; $d\delta_{ij}$ and $d\xi_{ij}$ are increments of average stress and strain; G^T and K^T- tangent moduli of deformation of shape and volume.

Tangent moduli of deformation G^T and K^T were approximated according to linear polynomial of the second degree with one variable:

$$\left.\begin{aligned} G^T &= G(S_{ij};\delta_{ij}) = A_0 + A_1\delta_{cp} + AS_{ij} \\ K^T &= K(\delta_{cp}) = B_0 + B_1\delta_{cp} + B_2\delta_{cp}^2 \end{aligned}\right\} \tag{2}$$

Approximating dependencies (2) are experimentally substantiated on the example of stabilometer triaxial tests (STT).

The parameters of the calculation model A0; A1; A2; Kp; B0; B1; B2 were defined based of the data of STT. The medium-grained sandy soil of the density Pd=1.65g/cm^3 and water content W=10% was used as the tested soil. All calculations were made using the numerical method of finite elements with a help of geotechnical software. The procedure of solving the non-linear problem was reduced to the well-known method of variable rigidity (Nguyen Van Hoa & Nikiforova. 2018), (Nikiforova & Nguyen Van Hoa. 2020), (Bulychev & Fotieva. 2017), according to which the matrix of rigidity was transformed at each step of the solution in accordance with the current level of stress-strain behavior and orientation of the vector of additional loading.

Figure 5a shows a characteristic graph of the shell contour displacement to the design position with inclusion of a geotechnical impact on strain-stress behavior of the surrounding soil bulk into the calculation. The results of simulation show (Figure 5b) that rectification of the shell contour displacement almost to the design position (from 32.8 cm to 9.01 cm) allows decreasing an area of distribution and a value of settlement of the soil bulk around the shell

several times (the area of distribution reduces from 45 m to 9 m; the value of settlement, respectively, from 150 cm to 8 cm).

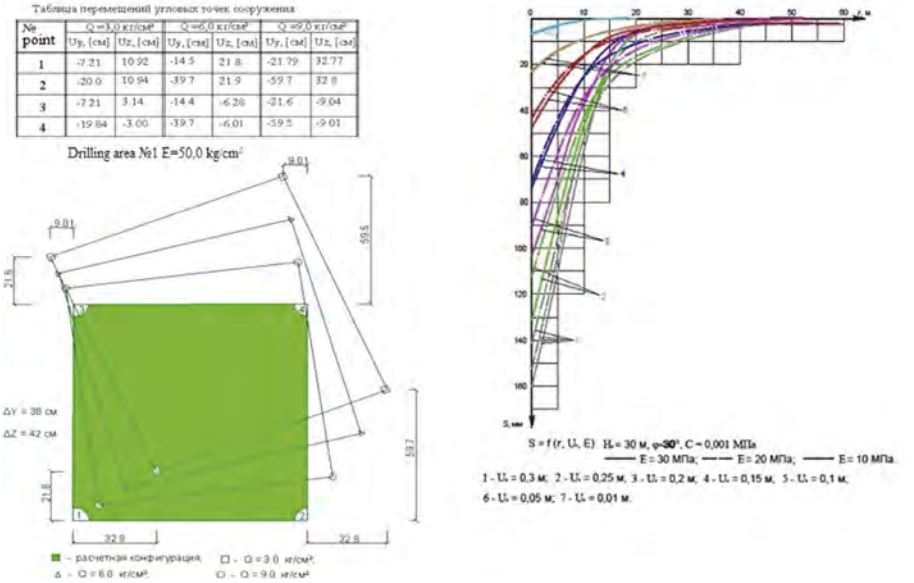

Figure 5. The displacement of the shell contour in continuous milieu: a - at correction of tilt under the conditions of action of a lateral additional load Q = 0.3- 0.9 MPa; b – the influence of a value of the shell contour displacement Ux on settlements of the soil surface at correction of tilt.

3 CONCLUSIONS

Simulation of the interaction of an unstable structure with the ground environment during immersion and the analysis of behavior fencing shell during its gradual increasing and lowering into the heterogeneous soil milieu allowed identifying a number of factors, which characterize its non-linear behavior in the conditions of joint interaction.

Physical non-linearity is caused by behavior in the elasto-plastic area of the soil bulk, which contacts with the lateral surface, during deviation of the structure from the vertical axis. Geometric non-linearity manifests itself when its geometry changes asymmetrically during instant-stepwise drops of the massive shell.

Unsteadiness of the processes of interaction of the massive structure with the soil milieu as well as itself causes the necessity of creating methods of adaptive control of the stress-strain behavior of the system "gravitational large body – heterogeneous host milieu".

Due to joint step-by-step making geotechnical and structural calculations a history of the processes of shell-soil milieu interaction is simulated, the parameters of the adaptive control of the system of strain-stress behavior, which are implemented with a help of external geotechnical impacts at the stage of construction of the structure, are predicted.

Cantilever steel tubular pile wall embedded in soft rock subjected to various loadings

S.M. Shafi & J. Takemura
Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT: Mechanical behavior of large stiffness cantilever steel tubular pile wall embedded in soft rock was investigated by centrifuge model tests under 50g. Two models were prepared with common wall height H=12m and pile diameter Φ=2m, and two embedment depths in soft rock (qu=1.4MPa) dr =2.5m and 3.0m in a prototype scale. Dynamic loadings were first applied to the wall retaining dry sand, and then static loading was simulated by rising water level in the sand. Second series of dynamic loadings were further applied to the wall with the wet sand. It was found that the dr increment of 0.5m could significantly reduce the wall displacement, but increase the moment load and thrust force to the wall, which suggesting the wall structural failure could be a critical condition even for the small dr of about 1.5Φ, especially during the dynamic loading.

1 INTRODUCTION

Embedded (un-propped) retaining walls (known as cantilever-type retaining walls) are commonly used for temporary and permanent structures depending on the site condition. In recent years, one of the popular forms of this retaining structure is cantilever-type steel tubular pile (CSTP) walls. Advanced technology like the rotary cutting press-in method allows applying this CSTP wall for various purposes (Kitamura and Kitamura, 2018). However, like other civil engineering structures, this retaining wall should satisfy the required performance under the design condition. Traditionally, cantilever-type retaining walls are designed considering relatively flexible retaining walls embedded in soft grounds for small retain height (H) (≤4m) (JTASP-PACTC. 2007). As shown in Figure 1(a), the application of CSTP walls might exceed the traditional retaining height. Also, different kinds of temporal load could be expected during the service period, like earthquakes or an increase of the groundwater level in the retained soil, as shown in Figure 1 (b).

This external loading might produce a significant moment load leading to large wall deflection for large retain height. However, if high stiffness (EI) wall, for example, a large pile diameter (Φ) steel tubular pile wall, is embedded in moderately stiff ground (like a soft rock), this large deflection could be untangled. Based on the design guideline by JTASP-PACTC (2007), the minimum required embedment depth ($d_r=L_o\geq 3/\beta$: where β is the characteristics value) could be very conservative for walls embedded in the hard ground (Takemura 2021). Kunasegaram and Takemura (2021) conducted centrifuge tests on simplified plate-type cantilever retaining walls with (d_r)<40% of the required d_r by guidelines. They observed no catastrophic failure with this small embedment depth against static loading by water rise. In this study, two centrifuge models were made following the test conditions of Kunasegaram and Takemura (2021). Sequential dynamic loadings and static loadings (by water rise) were applied to investigate the mechanical behavior of the wall and discuss the critical conditions which should be considered in the rational design of this type of wall.

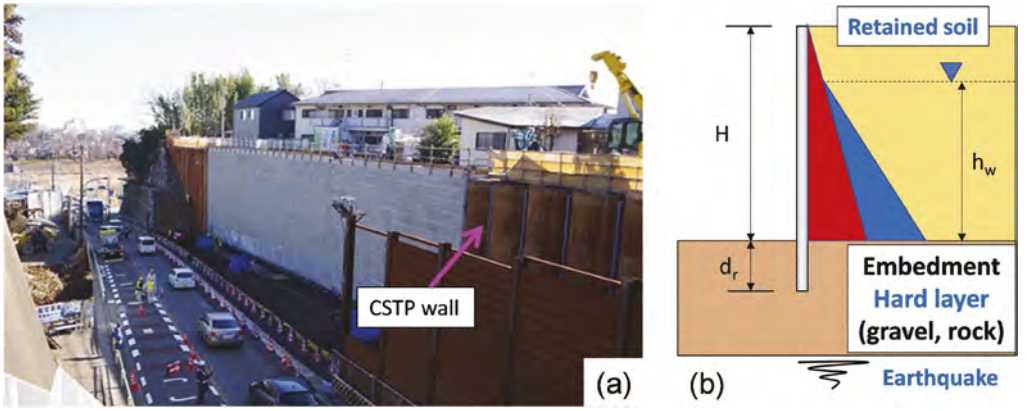

Figure 1. (a) Cantilever type large diameter steel tubular pile (CSTP) wall (Kitamura and Kitamura. 2018) and (b) various loading expected during design life.

2 CENTRIFUGE TEST

The side view of the model is illustrated in Figure 2. This model was made under 50g centrifugal acceleration, as shown in Figure 2 (a). A rigid frame container (shown in Figure 2 (c)) with inner dimensions of 600mm x 400mm x 250mm was used to prepare the model. A 33mm acrylic plate was attached to the back of the container to reduce the width. The model wall consisted of five steel tubular piles (SUS304, shown in Figure 2 (b)) firmly fixed at the top and spanned the width maintaining the plane strain condition. By air pluviation technique, Toyoura sand (maintaining Dr=85%) was poured into the rubber bag placed at the back of the wall. This rubber bag was used to define the boundary condition clearly and make a water-tight environment. Different sensors were used to measure different responses during shaking. More details about the model preparation can be found in Shafi et al. (2021). An artificially prepared soft rock with unconfined compressive strength (q_u) of 1.4MPa (on the 14th day of curing) was used as supporting ground. This soft rock was prepared with sand-

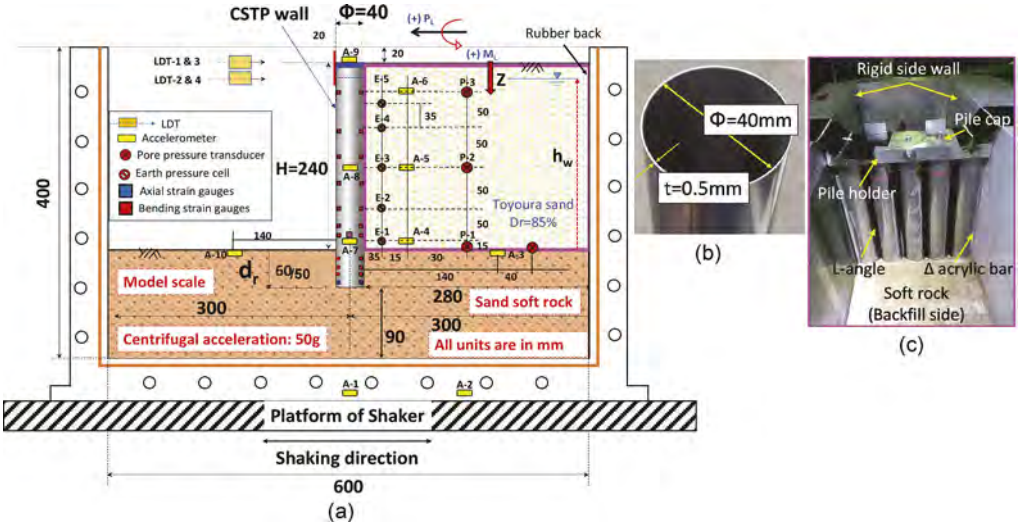

Figure 2. (a) 2D view of model (b) model pile used (c) modeled CSTP wall embedded in solidified soft rock before backfilling.

clay-cement and mixed with the appropriate amount of water. More details about the preparation of the artificial soft rock can be found in Kunasegaram & Takemura (2021).

The stability of the model CSTP wall was checked using the pressure distribution given by Padfield and Mair (1984). In this paper, the factor of safety (FS) is defined by rotational stability computed using the moment minimization technique (Madabhushi et al., 2005), assuming $\phi=0^o$ below the dredge level. The calculated FS for different water levels (h_w) is also shown in Figure 4 (b). In dry conditions, FS of about 2.3 and 1.9 can be ensured for cases 1 and 3, respecttively.

Also, the FS for model water levels is indicated in Figure 4 (b).

The details of the test conditions and loading sequence are given in Table 1. The properties of the wall were identical in all the tests, except for the rock embedded depth (d_r). Case 1 had d_r =3.0m, and case 3 had d_r=2.5m, smaller than the JTASP-PACTC (2007) recommendation calculated based on model conditions given in Table 1. A sinusoidal wave of a predominant frequency of 1Hz was used for dynamic loading, as shown in Figure 3 (a) and (b). The amplitude of the input motion (a_i) is defined by the absolute maximum magnitude measured by the accelerometer. The effective number of cycles (almost the same negative magnitude) is termed 'n_c' in this paper. Due to the variation in number of cycles, Arias intensity (A_i) (defined in Figure 3 (b)) is used as a reference value. The (a_i), (n_c) and (A_i) of each loading are given in Table 1. Static loading was applied by supplying water in the back, as shown in Figure 4 (a) (WR1). In total, water level (h_w) over 3H/4 was achieved by two times the water supply, as shown in Table 1. Both cases have similar loading sequences but different loading histories.

3 RESULT AND DISCUSSIONS

Unless stated otherwise, all the discussion in this paper will be based on the prototype scale. The increment in measured wall top displacement (δ_t), lateral pressure (σ_h) at different depths, and bending moment (M) during dynamic loading is shown in Figure 5 for case 1 shake 4. The solid black line shows residual/static components accumulation during shaking. During the dynamic loading, the residual (δ_t) increased after dynamic loading. Although the residual (δ_t) increased, there was a gradual increase in (σ_h) during shaking. This gradual increase in (σ_h) increased the total force acting on the wall, confirmed by the bending moment increase. Due to elastic resilience and good fixity in the rock part, this gradual increase in (σ_h) is observed with the increase in (δ_t). This phenomenon is termed 'resilience effect' in this paper. The increment in wall top displacement with water level (h_w) is shown in Figure 6. For identical h_w, the wall top displacement observed for d_r=3.0m is smaller than d_r=2.5m. The difference in wall top displacement becomes more visible as the h_w>.33H. However, small wall top displacement (<0.03%H) can be observed for cases 1 and 3 at h_w<0.33H.

Lateral pressure and bending moment distribution with depths are shown in Figure 7. The reference active (σ_{ha}) and at-rest (σ_{ho}) pressure are also shown for (σ_h) distribution. Similarly, the corresponding active moment (M_a) and at-rest moment (M_o) are shown for the bending moment. Based on the lateral pressure distribution (Figure 7a), the initial condition for cases 1 and 3 is observed to be greater than the active pressure. In the bending moment distribution, a similar observation can be made for case 1. However, in case 3, the measurement of the bending moment appears to be underestimated initially.

In Figure 7 (b) and (c), the (σ_h) distribution is drawn for before shake (before), after shake (residual), and maximum (Measured max.) value observed at each depth for cases 1 and 3, respectively. This measured max. value could be considered as an envelope of the maximum (σ_h) experienced by the wall during shaking. Similarly, bending moment distributions are drawn for before shake (before), after shake (residual), and Max. (the time when the max value is observed at Z=10.75m, as shown in Figure 5 (d)). Figures 7 (e) and (f) depict the bending moment distribution. Case 1 shows the stress concentration near the vicinity of the rock surface. For thin tubes, the 3D wall effect, such as stress concentration near the rock surface, can be expected, which cannot be demonstrated by the simplified plate wall model. In this paper, moment load (M_L) is calculated by linearly extrapolating the bending moment distribution up to the rock surface. Overall, the (σ_h) and (M) distribution diagrams show that the measured values increase after the dynamic loading. Especially, the increase in (σ_h) by shaking before water rise might cause the small displacement observed in Figure 6 at shallow water level (h_w<0.33H).

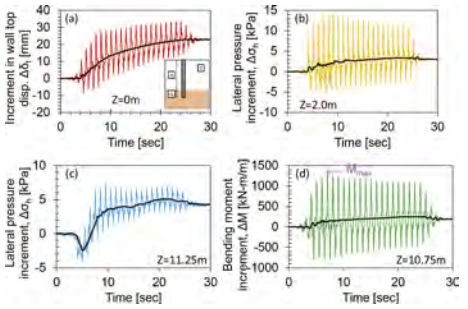

Figure 5. Example of time history of measured data (C1 shake 4).

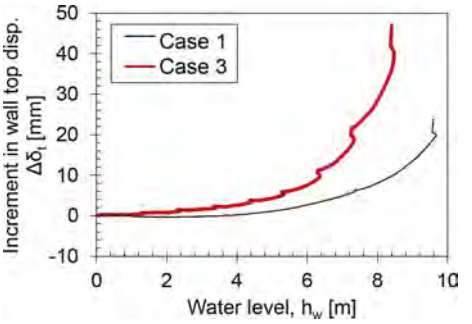

Figure 6. Increment in wall top displacement with water level (WR1).

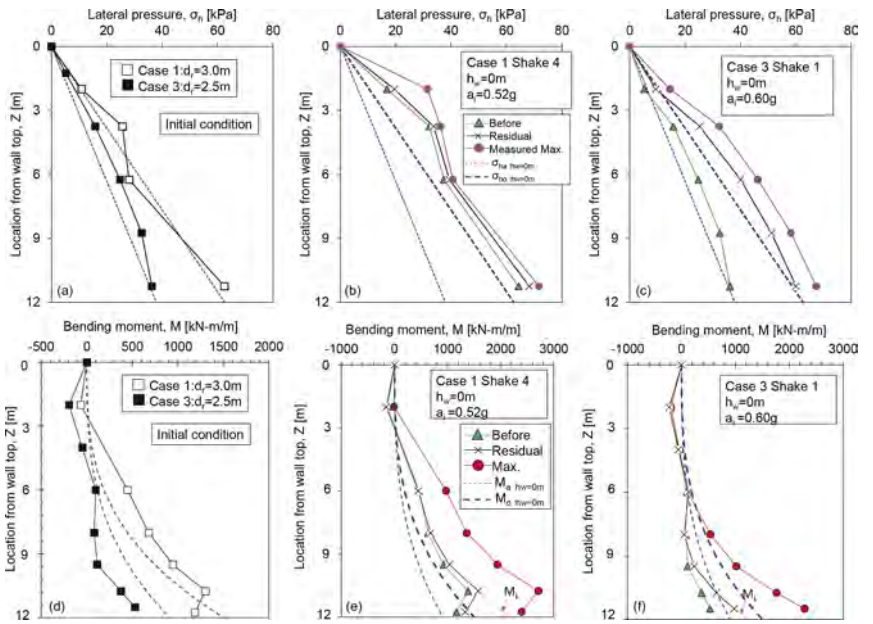

Figure 7. Lateral pressure and bending moment distribution with depths.

The variation of (δ_t) with the (A_i) is shown in Figure 8 (a). For similar (A_i), the (δ_t) observed for d_r=3.0m is smaller than the d_r=2.5m. Although case 1 has severe loading history yet, the overall displacement is almost half of case 3. So, reducing the (d_r) by 0.5m could significantly influence the (δ_t) behavior. Based on the wall and ground condition after the test, as shown in Figures 8 (b) and (c), no catastrophic failure can be confirmed.

The variation of the calculated ($P_{(residual)}$) and extrapolated ($M_{L(residual)}$) immediately after loading with the residual (δ_t) is shown in Figure 9. From the (σ_h) distribution diagram, the resultant thrust force (P) is back calculated. Figure 9 depicts an increase in ($P_{(residual)}$) and ($M_{L(residual)}$) with the increase in residual (δ_t) for both cases. However, for similar (δ_t), the observed ($P_{(residual)}$) and ($M_{L(residual)}$) is higher for d_r=3.0m than the d_r=2.5m. After the final loading, with a small increase in ($P_{(residual)}$) and ($M_{L(residual)}$), the (δ_t) increased significantly, especially for d_r=2.5m indicating the deterioration of the rock confinement. However, for d_r=2.5m, ($P_{(residual)}$) and ($M_{L(residual)}$) is still increasing, although the (δ_t) is >4%H, ensuring secured rock-wall confinement. The effective thrust force (P′) is normalized by the effective vertical force (Pv′) and plotted against the normalized wall top displacement in Figure 9 (b). The

active earth pressure coefficient (k_a) and a-rest earth pressure coefficient (k_o) are also shown in Figure 9 (b). Based on Figure 9 (b), the observed ratio after final loading is about 2 times the at-rest condition for both cases.

($P_{(max)}$) and ($M_{L(max)}$) calculated for the maximum condition are plotted against the (a_i) in Figure 10. Two reference lines are drawn for moment load and thrust force using Mononobe Okabe (1929) equation for dry condition. Based on Figure 10, during dynamic loading, the observed ($P_{(max)}$) and ($M_{L(max)}$) in wet conditions is larger than in dry conditions. For a large magnitude of the earthquake (a_i>0.5g), ($M_{L(max)}$) could be equal to or more than the actual yielding moment (0.65M_y observed by Kunasegaram and Takemura (2022) from single pile loading test) for d_r=3.0m. Therefore, structural (flexural) failure becomes more critical than the wall top displacement for large (d_r). For a_i>0.5g, in dry conditions, the observed ($P_{(max)}$) and ($M_{L(max)}$) becomes about 1.25 times the reference value.

4 CONCLUSIONS

From the centrifuge model tests on cantilever steel tubular pile wall embedded in soft rock, the following conclusions were drawn:

1. Although the applied loading conditions were more severer for the wall with embedment depth d_r=3.0m (1.5times pile diameter) than d_r=2.5m, this half meter d_r increment could significantly reduce the wall top displacement, 2.5%H for the former and 4.5%H for the latter. However, even for the large wall displacement with the small d_r, the wall-rock confinement could be ensured, not causing a catastrophic failure even after dynamic loading.
2. The observed moment load acting on the wall is greater for the large d_r than that of the small d_r. By the dynamic sequential loadings, the moment load (M_L) and thrust force (P) to the wall increased up to about 2 times those of at-rest conditions. Against the dynamic loadings in dry conditions with input acceleration over 0.5g, the maximum M_L and P became 1.25 times the corresponding value calculated from Mononobe Okabe (1929) equation.
3. The loads increasing with the increase of d_r could cause the wall bending moment to be larger than the yielding moment at a relatively small wall movement, suggesting that for the wall with large d_r, the structural (flexural) failure could be the most critical ultimate condition than the excessive wall displacement by the failure of soft rock.

Accuracy of determining pile capacity by static and dynamic methods in difficult ground conditions in Astana

A.R Omarov, A.Zh. Zhussupbekov, S.T. Mussakhanova & A.B. Issakulov
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: The article presents the results of the dynamic (DLT), static (SLT) and a new method of Pile Dynamic Analyze (PDA) tests of the reinforced concrete piles with rectangular section 30 x 30 cm and length 12m driven piles for problematic soil conditions of the "New Mosque" in Astana city. Field test are carry out in accordance with requirements GOST 5686, for definitions of bearing capacity of the piles in accordance with requirements SP RK 5.01-03-2013 and ASTM D4945. The test method is similar to that used on driven piles with the monitoring of hammer blows and subsequently analyzing the pile response to the stress wave propagation. A separate hammer or drop weight is usually brought to site to allow the dynamic load to be applied to driven pile. According to the results of tests were determined the possible depth of penetration and bearing capacity of driven piles. This geotechnical investigation is important for understanding the soil-pile interaction on difficult and problematical soil ground conditions related to the construction site.

1 INSTRUCTIONS

The congregation was built on a land plot of 10 hectares. The total area of the premises is 68,062 m². The total capacity of the mosque is 235 000 people, of which: 30 thousand men and 5 thousand women can pray simultaneously in the halls; 200 000 people can pray in the open air: 170 000 in the mosque yard and 30 000 in the area of the podium and stage. The mosque has four minarets 130 m high (see Figure 1).

Figure 1. Construction site "New Mosque" in new Capital of Kazakhstan.

DOI: 10.1201/9781003299127-202

Each minaret consists of five parts symbolizing the five pillars of Islam: shahada, namaz, fasting in the month of Ramadan, zakat and hajj. One of the minarets in the left wing is open to visitors and tourists can take an elevator up to the observation deck. The height of the big dome is 83.2 m and the diameter is 62 m. The entrance door of the mosque is 12.4 m high and weighs 1.5 tons and is handmade of hardwood. On the wall on the qiblah side are carved the 99 names of Allah, illuminated with golden light. The mosaic wall is 100 m long and 22.4 m high. The mosaic consists of 25 million glasses of different colors. The total area of the carpet is 15.525m^2, the thickness of the carpet is 15 mm. In the center of the main hall under the dome hangs a crystal chandelier, 27 m in diameter and weighing 20 tons.

The chandelier is made of 1,360,890 crystal fragments. Also in the four corners of the hall hang four chandeliers, each 8m in diameter. The first and second floors of the mosque have classrooms, a conference hall, a wedding hall, a Quranic reading hall, a TV studio, offices, staff rooms, stores, a museum and technical premises in addition to prayer rooms. The underground floor has a banquet hall with 440 seats, a closed parking lot with 405 seats, a lobby, a restroom, technical and ritual services area, sacrificial offering area and other rooms. In terms of mosque capacity, the Republican Chief Mosque in Astana is one of the 10 largest mosques in the world.

2 THE RESULTS OF ENGINEERING AND GEOLOGICAL RESEARCHES OF THE SITE

On the basis of field visual description, confirmed by the results of static sounding and laboratory tests of soils, it was found that to a depth of 17.0-27.0m in the geological structure of the site take part alluvial Quaternary deposits, represented by loam, sand, gravel and gravel soils, as well as eluvial soils of the Lower Carboniferous, represented by loam sands, sands, gravel and rubble soils. According to the drilling data, the groundwater on the survey area is at a depth of 3.00 - 3.60m. Under the conditions of the natural regime, the groundwater level is subject to seasonal fluctuations: the minimum standing is observed in March, the maximum standing is at the beginning of May. The amplitude of level fluctuations in the studied area was 1.0-1.5 m. It is recommended to take the level at 1.3 m higher than the established one for the period of surveying as the predicted one. Groundwater is fed mainly by infiltration of atmospheric precipitation, meltwater and floodwater. The area of aquifer spreading serves as the feeding area.

According to the results of chemical analyses, groundwater is characterized as sodium chloride, very hard, neutral, slightly alkaline, slightly acidic, slightly mineralized, brackish. In relation to steel structures ground water is corrosive. The degree of aggressiveness of ground water in relation to the cable lead sheathing is medium and high, in relation to the cable aluminum sheathing - high.

In relation to concrete of W4 grade, ground water is non-aggressive and slightly aggressive, in well 306-18 highly aggressive on Portland cement, in relation to reinforced concrete structures - moderately aggressive.

3 METHODOLOGY FOR LOAD TESTING OF PILES

3.1 *Static load tests by GOST*

Static load tests carried out for four piles on the construction site (see Figure 2). The measured relationships between the pile head load, L, and the head settlement, S, of the test piles are shown in Figure 3. It is seen from Figure 4 that the load-settlement curves of piles No.4, 9, 13 and No.14 are almost identical, having an ultimate shaft capacity of 1400 kN (Zhussupbekov *et, al* 2015 and Zhussupbekov *et, al* 2017 and Zhussupbekov *et, al* 2019).

In Kazakhstan, a safety factor of SLT is 1.2. Therefore, the design value of the allowable piles capacity, Q_d, was estimated to be Q_d= 1400/1.2=1167kN.

Figure 2. Test piles static loading method SLT by GOST.

According to SLT result, the load-settlement diagrams were drawing (see Figure 3) and compared with PDA results (see Figure 5).

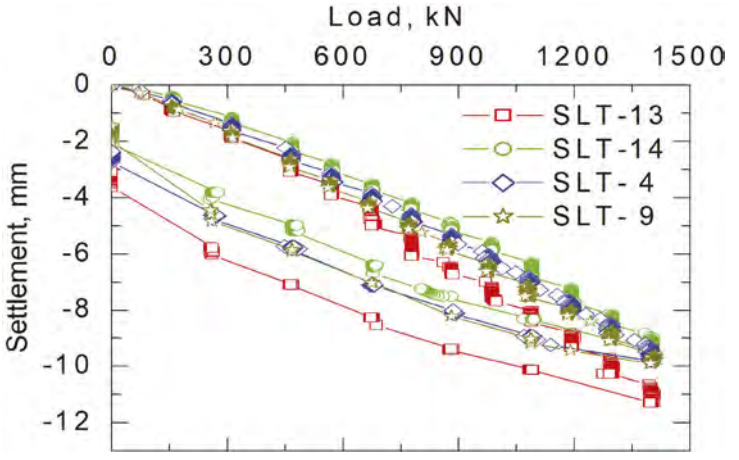

Figure 3. Results of Static load tests by GOST.

3.2 *Dynamic load test by ASTM (DLT - PDA)*

In Kazakhstan carry out dynamic test with using many types of pile driving machine hammers. Before beginning test pile driving on its surface painted whole length of piles through 1 m, but with last meter through each 0.1 m shown.

Pile driving was performed using the piling installation «Junttan PM-25" with hydraulic hammer HHK-7A with a mass of 7000 kg of the hammer and headband weight equal to 990 kg.

Figure 4 presents the monitoring results of PDA test showing pile dynamic compression and tension stresses, static pile capacity and blow counts versus pile penetration depth. CAPWAP analysis results (Figure 4) that include plots of measured pile head data obtained under the hammer blows from the end of driving and associated simulated pile head and toe static load-movement relationships are presented in the Figure 5.

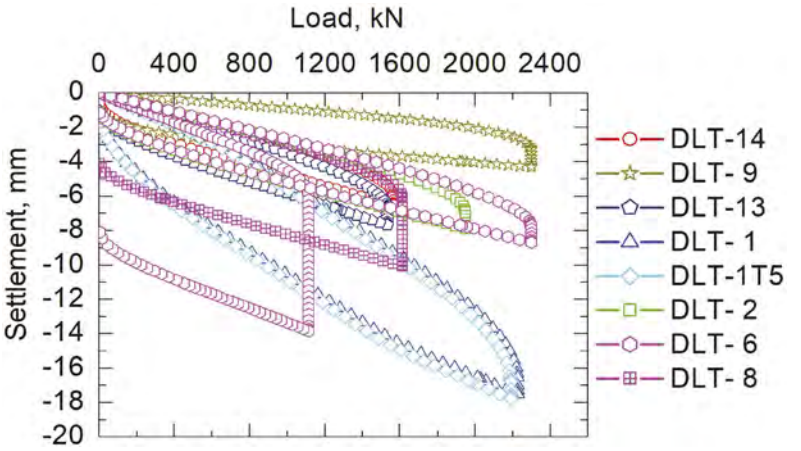

Figure 4. Results of Dynamic load tests by ASTM.

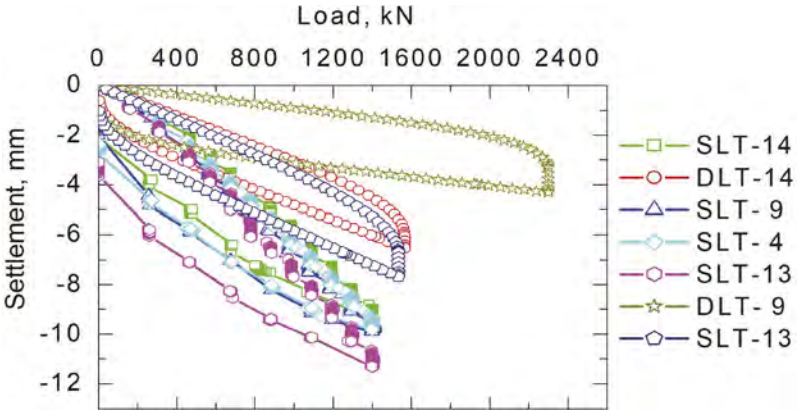

Figure 5. Results of DLT and SLT.

4 CONCLUSIONS

On the construction site of the main mosque hall of the facility "The main mosque for 30,000 places in Astana" static and dynamic tests of driven piles in the amount of 8 pieces were carried out.

The carrying capacity of the piles sunk to a depth of 7.5 m, according to the results of dynamic tests was 1600 kN.

The bearing capacity of the piles sunk to a depth of 7.5 m, according to the results of static tests was 1400 kN.

Allowed load on the pile, taking into account the coefficient of reliability $\gamma_k = 1.2$ in accordance with paragraph 3.10. SNiP RK 5.01.-03-2002 "Pile foundations", should be taken equal to 1176 kN.

DLT (PDA-ASTM) dynamic test shown more coincide with SLT result than traditional DLT test (GOST).

Analysis of interaction of boring CFA micro piles with problematic soil conditions Aksai, Kazakhstan

A.Zh. Zhussupbekov, A.R. Omarov, S.T. Mussakhanova & A.B. Issakulov
L.N. Gumilyov Eurasian National University, Astana, Kazakhstan

ABSTRACT: This paper presents the complex analysis of diverse field loading tests of four with diameter 600 mm CFA bored piles. Four static compression pile (by ASTM D1143) loading tests were carried out on the construction site. Static loading tests applied load to a deep-foundation element gradually for measuring foundation settlement. This test is used to measure the axial deflection of a vertical deep foundation when loaded in static axial compression. This vertical compression pile maintained load test is usually carried out to ensure the structural and geotechnical soundness of the pile and also to predict settlement of other piles. Applied load and head movement are measured for static axial compression load tests. The load-settlement and the load-displacement curves were obtained from field tests. Comparison of bearing capacity of bored piles with different length in problematic soil conditions of West Kazakhstan were discussed in this paper. The analysis showed that the bearing capacity of bored piles with different lengths corresponds to the design requirements. These investigations are important for understanding of soil-pile interaction on problematical soft soils ground of Aksai, Kazakhstan.

1 INTRODUCTION

The Karachaganak field is one of the world's largest oil and gas condensate fields located in northwest Kazakhstan and covering an area of more than two hundred eighty square kilometers. The Karachaganak field is located in a remote and challenging working environment with the ambient temperature ranging from minus forty degrees Celsius in winter to plus forty degrees in summer. The field, the top of which is located at a depth of around three thousand five hundred meters, is some one thousand six hundred meter thick and very complex and unique. Karachaganak Field is a gas condensate field in Kazakhstan. It is located about twenty three kilometers east of Aksai (Aksai) in the northwest of Kazakhstan. The field was once a massive Permian and Carboniferous reef complex covering an area thirty by fifteen square kilometers. Karachaganak field was discovered in northwestern Kazakhstan by Uralskneftegas-geologia in 1979 and first produced by Karachaganak in 1984. The shareholder group of ENI-Agip, BG Group, Texaco, and Lukoil operates the field under a 40-yr production-sharing agreement that was signed with the Republic of Kazakhstan in November 1997 to optimize technical and economic recovery. In the field, 252 wells have been drilled, with 163 available for production. An ongoing workover program has restored previously declining production to historic maximum levels.

The current work aims at investigating the ability for the enhancement of clay using CFA piles. The development in bearing capacity has been determined based on field tests carried out including top down static loading tests and pull out load tests. Moreover, the current work com-peres the cost between using normal piles in site project and use improvement of soil by use CFA piles. The paper suggests a method to validate the enhancement in bearing capacity of clay improved with CFA piles.

3 SOIL FIELD TEST BY PLATE LOAD TESTING

Plate Load Test is a field test for determining the ultimate bearing capacity of soil and the likely settlement under a given load. The Plate Load Test basically consists of loading a steel plate placed at the foundation level and recording the settlements corresponding to each load increment. The test load is gradually increased till the plate starts to sink at a rapid rate. The total value of load on the plate in such a stage divided by the area of the steel plate gives the value of the ultimate bearing capacity of soil. The ultimate bearing capacity of soil is divided by suitable factor of safety to arrive at the value of safe bearing capacity of soil. PLT tests by loading a plate with a diameter of 300 mm are made in accordance with requirement GOST20276 (1999) or ASTM D1194. The plate loading test (further PLT) was carried out in the workings at a depth of 1.2 m while maintaining the natural addition of soil, with a flat die 300 mm in diameter, to determine the elastic modulus of deformation (see Figure 1).

Testing with a flat PLT consisted in the fact that the stamp was placed on the bottom of the pit, on the previously cleaned and leveled surface of the ground, after which a step-by-step loading was performed on the stamp. The subsequent stage of loading was carried out after the decay of the deposit from the previous loading. As a support, beams fixed on both sides on the

anchor piles were used. Totally three tests one test in Plate Load Test 1 (further PLT–1), second test in Plate Load Test 2 (further PLT–2) a depth of 1.2 m had been made. The load intensity and settlement observation of the plate load test are plotted. The figure shown below shows a set of typical load settlement curves. Figure 1 shown the results the pressure-settlement diagrams of Plate load tests of PLT–1, PLT–2 and PLT–3.

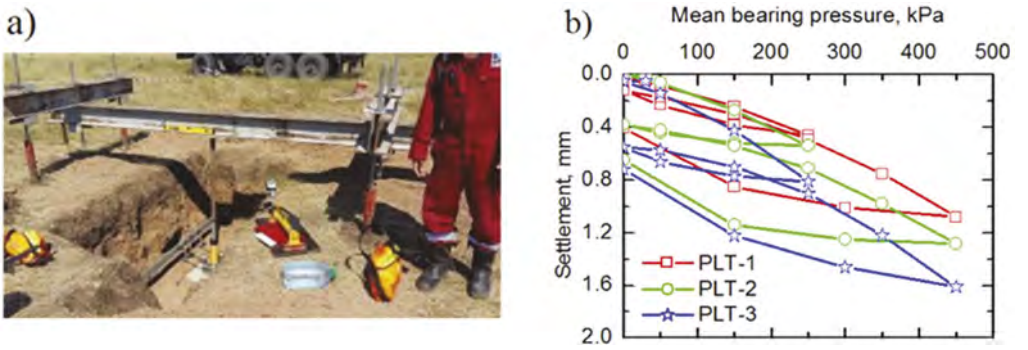

Figure 1. Plate load test: (a) Field test for determining the bearing capacity of the soil; (b) load-settlement curve (PLT–1, PLT–2 and PLT–3).

Modulus of deformation of soils in PLT–1 – 108,8MPa, PLT–2 – 86,1 MPa and PLT–3 – 61,7 MPa depth of 1.2 m.

4 STATIC LOADING PILE TEST (SLT BY ASTM D1143)

The CFA construction sequence is comprised of five stages in Figure 2:

- Stage 1. The digging tip of the auger is fitted with an expendable ca);
- Stage 2. The auger is drilled into the ground to the required depth;
- Stage 3. Concrete is pumped through the hollow stem, blowing off the expendable cap under pressure;
- Stage 4. Maintaining positive concrete pressure, the auger is withdrawn all the way to the surface;
- Stage 5. Reinforcement is placed into the pile up to the required depth.

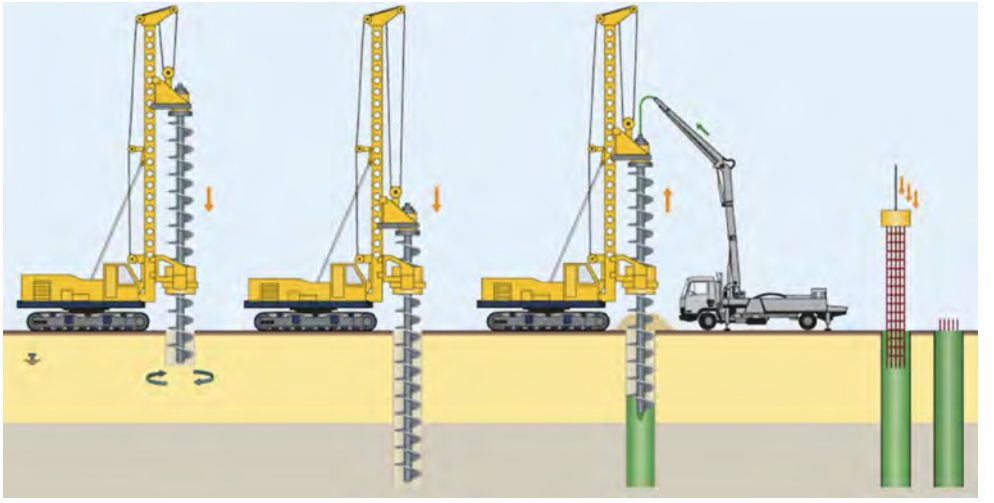

Figure 2. Technological process of CFA piles.

Bored piles, which have diameter of 600 mm and from depths 15.53 to 21.85 m have been executed at the Caspian Sea for more shipments platforms construction site (Zhussupbekov *et.al* 2016).

Static Loading Pile Test (further SLT) one of the more reliable field tests in analyzing pile bearing capacity. SLTs carried out for four piles on the construction site.

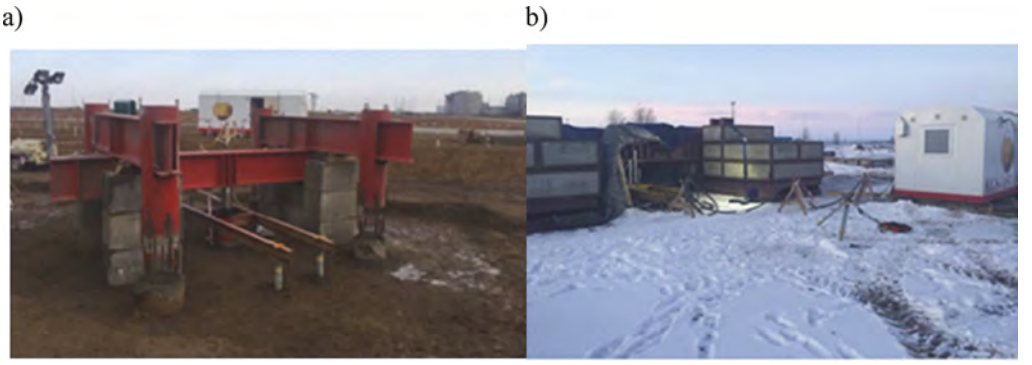

Figure 3. Field pile test by SLT (ASTM): (a) anchors pile system and (b) loading platform system.

It is seen from Figure 4 that the load-settlement curves of four piles SLT-1, SLT-2, SLT-3 and SLT-4 are almost identical, having an ultimate shaft capacity of 1050 kN for SLT-3 and SLT-4, and pile number SLT-2 to loading - 1310 kN and pile number SLT-1 to loading - 1975kN (Zhussupbekov & Omarov, 2016).

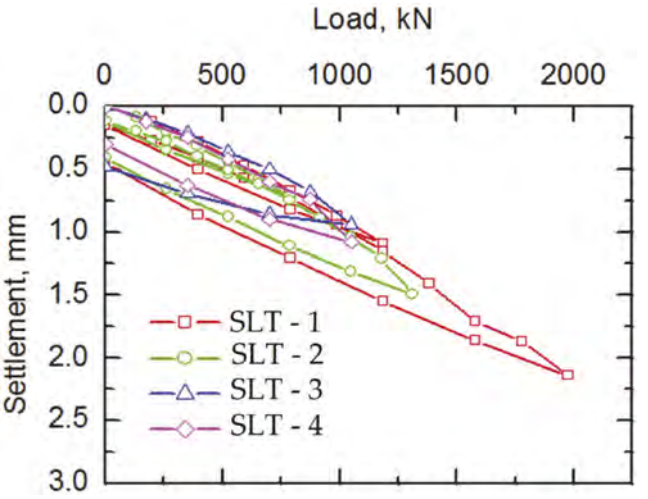

Figure 4. Load-settlement curves of four piles.

Pile static loading tests (top down) were performed on bored piles numbers: SLT-1, SLT-2, SLT-3 and SLT-4, which are with depth from 15.53 and 21.85. In SLT testing, the test load on the pile is specified for one and two cycles (one 1050 kN (for SLT-3,-4) and two cycles from 786 kN to 1310 kN (for SLT-2) and from 1185kN to1975kN (for SLT-1), respectively). Loading and unloading was carried out in the following sequence (for SLT-1): 0, 25, 50, 75, 100, 125, 150, 100, 50, 0, 25, 50, 100, 125, 150, 175, 200, 225, 250, 200, 150, 100, 50 and 0% of design. In the first cycle, the experimental pile was loaded to 150% of the design value (to 1185 kN); during

the second cycle, to 200% (maximal to 1975 kN). The hold time while loading was 60 min; while unloading −15 min. It took 300 min, respectively, to attain peak load (ASTM D1143/D1143M – 07, 2013). Table 2 presents a comparative analysis of the bearing capacity of piles, obtained by different method in this research (Zhussupbekov *et.al* 2016).

Table 2. Results of field piling static loading tests (top down load).

№	Pile numbers	Pile length, m	pile Diameter, mm	Overpressure loads on the pile, kN	Settlement at maximum pile load, mm
1	SLT-1	20.50	600	1975	2.14
2	SLT-2	15.53	600	1310	1.48
3	SLT-3	21.85	600	1050	0.94
4	SLT-4	21.72	600	1050	1.08

5 CONCLUSION

The results of the axial compression loading tests performed in soft to firm or stiff clays demonstrated the suitability of CFA bored pile foundations. The results of the loading testing program confirmed that the CFA bored pile is a viable deep pile foundation option for construction site Oil and Gas in remote areas Kazakhstan and demonstrated their advantages.

The results of the full-scale load tests are also used to validate the theoretical model used for CFA technology bored pile design installed in soft and problematical soils of Kazakhstan.

The bearing capacity of CFA technology boring piles according to the results of shown Table 2 amounted to be maximal load to (top down load, L) 1975kN, settlement (S) from 0.94 mm to 2.14 mm. These investigations are important for understanding of behavior of piles on problematical soil ground of Kazakhstan.

ABSTRACT: The Cargo Offloading Facility is an essential strategic project for the expansion of oil fields. The Cargo Offloading Facility is located along the quay and represents a special reinforced concrete surface supporting large cranes needed to unload both bulky and general cargo. According to the design drawings, the Cargo Offloading Facility construction site was planned by installing precast concrete joint piles. Investigation of the interaction of precast concrete joint piles used for the first time on construction site in Kazakhstan with complex soil conditions. In this paper the joint piles with the cross section of 400x400 mm and with pin-joined connection were considered and their interaction with the soil of Western Kazakhstan will be analyzed. Evaluation of bearing capacity of PCJP by interpretation methods of field test data, computational methods using the APILE analysis computer program and the Kazakhstan stand-ard, as well as a dynamic PDA (pile driving analyzer) method while piles driving.

1 INTRODUCTION

Kazakhstan is the world's ninth biggest country by size and the largest landlocked country, and it is the essential transportation hub between Russia, Central Asia, China and Europe. Cargo offloading facility (hereinafter – COF) has been built in the north-eastern part of the Caspian Sea in Western Kazakhstan for the development of transport infrastructure. This facility was started as a part of the Future Growth Project, which will enable the expansion of the large Tengiz oil field, where more than 23 thousand piles were installed. In 2017, a new cargo transportation route has been constructed from the Northeast Caspian Sea to Tengiz for creating access channel to the new facility on the port of Prorva, which designed for offloading the heavy vessels and barges delivered by marine transport. The construction of a cargo offloading facility is considered unique and is an important strategic project to expand oil fields in West Kazakhstan (see Figure 1).

The expediency of using pile foundations is explained by the need to ensure a high bearing capacity of structures. Their effectiveness essentially depends on the accuracy of determining the bearing capacity of the pile and the design load on it. Standards for the design of pile foundations are intended to determine their bearing capacity by an analytical method using reference generalized tables or according to field test data of a loaded pile by static or dynamic load. Before applying these methods, engineering and geological surveys are required to determine the indicators of the properties of each engineering-geological element in contact with the pile. The survey also allows the designer to assign the parameters of the piles and calculate their bearing capacity, which is traditionally considered to consist of the soil resistance under the tip and along the lateral surface of the pile (Zhussupbekov et. Al 2015).

According to the design drawings, COF construction site was planned to be installed by PCJP. This was the first experience of installing such type of piles in Kazakhstan. Applying PCJPs for the first time demanded a comprehensive approach. Therefore, it was decided to

first conduct their tests in a pilot site. In this study, the pilot site and COF site are marked as A and B (see Figure 2).

Figure 2. Cargo offloading facility.

In this paper, the work of precast concrete joint piles with soil of West Kazakhstan was investigated. This type of pile is one of the first products of Kazakhstani production that uses connecting material, and undoubtedly is of practical interest for modern construction of Kazakhstan. However, the application of dynamic tests by Pile Driving Analyzer (hereinafter – PDA) during the driving of precast concrete joint piles is of scientific interest .

2 ENGINEERING-GEOLOGICAL STRUCTURE OF THE CONSTRUCTION AREA

The project area is located along the east coast of the North East Caspian Sea, both onshore and offshore, near the Prorva oilfield, Kazakhstan. The project area is situated on the Northern Caspian Shelf. At present the North Caspian Sea has a limited water depth (maximum 5 to 8 m). The water level in the Caspian Sea depends on a balance between the inflow of river water and evaporation (Zhussupbekov & Omarov 2016).

This has resulted in large variations in sea level in the past. In the sedimentary succession within the planned construction site and with regard to lithology, depositional setting, structure, compositional petrology, state and physical and mechanical properties of sediments and with regard to the State Standard (GOST) 25100-95 the following geotechnical elements (GE) were specified. The physical and mechanical characteristics of soils at construction site A and B shown in the Tables 1 and 2 (Zhussupbekov & Omarov 2016).

Table 1. Physical and mechanical characteristics of soils at construction site A.

Layer thick ness, m	Geological formation	Soil type	General Consistency	γ_{sat}, kN/m^3	φ, deg	Su, kPa	E
0.5	new Caspian	Silt, slightly organic, calcareous	soft to firm	19.3	29.4	-	2.750
4	new Caspian	Sand, silty, calcareous	Medium dense to dense	20.2	31.5	-	30.000
4	Late Khvalynian	Clay, silty, calcareous	stiff	19.1	24.7	80	2.000
19	early Khvalynian	Clay, silty, calcareous	very stiff	20.2	24.7	150	2.000

Table 2. Physical and mechanical characteristics of soils at construction site B.

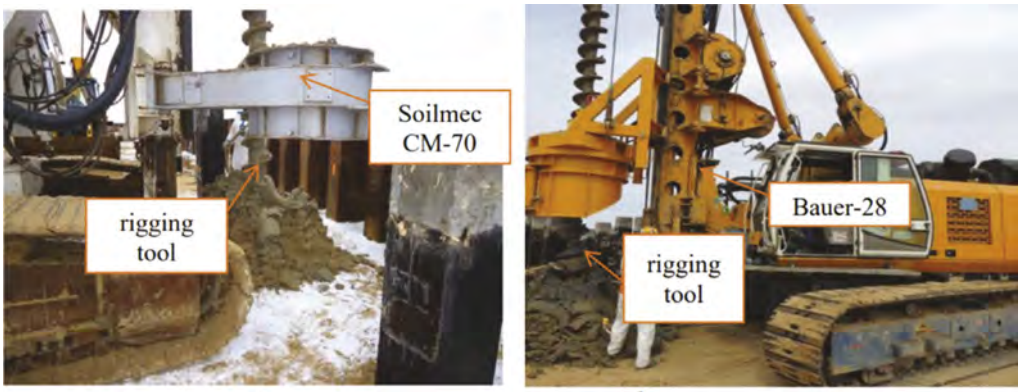
Layer thick ness, m	Geological formation	Soil type	General Consistency	γ_{sat}, kN/m^3	φ, deg	Su, kPa	E
4	new Caspian	Sand, silty, calcareous	Medium dense to dense	20.2	31.5	-	2.750
4	Late Khvalynian	Clay, silty, calcareous	stiff	19.1	24.7	80	30.000
4	inter Khvalynian	Sand, silty, calcareous	very dense	20	31.8	-	40.000
5	early Khvalynian	Clay, silty, calcareous	very stiff	20.6	23.8	150	4.000
10	early Khvalynian	Clay, silty, calcareous	very stiff	20.2	24.7	150	2000

Soils building up a geological environment at a depth down to 10 m from ground surface are salinized; salinity level is high; at sulfate nature of salinity they contain increased amount of carbonates, gypsum and insignificant amount of organic matters (humus). Loamy silt relates to slightly saturated clayey soil group; it possesses thixotropic properties Light silty clay possesses slight degree of swelling. The ground waters relate to the weak brine group in upgraded version. Water-and-soil environment possesses a medium degree of aggressivity in reference to W8 graded concrete. Soils possess high aggressivity to low-allowed and carbon steel.

3 INSTALLATION OF PRECAST CONCRETE JOINT PILES

The leader boreholes were made before installation of piles. The leader well is a well created for the subsequent immersion of a precast concrete pile. Leader wells are guide holes in the ground, greatly facilitating the process of sinking of the piles. The leader drilling allows piles to sink in vertical direction to a certain depth to reduce the noises occurred during the pile driving [111]. The boreholes were made with preaugering and pre-drilling methods. The pre-augering was

executed by clockwise rotating auger insertion up to designated depth and by removing rotating auger in counterclockwise direction. With this method, a few amount of soil was removed from borehole by a fully hydraulic, self-erecting drilling rig Soilmec CM-70 (see Figure 3a). In the pre-drilling method removing was performed without rotation by Rotary Drilling Rig Bauer-28 (see Figure 3b) (Zhussupbekov & Omarov 2017).



a – pre-auger by Soilmec CM-70; b – pre-drilling by Bauer-28

Figure 3. Pre-auger and pre-drilling processes.

The Junttan PM 25HD is a medium weight piling rig designed for pile driving steel and concrete piles. The rig has excellent stability and wide leader inclination angles. The recommended hammer weight is from 5000 to 9000 kg and the maximum pile length is 24 meters. The rig has proven productivity. The telescopic leader ensures easy and fast handling of piles. Top pile driving performance is guaranteed with Junttan hydraulic hammers. Piles were coated by corrosion protection material (bituminous) and marked by cross-lines every 0.25 m. (see Figure 4).

a – coated PCJP; b – installation of marked coated piles in boreholes

Figure 4. PCJP pile with protective coating and marked every 250 mm.

The head of bottom segment and the bottom of upper segment had steel plates "Emeca 3-Minute Splice", which had jointing and locking mechanisms. Two female (socket) and two male (stud) locking mechanisms are welded on opposite sides of each base plate (see Figure 5).

Figure 5. Two female (socket) and two male (stud) locking mechanisms.

Locking mechanisms are welded to long pieces of reinforcing bar. Two segments of PCJPs were gathered by the four locking pins (see Figure 6) (Zhussupbekov et.al 2018).

Figure 6. Installation of two segments of PCJP.

To ensure the integrity of precast concrete joint piles from destruction in the process of driving parts, a type of equipment was calculated with an effective impact energy according to the formula recommended in the SNiP and in the one-dimensional Wave Equation Analysis program. According to the results of calculations in this construction site, it was decided to use driving equipment with a hammer 9 ton for driving 27.5 m of precast concrete joint piles, for installation of 25.5 m piles – was used 7 ton equipment.

The leader drilling technology with pre-augering and pre-drilling methods for time saving, preserving of pile head was applied before the installation of precast concrete joint piles.

Protected from corrosion precast concrete joint piles were composed of upper segment with the length of 16.0 m and upper segment with the length of 11.5 m and 9.5 m on test area. During the driving piles nylon and wooden plates were used for protection pile head from

structural failure. The locking and jointing mechanism of two segments of pile were connected by the four pins (Zhussupbekov et.al 2019).

Dynamic tests were carried out on two parts of joint reinforced concrete piles separately, and the results of the bearing capacity were determined automatically by the program as an average value. After driving the first part of the joint pile, a pair of accelerometers and strain transducers were attached to the second part of the pile at 8 meters, the data of the piles were entered into the program, and the PDA dynamic tests were continued. After the execution of field part of dynamic test, selected blow data (often one of the last blows) are analyzed in the computer program Case Method &iCAP® in the software PDIPLOT2, Ver 2016.1.56.3.

CAPWAP (Case Pile Wave Analysis Program), which is based on wave equation. Pile model and soil model is initiated with measured value of pile velocity (Vmeasured(t)). The result of CAPWAP analysis is calculated response (Fcalculated(t)), which in the case of perfectly accurate pile and soil model data should be completely identical with the measured force curve.

Static loading tests of PCJPs were carried out according to the requirements of ASTM D1143 – Standard Test Methods for Deep Foundations Under Static Axial Compressive Load. Testing platform (see Figure 7) presented itself system from steel, which consists of metallic beam and 2 load platforms located on equidistant distances from the center main beams. For platforms used concrete blocks, which pack on one platform by total weight 200-205 (250) tons.

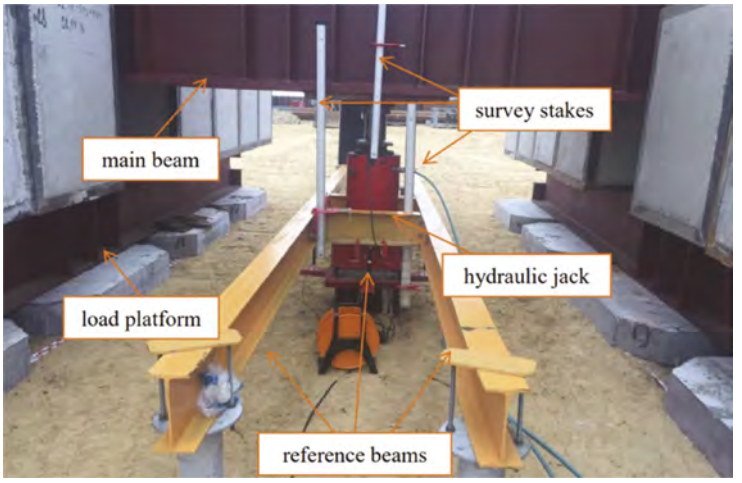


Figure 7. Testing platform for static compression load test.

As reference frame, two H-beams with h = 20cm and length 5.3 m were used which bolted with clamp to screw piles BAU 114*4*2000 drilled in soil with depth 1.5 m. (which were placed on either side of the pile on steel support brackets bolted on piles). The two beams acted as reference for the displacements sensors (see Figure 8a). The reference frames, was regularly checked with an optical level instrument to detect any movements and cross reference the movement of the pile (see Figure 8b).

The load and deflection readings are collected by a data logger, which simultaneously downloads data to a PC. Data is simultaneously displayed and stored for printing. With the concern of limit load, three SLTs were conducted with maximum load of 3278 kN at construction site A. For working load concern, four tests were conducted with maximum load of 1638 kN at construction site B (Zhussupbekov et.al 2019).

Tables 3 and 4 list the pile load test information at these construction sites respectively.

Three SLTs were conducted with maximum load of 3278 kN at construction site A. Figure 9a shows the load-settlement curves obtained from these tests. Four tests were conducted with maximum load of 1638 kN at construction site B. Figure 9b shows the results respectively.

4 DISCUSSIONS

Estimates of bearing capacity of the PCJPs tested at construction site A (where the maximum applied load was 3278 kN) by a variety of interpretation methods showed that the Chin and Decourt methods gave the highest values. The remaining interpretation methods provided results more or less similar (2000~3000 kN) to those obtained from the APILE analyses, PDA, and manual calculations.

Meanwhile, the bearing capacities of PCJPs at construction site B (where the maximum working load was 1639 kN) obtained using the De Beer, Fuller and Hoy, and Butler and Hoy methods, were considerably lower than those obtained from the APILE analyses, PDA, and manual

calculations (Table 5, illustrated in Figures 10a and b). This seems to be obvious, since the APILE, PDA, and manual calculations are only appropriate for prediction of ultimate bearing capacity. For the working load tested piles at construction site B, the interpretation methods only predicted yield capacities that were about 1/2 to 1/3 of the ultimate capacities. In general, despite the different approaches used, the results were found to be rational, and consistent with Kazakhstan construction requirements.

5 CONCLUSIONS

The interaction of precast concrete joint piles with the square section of 400*400 mm and with the length of 27.5 m with the surrounding soil ground during the construction of a port for offloading bulky goods were considered in this thesis. When assessing the reliability of a pile foundation, one of the determining ones is the question of the bearing capacity of the pile by soil. The greatest attention is paid to the bearing capacity of piles by static and dynamic load in classical and numerical and normative methods for identification of this parameter. The determination of the bearing capacity of precast concrete joint piles by interpretation methods, in the APILE software and by the SNiP formula presents particular interest to practicing engineers and scientists.

The use of precast concrete joint piles during the construction of a cargo offloading facility in Western Kazakhstan in the Prorva field present of particular interest to designers. The identification of an effective method for calculating the bearing capacity of precast concrete joint piles with a length of 27.5 m is determined by the first experience of using these piles at a construction site in Kazakhstan.

Based on the results of this study the following recommendations are made.

1. According to the results obtained from the seven field tests of piles by dynamic and static loads at the construction site of Cargo offloading facilities and the pilot site, it is considered the dynamic tests by PDA for application of identification of bearing capacity of precast concrete joint pile. Because the results of PDA show the similarity with static loading test, analytical methods as APILE analysis and calculation by equation from Kazakhstani standard. Dynamic test by PDA is economical and time saving. Although SLT is reliable but this test is very expensive and time consuming, hence researchers have been trying to come up with other efficient approaches.
2. The bearing capacity of precast concrete joint pile from static loading test data can be determined by conventional methods as Davisson, Chin, De Beer, Fuller and Hoy, Butler and Hoy. However, they are more appropriate for interpretation of high static loading test data, where settlements are bigger.
3. Estimation of bearing capacity of precast concrete joint pile can be made by APILE analysis program and equation from Kazakhstani standard.

ABSTRACT: The fiber optic sensing technologies such as Distributed Fiber Optic system and Fiber Bragg Grating system have received increasing demands in the geotechnical and structural engineering applications. This paper outlines the benefits of the fiber optic sensing systems compared to the conventional sensing systems. The applications, installation and monitoring approaches, and the results of several case studies are also presented in this paper. This paper gives an overview over several industrial applications of the fiber optic strain sensing systems, such as deep foundation testing, tunnel monitoring, and bridge health assessment.

1 INTRODUCTION

The development in construction technology and the growing populations have resulted in more mega structures and underground infrastructures built, especially in the urban areas. Therefore, geotechnical tests and structural health monitoring are very crucial to ensure the safe use of these civil structures during the long design service period.

The fiber optic sensing systems have been extensively applied in geotechnical and structural engineering in recent decades [1-5]. There are various types of fiber optic-based sensing systems such as Distributed Fiber Optic System (DFOS), Fiber Bragg Grating (FBG) system, etc. These systems have proven merits compared to the conventional sensors, such as (1) distributed measurement, (2) real-time static or dynamic measurements, (3) high stability and reliability, (4) immune to chemical and electromagnetic interference, (5) suitable for large scale engineering structures, (6) ease in installation, and (7) higher durability, survival rate and life span [6-12].

This paper showcases the industrial applications of two fiber optic strain sensing systems (i.e., DFOS and FBG) in the monitoring of deep foundation, tunnel, bridge and building. The authors aim to share their experience and challenges to improve the awareness and applications of fiber optic sensing systems in the civil industry.

2 FIBER OPTIC SENSING SYSTEMS

Strain is one of the most critical parameters used in most of the civil engineering designs. In this paper, the strain measurements are carried out using two fibre optic systems, i.e., the Distributed Fiber Optic Strain (DFOS) System and Fiber Bragg Grating (FBG) System.

DOI: 10.1201/9781003299127-205

The Brillouin Optical Time Domain Analyzer (BOTDA) is used measure the changes in frequency of backscattered light along the DFOS cables [3]. The change in frequency will then be changed into strain values by multiplying the coefficients. DFOS system is superior in static measurement however yet to be able to measure dynamic data.

The FBG system able to measure discrete strain data based on the principle of ultraviolet radiation reflection, which can measure both dynamic (thousand measurements per second) and static readings [13,14]. A change in the detected reflected wavelength indicates that strain is induced on the grating and thus, the strain of the structural element can be measured [14]. In a single fibre optic cable, a multitude of sensors can be fitted for many discrete data collection points with high resolution, accuracy, and monitoring frequency [13,14].

3 APPLICATIONS

3.1 *Deep foundation tests*

DFOS has several advantages over conventional discrete strain gauges in the application of foundation tests, i.e., ease of installation and doesn't require predetermined sensor location. DFOS is able to measure continuous strain along the pile (Figure 1), making it unnecessarily to predetermine the strain gauge level based on the different subgrade layers. The continuous strain profile provides better insight of the overall load distribution and stiffness difference between subgrade layers, making it easier for engineers to categorize the subgrade layers and friction mobilized.

The use of DFOS in deep foundation are included but not limited to bored pile, driven piles, steel piles, etc. The challenges are included the selection of proper fibre optic cables, installation approaches and higher entry cost (expensive logger) for the testing specialist.

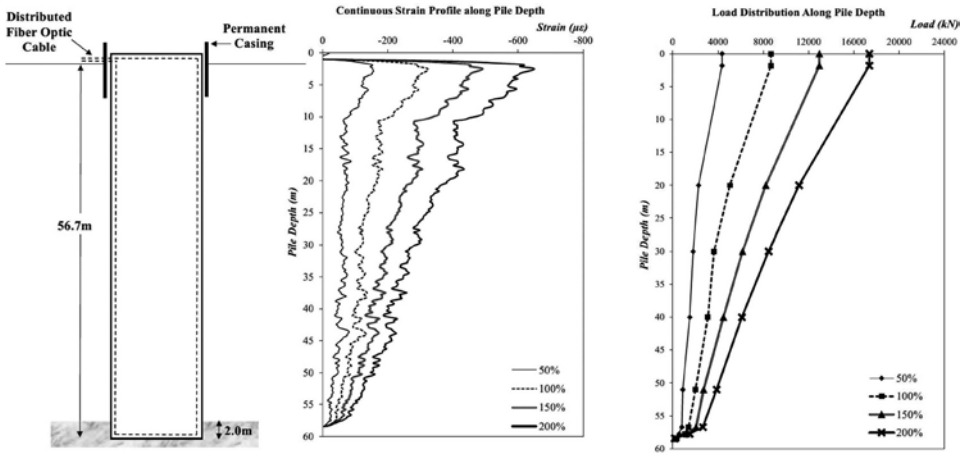

Figure 1. Application of DFOS for deep foundation static load test.

3.2 *Tunnel monitoring*

Maintenance and rehabilitation of an old aqueduct tunnel were carried out by strengthening approximately 25m tunnel section which experienced some collapsed. The collapsed section was approximately 2km from entrance, and was fully grouted prior to excavation, installation and steel ribs and shotcrete. In order to ensure the safety of workers during the work (from further collapse), forepole was installed prior to any excavation of the grouted section. Distributed fibre optic cables were installed inside forepoles to detect any unusual strain which can indicate the sign of further collapse.

After the installation of instrumented forepoles (with DFOS), excavation was done and steel ribs are installed. The distributed strain and temperature cables are then installed on the

steel ribs (as shown in Figure 2) prior to the shotcrete works. These strain and temperature cables on the steel ribs are used to assess the rehabilitated tunnel section's integrity after the completion of the maintenance and repair works.

In a nutshell, the DFOS was utilized in this aqueduct tunnel rehabilitation work for three main reasons (1) to ensure safety during excavation works, (2) to have long-term assessment after completion of work, and (3) this cannot be achieved using the conventional sensors (especially inside water transfer tunnel and the distance to entrance or monitoring station is too far).

The main challenge of the application of DFOS in a tunnel is the coordination of work. The instrumentation can be damaged during the construction work especially if the construction team are of different parties and do not understand the importance of instrumentation protection. The schedule for the instrumentation installation is also very critical as tunnelling work are normally be carried out 24 hours, delay in installation will causes delay in the tunnel construction work.

Figure 2. Application of DFOS for deep foundation static load test.

3.3 *Bridge health monitoring*

DFOS and FBG strain and temperature sensors were used during a load test on a old steel bridge. In order to assess the actual behaviour or condition of a 100-year-old bridge, static (resting locomotive) and dynamic (moving locomotive) load tests were carried out. After the assessment of steel bridge using Finite Element Analysis, several critical locations were identified and the FBG sensors were installed on these locations to measure the strain during the dynamic load test. While the DFOS cable was install along the bottom of the bridge to measure the response of the steel bridge under static load test. Biggest challenge of the application of FBG and DFOS in such an application is the temperature change. The difference in temperature on a steel bridge can be very significant and require a proper temperature compensation to be included during the analysis.

Figure 3. Application of DFOS and FBG sensors for 100-year-old bridge's static and dynamic assessment.

3.4 *Building slab monitoring*

In a project where the basement slab experienced cracks and underground water intrusion issue, DFOS system is one of the best options to monitor the condition of basement slab after all rehabilitation works are completed. The advantage of DFOS, in this case, fixed point DFOS, is that the range of strain is high (not easily break) and yet is capable of measuring cracks as small as 0.3mm. Installation of such cable in a basement slab is significantly easy as the whole cable functions as sensor. Installation of a 4km long fixed point DFOS cables inside a basement slab allows long term monitoring of the slab condition. The biggest challenge of such application is that the cable locations must be properly documented to avoid damaging the cable during the monitoring period.

4 CONCLUSIONS

The applications and merits of DFOS and FBG in geotechnical and structural engineering have been well demonstrated through 4 projects in this paper. Although the installation work of fiber optic sensing system is simple, the applicants must have knowledge in sensor selection, proper installation approach, design of the monitoring scheme, data collection and data interpretation. One limitation of fiber optic sensing system is the higher cost for the interrogator. However, with more experience and knowledge sharing, it will help in increasing the usage of these systems and therefore reduce the cost of the interrogator and sensors.

Application of electromagnetic waves for evaluating the integrity of model pile

Dongsoo Lee, Seokgyu Jeong, WooJin Han, Jinwook Kim & Jong-Sub Lee
Korea University, Seoul, Republic of korea

Jung-Doung Yu
Joongbu University, Goyang, Republic of korea

ABSTRACT: This study presents a pile-integrity testing method using electromagnetic waves. An experimental study is conducted using small-scale defective piles. Two types of defects are simulated in the middle of the model pile. One is a poorly mixed concrete section and the other is a void. A waveguide system for transmitting electromagnetic waves is configured by installing electrical wires alongside a rebar in the model pile. The electromagnetic waves are generated and detected using a time domain reflectometer. Consequently, the results revealed that poor-quality concrete decreases the amplitude and velocity of the electromagnetic waves. The void increases the amplitude and velocity of the electromagnetic waves. This study suggests that electromagnetic waves can be an effective tool for evaluating pile integrity.

1 INTRODUCTION

Pile foundations are important structural components as they transfer upper loads underground. Thus, defects in piles can adversely affect the stability of structures. Non-destructive methods, such as the sonic echo method and cross-hole sonic logging (CSL), are generally used to evaluate pile integrity. However, detecting the locations of defects in piles with a large diameter is challenging owing to the energy leakage to the soils. The CSL can assess only the concrete between access tubes. Therefore, a new method is required.

Recently, electromagnetic waves have been widely used to evaluate infrastructure integrity. Yu et al. (2020) suggested a smart monitoring system using electromagnetic waves to detect defects in rock bolts. Lee and Yu (2019) investigated variations in the velocity of electromagnetic waves in defective soil nails. The objective of this study was to investigate the suitability of electromagnetic waves for evaluating the integrity of piles. Laboratory experiments were conducted on two defective model piles. One had a poor-quality concrete section and the other had a void in the concrete. A transmission line was configured in the pile to transmit electromagnetic waves, and a time domain reflectometer (TDR) was used for the generation and detection of the electromagnetic waves. Analyses were performed based the reflection coefficient and velocity of the measured electromagnetic waves.

2 EXPERIMENTAL SETUP

2.1 *Model pile*

Two defective model piles were prepared for the experiments, as shown in Figure 1. The model piles were concrete columns with a water-cement ratio (w/c) of 35 %, and a single rebar

DOI: 10.1201/9781003299127-206

was installed at the center along the length of the column. The dimensions of each column were 3.0 m × 0.2 m × 0.2 m. The rebar was a deformed reinforcing bar with a diameter and length of 16.0 mm and 3.2 m, respectively. A two-conductor electrical wire was installed alongside the rebar to configure the transmission line. Two different types of defects with lengths of 1.0 m were introduced at the centers of the model piles. One was poor-quality concrete, and the other was a void, as shown in Figure 1(a) and 1(b), respectively. The poor-quality concrete was a mixture of water and cement with a w/c ratio of 55 %.

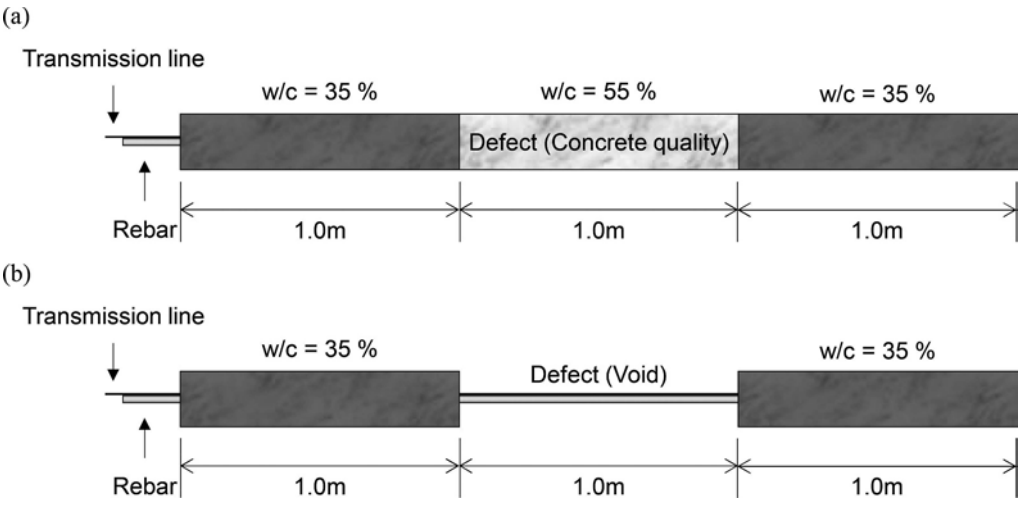

Figure 1. Defective model piles with: (a) poor-quality concrete; (b) void.

2.2 *Measurement system*

The measurement system was configured based on time domain reflectometry as illustrated in Figure 2. The measurement system included a computer, TDR, coaxial cable, and model pile, with the transmission line configured in the model pile. The TDR generated a step pulse with an amplitude of 150 mV. The rising time of the step pulse was 65 ps and the repetition rate was 2 MHz. The transmission line was connected to the TDR using a coaxial cable. Ten signals were stacked to improve the signal-to-noise ratio. The number of data points was set to 8192.

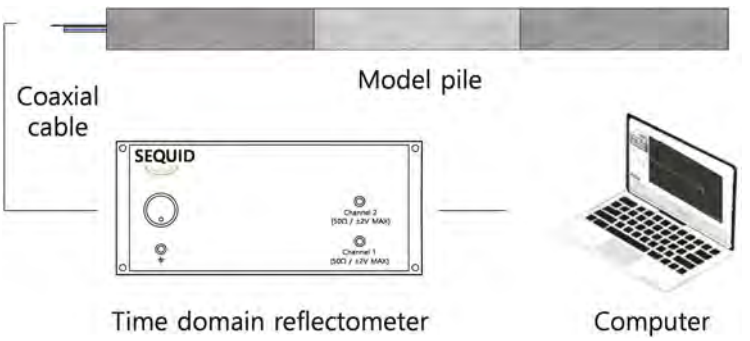

Figure 2. Measurement system.

3 EXPERIMENTAL RESULTS

3.1 *Defective model pile with poor-quality concrete section*

The measured signals are plotted in Figure 3. Reflection coefficient is defined as ratio of input output and input voltages. Also, it is a function of the electrical impedance difference between two media. Note that the impedance is inversely proportional to the dielectric constant. Thus, the reflection coefficient increases as the dielectric constant decreases. Electromagnetic waves reflected at the two ends of the pile were observed. The round-trip time (RTT) of the electromagnetic waves traveling along the length of the pile was 42.0 ns. The velocity of electromagnetic waves was calculated as the ratio of twice the travel length to the RTT. Velocity was calculated as approximately 1.43×10^8 m/s. In addition, the amplitude of the electromagnetic waves was reduced in the section with poor-quality concrete. This poor-quality concrete section can be represented using a reflection coefficient. The dielectric constant of the poor-quality concrete is greater than that of sound concrete. Thus, the reflection coefficient decreases in the poor-quality concrete section. The reflection coefficients for the sound sections exceeded 0.2. The reflection coefficients for the poor-quality concrete section ranged from 0.16 to 0.2. The reflection coefficients for the poor-quality concrete section were less than those for the sound sections.

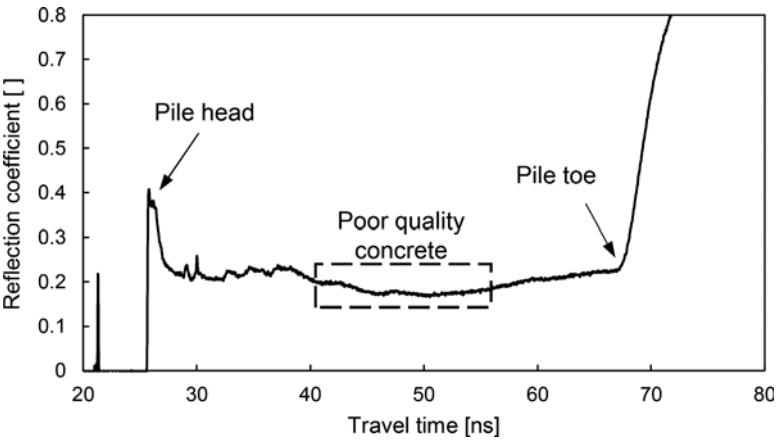

Figure 3. Measured signal for the defective model pile with poor-quality concrete section.

3.2 *Defective model pile with void*

The measured signals are shown in Figure 4. As in the defective model pile, where the poor-quality concrete is present, reflections of the electromagnetic waves occurred at both ends of the pile. The RTT was approximately 36.7 ns and the velocity was 1.63×10^8 m/s. Furthermore, the reflection of the electromagnetic waves owing to voids was clearly detected. The reflection coefficient increases in the void section because the dielectric constant of the void containing air is lower than that of the sound concrete. The reflection coefficients for the sound sections were calculated as approximately 0.2, whereas the reflection coefficient for the void section ranged from 0.25 to 0.37. The reflection coefficient for the void section was larger than that for the sound section.

4 CONCLUSIONS

Experimental studies were conducted to evaluate the local integrity of model piles. Two defective model piles each with a length of 3.0 m were manufactured for the experiments. A defect with a length of 1.0 m was introduced at the center of each model pile. One of the

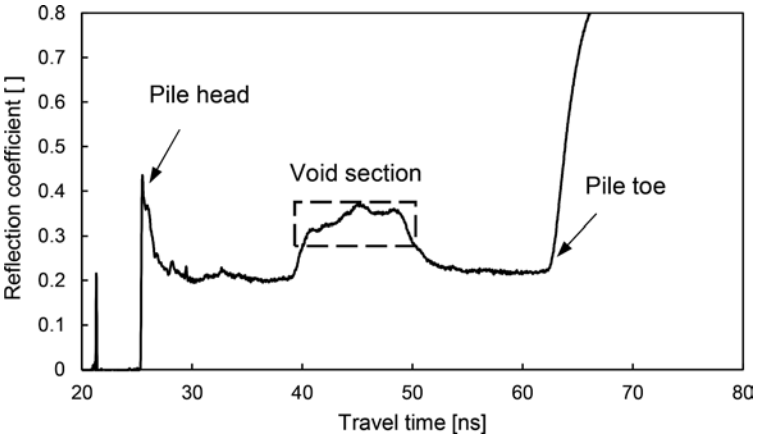

Figure 4. Measured signal for the defective model pile with void.

defects comprised poor-quality concrete, whereas the other was a void. Time domain reflectometry was used to measure the electromagnetic waves propagating on a transmission line in the model piles. The electromagnetic wave velocities were calculated, and the defective sections were evaluated using the reflection coefficient.

The conclusions of study are as follows.

- The experimental results revealed that the wave reflections at both ends of the piles were well-observed. The electromagnetic wave velocity of a defective pile with poor-quality concrete was lower than that of a defective pile with a void.
- For the reflection coefficient, the void section had a higher value than the sound concrete, and the poor-quality concrete section had a lower value than the sound concrete. The local integrity of a pile can be evaluated using the reflection coefficient of the time domain reflectometry signals.
- This study demonstrates that time domain reflectometry may be an effective tool for evaluating the integrity of pile foundations.

ABSTRACT: To obtain pile-soil response under lateral loading, the test pile shall be instrumented. Common pile instrumentation comprises of pairs of strain gauges fixed onto the reinforcement cages. However, this traditional instrumentation method is limited by the quantity of test points and installation quality is always questionable. Additional instrument like inclinometer casing with tip embedded in competent soil layer is also part of the requirement to measure the lateral pile deflection with pile top measurement as reference. With recent advancement in technology, distributed fiber optic sensing technique (BOTDA) is gaining its popularity especially in pile load test. By using distributed fiber optic sensing technique, it allows continuous strain measurement along the pile. This paper describes the method to compute the deflection profile from the fiber optic strain data. Comparative results show that the computed deflection profile is in good agreement with the traditional inclinometer readings. Additionally, the computed pile deflection is also compared to the pile head deflection measured by displacement transducers.

1 INTRODUCTION

Piled foundation typically are designed to resist axial loading. However, some elevated structures or marine structures are subjected to substantial lateral forces. It is essential that the design assumptions on pile lateral behaviour to be validated by physical test results. Typically, a lateral pile load test is instrumented with inclinometer, pairs of traditional strain gauges and displacement transducer at pile head. Traditional strain gauges have disadvantaged of limited strain measurement points that need to be pre-determined before the construction of pile, which occasionally lead to insufficient data at critical deflection point.

Brillouin distributed fiber optic sensing are widely applied in pile load test to obtain the strain distribution along the pile (De Battista et al., 2016). The full profile of strain distribution allows Engineer to assess the shaft friction at specific pile section as well as the concrete quality along the shaft. Further application of this technique includes the retaining structures monitoring (Mohammed et al., 2011, Xu et al., 2018, Wang et al., 2021), urban tunnel monitoring (Li et al., 2019) and soil slope monitoring (Minardo et al., 2015).

This paper presents the lateral load test on bored pile, instrumented with an innovative technique based on the optical fiber sensing that allows continuous strain measurement known as Brillouin Optical Time Domain Analysis (BOTDA). BOTDA is based on the analysis of back-scattered signals through two counter-propagating beams. The system has higher

DOI: 10.1201/9781003299127-207

accuracy, resist corrosion, anti-electromagnetic interference and it is suitable for long distance monitoring with high spatial resolution. In addition, duration of field works for the installation and preparation of instruments can be shortened by at least 80% which increases the overall construction productivity.

2 PILE INSTRUMENTATION AND TEST SETUP

2.1 *Test pile information and embedded instruments*

The 1200 mm diameter sacrificial bored pile with total length of 35.6 m was casted with concrete grade 50. The main reinforcement bar consists of 28 numbers of H40 with H16 circular links at 150mm center to center. Sub-surface geological condition is reported to consist of very soft sandy clay and hard sandy silt underlain by moderately weathered Siltstone, S(III). Concrete embedment type vibrating wire strain gauges were installed at specific elevation as shown in Figure 1 below. Two loops of distributed fiber optic strain sensors (DFOS) were installed in the pile. Loop A is installed in the loading direction while loop B is perpendicular to the loading direction. Two sets of traditional inclinometer casings were also installed to obtain the deflection profile under load.

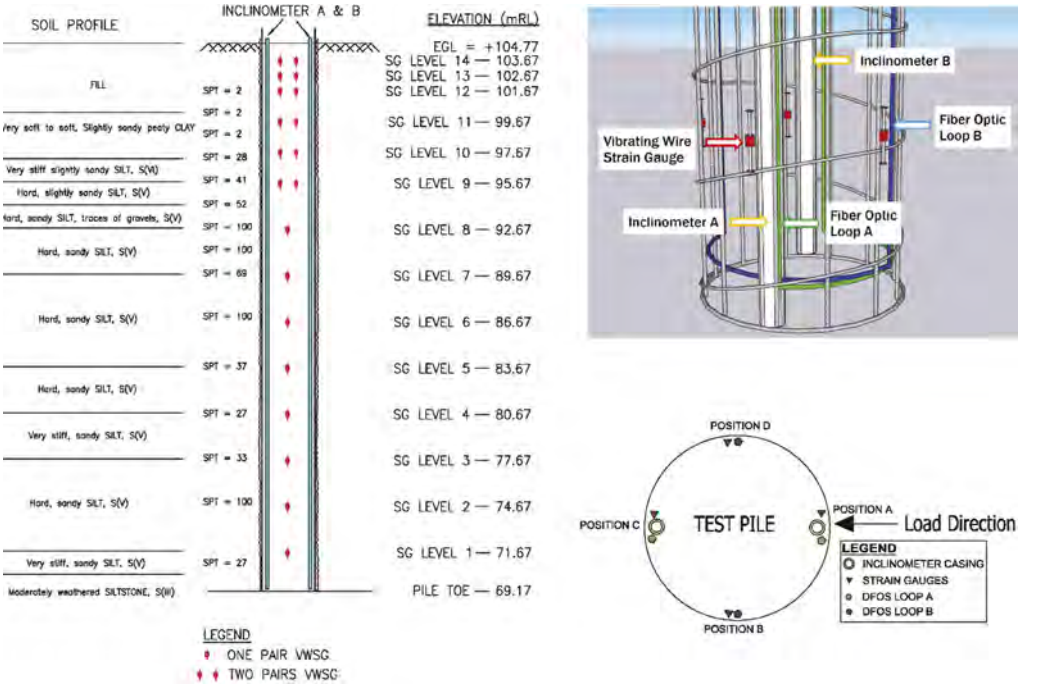

Figure 1. Schematic of strain gauges, 3-D illustration, and plan view of the test pile.

2.2 *Test setup*

Wide variety of arrangement for lateral load test are possible. For this particular test pile, a nearby sacrificial static load tested pile was used as reaction system. Pile head displacemet is monitored by using two numbers of linear vibrating wire displacement transducers (LVWDT) that attached on the pile and set to the reference beam. The reference beam is monitored by using a total station with reading taken for every load increments. The pile is loaded by using a 200T hydraulic jack with 200 mm stroke. Applied load is monitored directly by using load

cell, crosschecked with pressure transducer in the hydraulic system and pressure gauge on hydraulic pump. The site lateral load test setup is shown in Figure 2 below.

Figure 2. Lateral load test setup.

3 RESULT DISCUSSION

3.1 *DFOS data analysis*

Comparison of DFOS continuous readings and VWSG point readings are presented in Figure 3. At position C, that is compression zone under lateral loading, the vibrating wire strain gauges shows good agreement with the distributed fiber optic strain sensors. However, data captured at position A (tension zone) has shown significant variation which is mainly due to the measurement range of the vibrating wire strain gauges.

The compressive strain and tensile strain measured from distributed fiber optic strain sensing sensors can be used to compute the lateral deflection of the pile. By using equation 1 below, the measured strain profile is converted to curvature profile.

$$k(z) = \frac{1}{D}[\varepsilon 1(z) - \varepsilon 2(z)] \tag{1}$$

where D is the horizontal distance between two sensors, ε1 and ε2 is the tensile and compressive strain measurement. By integrating the curvature once and twice as per equation 2 and 3,

the gradient and deflection of the pile can be obtained. The toe of the pile is assumed not to move or rotate during the test; thus, the constant A and B is assumed as zero.

$$\emptyset(z) = \int k(z)\,dz + A \tag{2}$$

$$y(z) = \int \varphi(z)\,dz + B \tag{3}$$

where Ø is the gradient and y is the deflection. The curvature, gradient and deflection profiles are presented in Figure 4 below.

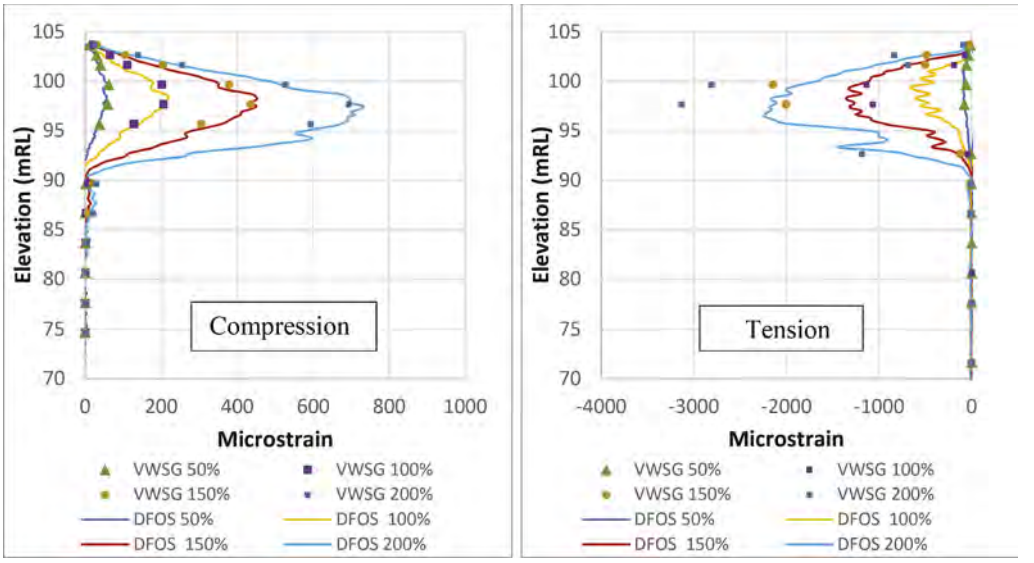

Figure 3. VWSG and DFOS comparison.

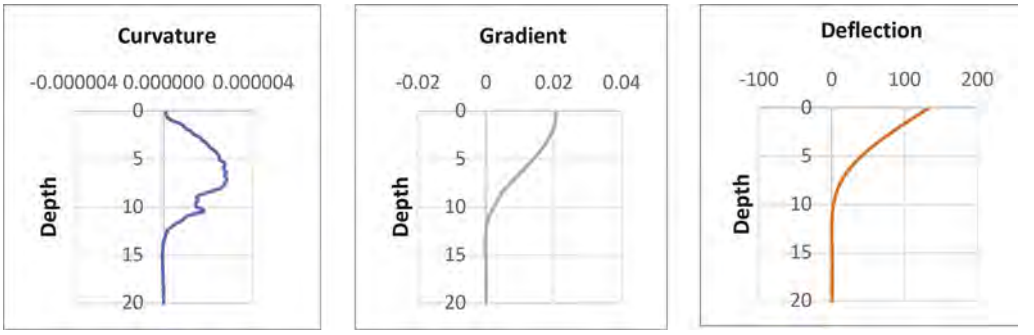

Figure 4. Curvature profile, gradient profile and deflection profile derived from DFOS data.

Figure 5 presents the comparison between measurement by pile top LVWDT, inclinometers and DFOS. It shows very close reading from the beginning of the test until the end of the test. For comparison between DFOS and inclinometer, the DFOS data is selected based on end time of the inclinometer manual readings. Thus, DFOS shows very good agreement with the inclinometer readngs. Refer to Figure 6 for the pile deflection profile comparison between DFOS and inclinometer.

Pile deflection profile computed by using VWSG point readings are presented in Figure 7. It is cleary seen that the computed profile is not identical to the other two profiles constructed by using DFOS continuos readings and inclinometer readings especially at 7-18m depth . Hence, the results indicate that continuos strain reading along the pile is important to obtain a higher accuracy deflection profile.

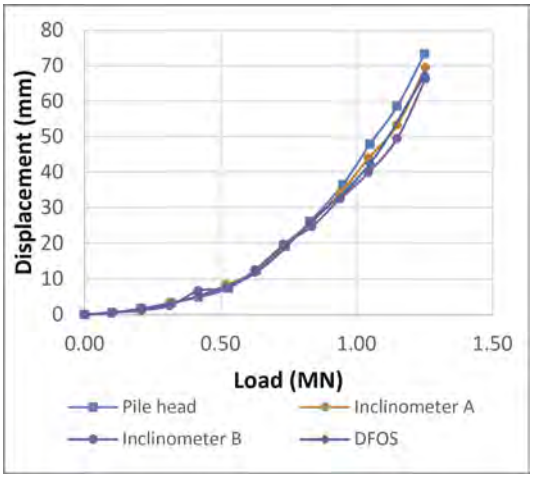

Figure 5. Comparison of pile top displacement and pile deflection profile.

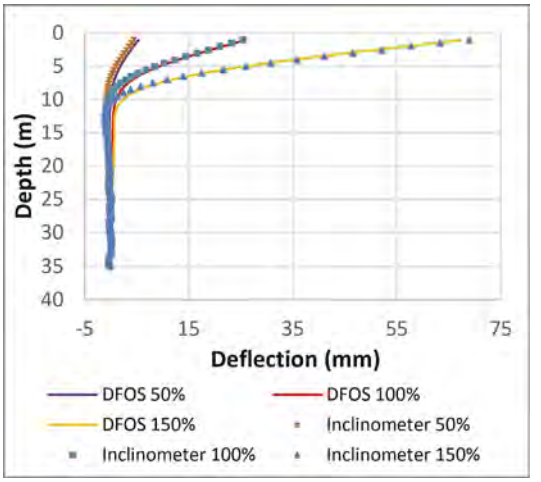

Figure 6. Comparison of pile deflection profiles between VWSG, DFOS and inclinometer.

4 CONCLUSION

A relatively new approach to pile test instrumentation by using distributed fiber optic sensing technology has been successfully carried out in Singapore. Based on the field test data, it shows that DFOS is suitable to be used as alternative instrument to replace inclinometer to measure the structure deflection. With continuous strain reading, the location where the maximum tensile and compressive strain occurred along the pile is accurately identified. Typical

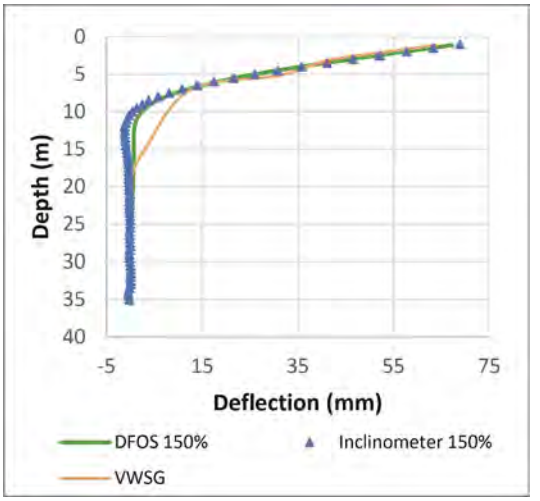

Figure 7. Comparison of pile deflection profiles between VWSG, DFOS and inclinometer.

vibrating wire strain gauge instrumentation work takes one to two days. By contrast, DFOS field instrumentation duration is shortened by at least 80% which increases the overall construction productivity.

Experimental study on the load transfer behavior of a deep foundation member induced by the settlement in sand

Suhyuk Park
Graduate Student, Department of Civil Systems Engineering, Ajou University, South Korea

Ilhan Chang
Associate Professor, Department of Civil Systems Engineering, Ajou University, South Korea

ABSTRACT: An experimental test was conducted to assess the bearing capacity and load transfer mechanism of a pile model considering progressive settlement in this study. Dry natural sand (Jumunjin sand) was used to compose a model ground, where the cylindrical soil tank has a dimension of 380 mm in diameter and 900 mm in height. 28 load transducers were embedded at the lower bottom of soil tank to measure the load variation due to pile penetration. A pile model was fabricated with acryl which has a diameter of 80 mm and length of 800 mm. The pile model was fabricated to measure both tip bearing and skin friction without interfering with other measurements. Test variables are the distance between the tip of the pile model and the bottom of the soil container. The experimental setup was available to analyze the bearing capacity and load transfer mechanism at different penetration depths which represents the settlement behavior of pile model.

1 INTRODUCTION

Foundation is a basis geotechnical engineering structure which transfers the overlying load to the ground. Generally, foundation structures can be classified into shallow and deep foundation types. Shallow foundation is used when the size and load amount of the overlying structure is relatively low and the ground has a high load carrying capacity, while deep foundations are used when the external load is large and the ground condition is insufficient. The deep foundation serves to transmit the load of the structure to the lower ground by installing an elongated member (e.g. pile) into the ground.

Despite several theoretical and empirical formulas (Terzaghi, 1943, Meyerhof, 1951, Vesic, 1967) are provided to assess the load carrying capacity of pile foundations, there are lack of experimental verifications on the load transfer and support mechanism of pile structures. Thus, this study attempts to perform an experimental study to analyze the vertical stress distribution around a pile structure considering different settlement levels.

2 MATERIALS AND METHODS

2.1 *Experimental apparatus and soil properties*

A cylindrical soil tank was used to assess the vertical stress distribution of the ground according to pile settlement and to indicate the load-displacement curve of the pile. The soil tank was fabricated with acryl having a diameter of 380 mm and height of 900 mm (Figure 1a). Wire mesh was attached to the inner perimeter of the soil tank to simulate an infinite frictional boundary condition.

A series of 7 load ring-shape plates were installed below the soil tank to measure the vertical stress increment at different distances from the center of the pile model during pile penetration

DOI: 10.1201/9781003299127-208

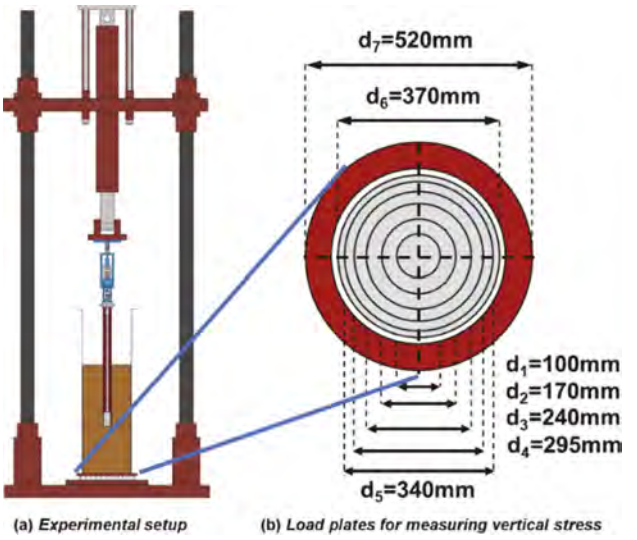

Figure 1. Experimental apparatus for pile driving.

(Figure 1b). 28 load transducers (4 for each ring-shape plate) were attached under the ring-shape load plates, to measure the average load transferred to each circumference individually.

The pile model was fabricated with PVC having a diameter of 80 mm and length of 800 mm. Surface skin friction was presented by attaching sand paper along the outer surface of the pile model. The pile measuring system was used to measure the tip load of the pile and the skin friction without mutual interference.

Dry jumunjin sand (D_{10} = 0.15 mm, D_{30} = 0.28 mm, D_{60} = 0.41 mm, C_u = 2.73, C_c = 1.23, USCS = SP) was used in this study. The unit weight of the model ground set to be 15.77 kN/m^3 (D_r = 21.56%) which is a loose sand deposit. The interparticle cohesion and friction angle were assessed as 0 kPa and 37° from a direct shear test (ASTM D3080-03).

2.2 *Test cases and experiment methods*

The distance from the tip of the pile model to the bottom of the soil tank was set as the main variable for this study. Three tip-to-bottom distances were considered as 20 cm (L20), 30 cm (L30), and 40 cm (L40).

Sand was poured into the tank by maintaining the pluviation height at 50 cm, to form a homogeneous ground condition. . The initial embedded depth of the pile model was set as 400 mm. After model ground formation with a pile embedded, the pile model was penetrated into the ground with a penetration rate of 1 mm/min using a hydraulic cylinder. The penetration was continued for 40 mm (time duration = 40 min).

3 RESULTS AND DISCUSSIONS

3.1 *Bearing capacity of pile*

The load-displacement curves obtained from laboratory tests are displayed in Figure 2. The tip bearing (Figure 2a) gradually increases with pile penetration, while skin friction (Figure 2b) increase up to 10 mm of pile penetration but then converges to a constant level (20 kPa) when the pile penetrated further (> 10 mm).

The bearing capacity of the pile model (Figure 2c) can be expressed by summating the tip bearing (Figure 2a) and skin friction (Figure 2b), where the inflection point in Figure 2c is regarded to be the total bearing capacity (qu) of the pile model. For instance, the inflection point appears at 15.45 mm of pile displacement and stress level of 47.6 kPa (q_u = 47.6 kPa for the L40 case).

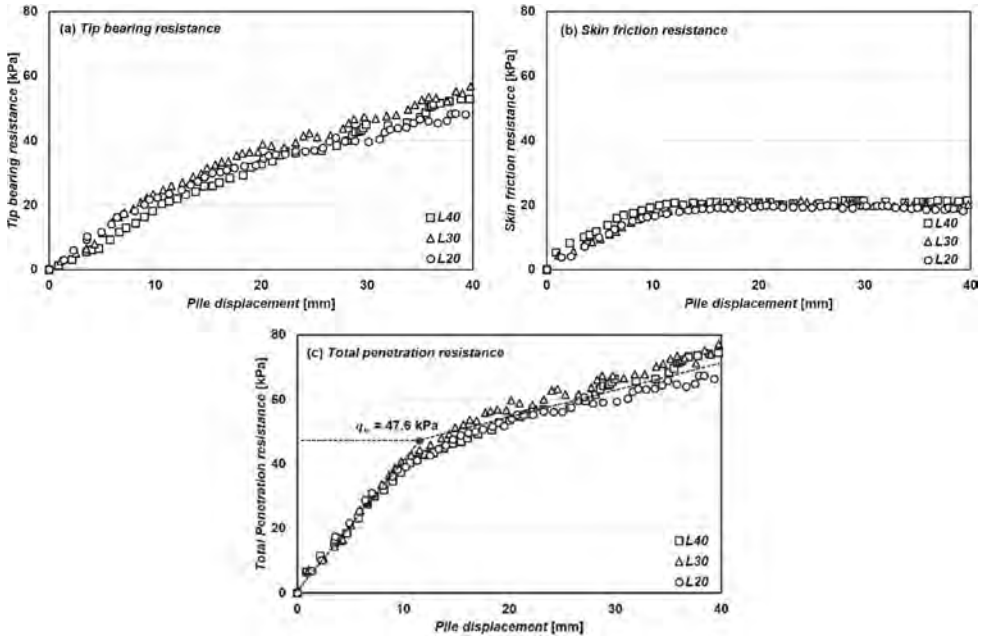

Figure 2. Penetration resistances induced by pile settlement.

3.2 *Stress distribution induced by settlement of pile*

Load transducers were used under the soil container to analyze the distribution of vertical stress induced by pile penetration. The forces measured on each load transducer were divided by the area and expressed as stresses. Figure 3 shows the figure for each stress. As shown in Figure 3, the x-axis represents the normalized distance from the pile center. Normalization was expressed by dividing the distance r from the pile center by the radius R of the soil

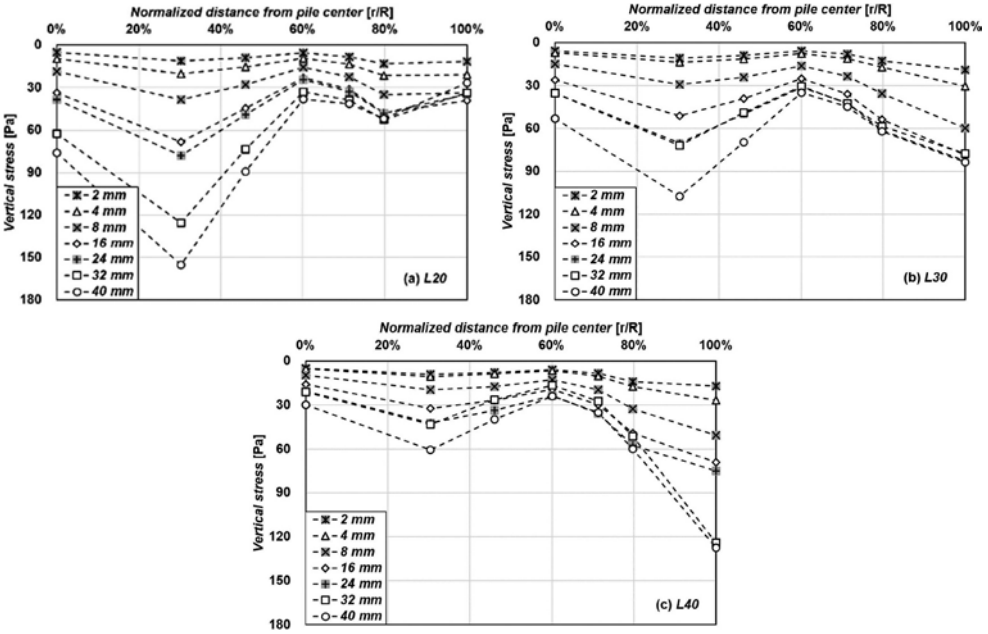

Figure 3. Stress distributions under pile.

container. In Figure 3, the y-axis represents the vertical stress inside the ground according to the pile displacement. As shown in Figure 3, legends represent pile displacement at each stage.

As shown in Figure 3a and b, the largest vertical stress occurred at r/R=30% point. As the pile settlement increased, the stress at the point within 60% close to the pile continued to increase. On the other hand, it was found that the stress at a point more than 60% away from the pile did not increase any more after a certain amount of pile displacement. This point is the point where the bearing capacity of the pile occurs, and it is 16mm. On the other hand, in Figure 3c, the largest vertical stress occurred where the r/R was 100%. Even when the pile displacement was 16mm or more, the vertical stress increased.

When the distance between the tip of the pile and the load plate was small, the vertical stress occurred at a place close to r/R. Whereas, when the distance between the tip of the pile and the load plate increased, the vertical stress was greatly generated in the place where r/R was far. This is because vertical stress near the deep foundation appeared large, and vertical stress far from the deep foundation appeared small (Grillo, 1948). However, in the case of L40, the vertical stress was larger where r/R was larger. This was analyzed to be due to the arching effect (Vesic, 1967) occurring at the interface of the soil container.

4 CONCLUSIONS

The purpose of this paper is to analyze tip resistance and skin friction induced by pile driving and to confirm the stress distribution under the pile. The following conclusions were obtained through model tests.

In all three cases, the load-displacement curves showed the same trends because the penetration depth of the pile was the same. Tip bearing according to pile displacement increased proportionally, but not the skin friction.

The bearing capacity of the pile was calculated using the sum of tip resistance and skin friction. Bearing capacity was calculated as the load where the extension line of the initial linear part and the extension line of the late linear part meet, and the bearing capacity of the pile is 47.6 kPa.

The stress distribution induced by pile settlement showed a different tendency for each case. When it was close to the tip of the pile, the stress was greater where r/R was close. In the case of a place far from the tip of the pile, the stress was larger at a place where r/R was far away. In addition, it was found that the stress did not change even if the pile displacement was 16 mm or more where the stress was small.

In this paper, the bearing capacity of the pile and the resulting stress distribution of the ground were analyzed. However, various factors affect the ground stress distribution induced by pile driving. Additional studies on the diameter of various piles and surface friction conditions are needed.

Measured axial capacities of driven pile in Metro Manila reclamation area using high strain dynamic load tests

R.T. Gonzales, R.A.C. Luna & G.P.D. Reyes
AMH Philippines, Inc., Quezon City, Metro Manila, Philippines

ABSTRACT: With the ever-growing population and continuous development of economy in the Philippines, more reclamation projects are being proposed and constructed to expand the land that would cater the spatial needs in the Metro Manila, the country's urban capital. As these various reclamation projects add constructible land areas along the coastlines of Metro Manila, several infrastructures spanning from government, business, commercial, and residential developments are being built as well. Majority of these structures are anticipated to be founded on pile foundations, signifying the importance of pile design and capacity verification. Design of piles are carried out using semi-empirical theoretical approaches and equations developed based on existing soil and rock mechanics concepts. In more recent years, the science and technology of pile testing have been evolving which provides an important tool in the monitoring, verification, and evaluation of integrity and pile capacity as well as optimization of theoretical capacities by yielding cost-effective engineering solutions.

1 INTRODUCTION

In the Philippines, the demand to reclaim land has increased very rapidly in the past decades not because of the scarcity of land but because of the need for valuable space that will be optimized by constructing vital and essential developments and infrastructure near the country's urban capital, Metro Manila.

The simplest method of land reclamation involves directly filling the area with large amounts of rock, clays, and sand fills, followed by compaction of these layers until the desired height is reached. Considering the highly compressible and weak soil layers in landfill areas, pile foundation is almost all the time warranted to carry the structures on top of the reclaimed embankment. Pile foundation transmits loads to underlying dense and hard soil and even bedrock, through frictional and end-bearing resistance. Also, if the expansive and collapsible soils are present in the site, piles may extend beyond the active zone/stable soils.

In order to verify and validate the calculated theoretical capacities of deep foundations, high strain dynamic load testing—a non-destructive load test that measures the mobilized soil resistance forces along the shaft and bearing capacity at the toe using reflection of the compressive stress waves that travel up and down the pile shaft—is carried out. Details are discussed in the following sections.

This paper presents both the theoretical and measured axial capacities of driven piles in Metro Manila reclaimed areas using high-strain dynamic load tests, with the objective of providing a process of verifying and optimizing of theoretical pile capacities and assessing the measured capacities relative to its geologic location.

2 SITE SUBSOIL CONDITION

Manila Bay is built on an extensive flood plain with very small variation in elevation. According to the Metropolitan Manila Development Authority (MMDA), Manila is "relatively flat of

DOI: 10.1201/9781003299127-209

about 0.81% to very gently sloping at 3.17%". The geology of the vicinity is underlain by recent deposits and residual soil deposits of variable thickness, consisting of clays, silts, and sand.

Several sites were explored by drilling boreholes, collecting and testing soil samples. Disturbed soil samples were obtained from Standard Penetration Test (SPT) American Society for Testing and Materials (ASTM D1586). SPT N-values taken from the boreholes within the reclaimed areas are generally indicative of very loose to medium dense relative condition within the upper layers, underlain by hard silt and very dense sand. Also, the recorded water levels during field investigations in most of the sites were relatively shallow given that mostly are located near offshore.

Figure 1 represents the recorded SPT N-values of drilled boreholes, with at least 15.0-meter depth, at several sites in Metro Manila reclaimed areas. Based on the plotted scatter diagram, most of the sites have relatively strong subsoil on the 1st meter depth, presumably the compacted layer of the landfill. The SPT N-values on the succeeding depth indicate very loose to loose sands and very soft to soft clay layers, i.e. SPT-N values < 10. These layers are underlain by the competent strata mostly attributed to the regional bedrock of Metro Manila, Guadalupe Tuff Formation (GTF) consisting of sandstones and siltstones, except on projects 6 and 7 where loose and soft soils persist until termination of boreholes.

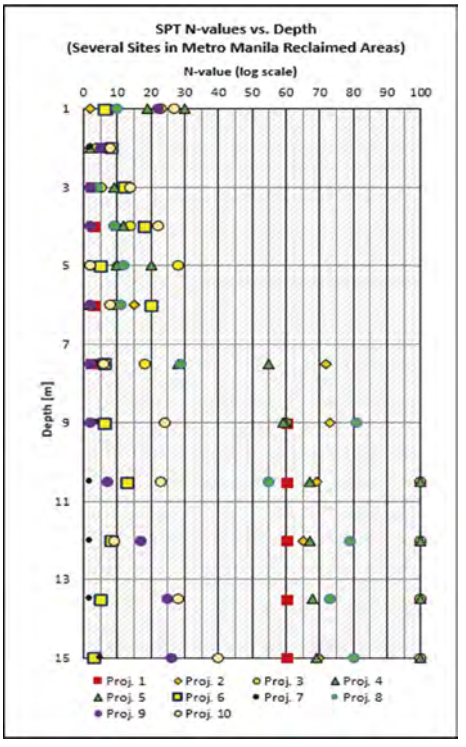

Figure 1. SPT N-Values vs. Depth.

Figure 2. Design allowable capacity per project location.

3 THEORETICAL PILE CAPACITY

Given that the subsurface conditions on a typical reclamation area in Manila consists of very loose to loose sands in the upper layers, driven piles are normally selected to prevent collapse of soil and adjacent existing structures during construction and installation.

Figure 2 presents the location of project sites where pile tests were conducted, as well as their respective design allowable axial capacities. These sites will be developed into various infrastructures such as office, commercial, and residential buildings as well as elevated parking

spaces. The piles were designed by calculating axial capacities based on the well-known methods of Meyerhof, Coyle & Castello, Reese & O'neil etc.

Most of the construction sites within these areas are surrounded by occupied or existing infrastructures already. Given the constraints for construction and the anticipated structural loads from the proposed developments, driven piles are deemed to be the appropriate pile type to be utilized. Driven piles are installed with the use of static pile driver and hammer weights. The pile driver pushes the piles by giving compressive pressure or by simply pushing it to the ground to reach its 'refusal' point based on design capacity.

The factor of safety generally ranges from 2.5 to 4.0. Table 1 presents the summary of test piles with their design allowable capacities, design pile size and actual pile embedment as per pile driving log.

Table 1. Summary of Pile Design Capacity, Size, and Length.

Design Pile Size	Design Allowable Capacity	Actual Pile Penetration in Meters					Total Pile per Capacity	Color Code
		< 10	10 to 15	15 to 20	20 to 25	> 25		
mm x mm	kN	pcs	pcs	pcs	pcs	pcs	pcs	
400 x 400	1000	2	4	5	5	0	16	
400 x 400	1050	0	0	0	1	9	10	
450 x 450	1100	7	7	10	0	0	24	
450 x 450	1200	2	0	2	0	0	4	
400 x 400	1350	0	0	0	10	9	19	
450 x 450	1500	0	0	0	6	6	12	
Total Piles per Size and Length		11	11	17	22	24	85	

As shown in the table, the areas where piles are embedded at relatively shallower depths (yellow areas) attained higher capacities even at smaller pile size (400mm) (See Figure 2 and Table 1 for color coding). For the areas with relatively deeper depths of hard strata (red areas), piles are required to be embedded at deeper depths and have larger pile size (450mm) to attain similar higher capacities as with the piles in the yellow areas.

4 MEASURED CAPACITIES USING PDA

Dynamic Load Testing (DLT) using a Pile Driving Analyzer® (PDA) is performed for all the project sites. The purpose of the DLT is to assess pile structural integrity, calculate pile driving stresses, and evaluate bearing capacity with test methodology and equipment in accordance with ASTM D4945-00. In this test, set/s of strain transducers and accelerometers are bolted at opposite faces of the pile to measure strain (force) and acceleration. An axial force is then applied on top of the pile with a pile driving hammer or large drop weight that will cause high strain at the top as well as generate waves that will travel through the length of the pile. After field testing, the results are further evaluated using the Case Method approach. This method is carried out and a more accurate estimate of the pile capacity is established by using CAPWAP (Case Pile Wave Analysis Program). CAPWAP is an iterative signal-matching technique that determines the most appropriate soil and pile resistance model that would result to a good match between the computed and measured force/velocity data.

Based on the results of the field testing and data post-processing, the measured allowable capacities per size and length are presented in Figure 3. These piles were tested at least seven (7) calendar days after driving.

The usual cross-sectional area of piles tested range from 1,600 cm^2 to 2,025 cm^2 with pile penetration that ranges from 8.0 meters to 28.0 meters in reference to the existing ground. All test piles attained their target capacities, which are twice the allowable capacity or safety

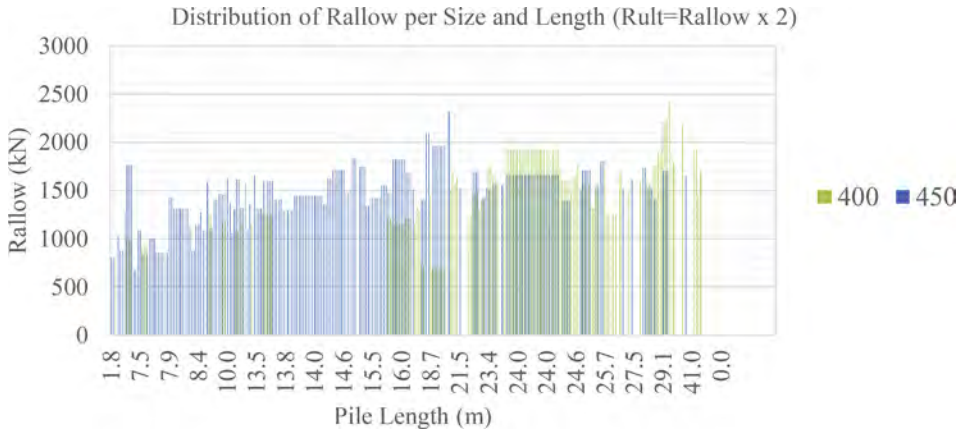

Figure 3. Distribution of Allowable Capacity per Size and Length.

factors equal to 2.0. In the exercise of attaining the target capacity, pile size and pile penetration can significantly affect the result.

Given the subsurface conditions at the reclamation areas as described in the previous section, 400 cm by 400 cm piles with less than 10 m penetration attained allowable bearing capacities of less than 1500 kN, while the 450 cm by 450 cm piles driven with less than 10 m mobilize allowable bearing capacities of about 2000 kN.

Most of the piles with 1600 cm^2 cross-sectional area and embedded at least 25.0 meters provide allowable bearing capacities greater than 2000 kN, while the larger pile, 2025 cm^2, provide allowable bearing capacities greater than 2000 kN with at least 15 m penetration. This shows that a larger pile size has a significant effect in the measured pile capacities.

As shown in Figure 4, 76% of the 400mm x 400mm piles are embedded > 20m, while only 30% of the 450mm x 450mm piles are embedded > 20m. Again, this shows that a slightly larger pile diameter can achieve higher capacities at shallower depths. The pile capacity pie charts also indicate that majority of the measured capacities of piles range from 1250kN to 1750kN for both pile sizes, with 450mm piles having a greater number of piles achieving those capacities (80%).

Table 2. Tabulation of Piles per Size, Capacity, and Length.

Pile Size	Pile Penetration	Number of piles based on measured allowable capacity in kN					Total Piles per Length
		< 1250	1250-1500	1500-1750	1750-2000	>2000	
m x mm	m	pcs	pcs	pcs	pcs	pcs	pcs
400 x 400	< 10	1	1	0	0	0	2
400 x 400	10 to 15	4	0	0	0	0	4
400 x 400	15 to 20	4	1	0	0	0	5
400 x 400	20 to 25	2	5	8	1	0	16
400 x 400	> 25	0	1	6	5	6	18
450 x 450	< 10	1	4	3	1	0	9
400 x 400	10 to 15	0	3	3	0	1	7
400 x 400	15 to 20	0	5	4	2	1	12
400 x 400	20 to 25	0	0	6	0	0	6
400 x 400	> 25	0	0	4	2	0	6
Total Piles per Capacity		12	20	34	11	8	85

Given the theoretical pile capacities discussed in the previous section, pile testing should be able to mobilize at least twice the allowable capacity, i.e. a safety factor of 2.0. In PDA testing practice, a minimum proven safety factor of 2.0 is considered acceptable. The measured ultimate capacities of all test piles range from 2.0 to 4.64 times the allowable capacities.

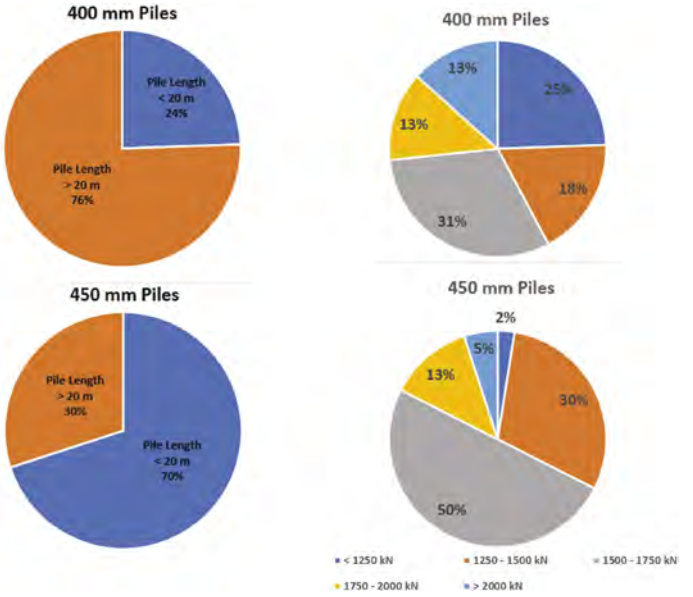

Figure 4. Distribution of pile embedment and pile capacities.

From Figure 5 and Table 3, it can be observed that to achieve similar values of pile capacities (1250 kN to 1750 kN) in the area, most of the 450mm size piles are embedded at relatively shallower depths, e.g. 18m or less, while 400mm size piles are embedded at depths until 30m, about 40% reduction in pile length. Moreover, majority of the 450mm piles attain relatively high safety factors, i.e. greater than 2.5, with FS ranging from 2.00 to 3.91. Factors of safety for the 400mm piles range from 2.03 to 2.96, except for those embedded at 28 to 30m where FS range from 3.42 to 4.64.

Table 3. Tabulation of calculated factors of safety and measured capacities.

Project	Pile Size	Pile Penetration	Theoretical Capacity	Rtoe*	Rskin*	Rtotal*	Safety Factor
	mm x mm	m	kN	kN	kN	kN	
A	450 x 450	11.71	1100	1216.86	1938.57	3155.43	2.87
B	450 x 450	13.90	1100	894.90	2230.10	3125.00	2.84
C	450 x 450	15.97	1200	590.00	2864.00	3454.00	2.88
D	400 x 400	16.49	1000	722.13	1722.13	2444.25	2.44

* Rtoe – Toe Resistance; Rskin – Skin Resistance; Rtotal – Total mobilized resistance.

Also presented are the proportion of the skin and tip resistance to the total measured pile capacities:

- Projects A, B, & C: Sites with 450m x 450m piles with measured axial capacities ranging from 2550 kN to 4643 kN. Pile embedment in these projects are relatively shallow, ranging from 7.0m to 19.9m. Calculated factors of safety are 2.32 to 3.91. 72% of the total pile bearing capacity is from shaft resistance.

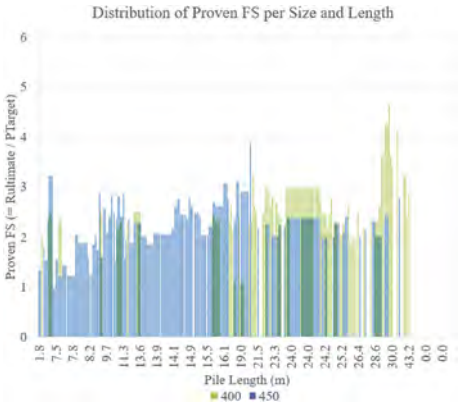

Figure 5. Calculated factor of safety per dimension.

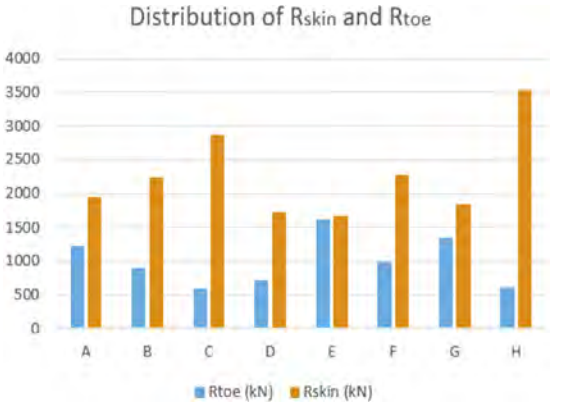

Figure 6. Distribution of rskin and rtoe.

- Project D: Site with 400m x 400m piles with allowable design capacities of 1000 kN and measured axial capacities ranging from 2030 kN to 2962 kN. Pile embedment range from 9.0m to 23.0m. Calculated factors of safety are 2.03 to 2.96. 70% of the total pile bearing capacity is from shaft resistance.
- Projects E, F, & G: Sites with 400m x 400m and 450mm x 450mm piles with measured axial capacities ranging from 2929 kN to 3765 kN. Pile embedment range from 22.8m to 28.8m, as expected for sites located farther from the original land mass. Calculated factors of safety are 2.00 to 2.79. 64% of the total pile bearing capacity is from shaft resistance.
- Project H: Site with 400m x 400m piles with measured axial capacities ranging from 3384 kN to 4870 kN. Pile embedment range from 20.4m to 33.3m, longest pile penetration tested within Manila Bay. Also, all of the calculated factors of safety in this project are relatively high, ranging from 3.22 to 4.64. 85% of the total pile bearing capacity is from shaft resistance, as expected for deep piles.

In summary, the results of the pile capacity analysis, each project is grouped according to depth of embedment, measured pile capacity, and percentage of skin resistance. Projects A, B, & D are sites located inside the original coastline of Manila Bay while Projects C, E, F, G, & H are sites located outside of the original coastline. Driven piles located inside the original coastline are designed to be embedded at relatively shallower depths (mean pile length of 11.7m to 16.5m) compared to the ones driven outside which are embedded at deeper depths (mean pile length of 25.2m to 28.7m) as thickness of the soil cover tends to increase to the direction of Manila Bay itself. Moreover, Projects A, B, & D have measured capacities ranging from 2030 kN to 4300 kN with 72% coming from the skin friction. Projects C, E, F, G, & H have measured capacities ranging from 2802 kN to 4870 kN with 65% derived from shaft resistance. The values indicate that as pile embedment increases, the contribution of toe resistance also slightly increases as compacted soil and/or competent layers are reached by the tip of the pile.

5 CONCLUSIONS

1. In designing piles located within a reclaimed area like Manila Bay, the study of the geology of the site is as important as the calculations of pile capacities. Depending on the subsurface conditions and the proximity to the bay area, pile design may be optimized by either using larger pile sizes with shorter lengths or smaller piles with deeper embedment depth.
2. As expected, larger pile sizes and deeper pile embedment yield higher pile capacities and factors of safety. For most of the project sites in Manila Bay, a larger pile cross section yields higher capacities even at shallower pile embedment when compared to the longer but

smaller piles. On the other hand, at very deep embedment, about 28m to 30m, resulting factors of safety are very high (FS=2.6 to 4.6) as the hard-competent strata is reached.

3. In the Manila Bay area, using smaller piles such as 400m x 400m piles require embedment depths at around 25m to attain typical mid-rise structure design capacities of 1,500 kN to 2,000 kN.
4. From the results of the pile capacity analysis (CAPWAP), about 70% of the total pile bearing capacity is carried by the shaft resistance. This is mainly due to the presence of very thick uppermost cohesionless soil layers and the absence of competent strata which are found at deeper layers.

Hybridnamic rapid load testing with an extended interpretation method of dynamic signals

S. Kamei, S. Lin & I. Yamamoto
Jibanshikenjo Co., Ltd., Tokyo, Japan

T. Matsumoto
Kanazawa University & Jibanshikenjo Co., Ltd., Tokyo, Japan

ABSTRACT: The Hybridnamic testing is a kind of falling-mass type rapid load test (RLT), by which several blows on a pile can be conducted easily and quickly. Hence, static load-displacement curve is constructed by connecting UnLoading Point (ULP) loads. This procedure is called UnLoading Point Connection (ULPC) method. ULP method or ULPC method is employed for cases of the relative loading duration $T_r = t_L/(2L/c)$ greater than 5, where t_L is loading duration, L is pile length and c is bar wave velocity. Segmental ULPC (SULPC) is proposed so that RLT can be employed even in cases of T_r less than 5. A case study was carried out to demonstrate the applicability of SULPC. Load-displacement curve from RLT with the SULPC method was comparable to that from the conventional static load tests.

1 INTRODUCTION

Twenty years have passed since the rapid loading test (RLT) of piles were newly added to the Japan Geotechnical Society (JGS) standard (JGS1815-2002). Until 2002, most of RLTs were conducted using the mass-launching method such as the Statnamic test developed by Middendorp et al. (1992). After 2002, most of RLTs in Japan are conducted using the falling-mass method with a soft-cushion placed on the pile head. The Hybridnamic device (Figure 1) developed by Jibanshikenjo Co. is a typical falling-mass method. In line with this, the number of loading cycles has also changed from one loading of the maximum planned load to multiple loading

Figure 1. Hybridnamic test device.

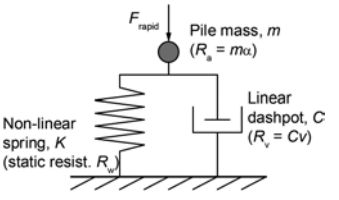

Figure 2. Modeling of pile and soil during RLT (after Middendorp et al, 1992, and Kusakabe and Matsumoto, 1995).

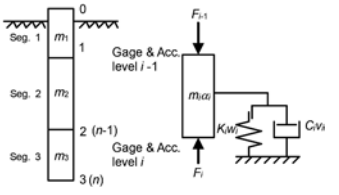

Figure 3. Segmental Unloading Point Connection (SULPC) method.

DOI: 10.1201/9781003299127-210

with the hammer drop height being raised in stages. Therefore, the interpretation method has shifted from the UnLoading Point (ULP) method to the UnLoading Point Connection (ULPC) method (Kamei et al. 2022), which provides a static load-displacement relationship simply by connecting ULPs without the need to obtain the damping constant C required in the ULP method.

As a result of the widespread use of the ULPC method as an interpretation method for RLT signals, some cases have emerged that pose challenges for the analysis of single mass model method in which the entire pile length is considered as a rigid body.

In this paper, as a new interpretation method to address these issues, the Segmental UnLoading Point Connection method (SULPC method) which is an extension of the Segmental UnLoading Point (SULP) method is proposed. The load-displacement relation of a pile from RLT is compared with the result of static load test (SLT).

2 SEGMENTAL UNLOADING POINT CONNECTION METHOD (SULPC METHOD)

Middendorp et al. (1992) treated the pile as a rigid mass during RLT assuming that the effects of wave propagation phenomena in the pile body are negligible. When a dynamic load F_{rapid} is applied to the pile, the static soil resistance R_{w} and dynamic soil resistance R_{v} act on the pile. These relationships are expressed in Equations 1 and 2, and Figure 2.

$$F_{\text{rapid}} = R_{\text{a}} + R_{\text{v}} + R_{\text{w}} = m\,\alpha + C\,v + R_{\text{w}} \tag{1}$$

$$R_{\text{soil}} = F_{\text{rapid}} - m\alpha \tag{2}$$

$$R_{\text{w}} = R_{\text{soil}} - \ C\,v \tag{3}$$

$$R_{\text{soil at ULP}} = R_{\text{ULP}} = R_{\text{w}} \tag{4}$$

where, F_{rapid} = Rapid load, R_{a} = Inertial force of pile, R_{v} = Dynamic soil resistance, R_{w} = Static soil resistance, m = Pile mass, α = Pile acceleration, C = Damping constant, v = Pile velocity, R_{ULP} = ULP resistance (static soil resistance).

Since the ULP method supposes that F_{rapid} equivalent to the ultimate pile bearing capacity is applied once, the damping constant C must be determined to estimate R_{w} (Eq. 3). However, the value of C may vary depending on the displacement and velocity of the pile.

At the maximum displacement w_{max} (called UnLoading Point, ULP) the pile velocity v is 0, hence R_{soil} is equal to R_{w} (R_{ULP}) as Equation 4.

In the Hybridnamic RLT, the hammer drop height h is increased in stages, and several blows are applied to the pile. In each blow, ULP load and the corresponding displacement are obtained. Therefore, by simply connecting the ULPs, the $R_{\text{w}} - w$ relationship can be easily obtained without the estimation of C. This interpretation is called UnLoading Point Connection (ULPC) method (Kamei et al. 2022).

Mullins et al. (2002) proposed the Segmental UnLoading Point (SULP) method for a pile instrumented at several pile sections. In the SULP method, force and acceleration are measured at the pile head whereas only force is measured at other pile sections. The velocity and acceleration at a particular measurement point other than the pile head are estimated using the measured force at that point, and the force and displacement at the pile head. Note that only the total static soil resistance is estimated in the SULP method by summing up the static soil resistance of each segment.

In the proposed Segmental UnLoading Point Connection (SULPC) method, forces and accelerations are measured at several sections of the pile (Figure 3). Soil resistance $R_{\text{soil}i}$ vs displacement w_i of segment i is estimated using the relation of Equation 5 (Step 2 in Table 1).

Table 1. Flow of SULPC.

Step 1 : Multi cycle rapid load test
Step 2 : Calculate relationship of soil resistance R_{soil} - displacement w and ULP load for each segment
Step 3 : Constuct static resistance R_w - displacement w relationship for each pile segment by connecting ULPs (SULPC)
Step 4 : Analize responses of elastic pile subjected to static loading using a load transfer method

Table 2. Specifications of test pile.

Item	Value
Length, L (m)	24.8

Cross-sectional area, A (m^2)	0.0346
Cross-sectional area, A (m^2)†	0.0376
Young's modulus, E (kPa)	2.00×10^8
Density, ρ (ton/m^3)	7.85
Mass, m (ton)	7.032
Bar wave velocity, c (m/s)	5048

† : including steel protection cover for strain gages.

$$R_{soil_i}(t) = F_{rapid_i}(t) - m_i \cdot \alpha_i(t) = F_{i-1}(t) - F_i(t) - m_i \cdot \alpha_i(t) \quad (5)$$

As several blows are applied to the pile in the Hybridnamic test as mentioned earlier (Step 1), static soil resistance R_{wi} vs w_i of segment i is constructed by connecting ULPs (Step 3).

The responses of the whole pile subjected to static pile head load are then calculated using a load transfer method (Step 4). In this calculation stage, the pile is treated as elastic, and non-linear soil resistance behavior estimated in Step 3 is considered at each pile node.

3 CASE STUDY

3.1 *Test description*

The test site was in Okayama Prefecture, Japan. The profiles of soil layers and SPT-N values are shown in Figure 4, together with pile embedment. The test pile was a steel pipe pile (SPP) having the specifications listed in Table 2. The pile was constructed using the down-the-hole hammer method. To increase plugging effect, concrete was filled inside the pile along a section of 1 D_o from the pile tip.

Two strain gages and two accelerometers were attached near the pile head (L1), and strain gages were instrumented at L2, L3 and L4. Furthermore, accelerometers were instrumented at L3 and L4. The acceleration α at L2 was obtained as the weighted mean value of α measured at L1 and L3. The outer surface of the pile section in the weathered rock between L3 and L4 was coated by a friction reduction material to ensure that the load on the pile head was sufficiently transferred to the pile tip.

Static load test (SLT) was carried out 29 days after the pile construction. In the SLT, 6-step load maintenance test was conducted followed by a continuous load test. RLTs using the Hybridnamic test device with a hammer mass of 44 ton was carried out 90 days after the SLT.

3.2 *Test results*

A total of 7 blows were conducted in the RLTs, increasing the hammer falling height h from 0.25 m to 3.0 m.

Figure 5 shows the measured dynamic signals in the RLT with h = 3.0 m. The relative loading duration T_r was 7.1, which satisfied the criterion of RLT ($T_r \geq 5$) specified in the JGS standard. Nevertheless, α at different levels were largely different showing that rigid body modeling of the pile was not adequate. It can be seen from the local pile displacements w that

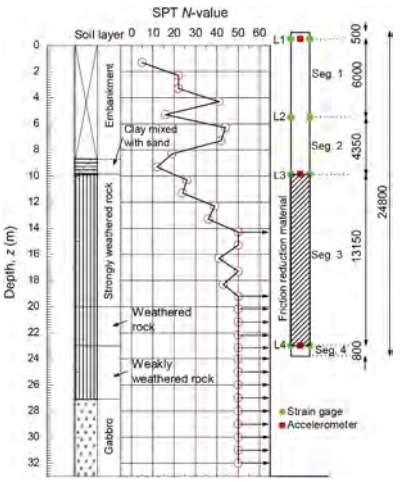

Figure 4. Profiles of soil layers and SPT-N values, together with pile embedment.

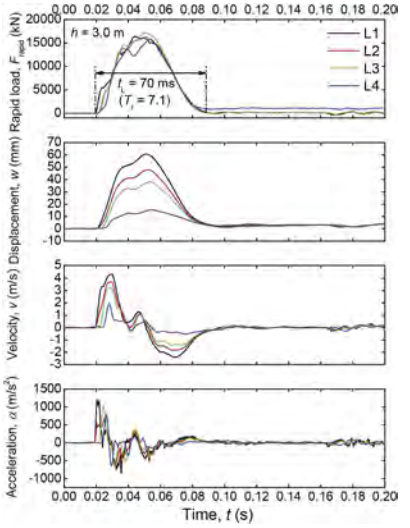

Figure 5. Measured dynamic signals (h = 3.0 m).

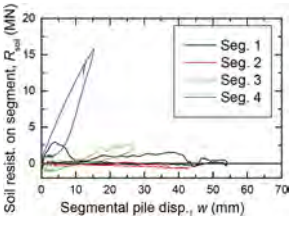

Figure 6. R_{soil} vs w of each pile segment (h = 3.0 m).

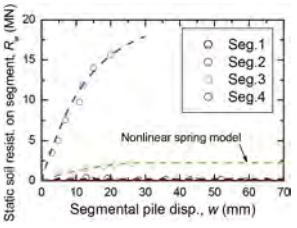

Figure 7. R_w vs w of each pile segment from multiple blows.

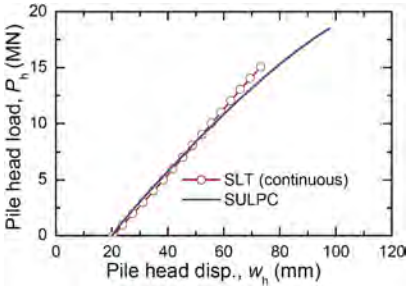

Figure 8. Static load-displacement curves from SULPC and SLT.

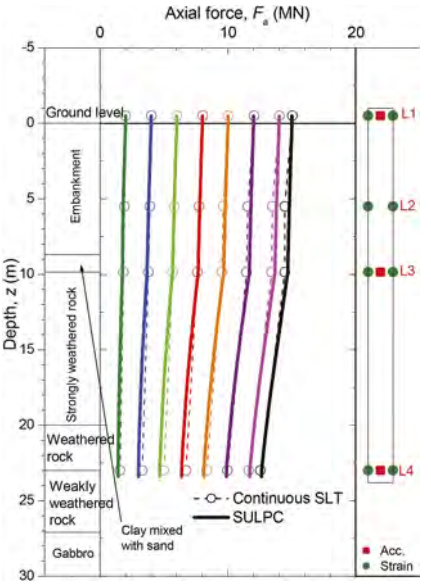

Figure 9. Axial pile force distributions from SULPC and SLT.

relatively large deformation of the pile was caused. Hence, the proposed SULPC interpretation was adopted.

Figure 6 shows the R_{soil} vs w in each segment estimated from the RLT with h = 3.0 m.

By connecting ULPs of each segment from all the 7 blows, the static soil resistance R_w vs w of each segment was obtained as shown in Figure 7. For the load transfer calculation, thus obtained R_w vs w was modeled by the dashed line for each segment.

Figure 8 shows the pile head load P_h vs pile head displacement w_h from the SULPC and the continuous SLT. The result from the SULPC is comparable with the SLT result.

Figure 9 shows the axial pile force F_a distributions from the SULPC interpretation and the continuous SLT. The results from the SULPC are again comparable with the SLT results.

4 CONCLUSIONS

A new interpretation method, SULPC, of RLT signals was proposed in this paper. The behaviors of a steel pipe pile from RLTs with the SULPC interpretation were comparable with those from SLT. The loading in this test was within the range of reloading. In future, similar comparison until ultimate load will be needed.

The authors would like to thank Mr. Tomohiro Fujita, Public Works Research Institute, for his supports in this research.

ABSTRACT: The Hybridnamic testing is a kind of falling-mass type rapid load test (RLT), by which several blows on a pile can be conducted easily and quickly. Hence, static load-displacement curve is constructed by connecting UnLoading Point (ULP) loads. This procedure is called UnLoading Point Connection (ULPC) method. ULP method or ULPC method is employed for cases of the relative loading duration $T_r = t_L/(2L/c)$ greater than 5, where t_L is loading duration, L is pile length and c is bar wave velocity. ULPC with Case method (ULPC_CM) is proposed in this paper so that RLT can be employed even in cases of T_r less than 5. A case study was carried out to demonstrate the applicability of ULPC_CM. Load-displacement curves from the ULPC_CM interpretation of RLT signals having smaller T_r less than 5 were comparable to the conventional static load test result.

1 INTRODUCTION

Twenty years have passed since the rapid loading test (RLT) of piles were newly added to the Japan Geotechnical Society (JGS) standard (JGS1815-2002). After 2002, most of the RLTs in Japan are conducted using the falling-mass method with a soft-cushion placed on the pile head. In line with this, the number of loading cycles has also changed from one loading of the maximum planned load to multiple loading with the hammer drop height being raised in stages. Therefore, the interpretation method has shifted from the UnLoading Point (ULP) method to the UnLoading Point Connection (ULPC) method (Kamei et al. 2022), which provides a static load-displacement relationship simply by connecting the ULPs without the need to obtain the damping constant C required in the ULP method.

As a result of the widespread use of the ULPC method as an interpretation method for rapid loading tests, some cases have emerged that pose challenges for the analysis of single mass model method in which the entire pile length is considered as a rigid body.

In this paper, as a new interpretation method to address these issues, the ULPC method invoking the Case method (ULPC_CM) is proposed.

2 HYBRIDNAMIC RAPID LOAD TEST DEVICES

Jibanshikenjo Co. Ltd. has developed several Hybridnamic test devices since 2003. The Hybridnamic test devices are "falling-mass type", in which a hammer mass in the steel frame is lifted using a hydraulic jack and free-dropped to apply rapid load to the pile head via a specially designed cushion on the pile head. By changing combination of stiffness of the cushion system K_{cushon}, hammer mass m_h and falling height of hammer h, loading duration t_L

DOI: 10.1201/9781003299127-211

and the maximum rapid load $F_{rapid(max)}$ can be easily controlled. In the current JGS standards, load test with the relative loading duration $T_r = t_L/(2L/c) \geq 5$, where L is the pile length and c is the bar wave velocity in the pile, is regarded as RLT.

3 UNLOADING POINT CONNECTION METHOD WITH CASE METHOD (ULPC_CM)

Middendorp et al. (1992) treated the pile as a rigid mass during RLT assuming that the effects of wave propagation phenomena in the pile body are negligible. When a dynamic load F_{rapid} is applied to the pile, the static soil resistance R_w and dynamic soil resistance R_v act on the pile. These relationships are expressed in Equations 1 and 2, and Figures 1 and 2.

$$F_{rapid} = R_a + R_v + R_w = m\ \alpha + C\ v + R_w \tag{1}$$

$$R_{soil} = F_{rapid} - m\ \alpha \tag{2}$$

$$R_w = R_{soil} - \ C\ v \tag{3}$$

$$R_{soil\ at\ ULP} = R_{ULP} = R_w \tag{4}$$

where, F_{rapid} = Rapid load, R_a = Inertial force of pile, R_v = Dynamic soil resistance, R_w = Static soil resistance, m = Pile mass, α = Pile acceleration, C = Damping constant, v = Pile velocity, R_{ULP} = ULP resistance (static soil resistance).

At the maximum displacement w_{max} (called UnLoading Point, ULP) the pile velocity v is 0, hence R_{soil} is equal to R_w (R_{ULP}) as Equation 4.

In the Hybridnamic RLT, the hammer drop height h is increased in stages, and the pile is loaded multiple times. In each blow, ULP load and the corresponding displacement are obtained. Therefore, by simply connecting the ULPs, the R_w - w relationship can be easily obtained without the estimation of C.

Kamei et al. (2022) point out that even if $T_r \geq 5$, there are cases where assumption of rigid mass modeling of a pile may not be adequate. To overcome this situation, Kamei et al. (2023, in press) proposes Segmental UnLoading Point Connection (SULPC) method. The SULPC method can be employed in case that the pile is instrumented with strain gages and accelerometers at several levels of the pile.

In many cases, however, dynamic signals are measured only near the pile head. Hence, a new interpretation method is proposed, in which the ULPC method (Kamei et al. 2022) and the Case method (Raushe et al. 1985) are combined as described below.

The Case method is a method based on one-dimensional stress-wave theory, in which the soil resistance R_t (= R_{soil}) of a pile during driving, and the static soil resistance R_s (= R_w) are obtained using an empirical coefficient called the J_c-factor.

First, the downward traveling wave F_d and the upward traveling wave F_u are calculated from the measured dynamic signals (axial force F and pile velocity v) (Equations 5 and 6). Then, using Equation 7, the time variation of the penetration resistance R_t of the pile is obtained (Figure 3).

$$F_d(x_m, t) = \frac{F(x_m, t) + Z \bullet v(x_m, t)}{2} \tag{5}$$

$$F_u(x_m, t) = \frac{F(x_m, t) - Z \bullet v(x_m, t)}{2} \tag{6}$$

$$R_t(x_m, t) = F_d\left(x_m, t - \frac{L_m}{c}\right) + F_u\left(x_m, t + \frac{L_m}{c}\right) \tag{7}$$

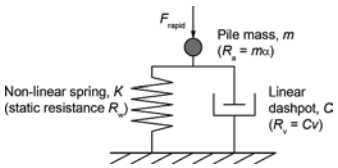

Figure 1. Modeling of pile and soil during RLT (after Middendorp et al. 1992, and Kusakabe and Matsumoto, 1995).

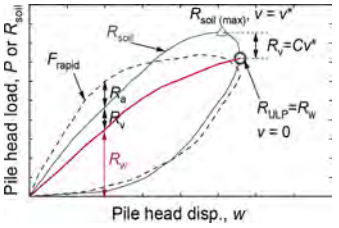

Figure 2. Relationship between load-displacement curve and soil resistance and ULP resistance.

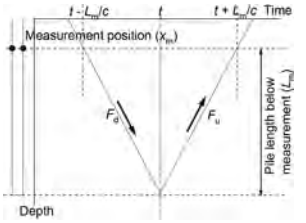

Figure 3. Case method (Raushe et al. 1985).

where, x: Coordinate along the pile axis (pile head = 0), x_m: Measurement position, v: Pile velocity, L_m: Pile length from measurement position to pile tip, Z: Impedance ($=EA/c$), F: Axial force, F_d: Downward force wave, F_u: Upward force wave, c: Bar wave velocity, E: Young's modulus of pile material, A: Cross sectional area of pile

The Case method evaluates the penetration resistance of the pile during driving, but the load-displacement relationship of the pile cannot be obtained by this method alone. Since the Case method is based on the one-dimensional wave theory, the penetration resistance of the pile can be evaluated correctly regardless of the pile length.

In the proposed ULPC_CM method, multiple blows (rapid load tests) are applied to a pile. The time variation of soil resistance R_{soil} is obtained from the Case method, and the time variation of pile displacement w is directly measured. Hence, $R_{soil} - w$ relation is easily obtained. R_{soil} at the maximum pile displacement (ULP) can be regarded as the static resistance R_w. Static load-displacement curve is constructed by connecting ULPs from the multiple blows.

As the ULPC_CM method is based on the one-dimensional stress-wave theory, it has the advantage of not requiring correction for pile inertia. Hence, the ULPC_CM method would be applied to RLTs on piles with $T_r < 5$.

4 CASE STUDY

4.1 *Test description*

The test site was in Ibaraki Prefecture, Japan. The profile of SPT-N values is shown in Figure 4, together with pile embedment. The test pile was a steel pipe pile (SPP) having the specifications listed in Table 1. The pile was constructed using the inner excavation method. Two strain gages and two accelerometers were attached near the pile head.

Static load test (SLT) with 5-step maintained load was carried out 29 days after the pile construction. RLTs using the Hybridnamic test device with a hammer mass of 23 ton was carried out 112 days after the SLT.

4.2 *Test results*

Figure 5 shows the measured dynamic signals in the RLT with $T_r = 3$. In the figure, soil resistance $R_{soil\ (ULP)}$ from the ULP method and $R_{soil\ (Case)}$ from the Case method are also shown. $R_{soil\ (ULP)}$ and $R_{soil\ (Case)}$ at the time of maximum displacement are the static soil resistance R_w from both methods.

By connecting R_w from the all blows, pile head load P_h vs pile head displacement w_h are obtained as shown in Figure 6. P_h vs w_h from both ULPC and ULPC_CM are comparable with the SLT result when $T_r = 5$. However, as T_r decreases, the results from ULPC overestimate the SLT result, while the results from the ULPC_CM are still comparable with the SLT result.

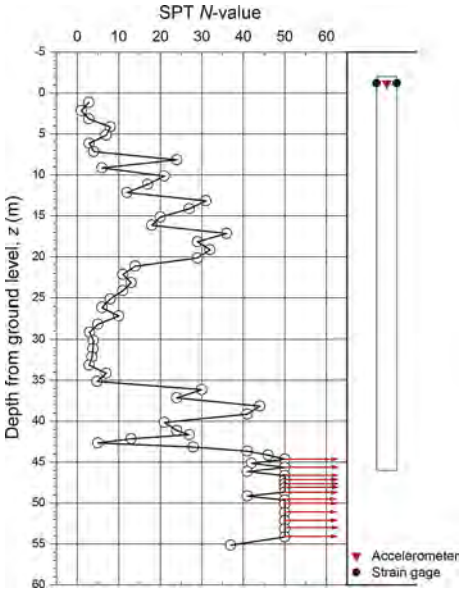

Figure 4. Profile of SPT-N values, together with pile seating.

Table 1. Specifications of the test pile.

Item	Value
Length, L (m)	48.0
Outer diameter, D_o (mm)	800
Inner diameter, D_i (mm)	750
Wall thickness, t_w (mm)	25
Cross-sectional area, A (m^2)	0.0609
Young's modulus, E (kPa)	2.00×10^8
Density, ρ (ton/m^3)	7.85
Mass, m (ton)	22.314
Bar wave velocity, c (m/s)	5133

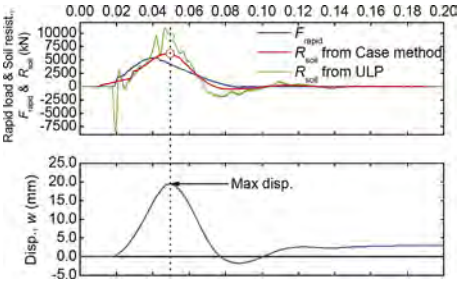

Figure 5. RLT signals (T_r = 3, h = 1.0 m).

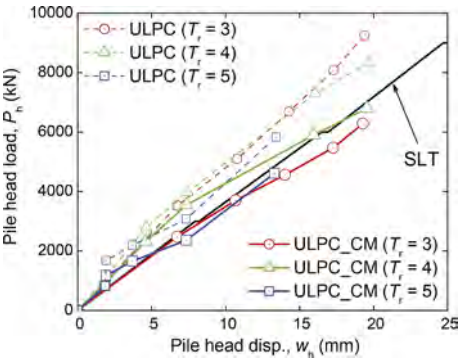

Figure 6. Comparison of load-displacement curves from SLT, RLTs with ULPC and ULPC_CM.

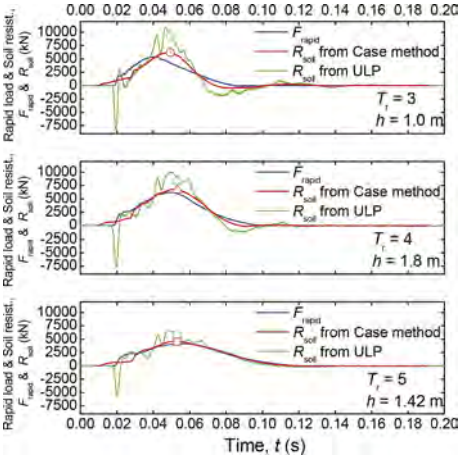

Figure 7. RLT signals (T_r = 3~5).

As shown in Figure 7, for T_r = 5, there is no significant difference between $R_{soil\ (Case)}$ and $R_{soil\ (ULP)}$; as T_r decreases to 4 and 3, the difference between $R_{soil\ (Case)}$ and $R_{soil\ (ULP)}$ increases. The results in Figures 6 and 7 indicate that the ULPC_CM method has a potential applicability to RLTs with T_r < 3.

5 CONCLUSIONS

A new interpretation method, ULPC_CM, of RLT signals was proposed in this paper. The load-displacement relations of an SPP from RLTs with the ULPC_CM interpretation were comparable with the SLT result until T_r was decreased to 3.

The loading in this test was within the range of reloading. In future, similar comparison between RLTs and SLT will be needed to examine the applicability of the ULPC_CM to obtain the load-displacement relation of a pile to the ultimate load. Furthermore, conduction of RLTs with $T_r < 3$ will be needed to discuss the application limit of ULPC_CM method for RLTs with smaller T_r.

ABSTRACT: The article deals with geotechnical design of pile foundations, especially by static load tests and by calculation using numerical models. The results of comparison analysis of bearing capacities drilling displacement system (DDS) boring piles obtained by static load tests and by standard are presented in article, as well as results of compression test of surrounding soil after DDS pile installation. Drilled Displacement System (DDS) piles are an innovative technology for pile foundations. These DDS piles are created by rotary drilling with a simultaneous full displacement of the soil in a horizontal direction. The optimal design of DDS piles can be obtained in soils that allow for a horizontal displacement, which causes an increase in the shaft's resistance. Significant differences between experimental (Static Load Test by GOST) and design (by Kazakhstan Standards) values of bearing capacity of DDS pile show us incomplete usage of DDS technology resourced. The results of numerical analysis of DDS and traditional boring pile modeling by FEM (Plaxis 2D) are also presented in the paper. The numerical results have been presented with equivalent static load-settlement curve. By results of numerical analysis coefficient of surrounding work is defined. These investigations are important for un-derstanding of soil-pile interaction on problematical soft soils ground of Astana, Kazakhstan.

Keywords: DDS, bored piles, FEM, bearing capacity

1 INTRODUCTION

Pile foundations are one of the most popular types of foundations on construction sites in Kazakhstan, the expediency of using which is explained by the need to provide a large load-bearing capacity of high-rise buildings and structures. Due to the emergence of new technologies and equipment for the construction of pile foundations, designers have a need to improve the current regulatory documents, which, unfortunately, do not have recommendations for the design of piles arranged according to modern technologies [1]. In this article, the work of a bored pile arranged by the DDS method without excavation was investigated. This technology is one of the latest products of German manufacturers and is undoubtedly of practical interest for modern construction in Kazakhstan. The main advantages of this technology are: high productivity of pile production; high economic efficiency; low noise and no vibration when installing piles; and most importantly, high load-bearing capacity of the pile [2,3]. Large differences between experimental (static tests) and calculated (normative) values of the bearing

DOI: 10.1201/9781003299127-212

capacity of bored piles arranged by the rolling method indicate that the resources of this technology are not fully used. The large values of the bearing capacity of the piles are explained by the fact that when the pile is installed, the excavation does not occur, the soil is radially displaced by the rolling of the drilling tool, thereby, as a result of compaction, there is a change in the strength and deformation characteristics of the soil around the pile. Thus, it becomes obvious that the work of displacement piles is different from the work of a traditional pile, and there are still many unresolved issues concerning this technology: the impact of displacement technology on the bearing capacity of piles; the effect of radial compaction of the surrounding array on the work of piles; the impact of displacement piles on the foundations of adjacent buildings and structures, etc.

2 FEATURES OF DDS TECHNOLOGY

The sequence of work on the installation of drilling piles manufactured using DDS technology includes the following operations (Figure 1): installation of drilling equipment at the drilling site; immersion of the drilling tool with a sealing system to the design mark; connection of the concrete pump followed by filling the well with concrete mixture and one-time extraction of the drilling tool; immersion in the well with concrete reinforcement frame to the design mark.

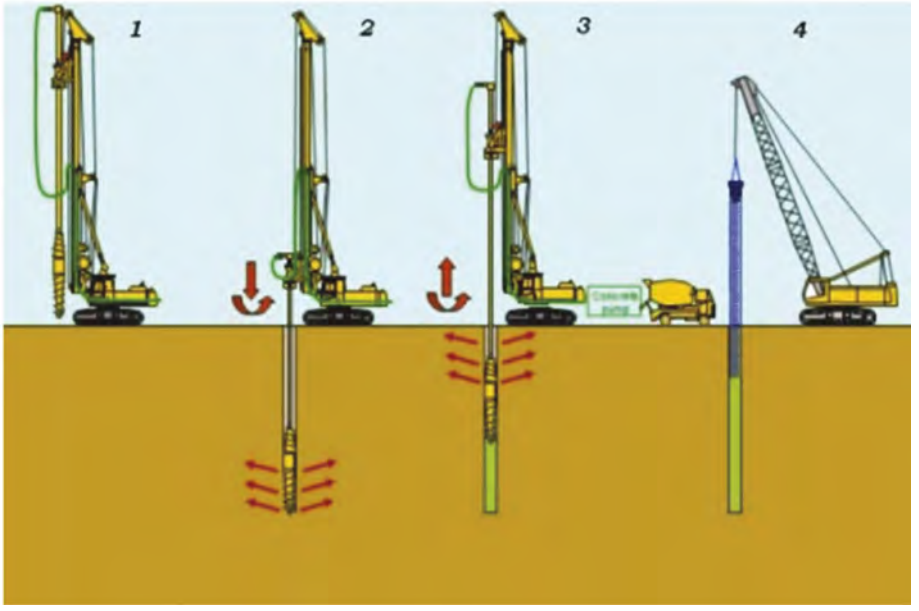

Figure 1. DDS pile devices.

A distinctive feature of the DDS technology is the drilling tool (Figure 2). When drilling the drilling tool down, simultaneously with drilling, the well is rolled out, as a result of which the radial compaction of the soil occurs without its excavation, when drilling up, the walls are compacted.

This technology allows you to arrange piles with a diameter of up to 0.6 m to a depth of up to 30 m. When calculating the productivity, the following parameters should be taken into account: the diameter of the pile, the amount of applied torque and pressing force, density (strength of the soil, compaction of the soil, power of the concrete pump [4].

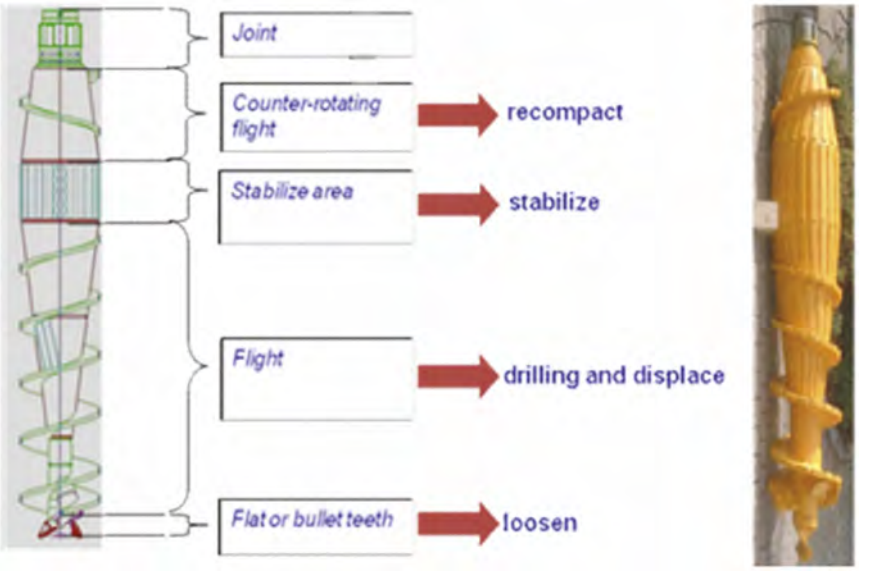

Figure 2. DDS pile drilling Auger.

3 STATIC TESTING OF DDS PILES

In order to clearly demonstrate the differences between the actual and design values of the bearing capacity, static tests of DDS piles were carried out. In total, 14 DDS piles were tested at two construction sites. At the first construction site "Khan Shatyry Shopping and Entertainment Center" 11 piles were tested, 8 of which with a diameter of 410mm, 18m long, 2 piles with a diameter of 500mm, 10m long and 1 pile with a diameter of 600m, 18m long. At the second construction site

"Production base of "KGS" LLP" three piles with a diameter of 500 mm and a length of 2.5m were tested. According to engineering and geological surveys, the geological structure of the survey site is attended by: IGE2 - alluvial medium-odd-quaternary deposits, presented in the form of alternating layers of clay, IGE3 - loamy and loamy–sandy soils, as well as IGE4 - medium-quaternary deposits, presented in the form of clay and loamy deposits [5].

The load on the pile was applied in steps of 400kN and 200kN to the limit of 2800kN with a CM- 158 hydraulic jack. The hydraulic jack force is regulated by the fluid supply from the pumping station and is fixed by a technical pressure gauge. The movement of the pile is measured by deflection meters with an accuracy class 0.01 mm, which are fixed on a reference system fixed to the ground. The reference system is independent of the movement of the system of beams and piles. Unloading was carried out in steps of 800kN and 400kN. For the criterion of the maximum permissible precipitation, the instructions regulated in the SNIP of the Republic of Kazakhstan were adopted 5.01-03-2002 - Pile foundations [6]. For the particular value of the maximum resistance of the pile Fu to the pressing load, the load should be taken, under the influence of which the tested pile will receive a draft equal to S and determined by Formula 1:

$$S_{\max.\text{Sett.}} = \zeta S_{u,mt} \tag{1}$$

$S_{u,mt}$ - the limit value of the average precipitation of the foundation of the projected building or structure, for industrial and civil single-storey and multi-storey buildings with a full frame is assumed to be 8 cm (for reinforced concrete structures) according to the instructions SNiP RK 5.01-01-2002 [7];

ζ- conversion coefficient from the limiting value of the average foundation settlement of the building or structure $S_{u,mt}$ to the pile settlement obtained during static tests with conditional stabilization (attenuation) of settlement is taken equal to 0.2 according to guidelines.

4 COMPARISON OF EXPERIMENTAL AND CALCULATED VALUES OF BEARING CAPACITIES OF DDS PILES

The experimental and calculated (according to the standards) values of the bearing capacities of DDS piles are presented in Table 1. It can be seen from the table that there is a significant difference between the experimental and calculated values of bearing capacities.

Table 1. Comparison of partial values of load-bearing capacities.

№	Geometric dimensions of the pile	Number of piles	Bearing capacity, kN		k = F_u/F_d coefficients
			Experimene al F_u	Calculated F_d	
	L = 17 m d = 410 mm	№1	2280	1545	1,48
		№2	2150	1545	1,39
		№3	2325	1545	1,50
		№4	2475	1545	1,60
		№5	2200	1545	1,42
		№6	2080	1545	1,35
		№7	2190	1545	1,42
	L = 17 m d = 600 mm		2700	2110	1,28
	L = 2 m d = 500 mm	№1	470	272	1,73
		№2	490	272	1,80
		№3	460	272	1,69

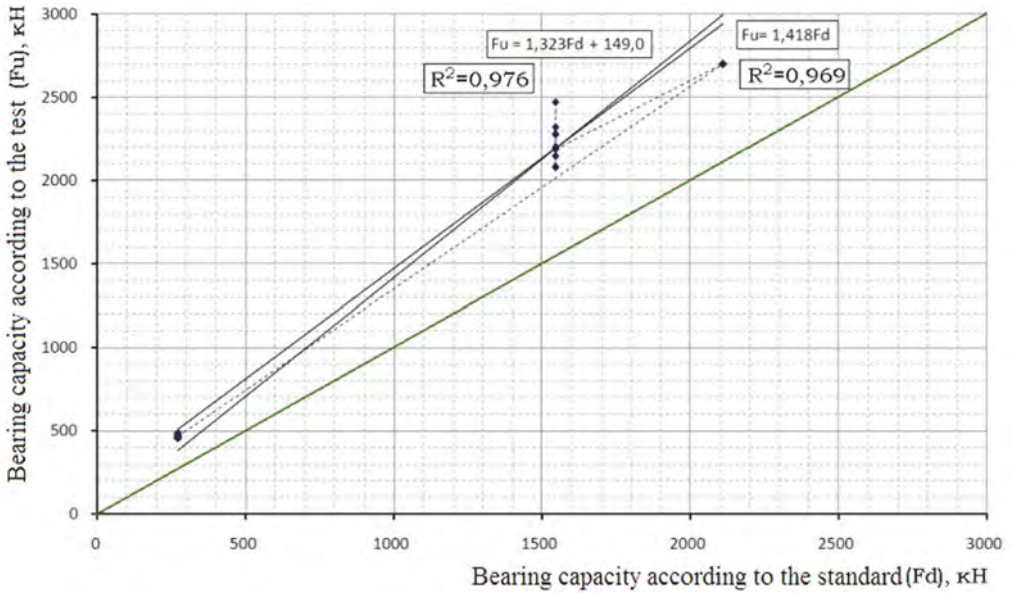

Figure 3. Comparative diagram of experimental F_u and calculated F_d bearing capacities of DDS piles [8].

A comparative diagram of experimental F_uu and calculated $F_d$bearing capacities of DDS piles is shown in Figure 3. As can be seen from the comparative diagram, all points are located above the diagonal, which indicates that all values of experimental bearing capacities are greater than the values of bearing capacities defined by standards.

5 LABORATORY TESTS OF SOIL COMPACTED AROUND THE PILE

The purpose of the laboratory study of the soil mass near the pile is to determine the effect of radial compaction on the physical and mechanical properties of the soil. To study the physical and mechanical properties, soil samples were taken before and after the installation of DDS piles at the construction site of the Khan-Shatyry Shopping and Entertainment Complex in Astana, where DDS piles of various diameters were used (previously mentioned). Soil samples for laboratory studies were selected after static tests of DDS piles at a distance of up to 0.1, 0.2, 0.4, 0.6, 08 and 1 m from the edge of the pile, in order to determine the soil compaction zone along the lateral surface of the pile. More than 30 test wells were drilled with a depth of up to 10 m with an interval of 0.5 m in depth. The distances between the wells were 0.2--1.2 m depending on the distance from the pile. Laboratory tests were carried out in accordance with GOST 12248-96 [9].

The test results were subjected to statistical processing, the purpose of which was to determine the zone of radial compaction, as well as to identify elements of randomness (random values), the cause of which may be the difficulty of extracting soil in an undisturbed state or the error of measuring instruments.

According to the test results, the radial sealing zone for IGE2 was 0.6-0.8 m, for IGE3 and IGE4 0.4-0.6 m. The obtained values of the modulus of deformation, the angle of internal friction and adhesion are displayed graphically in Figures 4-6. With the help of nomograms, it is possible to adjust the deformation modulus, the angle of internal friction and adhesion depending on the diameter of the DDS pile at the design stage [10-12].

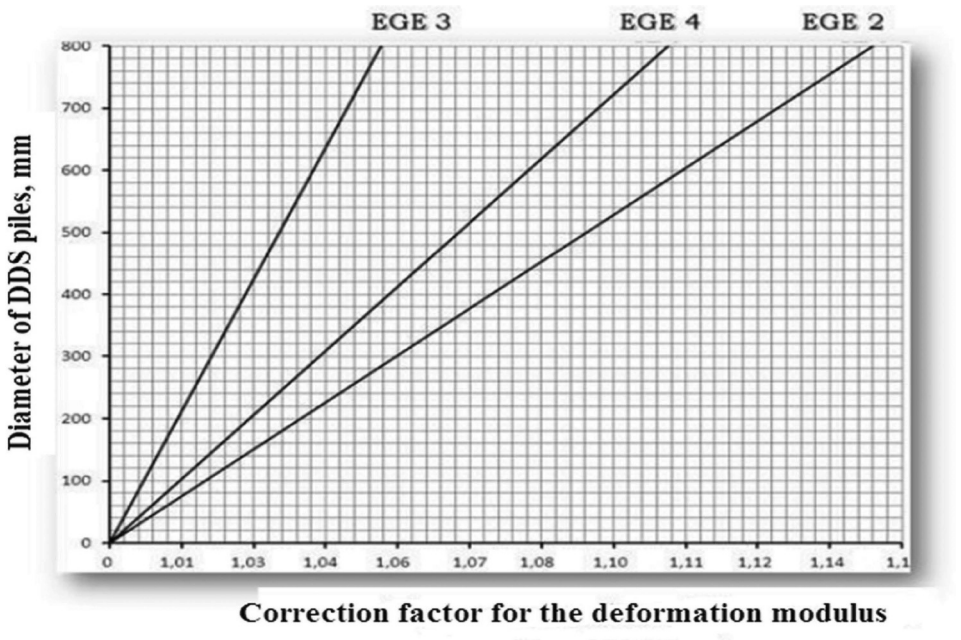

Figure 4. Nomogram for correction of the deformation modulus.

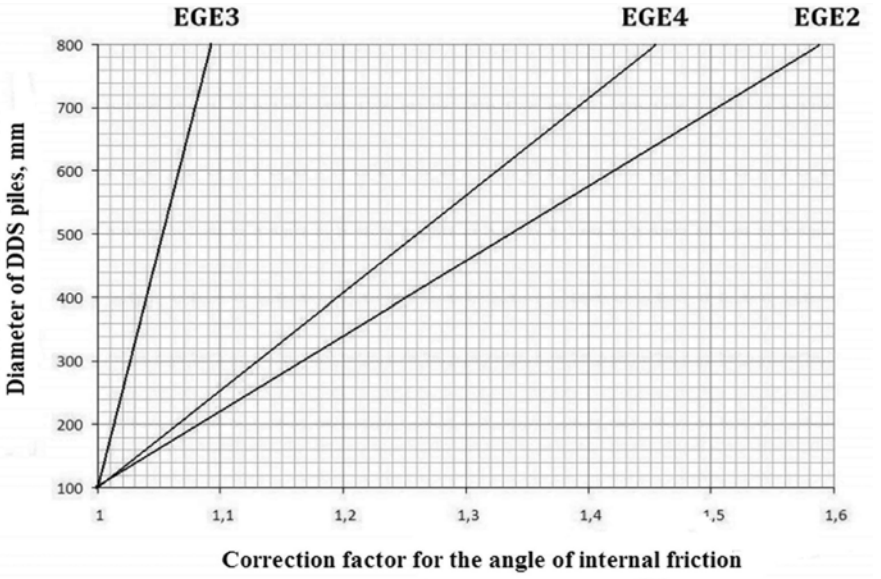

Figure 5. Nomogram for adjusting the angle of internal friction.

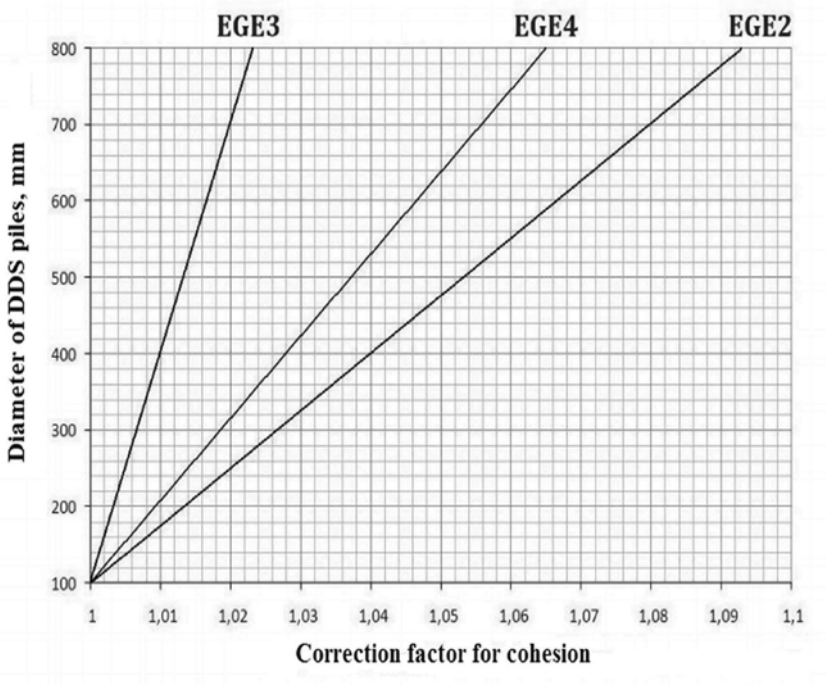

Figure 6. Nomogram for clutch adjustment.

6 NUMERICAL SIMULATION OF DDS PILES

The aim of the study is to determine the effect of soil compaction as a result of its displacement on the bearing capacity of the DDS pile.

Modeling of a bored pile is carried out in an axisymmetric formulation of a two-dimensional model of hardening soil. The dimensions of the geometric model are assumed from the condition that the stress distribution will be negligibly small within a given zone.

Figure 7 shows a geometric model of a bored pile, including the separation of soil within a separately considered engineering-geological element, the pile element and a uniformly distributed load on the pile. The separation of the soil within one IGE implies that the compaction of the soil under the lower end of the pile does not occur, therefore, the cluster located under the lower end of the pile is assigned the parameters obtained from the results of field and laboratory studies of soils before their compaction.

When modeling a DDS pile, the soil cluster located above the end of the pile is given soil parameters determined experimentally after the DDS pile is installed, taking into account the radial compaction zone. Presumably, the bearing capacity of the DDS pile is greater than the bearing capacity of a traditional pile. We introduce the coefficient k, which shows the numerical value of the differences in bearing capacity between DDS piles and traditional piles.

$$k = \frac{F_{d\,(PLX)}^{DDS}}{F_{d(PLX)}^{tr}}\ ,\quad \mathrm{k} \geq 1 \tag{2}$$

where: $F_{d\,(PLX)}^{DDS}$ - calculated soil resistance based on the results of numerical modeling of the DDS pile, kN;

$F_{d(PLX)}^{tr}$ - calculated soil resistance based on the results of numerical modeling of a traditional pile, kN.

Коэффициент условия работы сваи DDS,

it will be determined by formula 4, taking into account the coefficient k.

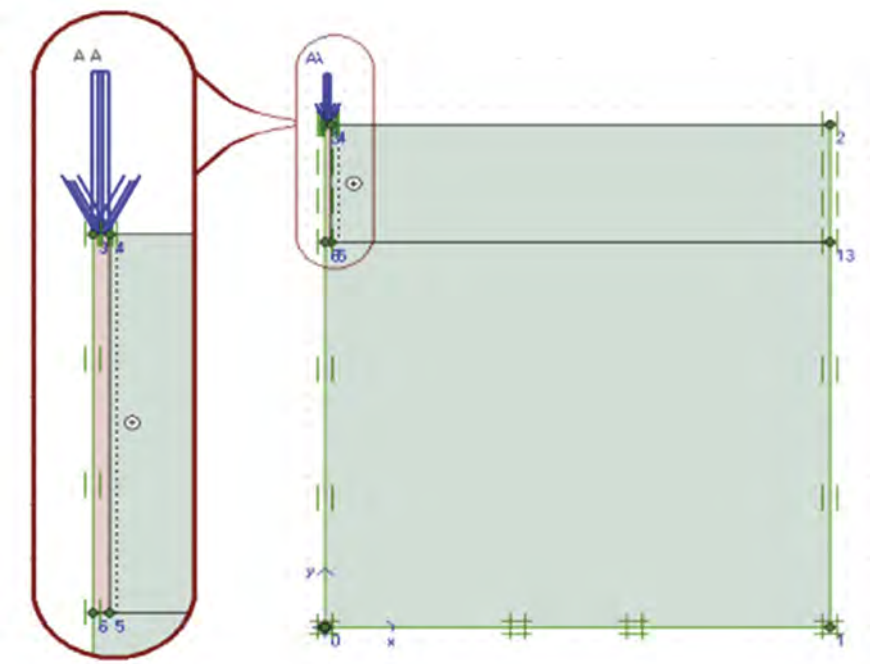

Figure 7. Geometrical model of DDS pile [13].

$$\gamma_{cf}^{DDS} = \frac{kF_a^{tr} - \gamma_c \gamma_{cr} RA}{u\gamma_c \sum f_i h_i} \quad (3)$$

where: γ_{cf}^{DDS} - coefficient of soil working conditions on the side surface of the pile DDS;
F_a^{tr} - estimated bearing capacity of a traditional pile;
$\gamma_c \gamma_{cr}$ - the same as Formula 2.

To determine the dependence of the bearing capacity of DDS piles and traditional piles, we will construct comparative diagrams showing the ratios of the values of the bearing capacity of traditional piles obtained by numerical modeling to the bearing capacity of DDS piles (Figure 8).

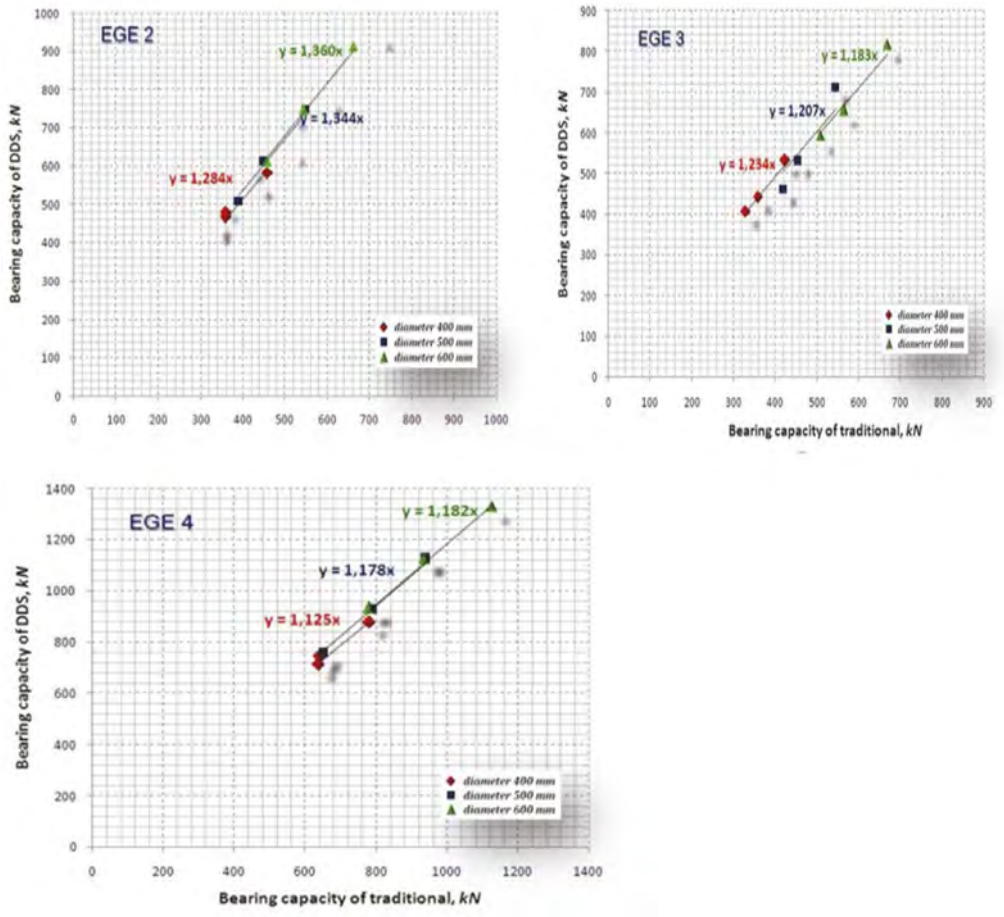

Figure 8. Simulation results.

It can be seen from the diagrams that the values of the coefficients of the soil working conditions on the side surface of the DDS pile are: for IGE2 – 1.38, IGE3 – 1.26, IGE4 – 1.2.

7 CONCLUSION

1. Static tests of DDS piles of various diameters were carried out, according to the results of which a comparative analysis of experimental bearing capacities of piles with normative

ones was carried out. The experimental values of the bearing capacity of DDS piles, on average, are 1.5 times higher than the calculated ones, which in turn indicates that the resources of DDS technology are not fully used.

2. Nomograms describing the dependence of the modulus of deformation, adhesion and the angle of internal friction on the diameter of the DDS piles were obtained. The adjustment of parameters can be used in the design of DDS piles with a diameter from 410 to 600 mm in engineering geological conditions similar to the conditions of the studied construction sites. The obtained dimensions of the radial seal were used in numerical modeling.
3. Based on the results of numerical modeling, an experimental-theoretical coefficient of the soil working conditions on the side surface of the pile DDS was obtained, equal to 1.28. At the same time, the difference between the experimental and calculated values of bearing capacities decreases from 1.51 to 1.14.

ABSTRACT: The article presents the results of investigation of soils in the base and reasons for the collapse of a reinforced concrete chimney. Based on the materials of the conducted studies, it was concluded that the main reason for the collapse of the reinforced concrete shaft of the chimney of coke oven batteries no. 5 and no. 6 of arcelormittal temirtau jsc (formerly karaganda metallurgical plant) is a decrease in the strength characteristics of concrete due to many years of constant moisture, freezing and thawing in the autumn winter-spring periods of time, and indirectly due to the lack of proper control over the technical condition of building structures of all areas of reinforcement of the reinforced concrete chimney shaft and assessment of their strength characteristics. The design of the reinforcement instead of its original purpose contributed to the development of negative consequences and the safe operation of the facility.

1 INTRODUCTION

Coke oven battery No. 5 with a capacity of 690 thousand tons of coke per year was put into operation on June 22, 1969 and is intended for processing coal charge to produce coke and coke oven gas.

The chimney of coke oven batteries No. 5 and No. 6 is designed to remove coke oven gas combustion products, built in 1965. Technical characteristics of the chimney: height H=100 m, diameter of the lower part of the pipe 8.0 m, upper part 4.0 m, thickness walls: bottom 320 mm, top 160 mm.

The material of the shaft is made in the form of a monolithic reinforced concrete structure made of concrete grade 300, the lining is made of ceramic brick grade 125, thermal insulation is made of diatomaceous bricks.

The last geodetic survey was carried out in April 2013. According to the results of the geodetic survey, the vertical deviation of the shaft to the south was 149 mm, to the west 208 mm, the magnitude of the deviations is within the allowable building codes for such structures.

On June 26, 2013, the reinforced concrete chimney of coke oven batteries No. 5 and No. 6 collapsed. When the upper part of the chimney fell, the direct coke oven gas pipeline with a diameter of 2600 mm, the charge conveyor gallery and the associated pipelines for steam, process water, electrical cable products were destroyed, followed by coke oven gas burnout in the damaged section of the direct coke oven gas pipeline.

DOI: 10.1201/9781003299127-213

2 TECHNICAL INSPECTION OF THE CHIMNEY

The chimney was subjected to an annual technical inspection. In 2005, a major overhaul was carried out with the replacement of metal structures, the restoration of a lightning rod, light signaling. In 2008, the blind area around the perimeter of the chimney was repaired.

A detailed instrumental examination of the chimney in order to determine the technical condition and assess the bearing capacity of the reinforced concrete structure and the remaining service life was not carried out.

Under such circumstances, the decrease in the strength characteristics of the material of the reinforced concrete structure was left without due attention and was not under the necessary technical control of the facility's operation services, which led to a complete loss of the bearing capacity of the chimney.

During the construction of the chimney of coke oven battery No. 5, deviations from the project were allowed. For this reason, from e.g. ± 0.0 m to elevation + 15.0 m, the walls of the reinforced concrete shaft were reinforced with a monolithic reinforced concrete belt made of M-300 concrete along the entire outer perimeter of the pipe.

When reinforcing the reinforced concrete pipe shaft, the design, construction and operating organizations ignored the technical design of all interfaces between the existing and new chimney structures, which led to the collapse of the reinforced concrete pipe after 50 years of its operation. Such circumstances required increased control over the technical condition of all sections of the reinforcement of the reinforced concrete shaft up to the level. +15.0 m (elevation of the upper part of the reinforced concrete reinforcement cage).

The scheme of reinforcing the reinforced concrete pipe shaft is shown in fig. one Specialists involved in the investigation of the cause of the collapse of a reinforced concrete chimney with a height of H \u003d 100m at elevation. +15m, conclusions were drawn about the possible cause of the emergency due to the constant leakage of water from the water supply systems of

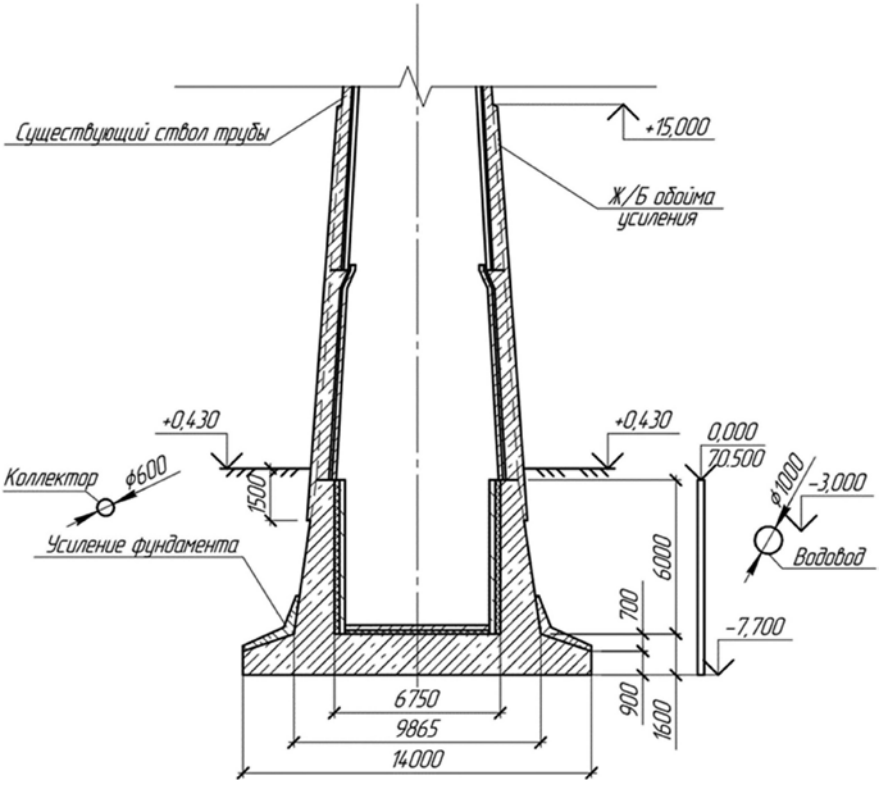

Figure 1. Monolithic reinforced concrete casing reinforcing the chimney shaft of coke oven battery No. 5.

underground utilities (a water conduit with a diameter of 1000.0 mm and a storm collector with a diameter of 600.0 mm) located at a short distance from the object (see Figure 1). For this reason, the need for additional engineering and geological studies of soils located below the sole of the monolithic foundation of the pipe, made in the form of a solid reinforced concrete slab, was determined.

Initial assumptions about the possible cause of the collapse of the chimney due to a decrease in the strength characteristics of soils located under the base of the foundation slab at el. -7.7 m and below were not confirmed.

Incorrect (incorrect) conclusions about the causes of the chimney accident were made on the basis of a technical report based on the results of engineering and geological surveys for the preparation of project documentation for the restoration of a 100.0 m high chimney of coke oven battery No. 5, 6.

3 ENGINEERING GEOLOGICAL SURVEYS

Table 1 shows the obtained values of the soil deformation modulus E (MPa), soil cohesion C (kPa), internal friction angle φ (deg.) obtained by a group of prospectors in April-May 2020 only in two test areas.

Table 1. Values of the soil deformation modulus E (MPa), soil cohesion C (kPa), internal friction angle φ (deg.) obtained in 2020.

		Plot №1			Plot №2		
Depth, m	Soil type	φ, deg	C, kPa	E, MPa	φ, deg	C, kPa	E, MPa
6.0	clay	14	25.0	3.5	14	25.0	3.5
6.5	clay	14	25.0	3.5	14	25.0	3.5
7.0	clay	14	25.0	3.5	14	25.0	3.5
7.5	clay	14	25.0	3.5	14	25.0	3.5
8.0	clay	14	25.0	3.5	14	25.0	3.5
8.5	clay	14	25.0	3.5	14	25.0	3.5
9.0	clay	14	25.0	3.5	14	25.0	3.5

Such uniformity of the physical and mechanical characteristics of clay soils, and even more so their location in depth (modulus of deformation, angle of internal friction, cohesion) called into question their reliability.

Long-term studies of the authors, previously published in the sources of technical information [1,2,3] given in Table 2, show their significant difference in the magnitude of the deformation moduli of clay soils, the main indicator of the strength and deformation properties of the material.

Table 2. Physical and mechanical properties of the soil.

Indicators	one	2	3
Soil specific weight γ, kN/m³	21.0	20.0	19.0
Specific weight of soil particles γ_s, kN/m³	27.5	26.5	25.8
Humidity ω, %	1.2	26.6	27.4
Plasticity I_p, %	28.0	19.5	13.5
Flow I_L	0	0.1-0.3	0.4-0.6
Porosity coefficient e	0.52	0.65	0.73
Angle of internal friction φ, deg	32	23	21
Adhesion coefficient C, MPa	0.05	0.02	0.01
Deformation modulus E, MPa	21.2	14.0	9.0

Note 1-3 numbers of landfills in the construction site of coke oven batteries No. 1-No. 7 of the Karmetkombinat (today ArcelorMittal Temirtau JSC).

These circumstances required additional studies of the physical and mechanical characteristics of clay soils located under the sole of the monolithic foundation of the chimney of coke oven battery No. 5.

Soil tests in the field with a stamp, conducted by Karaganda GIIZ LLP in July 2020, in accordance with GOST 20276-2012, were carried out in order to study the deformation properties of soils lying at a depth below the level of laying the sole of the chimney foundation. The experiments were carried out at a depth of 7.5 m, with round-shaped stamps with an area of 600 cm². Stamp No. 1 obtained a deformation modulus of 6.3 MPa, stamp No. 2 obtained a deformation modulus of 16.2 MPa (Figure 2).

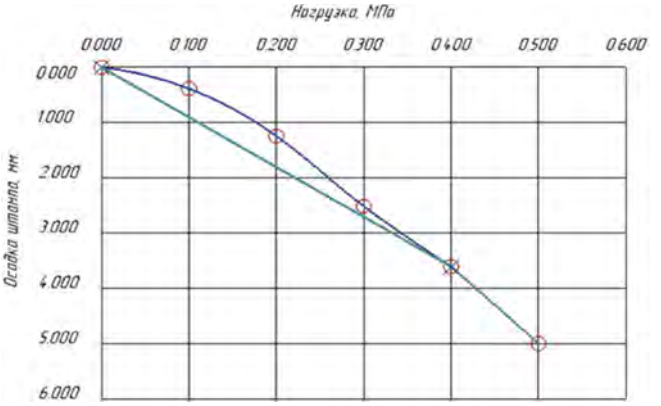

Figure 2. Soil testing with a stamp according to GOST 20276-2012. Graph of the dependence of the draft of the stamp on the load.

From the graph of the dependence of the stamp settlement on the load shown in Figure 2, it can be seen that the modulus of soil deformation at Poisson's ratio v=0.27 is equal to E=16.20 MPa.

4 CONCLUSION

Based on the materials of the conducted studies, it was concluded that the main reason for the collapse of the reinforced concrete shaft of the chimney of coke oven batteries No. 5 and No. 6 of ArcelorMittal Temirtau JSC (formerly Karaganda Metallurgical Plant) is a decrease in the strength characteristics of concrete due to many years of constant moisture, freezing and thawing in the autumn winter-spring periods of time, and indirectly due to the lack of proper control over the technical condition of building structures of all areas of reinforcement of the reinforced concrete chimney shaft and assessment of their strength characteristics. The design of the reinforcement instead of its original purpose contributed to the development of negative consequences and the safe operation of the facility.

Visiting Professor, Indian Institute of Technology Hyderabad, Hyderabad, India

ABSTRACT: The selection of proper design parameters for assessing pile's axial capacity involves a significant degree of uncertainty as design concepts aren't necessarily consistent with the methods or procedures involved in installation of piles. To obviate this lacuna and to develop a rational design procedure, a new technique for back-analyzing a cyclic pile load test is presented to estimate ultimate base and shaft resistances, as well as initial stiffnesses of the shaft and base of the pile. The novel method facilitates 'a priori' estimation of required pile design parameters based on geotechnical characteristics, geometry (shape, length, and diameter), construction methodologies, and other uncertainties present on the site during pile installation. The method was applied to the results of cyclic pile load tests for subsurface strata of typical Yamuna Sand overlying weathered rock at certain locations.

1 INTRODUCTION

The most efficient and cost-effective method for transferring heavy vertical, uplift, and lateral loads to deeper levels is a pile foundation. The pile's surrounding soil mass acts as support for the imposed loads. The interaction between piles and soil is three-dimensional and non-linear. Finding a closed form solution to such a case is extremely challenging if not impossible. Several approaches were developed to analyse and forecast the response of the composite pile–soil system. Faruque and Desai (1982) incorporated both numerical and geometric non-linearities in their three-dimensional finite element model. Rajashree and Sitharam (2001) developed a nonlinear finite element model for batter piles under lateral loading utilising a hyperbolic relation for static load and a modified hyperbolic relation incorporating degradation and gap for cyclic load conditions.

The ultimate capacity of the pile is evaluated using the strengths and unit weights of soil layers along depth, overburden pressure and other pertinent parameters. The initial maintained load test is always be performed to verify the predicted capacity. Since the values of strength, stiffness, interface resistance between the pile and the soil, lateral earth pressure coefficient with depth, soil stratification, etc., taken into account for estimating the ultimate capacity of the pile may differ from the actual in site values, the estimated capacity may not match in most situation with the actual at the site. Thus, the assessment of a pile's axial capacity entails a great deal of uncertainty in choosing the right design parameters, and the design guidelines aren't always in line with the processes/procedures involved in installation.

Predictions of the composite pile-soil system's reaction are made using a variety of techniques. The load-settlement curve/plot until failure load might be predicted a priori using the techniques by Whitaker and Cooke (1966), Burland et al. (1966), and Poulos (1972).

DOI: 10.1201/9781003299127-214

Brinch-Hansen (1963), Chin (1971a&b) and Chin and Vail, 1973), Davisson (1972), Fellenius (1989), etc. Kondner (1963) and Davisson (1972) have suggested techniques for determining the ultimate pile capacity based on a pile load tested to failure. These techniques relate to several concepts, such as restricting the maximum pile settlement and the settlement to load ratio. The form of the load-settlement curve is identified somewhat similar or close to hyperbolic by Chin (1971) and Brinch-Hansen (1973).

Seed and Reese (1957) and Coyle and Reese (1966) proposed the first axial load transfer curves. Different curve types, based on theory, experience, or both, were described in the literature depending on varying complexity levels and the number of soil characteristics. They are often created for certain ground and pile types (Randolph and Wroth 1978; Wang et al. 2012; Cecilia et al. 2017). Either an empirical relationship or a measurable soil deformation value is used to determine the stiffness of the load transfer curves. Based on correlations with observed soil resistance characteristics, Randolph and Wroth (1978) and Fleming (1992) employed an equivalent deformation modulus or oedometer modulus for the reaction of pile tip. If stiffness is inferred from the linear component of the curve using the standard correlations, the Randolph linear curves correspond to elastic estimate. To simulate side and base load transfer relevant for drilled piles in sands and clays, Hirayama (1990) used hyperbolic functions. The standard in-situ and laboratory test findings served as the basis for the parameters utilised to define these functions. By doing a back-analysis on pile load test data, Fleming (1992) proposed a technique to identify interaction parameters.

2 PROBLEM DEFINITION

Estimation of ultimate resistances, initial shaft and base stiffnesses based on load - displacement from pile load tests is crucial because it enables validation of *a priori* predictions based on geotechnical characteristics, geometry (shape, length, and diameter), construction methodology, and other uncertainties prevalent at the pile installation site. The purpose of this paper is to estimate ultimate shaft and base resistances as well as initial shaft and base stiffnesses using initial pile load tests. Single pile with a diameter of d, and length of L, subjected to an axial load, P, is considered, (Figure 1a). For this investigation, the total pile response and the pile shaft-soil, P_S, and base, P_B, resistances of the pile soil system are analysed using a Winkler type model with non-linear responses (Figure 1b).

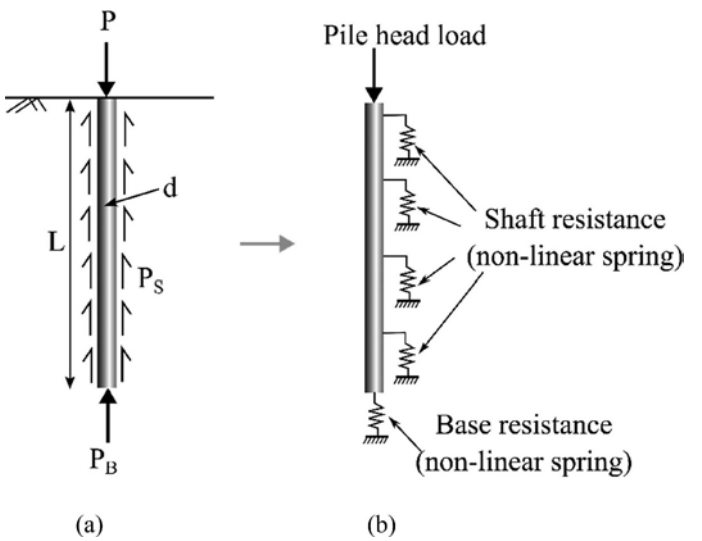

Figure 1. Definition sketch for a single rigid pile – soil system.

3 FORMULATION AND COMPUTATION OF PILE RESPONSE

A rigid pile subjected to axial loading derives its resistance from shaft and base of the pile. Figures 2a, b and c represent idealized representations (assumed to be hyperbolic) of load test results of a rigid pile, shaft (pile-soil) and base resistances respectively. The slopes of the curves 'A', 'B', and 'C' represent the stiffness modulus, k_p, of the rigid pile, k_τ of shaft and k_b base stiffness's respectively. P_u, τ_{max} and q_u are the ultimate load on pile, ultimate shaft and base resistances, respectively.

The load, P, in the pile at a displacement, δ, in the linear part of the load, and displacement curve is expressed as the sum of the resistances mobilized along the shaft and the base as

$$\begin{aligned} P &= k_p.\delta \\ &= \pi.d.L.\tau + \frac{\pi d^2}{4}.q \\ &= \pi.d.L.k_\tau.\delta + \frac{\pi d^2}{4}.k_b.\delta \end{aligned} \tag{1}$$

Where τ and q_b are the shaft and base resistances respectively.

Simplifying the stiffness, k_p, of the pile response, is expressed in terms of shaft and base stiffnesses as

$$k_p = \pi.d.L.k_\tau + \frac{\pi.d^2}{4}.k_b \tag{2}$$

Normalizing Equation (2) with respect to the pile's cross-sectional area ($\pi d^2/4$)

$$k_p{}^* = \frac{4.L}{d}k_\tau + .k_b \tag{3}$$

where $k_p{}^* = k_p/(\pi.d^2/4)$- normalized stiffness of the pile, k_τ and k_b are shaft and base stiffnesses respectively, Ultimate load capacity, P_{ult}, of the pile is the sum of ultimate shaft and base resistances as

$$P_u = P_s + P_b \tag{4}$$

$$P_u = \pi.d.L.\tau_{\max} + \frac{\pi d^2}{4}.q_u \tag{5}$$

where P_u, is ultimate pile load, P_s & P_b are the ultimate shaft and base resistances of pile respectively. Normalizing Equation (5) with $\pi d^2/4$

$$P_u{}^* = \frac{4.L}{d}\tau_{\max} + q_u \tag{6}$$

where $P^*{}_u = P_u/(\pi d^2/4)$.

The shaft resistance, τ, corresponding to a displacement, δ, can be expressed using hyperbolic relation as

$$\tau = \frac{k_\tau.\delta}{1 + \frac{k_{\tau,\delta}}{\tau_{\max}}} \tag{7}$$

Similarly, the base resistance, q_b, corresponding to a displacement, δ, can be expressed using hyperbolic relation as

$$q_b = \frac{k_b.\delta}{1 + \frac{k_{b,\delta}}{q_u}} \tag{8}$$

The load, P_1, corresponding to displacement, δ_1, is expressed in terms of the parameters defined already as

$$P_1 = \pi.d.L.\frac{k_\tau.\delta_1}{1 + \frac{k_\tau.\delta_1}{\tau_{\max}}} + \frac{\pi.d^2}{4}.\frac{k_b.\delta_1}{1 + \frac{k_b.\delta_1}{q_u}} \tag{9}$$

Normalizing Equation (9) by $\pi d^2/4$, and simplifying one gets

$$\frac{P_1{}^*}{\delta_1} = \frac{4.L}{d}\frac{k_\tau.\tau_{\max}}{\tau_{\max} + k_\tau.\delta_1} + \frac{k_b.q_u}{qu + k_b.\delta_1} \tag{10}$$

Substituting for k_b and q_u from Equations (3) and (6), Equation 8 is modified to

$$\frac{P_1{}^*}{\delta_1} = \frac{4.L}{d}\frac{k_\tau.\tau_{\max}}{\tau_{\max} + k_\tau.\delta_1} + \frac{1}{A_1}\left\{\left(k_p{}^* - \frac{4.L}{d}k_\tau\right).\left(P_u{}^* - \frac{4.L}{d}\tau_{\max}\right)\right\} \tag{11}$$

where $A_1 = \left(P_u{}^* - \frac{4.L}{d}\tau_{\max}\right) + \left(k_p{}^* - \frac{4.L}{d}k_\tau\right).\delta_1$ or

$$\frac{P_1{}^*}{\delta_1} - \frac{k_p{}^*.P_u{}^*}{A_1} = \left\{\frac{4.L}{d}\frac{.\tau_{\max}}{\tau_{\max} + k_\tau.\delta_1} - \frac{4.L}{d.A_1}.P_u{}^* + 16\left(\frac{.L}{d}\right)^2\frac{\tau_{\max}}{A_1}\right\}.k_\tau - \frac{4.L}{d.A_1}\tau_{\max}.k_p{}^* \tag{12}$$

Equation (12) in simple terms becomes

$$\mathrm{d_1} = \mathrm{C_1.k_\tau} + \mathrm{C_2}.\tau_{\max} \tag{13}$$

where $d_1 = \frac{P_1{}^*}{\delta_1} - \frac{k_p{}^*.P_u{}^*}{A_1}$, $C_1 = \frac{4.L}{d}.\left\{\frac{\tau_{\max}}{\tau_{\max}+k_\tau.\delta_1} - \frac{P_u{}^*}{A_1}.\frac{4.L}{d}\frac{\tau_{\max}}{A_1}\right\}$ &$C_2 = \frac{4.L}{d.A_1}.k_p{}^*$

Similarly $\mathrm{P_2}$ is evaluated for displacement δ_2 as

$$\frac{P_2{}^*}{\delta_2} = \frac{4.L}{d}\frac{k_\tau.\tau_{\max}}{\tau_{\max} + k_\tau.\delta_2} + \frac{k_b.q_u}{q_u + k_b.\delta_2} \tag{14}$$

$$d_2 = C_3.k_\tau + C_4.\tau_{\max} \tag{15}$$

where $d_2 = \frac{P_2{}^*}{\delta_2} - \frac{k_p{}^*.P_u{}^*}{A_2}$, $A_2 = \left(p_u{}^* - \frac{4.L}{d}\tau_{\max}\right) + \left(k_p{}^* - \frac{4.L}{d}k_\tau\right).\delta_2$,
$C_3 = \frac{4.L}{d}.\left\{\frac{\tau_{\max}}{\tau_{\max}+k_\tau.\delta_2} - \frac{P_u{}^*}{A_2}. + \frac{4.L}{d}\frac{\tau_{\max}}{A_2}\right\}$ &$C_4 = -\frac{4.L}{d.A_2}.k_p{}^*$

Equations (13) and (15) are solved to get $\mathrm{k_\tau}$ as

$$k_\tau = \frac{C_4 d_1 - C_2 d_2}{C_1 C_4 - C_2 C_3} \tag{16}$$

Since the ultimate shaft resistance, P_s, is often mobilized at relatively smaller displacement than δ_2, Equation (15) is simplified considering full mobilization of ultimate shaft resistance as

$$P_2{}^* = \frac{4.L}{d}.\tau_{\max} + \frac{k_b.q_u.\delta_2}{q_u + k_b.\delta_2} \tag{17}$$

Substituting for the values of q_u and k_b in Equation (17), τ_{max} is obtained as

$$\tau_{\max} = \frac{\left\{P_2{}^*.A_2 - \left(\frac{k_p{}^*}{k_\tau} - \frac{4L}{d}\right).P_u{}^*.k_\tau.\delta_2\right\}}{\left\{\frac{4L}{d}\left(A_2 - k_p{}^*.\delta_2 + \frac{4L}{d}.k_\tau.\delta_2\right)\right\}} \tag{18}$$

Equations (13) and (18) are solved iteratively for k_τ, k_b, τ_{max} and q_u.

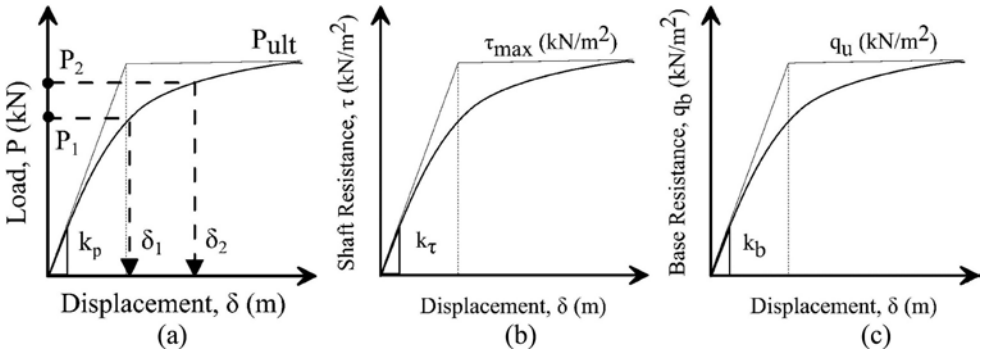

Figure 2. Modelling of (a) Typical pile load vs. Displacement; Assumed (b) Shaft vs. Displacement and (c) Base Resistance vs. Displacement curves.

3.1 *Estimation of P_U and k_P based on Chin (1971)*

The two essential factors needed to estimate the four unknown parameters (k_τ, k_b, τ_{max}, and q_u) of interest are the ultimate pile load capacity, P_u, and pile stiffness modulus, k_p. Chin's technique (Chin 1970 & 1971), which considers the relationship between load, P, and settlement, S, of a pile as hyperbolic, is used in the current analysis from among the methods available in the literature to determine ultimate capacity and initial stiffness of the pile. In Chin's (1971) approach, the ratio of S/Q is plotted versus S and a straight line fitting to the points. The initial pile – soil stiffness, k_p, and the final or ultimate pile load, P_u, are given by the inverses of the intercept, C_2, and slope, C_1, of the fitted line.

$$\frac{S}{Q} = C_1.S + C_2 \tag{19}$$

$$\mathrm{Qu} = \frac{1}{\mathrm{C_1}} \tag{20}$$

$$\mathrm{kp} = \frac{1}{\mathrm{C_2}} \tag{21}$$

where S is settlement of pile at load Q, C_1 and C_2 - slope and intercept of the straight line, respectively.

3.2 *SPT-N based methods for computing Axial Pile capacity*

The shaft and tip resistances for bored piles in sandy soils can be computed using SPT based correlations available in the literature. Many researchers (Aoki & Veloso, 1975, Decourt, 1982), Meyerhof 1976 and Reese & O'Neill, 1989) proposed empirical methods derived from back-analysis of databases of pile loading tests in correlation with N. The end bearing capacity is assumed to be proportional to a representative N_e value around the pile base:

$$\mathrm{qu} = \beta.\mathrm{Ne} \tag{22}$$

The limit skin friction stress at a given depth is proportional to the N value at this depth:

$$\tau_{max} = \eta.\mathrm{N} \tag{23}$$

β and η have the unit of stress and are respectively called tip resistance factor and skin friction factor. SPT-N based correlations from IS 2911 Part-1 were utilized in the current investigation to estimate the shaft and tip resistances for comparison.

3.3 *IS 2911 Part 4 method for the estimation of shaft and base resistances*

The analysis assumes the pile to be incompressible in the first instance and iteratively obtains approximate values of point resistance and skin friction. The method involves creating estimates of point resistance and skin friction by drawing a straight line parallel to the straight segment of curve I. (IS 2911 Part-4). The elastic compression of the pile, D, corresponding to these loads is calculated using the following formula using an estimate of skin friction and information of the loads on top of the pile:

$$D = \frac{\left(T - \frac{F}{2}\right)L}{AE} \tag{24}$$

where D = elastic compression of pile in cm, T - load on pile top in kgf, F - frictional resistance in kgf, L - length of the pile in cm, A - cross-sectional area of the pile in cm^2 and E – modulus of elasticity of the pile material in kgf/cm^2

The elastic compression of the subgrade values is then calculated by deducting the pile's elastic compression from its overall elastic recovery. These new values are then shown on a graph together with the corresponding loads on the top of the pile. If elastic compression of the subgrade results in a negative value, the value is to be ignored until it is positive. The steps are repeated to acquire new values for skin friction. Although successive approximation might go on incessantly, for the purposes of our study, the third iteration often gave accurate enough data for skin friction.

4 APPLICATION OF THE PROPOSED METHOD

The proposed method is applied to load-displacement plots of cyclic pile load test results obtained from initial load tests carried out Delhi – Gurgaon NH8 Access controlled Expressway Project. All the crossings necessitated flyovers with their foundations subjected to cyclic loads (both axial and lateral). The characteristic Yamuna Sand was reported in all the areas, followed by weathered rock, according to the site-specific soil investigation. For flyovers, the sandy substrata required the use of pile foundations. The design pile depth ranged from 12 m to 26 m at various places because of variation of the depth of the sandy layers. The diameter of each pile was 1.2 m. Piles were designed based on subsurface data as per IS 2911 for 435 T load. The formation of bored cast in situ piles involved the use of a rotating rig and M35 Grade concrete. In all the cases, test setup with 1000 T Kentledge was used.

The detailed properties of the soil strata in the test sites are reported in Table 1. The pile capacity is estimated using the procedure described in IS 2911 Part 1 Section 2 for piles installed in non-cohesive soils. The estimated shaft and end bearing resistance for the dimensions of the pile are presented in Table 2. The Initial Cyclic Pile load tests were conducted on test piles to validate the estimated safe axial capacities. The load-displacement data available is used to estimate initial stiffness modulus, k_p, and the ultimate load P_u, on pile. The data is analyzed based on the proposed method to estimate normalized shaft and base stiffness, k_τ and k_b, and corresponding ultimate shaft, τ_{max}, and base resistances, q_u, respectively. Equations (1) to (18) are used to perform the regression analysis. The detailed explanations for each test pile are given briefly.

Table 1. Geotechnical characteristics of the cyclic pile load test sites.

Sl. No	Site Location	Depth (m)	Stratum description	N	φ
1.	Rajokri Junction	0-12	Top layer of 0.5 m to 1.35 m of filled up material, followed by soft to hard yellowish brown/ brown/reddish brown sandy silt of low plasticity.	19	26
		12-20	Hard yellowish brown/brown/reddish brown sandy silt.	26	36
2.	IFFCO junction	0-4.5	Top 1 m of filled material followed by sandy silt with gravels extending up to 30.3 m.	12	28
		4.5-20	Sandy silt with gravels	30	37
3.	Rajiv junction	0-12	Homogeneous strata, with non-plastic sandy silt with gravels. The bulk density was assessed as 1.69 g/cc.	10	28
		12-20	Non-plastic sandy silt with traces of gravel. Bulk density of about 1.75 g/cc.	50	41
4.	Shankar junction	0-12	Non-plastic sandy silt with traces of gravel. Bulk density is 1.89 g/cc.	17-43	33
		12-20	Non-plastic sandy silt with traces of gravel. Bulk density of about 2.1 g/cc.	48	40

4.1 *Test Location – 1*

Figure 3 Shows the load - displacement plot for the initial cyclic pile load test (CPLT-1). The length and diameter of the pile installed are 20.25 m and 1.2 m respectively. The shaft and end bearing resistance for the pile are estimated to be 43.6 kPa and 5.7 MPa, respectively based on the empirical equations from IS 2911 Part 1 Section 2 for piles installed in non-cohesive soils. The shaft and base resistances using IS 2911-Part 4 are 65.49 kPa and 1.32 MPa respectively. The ultimate pile capacity, P_{ult}, from Chin's method is 6865 kN and the initial stiffness, k_p, 2500 MN/m (the intercept C_2 = 4e-7). According to the proposed approach, the predicted values k_τ, k_b, τ_{max}, and q_b, for the shaft and base resistances, are 16.4 MN/m3, 1099.1 MN/m3, 40.88 kPa, and 3.31 MPa, respectively. The load-settlement curve predicted using the estimated parameters corresponds very well with the actual load - settlement one.

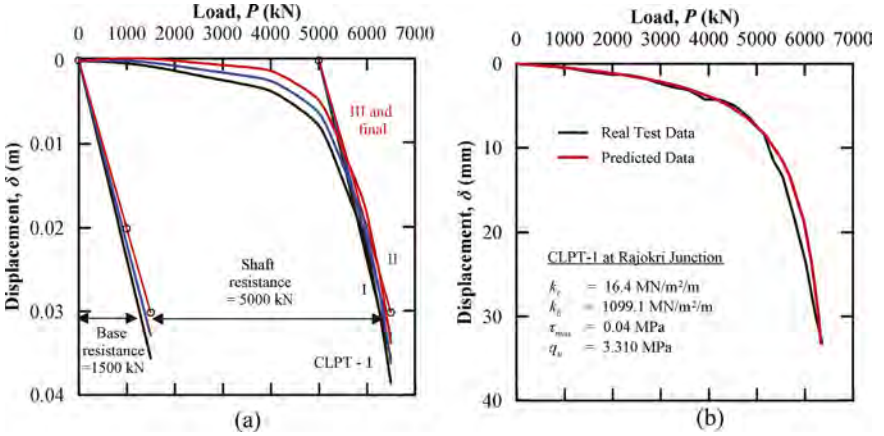

Figure 3. (a) Shaft and base resistances based on IS-2911 for CLPT-1 (b) Comparison of measured and predicted load-displacement curves for CPLT-1.

4.2 *Test Location – 2*

Figure 4 presents similar analysis, results and comparison of measured and predicted load-settlement curve for initial pile load test (CPLT-2). The length and diameter of the pile installed are 20.25m and 1.2m respectively. The ultimate load and initial stiffness modulus, k_p,
