This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' and device or material manufacturers' printed instructions, and their websites, before administering or utilizing any of the drugs, devices or materials mentioned in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Contents

Contributors

Preface

I OBSTETRIC DISORDERS

1 The diagnosis and management of preterm labor with intact membranes

Roberto Romero, Tinnakorn Chaiworapongsa, Francesca Gotsch, Lami Yeo, Ichchha Madan, and Sonia S. Hassan

2 Prelabor rupture of the membranes

Roberto Romero, Lami Yeo, Francesca Gotsch, Eleazar Soto, Sonia S. Hassan, Juan Pedro Kusanovic, and Ray Bahado-Singh

3 Cervical insufficiency

Sonia S. Hassan, Roberto Romero, Francesca Gotsch, Lorraine Nikita, and Tinnakorn Chaiworapongsa

4 Recurrent pregnancy loss

Christine E. Ryan and Danny J. Schust

5 Multiple gestation

Isaac Blickstein

6 Gestational hypertension and pre-eclampsia

Erol Amon and Erin Dickert

7 Coagulopathy in obstetrics*

Hung N. Winn and Roberto Romero

8 Amniotic fluid embolism*

Hung N. Winn

9 Placenta previa and placental abruption

Ann K. Lal and William J. Watson

10 Postpartum hemorrhage

Wade D. Schwendemann and William J. Watson

11 Septic shock

Bryan E. Freeman and Michael R. Foley

12 Invasive hemodynamic monitoring in obstetrics

Luis D. Pacheco, Shannon Clark, and Gary D. V. Hankins

13 Shoulder dystocia

Randall C. Floyd and James S. Smeltzer

14 Breech presentation

Randall C. Floyd and Martin L. Gimovsky

15 Cesarean section and vaginal birth after cesarean section

Jessica Winn and Hung N. Winn

II MATERNAL MEDICAL DISORDERS

16 Diabetes in pregnancy

Donald R. Coustan

17 Chronic hypertension and acute hypertensive crisis

William F. Rayburn and Lauren Plante

18 Rheumatologic diseases and antiphospholipid syndrome

Thomas J. Santoro, Michiyo Tomita, and Alfonse T. Masi

19 Sickle cell disease

Marc R. Parrish and John C. Morrison

20 Cardiac diseases in pregnancy

Saravanan Kuppuswamy and Sudarshan Balla

21 Dermatologic diseases and pregnancy

Holly Edmonds, Dana Ward, Ann G. Martin, and Susana Leal-Khoury

22 Endocrine diseases and pregnancy

Stephen A. Brietzke

23 Gastrointestinal diseases and pregnancy

Murtaza Arif, Anjana Sathyamurthy, Jessica Winn, and Jamal A. Ibdah

24 Hepatic disorders in pregnancy

Ghassan M. Hammoud and Jamal A. Ibdah

25 Neurologic disorders in pregnancy

Robert Burger, Terry Rolan, David Lardizabal, Upinder Dhand, Aarti Sarwal, and Pradeep Sahota

26 Sleep disorders and pregnancy

Pradeep Sahota and Sanjay Jain

27 Pulmonary diseases in pregnancy

Leah Lande, Abraham Sanders, and Dana Zappetti

28 Psychiatric disorders in pregnancy

Robin Kopelman and Scott Stuart

29 Renal diseases in pregnancy

Dana Negoï and Khaled Mohamed

III MATERNAL SURGICAL, MALIGNANCY, AND OTHER ISSUES

30 Acute abdomen in pregnancy

Nicole Fearing and William L. Holcomb

31 Trauma in pregnancy*

Hung N. Winn

32 Medical evaluation and management of pregnant patients undergoing non-obstetrical surgery

John G. Gianopoulos

33 Anesthesia and analgesia in pregnancy

Steven T. Fogel

*This chapter is not available.

- 34 Breast cancer and pregnancy**
Beth Kliethermes, Dani Stramer, and Edward R. Sauter
- 35 Neoplasia in pregnancy**
Nora T. Kizer and David G. Mutch
- 36 Chemotherapy in pregnancy**
Mark I. Hunter
- 37 Maternal obesity**
D. Yvette LaCoursiere and Thomas R. Moore
- 38 Medicolegal considerations**
Erol Amon and Gilad Gross
- 39 Drug abuse in pregnancy: Marijuana, LSD, cocaine, amphetamines, alcohol, and opiates**
Jacquelyn C. Howitt and Anita Bublik-Anderson
- 40 Tobacco and alcohol use during pregnancy**
Beth A. Bailey and Robert J. Sokol
- 41 Exercise and pregnancy**
Raul Artal
- 42 Ethical considerations**
Frank A. Chervenak and Laurence B. McCullough
- IV GENETICS AND FETAL DISORDERS**
- 43 Basic genetics and patterns of inheritance**
Dorothy K. Grange
- 44 Principles of teratology of drugs and radiation**
Frank R. Witter
- 45 Fetal programming**
Katherine E. Pelch, Jana L. Allison, and Susan C. Nagel
- 46 Assessment of fetal genetic disorders**
Teresa Martino, J. Pratt Rossiter, and Karin J. Blakemore
- 47 Preimplantation diagnosis of genetic diseases***
The-Hung Bui
- 48 First-trimester screening for aneuploidy**
Mark I. Evans and Howard S. Cuckle
- 49 Second-trimester screening for fetal abnormalities**
Jolene C. Muscat and Anthony M. Vintzileos
- 50 Genetic counseling**
Zoltán Papp, Valéria Váradi, and Júlia Hajdú
- 51 Fetal anomalies***
Hung N. Winn
- 52 Assessment of fetal brain abnormalities**
Ritsuko K. Pooh
- 53 Erythroblastosis fetalis**
Avinash Patil, Brian Brocato, Rebecca A. Uhlmann, and Giancarlo Mari
- 54 Fetal alloimmune thrombocytopenia**
Hung N. Winn
- 55 Nonimmune hydrops***
Hung N. Winn
- 56 Fetal arrhythmias**
Júlia Hajdú, Valéria Váradi, and Zoltán Papp
- 57 Fetal growth restriction**
Daniel L. Jackson, M. Y. Divon, and Hung N. Winn
- 58 Fetal demise***
Hung N. Winn
- V FETAL ASSESSMENT**
- 59 Application of 3D and 4D ultrasound in fetal medicine**
Eberhard Merz
- 60 Prenatal diagnosis of fetal abnormality using fetal cells in maternal circulation**
Gian Carlo Di Renzo, Elena Picchiassi, Michela Centra, and Giuliana Coata
- 61 Recent developments in fetal therapy**
Gihad E. Chalouhi and Yves Ville
- 62 Chorionic villus sampling**
Giovanni Monni, Maria Angelica Zoppi, and Carolina Axiana
- 63 Amniocentesis**
Aris Antsaklis and Marianna Theodora
- 64 Fetal echocardiography**
Caroline K. Lee, Erik C. Michelfelder, and Gautam K. Singh
- 65 Assessment of fetal behavior**
Asim Kurjak, Milan Stanojevic, Badreldeen Ahmed, Guillermo Azumendi, and Lara Spalldi-Barisic
- 66 Umbilical artery doppler sonography for fetal surveillance: Principles and practice**
Dev Maulik, David Mundy, and Timothy Bennett
- 67 Assessment of fetal well-being: Fetal heart rate monitoring and the fetal biophysical profile**
Yinka Oyelese, Martin Chavez, and Anthony M. Vintzileos
- 68 Intrapartum fetal heart rate monitoring***
Hung N. Winn
- 69 Amnioinfusion**
James Kerns, Erol Amon, and Hung N. Winn
- 70 Assessment of fetal age and fetal lung maturity***
Hung N. Winn
- 71 The maternal immune system during pregnancy**
Breton F. Barrier
- 72 Placental transport and metabolism**
Jeffrey M. Dicke

*This chapter is not available.

- 73 Fertilization and normal embryonic and early fetal development**
Asim Kurjak, Ritsuko K. Pooh, Aida Salihagic-Kadic, Iva Lausin, and Lara Spalldi-Barisic
- VI PERINATAL INFECTION AND NEONATAL DISEASE**
- 74 Group B streptococcus infection**
Jessica Winn and Hung N. Winn
- 75 Gonorrhea infection***
Hung N. Winn
- 76 Postpartum infections**
Dorothea Mostello
- 77 Urinary tract infections in pregnancy**
Steven R. Allen
- 78 Other bacterial infection: Lyme, granuloma inguinale, gardnerella vaginale, chancroid***
Hung N. Winn
- 79 Bacterial vaginosis in pregnancy: Evidence-based approaches**
James A. McGregor and Michael W. McCullough
- 80 Viral hepatitis in pregnancy**
Dennis Ng
- 81 Toxoplasmosis**
Edward R. Newton
- 82 Herpes***
Edward R. Newton
- 83 Cytomegalovirus (CMV)***
Hung N. Winn
- 84 Human immunodeficiency virus (HIV)**
Richard Basilan and William Salzer
- 85 Other viral infections**
Stanley A. Gall
- 86 Chlamydial infection**
Joyce A. Ibana and Danny J. Schust
- 87 Candida and parasitic infection: Helminths, trichomoniasis, lice, scabies, and malaria**
Jeanna M. Piper
- 88 Routine maternal immunizations for all pregnant women**
Stanley A. Gall
- 89 Neonatal diseases I**
John Pardalos
- 90 Neonatal diseases II**
Brian P. Hackett, Jeffrey Dawson, Akshaya Vachharajani, Barbara Warner, and F. Sessions Cole

*This chapter is not available.

Contributors

Badreldeen Ahmed

Feto-Maternal Unit, Department of Obstetrics and Gynecology, Hamad Medical Corporation, Doha, Qatar

Steven R. Allen

Section of Maternal-Fetal Medicine, Texas A&M Health Science Center, College of Medicine, Temple, Texas, USA

Jana L. Allison

Department of Obstetrics, Gynecology and Women's Health, University of Missouri School of Medicine, Columbia, Missouri, USA

Erol Amon

Department of Obstetrics, Gynecology and Women's Health, Maternal-Fetal Medicine, St. Louis University School of Medicine, St. Louis, Missouri, USA

Aris Antsaklis

Department of Obstetrics and Gynecology, University of Athens Medical School, Athens, Greece

Murtaza Arif

Division of Gastroenterology and Hepatology, University of Missouri School of Medicine, Columbia, Missouri, USA

Raul Artal

Department of Obstetrics, Gynecology and Women's Health, St. Louis School of Medicine, St. Louis, Missouri, USA

Carolina Axiana

Department of Obstetrics and Gynecology, Prenatal and Pre-implantation Genetic Diagnosis, Microcitamico Hospital, University of Cagliari, Cagliari, Italy

Guillermo Azumendi

Ultrasound Unit, Clinica Gutenberg, Malaga, Spain

Ray Bahado-Singh

Department of Obstetrics and Gynecology, Wayne State University, Detroit, Michigan, USA

Beth A. Bailey

Department of Family Medicine, James H. Quillen College of Medicine, East Tennessee State University, Johnson City, Tennessee, USA

Sudarshan Balla

Department of Internal Medicine, University of Missouri School of Medicine, Columbia, Missouri, USA

Breton F. Barrier

Department of Obstetrics, Gynecology and Women's Health, University of Missouri School of Medicine, Columbia, Missouri, USA

Richard Basilan

Department of Internal Medicine, University of Missouri School of Medicine, Columbia, Missouri, USA

Timothy Bennett

Department of Obstetrics and Gynecology, University of Missouri-Kansas City School of Medicine, Kansas City, Missouri, USA

Karin J. Blakemore

Department of Obstetrics and Gynecology, Johns Hopkins University Hospital, Baltimore, Maryland, USA

Isaac Blickstein

Department of Obstetrics and Gynecology, Kaplan Medical Center, Rehovot and the Hadassah-Hebrew University School of Medicine, Jerusalem, Israel

Stephen A. Brietzke

Department of Internal Medicine, University of Missouri School of Medicine, Columbia, Missouri, USA

Brian Brocato

Department of Obstetrics and Gynecology, University of Tennessee Health Science Center, Memphis, Tennessee, USA

Anita Bublik-Anderson

Private Practice, Obstetrics and Gynecology, Wausau, Wisconsin, USA

Robert Burger

Department of Neurology, University of Missouri School of Medicine, Columbia, Missouri, USA

Michela Centra

Department of Obstetrics and Gynecology, University of Perugia, Perugia, Italy

Tinnakorn Chaiworapongsa

Perinatology Research Branch, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, and Department of Obstetrics and Gynecology, Wayne State University, Detroit, Michigan, USA

Gihad E. Chalouhi

Department of Obstetrics and Fetal Medicine, Necker-Enfants-Malades Medical School, Paris Descartes University, Paris, France

Martin Chavez

Division of Maternal Fetal Medicine, Winthrop University Hospital, Mineola, New York, USA

Frank A. Chervenak

Department of Obstetrics and Gynecology, New York Weill Cornell Medical Center, New York, New York, USA

Shannon Clark

Department of Obstetrics and Gynecology, University of Texas Medical Branch, Galveston, Texas, USA

Preface

The discipline of Maternal-Fetal Medicine has made great progress since the first edition of this textbook (*Clinical Maternal-Fetal Medicine*) published nearly a decade ago. Basic, clinical, and translation research has allowed clinicians and scientists to improve the understanding of the mechanisms of disease, and improve the care of the mother and fetus.

We are of the view that Maternal-Fetal Medicine is one of the most challenging disciplines in medicine, because we care for two patients; one of whom, the fetus, is often inaccessible, difficult to examine, and optimal medical care requires balancing the interests of mother and fetus. Yet, the importance of our discipline has become increasingly clear, as the concept that the “child is the father of the man” has gained ground through growing evidence that insults sustained during intra-uterine life have a long-lasting effect and increase the risk for adult diseases (cardiovascular, metabolic, mental health, reproductive, etc.).

This book addresses the pathophysiology, diagnosis, and treatment of many important maternal medical and obstetric

complications, as well as fetal complications. It is intended to provide a review of clinically relevant topics in Maternal-Fetal Medicine. In contrast to the first edition, this book is available online rather than as a traditional print book. This approach was embraced to make its use easier for the readers. You will be able to search the book across chapters and provide feedback. In addition, updates could be more frequently done as the information develops.

This book could serve as a convenient reference for clinicians, fellows, residents and students who have the privilege of caring for the mother and fetus. We hope that the constant search for new understandings of the biology of pregnancy would allow us to improve the diagnosis and treatment of complications of pregnancy, and the health of future generations.

1 The diagnosis and management of preterm labor with intact membranes

Roberto Romero, Tinnakorn Chaiworapongsa, Francesca Gotsch, Lami Yeo, Ichchha Madan, and Sonia S. Hassan

INTRODUCTION

A preterm birth is one that occurs between fetal viability and 37 completed weeks of gestation (1–4). Delivery of a previable conceptus represents a spontaneous abortion rather than a preterm birth. Although the definition of “viability” varies among countries and even medical centers, the central idea is that a nonviable infant is so immature that there is no likelihood of survival in the extrauterine environment despite all medical support.

Prior to modern developments in neonatal care, a nonviable infant was defined as one weighing less than 500 g (see below). This definition is discouraged because preterm delivery should be defined by gestational age at birth, rather than birth weight. Although some have proposed to define a preterm birth as one that occurs between 20 and 37 weeks of gestation, we prefer to define preterm birth as one occurring between 24 and 37 weeks of gestation. Some neonates can survive if born around 24 weeks of gestation, but none at 20 weeks (5–8). This definition may need to be revised in the future if technological advances allow substantial survival of neonates born at less than 24 weeks of gestation.

A birthweight of 500 g has historically been used to define viability. However, this approach has limitations since viable neonates born after 24 weeks of gestation may be affected by intrauterine growth restriction (IUGR) and have birthweights below 500 g. Conversely, some previable infants may weigh more than 500 g. The threshold of 500 g is valuable when there is uncertainty about gestational age. An accurate definition of preterm birth has implications for the calculation of vital statistics and comparisons of the rates of preterm delivery among different countries and populations, an issue that is often overlooked (1).

Spontaneous Vs. Indicated Preterm Birth

Preterm births can be spontaneous or “indicated.” Spontaneous preterm labor can occur with either intact or prelabor rupture of the (fetal) membranes (PROM). “Indicated” preterm births are those that result from induced preterm labor or preterm cesarean delivery for maternal or fetal indications, such as pre-eclampsia and/or IUGR (3,9–13). Other causes include severe medical or surgical complications of pregnancy, some congenital anomalies, and complications of twin gestations (in particular, complications of monochorionic twins).

Of all preterm deliveries, spontaneous preterm labor with intact membranes occurs in 45% (23.2–64.1%), spontaneous

preterm labor following PROM occurs in 30% (7.1–51.2%), and preterm birth as a result of an indicated delivery occurs in 25% (18.7–35.2%) (14,15). In the United States, the rate of preterm delivery has increased by 14% since 1990—this has been attributed to “indicated” preterm births of singleton gestations, multiple gestations, and increased numbers of older parturients (16). Preterm births have been classified by gestational age. Table 1 presents the classification of preterm birth according to gestational age at birth and the contribution of each stratum (3).

THE COMMON PATHWAY OF TERM AND PRETERM LABOR

The traditional view that has dominated the study of preterm parturition is that spontaneous labor at term and preterm labor fundamentally involves the same processes, albeit occurring at different gestational ages. Indeed, term and preterm labor share a common pathway. We have defined the “common pathway of parturition” as the anatomic, biochemical, endocrinologic, and clinical events that occur in the fetus and/or mother in both term and preterm labor (17–22). Broadly conceptualized, the common pathway of parturition can be considered to have uterine (maternal and fetal) and extrauterine components. The uterine components (which are a subject of wide attention in clinical obstetrics) include increased uterine contractility, cervical ripening, and decidual/membrane activation (17,18). The extrauterine components include endocrinologic and metabolic changes associated with labor. For example, labor is associated with increased caloric metabolic expenditures (21), and an increase in maternal and fetal cortisol (20).

A fundamental difference between term and preterm labor is that the former results from “physiologic activation” of the common pathway, while the latter results from a pathologic process (pathologic activation) that extemporaneously activates one or more components of the common pathway (22).

Activation of the uterine components of the common pathway of parturition may be synchronous or asynchronous. Synchronous activation will result in clinical spontaneous preterm labor, and asynchronous activation will result in a different phenotype. For example, predominant activation of the membranes would lead to preterm PROM, of the cervix to cervical insufficiency, or of myometrium to preterm uterine contractions (Figs. 1 and 2). The activation of each component

This work is based on several review articles and chapters published previously by the first author in other publications. This work has been modified and adapted for this textbook. The original chapters are referenced and contain a more extensive discussion of the subject. This chapter has a clinical emphasis. The work has been primarily done by Roberto Romero, who is a government employee, and therefore, is not subject to copyright.

Table 1 Classification of Preterm Birth According to Gestational Age at Birth and the Contribution of Each Stratum

Proposed classification	Gestational age at birth (in weeks)	Frequency
Extreme preterm birth	<28	5%
Very early preterm birth	28 to 30-6/7	15%
Early preterm birth	31 to 33-6/7	20%
Late preterm birth	34 to 36-6/7	60–70%

Figure 1 Uterine components of the common pathway of parturition. Source: From Ref. 22.

confers a different risk for impending preterm delivery. For example, rupture of membranes is followed by the onset of labor in most cases within a short period of time. In contrast, most patients who present with increased uterine contractility without cervical change at an early gestational age deliver at term. Acute cervical insufficiency (formerly called “cervical incompetence”) may lead to late spontaneous abortion or early preterm delivery days or weeks after the diagnosis (23,24).

SPONTANEOUS PRETERM LABOR AS A SYNDROME

Preterm labor with intact membranes is a “syndrome” caused by multiple etiologies. The term “syndrome” refers to a combination of symptoms or signs identified as a discrete clinical entity (25). Symptoms and signs of preterm labor include increased uterine contractility, changes in cervical status (dilatation and effacement), and/or changes in membrane status (i.e., activation, which can be expressed subclinically as a positive fetal fibronectin, or overtly, such as rupture of membranes).

The proposed etiologies of the preterm labor syndrome are presented in Figure 3. The main causes are (i) intra-amniotic infection/inflammation (26–57); (ii) vascular disease mediated through ischemia (58–64); (iii) uterine overdistension [twin gestations (65), patients with polyhydramnios (66,67), and Müllerian duct abnormalities (68)]; (iv) stress (69–73); (v) cervical disease [congenital after diethylstilbestrol exposure (74–79), post-traumatic after conization (80–88), etc. (89)]; (vi) hormonal disorders that mediate a suspension of progesterone actions (90–98); (vii) allergic disease (99–107); and (viii) an abnormal allogeneic response in which there is a rejection-like mechanism by the maternal immune system of the conceptus (108–112).

We also believe that the entire spectrum of the mechanisms of the preterm labor syndrome has not been fully elucidated. In addition, some patients have preterm labor because more than

Figure 2 Clinical manifestations of preterm activation of the common pathway of parturition. Source: From Ref. 22.

Figure 3 The preterm parturition syndrome. Source: From Ref. 25.

one mechanism of disease operates simultaneously. For example, subclinical intra-amniotic infection leads to preterm labor through an inflammatory mechanism that involves chemokines, cytokines, and prostaglandins; yet, one of the effects of IL1 β (a cytokine involved in preterm parturition) can decrease progesterone action through activation of NF κ B (113–115). This transcription factor may lead to preterm cervical ripening and also to the activation of membrane and decidua. The interested reader is referred to recent reviews of the mechanisms responsible for the preterm labor syndrome (3,116).

There is an extensive body of epidemiologic literature identifying risk factors for preterm labor and delivery—for example, individuals of African-American origin (12,117–119), those with a low body mass index (120–124), or patients who smoke during pregnancy (125–127) are at increased risk (Table 2 lists commonly identified risk factors). Yet, the precise pathologic mechanism responsible for the increased risk has not been elucidated.

THE DIAGNOSIS OF PRETERM LABOR

The Importance of Diagnosis

The clinical diagnosis of preterm labor is important because patients at risk for preterm delivery can be offered (i) admission to the hospital, (ii) assessment for intra-amniotic infection, (iii) steroids, (iv) tocolysis, (v) antibiotic prophylaxis against group B streptococci, (vi) transport to a tertiary care center, and (vii) the option of magnesium sulfate for neuroprotection.

Criteria to Increase the Index of Suspicion

Preterm labor is suspected in patients with preterm gestations (before 36-6/7 weeks of gestation) who present with symptoms of increased uterine contractility, vaginal bleeding, pelvic

Table 2 Risk Factors Associated with Preterm Delivery**Sociobiological variables**

Age <17 years, >35 years
 Low BMI or pre-pregnancy weight <50kg (<120lbs)
 Poor nutritional status
 Single marital status
 Lower socioeconomic status
 Lower education
 Smoking
 Heavy alcohol consumption
 Illicit drug use (cocaine, heroin, etc.)
 Social factors (e.g., poor access to care, physical abuse)
 Working conditions—shift work, standing for long periods of time (>8 hours)

Past obstetric/gynecologic history

Prior preterm birth
 Multiple therapeutic and/or spontaneous abortions
 Uterine anomalies

Cervical surgery (cone biopsy, LEEP)

Characteristics of current pregnancy

Short inter-pregnancy interval (<6 months)
 In vitro fertilization/assisted reproductive techniques
 Multiple gestation
 Fetal conditions (e.g., structural malformations, chromosomal abnormalities, IUGR, fetal demise)
 Antepartum hemorrhage
 Amniotic fluid abnormalities—polyhydramnios, oligohydramnios
 Maternal medical conditions (e.g., hypertension, diabetes, asthma, thyroid disease)
 Maternal abdominal surgery
 Psychological factors (e.g., stress, depression)
 Infections during pregnancy (e.g., chlamydia, gonorrhea, trichomonas, bacterial vaginosis, asymptomatic bacteriuria, urinary tract infection, pyelonephritis, severe viral infections)
 Short cervical length
 Positive fetal fibronectin between 22 and 34 weeks
 Preterm contractions

Abbreviations: LEEP, loop electrosurgical excision procedure; IUGR, intrauterine growth retardation.

pressure and/or pain, expulsion of the mucus plug, and leakage of amniotic fluid. The latter is particularly important because if rupture of membranes is present, the management and prognosis are different from those of patients with preterm labor and intact membranes (15,128). For example, tocolysis is not indicated in patients with preterm prelabor rupture of membranes (129) (see the chapter on preterm PROM in this book).

“Threatened Preterm Labor,” “False Preterm Labor,” and “Rule out preterm labor”

Some authors and textbooks have employed these terms because approximately 15% of pregnant women present with symptoms and signs consistent with preterm labor, yet they do not deliver preterm (130). Results of randomized clinical trials of beta-adrenergic agents have shown that 47% to 50% of patients admitted with symptoms of preterm labor randomized to placebo treatment deliver at term (131). Some investigators have interpreted such findings as indicating that these patients were in “false preterm labor” or “threatened preterm labor” because they delivered at term when treated with placebo (intravenous hydration). However, there is an

implicit problem in requiring that a patient delivers preterm for the diagnosis of preterm labor to be correct: such view would imply that preterm labor inevitably leads to preterm delivery. In the pre-antibiotic era, pyelonephritis was associated with preterm labor and delivery. After the introduction of antibiotics (132), pyelonephritis has been associated with preterm labor but not necessarily preterm birth (133,134). This indicates that labor has a reversible phase in which early treatment may prevent preterm delivery (135).

The pathologic process responsible for preterm labor can have a spectrum of severity. Mild insults that can be managed by the homeostatic system do not lead to preterm delivery, but more severe insults would be required for progression to preterm delivery. A pregnant woman who sustains mild abdominal trauma (such as an automobile accident or a fall) may experience increased uterine contractility which eventually subsides. However, if the trauma leads to preterm separation of the placenta (abruptio placentae), preterm labor/delivery may occur.

True or False Labor: a Diagnostic Challenge

The diagnostic dilemma described in the previous paragraph is not exclusive to preterm labor, but it also applies to labor at term. Labor is a retrospective diagnosis that can be made with certainty only when the patient has delivered or when delivery is inevitable (e.g., a patient with preterm labor and advanced cervical dilation who has spontaneous rupture of membranes or, alternatively, a patient with preterm labor who is in the second stage of labor). Except for these rare circumstances, physicians will often encounter a patient who has some degree of activation of the three components of the terminal pathway of parturition (increased uterine contractility, cervical changes, and/or membrane decidual activation) and will need to decide whether or not to initiate therapeutic intervention.

The diagnosis of labor at term is also challenging. Nonetheless, the risk of an inaccurate diagnosis is lower because a fetus at term does not require steroids and other interventions which may be beneficial to the preterm neonate. Thus, the diagnosis of “false labor” at term carries different consequences from a misdiagnosis of preterm labor. Patients diagnosed with “false labor” at term typically present as if they were in the latent phase of labor and stop contracting after the administration of sedation, analgesia, or during a period of observation. Yet this diagnosis of “false labor” is not always correct; many labor wards have at least one story of a patient sent home who has delivered a few hours later outside the hospital or on her way back to the hospital. Since the neonates are born at term, such diagnostic errors generally do not have serious consequences; however, the possibility of shoulder dystocia, other obstetrical complications, or neonatal emergencies can transform this situation into a tragedy.

Does “False Preterm Labor” have Any Consequences?

Clinicians believe that an episode of preterm labor that resolves itself is benign. Yet these patients remain at risk for recurrent episodes of preterm labor and, more importantly, preterm delivery (136–138). An explanation for this is that a subclinical pathologic process may underline an episode of preterm labor. If the pathologic process worsens, this eventually may lead to preterm labor and delivery.

Synchronous and Asynchronous Activation of the Common Pathway

Activation of the common pathway of labor can occur with recruitment of the three components (i.e., synchronous) or with activation of mainly one component (i.e., asynchronous) (Figs. 1 and 2). The phenotypic definitions of the preterm labor syndrome depend on the specific pathway activated.

Most physicians and patients focus on increased uterine contractility as a sign of preterm labor—such symptoms are easily detected by patients and verifiable by the health-care provider. In contrast, cervical ripening (effacement and dilatation) is largely subclinical, and its diagnosis requires a pelvic examination or transvaginal sonography. Some patients may present with a short cervix (and even visible membranes) in the absence of demonstrable contractions—this phenotype is consistent with cervical insufficiency, typically occurring in the midtrimester.

Similarly, mild activation of the decidual/membrane component of the common pathway of labor is largely subclinical and can be detected by an elevation in the concentration of molecules involved in extracellular matrix degradation, such as fetal fibronectin (139–143), IL-6 (144–148), and matrix metalloproteinases (MMPs) (149–151) in the cervicovaginal fluid. Most asymptomatic patients with a positive fetal fibronectin after 22 weeks of gestation do not deliver preterm (even though the relative risk for preterm delivery is increased) (143,152,153). This indicates that decidual/membrane activation of this common pathway can occur without leading to inevitable preterm labor and delivery.

The Clinical Diagnosis of Preterm Labor

With the introduction and widespread utilization of tocolytic agents, several definitions of preterm labor were proposed. Notably, in 1975, Ingemar Ingemarsson (154) proposed that the criteria for the diagnosis should include (i) painful regular uterine contractions occurring at intervals of less than 10 minutes for at least 30 minutes by external tocography, (ii) a cervix that is effaced or almost effaced and dilated at least 1 to 2 cm, (iii) intact membranes, and (iv) a gestational age between 28 and 36 weeks. This definition was the basis for a randomized, double-blinded clinical trial of terbutaline in women with preterm labor and intact membranes (154). The gestational age limitation reflected neonatal survival at the time. Importantly, two components of the common pathway were required for the diagnosis (increased myometrial contractility and cervical change). Gonik and Creasy wrote a clinical opinion in 1986 (155), in which they proposed a definition of preterm labor that has been used subsequently in the literature. The definition is based on uterine contractility and cervical change, and was proposed to select patients for tocolytic treatment. A change in cervical status was required because of the concern about overtreating patients with painful Braxton-Hicks contractions without other evidence of preterm labor (156–158).

Uterine Contractility

Increased uterine contractility can be present in the absence of cervical change. Two types of uterine contractions have been identified using electromyography (159): (i) “contractures,” which are epochs of myometrial activity leading to a modest increase in intrauterine pressure and are of long duration, and

(ii) “contractions,” which are of short duration but increase intrauterine pressure. A switch from a predominant “contracture pattern” to a predominant “contraction pattern” can occur during normal labor or be induced by pathologic events such as intra-abdominal surgery, infection, or food withdrawal. The molecular basis of this switch is thought to be the development of gap junctions, which increase the transmission of cell-to-cell communication in the myometrium during labor. Efforts to differentiate contractures from contractions using clinically available external tocodynamometry have failed to distinguish between the patient at risk for preterm delivery and the one who is not at risk (160). Therefore, uterine contractility alone is not sufficient to reliably diagnose preterm labor. Recent modalities that use external electromyography may improve such a diagnosis, but these techniques are not yet clinically available (161–165).

Sonographic Cervical Length

The most important advance in the diagnosis of preterm labor has been the introduction of transvaginal sonography (79,166–168). Many investigators have shown that transvaginal sonography is more accurate than digital examination of the cervix (to assess dilatation and effacement) in predicting the risk of preterm birth (168,169). The data consistently indicate that women with a long cervix (defined as >30 mm) have a likelihood of preterm delivery of less than 5% (169,170). In contrast, women with preterm uterine contractions and with a cervical length of <15 mm have a probability of preterm delivery of 63% (171). Figure 4 illustrates the probability of preterm delivery in patients presenting with an episode of preterm labor—the shorter the cervix, the greater the risk of preterm delivery (168,172–174). Moreover, the shorter the cervix and the earlier the gestational age at presentation, the greater the risk of intra-amniotic infection (175).

Fetal Fibronectin

Another test frequently used to assess the risk of preterm delivery is fetal fibronectin. This glycoprotein is present in the

Figure 4 Predicted probability of delivery before 32 weeks of gestation, by cervical length (mm) and time of measurement (week of pregnancy), in women with a prior preterm birth. Source: From Ref. 504.

trophoblast–decidua interface and, like all fibronectins, acts as cellular “cement” to anchor trophoblast cells to the uterine wall (decidua). Decidual/membrane activation is a process whereby extracellular matrix is dissolved at this interface. Such a process is teleologically intended to weaken the membranes for membrane rupture during labor and also to prepare the membranes for separation from the uterine cavity after delivery. This intercellular “cement” has a unique glycosylation pattern, which is different from other fibronectins, and that is why it is called “fetal” fibronectin. Fortuitously, fetal fibronectin can be detected in vaginal and cervical fluids (142). It is interesting that fetal fibronectin can be detected between 16 and 20 weeks of gestation in normal pregnancy (176). However, normally it becomes undetectable (using a cut-off of 50ng/mL) after 22 weeks of gestation and becomes detectable again at term prior to the onset of labor (142,177).

After 22 weeks of gestation, a positive fetal fibronectin in cervicovaginal fluid is associated with an increased risk for preterm delivery in symptomatic and asymptomatic patients (142,178–182). However, the proportion of patients with a positive fetal fibronectin who will deliver preterm is small (low positive predictive value) in both symptomatic and asymptomatic patients (143,152,153). In contrast, this test is considered more valuable in identifying patients at low risk for preterm delivery (high negative predictive value) (183–185). The value of this test relates to its ability to identify the patient unlikely to deliver, therefore avoiding unnecessary intervention. The results of fetal fibronectin may be affected by a history of sexual intercourse within 24 hours (186), a pelvic examination during the same period of time, or vaginal bleeding. Each of these conditions may lead to what has been called a “false-positive” test (187). In contrast, the use of lubricant may lead to

a false-negative result. Amniotic fluid contains fetal fibronectin in high concentrations (187). Therefore, a positive test can occur if there is membrane rupture or if the sample is contaminated with amniotic fluid (187).

Combined Use of Cervical Sonography and Fetal Fibronectin in the Diagnosis of Preterm Labor

Several studies have examined the value of combining these tests to predict preterm delivery. A study by Gomez et al. (171) indicated that (i) cervical length in labor is a strong predictor of preterm delivery; (ii) a short cervix (defined as a cervical length of <15mm) identifies patients at high risk of impending preterm delivery (within 48 hours or 7 days of admission); (iii) a long cervix (defined as cervical length of 30mm or more) identifies patients at low risk of preterm delivery; (iv) a positive fetal fibronectin is also associated with spontaneous preterm delivery, but the likelihood ratio of a positive test is substantially lower for fetal fibronectin than for a short cervix (i.e., 3.6 vs. 9.2 for delivering at <35 weeks of gestation) (see Tables 3 and 4 for a detailed comparison of cervical length and vaginal fetal fibronectin); and (v) the combined use of sonographic cervical length and fetal fibronectin improves the prediction of preterm delivery over that provided by each test alone; however, this effect was observed only when the cervical length was <30mm (171,188). Therefore, there does not seem to be a justification for performing a fetal fibronectin when the cervical length is 30mm or more.

Our practice is to perform a vaginal speculum examination to exclude rupture of membranes (assess the presence of pooling and nitrazine testing, and collect samples for ferning) and obtain samples for microbiology (including group B streptococcus (GBS), and if the prevalence justifies, gonorrhea

Table 3 Risk of Spontaneous Preterm Delivery Within 48hours, 7days, and 14days According to Cervical Length Results and Vaginal Fibronectin Determination

	Delivery within 48hours	LR		Delivery within 7days	LR		Delivery within 14days	LR	
		+	-		+	-		+	-
Cervical length <15mm	36.7% (11/30)	6.7		56.7% (17/30)	8.7		56.7% (17/30)	6.9	
Cervical length ≥15mm	3.2% (6/185)		0.4	5.9% (11/185)		0.4	9.2% (17/185)		0.5
Cervical length <30mm	13.9% (15/108)	1.9		23.1% (25/108)	2.0		26.9% (29/108)	1.9	
Cervical length ≥30mm	1.9% (2/107)		0.2	2.8% (3/107)		0.2	4.7% (5/107)		0.3
Vaginal fetal fibronectin (+)	19.2% (10/52)	2.8		34.6% (18/52)	3.5		42.3% (22/52)	3.9	
Vaginal fetal fibronectin (-)	4.3% (7/163)		0.5	6.1% (10/163)		0.4	7.4% (12/163)		0.4
Prevalence of the outcome	7.9% (17/215)			13.0% (28/215)			15.8% (34/215)

Prevalence of the outcome		7.9% (17/215)	13.0% (28/215)	15.8% (34/215)	8.9% (9/101)	15.8% (34/215)

and *Chlamydia trachomatis*). We collect a sample using a Dacron swab, and save it to assess fetal fibronectin concentration and perform an endovaginal ultrasound examination to measure cervical length. This is followed by a digital examination if the membranes are intact.

Approximately 50% of patients presenting with preterm contractions will have a cervical length of 30mm or more, and this will make testing for fetal fibronectin unnecessary (171). However, if the cervical length is <30mm, a fetal fibronectin test may be performed to improve the assessment of the likelihood of preterm delivery. The magnitude of the increase is presented in Tables 5 and 6 and in Figure 5. A practical approach is to restrict fetal fibronectin testing between 20 and 30mm (188), because the patients who have a cervical length below 20mm are already at high risk of preterm delivery, and the management would not be affected by the improvement in risk estimation derived from the performance of the two tests. This method is consistent with the study of Hincz et al. (189), who proposed a two-step approach.

Preterm labor is a worldwide challenge, and the performance of tests for the diagnosis of preterm labor should consider the availability of resources. In most countries, assessment of preterm labor can be conducted with transvaginal sonography without the performance of a fetal fibronectin test. Cervical length can be determined with transvaginal sonography or even with transperineal sonography in centers that do not have an endovaginal probe (190). Ultrasound is widely available in virtually all obstetrical units, and the results can be obtained immediately. An immunoassay for fetal fibronectin or another analyte can be expensive and impractical. The recent development of a bedside test for fetal fibronectin has clinical appeal (191,192).

DIAGNOSTIC WORKUP OF PRETERM LABOR

The clinical assessment of patients presenting with symptoms of preterm labor should include (i) a history of previous pregnancies and risk factors (e.g., prior preterm delivery, prior second-trimester abortion); (ii) current pregnancy status; (iii) presenting complaint(s); (iv) physical examination;

(v) monitoring of fetal heart rate and uterine contractions; (vi) vaginal examination (speculum and/or digital); (vii) collection of cervicovaginal samples for microbiology (streptococcus group B (GBS), chlamydia, gonorrhea, Gram stain for bacterial vaginosis (BV)); (viii) urinalysis, culture, and sensitivity; (ix) amniocentesis; (x) fetal fibronectin; and (xi) ultrasound (estimated fetal weight, number of fetuses, placental location, fetal presentation and lie, amniotic fluid volume, and transvaginal cervical length).

Evaluation for Subclinical Intra-amniotic Infection

Intra-amniotic infection is a frequent and important cause of premature labor and delivery (33,193–203). Most of these infections are subclinical in nature, and only 12.5% of patients with a positive amniotic fluid culture for microorganisms will have a fever or meet the definition of clinical chorioamnionitis (193). Patients with intra-amniotic infections are more likely to deliver despite the administration of tocolytic agents (204), mothers are at an increased risk for pulmonary edema (205–211) and neonates for sepsis and other neonatal complications, such as intraventricular hemorrhage and periventricular leukomalacia.

Amniocentesis is offered to patients to assess the microbial state of the amniotic cavity and fetal lung maturity. The amniotic fluid is considered to be sterile for bacteria. Therefore, the identification of bacteria by culture (33,193,212) or microbial footprints with molecular techniques (213–216) is evidence that microbial invasion of the amniotic cavity has occurred. These infections result, in the majority of cases, from microorganisms normally present in the vagina, which cross the endocervical canal and intact membranes and gain access to the amniotic cavity (196). Microorganisms can proliferate and gain access to the fetus. Aspiration of infected fluid may lead to congenital pneumonia (217), but other infections such as otitis, conjunctivitis, and omphalitis can occur by direct spread of microorganisms from infected amniotic fluid. Seeding from any of these sites to the fetal circulation may lead to bacteremia and sepsis. The frequency of intra-amniotic infection in patients with preterm labor and intact membranes is approximately 10% (193,218); however, the lower the gestational

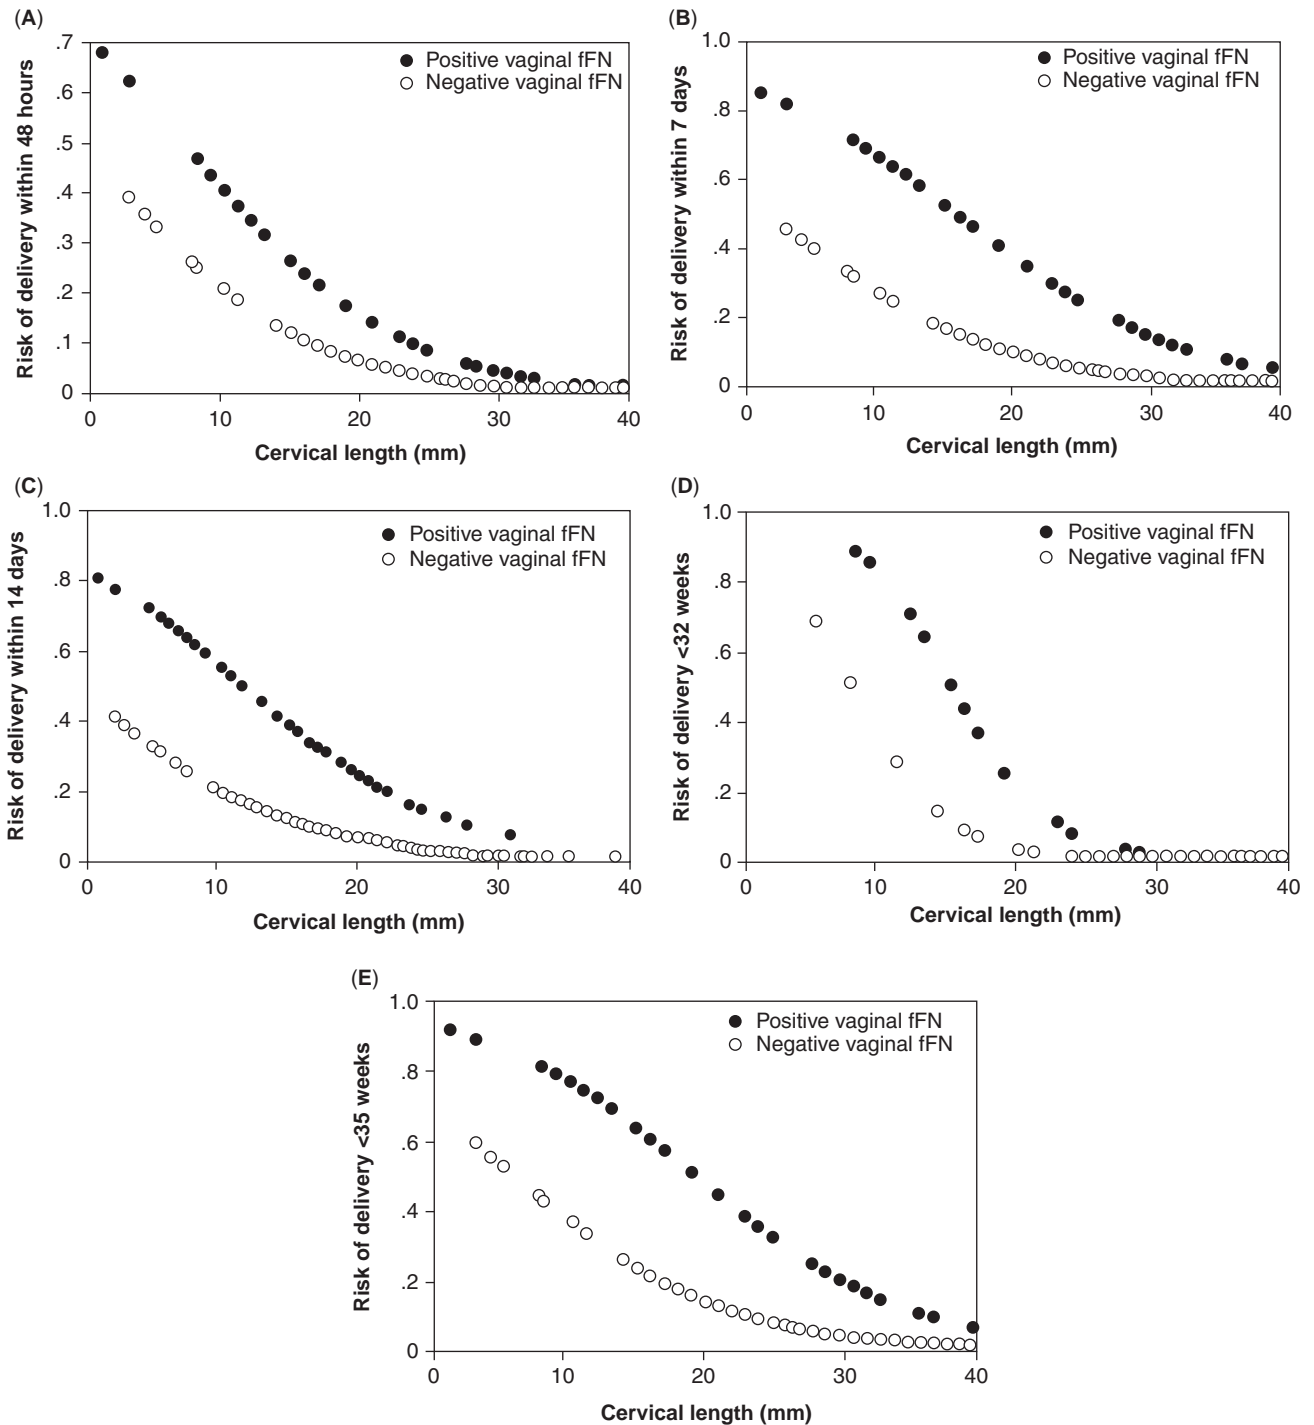

Figure 5 Risk of spontaneous preterm delivery within (A) 48 hours, (B) 7 days, (C) 14 days, (D) delivery <32 weeks, and (E) <35 weeks, according to cervical length results and vaginal fetal fibronectin (fFN) determination. Source: From Ref. 171.

age at presentation and the shorter the cervix, the higher the frequency of intra-amniotic infection and intra-amniotic inflammation (219). The organisms most frequently found in the amniotic cavity are genital mycoplasmas (33,51,193,195,200,220) and aerobic and anaerobic infections. Fungi have been identified in pregnancies with a retained intrauterine contraceptive device (221–225).

Amniocentesis is easy to perform in patients with preterm labor and intact membranes. The likelihood of infection is assessed by rapid tests, such as a Gram stain of amniotic fluid (204), amniotic fluid white blood cell count (226), and a

glucose determination (227). A positive Gram stain of amniotic fluid has a specificity of 99% for intra-amniotic infection (false-positive rate 1%) (193). However, it has a limited sensitivity because genital mycoplasmas cannot be seen on a Gram stain due to their small size. Gram stain examinations must be performed by experienced laboratory staff, because artifacts and crystals of the reagents may be confused with bacteria by inexperienced individuals.

Neutrophils are not normally present in amniotic fluid. The presence of neutrophils is indicative of intra-amniotic inflammation (226). An amniotic fluid white blood cell count

can be performed easily in a hemocytometer chamber, which is universally available in hospitals worldwide. It is the same chamber used to perform white blood cell counts in peripheral blood. In patients with intact membranes, a white blood cell count above 50 cells/mm³ has a sensitivity of 80% and a specificity of 87.6% in the detection of a positive amniotic fluid culture (226). If patients have an elevated white blood cell count, but the Gram stain is negative, an infection with genital mycoplasmas must be suspected.

Glucose is a normal constituent of amniotic fluid, and the concentration of glucose decreases with advancing gestational age (227). In the presence of infection or inflammation, the concentrations of glucose in the amniotic fluid decreases (227). This has been attributed to a combination of the consumption of glucose by microorganisms and by activated neutrophils involved in host defense and microbial killing. A glucose concentration can be performed by standard analyzers, and it is important to alert laboratories that the amniotic fluid glucose concentration is much lower than that of plasma or serum. A glucose concentration of <14mg/dL has a high sensitivity and specificity for the detection of intra-amniotic infection (212,228,229).

The determination of amniotic fluid interleukin-6 (IL-6) is a sensitive method to detect intra-amniotic inflammation. A concentration above 2.6ng/mL identified patients at risk for a positive amniotic fluid culture or impending delivery (218). Moreover, these patients are at increased risk for perinatal morbidity or mortality. Importantly, patients with an elevated amniotic fluid IL-6 and a negative amniotic fluid culture have a similar outcome as patients with a positive amniotic fluid culture (218). This suggests that there may be infections that cannot be detected with current methods (230) or, alternatively, that intra-amniotic inflammation due to non-infectious etiology is present (231–233) and this is associated with adverse outcome.

Neutrophils produce a collagenase, which is called matrix metalloproteinase 8 (MMP-8). MMP-8 has been proven to be an excellent marker for intra-amniotic infection/inflammation (234,235). Amniotic fluid MMP-8 >30ng/mL has a sensitivity of 82.4%, specificity of 78%, positive predictive value of 36%, and negative predictive value of 97.7% for the prediction of intra-amniotic infection, defined as positive amniotic fluid culture (235). A rapid test (MMP-8 PTD Check test; SK Pharma Co. LTD, Korea) has been produced (236,237), which has high sensitivity and specificity, as well as likelihood ratios for a positive and a negative result (238).

Amniotic fluid cultures should be performed for aerobic and anaerobic bacteria, as well as for genital mycoplasmas. Bacteria take time to grow and results may take several days. Molecular microbiologic techniques are becoming available and would allow detection of bacteria and identification of the organisms in 8 hours or less (239,240).

The detection of microorganisms or intra-amniotic inflammation is a poor prognostic sign. Patients with preterm labor with intact membranes and documented intra-amniotic infection/inflammation are unlikely to respond to tocolysis (193,218,239,241) and are at risk of developing pulmonary edema (205,242,243) if attempts are made to delay delivery with tocolysis. Therefore, our approach is to suspend the administration of tocolysis in these patients. We continue to administer steroids because there is evidence that they cross

the placenta and may downregulate the fetal inflammatory response syndrome (244). In patients with preterm PROM, the management depends upon gestational age. The higher the gestational age (e.g., >33 weeks), the better the outcome if the decision is to deliver the patient. On the other hand, at a gestational age of <32 weeks, treatment must be individualized. We have previously reported that it is possible to eradicate intra-amniotic infection in patients with preterm PROM (245,246), as well as in patients with a sonographic short cervix with antibiotic treatment (247).

Amniotic fluid can also be tested for fetal lung maturity. This can be done with the standard tests, including the lecithin/sphingomyelin (L/S) ratio, phosphatidylglycerol, TDx-FLM surfactant albumin ratio, and lamellar body count. In the presence of lung maturity, heroic measures with aggressive tocolysis should be considered carefully.

Performance of amniocentesis in patients with preterm labor is valuable to identify patients at risk for intra-amniotic infection/inflammation and can be performed by individuals with expertise in ultrasound and invasive procedures. We explain to patients that examination of amniotic fluid is necessary to detect the presence of infection and identify the microorganism, and that infection is a frequent cause of preterm delivery. Although a randomized clinical trial of amniocentesis versus management without amniocentesis has not been performed, we believe that amniocentesis is indicated to identify intra-amniotic infection/inflammation. In any other specialty in medicine, identification of infection and the microorganism is undertaken. It is only in obstetrics that some are hesitant to identify this process. We believe that the benefits of identifying intra-amniotic infection/inflammation and establishing fetal lung maturity outweigh the risks of amniocentesis, which is today a minimally invasive procedure (248–252).

TREATMENT OF PRETERM LABOR

Glucocorticoids

The idea that glucocorticoid administration could induce fetal lung maturity was first proposed by Liggins et al. more than 50 years ago (253). While studying the mechanisms of the onset of parturition in sheep, Liggins reported that administration of steroids to the fetal sheep induced preterm labor and that neonatal lambs born under these circumstances had inflated rather than collapsed lungs. Aeration of the lungs was attributed to the effects of steroids in inducing the production of pulmonary surfactant. This observation was followed by a randomized clinical trial in humans in which betamethasone was reported to decrease the rate of respiratory distress syndrome (254). Subsequently, multiple randomized clinical trials using either betamethasone or dexamethasone were reported (254–275). Systematic reviews of such trials have been performed since 1990, and they have consistently concluded that the beneficial effects of corticosteroids in neonatal outcome extend beyond inducing fetal lung maturity (276,277). Glucocorticoid receptors are expressed in many organs; and hence, the potential benefit in reducing morbidity such as intraventricular hemorrhage, necrotizing enterocolitis, etc.

The most recent systematic analysis reported by Roberts and Dalziel (276) included the review of 21 trials (3885 women and 4269 infants). Administration of corticosteroids was associated with a significant reduction in neonatal death, respiratory

Figure 6 Impact of antenatal corticosteroids before anticipated preterm birth on perinatal outcomes. Abbreviation: C.I., confidence interval. Source: From Ref. 276.

distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, admission to neonatal intensive care unit, and neonatal infection within the first 48 hours of life (Fig. 6) (276). In addition, these benefits accrue without an increased risk of clinical chorioamnionitis, puerperal sepsis, or the risk of stillbirth.

The agents administered are either dexamethasone or betamethasone because they cross the placenta readily, are weaker immunosuppressors than other glucocorticoid steroids, and have a longer duration of action than cortisol. The standard dosage of betamethasone consists of two intramuscular 12-mg doses (24 hours apart), while four intramuscular doses of 6 mg of dexamethasone should be administered at 6-hour intervals. Oral administration of dexamethasone is not recommended, because it has been associated with an increased risk of neonatal intraventricular hemorrhage (IVH) and sepsis compared with intramuscular administration (278,279).

Betamethasone is preferred over dexamethasone because its administration results in a greater reduction in respiratory distress syndrome and puerperal infection (280) while the use of dexamethasone is associated with a lower frequency of intraventricular hemorrhage than betamethasone. However, most investigators believe that there is still equipoise between the two drugs (255,276,280–283).

Glucocorticoids provide beneficial effects to patients between 24 and 33-6/7 weeks of gestation (276). Some data suggest that there are beneficial effects at 23 weeks of gestation (284), while more studies are required to establish efficacy between 34 and 36-6/7 weeks of gestation (285,286).

Long-term follow-up studies have not uncovered complications in children exposed to a single course of antenatal steroids, and one study has followed these infants for 30 years (287).

Although many believe that the benefits of antenatal steroid administration occur after 24 hours of initiation of therapy, there is evidence that when delivery occurs between the first and second dose of betamethasone, there is still a reduction in the rate of neonatal death, intraventricular hemorrhage, and the need for vasopressors (288). Therefore, benefits accrue even if 48 hours have not elapsed since the administration of the first dose of steroids. On the other hand, the beneficial effects of antenatal corticosteroids are not demonstrable in babies born more than 7 days after treatment, and the birth weight is significantly reduced (276,289).

Should Steroid Administration Be Repeated After 7 days?

Several randomized clinical trials have been conducted to address this question. Moreover, a systematic review including five trials has been reported (290). The trial reported by Crowther et al. (291) (Australasian Collaborative Trial of Repeat Doses of Steroids) randomized 982 women (1146 neonates) at less than 32 weeks of gestation who had received a single course of antenatal corticosteroids to receive weekly betamethasone or placebo (291). Repeated corticosteroids led to a significant reduction in the rate of respiratory distress syndrome (33% vs. 41%; $p = 0.01$), severe lung disease (12% vs. 20%; $p = 0.0003$), less frequent oxygen therapy (56% vs. 63%; $p = 0.03$), and shorter duration of mechanical ventilation ($p = 0.01$) (291).

In contrast, a randomized controlled trial conducted in the United States by Wapner et al. (292) randomly assigned 495 women at 23 weeks of gestation to receive either betamethasone or placebo weekly between 7 and 10 days after the initial dose of steroids. The primary outcome of the trial was neonatal morbidity as a composite score. There was no difference between those patients allocated to repeat steroids versus placebo (8% vs. 9.1%; $p = 0.6$) (292). Neonates in the repeat steroid group had a significantly lower frequency of surfactant administration, mechanical ventilation, continuous positive airway pressure, and pneumothorax. However, the frequency of small for gestational age (<10th percentile) was higher in infants exposed to repeated doses of steroids than in the control group. Importantly, the frequency of cerebral palsy was higher in neonates that received four or more courses of maternal corticosteroids, but this was not statistically significant [2.4% (6/248) vs. 0.4% (1/238)] (293). There were no differences in physical or neurocognitive outcomes in this trial. By contrast, Crowther et al. (294) noted a higher frequency of children with behavioral problems (e.g., attention deficit and emotional reactivity), but no differences in the frequency of cerebral palsy [repeat steroids, 4.2% (22/521) vs. 4.8% (25/528)].

There are several differences in these two trials. The dose in the study of Crowther et al. was 11.4mg/week of betamethasone, while the study of Wapner et al. used 24mg/week. Also, more women received four or more doses of steroids in the Wapner et al. trial than those in the Crowther et al. trial.

Murphy et al. (295) reported results of a randomized clinical trial of the multiple courses of antenatal corticosteroids for preterm birth. In this study, 1858 women between 25 and 32 weeks who were undelivered 14 to 21 days after the initial dose of steroids were randomized to repeat doses of steroids ($n = 973$) or placebo ($n = 921$) every 14 days until 33 weeks of gestation or delivery, whichever came first. The primary endpoint was a composite of perinatal morbidity and mortality. Infants exposed to multiple courses of steroids had similar morbidity and mortality rates to those allocated to placebo (12.9% vs. 12.5%). In this study, exposure to steroids was associated with a lower birth weight, lower length at birth, and smaller head circumference. The authors concluded that multiple courses of steroids could not be recommended.

An individual patient meta-analysis is in progress but results are not available at the time of this writing. The American Congress of Obstetricians and Gynecologists has recommended that only one course of betamethasone (12mg in two doses, 24 hours apart) should be given to women in preterm labor. In contrast, in Australia and New Zealand, repeat doses are given weekly to women at risk up to 32 weeks of gestation.

Another strategy for repeat steroids is what is referred to as “rescue” therapy. In this instance, repeat steroids are administered only to patients with impending delivery. In a study by Garite et al. (296), patients who were diagnosed to have an episode of preterm labor at less than 33 weeks and received a complete course steroids before 30 weeks more than two weeks ago were randomized to receive either a single “rescue” course of betamethasone (12mg; 2 doses, 24 hours apart) or placebo. Patients with rupture of membranes, advanced cervical dilatation (>5cm), and chorioamnionitis

were excluded. Of the 433 patients randomized (223 to “rescue” steroids and 214 to placebo), 55% in each group delivered at less than 34 weeks of gestation. In the rescue group there was a significant reduction in the primary outcome (composite neonatal morbidity below 34 weeks) (43.9% vs. 63.6%; OR 0.45; 95% CI, 0.27–0.75; $p = 0.002$). There was also a significant decrease in respiratory distress syndrome, ventilatory support, and surfactant use (296). This observation suggests that “rescue” therapy can be considered with an understanding that prediction of the patient who is at risk of impending delivery is difficult.

TOCOLYTIC THERAPY

The basic premise behind the use of tocolytic treatment is that the administration of pharmacologic agents can inhibit myometrial contractions, prolong pregnancy, and reduce the rate of neonatal morbidity and mortality. Intravenous alcohol was the first agent introduced to delay preterm delivery (297). Its use was accompanied by an unacceptable rate of maternal complications. Since that time, multiple pharmacologic agents have been used, including beta-adrenergic agents, magnesium sulfate, oxytocin receptor antagonists, calcium-channel blockers, nitroglycerin, and prostaglandin synthase inhibitors. Decades of research indicate that tocolysis can prolong pregnancy for 48 hours to 7 days (298–301). This prolongation of gestation is considered beneficial, because it allows the transfer of patients to a tertiary care facility and, importantly, the administration of corticosteroids. The hope that the use of tocolysis would reduce the rate of preterm birth has not been realized. It is possible that the ideal agent has not been identified. Alternatively, it is possible that tocolysis, as a strategy, would not succeed if a serious pathologic process which has led to activation of the myometrium and other components of the common pathway of parturition is not treated. For example, the administration of beta-adrenergic agents in patients with documented intrauterine infection is not effective in prolonging pregnancy and may result in an increased rate of maternal pulmonary edema (205,242,243). Therefore, many studies of tocolysis are confounded by including patients who will not benefit from inhibition of uterine contractility.

Beta-adrenergic Receptor Agonists

The first and only agent approved for tocolysis in the United States by the Food and Drug Administration (FDA) was ritodrine, a selective beta-2 adrenergic agent. This drug is no longer marketed in the United States. This class of agents achieves myometrial relaxation by binding to the beta-2 adrenergic receptor and increasing the levels of intracellular cyclic adenosine monophosphate, which, in turn, activates protein kinase, inactivates myosin light-chain kinase, and inhibits myometrial contractility (302–304). Agents in this class include terbutaline and fenoterol (4). A meta-analysis including 11 randomized clinical trials (1320 women) in which beta-adrenergic agents were compared with placebo indicates that these agents reduce the rate of delivery within 48 hours, but not within 7 days (300). There was no evidence of a significant decrease in perinatal or neonatal morbidity and mortality.

The use of beta-adrenergic agents is associated with maternal and fetal side effects. The most common are maternal and fetal tachycardia, tremor, headache, nausea,

vomiting, hypokalemia (301), and hyperglycemia (300,301). Hypotension due to peripheral vasodilatation is a common problem (305). Maternal cardiac arrhythmias and myocardial ischemia have been reported during the course of tocolysis with these agents (306). The onset of chest pain should be taken seriously during the course of therapy. Because of metabolic effects (hyperglycemia) of beta-adrenergic agents, it is best to use other agents in patients with glucose intolerance. Neonatal side effects include hypoglycemia (4), hypocalcemia (4), and myocardial damage (case reports) (307).

There is no evidence that maintenance treatment with either oral or subcutaneous beta-adrenergic agents is beneficial. Some have used subcutaneous terbutaline administered via a pump; however, randomized clinical trials do not show evidence of efficacy (308,309). Recently, the FDA has issued a black-label warning for terbutaline administration based upon reports of some maternal deaths associated with its use (310,311). Fenoterol is used in Europe, and there is considerable experience with this agent in Germany.

A common practice in patients who present with preterm uterine contractions is to administer a single subcutaneous dose of terbutaline. Patients in whom contractions persist are at increased risk for preterm delivery (312).

Magnesium Sulfate

This tocolytic agent can cause a reduction in uterine contractility *in vitro* and *in vivo* (313). Magnesium hyperpolarizes the cellular membrane and inhibits myosin light-chain kinase activity by competing with intracellular calcium (314–316). Despite its wide utilization in the United States, the largest randomized clinical trial in which magnesium sulfate was compared with placebo concluded that magnesium sulfate was not effective in prolonging pregnancy (317). Meta-analyses of randomized trials in which magnesium was compared with placebo or other agents do not show differences in prolongation of pregnancy for 48 hours (318). Maternal and neonatal side effects of magnesium sulfate are well known since this drug is used to prevent seizures in pre-eclampsia. Common side effects include nausea and vomiting, a metallic taste in the mouth, lethargy, and hot flashes. Pulmonary edema has been reported in patients receiving this drug. Since magnesium crosses the placenta, prolonged administration can lead to hypermagnesemia in the neonate. A systematic review reported by Crowther et al. (318) in which more than 2000 women were included in 23 trials concluded that magnesium was not effective in preventing preterm delivery and was associated with an increased risk of death (fetal and pediatric) (RR 2.8; 95% CI, 1.20–6.62). Grimes and Nanda have called for a discontinuation of magnesium sulfate as a tocolytic agent (319). There is no evidence that oral magnesium administration can prevent preterm birth or is effective for maintenance of tocolysis.

Calcium-Channel Blockers

These agents inhibit uterine contractility by blocking the calcium channels and, thereby, the influx of calcium through the cell membrane as well as the release of intracellular calcium from the sarcoplasmic reticulum (320,321). Nifedipine is the most popular agent used as a tocolytic agent. Its use is based on comparative trials with beta-adrenergic agents.

A recent systematic review indicates that nifedipine is as effective as beta-adrenergic agents in delaying delivery for 48

hours (298). However, nifedipine was superior to beta-adrenergic receptor agonists in delaying delivery of 7 days within initiation of therapy and also in improving clinically important neonatal outcomes such as respiratory distress syndrome, necrotizing enterocolitis, intraventricular hemorrhage, jaundice, admission to the neonatal intensive care unit (NICU), and length of stay in the NICU. Moreover, nifedipine use was associated with fewer maternal side effects and a lower rate of discontinuation of treatment than beta-adrenergic agents. Follow-up of infants exposed to either nifedipine or beta-adrenergic agents showed no difference in neurodevelopmental status at 2 years of age (322), or psychological or motor function at 9 to 12 years of age (323). There are insufficient data to assess the efficacy of nifedipine against oxytocin receptor antagonists or nitric oxide. There was no evidence that maintenance therapy with nifedipine was efficacious. The proposed dose of administration is 10mg orally or sublingually. If contractions persist, this dose can be repeated every 15 to 20 minutes up to a maximal total dose of 40mg during the first hour of treatment, then 20mg orally every 6 to 8 hours for 2 to 3 days. The side effects of nifedipine include headache, flushing, dizziness, hypotension, and nausea (324). Suppression of maternal heart rate, contractility, and left ventricular systolic pressure may also occur. Concurrent administration of magnesium with calcium-channel blockers may result in neuromuscular blockade and pulmonary edema (325,326). However, a retrospective case-control study concluded that the use of nifedipine and magnesium sulfate together in patients with pre-eclampsia does not increase the risk of serious magnesium-related effects including neuromuscular blockade (327).

Prostaglandin Synthase Inhibitors

Prostaglandins are considered the universal mediators of labor and can induce uterine contractility and cervical ripening. The therapeutic target is the cyclooxygenase (COX) enzyme, which catalyzes the conversion of arachidonic acid to the intermediate product of prostaglandins, PGH. There are two COX enzymes, COX-1 and COX-2. The former is the constitutive enzyme, and the second is the inducible enzyme. Indomethacin is a non-specific inhibitor of COX, while nimesulide is a specific inhibitor of COX-2. One of the randomized clinical trials in which indomethacin was compared with placebo concluded that indomethacin resulted in a reduction in the rate of preterm birth (defined as <37 gestational weeks) (328,329). However, this trial included only 36 women, and there was no difference in neonatal outcome. Comparative trials (with either beta-adrenergic agents or magnesium sulfate) show that COX inhibitors reduced the rate of preterm birth before 37 weeks and the frequency of adverse events (329). However, there was no demonstrable improvement in neonatal outcome. Two studies comparing non-selected COX inhibitors versus COX-2 inhibitors did not demonstrate differences in maternal and neonatal outcome (329–331). It is recognized that the trials have been of small sample size.

Adverse events include nausea, vomiting, heartburn, gastrointestinal bleeding, and impairment of platelet function (prolonged bleeding time). Indomethacin should not be administered in patients with peptic ulcer, kidney, or liver

disease. The drug crosses the placenta readily, and the most common side effects include stenosis of the fetal ductus arteriosus and oligohydramnios (328,332). There is also a concern about impairment of platelet function in the neonates (333). However, a meta-analysis of 28 studies showed no significant differences in the rates of intraventricular hemorrhage, patent ductus arteriosus, necrotizing enterocolitis, and neonatal mortality between the two groups (334). The standard recommendation is not to use the agent after 32 weeks of gestation or longer than 50mg (4). Indomethacin is used as an acute tocolytic. The oral dose of indomethacin is a 50 mg loading dose, followed by 25 to 50mg every 6 hours for 48 hours (total duration of treatment). The drug can also be administered rectally as a suppository.

Nitric Oxide Donors

Nitric oxide can induce relaxation of smooth muscle by increasing cyclic guanosine monophosphate, which inhibits myosin light-chain kinases. Nitroglycerin is a nitric oxide donor. The initial trials with nitroglycerin for tocolysis suggested that it was comparable with ritodrine (335). A randomized, double-blind, placebo-controlled trial was conducted in which patients ($n = 153$) with preterm labor (between 24 and 32 weeks of gestation) were randomized to receive transdermal nitroglycerin (0.4mg/h) or placebo patches (336). The primary endpoint of this study was a composite of neonatal morbidity and mortality. Infants born to mothers allocated to transdermal nitroglycerin had a significantly lower composite neonatal outcome compared with placebo (RR 0.29, 95% CI 0.08–1.00; $p = 0.048$). The number needed to treat was 10. Preterm birth prior to 28 weeks of gestation was reduced by 50% (RR 0.50, 95% CI 0.23–1.09). Patients receiving nitroglycerin had significantly more maternal side effects than those allocated to placebo. The most common side effects were headache and local irritation from the patch. Importantly, in this trial, none of the subjects received other tocolytics from randomization to delivery. Therefore, this is a unique trial in the history of tocolytic therapy. Long-term follow-up of infants enrolled in a previous trial of nitroglycerin patches versus beta-adrenergic agonists showed that there was no significant difference in psychometric testing at the age of 2 (337).

Oxytocin Receptor Antagonists

Oxytocin is a powerful stimulant of myometrial contractions. Its receptor is widely distributed in myometrium and decidua. Atosiban, an oxytocin receptor antagonist, can block spontaneous and oxytocin-induced uterine contractility. This agent is used widely in Europe, but is not available in the United States.

Comparative randomized clinical trials in which patients were allocated to beta-mimetic agents or atosiban indicated that atosiban had the same efficacy, but fewer maternal adverse events (338–341). These studies were conducted by a worldwide atosiban versus beta-adrenergic agonists study group and included comparisons of this agent with ritodrine, salbutamol, and terbutaline. Tocolytic effectiveness was similar in terms of gestational age at delivery, but maternal side effects, particularly cardiovascular adverse events, were less frequent in patients allocated to atosiban than in patients allocated to

beta-adrenergic agents (8.3% vs. 81.2%, $p < 0.001$) (341). This was associated with a lower rate of discontinuation of treatment due to side effects (1.1% vs. 15.4%, $p = 0.0001$).

A large randomized clinical trial in which patients in preterm labor were allocated to either atosiban- or placebo-initiated treatment showed that atosiban-treated patients were significantly less likely to deliver within 24 hours, 48 hours, and 7 days than patients with placebo-initiated treatment (342). There was no difference in the interval from enrollment to delivery between the two groups. In this study, the rate of fetal/infant death was greater in patients allocated to atosiban than placebo. This was attributed to an excess number of patients with gestational ages less than 24 weeks allocated to the atosiban arm compared with the placebo-initiated treatment. Similarly, there was an excess of infection-associated preterm labor and delivery in patients allocated to atosiban. This concern for safety was probably the reason the FDA did not approve atosiban in the United States. Another randomized clinical trial in which patients with an episode of preterm labor were treated with atosiban and subsequently randomized to either maintenance therapy with atosiban (subcutaneous pump) or placebo showed that maintenance therapy was not associated with a reduction in the rate of preterm delivery (343). However, in this trial, prolonged exposure to atosiban did not result in an excess of fetal or infant death. This finding, coupled with the extensive experience in Europe with atosiban, makes it unlikely that there is a toxic effect of atosiban on the fetus.

Antibiotics in Preterm Labor

Several randomized clinical trials have tested the effect of antibiotics versus placebo in patients with an episode of preterm labor (344–354). A systematic review of such intervention demonstrated that antibiotic administration (ampicillin and/or erythromycin) does not reduce the rate of preterm delivery or neonatal complications. The largest trial conducted to date is the ORCALE II trial (346), in which 6295 women were randomized to placebo, amoxicillin/clavulanic acid, erythromycin, and the combination of amoxicillin/clavulanic acid and erythromycin.

The study that followed the infants enrolled in the ORACLE II trial at the age of 7 years indicated that those exposed to antibiotics have an increased rate of cerebral palsy, which was modest in magnitude, but statistically significant (355). This unexpected observation suggests that antibiotic administration to women without demonstrable infection could cause harm. However, the precise mechanism by which antibiotic administration can cause neurologic injury is unknown. One possibility is that antibiotics may cause the release of microbial products, which could initiate an inflammatory reaction, and change the nature of the host–microbial interaction in normal pregnancy and fetal life. These observations, and the lack of efficacy of adjuvant antibiotics in the prevention of preterm delivery and neonatal morbidity, suggest that antibiotics should not be used in patients with preterm labor and intact membranes. However, this does not apply to the prevention of vertical transmission of GBS. Antibiotic administration is effective in reducing the rate of neonatal GBS sepsis and should be used in patients at risk (356–361). The recommended treatment is penicillin G 5 million units intravenously, followed by 2.5 to 3 million units every 4 hours. Patients allergic

to penicillin can receive either clindamycin (900mg IV every 8 hours) or erythromycin (500mg IV every 6 hours), if the isolate microorganism is susceptible to clindamycin or erythromycin, or vancomycin (1g IV every 12 hours) if the isolate microorganism is resistant to the clindamycin or erythromycin or in cases of unknown susceptibility (362).

Magnesium Sulfate for Neuroprotection

Preterm delivery is a major risk factor for cerebral palsy. Several randomized clinical trials have been conducted to test the effect of magnesium sulfate in the prevention of cerebral palsy after a report by Nelson and Grether (363) suggesting that *in utero* exposure to magnesium sulfate was associated with a lower rate of cerebral palsy in infants born weighing less than 1500g.

A systematic review of six trials (364), involving 4796 women and 5357 infants, indicated that antenatal magnesium sulfate was associated with a significant reduction in the risk of cerebral palsy (RR 0.69, 95% CI 0.55–0.88), moderate or severe cerebral palsy (RR 0.64, 95% CI 0.44–0.92), and substantial gross motor dysfunction (RR 0.60, 95% CI 0.43–0.83). There was no overall difference in the risk of total pediatric mortality (RR 1.01, 95% CI 0.89–1.14). Minor side effects were more frequent among women receiving magnesium sulfate. Therefore, we recommend the use of magnesium sulfate for neuroprotection in women at high risk for preterm delivery before 34 weeks of gestation. The loading dose of magnesium sulfate is 6g and the maintenance dose 1 to 2g/h, for 24 hours. This treatment should be restricted to patients expected to deliver within 24 hours. It has been used in patients with both intact and ruptured membranes. Using this approach, it has been estimated that the incremental cost of preventing one case of cerebral palsy would be approximately \$10,291 (95% CI \$6135–\$29,685) (364).

Prediction of Spontaneous Preterm Delivery

The risk factors associated with preterm delivery/preterm PROM (3) include a sonographic short cervix (2,166–169, 173,174,247), African-American race (365–368), and a prior history of preterm delivery (2,369). There is conflicting evidence of the efficacy of antibiotic treatment for BV in women with a prior preterm birth. Some studies suggest a benefit to the use of antibiotics for these patients (370–372) and others have not shown this benefit (373–376). A systematic review of seven randomized clinical trials demonstrated no evidence of benefit for screening or treating low-risk pregnant women who are asymptomatic for BV. Furthermore, they found no advantage to screening for and treating BV in the general population of pregnant women who are asymptomatic for BV (373).

Fetal fibronectin has been used in the evaluation of asymptomatic women to predict their risk of preterm delivery. Numerous meta-analyses (176,184,377–380) have concluded that cervicovaginal fetal fibronectin testing might be clinically useful in the prediction of preterm birth, with an emphasis given to the high negative predictive value of the test, particularly in women who are symptomatic of threatened preterm labor and for delivery within 7 to 10 days of sampling. Kurtzman et al. (381) have proposed the use of quantitative fetal fibronectin screening in asymptomatic women with a

prior preterm delivery. This group demonstrated that quantitative fetal fibronectin assessment at 24 weeks of gestation could be used to predict the risk of spontaneous preterm delivery before 34 weeks of gestation, and that this risk increased as the quantity of fetal fibronectin (FFN) increased [compared with an FFN = 0 ng/mL; RR 2.42 (FFN 1–49ng/mL; 95% CI 0.76–5.66), 4.68 (FFN 50–199ng/mL; 95% CI 1.28–10.95), and 9.94 (FFN>200ng/mL; 95% CI 2.90–19.67)] (381).

Recently, Conde-Agudelo and Romero conducted a systematic review and meta-analysis of 15 studies investigated the accuracy of cervicovaginal fetal fibronectin in predicting preterm birth in women with multiple gestations (382). This study demonstrated that among asymptomatic women with multiple or twin pregnancies, the pooled sensitivities, specificities, and positive and negative likelihood ratios for predicting preterm birth before 32, 34, and 37 weeks of gestation ranged from 33% to 45%, 80% to 94%, 2.0 to 5.5, and 0.68 to 0.76, respectively. Among women with twin pregnancies and threatened preterm labor, the test was most accurate in predicting spontaneous preterm birth within 7 days of testing (pooled sensitivity, specificity, and positive and negative likelihood ratios of 85%, 78%, 3.9, and 0.20, respectively).

These findings provided evidence that cervicovaginal fetal fibronectin has limited accuracy in predicting spontaneous preterm birth in both asymptomatic and symptomatic women with multiple pregnancies because the likelihood ratios for positive and negative test results generated only minimal to moderate changes in the pretest probabilities of preterm birth. The test is most accurate in predicting spontaneous preterm birth before 32 weeks of gestation in asymptomatic women with multiple or twin pregnancies, and spontaneous preterm birth within 7 days of testing in women with twin pregnancies and threatened preterm labor (382).

A Short Sonographic Cervical Length: a Powerful Predictor of Preterm Delivery

Cervical sonography is the most objective and reliable method to assess cervical length (168,172–174,383,384). Furthermore, cervical length is the most powerful predictor of spontaneous preterm delivery. The shorter the sonographic cervical length in the midtrimester, the higher the risk of spontaneous preterm labor/delivery (168,173,174,383). There is no agreement as to what is a sonographic short cervix. For example, Iams et al. (174) proposed that a cervix of 26mm or shorter at 24 weeks of gestation increases the risk for spontaneous preterm delivery (RR 6.19, 95% CI 3.84–9.97). The prevalence of spontaneous preterm delivery (defined as <35 weeks) in this study was 4.3%, and the positive predictive value was 17.8% for a cervical length of ≤ 25 mm at 24 weeks of gestation (174). Thus, most women with a short cervix (defined as ≤ 25 mm) and no history of previous preterm birth will not deliver a preterm neonate. Other investigators have proposed a cut-off of 15mm (173,383), because a cervical length of 15mm or less is associated with nearly a 50% risk of spontaneous preterm delivery at 32 weeks of gestation or less, when neonatal morbidity is substantial (171,173,219,247,383,385–390). To et al. (385) have developed a method to assess the risk of preterm delivery for individual patients using sonographic

cervical length and other maternal risk factors such as maternal age, ethnic group, body mass index, cigarette smoking, and previous cervical surgery. Importantly, sonographic cervical length is the single most powerful predictor for preterm birth in the index pregnancy (172,384) and is far more informative than a history of previous preterm birth (172,385,391). This has implications in the selection of patients for future trials and the interpretation of past trials. Specifically, all trials conducted to date (392–396), except one (397), have identified patients for study based upon a history of previous preterm birth. As much as preterm birth is a syndrome, it is likely that the risk conferred by a previous preterm delivery may vary within and between populations. This may explain the apparent contradictory results between trials [i.e., conflicting reports of trials of vaginal progesterone (395,396) and the wide range of preterm birth among control groups (394–396)].

Sonographic cervical length is not a screening test for spontaneous preterm delivery because only some of the patients who will have a spontaneous preterm birth have a short cervix in the midtrimester. However, sonographic cervical length is a method for risk assessment for spontaneous preterm delivery. Its importance derives from the observation that, as a fraction of patients with a history of previous preterm birth who shorten their cervix during the index pregnancy may benefit from therapeutic cervical cerclage (398,399), patients with a short cervix may benefit from vaginal progesterone administration to reduce the rate of spontaneous preterm birth (397).

Cervical ultrasound is a powerful tool in performing risk assessment for spontaneous preterm birth. It is simple to perform, inexpensive when performed at the time of second-trimester screening for anomalies, informative, and can provide an estimate of risk in primigravidae. We believe that measuring cervical length should be part of standard sonographic examination in the midtrimester. Other tools may help to refine the estimation of risk. Such tools can range from vaginal fibronectin (219,400), the collascope (165,401–403), amniotic fluid analysis (220,226,227,235,238,404–407), and the presence/absence of “amniotic fluid sludge” (408,409), to genetic analysis of DNA variants of the progesterone receptor (410–413). These may help determine patients who will respond to progestogens or other treatments and those who will not and realize “personalized perinatal medicine” in the 21st century.

Amniotic Fluid “Sludge”

Particulate matter in the amniotic fluid is present in about 4% of pregnancies during transvaginal ultrasound in the first and early second trimesters (414). Particulate matter in the first two trimesters of pregnancy has been associated with intra-amniotic bleeding (415,416) and the acrania-encephaly sequence (417), and has been observed in women with high concentrations of maternal serum α -fetoprotein (418). In contrast, in the last trimester of pregnancy, particulate matter and “echogenic amniotic fluid” have been attributed to the presence of vernix caseosa and/or meconium (419–422), and with a lecithin–sphingomyelin ratio indicative of lung maturity (423,424).

Amniotic fluid “sludge” is defined as particulate matter seen in the proximity of the internal cervical os during a

transvaginal sonographic examination of the cervix and occurs in 1% of uncomplicated pregnancies (408) (Fig. 7). The first description of amniotic fluid sludge was in patients in preterm labor. Espinoza et al. (408) conducted a retrospective study of 84 patients in preterm labor with intact membranes. The prevalence of amniotic fluid sludge was 22.6% (19 of 84) in patients with preterm labor. Patients with amniotic fluid sludge had a higher frequency of positive amniotic fluid cultures [33.3% (6 of 18) vs. 2.5% (1/40), $p = 0.003$] and histological chorioamnionitis [77.8% (14 of 18) vs. 19% (11 of 58), $p < 0.001$], and a higher rate of spontaneous preterm delivery within 48 hours [42.9% (6 of 14) vs. 4.4% (2 of 45), $p = 0.001$], within 7 days [71.4% (10 of 14) vs. 115.6% (7 of 45), $p < 0.001$], less than 32 weeks [75% (9 of 12) vs. 25.8% (8 of 31), $p = 0.005$], and less than 35 weeks [92.9% (13 of 14) vs. 37.8% (17 of 45), $p < 0.001$] than those without amniotic fluid “sludge.” Stepwise logistic regression analysis indicated that the presence of sludge was independently associated with the likelihood of spontaneous delivery within 48 hours and 7 days, but not less than 32 weeks or less than 35 weeks. Survival analysis demonstrated that patients with amniotic fluid “sludge” had a shorter examination-to-delivery interval compared with those without “sludge” [sludge median: 1 day (interquartile range: 1–5 days) versus no sludge, median: 33 days (interquartile range: 18–58 days); $p < 0.001$]. These results indicate that amniotic fluid “sludge” during transvaginal examination of the cervix is a risk factor for intra-amniotic infection, histological chorioamnionitis, and impending preterm delivery (408).

The presence of amniotic fluid “sludge” on transvaginal examination in asymptomatic patients is also associated with delivery within 14 days of ultrasound and preterm delivery at less than 32 and less than 34 weeks (409,425). Amniotic fluid sludge has also been identified as an independent risk factor for spontaneous preterm delivery at less than 28 weeks, less than 32 weeks, and less than 35 weeks of gestation; and for preterm PROM; intra-amniotic infection; and histological chorioamnionitis (409). Furthermore, asymptomatic patients with amniotic fluid sludge had shorter ultrasound-to-delivery and ultrasound-to-preterm PROM intervals than those without sludge (409,425).

Recently, amniotic fluid sludge has been demonstrated to represent a biofilm (426,427). A sample of sludge was retrieved by transvaginal amniotomy under ultrasound guidance from a patient at 28 weeks with spontaneous labor and clinical chorioamnionitis. Grossly, the sludge had a “pus-like” appearance and the Gram stain showed gram-positive bacteria. The amniotic fluid culture was positive for *Streptococcus mutans*, *Mycoplasma hominis*, and *Aspergillus flavus*. Of interest, the results of the amniocentesis performed at the time of admission for preterm labor were negative for intra-amniotic infection (426,427). The aspirated sludge was then analyzed further. Scanning electron microscopy showed flocs of amniotic fluid sludge that consisted of bacterial cells and the exopolymeric matrix material that are typical of a biofilm (Fig. 8) (427). The evidence that sludge represents a biofilm in this case includes the following: (i) the presence of bacteria detected by fluorescence *in situ* hybridization, with the use of a probe against the conserved sequence of prokaryotes; (ii) bacterial aggregates were separated by material that resembled

Figure 7 Amniotic fluid “sludge” seen in proximity of the internal cervical os during a transvaginal sonographic examination of the cervix. Source: From Ref. 505.

Figure 8 Examination of sludge using scanning electron microscopy. Source: From Ref. 427.

a matrix; and (iii) lectin-based identification of exopolymeric matrix that stained with wheat germ agglutinin (427).

The clinical significance of this relates to the challenges encountered with diagnosis and treatment of this condition. First, the diagnosis of microbial invasion in the presence of biofilms is extremely challenging, and current cultivation techniques are inadequate to detect such infections. The consequences are that the frequency of infection of the amniotic cavity may be underestimated and that molecular microbiologic techniques will be required to improve diagnosis. Second, the optimal treatment of biofilm-related infections represents a challenge in clinical medicine. Antimicrobial agents appear to be inactivated or fail to reach bacteria within a biofilm. Interestingly, bacteria within biofilms have increased resistance to antimicrobial compounds even though the same bacteria can be sensitive to the same agent if grown under standard conditions (428–431). Thus, the difficulties in treating intra-amniotic infection may be due to the refractoriness of biofilms to conventional antibiotic treatment. Third, biofilms in the amniotic fluid may

represent a unique form of these structures, which can be dislodged by fetal movement, resulting in seeding of planktonic bacteria and the eliciting of an inflammatory response.

Progestogens for the Prevention of Preterm Birth

The importance of progesterone in the maintenance of mammalian pregnancy is well-established (90,97,116,432–446), and the suspension of progesterone action is believed to be central to the initiation of parturition in most mammalian species, including primates (90,97,410,436,438,442,443,447). Yet the precise mechanism for this in humans has not been elucidated (90,97,98,436,439,443,448–451).

Progestogen (a term that, like progestins, describes both “natural” progesterone and synthetic compounds with progesterone action) (452) administration to prevent spontaneous abortion (453–465) and preterm birth (392–395,397, 454,466–469) has been a subject of investigation for several decades. The use of progesterone in the first trimester of pregnancy to “support corpus luteum function” is a well-established clinical practice (453,455,456,460,461,463,465,470), and formulations of progesterone for this indication have been approved by the FDA (<http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm>) and regulatory agencies in Europe and other countries (471).

The results of the early trials for the use of progestogens for the prevention of preterm birth or recurrent abortion were contradictory; as were the meta-analyses of such trials (470,472,473). For example, the meta-analysis of Goldstein et al. (473) included trials employing several progestational agents and could not demonstrate a beneficial effect of progesterone on the prevention of preterm birth. The meta-analysis of Professor Marc Keirse (472) focused only on studies of 17 alpha-hydroxyprogesterone caproate and examined its effect on different endpoints: “early curtailment of gestation, whether by miscarriage (<20 weeks or <500g) or by preterm birth (<37 weeks).” Despite these encouraging results, little clinical research on the subject was conducted for more than a decade.

The Use of Progestogens in Women with a Prior History of Preterm Birth

In 2003, two trials were reported in women with a prior history of preterm birth. The first study Fonseca et al. (395) randomized 142 women with risk factors for preterm birth to receive 100 mg vaginal progesterone or placebo between 24 and 34 weeks of gestation (395). In this trial, the rate of preterm delivery at both <37 and <34 weeks was significantly lower in women allocated to progesterone treatment than to placebo [<37 weeks, progesterone 13.8% (10/72) vs. placebo 28.5% (20/70), $p = 0.03$; and <34 weeks, progesterone 2.8% (2/72) vs. placebo 18.6% (13/70), $p = 0.002$].

Another trial (by Meis et al.) (394) evaluated the use of weekly injections of 17 alpha-hydroxyprogesterone caproate (250 mg IM between 16 and 36 weeks, $n=310$; and placebo, $n = 153$) in women with a prior preterm birth. The authors reported a reduction in the rate of preterm birth before 37 (36.3% vs. 54.9%, RR 0.66, 95% CI 0.54–0.81) and 35 (20.6% vs. 30.7%, RR 0.67, 95% CI 0.48–0.93) weeks of gestation.

The largest randomized clinical trial in which patients with a history of a previous spontaneous preterm delivery were allocated to receive vaginal progesterone (90 mg/day) in a bioadhesive formulation/gel or placebo was conducted by O'Brien et al. (396) The primary endpoint for the trial was preterm delivery (≤ 32 weeks). All patients had transvaginal sonography to determine the cervical length at enrollment and at 28 weeks. Randomization-to-delivery interval in patients who received tocolytic therapy for preterm labor or shortening of the cervix was considered a secondary outcome.

This multinational trial involved 53 centers and 659 women with a singleton pregnancy who were randomized, between 18 and 22 completed weeks of gestation, to receive daily treatment with vaginal progesterone gel or placebo (396). Progesterone or placebo was self-administered either until delivery, 37 weeks of gestation, or the occurrence of premature rupture of membranes. Vaginal progesterone did not reduce the rate of preterm birth at ≤ 32 , ≤ 35 , or ≤ 37 weeks of gestation. Moreover, there was no difference in neonatal and maternal outcomes. The results of this study conflict with those of the initial trial reported by Fonseca et al. (395).

The Use of Progestogens to Prevent Preterm Birth in Multiple Gestations

Multiple gestation is a risk factor for preterm birth (369,474–486). Uterine overdistention has been implicated as a mechanism responsible for the excess rate of preterm labor in this subset of patients (22,487,488). Progesterone down-regulates the expression of contraction-associated proteins (113–115,489–491); therefore, it is possible that progestogens may reduce the rate of preterm birth in multiple gestations. Consequently, investigators have tested whether progestogens can prevent preterm birth in these pregnancies (397,466,468).

More than 25 years ago, Hartikainen-Sorri et al. (466) reported a double-blind, placebo-controlled clinical trial of 17 alpha-hydroxyprogesterone caproate administration in 77 women with twin pregnancies enrolled between 28 and 33 weeks of gestation. Weekly intramuscular injection of 250 mg of 17 alpha-hydroxyprogesterone caproate or placebo were initiated at the time of enrollment and discontinued at 37 weeks of gestation or when delivery

occurred before term. The administration of 17 alpha-hydroxyprogesterone caproate did not reduce the rate of preterm birth (<37 weeks) or perinatal morbidity.

The issue has been revisited recently. Rouse et al. (468) reported a multicenter, placebo-controlled, double-blind, randomized clinical trial of 17 alpha-hydroxyprogesterone caproate for prevention of preterm birth in twin pregnancies, which included 655 women enrolled between 16 and 20 completed weeks of gestation. Patients were allocated to receive weekly injection of 250 mg of 17 alpha-hydroxyprogesterone caproate or placebo until 34 completed weeks of gestation or delivery. The primary outcome was a composite of fetal death or delivery before 35 completed weeks of gestation, which occurred in 41.5% (135/325) of patients in the 17 alpha-hydroxyprogesterone caproate group and in 37.3% (123/330) of those in the placebo group [RR 1.1 (95% CI 0.9–1.3)]. No benefit to the use of 17 alpha-hydroxyprogesterone caproate was demonstrated in twins.

In a sub-analysis of their randomized trial of vaginal progesterone versus placebo in 24 women with twin gestations and a short cervix (≤ 15 mm), Fonseca et al. (397) reported that progesterone administration was associated with a non-significant reduction in the rate of preterm delivery.

Norman et al. (492) reported the results of a randomized clinical trial of vaginal progesterone in 500 women with twin gestations. The use of vaginal progesterone beginning at 24 weeks of gestation was not associated with a reduction in the risk of preterm delivery before 34 weeks of gestation. Collectively, the results of these studies indicate that prophylactic progesterone administration does not reduce the rate of preterm delivery in women with twin pregnancies.

Recently, Caritis et al. (493) reported that the use of 17 alpha-hydroxyprogesterone caproate in triplet gestations did not reduce the rate of preterm delivery.

Sonographic Cervical Length to Identify the Patients who may Benefit from Progesterone Treatment

Facchinetti et al. (494) reported the results of a randomized prospective clinical trial in which women with preterm labor and intact membranes (25 to 33–6/7 weeks) were allocated to either observation or intramuscular administration of 341 mg of 17 alpha-hydroxyprogesterone caproate twice a week until 36 weeks of gestation or delivery, and sonographic cervical length measured at discharge as well as at 7 (7–9) and 21 (18–21) days later. Patients allocated to receive 17 alpha-hydroxyprogesterone caproate had a longer sonographic cervical length than those in the observation group. These findings, coupled with experimental data, suggest that progesterone may have major effects in the uterine cervix.

Two clinical lines of evidence support that cervical status may identify the patient who could benefit from progestogen administration (397,495). First, a recent randomized clinical trial reported by Fonseca et al. (397) indicates that vaginal progesterone reduces the rate of preterm birth by 44% (from 34.4% in the placebo group to 19.2% in the progesterone treatment group) in women with a sonographic short cervix. Second, a secondary analysis of a study by DeFranco et al. (495) suggests that patients with a short cervix may benefit from vaginal progesterone administration.

Fonseca et al. (397), working with the Fetal Medicine Foundation Second Trimester Screening Group, conducted a randomized, double blind, placebo-controlled trial in which women with a short cervix (≤ 15 mm by transvaginal ultrasound), between 20 and 25 weeks of gestation, were allocated to daily vaginal administration of 200 mg of micronized progesterone or placebo (safflower oil) from 24 to 34 weeks. The frequency of spontaneous preterm delivery at < 34 weeks (primary endpoint for the trial) was significantly lower in the progesterone group than that in the placebo group [19.2% (24/125) vs. 34.4% (43/125); $p = 0.007$]. A secondary analysis of this trial indicated that among women without a history of delivery before 34 weeks, the incidence of preterm birth was significantly lower in women receiving progesterone than in those allocated to placebo [17.9% (20/112) vs. 31.2% (34/109); RR 0.57, 95% CI 0.35–0.93; $p = 0.03$]. The trial was not designed to test whether progesterone administration could reduce neonatal morbidity and such a reduction was not observed (397).

DeFranco et al. (495) reported a retrospective analysis of the effect of vaginal progesterone on pregnancy outcome (preterm birth and infant outcome) as a function of cervical length. The hypothesis for this study was that the effect of prophylactic vaginal progesterone may vary according to cervical length. To test this concept, all patients eligible to participate in the trial of O'Brien et al. (396) had a sonographic measurement of the cervix at the time of enrollment. Patients without a previous preterm birth and a cervical length of ≤ 25 mm were subjected to a separate randomization procedure (to vaginal progesterone or placebo) and excluded from the main trial. The rationale for this was that the main trial tested the effect of vaginal progesterone on patients with a history of preterm delivery regardless of cervical length. However, after the completion of the main trial, only nine patients had been enrolled in the "short cervix only" arm of the trial. Analysis of the effect of progesterone on nine patients with a short cervix was not meaningful. Therefore, the investigators modified their initial plan so that the analysis included women enrolled in the main trial (and therefore, with a history of previous preterm birth). The authors divided the patient population into quartiles according to cervical length at enrollment and tested whether outcomes were different as a function of cervical length (the lowest quartile was a cervical length of ≤ 32 mm). Although there was a delay in delivery, progesterone administration did not result in a significant difference in outcome in patients in the lowest quartile.

The authors (495) then explored the effect of vaginal progesterone as a function of cervical length using two new cut-offs: ≤ 30 and < 28 mm. For the cut-off of 30 mm, there was a trend for a longer randomization-to-delivery interval in women allocated to progesterone than those allocated to placebo (Wilcoxon $p = 0.043$, log-rank $p = 0.057$) (432). However, there was no difference in the frequency of preterm delivery at ≤ 32 weeks.

With the second cut-off (< 28 mm), patients who had received vaginal progesterone had a lower rate of spontaneous preterm delivery at ≤ 32 weeks of gestation. Though this was not observed for preterm delivery defined as ≤ 35 weeks or ≤ 37 weeks. It is noteworthy that the frequency of newborn intensive care unit admission was lower in women with a

cervical length of ≤ 30 and < 28 mm and who had received progesterone treatment than in those allocated to the placebo group. The same was the case for the duration of newborn intensive care unit length of stay (495). This analysis provided the first hint that vaginal progesterone administration may improve infant outcome in properly selected patients. It is important to stress, however, that these conclusions were derived from a secondary analysis that was intended to be hypothesis-generating (496).

Hassan et al. (497) conducted a multicenter, randomized, placebo-controlled trial that enrolled 465 asymptomatic women with a singleton pregnancy and a sonographic short cervix (10–20 mm) at 19 to 23-6/7 weeks of gestation. Women were randomly allocated to receive vaginal progesterone gel ($n = 235$) or placebo ($n = 223$) daily from 20 to 23-6/7 weeks to 36-6/7 weeks, preterm rupture of membranes, or delivery, whichever occurred first. The primary endpoint was preterm birth before 33 weeks of gestation. Women allocated to receive vaginal progesterone had a lower risk of preterm birth before 33 weeks than those allocated to placebo [8.9% ($n = 21$) vs. 16.1% ($n = 36$), relative risk (RR) 0.55, 95% confidence interval (CI) 0.33–0.92, $p = 0.02$]. The effect remained significant after adjustment for co-variables (adjusted RR 0.52, 95% CI 0.31–0.91, $p = 0.02$). Vaginal progesterone was also associated with a significant reduction in the risk of preterm birth before 28 (5.1% vs. 10.3%, RR 0.50, 95% CI 0.25–0.97, $p = 0.04$) and 35 weeks (14.5% vs. 23.3% RR 0.62, 95% CI 0.42–0.92, $p = 0.02$), respiratory distress syndrome (3.0% vs. 7.6% RR 0.39, 95% CI 0.17–0.92, $p = 0.03$), any morbidity or mortality event (7.7% vs. 13.5% RR 0.57, 95% CI 0.33–0.99, $p = 0.04$), and birth weight < 1500 g [6.4% (15/234) vs. 13.6% (30/220), RR 0.47, 95% CI 0.26–0.85, $p = 0.01$]. There were no differences in the incidence of adverse events between the groups. The conclusion of this study was that the administration of vaginal progesterone gel to women with a sonographic short cervix in the midtrimester is associated with a 45% reduction in the risk of preterm birth before 33 weeks of gestation and improved neonatal outcomes.

In conclusion, patients with a previous history of spontaneous preterm delivery can be offered 17 alpha-hydroxyprogesterone caproate for the prevention of recurrent preterm delivery (394). It is important to counsel the patients following the determinations of the FDA indicating that this agent reduces the risk of preterm birth in subsequent pregnancies (394), but there is no solid evidence of improvement in neonatal outcome (394). Patients should also be counseled about the safety signal identified by the FDA, namely, a potential increase in the risk of pregnancy loss in the midtrimester (498).

Patients with a short cervix (10–20 mm) should be offered vaginal progesterone for the prevention of preterm birth and improvement in infant outcome. The approach of universal screening with transvaginal cervical length in the midtrimester followed by the use of vaginal progesterone appears to be cost-effective and allows the prevention of preterm delivery in nulliparous women (497,499,500).

Mode of Delivery

Preterm birth per se is not an indication for cesarean delivery. In the last two decades, there has been an interest in determining whether cesarean delivery could improve the

outcome of preterm birth. Efforts to conduct randomized clinical trials have not been effective in enrolling patients. Grant et al. (501), while conducting a systematic review of six trials of elective versus selective cesarean delivery, for infants less than 30 weeks of gestation, emphasized the difficulties in the execution of the trial and recommended that decision making should be individualized taking into account par-enteral preferences.

Therefore, cesarean delivery is currently performed for obstetrical indications, such as breech presentation, and fetal distress. The performance of a cesarean section in an early preterm gestation (<30 weeks) is often associated with an incision in the uterine corpus, because the lower uterine segment is not formed. This would increase the risk of uterine rupture in subsequent pregnancies, as well as complications associated with implantation of the placenta on the uterine scar (502). There is little evidence that the fetus may benefit from cesarean delivery and, therefore, the increased maternal risk for subsequent pregnancies does not appear to be justified.

In terms of the management of a vaginal delivery, some evidence suggests that delivery with intact membranes may improve umbilical artery pH by reducing the effect of mechanical forces on the fetus and umbilical cord. There is little evidence that the performance of a "prophylactic" outlet forceps or "elective" episiotomy improves neonatal outcome. Vacuum extraction is considered to be contraindicated in preterm neonates.

Timing of clamping of the cord deserves consideration. Randomized clinical trials of delayed versus early cord clamping indicate that delayed clamping is associated with a reduction in the need for transfusions of the infant for anemia (RR 2.01, 95% CI 1.24–3.27), neonatal hypotension (RR 2.58, 95% CI 1.17–5.67), and IVH (RR 1.74, 95% CI 1.08–2.81) (503).

SUMMARY

It is becoming increasingly clear that preterm labor, preterm PROM, and cervical insufficiency are syndromes caused by multiple pathologic processes leading to increased myometrial contractility, cervical remodeling, and/or membrane activation. The clinical presentation will depend upon the nature and timing of the insults on the various components of the common pathway of parturition. This view has important implications for the understanding of the biology of preterm parturition, as well as its diagnosis, treatment, and prevention.

INTRODUCTION

Prelabor rupture of the membranes (PROM) is rupture of the chorioamniotic membranes before the onset of labor (1). The “latency period” is the interval between PROM and the onset of labor. There is no agreement about the length of the interval between the rupture of the membranes and the onset of labor required to diagnose PROM. This period of time has varied between 1 and 12 hours in the literature (2–9). The consequences of PROM depend on gestational age; therefore, this condition has been classified as “preterm PROM” or “term PROM,” depending upon whether the event occurs before or after 37 weeks of gestation (2–12). The term “previable PROM” has been applied to gestations in which this complication occurs before 23 weeks (12), while “preterm PROM remote from term” refers to the time frame between viability and about 32 weeks, and “PROM near term” is that which occurs between 32 and 36 weeks (12).

FREQUENCY, TIMING, AND SITE OF MEMBRANE RUPTURE

Frequency

Term PROM occurs in approximately 10% of patients, while the frequency of preterm PROM is 2% to 3.5% (5,13–17). Preterm PROM accounts for 30% to 40% of preterm deliveries and, therefore, is a leading clinically identifiable cause of preterm birth and a major contributor to perinatal morbidity and mortality (2,5,13,14,16–19). It has been estimated that in the United States, approximately 150,000 women are diagnosed with preterm PROM every year (20).

Spontaneous Rupture of Membranes in Normal Pregnancy

Figure 1 shows the proportion of women with spontaneous rupture of membranes as a function of cervical dilatation (21). Most patients rupture the chorioamniotic membranes at the end of the first stage of labor, hence the rationale for defining PROM as rupture of membranes before the onset of labor.

The site of rupture is generally located in the most dependent part of the uterine cavity in close proximity to the cervix (22). After invasive procedures such as fetoscopy, rupture of membranes can occur away from the cervix. The frequency with which spontaneous rupture of membranes occurs away from the most dependent part of the uterus (high leak) is unknown.

PRETERM PROM AS AN OBSTETRICAL SYNDROME

The current taxonomy of disease in obstetrics is largely based on the clinical presentation of the mother and not the mechanism responsible for disease. For example, the term “rupture of membranes” refers to a clinical condition in which amniotic fluid leaks from the amniotic cavity into the lower genital tract. However, the term ROM does not provide information about the cause (e.g., infection, a vascular insult, a weakness in the structure of the membranes, trauma caused by an invasive procedure [endoscopy], or other mechanisms of disease). We have proposed that the classification of diseases in obstetrics is at a stage in which we recognize syndromes caused by multiple mechanisms (23). The features of these obstetrical syndromes are (i) multiple etiologies, (ii) a long subclinical phase, (iii) frequent fetal involvement, (iv) adaptive clinical manifestations, and (v) predisposition due to gene–environment interaction (24).

Preterm PROM is one of the “great obstetrical syndromes” (23). Multiple pathologic processes can lead to preterm PROM. The chronic nature of the pathologic process leading to preterm PROM can be inferred from the observations that women with a short cervix (<25 mm) in the midtrimester (25), a positive fetal fibronectin (FFN) in vaginal fluid (25), bacterial vaginosis (BV) (25), and bleeding in the first and second trimesters of pregnancy (25–27) are at risk for the subsequent development of preterm PROM. Fetal involvement has been demonstrated, as 10% of all fetuses with preterm PROM have evidence of fetal bacteremia demonstrated by cordocentesis (28). We have proposed that PROM is not the result of an accident, but rather a mechanism of host defense in the context of intrauterine infection (or other insults), and that spontaneous rupture of membranes occurs to facilitate the drainage of an infected cavity (intra-amniotic infection), as well as to initiate labor (amniotomy is often followed by the onset of labor in term or preterm gestation). Therefore, rupture of membranes may be considered adaptive in nature. Other mechanisms of disease, such as chronic chorioamnionitis, in which there is infiltration of the chorion laeve with lymphocytes but no evidence of infection, represent another potential mechanism for preterm PROM (29). The underlying mechanism of disease appears to be immune in nature: maternal rejection of the fetal allograft. Fetuses born to mothers whose placentas are affected with chronic chorioamnionitis have evidence of a fetal inflammatory response syndrome (FIRS). We propose that the

This work is based on several chapters that were published previously by the authors in other textbooks. This work has been modified and adapted for this textbook. The original chapters are referenced and contain a more extensive discussion of the subject. This chapter has a clinical emphasis. The work has been primarily done by Roberto Romero, who is a government employee, and therefore, is not subject to copyright.

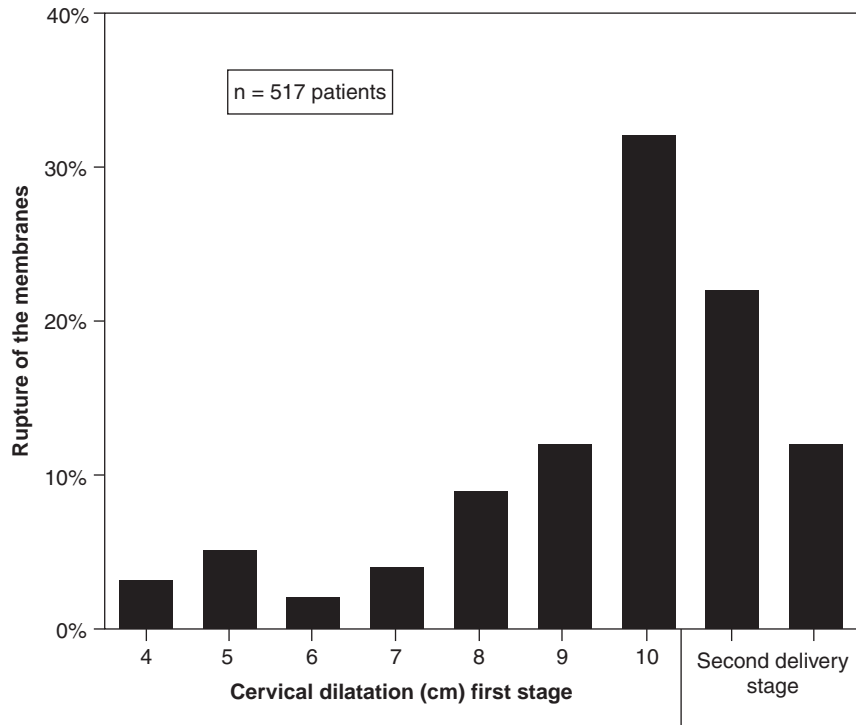

Figure 1 Rupture of membranes as a function of cervical dilatation and stage of labor. Percentage distribution for 517 normal spontaneous deliveries without medication or maneuvers; vertex presentation. Source: From Ref. 21.

initiation of labor in these cases is the result of a combination of a fetal inflammatory response and the maternal damage of chorion laeve by the lymphocytes and natural killer cells, which are capable of inducing apoptosis of the trophoblast (29). In this context, rupture of membranes and the initiation of labor may also be adaptive in nature because the fetus is in a hostile environment unrelated to infection.

Finally, there is evidence that genetic factors predispose to preterm PROM. Polymorphisms for genes coding for MMP-1 (30), MMP-9 (31), MMP-8 (32), and SERPINH1 (33) in the fetus have been associated with spontaneous rupture of membranes in case-control studies. Environmental factors, such as BV (25,34) or a pro-inflammatory vaginal milieu (35), have also been associated with PROM. Evidence for a gene–environment interaction for preterm birth has been demonstrated between BV and a polymorphism for the pro-inflammatory cytokine, TNF- α (36,37). It is also possible that gene–gene interactions are operative. The genetic predisposition for preterm PROM is likely to result from the effect of multiple alleles, which individually confer a small risk for preterm PROM. Epigenetic changes in MMP-1 have been found to be associated with preterm PROM (38). Collectively, the evidence reviewed above supports the concept that preterm PROM is not a single condition, but one of the “great obstetrical syndromes.”

Mechanisms of Disease Implicated in Preterm PROM

1. *Intra-amniotic infection/inflammation*: Preterm PROM is associated with positive amniotic fluid cultures for bacteria at the time of admission in approximately 30% of cases (39). With the use of molecular techniques, about 50% of cases have microbial footprints in the amniotic cavity at the time of admission (40). However, intra-amniotic infection can be a

primary cause of PROM or a consequence of the rupture of membranes. There is evidence that infection precedes preterm PROM in a fraction of cases. In a study in which amniotic fluid cultures for microorganisms (41–43) and pro-inflammatory cytokines (44) were measured in the amniotic fluid of women undergoing midtrimester amniocentesis, some women with positive cultures or elevated biomarkers of inflammation subsequently developed preterm PROM (41–43).

2. *Vascular pathology*: In a study examining histologic lesions of the placenta, Arias et al. found that women who delivered with preterm PROM fell, in general terms, into two subgroups: those with acute histologic chorioamnionitis and those with vascular lesions of the placenta (45). Some patients have both types of lesions (46). The vascular lesions observed include “failure of physiologic transformation of the spiral arteries” (47,48), atherosclerosis, fibrinoid necrosis of the decidual vessels, and decidual vessel thrombosis consistent with decidual vasculopathy (49). Vaginal bleeding during pregnancy is a risk factor for preterm PROM (50). We have proposed that some patients who bleed in the first or second trimester of pregnancy have a disorder of decidual hemostasis (50). Vaginal bleeding may predispose to membrane rupture by causing a separation between the chorioamnion and the decidua, which weakens the fetal membranes (50). Alternatively, during the formation of a retroplacental clot, thrombin is generated (51). This enzyme can stimulate the production of MMP-1 (52) and MMP-3 (51) by decidual cells in culture media of chorioamniotic membranes (53). These MMPs can degrade fibrillar collagen (types I and III) and other components of the extracellular matrix of the chorioamniotic membranes (54). The mechanisms responsible for defective decidual hemostasis during pregnancy have not been identified. It is possible that vascular disease leading to microthrombosis in the decidua leads to local necrosis and bleeding.

Table 1 Risk Factors Associated with Preterm PROM (at Less Than 35 weeks) Stratified by Parity (25)

Risk factor	Nulliparous		Multiparous	
	Odds ratio	95% confidence interval	Odds ratio	95% confidence interval
Cervical length ≤ 25 mm	9.9	3.8–25.9	4.2	2.0–8.9
Previous preterm birth with preterm PROM	–	–	4.1	2.0–8.7
Previous preterm labor with intact membranes	–	–	2.6	1.2–5.3
Working during pregnancy	5.3	1.5–18.7	n.s.	n.s.
Medical complications	4.2	1.1–16.0	n.s.	n.s.
FFN (+)	n.s.	n.s.	n.s.	n.s.
BV	n.s.	n.s.	n.s.	n.s.
FFN (+) and absent BV	n.s.	n.s.	9.0	3.6–22.5
FFN (–) and present BV	n.s.	n.s.	2.8	1.2–6.3

Abbreviations: FFN, fetal fibronectin; BV, bacterial vaginosis; n.s., non-significant. Source: From Ref. 25.

In some cases, vaginal bleeding will be the only clinical manifestation of intrauterine infection (50). This association is important because women with preterm PROM often have clinical or subclinical abruptions, and histologic examination of the membranes indicates that acute chorioamnionitis is frequent in patients with abruption (55).

3. *Uterine cervical pathology*: Women who had surgery in the lower genital tract, such as cervical conization (56,57) or previous spontaneous abortions (58), are at greater risk for preterm PROM. Buchmayer et al. reported that a history of two or more spontaneous abortions was associated with an odds ratio of 4.1 (95% CI: 2.2–7.8) for preterm PROM (58). We propose that some degree of cervical insufficiency (e.g., a short cervix resulting in an inadequate mucous plug) predisposes to ascending intrauterine infection (59,60). This hypothesis would explain the link between a short cervix and subsequent preterm PROM (25). It is noteworthy that a cervical length <25 mm confers an increased risk for preterm PROM before 35 weeks of gestation in nulliparas (OR: 9.9) as well as in multiparas (OR: 4.2) (25).

4. *Acquired or congenital connective tissue disorders*: There is evidence that a connective tissue disorder, which can affect the membranes (the chorioamniotic membranes are fetal tissue), may predispose to preterm PROM. For example, patients with Ehlers–Danlos syndrome are at increased risk for preterm PROM if they carry an affected fetus (61). However, the attributable risk of Mendelian disorders for preterm PROM is extremely low. It is likely that a genetic predisposition to preterm PROM can be due to the effect of multiple genes. Indeed, a relationship between polymorphisms in the promoter region of genes encoding for MMPs may also predispose to membrane rupture (MMP-1 (30), MMP-8 (32), MMP-9 (31), and SERPINH1 (33)). Polymorphisms may confer a mild to moderate risk, but this risk may be increased in patients who have a relative deficiency of vitamin C (environmental contribution).

CLINICAL RISK FACTORS FOR MEMBRANE RUPTURE

Harger et al. reported a comprehensive analysis of risk factors associated with preterm PROM in 341 women with preterm PROM (20–36 weeks) and 253 controls matched for maternal age, gestational age, parity, type of care (private vs. clinic), and previous vaginal or cesarean delivery (62). Three factors associated with preterm PROM were identified: (i) previous

preterm delivery, (ii) vaginal bleeding during the index pregnancy, and (iii) cigarette smoking. Similar findings have been reported in a case-control study of 138 patients with preterm PROM and 267 controls (63). Vaginal bleeding, smoking, and low socioeconomic class were also found to be independent risk factors for preterm PROM.

In a large, multicenter, observational cohort study, Mercer et al. reported the risk factors for preterm PROM (less than 35 weeks), stratified according to parity (Table 1) (25). In conclusion, vaginal bleeding, a short cervix (<25 mm), a history of previous spontaneous preterm delivery (with intact or ruptured membranes), and smoking are risk factors for preterm PROM in the index pregnancy. A history of preterm birth with preterm PROM in a previous pregnancy confers a high risk for recurrence (approximately 20%) (56).

CLINICAL CONSEQUENCES OF PREMATURE RUPTURE OF THE MEMBRANES

Preterm Parturition

Preterm PROM is followed by the onset of labor and delivery within a week in the majority of cases. The duration of the latency period is inversely related to the gestational age. The lower the gestational age, the longer the latency period (64–66). Cox et al. described the natural history of preterm PROM in 298 patients managed expectantly without the use of steroids, tocolytics or prophylactic antibiotics (64). Of the 267 patients who gave birth to infants weighing ≥ 750 g, only 7% remained undelivered for more than 48 hours after admission.

Wilson et al. reported the outcome of 143 patients with preterm PROM managed expectantly; only 18% of patients remained undelivered 1 week after admission (65). Maternal febrile infectious morbidity (antepartum and postpartum) occurred in 10% of patients, and the neonatal death rate was 13.1%.

The most comprehensive study of the natural history of preterm PROM was reported by Nelson et al., who evaluated the outcome following expectant management of 511 women with a singleton gestation and preterm PROM between 20 and 36 weeks (66). Fifty-two percent of patients delivered within 48 hours, while 12.9% remained undelivered after 1 week. The perinatal death rate was 8.4%. Not surprisingly, most deaths occurred at gestational ages of less than 28 weeks (42.7%). Maternal infection occurred in 21.7%, and the

occurrence of fetal death was strongly associated with infection. The perinatal mortality was higher in neonates born to infected mothers with preterm PROM before 28 weeks than after 28 weeks (46.6% vs. 1.2%), as was infection-related morbidity (36% vs. 19.8%).

Infection

Rupture of the membranes is strongly associated with maternal or fetal infection. Maternal infection can be expressed as clinical chorioamnionitis. However, most women who have microbial invasion of the amniotic cavity (MIAC) do not have evidence of infection (67), such as fever, leukocytosis, etc. Indeed, in our experience, only 20% of patients with preterm PROM and a positive amniotic fluid culture for bacteria have clinical evidence of chorioamnionitis (68).

The prevalence of positive amniotic fluid cultures in women with preterm PROM is 32.4% (39), whereas in term PROM, the prevalence is 34.3% (69). However, this represents a minimum estimate of the frequency of infection, because the frequency is dependent upon the isolation of microorganisms with standard microbiologic techniques, which underestimate the true rate of infection. The application of molecular microbiologic techniques (cultivation independent) has yielded a higher rate of microbial footprints (50%) (40). Patients who have a positive PCR result for microorganisms, but a negative culture, have comparable outcomes with those who have a positive amniotic fluid culture for microorganisms (70).

Genital mycoplasmas (*Ureaplasma urealyticum* and *Mycoplasma hominis*) are the most frequent isolates from the amniotic fluid, followed by *Streptococcus agalactiae*, *Fusobacterium* species, and *Gardnerella vaginalis*. Polymicrobial infection is found in 26.7% of cases (28,68,71–75) and an inoculum size greater than 10^5 colony-forming units per milliliter is found in 23% of patients (75). The most common microorganisms isolated from women with term PROM are *U. urealyticum*, *Peptostreptococcus*, *Lactobacillus*, *Bacteroides* species, and *Fusobacterium* (69).

Patients with intra-amniotic infection are more likely to develop chorioamnionitis, endometritis, and neonatal sepsis than patients with negative amniotic fluid cultures on admission (28,68,71–86). The frequency of respiratory distress syndrome (RDS) is twofold higher in neonates born to women with positive amniotic fluid cultures than in those born to women with negative cultures (80).

One study has examined the relationship between MIAC and the onset of preterm labor in women with PROM (68). Patients in labor on admission had a higher rate of positive amniotic fluid cultures than women admitted with preterm PROM who were not in labor (39% vs. 26%, $p = 0.049$). Moreover, 75% of patients who were not in labor on admission, but subsequently went into spontaneous labor, had a positive amniotic fluid culture around the time of the onset of labor.

Zlatnik et al. conducted a unique study in which the results of amniotic fluid culture were not used in patient management. A higher proportion of patients with positive amniotic fluid cultures delivered within 7 days, as compared with those with negative cultures (positive cultures: 89% vs. negative cultures: 45%, $p = 0.04$) (75). These data support a relationship between MIAC and the onset of preterm labor.

Can routine antibiotic administration eradicate intra-amniotic infection and prevent secondary infection? A recent study investigated the course of MIAC in 46 patients with preterm PROM (87). All underwent amniocentesis upon admission, with an 18% prevalence of intra-amniotic inflammation (defined as an amniotic fluid white blood cell (WBC) count $\geq 100/\text{mm}^3$) and a 15% prevalence of MIAC. Patients without evidence of intra-amniotic inflammation or MIAC were treated with ampicillin and erythromycin for 7 days. Those with intra-amniotic inflammation or MIAC were treated with ceftriaxone, clindamycin, and erythromycin for 10–14 days. At the time of the second amniocentesis, six of the seven patients with a prior diagnosis of MIAC were again positive for microorganisms. Of 18 patients with intra-amniotic inflammation, only 3 showed no evidence of inflammation after antibiotic treatment. Of note, among patients with no evidence of intra-amniotic inflammation or MIAC at admission, 32% developed inflammation despite therapy. Five of the nine patients in question had positive amniotic fluid cultures. These observations suggest that systemic treatment with these antibiotics may not alter the natural course of intra-amniotic infection in preterm PROM.

Evidence that fetal infection (bacteremia) is frequently present in preterm PROM was provided by Carroll et al., who performed amniocentesis and cordocentesis at the time of presentation with PROM (88). The frequency of positive fetal blood culture was 15%. The authors found that for patients with positive amniotic fluid and fetal blood cultures, the median time to delivery was 2 days (range: 1–5), compared with 41 days (range: 1–161) for patients with negative cultures in both amniotic fluid and fetal blood. In the case of patients with MIAC and negative fetal blood cultures, the median interval to delivery was 9 days (range: 1–37) (88).

The microorganisms isolated from septic newborns are similar to those found in the amniotic fluid. In a study of 221 patients with preterm PROM, 6 cases with culture-proven neonatal sepsis were found (68). In five of these cases, the microorganisms were the same as those found in the amniotic fluid; in the remaining case, the amniotic fluid culture 48 hours before delivery had been negative (68). The practical implication of this observation is that an amniocentesis performed before delivery may provide microbiologic information helpful in guiding antibiotic choice for the newborn.

Fetuses with preterm PROM can mount a systemic inflammatory response (89). The term “fetal inflammatory response syndrome” refers to an elevation in the fetal plasma concentration of IL-6 (>11 pg/mL) that was associated with severe neonatal morbidity (89) and a shorter cordocentesis-to-delivery interval (90).

Fetal microbial invasion or other insults result in a systemic inflammatory response that can progress toward multiple organ dysfunction, septic shock, and perhaps death in the absence of timely delivery. Evidence of multisystemic involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9 (91), an enzyme involved in the digestion of type IV collagen and in the pathophysiology of preterm PROM (92). Moreover, several fetal organs including the hematopoietic system (93–95), adrenals (96), heart (97), brain (98,99), lungs (100,101), and skin (102) are target organs during FIRS.

Pathologic examination of the umbilical cord is an easy approach to determine whether fetal inflammation was present before birth. Funisitis and chorionic vasculitis are the histopathologic hallmarks of FIRS (103). Funisitis is associated with endothelial activation, a key mechanism in the development of organ damage (104), and neonates with funisitis are at increased risk for neonatal sepsis (105) and long-term complications, such as bronchopulmonary dysplasia (BPD) (99) and cerebral palsy (101). Indeed, newborns with funisitis are at more than a twofold increased risk for intraventricular hemorrhage (IVH) (106) and have an 11-fold risk for the development of periventricular echolucencies (107). In the context of FIRS, the combination of inflammatory changes in the brain and fetal systemic hypotension may increase the likelihood of brain injury (108). Collectively, these observations suggest that a subset of fetuses presenting with preterm PROM have bacteremia and/or FIRS that may contribute to fetal organ damage.

The traditional view has been that MIAC is the consequence of membrane rupture. However, evidence suggests that PROM may be the result of subclinical infection and inflammation. Naeye and Peters reported in 1980 that patients with preterm PROM 1 to 4 hours before the onset of labor had a higher prevalence of histologic chorioamnionitis than patients who delivered preterm without PROM (109). Because it is unlikely that inflammation of the chorioamniotic membranes develops in 4 hours, these data suggest that, in these cases, histologic chorioamnionitis precedes rather than follows PROM. Several lines of evidence suggest that the most likely cause of histologic chorioamnionitis is subclinical infection. Bacteria have been recovered from 72% of placentas with histologic chorioamnionitis (110). Furthermore, we have demonstrated a good correlation between a positive amniotic fluid culture for microorganisms and histologic chorioamnionitis (111).

MIAC can also be the consequence of PROM. The frequency of positive amniotic fluid cultures increases with time. Indeed, 75% of patients who were quiescent on admission and subsequently went into labor had a positive amniotic fluid culture (68). Only 25% of these patients, however, had a positive culture on admission, and the remaining 50% became positive during the latency period (68). These observations are consistent with those of Naeye and Peters, who showed that the incidence of histologic chorioamnionitis increases with the duration of the latency period (109). In addition, the authors reported that histologic chorioamnionitis (defined as the presence of 4–15 neutrophils in the chorionic plate) in PROM was two- to threefold more common when rupture of membranes occurred just before the onset of labor than when it occurred after labor began (109). This suggests that inflammation (and probably infection) is, in many cases, not only a consequence of PROM, but also its cause.

Abruptio Placentae

Abruptio placentae occurs more frequently in patients with preterm PROM than in those with preterm labor and intact membranes (2.29% vs. 0.86%, respectively, RR: 3.58, 95% CI: 1.74–7.39) (112). The same conclusion was reported in a systematic review (113) and a population-based epidemiologic study (114). Nelson et al. proposed that leakage of fluid after

PROM may lead to a disproportion between the placental and uterine surfaces that would favor placental separation (115). In the context of preterm PROM, the incidence of abruptio placentae increases with the severity of oligohydramnios (12.3% for patients with a vertical pocket of 1–2 cm vs. 3.5% among those with a vertical pocket > 2 cm) (116). However, two groups of investigators using subjective means to estimate amniotic fluid volume could not confirm this observation (117,118).

An alternative hypothesis to explain the relationship between abruptio placentae and preterm PROM postulates that a disorder of decidual hemostasis leads to separation of the membranes from the decidua, with subsequent compromise of their nutritive support, weakening of the membranes, and eventual rupture. Indeed, patients with abruptio placentae after preterm PROM have a higher incidence of vaginal bleeding before rupture and during the latency period than patients without abruptio placentae.

Infection/inflammation within the decidua could also facilitate premature placental detachment. Indeed, there is an association between histologic chorioamnionitis and abruptio placentae (55,119). The relative risk for abruption is 9.03 (95% CI: 2.80–29.15) when chorioamnionitis is associated with preterm PROM (112).

Pulmonary Hypoplasia

The frequency of pulmonary hypoplasia is related to gestational age at the time of membrane rupture, and its presence increases the risk of neonatal death and other complications such as pneumothorax and persistent pulmonary hypertension.

Three studies examined the frequency of pulmonary hypoplasia in the context of preterm PROM. Vergani et al. conducted a prospective study of patients with PROM before 28 weeks of gestation managed conservatively and found that the frequency of pulmonary hypoplasia was 28% (120). Gestational age at the time of PROM and presence of oligohydramnios, but not the latency period, were independent predictors of pulmonary hypoplasia (120).

Rotschild et al. studied 88 neonates born to mothers with PROM occurring before 29 weeks and a latency period of at least 1 week (121). The prevalence of pulmonary hypoplasia was 16%. Gestational age at the time of PROM, but not the duration of the latency period or the severity of oligohydramnios, was associated with pulmonary hypoplasia. The risk of pulmonary hypoplasia when PROM occurs at 19 weeks was 50%, whereas it was only 10% when the membranes ruptured at 25 weeks.

Winn et al. prospectively studied 163 patients with preterm PROM from 15 to 28 weeks of gestation (122). The incidence of pulmonary hypoplasia was 12.9%. The authors reported that gestational age at rupture of the membranes, latency period, and either the initial or the average amniotic fluid index (AFI) had significant influence on the development of pulmonary hypoplasia.

The role of duration of rupture of membranes in the development of pulmonary hypoplasia is not clear. Univariate analysis demonstrated an association between the duration of rupture of membranes and the occurrence of pulmonary hypoplasia (120,123–125). However, there is an inverse

relationship between the duration of the latency period and the gestational age at the time of membrane rupture. Multivariate analysis has not shown a significant effect of the duration of PROM in the development of pulmonary hypoplasia (120).

Whereas Rotschild et al. (121) reported that the severity of oligohydramnios was not a factor in the development of pulmonary hypoplasia, both Vergani et al. (120) and Winn et al. (122) reported that amniotic fluid volume was an independent predictor of its development. The discrepancy between studies may be explained by the (i) determination of amniotic fluid volume, (ii) exclusion of patients, and (iii) definition of pulmonary hypoplasia.

Fetal Compression Syndrome

The fetal compression syndrome was originally described in the context of oligohydramnios and renal agenesis (126). Classically, it includes limb position deformities and craniofacial defects that are thought to result from physical compression inhibiting fetal growth and movement (127,128). Nimrod et al. reported an incidence of 12% in women with preterm PROM, most occurring when the latency period was longer than 5 weeks (124). Blott and Greenough found that 46% of infants born after prolonged membrane rupture (more than 4 weeks) had limb deformities (129). The median duration of rupture in the group with deformities was 28 days, compared with 9 days in infants without deformities.

Fetal Growth Restriction

Preterm delivery resulting from preterm labor and intact membranes or preterm PROM has been associated with “fetal growth restriction.” Most studies are cross-sectional and have not separated preterm PROM from preterm labor with intact membranes (130,131). One interesting study determined the fetal growth rate for biometric parameters in a cohort of 69 singleton pregnancies complicated with preterm PROM (24–31 weeks) and who remained undelivered for more than 14 days. The mean growth velocity of the head and abdominal circumference was significantly lower than that of the control group ($n = 345$ normal pregnancies). Neonates who had either IVH, periventricular leukomalacia (PVL), or cerebral palsy had a lower growth velocity than those not affected with these disorders (132).

Fetal Death

The rate of fetal death in preterm PROM is approximately 1% when this complication is diagnosed after 24 weeks and 15% if PROM occurs before (20). The etiology for fetal death remains unknown. Fetal infection, placental abruption, fetal growth restriction, umbilical cord prolapse, or accidents (resulting from compression in cases of severe oligohydramnios) have been implicated.

Fetal death, in the context of intrauterine infection, has been attributed to microbial invasion of the fetus, where the unborn child fails to deploy an inflammatory response which is sufficiently intense to stimulate labor. Indeed, the frequency of histologic chorioamnionitis (maternal inflammatory response) is nine times more frequent than funisitis (a fetal inflammatory response) in patients with stillbirth (133). In this case, *in utero* fetal death would represent failure of the host response mechanisms dealing with intrauterine infection.

This concept is supported by a genetic association study which demonstrated that fetal carriage of allele 2 of the gene encoding for the IL-1 receptor antagonist (IL-1ra) is associated with fetal death (134). An excess of IL-1ra in the fetal compartment may limit the ability of the fetus to deploy a pro-inflammatory response and limit the effectiveness of the mechanisms available for host defense, including the ability to initiate labor to exit a hostile intrauterine environment.

DIAGNOSIS

Presenting Symptoms

The most common presentation of PROM is a watery vaginal discharge or a sudden gush of fluid from the vagina, as reported by the patient. Obtaining information about the timing of the initial loss of vaginal fluid, color and consistency of the discharge, and any odor may help to differentiate PROM from loss of the mucous plug in early labor, vaginal discharge associated with infection, normal leukorrhea of pregnancy, and urinary incontinence (sometimes present in pregnancy), as well as to determine the presence of blood or meconium in the amniotic fluid.

Vaginal Examination

Evaluation of the patient begins with a sterile speculum examination. Visualization of a vaginal pool or obvious leakage of fluid from the cervix into the posterior fornix is considered evidence that PROM has occurred. Increasing intra-abdominal pressure may assist in the visualization of this sign. If no fluid is present in the posterior fornix, the patient can be reexamined after resting in the supine position to allow for accumulation of fluid in the posterior fornix. Additionally, a speculum examination allows for collection of vaginal and cervical cultures and amniotic fluid to assess fetal lung maturity, as well as to rule out cord prolapse.

A sterile swab of fluid should be obtained from the posterior fornix and placed on a clean glass slide and on a piece of nitrazine paper. Amniotic fluid, when put on a slide and allowed to dry, will show arborization (ferning) under the microscope at low magnification (135). This method has an overall accuracy of 95% (136). Rare false-positive ferning results have been described in association with fingerprints on the slide or contamination with semen and cervical mucus (137,138). False negatives (5–10%) may be caused by dry swabs or by contamination with blood (135,139,140). The slide should be evaluated after at least 10 minutes of drying to decrease the false-negative rate (141).

Should a digital examination of the cervix be performed in patients with preterm PROM? The traditional view has been that “once an examination has been performed, the clock of infection starts to tick.” Adoni and coworkers reported a study in which the latency period and incidence of chorioamnionitis were evaluated in patients with preterm PROM (26–34 weeks) who underwent a digital examination or a sterile speculum examination (142). The latency period was longer in patients undergoing speculum examination than in those digitally examined (9.5 days \pm 1.5 vs. 3.1 days \pm 0.5, $p < .005$). No significant difference in the incidence of chorioamnionitis was found. Lewis and associates prospectively collected data on 271 singleton pregnancies with preterm PROM (143). Patients

who underwent digital examination had shorter latency periods than those who had speculum examination (digital examination: 2.1 days \pm 4.0 vs. speculum examination: 11.3 days \pm 13.4, $p < 0.0001$).

Sukcharoen et al. performed a retrospective study in which women with preterm PROM had digital examinations or speculum examinations. The authors reported no differences in latency periods or neonatal outcomes in the study groups. However, patients who underwent digital examinations had a higher frequency of chorioamnionitis (digital exam: 12% vs. speculum exam: 3.1%, $p < 0.05$) (144).

Schutte and colleagues retrospectively examined the incidence of neonatal infection in patients with PROM according to the interval between initial digital vaginal examination and delivery (145). The incidence of neonatal infection was higher in patients examined more than 24 hours before delivery than in those whose first vaginal examination occurred less than 24 hours before delivery (33% vs. 5%, $p < 0.0001$).

The only justification for performing a digital examination is to determine cervical status. In preterm gestation, this information rarely alters clinical management, but in term gestation, the cervical state may influence decisions regarding induction. There is a strong relationship between the results of sterile speculum examination and digital examination of the cervix (146–148). This was demonstrated in a study in which visual speculum and digital cervical examinations in women in labor were performed by two separate blinded examiners within 5 minutes of each other. Visual examination underestimated actual cervical dilation by only 0.6 cm (95% CI: 0.58–0.62).

Biochemical Studies to Diagnose Rupture of Membranes

The biochemical properties of the amniotic fluid are the basis to distinguish it from other fluids that can be observed in the vagina (i.e., cervical secretions, urine, and semen). The normal pH of the vagina is 4.5 to 5.5 during gestation, and that of the amniotic fluid is 7.0 to 7.5. Nitrazine paper turns from yellow to blue when exposed to any alkaline fluid (i.e., pH of 7.0 or more) and the use of nitrazine paper has been reported to have an accuracy of 93.3% (136) to determine the presence of amniotic fluid in the vagina. False-positive results range from 1% to 17% and can result from alkaline urine, blood, semen, vaginal discharge in cases of BV, or *Trichomonas* infection (149). False negatives may occur in up to 10% of cases.

Additional biochemical tests for the diagnosis of PROM include diamine oxidase (DAO) activity (150), prolactin concentration (151–153), alpha-fetoprotein (AFP; sensitivity: 94.5% and specificity: 95.4%) (151,154), and insulin-like growth factor-binding protein-1 (IGFBP-1) (155). AFP has been reported to be better than prolactin and more practical than DAO assay with an overall accuracy of 98% (156,157). IGFBP-1 determinations have a sensitivity of 74.4% and specificity of 92.6% (155). Overall, the sensitivity, specificity, and positive and negative predictive values of the different diagnostic tests presented today in comparison with the nitrazine test are good (158–163).

The assay for FFN is useful in the identification of patients at risk for preterm and term labor and imminent delivery. However, doubts still exist about its diagnostic value in PROM (164). Eriksen reported that for the detection of term PROM,

FFN had a sensitivity of 98.2%, but a specificity of only 26.8% (165). Although the authors proposed that the false positives were the result of the detection of small amounts of amniotic fluid not detected by clinical tests (pool, nitrazine, and ferning), an alternative explanation is that a positive FFN detects degradation of the extracellular matrix in the fetal–maternal interface that precedes the clinical onset of labor rather than PROM. Support for the hypothesis derives from the observation that patients without PROM but with positive cervical FFN are more likely to deliver within 72 hours than those with negative cervical FFN (164,166–173). In conclusion, the detection of cervicovaginal FFN is not specific for PROM.

Transabdominal Injection of Dye

When the diagnosis of preterm PROM is not clear, a transabdominal injection of dye (indigo carmine, Evans blue, fluorescein) into the amniotic cavity may be used for confirmation (174–177). Methylene blue should not be used as it may cause fetal methemoglobinemia (178–180). A tampon in the vagina can document subsequent dye leakage in cases of PROM.

INITIAL ASSESSMENT

The initial evaluation of a patient with preterm PROM includes (i) accurate assessment of gestational age, (ii) estimation of fetal weight and presentation, (iii) evaluation of the risk of infection, (iv) determination of lung maturity, (v) assessment of fetal well-being, and (vi) exclusion of occult cord prolapse.

Ultrasound Examination in the Evaluation of Patients with Preterm PROM

The initial ultrasound examination aims to (i) assess fetal viability, biometry, and presentation; (ii) quantify amniotic fluid volume; (iii) rule out fetal anomalies; and (iv) confirm gestational age. The sonographic examination of fetuses with PROM may be challenging due to the reduced amniotic fluid volume. For example, sonographic estimates of fetal weight have been shown to underestimate the birth weight (181–183).

Diagnosis of Intrauterine Infection in Preterm PROM

Amniocentesis can be used for the evaluation of the microbiologic state of the amniotic cavity and of fetal lung maturity in the patient with preterm PROM (184). Results of amniotic fluid analysis provide a rational approach to the management of preterm PROM. Patients without evidence of infection/inflammation and lung immaturity could be managed expectantly while those with evidence of infection could be managed using algorithms tailored to the gestational age (see management section).

One randomized clinical trial examined the value of amniocentesis in preterm PROM (185). Forty-seven patients (26–34 weeks of gestation with an accessible amniotic fluid pocket) were randomized to amniocentesis or no amniocentesis. Indications for induction of labor included positive Gram stain of amniotic fluid or mature fetal lungs, as determined by a lecithin-to-sphingomyelin (L/S) ratio of more than 2 or positive phosphatidylglycerol (PG). Neonates born to women

Table 2 Diagnostic Indices and Predictive Values of Different Amniotic Fluid Tests in the Detection of Positive Amniotic Fluid Culture in Patients with Premature Rupture of the Fetal Membranes

Amniotic fluid tests	Sensitivity %	Specificity %	Positive predictive value %	Negative predictive value %
Gram stain (187)	34.8	96.4	88.9	63.9
IL-6 (≥ 7.9 ng/mL) (85)	80.9	75	66.7	86.4
MMP-8 (>30 ng/mL) (187)	76.1	61.8	62.5	75.6
WBC count (≥ 30 cells/ μ L) (187)	55.6	76.4	65.8	67.7
WBC count (≥ 50 cells/ μ L) (85)	52.4	83.8	66.7	74
Glucose (<10 mg/dL) (85)	57.1	73.5	57.1	73.5
Glucose (<14 mg/dL) (85)	71.4	51.5	47.6	74.5
Gram stain + WBC count (≥ 30 cells/ μ L) (187)	62.2	76.4	68.3	82.5
Gram stain + glucose (<10 mg/dL) (85)	66.7	73.5	60.9	78.1
Gram stain + IL-6 (≥ 7.9 ng/mL) (85)	80.9	75	66.7	86.4
Gram stain+ MMP-8 (>30 ng/mL) (187)	82.6	61.8	64.4	81
WBC count (≥ 30 cells/ μ L)+ MMP-8 (>30 ng/mL) (187)	80	60	62.1	78.6
Gram stain + WBC count (≥ 30 cells/ μ L) + glucose (<10 mg/dL) (85)	76.2	60.3	54.2	80.4
Gram stain + WBC count (≥ 30 cells/ μ L) + IL-6 (≥ 7.9 ng/mL) (85)	85.7	61.8	58.1	87.5
Gram stain + WBC count (≥ 30 cells/ μ L) + MMP-8 (>30 ng/mL) (187)	84.4	60	63.3	82.5
Gram stain + glucose (<10 mg/dL) + IL-6 (≥ 7.9 ng/mL) (85)	85.7	52.9	52.9	85.7
Gram stain + WBC count (≥ 30 cells/ μ L) + glucose (<10 mg/dL) + IL-6 (≥ 7.9 ng/mL) (85)	92.9	47.1	52	91.4

who had amniocenteses had a lower incidence of “fetal stress” during labor (diagnosed by fetal heart rate tracing) and a shorter hospital stay than those born to women who were randomized not to have amniocenteses [“fetal distress”: 4% vs. 32%, $p < 0.05$; hospital stay (median): 8.5 vs. 22 days, $p < 0.01$]. No differences in the rate of neonatal sepsis, maternal chorioamnionitis, or endometritis were noted between the two groups. This study had limited power to detect differences in neonatal morbidity.

The analyses of amniotic fluid used to detect the presence of MIAC or intra-amniotic inflammation include (i) Gram stain, (ii) a quantitative WBC count, (iii) glucose concentration, and (iv) microbial cultures for aerobic and anaerobic bacteria, as well as genital mycoplasmas. Patients with a negative Gram stain (read by experienced personnel) and a high WBC count (more than 30 cells/ μ L) are at a high risk of having microbial invasion with genital mycoplasmas, which are not visible on Gram stain examination. Lower concentrations of glucose in amniotic fluid (<10 mg/dL) can serve as an additional marker for MIAC. The results of amniotic fluid culture may take days to be available. Therefore, most centers rely on the determination of intra-amniotic inflammation because the outcome of preterm PROM in patients with intra-amniotic inflammation is similar to those with MIAC proven with standard microbiologic techniques (186). Table 2 summarizes the diagnostic criteria and predictive values of different amniotic fluid tests in detecting positive amniotic fluid cultures in patients with preterm PROM (85,187). Amniotic fluid IL-6 performed best in detecting MIAC as well as in identifying patients at risk for impending preterm delivery and neonatal complications. We have shown that amniotic fluid IL-6 is a sensitive test for the prospective diagnosis of acute histologic chorioamnionitis (IL-6 of more than 17 ng/mL had a sensitivity of 79% and specificity of 100%), significant

neonatal morbidity (sepsis, RDS, pneumonia, IVH, BPD, and necrotizing enterocolitis (NEC)), and mortality (IL-6 of more than 17 ng/mL had a sensitivity of 69% and a specificity of 79%) (188). Other rapid tests reported for the detection of MIAC include amniotic fluid catalase (79), alpha₁-antitrypsin (84), limulus amoebocyte lysate test (83), and bacterial PCR (189).

A rapid bedside test for the detection of MMP-8 in amniotic fluid has been developed. This kit has been reported to have high accuracy in the identification of patients with MIAC and inflammation among patients with preterm labor and intact membranes (190). Future studies may determine the utility of this test in the identification of patients with intra-amniotic infection/inflammation among patients with preterm PROM.

The risk of amniocentesis, when performed by experienced individuals, appears to be extremely low. Yeast and colleagues specifically addressed this issue in 91 patients with preterm PROM in whom amniocenteses were performed (191). A retrospective review of neonatal records uncovered no evidence of fetal trauma with any procedure. This study also found that the incidence of spontaneous labor in patients who underwent amniocentesis was no different from that of patients who did not undergo amniocentesis secondary to oligohydramnios or an anterior placenta. The authors concluded that their study failed to show that amniocentesis might induce labor.

Assessment of Lung Maturity

Lung maturity can be assessed from the amniotic fluid obtained by amniocentesis or from the vaginal pool. The latter has the advantage of being less invasive and more feasible in patients with oligohydramnios. Amniotic fluid from the vaginal pool can be collected in three ways: (i) from

the posterior vaginal fornix by sterile speculum examination, (ii) in a clean bedpan maintained under the patient, or (iii) by the use of obstetric perineal pads left in place for 12 to 24 hours to ensure saturation (192–195). The success rate in obtaining fluid within 48 hours with these noninvasive techniques ranges from 54% to 100% (194,195). Using a pad to detect PG, Estol et al. found a sensitivity of 88%, specificity of 76%, positive predictive value of 34%, and negative predictive value of 98% (196). Lewis et al. investigated the value of a rapid antibody agglutination method (Amniostat FLM) to detect PG in vaginal pool samples (197). Of 201 patients between 26 and 36 weeks of gestation, 36 had positive PG, and none of the infants born to these mothers developed RDS. PG was detectable only after 30 weeks of gestation.

The reliability of lung maturity tests from amniotic fluid collected vaginally has been challenged (198,199). This section reviews the correlation between the L/S ratio and PG results in amniotic fluid obtained by amniocentesis and from the vaginal pool. Shaver and associates compared the phospholipid profile of paired amniotic fluid samples in 28 patients with preterm PROM (192). No significant difference was found in the concentrations of PG, phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine in amniotic fluid obtained by the two sampling methods. The L/S ratio was higher in fluid collected transvaginally than in fluid collected transabdominally, but this difference did not reach statistical significance. The only phospholipid clearly increased by vaginal contamination was lysolecithin.

Dombroski et al. reported a study in which amniotic fluid was obtained by amniocentesis in patients at term in labor (200). Thirty minutes after artificial rupture of membranes, a vaginal sample of amniotic fluid was collected. L/S ratios obtained from amniotic fluid in the vaginal pool samples were significantly lower than those obtained by amniocentesis. However, in 22% of cases, L/S ratios were higher in the vaginal pool samples than amniocentesis.

Several studies have examined the value of PG determinations in amniotic fluid obtained transvaginally. Stedman et al. reported that of 25 patients with PROM between 26 and 34 weeks, 60% had positive PG and none of their neonates developed RDS (within 72 hours of the test) (193). Among the newborns of the 10 patients with negative PG, four developed RDS. Similarly, Brame and MacKenna reported no cases of neonatal RDS in 36 patients with PG found in vaginal fluid (194).

The possibility that bacterial contamination from vaginal secretions may lead to false-positive PG results has been raised by Schumacher and associates, who reported that one patient had PG detected in the fluid from the vaginal pool, but not in the fluid retrieved by transabdominal amniocentesis (199). The neonate developed respiratory insufficiency that was attributed to either RDS or pneumonia (the amniotic fluid culture was positive for bacteria). These investigators also demonstrated that bacteria might be a source of PG. Therefore, excessive bacterial contamination may alter results of PG determinations. It would seem prudent to minimize the interval between sample collection and assay in the hope of preventing bacterial growth in the sample.

Three studies have reported neonatal outcome and L/S ratio results in preterm PROM (194,195,201). In two of the studies, a mature L/S ratio was an indication for delivery (195,201). In the third study, the presence of PG was used as an indication for delivery (194). The data are consistent: with a mature L/S ratio, the risk of RDS is low. An L/S ratio of more than 2 was found in 103 patients, and none of the neonates developed RDS.

The available evidence indicates that fetal lung maturity studies can be performed on amniotic fluid obtained from the vagina, and that a mature L/S ratio or the presence of PG is associated with a very low risk of RDS. Moreover, this noninvasive, low-risk approach allows for serial L/S and PG determinations.

A mature phospholipid test has been demonstrated in approximately 50% of patients with preterm PROM at gestational ages of less than 34 weeks (72,74,185). Garite and associates reported that none of the neonates with an L/S ratio of 1.8 or greater developed RDS (74). The incidence of this complication in neonates with an immature L/S was 33%.

Two randomized clinical trials have examined the outcome of induction of labor in patients with a mature result. In the first trial, 47 patients with preterm PROM (less than 36 gestational weeks) and mature amniotic fluid indices were randomized to either prompt delivery or expectant management (202). A mature test was defined as an L/S ratio above 2 or a Foam Stability Index (FSI) of 47 or more (often from vaginal fluid). There was no difference in perinatal mortality between the two groups. There were no cases of RDS in the expectant management group, but two in the prompt delivery group. One newborn died from severe hyaline membrane disease (birth weight 900 g, vaginal FSI = 48), and the other neonate survived (birth weight 1700 g, vaginal L/S = 2.0). There were no differences in the rate of neonatal sepsis or other neonatal complications in the two groups. However, the only two cases of intracranial hemorrhage occurred in the prompt delivery group. Maternal chorioamnionitis was more common in the expectantly managed group than in the delivery group (38% vs. 8%, $p < 0.02$).

Mercer et al. reported the results of a randomized clinical trial in which 93 women with mature amniotic fluid phospholipid studies (vaginal or transabdominal amniocentesis FSI ≥ 47) were randomized to induction of labor with oxytocin or expectant management (bed rest) (203). Maternal chorioamnionitis was more frequent in the expectant group. However, this difference did not reach statistical significance. There were no significant differences in the cesarean delivery rate or in the incidence of confirmed neonatal sepsis between the groups. Suspected sepsis was higher in neonates born to women in the expectant group, as was antibiotic administration and septic workups. However, neonatologists were not blinded to treatment allocation.

Assessment of Fetal Well-Being

The goal of fetal evaluation is to identify fetal infection/inflammation or a pathologic process, which increases the risk of antepartum or neonatal death. Methods of fetal surveillance include the non-stress test (NST) and the components of the biophysical profile (BPP).

NST

The differential diagnosis of a nonreactive NST is (i) preterm gestation, (ii) infection, and (iii) hypoxia. The interpretation and the significance and management of fetal heart rate decelerations associated with umbilical cord compression due to oligohydramnios are also a challenge.

Fetuses with preterm PROM between 24 and 37 weeks have a significantly higher incidence of reactive tracings than gestational age-matched counterparts with intact membranes (204–206). This has been attributed to “accelerated fetal central nervous system maturation” and umbilical vein compression with resulting fetal heart rate accelerations (207). Thus, lack of reactivity should not be ascribed to preterm gestation without further investigation.

A nonreactive NST is frequently observed in fetuses with MIAC. Three studies (208–210) have found the NST to be an insensitive predictor of infection-related outcome. A major issue is the high false-positive rate (approximately 35%) of the NST for the detection of infection. Therefore, a nonreactive NST is not sufficient to diagnose infection. Evaluation of other biophysical parameters and the results of amniocentesis are recommended before delivery can be indicated (see below).

Assessment of Amniotic Fluid Volume

Contrary to what is generally believed, rupture of membranes is not necessarily associated with oligohydramnios. Harding et al. noted that the AFI in patients with preterm PROM remains stable after the rupture of membranes, with the mean AFI on admission being 5.9 ± 2.5 cm and on the day of delivery 5.4 ± 2.0 cm (211). Moreover, Vintzileos et al. reported that 65.5% of patients with PROM had a vertical pocket of amniotic fluid greater than 2 cm, while 15.5% had a vertical pocket between 1 and 2 cm. Only 19% had a vertical pocket less than 1 cm (212).

Several studies have examined the relationship between oligohydramnios and outcomes in PROM. Patients with a vertical amniotic fluid pocket <1 cm have a shorter latency period and a higher incidence of chorioamnionitis and neonatal sepsis than patients with a vertical pocket greater than 2 cm (212). Similar findings were reported by Gonik et al. (213). Women with a vertical amniotic fluid pocket of <1 cm had a higher incidence of chorioamnionitis and endometritis than those with an amniotic fluid pocket of >1 cm. No difference in the duration of the latency period between the two groups was found (213).

Hadi et al. reported that chorioamnionitis occurred in 26.4% of women with an amniotic fluid pocket of less than 2 cm (214). Similarly, Lao et al. (215) used a cutoff of 2 cm as the largest pocket of amniotic fluid to define oligohydramnios and found that the frequency of chorioamnionitis and funisitis was higher in patients with oligohydramnios than in those without reduced amniotic fluid volume (chorioamnionitis: 55.3% vs. 29.3%; funisitis: 44.7% vs. 16.7%). A reduction in amniotic fluid volume was also associated with MIAC.

There is an association between reduced amniotic fluid volume and maternal or neonatal infection-related morbidity and MIAC. The reason for the high rate of infection in patients with oligohydramnios is unknown. Intra-amniotic infection may alter amniotic fluid dynamics, leading to a reduction in fluid volume. Yoon et al. proposed that redistribution of blood

flow away from the kidneys might take place as part of the host response to microbial products, and this may lead to oligohydramnios (216).

Patients with decelerations have a lower AFI than those without decelerations ($4.32 \text{ cm} \pm 1.67$ vs. $6.47 \text{ cm} \pm 3.59$, $p < 0.01$) (217). This observation suggests that cord compression due to oligohydramnios may be the mechanism behind variable decelerations observed in patients with PROM.

Preterm PROM is associated with a significant and prolonged reduction of fetal breathing movements lasting approximately 2 weeks (218,219). This phenomenon seems to be related to rupture of membranes per se, rather than to infection, hypoxia, or intrauterine growth restriction, even though the precise mechanisms are unknown. Membrane rupture leads to a reduction in intra-amniotic pressure and, thus, favors loss of lung fluid. Teleologically, a reduction in fetal breathing may be a mechanism to protect against lung fluid loss and pulmonary hypoplasia.

Vintzileos was the first to document an association between infection and decreased fetal breathing activity in preterm PROM (220,221). Subsequently, we confirmed these findings and documented that women with positive amniotic fluid cultures had fewer and shorter episodes of fetal breathing activity than women with negative amniotic fluid cultures (222).

The presence of fetal breathing has a very high negative predictive value (approximately 95%) for MIAC and neonatal sepsis. However, the absence of breathing activity has a limited positive predictive value (approximately 50%) for either of these two outcomes and, thus, it cannot be used as an indication for delivery. Therefore, the presence of breathing indicates that infection is unlikely.

Intra-amniotic infection is associated with a dramatic reduction in fetal body movements (222). Decreased fetal motion in the context of infection may be the counterpart of the reduction in motor behavior observed during the course of febrile illnesses in adults and children.

The BPP has been found to be helpful in the management of patients with PROM (204,207–210,220,222–227). Vintzileos et al., using logistic regression analysis, demonstrated that each component of the BPP contains useful information for the prediction of infection-related morbidity (defined as maternal chorioamnionitis, possible neonatal sepsis, and proven neonatal sepsis). In their first study, a modified BPP scoring system that incorporated placental grading (with a maximal score of 12) was used (220). A BPP score of 7 or less was much better than any single component of the BPP in the prediction of infection-related outcome. Placental grading was the only parameter that had no predictive value. Thus, it was excluded from subsequent studies. The diagnostic indices of a BPP score ≤ 7 (performed 24 hours before delivery) were sensitivity 94%, specificity 97%, positive predictive value 95%, and negative predictive value 97% in a population with a prevalence of infection-related outcome of 30%. This study was observational in nature and, thus, the BPP was not used for patient management.

Subsequently, Vintzileos et al. compared the outcome of pregnancy in patients managed with serial BPPs with two historical control groups: (i) expectant management without BPP or amniocentesis and (ii) management with a single amniocentesis on admission (228). A BPP score ≤ 7 on two

*Original author used gestational age cutoff of 23 weeks.

examinations 2 hours apart was used as an indication for delivery. An abnormal score required a nonreactive NST and absence of fetal breathing. The results of this study indicated that patients managed with daily BPPs had a lower rate of overall neonatal sepsis (suspected and culture proven) than patients in either control group. This study did not provide the frequency of other indices of neonatal morbidity (e.g., RDS, IVH, duration of mechanical ventilation) in the different groups. This issue is important, since 14 patients who were delivered because of a low BPP score showed no evidence of neonatal infection and, thus, could be considered false positives. If intervention was not associated with an increased rate of other neonatal complications, management with serial BPPs would seem a reasonable approach. The investigators found that the BPP had limitations when the interval between the test and the delivery was longer than 24 hours and that maternal infection without fetal infection was not correlated with the results of the BPP scoring. Vintzileos et al. subsequently reported on 111 fetuses with preterm PROM followed with daily BPPs and found that the more biophysical activities became compromised, the higher the incidence of infection-related complications (207).

It is noteworthy that subsequent to this work, three studies (223,224,227) reported an association between the results of the BPP and infection-related outcomes, and others could not confirm such an association (225,226). Our explanation for the apparent discrepancy is that studies reporting negative results used the BPP at less frequent testing intervals (48- to 72-hour intervals) than the daily testing used in positive reports.

MANAGEMENT OF PATIENTS WITH PREMATURE PROM

The management of patients with premature PROM depends on the gestational age at the time of membrane rupture (Fig. 2).

Previaible PROM

The major complications of previable PROM are maternal infection, late abortion/preterm labor, low neonatal survival, and a high risk of neurologic complications (Fig. 3) (229,230). Patients are generally offered two options: induction of labor or expectant management. The presence of intra-amniotic inflammation/infection in amniotic fluid analysis carries a poor prognosis because of the risk of spontaneous preterm labor as well as fetal morbidity. Management of these patients requires an in-depth discussion involving the parents, neonatologists, and obstetricians and careful documentation in the medical record. The value of antibiotic or corticosteroid administration in previable PROM has not been established. However, our practice is to administer antibiotics to the patient who desires expectant management. A systematic review of previable PROM indicates that the quality of the evidence to support the management is not high (231).

Leakage of amniotic fluid after second-trimester amniocentesis should be considered a separate entity from previable PROM. It occurs in 1.2% of patients and is usually transient in nature (232). The risk of delayed PROM in these cases is no different from that in the general population (233).

PROM Remote from Term (24 to 31-6/7 Weeks of Gestation)

The management goals are to (i) exclude intra-amniotic infection/inflammation and (ii) institute expectant management in patients without documented infection/inflammation (Fig. 4).

Intra-amniotic Infection/Inflammation and Its Management

The most accurate method for diagnosis of intra-amniotic infection/inflammation is amniocentesis. Once intra-amniotic infection/inflammation is identified in patients between 24 and 31 completed weeks of gestation, the optimal management is a challenge: the earlier the gestational age, the more difficult the dilemma. In patients who are close to 32 weeks

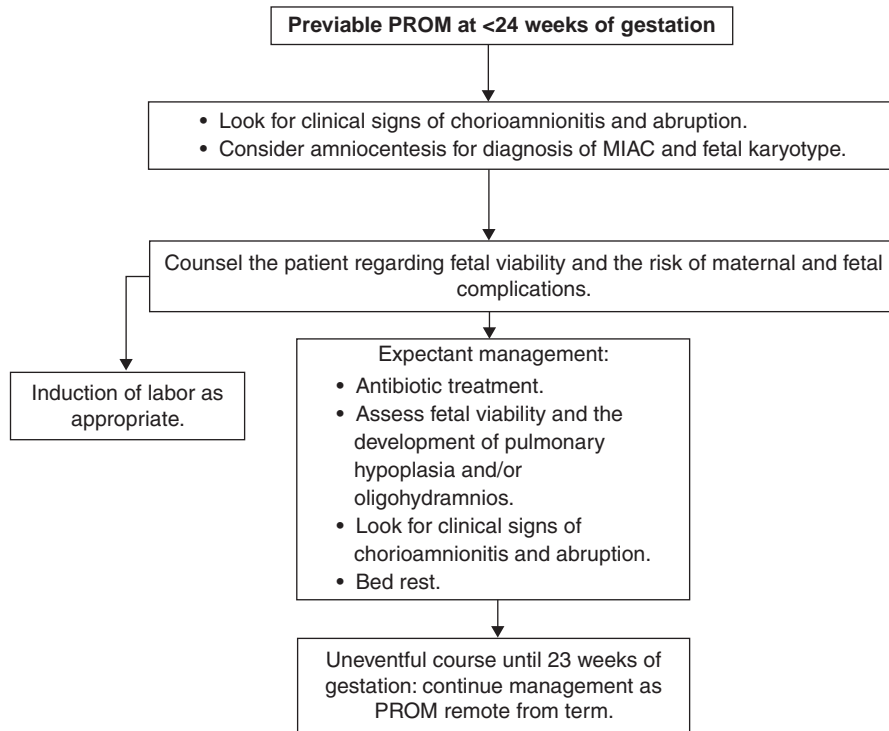

Figure 3 Management of previable prelabor rupture of the membranes (PROM) (before 24 weeks of gestation). Abbreviations: MIAC, microbial invasion of the amniotic cavity. Source: From Ref. 235.

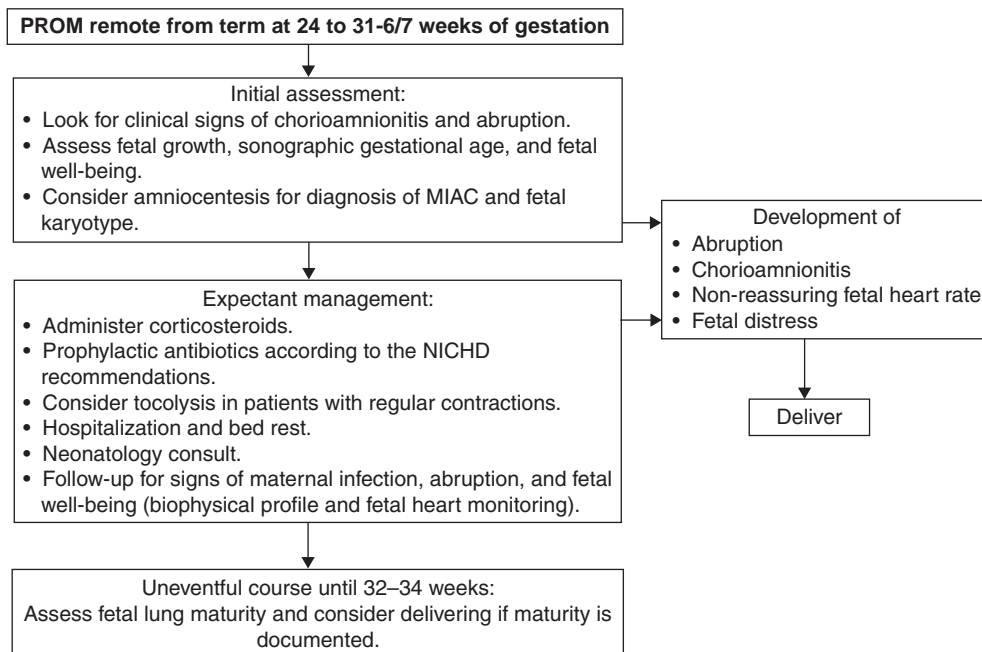

Figure 4 Management of prelabor rupture of the membranes (PROM) remote from term (between 24 and 31-6/7 weeks of gestation). Abbreviations: MIAC, microbial invasion of the amniotic cavity; NICHD, National Institute of Child Health and Human Development, NIH/DHHS. Source: From Ref. 235.

of gestation, delivery would avoid continuous exposure to microbial products and inflammatory agents and would be unlikely to increase neonatal morbidity. These patients are managed in our unit with detailed counseling, antibiotic administration, and delivery. In contrast, in patients close to 24 weeks of gestation, the option of parenteral administration of antibiotics is considered to eradicate intra-amniotic infection and inflammation. Patients are informed that this

alternative may prolong pregnancy, eradicate intra-amniotic infection, and reduce the risk of extreme prematurity, but that it requires intensive surveillance and repeat evaluation of the amniotic cavity to ensure eradication of microorganisms and reduce intra-amniotic inflammation (as determined by the amniotic fluid WBC count). Despite these interventions, the risk for infection and prematurity is not eliminated. Broad coverage is recommended before the results of cultures are

available and this approach modified once the specific microorganisms involved are identified. The choice of antibiotics is informed by the results of microbial cultures. Our choice for broad coverage antibiotics includes azithromycin, clindamycin, and ampicillin. We have also used a combination of ceftriaxone, clindamycin, and erythromycin for 10 to 14 days (87). Azithromycin is included because *U. urealyticum* is the most frequent microorganism found in the amniotic cavity (67).

Antibiotic treatment aimed at the eradication of intra-amniotic infection should not be confused with the prophylactic treatment, which is now the standard of care for patients with preterm PROM, regardless of whether the inflammatory/infection state of the amniotic fluid is known. Thus, patients in this gestational age range, without evidence of infection and inflammation, are given prophylactic treatment with antibiotics (ampicillin and erythromycin). The patient in whom an amniocentesis cannot be performed is managed taking into account the results of biophysical testing, and antibiotics and steroids are administered.

In summary, the management of PROM between 24 and 31 completed gestational weeks comprises (i) maternal and fetal inpatient surveillance in a tertiary medical center, (ii) administration of corticosteroids to accelerate fetal lung maturity (234), and (iii) antibiotic administration, which may be therapeutic or prophylactic (235,236).

“Prophylactic” Antibiotic Administration

Antibiotic administration has now become standard of care in patients with preterm PROM. This practice is based upon the results of several randomized clinical trials, in which antibiotic administration is associated with prolongation of pregnancy, a reduced rate of maternal chorioamnionitis (237), and a reduced frequency of neonatal morbidity, measured as “composite neonatal outcome” (238). This approach has been often referred to as “prophylactic” antibiotic administration. However, this may be a misnomer. One-third of women with preterm PROM have a positive amniotic fluid culture on admission (39); furthermore, the frequency of MIAI increases as the patients are being observed in the antepartum ward to the point that at the time of the onset of labor, 75% of patients will have a positive amniotic fluid culture for microorganisms (68). These studies were conducted before the administration of prophylactic antibiotics and demonstrate that microorganisms are present at admission and that secondary infection of the amniotic cavity occurs during expectant management. It would be inaccurate to refer to “prophylactic” administration as therapy instituted with patients who have a proven infection (one-third of all patients). Anti-microbial therapy may prolong pregnancy by controlling microbial proliferation of an existing infection and preventing secondary infection/inflammation. However, antibiotic administration is not uniformly efficacious in eradicating microbially proven intra-amniotic infection (87).

Several investigators have conducted randomized clinical trials to assess the potential benefits of prophylactic antibiotic administration in patients with preterm PROM (238–251). Mercer et al. (251) reported a randomized clinical trial in which patients were allocated to receive intravenous ampicillin (2 g every 6 hours) and erythromycin (250 mg every 6 hours for 48 hours, followed by oral amoxicillin and erythromycin

base (every 8 hours for 5 days) versus placebos. Recruitment was restricted to patients with a gestational age ranging from 24 to 32 weeks. Group B *Streptococcus* (GBS) carriers were identified and treated, and tocolysis and steroids were not administered after randomization. The primary outcome of the trial was a composite variable that included any of the following: fetal or infant death, RDS, severe IVH, stage II or III of NEC, or sepsis within 72 hours of birth (251). Antibiotic administration was associated with prolongation of pregnancy and a significant reduction in the rate of RDS (RR: 0.83, 95% CI: 0.69–0.99), NEC (RR: 0.4, 95% CI: 0.17–0.95), clinical chorioamnionitis, and the composite primary outcome, which is an index of fetal/infant morbidity and mortality (RR: 0.84, 95% CI: 0.71–0.99). These differences were not demonstrated in GBS carriers, an observation attributable to antibiotic administration to patients allocated to the placebo group for this clinical indication and thus obscuring the potential effects of antibiotic administration (251).

In the ORACLE study (238), 4826 women with preterm PROM were randomly assigned to (i) erythromycin, (ii) co-amoxiclav (amoxicillin and clavulanic acid), (iii) erythromycin and co-amoxiclav, and (iv) placebo. The study included patients before 36–6/7 weeks from 161 medical centers. Tocolysis and corticosteroid administration was left to the discretion of the attending physician. The primary outcome measure was a composite variable, which included neonatal death, chronic lung disease, or major cerebral abnormality before discharge from the hospital.

Among neonates of patients with singleton gestations allocated to erythromycin only, fewer had the primary composite outcome than those in the placebo group (11.2% vs. 14.4%, $p = 0.02$). Erythromycin treatment alone significantly reduced the proportion of patients delivering within 48 hours in comparison with the placebo group. The combination of erythromycin with co-amoxiclav significantly reduced the proportion of patients delivering within a week of admission. Similarly, co-amoxiclav administration alone, or in combination with erythromycin, significantly reduced the proportion of patients delivering within 48 hours and within 7 days from admission, compared with the placebo group (238).

The neonatal effects of erythromycin treatment included a reduction in the need for exogenous surfactant, in neonates needing 21% O₂ administration for 48 hours after delivery, as well as a reduction of the positive neonatal blood cultures (238). Co-amoxiclav had a similar effect on the proportion of neonates needing 21% O₂ administration for 48 hours after delivery. Of note, the rate of suspected and proven NEC was significantly higher in the group of neonates whose mothers were treated with co-amoxiclav as a single or combined therapy. The authors attribute their findings to the wide and nonspecific effect of this broad-spectrum antibiotic that may change the flora of the premature neonates and induce growth of pathologic bacteria that induce NEC (238).

Lovett et al. did not demonstrate an association between prophylactic antibiotic treatment of patients with preterm PROM with co-amoxiclav and an increased incidence of NEC in comparison with placebo (252). The studies differ in the antibiotic regimen, as well as in the gestational age at inclusion and the number of patients. Therefore, comparison

of the studies is difficult. The recommendation of the investigators in the ORACLE I trial was to use erythromycin and avoid using co-amoxiclav in patients with preterm PROM (238). Recently, a systematic review by Kenyon et al. confirmed these results (253).

According to Kenyon et al., the number of patients needed to treat to prevent one adverse outcome remains high [chorioamnionitis: 10 (95% CI: 7–34); delivery within 48 hours: 9 (95% CI: 6–20); delivery within 7 days: 7 (95% CI: 5–15); neonatal infection: 17 (95% CI: 12–50); abnormal cerebral ultrasonography before discharge: 69 (95% CI: 35–1842)] (253). It is possible that the wide confidence intervals reflect the range of gestational ages of patients included in the systematic review.

The follow-up of children to the age of seven enrolled in the ORACLE I trial has demonstrated that any antibiotic treatment (erythromycin or co-amoxiclav) did not have a significant effect on the overall level of behavioral difficulties, on specific medical conditions on the proportion of children achieving each level in reading, writing, or doing mathematics (254). Therefore, it seems that the short-term benefits of antibiotic administration do not result in detectable differences in outcome at the age of seven.

Can Antibiotic Treatment of Women with Documented Intra-amniotic Infection Alter the Natural History of Preterm PROM?

The traditional view has been that clinical chorioamnionitis should be managed by immediate delivery, and this view has been extended to the management of subclinical intra-amniotic infection (255). There is evidence that both of these conditions can be treated *in utero* without interruption of pregnancy. Ogita and colleagues first reported the successful treatment of established chorioamnionitis with antibiotic treatment via a transcervical catheter (256). Subsequently, we reported that giving antibiotics to a mother with preterm PROM at 29 weeks and an amniotic fluid culture positive for *Bacteroides bivius*, *Veillonella parvula*, and *Peptococcus* without clinical signs of chorioamnionitis resulted in eradication of MIAC (257). In a second case, we were successful at eradicating *U. urealyticum* from the amniotic cavity with antibiotic treatment (258).

The effects of antibiotics on the natural history of MIAC in patients with preterm PROM has been reported by Gomez et al. (87). Patients who underwent amniocentesis upon admission and those without evidence of intra-amniotic inflammation or MIAC were treated with ampicillin and erythromycin for 7 days. By contrast, patients with intra-amniotic inflammation or MIAC were treated with ceftriaxone, clindamycin, and erythromycin for 10 to 14 days. Patients who remained undelivered after the conclusion of the course of antibiotics underwent a second amniocentesis. Six of seven patients who had MIAC at the time of the first amniocentesis still had positive amniotic fluid cultures for microorganisms after a full course of antibiotic treatment. Of the 18 patients with intra-amniotic inflammation, most 15 still showed evidence of an elevated WBC count in amniotic fluid after antibiotic administration. Therefore, antibiotic administration did not eradicate MIAC or intra-amniotic inflammation. Moreover, among patients with no evidence of intra-amniotic inflammation, 32% developed

inflammation despite therapy, and among those without MIAC, 55% developed a positive amniotic fluid culture (87). These data raise important questions about the effect of antibiotics and the nature of the invading microorganisms in preterm PROM.

Should Corticosteroids Be Administered to Patients with Preterm PROM Remote from Term?

A systematic review included 13 randomized clinical trials and demonstrated a reduction in the incidence of RDS, IVH, and NEC (RR: 0.56, 95% CI: 0.46–0.70; RR: 0.47, 95% CI: 0.31–0.70; RR: 0.21, 95% CI: 0.05–0.82, respectively) in newborn to mothers who had been given corticosteroids (259). A nonsignificant trend of reduced neonatal mortality was observed; moreover, no increase in neonatal and fetal infection was observed (259). Steroid treatment was associated with a modest, yet significant, increase in the risk of puerperal endometritis (RR: 2.42, 95% CI: 1.38–4.24), but no significant increase in neonatal sepsis. Similar findings were reported in an earlier meta-analysis, which included fewer trials, by Crowley (260,261).

Clinical investigators have compared expectant management with steroid administration for 48 hours followed by delivery. However, induction of delivery immediately after steroid administration is associated with an increased risk of RDS and, therefore, is best avoided (261). The 1994 National Institutes of Health Consensus Conference recommended the use of corticosteroids in pregnancies complicated by preterm PROM with expected delivery between 24 and 30 to 32 weeks of gestation (234). This recommendation was based largely on data suggesting that the incidence of IVH was lower in neonates exposed to corticosteroids (234). The modest increased risk of puerperal infection is considered easy to manage. A meta-analysis comparing the outcome of treatment with antibiotics and steroids versus antibiotics without steroids found that steroid administration diminished the beneficial effects of antibiotics in reducing the rate of chorioamnionitis, endometritis, neonatal sepsis, and IVH (262).

How Many Courses of Corticosteroids Should Be Administered?

Repeated courses of corticosteroids have been used to enhance their effects. However, recent data have raised questions about the safety of repeated corticosteroid administration based on studies in humans and animals. Guinn et al. performed a double-blind, randomized, controlled trial, where women at risk for preterm delivery received one course of betamethasone or dexamethasone at admission and were randomly allocated for subsequent weekly courses of either betamethasone or placebo until 34 weeks of gestation or delivery (263). There were no significant differences in the frequency of composite neonatal morbidity (severe RDS, BPD, severe IVH, PVL, proven sepsis, NEC, or perinatal death) between the study groups (weekly course: 22.5% vs. single course: 28%, $p = 0.16$). However, when the analysis was stratified by gestational age, patients who delivered between 24 and 27 weeks who received a single course had a higher rate of composite neonatal morbidity and severe RDS than those in the weekly course group. An important limitation of this study is that the authors did not control for the use of surfactant, which was more

frequent in the single-course group (single course: 24% vs. weekly course: 15.6%, $p = 0.01$) (263). This subject is covered in detail in the chapter on preterm labor.

Tocolysis

Meta-analysis of the four randomized trials of tocolysis in preterm PROM (264–267) indicates that tocolysis does result in prolongation of pregnancy of more than 48 hours. However, no study has shown an improvement in maternal or neonatal outcomes. Therefore, there is no evidence to support the use of intravenous tocolysis in women with PROM.

Should a Cervical Cerclage Be Removed in a Patient Who Presents with Preterm PROM?

Cerclage removal has been advocated to reduce the risk of infection-related complications (268), while leaving the cerclage in place has been recommended to prolong pregnancy. Yeast and Garite reported the results of a case-control study in which the outcome of patients with cervical cerclage removed after preterm PROM was compared with that of patients with PROM of a similar gestational age (269). There was no difference in the incidence of chorioamnionitis or other infectious complications and neonatal outcome between the two groups. The interval between PROM and delivery was not significantly different between patients with and without cerclage. Blickstein and associates reported similar findings after comparing the outcome of 32 patients with cerclage and 76 without cerclage (270). In contrast, Goldman and colleagues compared the outcome of 46 women with preterm PROM in whom the cerclage was not removed with that of 46 women with preterm PROM without cerclage (271). Patients with a cerclage had a significantly shorter PROM-to-delivery interval and lower gestational age at delivery than patients without the cerclage. However, the rates of chorioamnionitis, other infection-related complications, and neonatal outcome were not different between the two groups. Ludmir et al. evaluated the role of immediate cerclage removal in preterm PROM in 30 women (272). In 20 women, the cerclage was removed immediately after the diagnosis of ruptured membranes was made, while in 10 women, the cerclage was retained after the membranes ruptured. Thirty-three patients with preterm PROM without cerclage served as controls. A greater proportion of women with a cerclage left in place delivered after 48 hours (90% vs. 50%, respectively). However, perinatal mortality was significantly higher in infants born to women in whom cerclage was retained in comparison with immediate removal or the control group (70% vs. 10% vs. 18%, respectively). Seventy-one percent of neonatal morbidity was attributable to sepsis. The authors did not use broad-spectrum antibiotic treatment, which may explain this observation (272).

McElrath et al. reported a case-control study from a 12-year experience, comparing removal versus non-removal of cerclage in patients with preterm PROM (273). Eighty-one women with premature PPROM who had a cerclage were included, in which 30 (37%) had their cerclage removed at presentation, and 51 (63%) retained the cerclage until delivery. The authors concluded that retention of cervical cerclage after premature rupture of the membranes occurring before 34 completed weeks of gestation is associated with comparable clinical outcomes with respect to latency and neonatal

morbidity and mortality, when compared with removal of the cerclage. The same authors compared patients with preterm PROM who had a cerclage versus those with preterm PROM without a cerclage, and reported that patients with a cerclage had a lower gestational age at membrane rupture than those without a cerclage (29.6 ± 3.0 weeks vs. 31.7 ± 2.8 weeks). However, there was no difference in the latency period between the groups. Neonatal mortality was higher among patients in the cerclage group. This difference became non-significant when the analysis was stratified into three gestational age groups (<28, 28–30, and >30 weeks). There were no significant differences in the rates of RDS, IVH and neonatal sepsis between the study groups (274).

In summary, the evidence indicates that patients with preterm PROM and a cerclage could be managed by leaving the cerclage in place and maintaining close surveillance to detect maternal and/or fetal infection. However, removal of the cerclage is a legitimate alternative.

Home Care Vs. Hospital Care

Practice Bulletin No. 80 of the American College of Obstetricians and Gynecologists (275) stated that the safety of expectant management at home has not been established, although management of selected patients at home with careful observation has been reported. The potential disadvantages of home care include the risk of delivering a preterm infant outside a tertiary center and the implicit delay in obstetric intervention if fetal distress or infection occurs. The advantages of home care include decreased costs and psychologic benefits to the patient.

Two studies have compared home care with hospital care. The first, a small, randomized trial of women with PROM at less than 37 weeks of gestation, had strict criteria for home care (276). Only patients undelivered after 72 hours (60% delivered in less than 72 hours), in cephalic presentation, with negative amniotic fluid culture (by amniocentesis), cervical dilation of less than 4 cm on speculum examination, and at least one amniotic fluid pocket of more than 1 cm (22% had oligohydramnios) were eligible for participation. Follow-up included biweekly NST, weekly ultrasound examination, and corticosteroid administration. Fifty-five patients were randomized; 27 to home care and 28 to remain in-hospital. There was no difference in the latency period, gestational age at delivery, chorioamnionitis (11.1% vs. 14.3%), neonatal morbidity (3.7% vs. 7.1%), RDS (3.7% vs. 7.1%), or neonatal pneumonia (18.5% vs. 10.7%) (276).

The second study of home care was a retrospective study of patients with preterm PROM between 20 and 30 weeks of gestation, in which 19 of 21 women undelivered after 7 days were discharged home (277). All patients had “adequate or slightly diminished amniotic fluid volume.” Of 19 women, 11 delivered at term. No neonatal deaths occurred, and there was one case of maternal and neonatal sepsis in a woman managed at home (she was infected with human immunodeficiency virus). One case of neonatal sepsis occurred in an infant born to a woman who was managed in-hospital and delivered preterm.

The data available are insufficient to recommend management of preterm PROM outside tertiary-care centers. We believe that fetuses with preterm PROM require careful

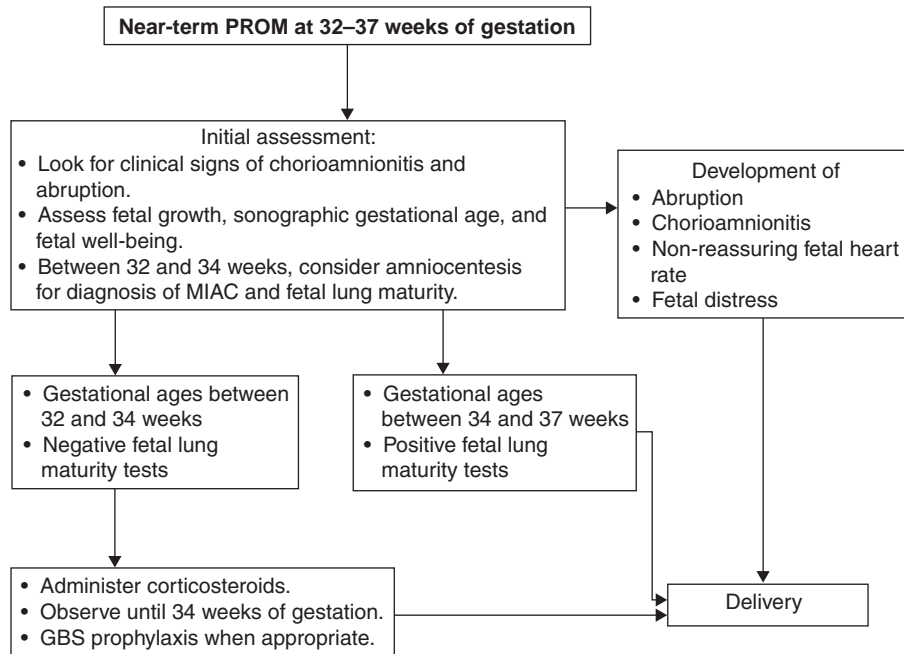

Figure 5 Management of near-term prelabor rupture of the membranes (PROM) (between 32 and 37 weeks of gestation). Abbreviations: MIAC, microbial invasion of the amniotic cavity; GBS, Group B *Streptococcus*. Source: From Ref. 235.

surveillance, which is rarely available outside a hospital environment.

What Is the Appropriate Time for Induction?

Today, the standard of care for patients presenting with preterm PROM remote from term is expectant management (20,235,236). This management significantly reduces the neonatal complications related with prematurity (20,235,236); however, the longer the latency period, the higher the risk for chorioamnionitis and abruption (202,278–280).

Cox and Leveno performed a prospective study comparing induction versus expectant management of patients presenting with preterm PROM between 30 and 34 weeks. There were no significant differences in neonatal morbidity. However, the frequency of chorioamnionitis was significantly higher in the expectant management group (2% vs. 15%, $p = 0.009$). Of note, 74% of the expectant management group delivered within 72 hours (281).

The timing of delivery is a determinant of the presence of major, but not minor, composite neonatal morbidity. Indeed, major composite neonatal complications (RDS, IVH, intubation, BPD, seizure, NEC, bowel perforation, retinopathy of prematurity, meningitis, pneumonia, primary pulmonary hypertension, and patent ductus arteriosus) decrease substantially after 32 weeks of gestation (282). In contrast, minor composite neonatal outcomes (hyperbilirubinemia, transient tachypnea of the newborn, hyper- or hypoglycemia and hyper- or hyponatremia) decrease only after 34 weeks of gestation. Mercer et al. demonstrated that, in patients with preterm PROM, delivery after 32 weeks of gestation was not associated with a significant increase in neonatal morbidity (203). The development of chorioamnionitis, placental abruption, or non-reassuring fetal heart rate tracing often requires induction of labor and delivery, regardless of gestational age.

PROM near Term (32 to 36 Weeks of Gestation)

Mercer et al. demonstrated that there were no differences in the maternal and neonatal outcomes of expectant management and induction of labor in this gestational age window (Fig. 5) (203). However, there was a trend toward a higher incidence of chorioamnionitis in the expectant management group (203). Cox and Leveno reported a higher incidence of chorioamnionitis (281). One approach to management is to perform an amniocentesis for fetal lung maturity between 32 and 34 weeks and, if the result is mature, to proceed with induction of labor in order to reduce maternal morbidity (235,281,283). In cases with negative fetal lung maturity, the management is not clear. Some physicians will choose expectant management until 34 weeks, while others will administer corticosteroids and induce labor 48 hours later (284). There are not sufficient data in the literature to support either course of action. In a survey that was conducted in the United States during 2003 among members of the Society of Maternal Fetal Medicine, 42% will induce labor in patients presenting with premature PROM and positive lung maturity at 32 weeks (284). In cases with unknown fetal lung maturity, 58% will postpone delivery to 34 weeks of gestation (284).

In summary, patients between 32 and 34 weeks need assessment of lung maturity, and if the profile is consistent with maturity, the patients could be offered induction of labor. In cases without evidence of fetal lung maturity, there are not sufficient data as to the optimal management approach. Mercer et al. proposed that women with PROM after 34 weeks should be delivered (12).

PROM AT TERM

The management of patients with PROM at term includes (i) exclusion of cord prolapse, (ii) detection of infection, and (iii) evaluation of fetal well-being. If any evidence exists of fetal compromise or infection, induction of labor or delivery is the

management of choice. For other patients, the relevant management issues include deciding between (i) induction or expectant management and (ii) when and how induction should be undertaken (285–308).

The natural history of term PROM is that 90% of women will be in spontaneous labor within 24 hours (308). Nulliparous women have a longer latency period than multiparous women (291,298,303). Patients with an unfavorable cervix at presentation and those who are not in labor within 6 hours of rupture of membranes generally do not initiate labor spontaneously within 24 hours and represent a management dilemma (307).

The largest clinical trial in term PROM (292) included 5041 patients who were randomly allocated to four groups: (i) immediate induction with oxytocin, (ii) expectant management followed by induction with oxytocin after 4 days, (iii) induction of labor with vaginal prostaglandin E₂ (1–2 mg, followed by IV oxytocin; if not in labor in 4 hours, a second dose of prostaglandin E₂), and (iv) expectant management followed by induction of labor with prostaglandin E₂, if labor had not begun within 4 days. The primary outcome of the trial was probable neonatal infection (clinical and laboratory signs). Secondary outcomes were the need for cesarean delivery and the patient's evaluation of their treatment. The results showed no difference in neonatal infection and cesarean delivery rate between the induction groups (oxytocin vs. prostaglandin E₂). However, the incidence of chorioamnionitis was lower in patients allocated to induction of labor. Satisfaction with their obstetrical care was higher for patients allocated to induction of labor.

Mozurkewich and Wolf, in their meta-analysis of 23 studies including 7493 women, demonstrated that induction of labor is superior to expectant management (299). The meta-analysis compared three policies: (i) immediate induction with oxytocin, (ii) induction of labor with vaginal or endocervical prostaglandin E₂ gel suppositories or tablets, and (iii) expectant management that sometimes has included delayed induction with oxytocin. The frequency of chorioamnionitis and endometritis was significantly lower in patients undergoing immediate induction of labor with oxytocin than in those managed expectantly (OR: 0.67, 95% CI: 0.52–0.85 and OR: 0.71, 95% CI: 0.51–0.99, respectively). The rate of chorioamnionitis was significantly higher in patients who received vaginal prostaglandins than in those induced with immediate administration of oxytocin, but lower than that of patients in the expectant management group (OR: 1.55, 95% CI: 1.09–2.21 and OR: 0.68, 95% CI: 0.51–0.91, respectively). The rates of cesarean delivery and neonatal infection were not different among the three management schemes. Based on these data, we endorse a policy of immediate induction of labor in patients with term PROM. Antibiotic administration is justified before cesarean delivery for obstetric indications or for carriers of GBS.

Tan and Hannah (309) performed a meta-analysis of 18 trials comparing induction of labor with oxytocin versus expectant management in patients with PROM at or near term. Induction of labor with oxytocin was associated with a lower risk of chorioamnionitis (OR: 0.63, 95% CI: 0.51–0.78), endometritis (OR: 0.72, 95% CI: 0.52–0.99), and neonatal infection (OR: 0.64, 95% CI: 0.44–0.93). Cesarean delivery

rates were not statistically different. Oxytocin was associated with a more frequent use of pain medication and internal fetal heart rate monitoring. Another meta-analysis of 15 RCTs by Lin et al. included (i) six studies (n = 453) of misoprostol versus placebo or expectant management and (ii) nine studies (n = 1130) of misoprostol versus oxytocin for labor induction with term PROM (310). There were no significant differences in the frequency of chorioamnionitis, neonatal sepsis, or cesarean delivery among study groups.

Expectant management at home of patients with PROM at term is not recommended. This recommendation is based upon the report of Hanna et al. that home care was associated with an increased risk of neonatal infections (OR: 1.97, 95% CI: 1.00–3.90) and cesarean delivery in patients not colonized with GBS (OR: 1.48, 95% CI: 1.03–2.14) (311).

ACKNOWLEDGEMENT

This work was conducted by members of the Perinatology Research Branch of the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) of the National Institutes of Health (NIH) and funded by the Intramural Program of NICHD/NIH.

3 Cervical insufficiency

Sonia S. Hassan, Roberto Romero, Francesca Gotsch, Lorraine Nikita, and Tinnakorn Chaiworapongsa

INTRODUCTION

The uterine cervix has a central role in the maintenance of pregnancy and in normal parturition. Preterm cervical ripening may lead to cervical insufficiency or preterm delivery. Moreover, delayed cervical ripening has been implicated in a prolonged latent phase of labor at term. This chapter will review the anatomy and physiology of the uterine cervix during pregnancy and focus on the diagnostic and therapeutic challenges of preterm cervical ripening and the role of cerclage in obstetrics.

ANATOMY AND FUNCTION OF THE UTERINE CERVIX

The uterus is composed of three parts: corpus, isthmus, and cervix. The corpus is the upper segment of the organ and predominantly contains smooth muscle (myometrium). The isthmus lies between the anatomical internal os of the cervix and the histologic internal os and, during labor, gives rise to the lower uterine segment. The anatomical internal os refers to the junction between the uterine cavity and the cervical canal, while the histologic internal os is the region where the epithelium changes from endometrial to endocervical (1). The term “fibromuscular junction” was introduced by Danforth, who identified the boundary between the connective tissue of the cervix and the myometrium. The fibromuscular junction is in close proximity to the histologic internal os (2) (Figures 1A–D) (3).

Function of the Uterine Cervix

The main function of the uterine cervix is to serve as a barrier to the expulsion of the conceptus. The endocervical glands generate mucous, which forms the mucous plug, an anatomical and biochemical barrier to microorganisms. “Cervical ripening” is a term used to describe the changes in cervical dilatation, effacement, and consistency, which generally precede the onset of spontaneous labor. This process is associated with complex changes in the extracellular matrix aimed at increasing cervical compliance. The conventional view has been that uterine contractions lead to cervical change, a concept based on the relationship between increased uterine contractility and cervical dilatation during spontaneous labor at term. However, the process of cervical ripening begins weeks before the onset of labor. Similarly, preterm cervical ripening can occur without a demonstrable increase in uterine contractility. Experimental evidence indicates that cervical changes can occur even if the cervix is transected from the myometrium; therefore, these two components of the uterus

(fundus and cervix) can undergo changes in the preparation for labor, which are independent from each other.

A Brief Summary of the Biology of Cervical Ripening and Remodeling

The uterine cervix is essentially a connective tissue organ. Smooth muscle accounts for <8% of the distal part of the cervix (4). Cervical competency, defined as the ability of the cervix to retain the conceptus during pregnancy, is unlikely to depend upon a traditional muscular sphincteric mechanism. Experiments in which strips of human cervix have been incubated with vasopressin (a hormone that induces smooth muscle contractility) indicate that the contractile response of the cervix is substantially lower than that of the tissue obtained from the isthmus of the uterine fundus (5). It is now well established that the normal function of the cervix during pregnancy depends upon collagen synthesis and extracellular matrix.

The connective tissue remodeling of the uterine cervix during pregnancy has been proposed to occur in four stages: (i) softening, (ii) ripening, (iii) dilatation, and (iv) repair (6). These phases are overlapping and cannot be sharply separated during gestation (Fig. 2). The interested reader is referred to the reviews and original work by numerous authors (2,6–31) for a detailed discussion of the biochemical and cellular events underlying cervical remodeling during pregnancy and labor.

Word et al. have proposed that early in pregnancy, tensile strength of the softened cervix is maintained by increasing collagen synthesis and cervical growth (6). Collagens type I and III confer tensile strength. During cervical ripening, the cervix becomes thin and pliable, and the collagen concentrations are decreased. This decrease is due to a relative increase in hydrophilic glycosaminoglycans and non-collagenous proteins. The increased expression of aquaporin water channels leads to tissue hydration; this, in turn, disperses collagen fibers and increases collagen solubility and its susceptibility to endogenous proteases. The primary glycosaminoglycan involved is decorin, which protects collagen fibers; however, later in gestation, decorin decreases and hyaluronan increases. The latter can weaken the interaction between collagen and fibronectin, contributing to collagen dispersal (6). Hyaluronan has been found in human endocervical mucous (32). Mahendroo’s laboratory has demonstrated that, in mice, the hyaluronan content of the cervix is increased with advancing gestational age along with the expression of the

This work is based on several chapters that were published previously by the authors in other textbooks. This work has been modified and adapted for this textbook. The original chapters are referenced and contain a more extensive discussion of the subject. This chapter has a clinical emphasis. The work has been primarily done by Roberto Romero, who is a government employee, and therefore, is not subject to copyright.

enzyme hyaluronan synthase 2 (28). Low-molecular weight hyaluronan can bind CD44 and activate macrophages to produce chemokines that attract inflammatory cells (33). Thus, the current understanding is that once collagen is solubilized, an inflammatory cascade is initiated. Studies in humans are necessary to determine the biochemistry of these processes. Strong evidence suggests that a suspension of progesterone action can lead to cervical ripening (34,35).

ORIGIN OF THE CONCEPT OF CERVICAL INCOMPETENCE/INSUFFICIENCY

One of the first descriptions of “cervical incompetence” has been attributed to Cole, Culpepper, and Rowland in 1658 (36), who wrote in a chapter on the state of being barren: “the second fault in women which hindered conception is when the seed is not retained or the orifice of the womb is so slack that it cannot rightly contract itself to keep in the seed; which is chiefly caused by abortion or hard labor and childbirth, whereby the fibers of the womb are broken in pieces one from another and the inner orifice of the womb overmuch slackened” (37). The term “cervical incompetence” was mentioned by Gream in an article published in the *Lancet* in 1865 (38). Interestingly, the earliest observations were made nearly 300 years before surgical treatment was developed by Shirodkar (39) and, subsequently, McDonald (40). Although the term “cervical incompetence” has been used for many years (41), this condition is now referred to as “cervical insufficiency” to avoid the negative connotation that the term “incompetence” may imply to patients (42).

Defining Cervical Insufficiency

Definitions of cervical insufficiency have been proposed by many authors and vary slightly. Such definitions need to be examined critically, particularly in light of recent observations with ultrasound and results of studies that have reframed the concept of cervical insufficiency.

The clinical diagnosis of cervical insufficiency has been traditionally applied to patients with a history of recurrent midtrimester spontaneous abortions and/or early preterm deliveries in which “the basic process is thought to be the failure of the cervix to remain closed during pregnancy” (41). The assumption is that cervical dilatation and effacement have occurred in the absence of increased uterine contractility (41). The presenting symptom is sometimes considered to be a feeling of vaginal pressure, possibly caused by protruding membranes in the midtrimester of pregnancy. Sometimes the membranes rupture. Typically, there is no vaginal bleeding, the fetuses are often born alive, and the labor is short (40,41,43).

We find it difficult to establish a causal relationship between the clinical presentation outlined above and its attribution to a primary cervical disease (i.e., “insufficiency”) (42). Clearly, a condition exists in which patients present before 24 weeks of gestation with a dilated and effaced cervix in which the membranes protrude into the vagina (Fig. 3). This condition can often be visualized on ultrasound as illustrated in Figure 4.

Harger, in a review of the literature, defined “cervical insufficiency” as “the inability of the uterine cervix to retain a pregnancy in the absence of contractions or labor” (44). However, the use of this definition in clinical practice is problematic. How can an obstetrician identify “the inability of

Figure 3 A patient who presented prior to 24 weeks of gestation with a dilated and effaced cervix in which the membranes are protruding into the vagina. Roberto Romero, MD and Karim Kalache, MD. Cover Image - American Journal of Obstetrics and Gynecology, Jan 2006 – Dec 2006 (Vol 194.1–195.6).

Figure 4 An ultrasound image demonstrating a dilated cervix in a patient with suspected cervical insufficiency.

the cervix to retain the pregnancy”? There is no clinical test that would allow this determination. Some have proposed that the response to treatment offers criteria for the diagnosis.

Namely, a patient with a history of recurrent midtrimester pregnancy losses who is subsequently treated with a cerclage and delivers at term could be considered to have cervical insufficiency, and hence, the claim that such patient needs a cerclage in every subsequent pregnancy; yet, observational studies do not support this conclusion.

One approach by some authors to examine the accuracy of the diagnosis of cervical insufficiency is to determine pregnancy outcome in patients with this diagnosis who did not have treatment in subsequent pregnancies. In 1961, Dunn and Dans (45) reported the outcome of 30 patients who had two or more consecutive midtrimester abortions without an intervening first-trimester abortion. Interestingly, 13 of the 30 patients had three consecutive midtrimester abortions. The authors reasoned that if cervical insufficiency was the operative mechanism for pregnancy failure, it would be expected that all subsequent untreated pregnancies would result in pregnancy loss; however, this was not the case. Indeed, in 50% of cases, patients delivered neonates who exceeded 28 weeks of gestation and weighed >1000 g. Thus, the authors proposed that the spontaneous “cure rate” of this entity would be 50%. The editor of *Obstetrical and Gynecological Survey* published a commentary (46) in which he argued that a more appropriate endpoint for spontaneous cure would be delivery at term in the subsequent pregnancy. Although he recalculated the spontaneous “cure rate” to be 20%, a clear message of the study is that even in patients with two and sometimes three midtrimester abortions, term pregnancy is possible without a cerclage.

In 1984, Socol et al. (47) reported the outcome of a group of patients who had previously delivered a live-born infant between 20 and 32 weeks of gestation. In the subsequent pregnancy, some patients were treated with a cervical cerclage and others were not (at the discretion of the practitioner). The rate of preterm delivery was 36% (5/14) in patients who had a cerclage and 38% (10/26) in those managed expectantly. One interpretation of this data is that delivery at term was frequently possible in patients with a previous midtrimester pregnancy loss or early preterm delivery without a cervical cerclage.

Yet obstetricians often face the clinical dilemma of how to manage a patient who had a previous successful pregnancy with a cervical cerclage. Was the first cerclage truly necessary? Would the patient have delivered at term regardless of the placement of the cerclage? These questions are pervasive because of the subjective nature of the diagnosis. For example, some obstetricians place a cerclage after a midtrimester pregnancy loss with rupture of membranes, while others consider that this is not enough evidence of cervical insufficiency to justify the operation.

In a 1994 article entitled “Once a cerclage, not always a cerclage,” Fejgin et al. (48) reported the pregnancy outcome of patients who had a history of at least one pregnancy in which a McDonald cerclage had been placed and the physician caring for the subsequent pregnancy was uncertain as to whether the procedure was necessary. A committee of three obstetricians reviewed the history, a hysterosalpingogram when available, and the results of a pelvic examination. There were 35 patients who had 58 pregnancies with a cerclage, and 52 subsequent pregnancies without the procedure. The outcome of pregnancies without a cerclage was better than those with a cerclage.

Collectively, these retrospective studies question the accuracy of the diagnosis of cervical insufficiency and/or the effectiveness of cerclage. The results of these studies (and others) are at the root of the controversy about the nature of this clinical entity, its diagnosis, and the precise role of cerclage in clinical medicine.

There is no objective diagnostic test for cervical insufficiency. The diagnosis is often made in a patient in the midtrimester who presents with dilatation of the cervix and different degrees of membrane prolapse. The evaluation of the nonpregnant patient represents an unsolved challenge. Several methods have been proposed for the identification of the patient at risk for cervical insufficiency, including (i) the passage of Hegar dilators (6–8 mm) or Pratt dilators through the internal cervical os (49–51), (ii) the use of a balloon test (52), or (iii) the ability of the cervix to hold an inflated Foley catheter during hysterosalpingography (53). However, there is a paucity of scientific evidence to support the value of these tests in predicting subsequent pregnancy outcome (44).

SONOGRAPHIC CERVICAL LENGTH

Digital examination of the cervix was the method used to determine cervical status (effacement, dilatation, position, and consistency) before the introduction of ultrasound. Bishop developed his cervical scoring system primarily to predict when spontaneous labor at term would occur and found that the higher the score, the sooner the labor would start (54). Wood et al. (55) were the first to report that a short cervix was a risk factor for preterm labor and delivery. A large study reported by Papiernik consisted of serial digital examinations in 8303 women, where dilatation of the internal os was the strongest risk factor for preterm delivery. A short cervix (≤ 1 cm) also increased the risk (56). These findings have been confirmed by others (57–62). However, digital examination is subjective and has limitations. For example, the coefficient of variation for effacement has been reported to be 26% (63). Moreover, evaluation of effacement requires placing the examining finger in close proximity to the fetal membranes. Sonographic imaging of the cervix is less invasive and more objective in assessing cervical length as well as changes in the anatomy of the internal os (64).

Transvaginal sonography is superior to transabdominal for examination of the cervix (64,65). Numerous studies have proven that the shorter the sonographic cervical length in the midtrimester, the higher the risk of spontaneous preterm labor/delivery (66–70). However, there is no agreement concerning what constitutes a sonographic short cervix. For example, Iams et al. (67) proposed that a cervix of 26 mm or shorter at 24 weeks of gestation increases the risk of spontaneous preterm delivery (Relative Risk (RR) 6.19, 95% CI 3.84–9.97). The prevalence of spontaneous preterm delivery (defined as <35 weeks) in this study was 4.3%, and the positive predictive value was 17.8% for a cervical length ≤ 25 mm at 24 weeks of gestation (67). Thus, most women with a short cervix (defined as 25 mm or less) will not deliver a preterm neonate. Other investigators have proposed a cut-off of 15 mm, because a cervical length of 15 mm or less is associated with nearly a 50% risk of spontaneous preterm delivery at 32 weeks of gestation or less when neonatal morbidity is substantial (68,70).

It is important to stress that sonographic cervical length is not a screening test for spontaneous preterm delivery, because

only a fraction of all patients who will have a spontaneous preterm birth have a short cervix in the midtrimester. Sonographic cervical length is only a method for risk assessment for spontaneous preterm delivery and not a screening test. Cervical length can modify the *a priori* risk for preterm delivery. For example, a woman with a history of preterm delivery or one with a twin or triplet gestation will have a higher risk for preterm delivery than a patient with the same cervical length, but without such history (71–80). It is now possible to provide women with an individualized estimation of risk for preterm delivery based upon cervical length and whether they have a history of preterm birth (81).

CERVICAL SUFFICIENCY/INSUFFICIENCY AS A CONTINUUM

The hypothesis that cervical competence or sufficiency represents a spectrum was studied by Parikh and Mehta, who used digital examination of the cervix and concluded that degrees of cervical competence did not exist (82). Iams et al., (83) using sonographic examination of the cervix, concluded that cervical competence was a continuum. The authors reported a strong relationship between cervical length in pregnancy and previous obstetrical history. This relationship is nearly linear. However, patients with a typical history of an incompetent cervix appear to represent a different group than those who delivered preterm (83). Similar results have been reported by Guzman et al. (84). Collectively, these studies suggest that there is a relationship between a history of preterm delivery and the cervical length in a subsequent pregnancy. Inasmuch as patients with a short cervix are at increased risk for a midtrimester pregnancy loss or spontaneous preterm delivery with intact or ruptured membranes, a short cervix could be considered as the expression of a spectrum of cervical diseases or functions. However, it is noteworthy that some women with a short cervix have an adverse pregnancy outcome, while others have an uncomplicated term delivery (65–70,83–97). Indeed, approximately 50% of women with a cervix of 15 mm or less deliver after 32 weeks (70). This indicates that cervical length is only one of the factors determining the degree of cervical competence and that a short cervix should not be equated with “cervical insufficiency.”

CERVICAL INSUFFICIENCY IS A SYNDROME

In a manner similar to preterm labor, pre-eclampsia, small for gestational age, fetal death, and preterm premature rupture of membranes (PROM), the clinical conditions that describe cervical insufficiency can be considered “an obstetrical syndrome” (98). Cervical ripening in the midtrimester may be the result of (i) the loss of connective tissue after a cervical operation such as conization (99–101) or loop electrosurgical excision procedure (LEEP) (101), (ii) a congenital disorder such as cervical hypoplasia after diethylstilbestrol (DES) exposure (102–105), (iii) intrauterine infection (106–108), (iv) a suspension of progesterone action (34,35): there is experimental evidence that progesterone can reverse cervical compliance induced by the administration of dexamethasone to pregnant sheep (109). Moreover, recent studies have indicated that progesterone administration to women with a short cervix can reduce the rate of preterm birth (110,111), or (v) a cervical disorder. Each of these different causes of the syndrome could be affected by genetic or environmental

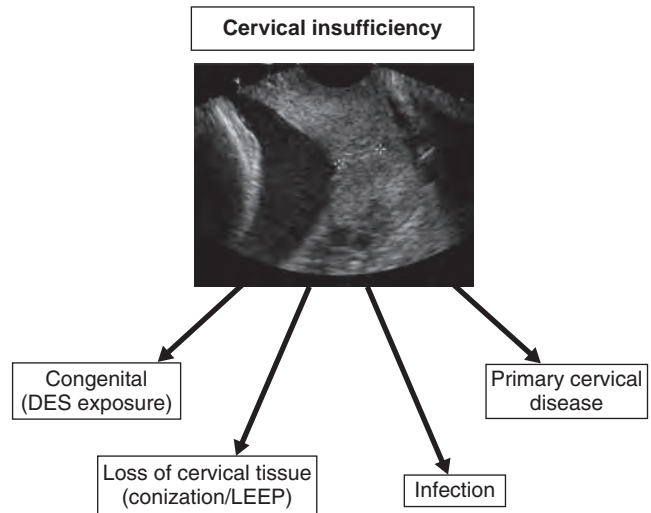

Figure 5 The proposed causes of the “cervical insufficiency syndrome.” Abbreviations: DES, diethylstilbestrol; LEEP, loop electrosurgical excision procedure. Source: From Ref. 42.

factors (Figure 5) (42). Moreover, more than one mechanism of disease may be operative in a specific patient. The possibility of novel and yet to be discovered mechanisms of disease playing a role must also be considered.

PREVIOUS TRAUMA AS A CAUSE FOR CERVICAL INSUFFICIENCY

Procedures such as laser ablation, LEEP, and cold-knife conization may increase the risk of a preterm birth (100,112–118). In a recent retrospective study by Shin et al., the rate of preterm delivery was significantly higher in women with a history of a conization when compared with those without one [32.1% (18/56) vs. 15.2% (3355/22,070), $p < 0.001$]. Yet the use of a McDonald cerclage ($n = 25$) was not associated with a reduction in the rate of preterm delivery when compared with those without cerclage ($n = 31$) (expectantly managed group vs. cerclage group; <28 week, 6.5% vs. 8.0%, $p = 1.000$; <34 week, 19.4% vs. 20.0%, $p = 1.000$; <37 week, 29.0% vs. 36.0%, $p = 0.579$) (119).

CONGENITAL CERVICAL INSUFFICIENCY

Exposure to DES in utero has been reported to increase the risk of second-trimester pregnancy loss fivefold (6.3% in DES exposed vs. 1.6% in the control group) (120).

There is evidence of familial aggregation in cervical insufficiency. In one study, approximately 25% of patients with cervical insufficiency had a first-degree relative with a similar diagnosis (121). This has been attributed to genetic factors involved in the regulation of extracellular matrix, specifically, polymorphisms in the genes encoding for collagen 1 alpha 1 (COL1A1) and transforming growth factor beta (TGF β) (121), and recently IL-10 (122). A genetic predisposition to cervical insufficiency has been reported in women with Ehlers–Danlos syndrome (123,124) and Marfan syndrome (125–128).

“CERVICAL INSUFFICIENCY” AS A CLINICAL MANIFESTATION OF INTRAUTERINE INFECTION

A proportion of patients presenting with asymptomatic cervical dilatation in the midtrimester have microbial invasion of the amniotic cavity (MIAC) (106,107) that can be as high as

51.5% (106). MIAC may be due to premature cervical dilatation with the exposure of the chorioamniotic membranes to the microbial flora of the lower genital tract. Microorganisms may gain access to the amniotic cavity by crossing intact membranes (106). Under these circumstances, infection would be a secondary phenomenon to primary cervical disease. An alternative is that intrauterine infection or one caused by activation of microorganisms present within the uterine cavity (129) in the second trimester of pregnancy produces myometrial contractility and cervical ripening. Since uterine contractions are usually clinically silent in the midtrimester of pregnancy, the clinical picture of an infection-induced spontaneous abortion may be indistinguishable from that of an incompetent cervix (106,130). The most frequently isolated organisms from the amniotic fluid in women with suspected cervical insufficiency include *Ureaplasma urealyticum* and *Ureaplasma parvum* (106,131,132). We have established that 9% (5/57) of women with a short endocervix (<25 mm) have microbiologically proven intra-amniotic infection (108), suggesting that these infections are subclinical and may precede the development of the clinical picture of acute "cervical insufficiency" (dilated and effaced cervix with bulging membranes).

CERCLAGE

Cervical cerclage was introduced in 1955 by V. N. Shirodkar, Professor of Midwifery and Gynecology at the Grant Medical College in Bombay, India (39). The procedure was developed in response to his observation that "some women abort repeatedly between the fourth and seventh months and no amount of rest and treatment with hormones seemed to help them in retaining the product of conception" (39). Shirodkar referred to a group of 30 women who had had at least four abortions (some between 9 and 11 weeks). He stated that in his opinion, "95% of cases were due to a weak cervical sphincter and the other few to an underdeveloped or malformed uterus, etc" (39). Shirodkar emphasized that his work was confined to women in whom he could prove the existence of weakness of the internal os by "repeated internal examinations" (39). Ian McDonald, from the Royal Melbourne Hospital, reported in 1957 his experience with 70 patients who had a suture of the cervix for inevitable miscarriage (40). The history of this procedure is relevant since 50 years after its introduction: cerclage is being used for indications different from those originally intended, and there is conflicting evidence about its efficacy for the new indications (e.g., prevention of preterm birth in women with a sonographic short cervix) (39,40,90-92,95-97,133-154).

There are several approaches to cervical cerclage: (i) the Shirodkar method (39), (ii) the McDonald method (40), (iii) the Wurm procedure (155), and (iv) transabdominal (156). The latter has been performed using a laparotomy approach and later described, laparoscopically (157,158). The most widely used procedure is the McDonald cerclage.

Complications of Cerclage

The risks associated with the use of cerclage include those that can occur intra-operatively (anesthetic complications, blood loss, rupture of membranes), in the post-operative period (subclinical or clinical chorioamnionitis, preterm PROM, cervical laceration, preterm contractions), and at the time of labor and delivery (cervical laceration, cervical dystocia, sepsis,

uterine rupture) (159-170). The rate of each complication varies as a function of the indication for the cerclage, type of cerclage, and the state of the cervix and amniotic membranes at the time of surgery (161,164,167). Complications commonly reported include preterm PROM (elective 2.8-36.3%, emergency 2.8-52.2%) (162,167-170), preterm contractions (36-39%) (168), cervical lacerations (elective 0-14%, emergency 0-23.8%) (166-169, 171), uterine rupture (<0.1%) (172), chorioamnionitis (elective 5.2-14.9%, emergency 4-39.1%) (162,167,169,170,172), sepsis (0.34%) (166), and bleeding (14.9%) (168).

Harger (169) reported the outcome of 251 patients; 202 who underwent a cerclage placed based upon history and 49 in which cerclages were placed due to cervical dilation. The mean blood loss was 30 ml in those patients who underwent a McDonald cerclage and 44 ml in those who had a Shirodkar procedure. Two patients who had undergone an emergency cerclage lost 150 ml of blood. The risk of pregnancy loss "apparently caused by elective procedures" was 2% (4/202). Acute chorioamnionitis occurred in 1.2% of patients. Cervical lacerations occurred more frequently at the time of labor in women who had a Shirodkar or McDonald cerclage than in those without a cerclage (n = 55,688) (Shirodkar: 11% and McDonald: 14% vs. control group: 2.18%, $p < 0.001$). Furthermore, the authors argued that some cesarean sections in women who underwent cerclage (McDonald or Shirodkar) may be attributed to cervical scarring as a result of the surgery.

Charles and Edwards noted an increased risk of complications in patients undergoing cerclage after 19 weeks of gestation. The rate of rupture of the membranes within 5 days of the procedure was 19.5%, preterm PROM (26-34 weeks of gestation) 52.2%, and chorioamnionitis 39.1% in these patients (162).

In a retrospective review of 482 singleton pregnancies who underwent cerclage placement [McDonald cerclage (n = 377), Shirodkar (n = 104)] over a 6-year period, Treadwell et al. (167) reported that PROM occurred in 38% of patients and was the most frequent complication. The prognostic factors determining gestational age at delivery were gestational age at the time of cerclage, cervical dilation, and number of prior pregnancy losses before 24 weeks of gestation. The rate of cervical laceration was 6.7% and was similar for both emergency and elective cerclages. Of interest, the primary cesarean delivery rate of patients who had undergone a Shirodkar cerclage was higher than those who had undergone a McDonald cerclage (31% vs. 17%, $p < 0.005$).

Cerclage in Patients with Acute Cervical Insufficiency

Only one randomized clinical trial has tested the effect of cerclage in patients with acute cervical insufficiency. Patients were identified if they presented with a dilated cervix and membranes at or below a dilated external os before 27 weeks of gestation. Patients were treated either with emergency cerclage and indomethacin (n = 13), or bed rest only (n = 10). Indomethacin was only given to one group. Preterm delivery before 34 weeks of gestation was significantly less frequent in patients allocated to have an emergency cerclage and indomethacin than in those managed expectantly [54% (7/13) vs. 0% (0/10); $p = 0.02$]. Antibiotics were administered to both groups of patients (173). Acute cervical insufficiency, however, can present with different degrees of severity. A patient with a dilated cervix in whom the membranes

are visible but within the uterine cavity is not the same as the patient who has prolapsed “hourglass” membranes in the vagina with a fetal presenting part. The latter group represents a greater surgical challenge and is often associated with subclinical intrauterine infection. One recommendation is to place the patient in the Trendelenburg position and to allow reduction of the membranes to the amniotic cavity. Since patients with intra-amniotic inflammation/infection have a poor prognosis if a cerclage is placed, an amniocentesis is performed to look for infection/inflammation. The workup includes an amniotic fluid Gram stain, white blood cell count, glucose, and culture for aerobic and anaerobic bacteria as well as genital mycoplasmas. If a cerclage is placed, patients are often followed by transvaginal ultrasound. The length of the cervix after a cerclage has some prognostic value about the likelihood of success (174–177).

Cerclage to Prevent Preterm Delivery in Women with a Short Cervix without a History of Preterm Delivery

The largest randomized clinical trial in which cerclage was used in patients with a sonographic cervical length ≤ 15 mm was conducted by the Fetal Medicine Foundation of the United Kingdom (150). Cervical length was measured in low-risk patients at a median gestational age of 23 weeks, and those with a cervix ≤ 15 mm were randomized to either the expectant management ($n = 126$) or cerclage group ($n = 127$). The rate of preterm delivery at < 33 weeks of gestation was not significantly different [expectant management group 26% (33/126) vs. cerclage group 22% (28/127)]. The conclusion of this study is that cerclage placement in patients with a short cervix without risk factors for preterm delivery does not reduce the rate of preterm birth, neonatal morbidity, or the rate of perinatal death (150).

Prophylactic Cerclage and Cerclage in Patients with a History of Preterm Delivery and a Short Cervix

The role of prophylactic cerclage in high-risk patients without a sonographic short cervix for the prevention of preterm delivery/midtrimester abortion (by history) is unclear (144,152,165,178,179). While the largest trial conducted prior to the introduction of ultrasound evaluation of the cervix suggested a modest beneficial effect (179), other trials (165,178) and systematic reviews (41) prior to the use of ultrasound have indicated that the evidence of effectiveness for prophylactic cerclage is either weak or nonexistent.

In the Cervical Incompetence Prevention Randomized Cerclage Trial (CIPRACT) study, Althuisius et al. (135,180) randomized 73 pregnant women at < 15 weeks of gestation with risk factors for “cervical incompetence” to have a prophylactic cerclage ($n = 23$) or be observed ($n = 44$). Four patients had a spontaneous abortion during the first trimester and two were lost for follow-up. The risk factors of “cervical incompetence” included the history of preterm delivery before 34 weeks of gestation, previous preterm PROM before 32 weeks of gestation, history of cold-knife conization, DES exposure, and a Müllerian duct abnormality. Prophylactic cerclages (i.e., McDonald) were generally placed between 10 and 12 weeks (later if enrolled at a later gestational age) using a braided polyester thread. In both groups, cervical length was evaluated every 2 weeks after randomization. The

rate of preterm delivery (< 34 weeks) was similar in both groups [prophylactic cerclage 13% (3 of 23) vs. observation 14% (6 of 44); $p > 0.05$] as well as the neonatal survival [prophylactic cerclage 91% (21 of 23) vs. observation 93% (41 of 44); $p > 0.05$]. Patients allocated to the observation group were followed with serial sonography. If the cervical length shortened (< 25 mm) before the 27th week of gestation, patients were randomized to both therapeutic cerclage and indomethacin with bed rest ($n = 20$) or bed rest alone ($n = 16$). Patients who received a cerclage and indomethacin had a lower rate of preterm delivery at < 34 weeks and composite neonatal morbidity (neonatal intensive care unit admission or neonatal death) [0% vs. 44% (7 of 16), $p = 0.002$; and 5% (1 of 19) vs. 50% (8 of 16), $p = 0.005$].

By contrast, Rust et al. (91,181) randomized 113 patients presenting with a short cervix (< 25 mm) or funneling ($\geq 25\%$) between 16 and 24 weeks into the therapeutic cerclage group ($n = 55$) and the no-cerclage group ($n = 58$). The population included patients with and without risk factors for preterm birth. All patients underwent amniocentesis to exclude intra-amniotic infection and received 48 hours of therapy with indomethacin and antibiotics. There were no significant differences between the two groups with respect to the rate of preterm delivery at < 34 weeks of gestation (35% vs. 36.2%), readmission for preterm labor (52% vs. 53%), placental abruption (11% vs. 14%), chorioamnionitis (20% vs. 10%), and the perinatal death rate (13% vs. 12%).

The CIPRACT study (135,152) enrolled only patients at risk for preterm delivery, while in the trial of Rust et al. (91,181), 13% of patients were at low risk. The positive predictive value for a short cervix to predict preterm delivery is higher in patients with a history of preterm birth. The fact that the rate of preterm delivery in the control group of the CIPRACT study was higher than that of the study of Rust et al. (43.8% vs. 36.2%) may explain, at least in part, the different results between these two studies.

Berghella et al. (146) conducted a randomized clinical trial of the use of McDonald cerclage in women with one or more risk factors for preterm birth (one or more prior deliveries at < 35 weeks, two or more curettages, history of DES exposure, cone biopsy, Müllerian anomaly, or twin gestation). Sixty-one patients with a cervical length < 25 mm or funneling $> 25\%$ were randomized to cerclage or bed rest. The authors reported that 47 pregnancies (77%) were high-risk singleton gestations.

There was no significant difference in the rate of preterm birth prior to 35 weeks in women who underwent cerclage (14 of 31; 45%) compared with those in the bed rest group (14 of 30; 47%) (RR 0.94; 95% CI 0.34–2.58). Similarly, patients with a singleton gestation and a prior preterm birth at < 35 weeks of gestation and a cervical length < 25 mm ($n = 31$ women) also had no benefit from cerclage placement (40% vs. 56%; RR 0.52; 95% CI 0.12–2.17) (146).

Owen et al. (153) reported a randomized clinical trial in which women with a prior spontaneous preterm birth before 34 weeks of gestation and a short cervix (defined as a cervical length < 25 mm) were randomly assigned to have a cerclage or to be managed expectantly. The primary endpoint for the trial was birth at < 35 weeks of gestation. Of the 302 patients randomized, 148 were allocated to the cerclage group and 153 to the non-cerclage group. There was a non-significant decrease

in the primary endpoint (delivery at <35 weeks of gestation) in women allocated to the cerclage group than in the non-cerclage group (32% vs. 42%; OR 0.67; 95% CI 0.42–1.07; $p = 0.09$). A post hoc analysis demonstrated that the rate of preterm delivery at <35 weeks was significantly lower in women with a cervical length below 15 mm, and there was no demonstrable effect in women with a cervical length between 16 and 24 mm. This study reported that cerclage reduced the rate of preterm birth and perinatal mortality. The results of the secondary analysis (<15 mm) are considered to be hypothesis-generating.

A meta-analysis of five trials in which women had singleton gestations, previous spontaneous preterm birth, and cervical length <25 mm before 24 weeks of gestation demonstrated that placement of a cerclage was associated with a lower rate of preterm birth before 35 weeks of gestation [28.4% (71/250) vs. 41.3% (105/254); RR 0.70, 95% CI 0.55–0.89]. Moreover, an index of perinatal mortality and morbidity (composite index) was significantly reduced in patients who had a cerclage (15.6% in the cerclage group vs. 24.8% in patients without cerclage, RR 0.64, 95% CI 0.45–0.91). Subgroup analysis demonstrated that in women with a cervical length of 15.9 mm or less, cerclage was associated with significant prevention of preterm birth at <37, 35, 32, and 28 weeks. The authors also examined the effect of cerclage as a function of cervical length. In patients with a sonographic cervical length of 16–24.9 mm, cerclage was associated with a significant reduction in the rate of preterm birth at <37 and <24 weeks of gestation (154). The authors stated that, based on their findings, “the effect of this intervention is important but clearly not the solution to the whole problem of preterm birth” and call for “further understanding of the pathophysiology of spontaneous preterm birth.” Thus, cerclage may be effective in reducing the rate of preterm birth in a subset of patients.

PESSARY IN WOMEN WITH CERVICAL INSUFFICIENCY AND/OR A SHORT CERVIX

The first report of the use of a pessary for the treatment of cervical “insufficiency” was in 1959 (182). Advocates for pessaries to prevent preterm delivery argued that their use should be considered in women with suspected cervical insufficiency because cerclage had not been proven to be efficacious in the prevention of preterm birth, and pessaries would not have the complications known to occur with cerclage. Vaginal pessaries are inexpensive, can be readily placed and removed, and allow outpatient management (without anesthesia) (183).

Several studies have evaluated the use of a pessary to prevent preterm delivery in women with suspected cervical insufficiency based upon history. Most of these reports consist of small case series (183–191).

Arabin et al. (187) reported sonographic cervical length measurements on patients with a prior spontaneous preterm birth before 36 weeks of gestation or early symptoms of preterm labor (pressure or contractions) and twin pregnancies. Patients with a cervical length ≤ 15 mm between 22 and 28 weeks of gestation were offered the use of a silicone pessary (Arabin pessary). The outcome of 11 patients who had a pessary was compared with a gestational age and cervical length–matched group. The control group consisted of 12 singleton pregnancies and 23 twin gestations. Placement of a

pessary was associated with a higher gestational age at delivery in both the singleton and twin gestations [for singletons, the mean gestational age at delivery was 38 (36–6/7 to 41) vs. 33–4/7 weeks (26–38), $p = 0.02$; for twins, 35–6/7 (33 to 37–4/7) vs. 33–2/7 weeks (24–4/7 to 37–2/7), $p = 0.02$]. None of the 12 singleton gestations with a pessary delivered prior to 36 weeks of gestation [pessary 0% (0/12) vs. control 50% (6/12), $p < 0.001$] (187). Based on these results, several trials are now in progress to determine whether a pessary can reduce the rate of preterm birth in women with a short cervix in both singleton and twin gestations (Carreras, Nicolaides, Palacio, Moratonas, Nizard). At this time, there is no evidence that cerclage is effective in twin gestations.

PROGESTERONE FOR THE PREVENTION OF PRETERM BIRTH IN WOMEN WITH A SONOGRAPHIC SHORT CERVIX

Vaginal progesterone reduces the rate of preterm delivery at <28, <33, <34, <35 weeks of gestation (110, 111), as well as the rate of respiratory distress syndrome and neonatal morbidity (111). The role of vaginal progesterone in the prevention of preterm birth in women with a sonographic short cervix is discussed further in the chapter focusing on preterm labor in this book (Chapter 1).

4 Recurrent pregnancy loss

Christine E. Ryan and Danny J. Schust

INTRODUCTION

Recurrent pregnancy loss (RPL) can be devastating to families involved. It is defined as three or more spontaneous or two or more consecutive losses prior to 20 weeks of gestation. It can be subdivided into preclinical losses at less than 6 weeks or clinical losses at greater than or equal to 6 weeks of gestation. Clinical losses can be further subclassified as embryonic (crown–rump length is at least 5 mm with no cardiac activity) or fetal (10–20 weeks without cardiac activity). Other experts have instead subdivided the losses into early (prior to 12 weeks of gestation) or late (between 12 and 20 weeks). Primary RPL exists if a couple has never carried a pregnancy to viability, whereas secondary loss is present if at least one viable term pregnancy has been achieved.

In considering the incidence of this disorder, one must keep in mind the baseline risk of miscarriage: fetal viability is achieved in only 30% of all conceptions and at least 50% of pregnancies are lost before a missed period (1). Among clinically recognized pregnancies, 10% to 15% still undergo sporadic loss during the first or early second trimester (2). RPL occurs in 1% to 4% of couples, with a definite cause identified in no more than 40%. Risk of subsequent loss, stratified by the number of prior losses, is detailed in Table 1.

It follows that the workup of couples with recurrent loss can justifiably be undertaken after two or more consecutive losses as the risk of recurrence is similar to that after three losses (2). Furthermore, the frequency of identifiable causative factors is similar after two or three losses. Other experts have suggested proceeding with workup for couples only after three consecutive losses at less than 10 weeks, unless the couple has had a previous euploid loss or experiences concomitant infertility or advanced maternal age (3). This latter approach can be justified by the fact that 25% of women aged 30 or less will have a subsequent loss whereas 50% to 60% of women at or beyond age 40 will experience a repeated loss (4,5).

PRECONCEPTION EVALUATION

Upon presentation to the clinic, it is imperative to have an organized diagnostic approach in order to avoid overwhelming either the affected couple or the provider. We recommend evaluation after a second consecutive loss without prior live-born child, a third loss if the couple has had a prior live-born child, or after two losses in the presence of infertility or advanced maternal age.

History should include age; past medical history and medications; characteristics, pattern, and gestational age of prior losses; exposure to toxins or recent travel; previous gynecologic or obstetrical infections; previous workup; family history [cycle regularity, spontaneous losses, diethylstilbestrol (DES) exposure, genetic syndromes, and thromboses]; and a thorough review of systems (e.g., rheumatic diseases). Karyotypes of prior losses

should be recorded if available. A general overall physical examination should then be performed including a pelvic examination.

Testing can then be offered. Keep in mind when ordering tests that nocturnal gonadotropin-releasing hormone pulses do not resume until 4 weeks postpartum, so some endocrine evaluations [prolactin (PRL), follicle-stimulating hormone (FSH), if indicated] should not be pursued until at least one month after a loss. Anticardiolipin antibodies, homocysteine, and protein S levels are altered by pregnancy and may not return to baseline until 6 to 12 weeks postpartum, further supporting a slight delay before initiating the workup (Table 2).

As a final note on the general evaluation, it is important that prenatal vitamin supplementation is recommended to all preconceptional patients. Poor dietary intake of vitamins has been associated with spontaneous pregnancy loss. For example, a folate level of 2.2 ng/mL (4.9 nmol/L) is associated with an increased rate of sporadic loss with an odds ratio of 1.47 (95% CI 1.01–2.14) (6). A recent Cochrane review of randomized trials, however, showed that vitamin supplementation does not prevent miscarriage or stillbirth. They do, however, lessen the likelihood of developing pre-eclampsia and have been shown to increase the likelihood of multiple gestations (7). Other benefits include lesser likelihood of neural tube defects, anemia, or other vitamin-associated deficiencies that may be common in pregnancy.

The remainder of this chapter will focus on the evidence supporting or refuting various proposed etiologies for RPL and their respective evidence-based management strategies.

ETIOLOGY AND MANAGEMENT

Uterine Abnormalities

With the exception of the septate uterus and possible acquired anomalies, uterine abnormalities are more commonly associated with second rather than first-trimester losses. These abnormalities include congenital anomalies of fusion or resorption, fibroids and polyps, synechiae or Asherman syndrome, and DES exposure. The diagnostic modalities for appropriate diagnosis include hysterosalpingogram (HSG), hysteroscopy, sonohysterography, laparoscopy, MRI, or three-dimensional ultrasonography. Each modality has advantages and disadvantages. For example, the sensitivity and specificity of standard two-dimensional transvaginal ultrasonography in diagnosing a uterine septum are 100% and 80%, respectively, while sensitivity and specificity using MRI are both 100% (8). Three-dimensional ultrasonography can be added after an abnormal two-dimensional ultrasound to improve the aforementioned specificity. Three-dimensional sonography is preferred over hysterosalpingography as the former test is less expensive and less invasive and allows for improved visualization of the endometrial cavity and myometrium. Three-dimensional ultrasonography can reliably delineate between septate and bicornuate uteri (9,10).

Anomalies

Overall, the presence of a congenital uterine anomaly appears to almost double the risk of RPL: anomalies have been identified in 6.3% of recurrent loss patients versus 3.8% of fertile women ($p < 0.05$). In one investigation, the breakdown of specific anomalies among RPL patients was 1.9% bicornuate (vs. 0.4% among fertile women, $p < 0.01$), 2% septate, and 1% arcuate uteri, with latter two not holding a statistically significant difference when compared with fertile women (Table 3) (11).

One common current theory holds that the causative factor for loss in patients with a septate uterus is implantation on the septum itself. This is thought to result in inadequate placentation secondary to poor septal vascularity and resultant early demise. This theory is supported by the timing of losses: early first trimester with septate uteri versus second-trimester losses or preterm deliveries with bicornuate and unicornuate uteri (13). In addition, although the vascular density of septa is similar to normal myometrium (14), a study of 12 pregnancies in women with septate uteri revealed that the only four successful pregnancies were those that had implanted away from the septum (15). Furthermore, several uncontrolled studies have shown that septum resection leads to an improved rate of successful subsequent pregnancy. A retrospective case series showed that 70% to 85% of RPL patients who underwent surgical correction of bicornuate and septate uteri delivered viable infants in the next pregnancy (16). Hysteroscopic resection of uterine septa

leads to comparable subsequent pregnancy rates with those seen after metroplasty (16), leading the American College of Obstetricians and Gynecologists (ACOG) to make a compendium recommendation supporting hysteroscopic resection. No prospective controlled studies have been undertaken. Extensive surgical procedures, such as Strassman unification, are rarely undertaken.

The contribution of the arcuate uterus to RPL is more controversial. One study of 61 RPL patients identified an arcuate uterus in 15% via three-dimensional ultrasound and hysteroscopy versus 3% of 1000 general gynecologic patients (17,18). Others, however, have argued against the presence of an association (19,20).

Leiomyomata and Polyps

Theories concerning the contribution of leiomyomata or endometrial polyps as an etiology of RPL have centered on their disruption of endometrial vasculature, the intrauterine cavity, or tubal patency. Either polyps or fibroids may act as foreign bodies, similar to intrauterine devices, and thus disrupt pregnancy. The direct association between submucosal fibroids and RPL has had some controversy in the past although uncontrolled studies do reveal an association. Intramural fibroids have been proven to interfere with implantation of in vitro fertilization pregnancies, though little data are available relative to intramural fibroids and RPL. The rate of spontaneous loss decreases after removal of fibroids over 5 cm in diameter, regardless of their location (21) and, therefore, resection is recommended. Hysteroscopic approaches for fibroid removal are preferred when possible.

Synechiae

Uterine synechiae may occur after uterine infection, intrauterine curettage, or other uterine instrumentation. Synechiae have been found in 5% of patients with RPL. Hysteroscopy is typically recommended to lyse these adhesions, although strong data to support this treatment are lacking.

Table 1 Risk of Subsequent Pregnancy Loss

After one successful pregnancy	12%
After two consecutive losses	24–26%
After three consecutive losses	
With at least one previous live birth	30%
Without previous live birth	32–45%
After four consecutive losses	40–50%

Table 2 Diagnostic Evaluation

Anatomic	Sonohysterogram or hysteroscopy MRI if indicated
Genetic	Parental karyotype and conceptus cytogenetic results Genetic counseling if indicated
Thrombophilias	(Consider full testing if >10-week loss, history of VTE, family history of thrombosis, or non-Caucasian) All patients: factor V Leiden, PT G20210A mutations, homocysteine level APC resistance Consider AT III, PC, and PS deficiency testing in all Asian patients
Immunologic	(Low or unsustained, moderately positive values are not clinically significant) Russel's viper venom time (RVVT) (=lupus anticoagulant) Anticardiolipin antibodies (IgG or IgM) Anti- β 2 glycoprotein I antibodies (IgG and IgM) Consider antithyroid antibodies
Endocrine	Luteal phase duration (positive ovulation kit test till day 1 menses; <13 days indicative of deficiency) Day 3 FSH (for ovarian reserve), TSH, PRL (if menses irregular or with galactorrhea) If menses irregular with signs of PCOS, consider androgens, SHBG, 17OHP, and insulin sensitivity testing

Abbreviations: MRI, magnetic resonance imaging; VTE, venous thromboembolism; FMH, family medical history; FVL, Factor V Leiden; PT, prothrombin; APC, activated protein C—15% of activated protein C resistance is not due to FVL; AT, antithrombin; PC, protein C; PS, protein S; Ig, immunoglobulin; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; PRL, prolactin; PCOS, polycystic ovarian syndrome; SHBG, sex hormone-binding globulin; 17OHP, 17-hydroxyprogesterone.

DES Exposure

While isolated spontaneous loss is more common with a history of DES exposure (22), little data exist regarding its relation to RPL. No approach to the correction of anatomic abnormalities related to DES exposure has been successful. It does, however, seem warranted to seek this history, as the implications go beyond maintenance of pregnancy.

Cervical Incompetence

A Cochrane review of six trials, including 2175 women, found there to be no benefit for either prophylactic or therapeutic cervical cerclage among patients with presumed cervical incompetence and any adverse pregnancy outcomes (including RPL). For prophylactic cerclage, no reduction was seen in overall pregnancy loss and preterm delivery rates in the overall analysis, although a small decrease in births prior to 33 weeks was reported in one of the included trials (RR 0.75, 95% CI 0.58–0.98). Additionally, the use of therapeutic cerclage upon ultrasound findings of decreased cervical length failed to positively alter total pregnancy loss, early pregnancy loss, or preterm delivery rates (23).

Genetic Factors

Parental chromosomal anomalies are identified in 4% of couples with RPL versus 0.2% of couples in the general population. Maternal anomalies are identified in a 3:1 ratio relative to paternal anomalies. Of spontaneous abortions, 60% to 75% have an abnormal fetal karyotype (24). These fetal chromosomal abnormalities have a more prominent role in single losses than recurrent losses. In fact, as the number of pregnancy losses increases for any given couple, the risk of fetal chromosomal aberrations decreases. In other words, loss of a chromosomally abnormal fetus carries a higher chance of subsequent live birth than loss of a euploid embryo (25,26). To this point, if the karyotype of the first abortus is aneuploid, then the karyotype of the second successive loss is abnormal in 50% to 70%; if the first is chromosomally normal, then the incidence of a karyotypic abnormality in the second loss is decreased to 20% (27,28).

At least half of clinically recognized, isolated spontaneous abortions have a chromosomal anomaly. Of these, 56% are trisomic, 20% are polyploid, 18% exhibit monosomy X, and 4% carry unbalanced translocations (29). For comparison, 70% of preclinical spontaneous losses are chromosomally abnormal whereas only 5.6% of second- and third-trimester losses carry these abnormalities (30,31). It has been suggested that the majority of these losses may be secondary to maternal

aging rather than nonrandom events (32,33). Preimplantation genetic diagnosis (PGD) studies have irrefutably demonstrated that 50% of embryos from RPL couples have aneuploidy (34,35).

The ACOG recommends karyotype screening of all RPL couples. This recommendation is based (i) on the couple’s desire to identify a cause, (ii) on the fact that the couple may benefit from prenatal genetic testing if a balanced chromosomal abnormality is identified, and (iii) on the fact that normal appearing offspring may carry the abnormality and thus have potential reproductive complications of their own (2).

Aneuploidy

One aneuploid loss increases the risk of a subsequent aneuploid loss (36). Trisomies are the most common anomaly as a group, led by trisomy 16. Still, the single most common aneuploidy found in first-trimester pregnancy loss specimens is 45 X,0. Some experts therefore suggest that it would be prudent to perform cytogenetic analysis of second and subsequent losses, understanding that a trisomic loss does not increase the risk of recurrent loss (33). In fact, recurrent aneuploidy or polyploidy, though seen with sporadic loss, has not been proven to be associated with recurrent loss when stratified for age (37). If the karyotype of an abortus is found to be aneuploid, a maternal cause for loss can be effectively excluded. The discovery of a legitimate cause for the loss may also be a source of comfort for the grieving family.

A recent study examined 420 losses from 285 couples and compared the frequency of chromosomal anomalies among recurrent loss patients with the frequency among patients without such a history. Significant differences were found between the two groups in the distribution of cytogenetic abnormalities, but the difference dissipated after stratification for maternal age. In younger women (i.e., less than 36 years of age), more spontaneous losses were euploid (37), suggesting other etiologies for RPL.

It is important to note that generalized screening for aneuploidy (as opposed to screening for a specific genetic abnormality using PGD) among embryos from chromosomally normal couples with a history of RPL is not currently recommended. Once considered promising, a recent review article concluded that preimplantation genetic screening (PGS) does not increase pregnancy rates in patients at risk of aneuploidy, including couples experiencing RPL (38). This is not surprising, however, given the current limitations on the numbers of chromosomes that can be screened using PGS. The outcomes of this intervention among recurrent loss patients should, therefore, be revisited when techniques for simultaneously screening all 23 chromosomes, such as complete genomic hybridization, become widely available.

Chromosomal Rearrangements

Overall, 2% to 4% of RPL couples have a partner with a chromosomal rearrangement (2). This is less common if there is no history of prior stillbirth or anomalous infant: 2.4% of females and 1.6% of males with no such history versus 4.6% of females and 1.7% of males with the aforementioned history (39). In these situations, family history may be telling as the translocation may have been in the lineage for multiple generations prior to detection. Although the carrier parents

Table 3 Reproductive Performance with Different Uterine Malformations

	Spontaneous abortion (%)	Preterm delivery (%)	Live birth (%)
Didelphys	20	53.3 ^{b,c}	40 ^f

Table 4 Thrombophilias and Recurrent Pregnancy Loss

Study	Associations supported	Associations refuted
Rey 2003 (meta-analysis of 31 studies)	RPL <13 weeks associated with FVL (G1691A), Activated protein C resistance, PT gene mutation (20210A), and PS deficiency	MTHFR, PC deficiency, and ATIII deficiency were not associated
Kovalesky 2004 (meta-analysis of 16 studies)	RPL (two or more first- or second-trimester losses) associated with FVL and PT gene mutation	
Krabbendam 2005 (review of 69 studies)	Hyperhomocysteinemia, antiphospholipid antibodies, FVL, and activated protein C resistance are associated with early RPL	

Abbreviations: RPL, recurrent pregnancy loss; FVL, Factor V Leiden; MTHFR, methyltetrahydrofolate reductase; PC, protein C; ATIII, antithrombin III deficiency; PT, prothrombin; PS, protein S.

are balanced in their chromosomal content, segregation during meiosis results in duplication or deficiency in the chromosomal constitution of some of the gametes. The incidence of de novo translocations is 1/2000 for reciprocal translocations (which makes up 60% of anomalies and yields normal gametes one-half of the time) and 1/9000 for Robertsonian translocations (40% of anomalies and yields normal gametes one-third of the time) (40). A natural selection of sorts appears to occur among sperm from men with balanced translocations, explaining why female carriers generally have a 10% risk of a subsequent abnormal live birth whereas the risk for male carriers is only 1%.

Therapy for the couples with RPL and balanced translocations relies on genetic counseling and discussion of options for prenatal diagnosis, donor gametes for the affected partner, or PGD with implantation of unaffected embryos. For fully evaluated RPL couples in whom one partner carries a structural chromosomal rearrangement, the subsequent live-birth rate is greater than 70% after evidence-based treatment, close monitoring, and supportive care (41).

Other

Other chromosomal anomalies associated with pregnancy loss tend to involve the X-chromosome. Women with Turner mosaicism who become pregnant are more susceptible to spontaneous loss. Of 160 pregnancies in these mosaic patients, 29% ended in spontaneous loss, 20% delivered children with malformations, and 7% resulted in perinatal death (42). Additionally, highly skewed X-chromosome inactivation may be responsible for otherwise unexplained recurrent losses (43). However, as commercial tests are generally unavailable for X-inactivation and other rare genetic abnormalities, testing is generally not available, performed, or recommended.

Thrombophilias

Thrombophilias include a diffuse group of inherited hypercoagulable states. The most often discussed include Factor V Leiden (FVL), prothrombin (PT) G20210A promoter mutation, deficiencies of proteins C and S (PC and PS, respectively), antithrombin III deficiency (ATIII), and hyperhomocysteinemia [including abnormalities in methyltetrahydrofolate reductase (MTHFR)] function. The antiphospholipid syndrome (APS) is another hypercoagulable state associated with RPL, but it is acquired and will be discussed separately under the Immunology section. It has been suggested that patients to be tested for

familial hypercoagulability should include those with unexplained fetal death beyond 10 weeks, personal history of venous thromboembolism, a suggestive family history, and those with at least three first-trimester losses.

The presence of two or more heritable thrombophilic defects has been associated with adverse outcomes, including pre-eclampsia, thrombosis, intrauterine growth restriction (IUGR), and even fetal death (44). The association between RPL and hypercoagulable states continues to be somewhat controversial with some research supporting (45–48) and other reports refuting (49–53) an association. The results of two recent meta-analyses and one review have been summarized in Table 4. Since controversy continues, it is useful to discuss the individual defects separately.

First, consider FVL and the PT promoter gene mutation. These mutations are common and carry low thrombotic risk in the heterozygotic state. They are reported to be present in approximately 9% and 3% of Caucasian women in the United States, respectively. These two thrombophilias have been associated with 25% of isolated thromboses and 50% of familial thromboses. Among RPL patients (with at least three losses and no successful pregnancies), the prevalence of FVL is 9% (OR 2.6, 95% CI 1–6.7, $p = 0.048$) (48). Furthermore, a prospective case-control study of FVL patients has shown lower pregnancy success rate among women with FVL who were not treated with anticoagulants (54).

The autosomal-dominant deficiencies in ATIII, PC, and PS are much less common in Caucasians, but carry a significantly greater thrombotic risk. These three mutations double the relative risk of abortion and stillbirth in carriers when compared with women who test negative (RR 2, 95% CI 1.2–3.3) (55). Diagnosis, however, can be affected by many factors. Oral contraceptive pills increase levels of both PC and PS while decreasing ATIII. Cigarette smoking decreases levels of PC and PS, while pregnancy decreases only the level of PS. Protein C and S testing can evaluate protein function or antigen levels. Protein S functional screening is non-diagnostic if less than 60% and antigenic levels should be performed.

Hyperhomocysteinemia may be caused by MTHFR mutation (heritable) and/or low levels of vitamin B6 or B12, or folate (acquired). Random homocysteine levels are considered mildly elevated at 16 to 24 $\mu\text{mol/L}$, moderately elevated at 25 to 100 $\mu\text{mol/L}$, and severely elevated at $>100 \mu\text{mol/L}$. Dietary supplementation with vitamins B₆, B₁₂, and folate can

Table 5 Diagnostic Criteria for Antiphospholipid Syndrome

Patients should have at least one clinical and one laboratory criteria

Clinical criteria

- ≥ 1 clinical episodes of arterial, venous, or small-vessel thrombosis
- ≥ 1 unexplained pregnancy loss of a morphologically normal fetus of at least 10 weeks of gestation
- ≥ 1 preterm births of a morphologically normal newborn at <34 weeks of gestation due to severe pre-eclampsia or placental insufficiency
- ≥ 3 unexplained consecutive spontaneous abortions before 10 weeks of gestation, with anatomic, hormonal, and parental structural genetic factors excluded

Laboratory criteria: the same antibody must be present on two separate occasions ≥ 12 weeks apart

- Anticardiolipin IgG and/or IgM, present in medium or high titers (>40 GPL or MPL)
- Anti β_2 -glycoprotein-1 IgG and/or IgM, present in titers >99 th percentile
- Lupus anticoagulant, detected according to the guidelines of the International Society on Thrombosis and Hemostasis

Source: Adapted from Ref. 65.

normalize homocysteine levels, but has not yet been shown to decrease thrombotic risk (56).

To summarize, evidence is mounting that supports the association between heritable and acquired thrombophilias and RPL as well as other adverse pregnancy outcomes. Our best data to date are from Caucasian populations and support to testing for FVL, PT promoter gene mutations, activated protein C resistance, homocysteine elevations, and the APS (dealt with in more detail in the next section). In non-Caucasian patients, the data are more limited and additional testing may be prudent. For instance, protein C, protein S, and ATIII deficiencies are significantly more common among patients of Asian descent than among Caucasian patients.

Ideal treatment for patients with heritable thrombophilias and RPL remains to be determined. A recent Cochrane review of anticoagulants for the treatment of RPL in the absence of APS noted that when 20 females with fetal loss after the 20th week and a thrombophilic defect were randomized to enoxaparin or aspirin, enoxaparin increased the live-birth rate (RR 10, 95% CI 1.56–64.2). Live-birth rates were unchanged, however, in controlled studies of aspirin versus placebo. The review's summary recommendation was that "data are too limited to recommend use of anticoagulants" in the setting of two or more spontaneous losses or one late intrauterine fetal death without apparent causes other than inherited thrombophilias except for anticardiolipin antibodies (57). The formal ACOG statement agrees that "whether antithrombotic treatment improves subsequent pregnancy outcome is uncertain" (2). Further trials are therefore needed.

Immunologic

APS

APS or Hughes syndrome is present in and felt to be responsible for 5% of RPL. In this syndrome, losses more commonly occur beyond 10 weeks of gestation, generally during the second or even early third trimesters (58,59). The mechanisms for APS-related losses are thought to be related to impaired vascular flow to the fetus. Since blood flow in placental vessels is not established until at least 9 to 10 weeks of gestation, losses at less than 10 weeks of gestation may be the result of impaired gestational nutrition, which occurs via diffusion prior to the establishment of intervillous blood flow. Thereafter, theories propose that thrombosis and vasoconstriction may occur due to antiphospholipid antibody binding to platelets and vascular endothelial membranes (60).

Other researchers purport that the antibodies in APS cause inhibition of cytotrophoblastic fusion, invasion, and differentiation and that this inhibition in turn leads to recurrent pre-embryonic or embryonic pregnancy loss (61–63).

Diagnosis of APS is based on an international consensus that was most recently updated in their criteria in 2006 (Table 5). The syndrome may be subdivided into primary (no other related disease present) or secondary (systemic lupus erythematosus (SLE), valvular heart disease, or other rheumatic diseases coexist). ACOG recommends testing all RPL patients for APS laboratory criteria as outlined in Table 5. Although there exists evidence linking antiphosphatidylserine antibody positivity to early RPL, its role in diagnosis, treatment, and prognosis remains controversial (64,65).

Numerous interventional studies have been performed in patients with RPL. The most promising approaches involve various regimens of aspirin and heparin. In controlled studies, combinations of aspirin, low molecular-weight heparin (LMWH), and human chorionic gonadotropin (hCG) as well as unfractionated heparin and aspirin led to 70% to 75% successful pregnancy outcome versus 50% in untreated controls (66,67). Heparin clearly lends benefit, as shown in Empson's study, where addition of heparin to aspirin when compared with aspirin alone resulted in a 54% decreased rate of pregnancy loss (RR 0.46, CI 0.29–0.71) (68). Heparin also proved more effective than intravenous immunoglobulin (IVIG) in randomized trials (69). A low-dose aspirin versus placebo study is currently underway. LMWH has also been suggested as an effective alternative to unfractionated heparin (67,70–72) although not all investigators agree. Steroids should not be given if no other clinical indication is present, as they have been shown to decrease the live-birth rate and increase the rate of fetal and maternal complications (73,74).

Current recommendations for the treatment of patients with APS and RPL (but no prior thrombotic episode) support initiation of heparin at the time of a positive pregnancy test. If given LMWH, these patients are maintained on prophylactic doses through approximately 36 weeks of gestation when it is recommended to convert to unfractionated heparin to decrease the risk of hematoma with epidural placement or hemorrhage at the time of delivery. Anticoagulation prior to conception is discouraged due to the risk of hemorrhage with ovulation. Therapeutic rather than prophylactic doses of LMWH or unfractionated heparin should be used if a history of thrombosis is present. Close maternal and fetal surveillance

should be performed instituted in all patients with a history of APS due to the increased risk of significant perinatal morbidity including pre-eclampsia, IUGR, and preterm labor. Finally, since the risk of thrombosis continues to be increased during the first 6 weeks postpartum, anticoagulation should be continued after delivery bridge this time period.

Thyroid Antibodies

Associations have been made between the presence of thyroid antibodies and spontaneous abortion. An increased rate of spontaneous pregnancy loss is seen with autoantibodies to thyroglobulin or thyroid peroxidase (TPO) if identified in early pregnancy or immediately before conception (75,76). In other studies, the presence of antithyropoxidase antibodies increased the risk of spontaneous loss from 23% to 50% (77). A meta-analysis published in 2004 found the odds ratio for spontaneous miscarriage in the presence of thyroid antibodies to be 2.73 (95% CI 2.2–3.4) using 8 case-control studies and 2.3 (95% CI 1.8–2.95) using 10 longitudinal studies (78).

Antimicrosomal and antithyroglobulin antibodies have been identified with increased frequency among females experiencing RPL. An investigation of RPL patients in 2000, however, concluded that if the patient is euthyroid, the presence of antithyroid antibodies does not affect pregnancy outcomes (Rushworth 2000). Nevertheless, much additional work has been done since 2000 that suggests otherwise and, although not specific to the recurrent loss population, is worthy of discussion. Studies have shown that patients with subclinical hypothyroidism (antibody status not delineated) do experience significantly increased rates of adverse obstetric events (Abalovich 2002, Casey 2005). A more recent study prospectively divided 984 euthyroid pregnant women into three groups: those with positive TPO antibodies to whom they gave levothyroxine (group A), those with antibodies that did not receive levothyroxine (group B), and controls who were negative for antibodies and untreated (group C). These researchers found a similar miscarriage rates for groups A and C (3.5 and 2.4%, respectively), but both A and C had significantly lower miscarriage rates than women in group B at 13.4% [$p < 0.05$, RR 1.72 (95% CI 1.13–2.25) and $p < 0.01$, RR 4.95 (95% CI 2.59–9.48), respectively]. Additionally, untreated antibody-positive women (group B) had a higher preterm delivery rate (22.4%) than women in group A (7%) ($p < 0.05$, RR 1.66 (95% CI 1.18–2.34)) or group C (8.2%) ($p < 0.01$, RR 12.18 (95% CI 7.93–18.7)) (79). These data support treatment of euthyroid pregnant women who test positive for TPO antibodies with levothyroxine to decrease the rates of both spontaneous abortion and preterm delivery. Further study in patients with a history of RPL is certainly warranted. It is, however, important to note that in the presence of anti-TPO antibodies, the risk of developing hypothyroidism during pregnancy or the postpartum period is increased. Therefore, it is recommended that the thyroid-stimulating hormone be checked during each trimester and after delivery in antibody positive women (80,81).

Antinuclear Antibodies

It has been reported that 7.5% of RPL females, compared with less than 2% of controls, test positive for antinuclear antibodies (ANA) (82). Still, testing for ANA among RPL patients does not appear to be helpful in the absence of

co-existent rheumatic autoimmune disorders. Subsequent pregnancy outcomes among RPL patients with an untreated, isolated, positive ANA is no different from those who test negative. In a randomized trial, patients with positive autoantibodies (including ANA) had no difference in outcomes when treated with prednisone and aspirin versus placebo (74). Data, therefore, do not support testing for ANA or treating positive results.

SLE

Patients with SLE have increased rates of both spontaneous and recurrent pregnancy loss in all trimesters. Not surprisingly, the most sensitive marker for poor pregnancy outcome among this group is the presence of antiphospholipid antibodies, which are seen in 37% of SLE patients (83,84). Additional predictors of poor prognosis include preexisting renal disease and the number and severity of pre-pregnancy lupus flares (85,86). Patients who meet the criteria for the APS should be treated with heparin and low-dose aspirin (see above).

Alloimmune Disorders

Alloimmune disorders are purported to cause pregnancy loss via an abnormal cell-mediated maternal immune response to placental or fetal antigens. One hypothesis for alloimmune RPL holds that in normal pregnancies, maternal production of a blocking factor prevents rejection of the fetus and that these factors are missing in women experiencing RPL (87). Evidence used to support this theory includes (i) the tendency for RPL partners to share human leukocyte antigens, (ii) the fact that females experiencing RPL often do not produce purported serum blocking factors, and (iii) the fact that women with a history of RPL commonly produce anti-leukocytotoxic antibodies against paternal leukocytes (2). The blocking factor hypothesis has been widely studied, but is poorly supported.

Among RPL patients, there is a proposed dysregulation of normal immune mechanisms at the maternal–fetal interface. Theories suggest that a T helper cell type 2 (Th-2) cytokine predominance is necessary for successful pregnancy and that T helper cell type 1 (Th-1) cytokines (IFN- λ and TNF- α) negatively affect embryo and trophoblast viability (88–90). One investigator demonstrated that production of an embryotoxic factor (possibly like IFN- λ) from RPL patient leukocytes cocultured with placental extracts predicted subsequent pregnancy failure (88). These findings have not been successfully reproduced in other studies (91). Testing for embryotoxic factor and treatment based on such testing is not currently recommended.

Decidual NK-like cells that secrete transforming growth factor may also be required for successful pregnancy (92). Studies show both increased (93) and decreased (92,94) NK-like cell number in luteal phase endometrial biopsies from recurrent loss patients. Subsequent pregnancy outcomes may be worse with increased decidual NK cell numbers (95). Furthermore, higher levels of circulating NK cells have also been shown to predict poor outcome with the next pregnancy (96,97). The relationship of peripheral NK cell numbers and activity of the NK-like cells present at the site of implantation is unclear.

To date, no specific testing regimens or treatments for abnormal alloimmune responses among RPL patients have been definitively shown to predict future pregnancy outcomes (3,98,99). Flow cytometric assays to document maternal antibodies to paternal leukocytes have been proposed and do offer biologic plausibility. However, investigations into the role of these allo-antibodies have lacked controls and no efficacious therapies have resulted. Randomized controlled trials of mononuclear cell immunization for patients with a history of RPL have yielded conflicting results. Although initial investigations appeared promising (100), further studies have concluded that immunotherapy to stimulate tolerance is not effective. Rather, alloimmune mononuclear cell immunization increases the rate of pregnancy loss when compared with placebo while carrying the infectious disease and allergic risks of transfusions with several other blood products (101). Trials using IVIG in patients with RPL have been fairly extensive with five randomized trials demonstrating a benefit with intervention (102) while other investigations and two meta-analyses have shown no benefit (103–107). A recent Cochrane review of this topic concluded that “paternal cell immunization, third party donor leukocytes, trophoblast membranes, and IVIG provide no significant benefit over placebo in improving the live birth rate” (108). In light of this body of evidence, a recent ACOG practice bulletin stated that HLA typing, measurement of maternal anti-leukocyte antibodies against paternal leukocytes, and measurement of maternal serum blocking factors do not predict the outcome of subsequent pregnancies. Furthermore, luteal phase biopsy for the presence of decidual NK cells, testing for percentage of NK cells in maternal peripheral blood, and testing for embryotoxic factor are not indicated in patients with a history of RPL. In short, alloimmune testing is not indicated and no beneficial immunologic treatment options are currently available.

Maternal Infection

Although no single infectious agent has been clearly linked as causative in recurrent loss, several infectious agents have been linked to sporadic losses. These include vaginal and cervical culture-proven infections with *Toxoplasma gondii*, rubella, herpes simplex virus, measles, cytomegalovirus, coxsackievirus, *Listeria monocytogenes*, *Chlamydia trachomatis*, and *Mycoplasma hominis*. RPL patients do exhibit increased rates of endometrial colonization with *Ureaplasma urealyticum* (109). In light of the large number of possible infectious agents, it could be cost-effective to treat each partner empirically with azithromycin 1 g or doxycycline 100 mg twice daily for 10 days rather than performing multiple repeat cultures. The risks associated with this approach are low. It is also reasonable to completely omit diagnostic testing and treatment for infectious etiologies in RPL as ACOG recommends that tests for these agents are generally not useful and empiric antibiotics not warranted.

Endocrine

Before considering individual endocrine abnormalities that have been associated with RPL, it is important to highlight that no current evidence exists to support that any asymptomatic endocrine or metabolic diseases directly cause RPL.

Luteal Phase Defect

Luteal phase defect (LPD) is one of the most scrutinized of the proposed endocrine causes of RPL. It is hypothesized that with LPD, a defective corpus luteum produces insufficient amounts of progesterone, preventing implantation or impairing pregnancy maintenance. It is also hypothesized that poor follicular-phase oocyte development often precedes and causes LPD due to disordered estrogen secretion and dysfunction of the corpus luteum. This may also lead to increased luteinizing hormone levels and a hyperandrogenic decidual environment.

The diagnostic criteria for LPD require a histologic lag of more than 2 days between dating of an endometrial specimen and the documented day of the menstrual cycle. This lag must be documented in two cycles. This definition introduces the first line of criticism concerning the relationship of LPD with RPL: there is considerable inter-observer (110–112) and intra-observer (113,114) variations in histologic interpretation of the endometrial biopsy. It has been estimated that had a different pathologist read an individual biopsy, the “in-phase” or “out-of-phase” classifications would change in 20% to 40% of cases (112,115). Although LPD has been more often associated with RPL than with subfertility, the utility of the test is called into question by the fact that no histologic differences can be documented in the biopsy specimens from fertile and infertile women (116). Furthermore, LPD is common in all women tested. Females without a history of pregnancy loss show histologic LPD in up to 50% of single biopsies and 25% of sequential cycles (117).

Proposed treatments for LPD in patients with RPL have included artificial insemination, ovarian stimulation with clomiphene citrate or gonadotropins, administration of hCG, and progesterone supplementation. Administration of hCG to support the corpus luteum was tested in an international, multicentered randomized trial of 75 women. In this trial, injection of 10,000 IU of hCG at the diagnosis of pregnancy followed by 5000 IU weekly was compared with injection of placebo. No significant differences were noted in pregnancy outcomes (118). Abnormal expression of endometrial progesterone receptors or endometrial adhesion molecules during the window of implantation have been detected in women with impaired fertility and/or pregnancy outcomes and these can sometimes be reversed using supplemental progesterone or clomid (119). This restoration of endometrial protein expression may be a biomarker for resumption of normal endometrial function. Further support for the use of progesterone in the treatment of patients with RPL can be found in a recent Cochrane review. This meta-analysis of 15 trials including 2118 women showed no statistically significant difference when progesterone was used for the prevention of isolated spontaneous miscarriage (OR 0.98, 95% CI 0.78–1.24). By contrast, among women with three or more consecutive pregnancy losses, a benefit of progesterone supplementation was noted (OR 0.38, 95% CI 0.2–0.7), regardless of the route of administration and with no adverse effects for mother or baby (120). Although the utility of progesterone supplementation in women with otherwise unexplained RPL is clear, it remains unclear whether the mechanism of progesterone action is through correction of LPD, through immune modulation, or through alternative or additional activities.

Thyroid Disease

While inadequately treated hyper-, hypo-, and subclinical hypothyroidism have been associated with an increased rate of isolated spontaneous pregnancy loss and preterm delivery, no causal relationship has been established with RPL (121). Clinical thyroid dysfunction has also been linked with pregnancy complications such as low birth weight, placental abruption, reduced childhood intelligence quotients, and fetal death (122). Due to these associations, it is recommended that patients receive treatment for thyroid disorders and become euthyroid prior to attempting pregnancy. For additional discussion of this topic, please refer to the previous section on thyroid auto-antibodies and RPL.

Diabetes Mellitus, Insulin Resistance, and Polycystic Ovarian Syndrome

Diabetes mellitus is a risk factor for many adverse pregnancy outcomes. It is well established that poor diabetes control leads to an increased rate of spontaneous loss, while improved glucose control using insulin leads to decreased loss rates (123–125). Tight preconceptional glucose control is essential among RPL patients with diabetes mellitus.

The prevalence of insulin resistance is also higher among RPL patients than controls (27% compared with 9.5%; OR 3.55, 95% CI 1.4–9.01) (126). This may indicate causality. In fact, results from small retrospective studies support this in that treatment of insulin-resistant RPL patients with insulin-sensitizing agents appears to improve pregnancy outcomes (127–129).

Obesity itself has also been proven to carry an increased risk for pregnancy loss. A body mass index of over 30 kg/m² is associated with a 1.2 odds ratio of first-trimester loss (95% CI 1.01–1.46) and a 3.5 odds ratio for RPL (95% CI 1.03–12.01) (130).

Among patients with RPL, ultrasonographic evidence of polycystic-appearing ovaries has been found more commonly than in the general population (131–134). The presence of polycystic ovaries itself did not predict worse outcomes than the finding of normal ovaries (131–134), although among women with polycystic ovarian syndrome, those who suffer pregnancy loss tend to have higher levels of circulating androgens than those who have successful pregnancies (134).

In summary, while no single treatment has definitively proven to improve pregnancy outcomes among patients with disorders of glucose metabolism, evidence is mounting that weight loss and improved glucose control using insulin sensitizers or optimized insulin regimens will probably increase pregnancy maintenance.

Decreased Ovarian Reserve

The prevalence of elevated FSH levels among RPL patients is similar to that of an infertility population (135). Women with unexplained RPL, however, have a greater incidence of elevated day 3 FSH levels than RPL patients with an identified etiology. Among 57 women with three or more spontaneous pregnancy losses, 31% of those with unexplained losses (n = 36) had day 3 FSH levels greater than 10 mIU/mL compared with only 5% of women with explained losses (136). Testing for ovarian reserve among older RPL patients may help to determine the level of urgency in diagnostic testing and interventions.

Table 6 Nonsteroidal Anti-inflammatory Drug Use and Risk of Pregnancy Loss

	Hazard ratio (95% CI)
Users overall	1.8 (1.0–3.2)
Gestational age at first use:	
At conception	5.6 (2.3–13.7)
After conception	1.2 (0.5–2.6)
Duration of use:	
≤1 week	1.3 (0.7–2.6)
>1 week	8.1 (2.8–23.4)
<i>Abbreviation:</i> CI, confidence interval. <i>Source:</i> Adapted from Ref. 138.	

Hyperprolactinemia

Elevated levels of PRL induce LPDs and may decrease progesterone production by the corpus luteum. Hyperprolactinemia is also thought to interact with the hypothalamic–pituitary–ovarian axis to cause inadequate follicular development and oocyte maturation. After evaluation for intracranial lesions, treatment of elevated serum PRL levels in women experiencing RPL can be safely undertaken with bromocriptine or cabergoline. Pharmacologic normalization of the PRL levels has been proven to improve pregnancy success rates among RPL patients (137).

Environmental/Occupational Factors and Habits

No associations have been clearly established between RPL and environmental factors, occupational exposures, or work itself. Furthermore, exercise has not been proven to increase the rate of sporadic loss, though no studies have been conducted involving recurrent loss patients.

It is important to recognize, however, that some environmental exposures lead to a slight, but statistically significant, increase in the rate of isolated spontaneous pregnancy losses including nonsteroidal anti-inflammatory drugs (Table 6), tobacco, alcohol, and heavy caffeine use. These may act in a dose-dependent fashion or synergistically. Their discussion with RPL patients must be carefully approached to avoid generating guilt. It may be useful to discuss these factors as methods to maximize desirable pregnancy outcomes.

Tobacco Abuse

Smokers incur a 1.4- to 1.8-fold increase in their risk of pregnancy loss (139,140), and secondhand smoke leads to a 1.52- to 2.18-fold increase in the risk (141). It remains important to encourage both partners to attempt smoking cessation.

Alcohol

Drinking more than one alcoholic beverage per day carries an adjusted odds ratio for spontaneous pregnancy loss of 4.84 (95% CI 2.87–8.16) (142). Additionally, the average number of daily drinks is directly proportional to the risk of second-trimester pregnancy loss, irrespective of age, parity, race, marital status, smoking, or the number of previous spontaneous losses or induced abortions (143) (Table 7).

Coffee and Caffeine

Excessive caffeine intake has an established link to an increase in the risk of isolated spontaneous pregnancy loss of fetuses with normal karyotypes among nonsmokers (144).

Table 7 Alcohol Use and Age-Adjusted Relative Risk of Pregnancy Loss

Average no. of drinks	First-trimester loss rate	Second-trimester loss rate
<1/day	1.12 (ns)	1.03 (ns)
1–2/day	1.15 (ns)	1.98 (<i>p</i> < 0.01)
≥3/day	1.15 (ns)	3.53 (<i>p</i> < 0.01)

Abbreviation: ns, non-significant *p* value. *Source:* Adapted from Ref. 143.

Table 8 Caffeine Intake and Risk of Pregnancy Loss

Caffeine intake	Pregnancy loss risk
100–299 mg/d	RR 1.3 (95% CI 0.9–1.8)
300–499 mg/d	RR 1.4 (95% CI 0.9–2)
≥500 mg/d	RR 2.2 (95% CI 2.3–3.8)
≥375 mg/d	Adjusted OR 2.21 (95% CI 1.53–3.18) (142)

Abbreviations: RR, relative risk; OR, odds ratio.

Table 9 Etiology-Specific Interventions for Patients with Recurrent Pregnancy Loss

Disorder	Intervention
Anatomic	
Müllerian anomalies	• Hysteroscopic resection of septa, adhesions, submucosal fibroids, and polyps
Intrauterine synechiae	• Myomectomy for intramural and subserosal fibroids >5 cm
Asherman’s Syndrome	
Leiomyomata	
Endometrial polyps	
Genetic	
Parental balanced translocations	• Genetic counseling • IVF with pre-implantation genetic diagnosis • Donor gametes
Thrombophilic (heritable)	
	• Combined thrombophilic defects—therapeutic anticoagulation • Isolated defect and no personal or strong family history of thrombotic complications—prophylactic anticoagulation • Hyperhomocysteinemia—supplemental folic acid (0.4–1.0 mg/day), vitamin B ₆ (6 mg/day), and possibly vitamin B ₁₂ (0.025 mg/day)
Immunologic	
Antiphospholipid antibody syndrome	• Low-dose aspirin plus prophylactic heparin in women without a history of a systemic autoimmune disease like SLE or a history of thrombosis • Full anticoagulation if history of thrombosis or systemic autoimmune disease
Endocrine	
PCOS	• Metformin
Hypothyroidism	• Thyroid-hormone replacement
Luteal phase defect/unexplained	• Progesterone supplementation
Diabetes mellitus	• Appropriate management of diabetes, insulin if indicated
Other	
Environmental exposures	• Limit exposures to maximize pregnancy outcomes (e.g., tobacco, alcohol, caffeine)
All patients/unexplained	• Progesterone supplementation • Daily aspirin (81–100 mg), if losses at greater than 13 weeks of gestation

Abbreviations: IVF, in vitro fertilization; LMWH, low molecular-weight heparin; SLE, systemic lupus erythematosus; PCOS, polycystic ovarian syndrome.

The half-life of caffeine is halved in smokers and is doubled in users of oral contraceptives. See Table 8 for the caffeine dose-related increases in the risk of spontaneous pregnancy loss.

Irradiation

The incidence of chromosomal anomalies among spontaneously expelled ova is higher among couples in which either the female or the male was exposed to irradiation prior to conception (145). These data provide validity to the generally accepted recommendation that both partners avoid irradiation when attempting pregnancy.

Environmental Toxins

Anesthetic gases, tetrachloroethylene (a dry-cleaning chemical), lead, mercury, and isotretinoin (Accutane) have all been associated with an increased rate of spontaneous pregnancy loss. Organic solvents have rarely been linked to sporadic loss.

Unexplained

Much research has been devoted to possible therapeutic options for couples with unexplained RPL. Two recent studies have evaluated the role of preimplantation genetic screening for couples with idiopathic RPL. They have yielded conflicting results. Munne et al. studied 58 couples with unexplained RPL among whom the female partner was 35 years of age and older. The authors performed PGS for chromosomes X, Y, 13, 15, 16, 17, 18, 21, and 22 and transferred up to four embryos (euploid for these particular chromosomes). The subsequent miscarriage rate after identification of a gestational sac was 15.7%, which was lower than expected. They also found the “take-home” baby rate per retrieval to be 36% (146). Work by Platteau and colleagues (147) included 49 women with idiopathic RPL in a prospective cohort study. Their embryos were tested for abnormalities in chromosomes X, Y, 13, 16, 18, 21, and 22. For women less than age 37, the pregnancy rate per cycle initiated was 23%, whereas for women at or beyond

37 years of age, the rate dropped drastically to 3%, with 44% and 67% aneuploidy rates, respectively. Like Shahine and colleagues (38), these researchers concluded that no therapeutic evidence currently exists to support the use of in vitro fertilization with or without PGS for idiopathic RPL patients. Oocyte donation may be effective (148). Randomized controlled trials are needed.

Other studies have supported or refuted the benefit of various other treatment options. In considering the following, keep in mind that a meta-analysis from 1995 (149) concluded that 60% to 70% of unexplained RPL couples will have success with the next pregnancy in the absence of intervention; this provides both a frame of reference for evaluation of treatment success and an encouraging fact with which to counsel patients. After negative testing with karyotyping, HSG or hysteroscopy, and antiphospholipid antibodies for second-trimester losses, patients with recurrent loss beyond 13 weeks had an improved live-birth rate with daily low-dose aspirin (OR 1.88; 95% CI 1.04–3.37) (150). Providing supportive care to idiopathic first-trimester RPL couples is perhaps one of the best interventions, leading to a live-birth rate near 75% (vs. 50% of those not attending an early pregnancy clinic; $p = 0.002$) (4). Appropriately timed intercourse may also improve outcomes as intercourse remote from ovulation has been associated with an increase spontaneous loss rate due to chromosomal anomalies (145,151). Requiring bed rest for RPL patients during pregnancy is not supported by evidence (RR 1.54, 95% CI 0.92–2.58), although bed rest alone did perform better when compared with supplemental hCG without bed rest in a Cochrane review (RR 2.5, 95% CI 1.22–5.11) (152). An additional Cochrane review has been performed to evaluate the utility of hCG administration to treat women with a history of unexplained RPL. Randomized trials comparing the use of hCG in early pregnancy versus placebo or no treatment for women with two or more miscarriages ($n = 180$) showed a decreased risk of pregnancy loss among hCG-treated patients (OR 0.26, 95% CI 0.14–0.52) (153). Readers are encouraged by the authors of this study to interpret the data cautiously due to a large influence on the data by the two weakest studies. These authors therefore conclude that “there is not enough evidence to evaluate the use of hCG during pregnancy to prevent miscarriage” in patients with unexplained RPL (153).

It has been shown in meta-analyses that treatment of unexplained RPL with progesterone supplementation is useful (see above). We recommend the use of vaginal progesterone, typically 100 mg twice daily, starting 3 days after ovulation during cycles in which the couple is attempting conception. Progesterone supplementation is thought to have implications in treating both immune and luteal phase aberrancies though specific mechanisms are unclear.

POSTCONCEPTION EVALUATION

Close monitoring of subsequent pregnancies leads to an increased pregnancy success rate among patients with a history of RPL (154). These couples are prone to heightened senses of anger, depression, anxiety, and even psychoses. Careful evaluation for signs and symptoms of these disorders is warranted. The availability of counseling services, with or

without the use of support groups and/or a reproductive psychiatrist, is strongly encouraged.

SUMMARY

The assessment and management of patients with RPL continue to be somewhat controversial and both are likely to remain so. The disorder itself is multifactorial and the baseline rate of isolated pregnancy losses secondary to spontaneous fetal aneuploidy is high. The prognosis for most patients, even in the absence of a defined etiology, is remarkably good, making assessment of the utility of a given diagnostic test or intervention difficult in the absence of very large trials.

Evidence does exist for etiologies that should be excluded and effective treatment regimes for most diagnosed etiologies are available. After a thorough evaluation, if the resulting diagnosis is unexplained RPL, interventions such as progesterone supplementation, aspirin therapy (in selected patients), conception timing, and close clinical follow-up during early pregnancy have merit. Table 2 lists our recommendations for useful diagnostic testing in patients with a history of RPL. Table 9 lists etiology-specific interventions.

5 Multiple gestation

Isaac Blickstein

INTRODUCTION

The human female is clearly programmed to ovulate a single oocyte, to carry a singleton fetus, and to nurse one neonate at a time. Consequently, multiple pregnancies overwhelm the uterine (maternal) capacity to adequately nurture the fetuses as animal and human models have repeatedly confirmed the inverse relationship between birth weight and gestational age at delivery and litter size. This natural sequence is relatively rare (about 1 twin pair per 80–100 births) and is extremely rare in the case of high-order multiple pregnancies.

The infrequency of high-order multiple gestations might be understood from the quasi-mathematical relationship, known as the Hellin-Zellany rule for twins, triplets, and quadruplets (1). This rule states that if the frequency of twins in a given population is $1/N$, then the frequency of triplets will be $1/N^2$ and that of quadruplets $1/N^3$. The Hellin-Zellany relationship appears quite accurate as long as the population remained homogeneous and enjoyed natural procreation. However, deviations from the rule were observed already in the thirties of the 20th century mainly because of racial differences in the frequency of dizygotic (DZ) twinning. A second, and much more dramatic deviation from the Hellin-Zellany relationship, occurred during the emergence of effective treatment of infertility. Indeed, within a very small fraction in human history, the natural order of multiples has been profoundly changed. Physician-made (i.e., *iatrogenic*) multiple gestations are now seen in most developed countries with frequencies approaching 50% of twins and more than 75% of high-order sets.

Iatrogenic multiple gestations, the major contributors to the epidemic of multiple pregnancies, did not arise *ex vacuo*. Women nowadays are able to rely on efficient modern fertility treatment when deciding on postponing childbirth. Advanced maternal age, by itself an established risk for natural multiples, is thus a significant risk factor for age-related reduced fecundity and for the increased need for fertility treatment. It appears that social trends act in concert with available assisted procreation techniques to increase the risk of multiple pregnancy. Consequently, all developed countries exhibited a dramatic increase in multiple births. For example, the ratio of induced to spontaneous twins in the East Flanders (Belgium) over the last two decades changed dramatically from 1:46 into 1 in every 2–3 twin pairs (1). This population-based trend might be even more accentuated in hospital-based data.

Data from England and Wales and the United States demonstrate decreasing rates of higher order multiple births and represent a striking and optimistic change in trend when compared with the previous steep fourfold increase since the early 1980s (2). At the same time, however, the incidence of other and by far more frequent multiples—twins—continued to escalate on both sides of the Atlantic Ocean. Regardless of

the probable reasons for this change (2), twins are predictably associated with significantly increased likelihood of perinatal morbidity and mortality and, therefore, the implications of the ever-increasing multiple birth rates is a major public health issue. For example, the contribution of infertility treatment can be appreciated from as yet unpublished data of the Israel Neonatal Network on very low-birth weight (VLBW) infants (<1500 g). The data indicate that roughly one-third of all VLBW infants are from multiple pregnancies, three-fourth of which are iatrogenic multiples (i.e., about one-fourth of all VLBW infants are iatrogenic multiples). Interestingly, the proportion of iatrogenic twins conceived by assisted reproductive technology (ART) to those conceived by ovulation induction increased over the period 1996–2005, but at the same time, this proportion decreased for iatrogenic triplets.

BIOLOGY

Most human conceptions (>99.2%) result from a single zygote [i.e., monozygotic (MZ)] following the fertilization of a single egg by a single spermatozoon. In the remaining cases, more than one egg is ovulated and fertilized, resulting in polyzygotic conceptions [DZ, trizygotic, etc.]. The polyzygotic conception occurs more often in taller, older, parous, heavier, and black women, pointing to a genetic predisposition. However, the exact mechanism whereby the ovary is naturally stimulated to release more than one egg per cycle is basically unknown. By contrast, all infertility treatments are associated with ovarian stimulation, multiple ripe ovarian follicles, polyovulation, and multiple conceptions.

The vast majority of MZ conceptions result in singleton birth. In only a small fraction of the cases (0.4% of all natural conceptions), the zygote splits to form an MZ twin gestation. Available hypotheses proposed to explain the mechanism of zygotic splitting fail to explain why MZ twins are more prevalent after all methods of assisted reproduction (3) and which structure is likely to control this phenomenon. It was hypothesized (4) that a small proportion of oocytes might have an inborn propensity to undergo splitting upon fertilization leading to the constant prevalence of spontaneous MZ twins among different populations. Ovarian stimulation—the common denominator of all infertility treatments—would then predictably increase the number of available splitting-prone oocytes and as a result would increase the chance for such oocytes to develop upon fertilization into MZ twins. An intact zona pellucida seems to be required to control embryonic division into two distinct cell lines and to prevent ill-timed hatching. Human fertilized oocytes are able to undergo binary fissions, just as in the nine-banded armadillo (the only other mammal that produces MZ quadruplets), and to produce a variety of

Figure 1 Quadrochorionic quadruplets. This first-trimester scan demonstrates the thick inter-twin membranes (several lambda signs).

Figure 2 Monozygotic twins. At this stage, the twins are very close to each other and an inter-twin membrane is not visualized.

combinations of MZ pregnancies. Importantly, this hypothesis does not negate previous genetically sound hypotheses, but places them into a broader perspective in light of observations from modern infertility treatment (4).

The increased frequencies of iatrogenic multiples changed the proportion of DZ and MZ twinning. In a population comprising mainly spontaneous gestations, the usual quoted frequency of MZ twinning is about one-third of the twin population, whereas in a population comprising a large proportion of iatrogenic conceptions, the expected MZ rate is 1 in 10 to 14 twin gestations.

ZYGOSITY, CHORIONICITY, AND PLACENTATION

DZ twins have two placentas (separate or fused), each with its chorion and amnion, forming the so-called dichorionic (DC) placenta. The inter-twin membrane comprises four layers (one chorion and one amnion from each twin) and usually appears as a thick septum during the optimal time of sonographic diagnosis at 11 to 14 weeks of gestation (Fig. 1). However, the triangle of decidual tissue between the reflections of the membranes, known as the “lambda” sign, is more easily identified and is pathognomonic of poly-chorionicity (Fig. 1). After birth, a DC placenta is confirmed by simply counting the placental discs and/or the number of layers in the inter-twin membrane.

MZ placentation, however, is presumably depended on the stage of embryonic development at which the split occurs. Early splits (about one-third) would result in DC placentas, whereas later splits result in monozygotic (MC) placentas. Moreover, if the amnion has not yet differentiated, the MC placenta includes two amniotic sacs: the MC-diamniotic placenta (about two-thirds of the cases). If the split occurs after differentiation of the amnion (i.e., >8 days after fertilization), an MC-monoamniotic placenta develops. Finally, even later splits are believed to result in all varieties of conjoined twins.

The sonographic diagnosis of an MC placenta is usually initiated by the absence of sonographic signs of DC placentation. In such a case, one should look for the tau sign, i.e., reflection of a thin inter-twin membrane (Fig. 2). If a first-trimester sonographic diagnosis is not available, a subsequent

scan might become less accurate, but a methodical assessment of chorionicity is nevertheless required.

The early diagnosis of chorionicity does not require high-tech imaging and is of utmost clinical importance. At times, however, complex cases of high-order multiples and/or ill-defined chorionicity–amnioticity arrangements might be a diagnostic challenge.

A distinction should always be made between zygosity and chorionicity. Because MZ twins with a DC placenta cannot be differentiated clinically from same-sex DZ twins (half of all DZ pairs) who also have a DC placenta, zygosity can be determined with certainty only in the DC-unlike-sex twins (all must be DZ twins) and in twins with an MC placenta (all must be MZ pairs). Simple calculation reveals that we are blind to zygosity in about 45% of the cases, and zygosity determination must be performed by DNA testing. Importantly, nothing should be said about zygosity to parents of same-sex twins with a DC placenta.

THE FIRST-TRIMESTER SONOGRAPHY

As suggested in Figures 1 and 2, a “window of opportunity” exists between 10 and 14 weeks for the best sonographic assessment of chorionicity. Admittedly, not all first-trimester pregnancies are scanned and therefore early losses of one or more embryos of a multiple pregnancy are missed (the so-called vanishing twin syndrome, VTS) and the true incidence of multiples is thus underestimated. The first-trimester scan should count the number of gestational sacs, the number of embryos, and the chorionic and amniotic arrangements. Ideally, the relative position of each embryo should be noted in a general “map” of the pregnancy, designating each embryo/fetus as being right/left, upper/lower, etc. Such “mapping” seems useful to provide and enhance some form of in utero individualized follow-up of the multiples.

Although each member of the multiple gestations has the same maternal-age-dependent risk for chromosomal anomalies, pure probability calculations show that the risk for a mother that one of her twins will have trisomy 21 is greater than that of a mother of a singleton. Roughly, this risk is

increased by 5/3, thus a 32-year-old mother of twins has the same risk of one infant with trisomy 21 as a 35-year-old mother of a singleton (5–7).

Because multiples are more commonly seen in older mothers (5) and invasive cytogenetic procedures (amniocentesis or chorionic villus sampling) carry a greater risk of pregnancy loss when performed in multiples, there is a genuine utility to noninvasive screening of aneuploidy to minimize the need for invasive procedures in these premium pregnancies (7). Regrettably, screening tests like the triple test [second-trimester maternal serum human chorionic gonadotropin (hCG) or free beta-hCG, alpha-fetoprotein, and unconjugated estriol] have a significantly lower predictivity for trisomy 21 in multiples compared with singletons (7). Thus, sonographic screening by measuring nuchal translucency (NT) thickness in each fetus should be offered to women who require genetic counseling. Flow in the ductus venosus (DV) might be measured to reduce the false-positive rate associated with NT measurement.

MATERNAL CONSEQUENCES

The changes in women's role in Western societies witnessed after World War II were facilitated by effective contraception, allowing ample time to achieve education and a career. This, in turn, resulted in increased maternal age at first delivery. Regrettably, age and fecundity are inversely related and infertility treatment to achieve a pregnancy often becomes inevitable for the older woman. Because all infertility treatments carry an increased risk of multiple gestations, the end result of these socio-medical trends is an increased age of the cohort of mothers of multiples. U.S. data clearly show that the increase in maternal age is more marked in high-order multiple pregnancies than in twins and in twins than in singletons, with a net result of multiples being more often delivered to older mothers in whom chronic disease conditions have already accumulated (5).

It goes without saying that a multiple pregnancy overwhelms the maternal homeostasis. Considering that the average fetus has a similar birth weight until 28 weeks (around 1000 g) irrespective of plurality, it appears that by 28 weeks, the mother of twins and the mother of triplets has accumulated twice and three times the fetal mass of singletons, respectively. This excess of fetal mass comes from either existing maternal resources or from supplemental energy that must be added throughout early gestation. It is also clear why all maternal systems are overwhelmed and some may be only a step away from clinical insufficiency in the advanced multiple pregnancy.

The overwhelmed maternal homeostasis is vividly demonstrated by the increased frequency of clinically significant anemia as a result of either depleted maternal iron stores or inadequate iron supplementation. Also the increased cardiac output has been estimated to increase in certain clinical situations to as much as two to three times the normal value. It is therefore understandable why cardiac function so easily turns into dysfunction when additional load, such as beta-sympathomimetic tocolysis, fever, premature contractions, and so on, is created.

Regardless of the inherent changes in maternal physiology due to the multiple pregnancy, some maternal disease

conditions are more frequent in multiple gestations. The best example is the two to three times increased incidence of hypertensive disorders (8,9) and their most dangerous complication—eclampsia—is six times more frequent among mothers of multiple gestations (10). Moreover, pre-eclampsia occurs earlier in multiples than in singletons and often occurs in a more severe form. It appears that a plurality-dependent risk of pre-eclampsia exists. For example, with the current epidemic dimensions of multiple gestations, it has been shown that the risk of hypertensive disorders in triplets is higher than that in twins, and the risk in twins is higher than that in singletons (8). In addition, numerous reports exist on the resolution of severe pre-eclampsia following intrauterine demise of a twin. Interestingly, the reason for the increased risk of hypertensive disorders among multiples is still unclear, but data seem to support an association with the increased placental mass, that is, hyperplacentosis (8,11). At this point it is important to mention that several rare but potentially pre-eclampsia-related conditions such as acute fatty liver of pregnancy are also more frequent in multiple gestations and seem to demonstrate the plurality-dependent risk pattern.

The other hyperplacentosis-related condition—gestational diabetes—seems also to be increased among mothers of multiples. Critical reading of the literature suggests that most stimulation tests to detect glucose intolerance of various degrees showed a diabetogenic effect of multiple gestations, whereas demographic analyses failed to show increased rates of gestational diabetes (12).

However, the latter studies were conducted in the era before the epidemic of iatrogenic multiples and before the effect of older maternal age could be documented (12). It is also possible that in the multiple gestations, an equilibrium is created between the increased glucose levels produced by hyperplacentosis and the glucose pumping effect created by the growing mass of the multiples. It has been shown that the risk of gestational diabetes is also plurality dependent, as is the case for hypertensive disorders (13).

All mothers of multiples are at considerably greater risk of preterm labor and delivery. Quite often, preterm contractions with or without cervical changes necessitate tocolytic treatment. Many prophylactic measures, including progesterone, cervical sutures (cerclage), beta-sympathomimetics, bed rest, and hospitalization, were proposed to reduce the preterm birth rates, but failed to demonstrate a significant reduction of this common complication of multiple pregnancy. Nevertheless, expecting mothers of multiples are frequently asked to leave work and to conduct a more sedentary lifestyle. Two promising prophylactic measures are at an empirical stage: early maternal weight gain (14,15) and further studies on progesterone derivatives (16). The former approach is based on the contention that multiple pregnancy is a state of magnified nutritional requirements (14). An adequate amount and pattern of gestational weight gain, including BMI-specific weight gain goals by 20 and 28 weeks of gestation, as well as other nutritional interventions, has been associated with significantly better fetal growth and longer gestations in twin pregnancies (14). In this context, it is unknown how many of normal or overweight woman will turn obese at the end of pregnancy and remain obese thereafter, and if the beneficial

effect of weight gain is equally important in women with high-compared with low pre-gravid BMI (15).

Although the results of earlier trials were disappointing (16), many randomized controlled trials are currently ongoing to find the usefulness of progesterone and progestogens as prophylactic measures against preterm birth in multiples. This interest seems to suggest that many researchers believe that progesterone might have an effect on multiples as it has on singletons, but the best derivative, route of administration, and dose are still unknown.

Table 1 lists the most common maternal complications during multiple gestations (17).

FETAL NEONATAL CONSEQUENCES

All animals, including the *Homo sapiens*, demonstrate an inverse relationship between litter size and both gestational age and birth weight. In the human, the average gestational age at

birth is around 40 weeks for singletons, 36 weeks for twins, 32 weeks for triplets, and 29 weeks for quadruplets. Although multiple pregnancies exhibit many specific complications, the consequences of prematurity are by far the most common and are the most important public health concern.

Malformations

It is customary to cite a two- to threefold increased risk of malformations among multiples. Arguments against this view suggest that twins are more closely examined and therefore a selection bias exists when describing malformations in a twin population. Regardless, the increased risk seems to be primarily related to MZ twinning whereas the malformation rates of DZs are similar to that of singletons (18). The higher malformation rate among MZs is hypothetically related to a common teratogen: the one that causes the split of the zygote is also responsible for the malformation.

Malformations among multiples are commonly grouped into four types (Table 2) (18). The first includes malformations that are more frequent among multiples, in particularly those affecting the central nervous and cardiovascular systems. The second type involves malformations related to MZ twinning such as twin reverse arterial perfusion (TRAP) sequence and the various forms of conjoined twins. The third type relates to consequences of placental malformations, in particular the MC placenta, resulting in twin–twin transfusion syndrome (TTTS) and/or selective severe discordance. Finally, the fourth type involves skeletal (postural) deformities such as clubfoot and dolichocephaly that are caused by intrauterine fetal crowding.

Certain malformations might have a major impact on the normal co-twin. For instance, in the TRAP sequence, the circulation of the severely anomalous acardiac–acephalic twin is entirely supported by the normal (pump) twin. Sooner or later, this cardiac overload will lead to cardiac insufficiency. Similarly, both twins in the TTTS are completely normal but the anomalous transplacental shunt of blood might cause serious morbidity in both twins. The most striking example is the case of single fetal demise in MC twins, whereby the surviving fetus frequently dies or becomes seriously damaged in utero soon after the death of the first twin.

Most structural anomalies can be detected by a comprehensive sonographic scan aided by echocardiography and Doppler velocimetry. Once a serious anomaly is detected, the patient might be counseled and offered selective reduction of the anomalous twin. In multichorionic multiples, selective reduction is accomplished by ultrasound-guided intracardiac injection of potassium chloride. However, because of the risk to the survivor in MC sets, highly invasive procedures (selective cord occlusion) are used to interrupt the umbilical circulation of the anomalous twin. When indicated and permitted, selective termination of an anomalous twin in an MC set is best accomplished by bipolar cord occlusion. At times, the umbilical cord of the twin affected by the TRAP sequence is too edematous and an intrafetal radiofrequency technique might be used.

Because of the increased frequency of fetal malformations, all MC twins, and ideally all twins, should undergo a detailed anatomical scan at 18 to 22 weeks of gestation. If the cardiac assessment shows a normal “four-chamber” view and outflow

Table 1 Maternal Complications More Frequently Seen in Multiple Pregnancies

Hypertensive diseases	
• Pre-eclamptic toxemia	
• HELLP syndrome	
• Acute fatty liver	
• Pregnancy-induced hypertension	
• Chronic hypertension	
• Eclampsia	
Anemia	
Gestational diabetes mellitus (?)	
Premature contractions and labor	
• Complications associated with tocolysis	
Delivery-associated complications	
• Cesarean section	
• Operative delivery	
• Premature rupture of membranes	
• Postpartum endometritis	
• Placental abruption	
<i>Abbreviation:</i> HELLP, hemolysis, elevated liver enzymes, low platelets.	

Table 2 Categories of Structural Defects in Twins

Category	Defect
Malformations more common in twins than in singletons	Neural tube defects
	Hydrocephaly
	Congenital heart disease
	Esophageal and anorectal atresias
	Intersex
Malformations unique to monozygotic twins	Genitourinary tract anomalies
	Amniotic band syndrome
	TRAP sequence
Placental malformations	Conjoined twins
	Twin embolization syndrome
	Single umbilical artery
Deformations due to intrauterine crowding	Twin–twin transfusion syndrome
	Velamentous cord insertion
	Skeletal (postural) abnormalities
<i>Abbreviation:</i> TRAP, twin reverse arterial perfusion. <i>Source:</i> Adapted from Ref. 18.	

tract, it is believed that an anatomical echocardiography seems unnecessary.

All invasive procedures in multiple pregnancies (amniocentesis, chorionic villus sampling, and the reduction methods) are associated with the risk of 5% to 10% of membrane rupture and loss of the entire pregnancy. When an invasive procedure is considered during the second trimester, the risk of extremely preterm birth of the normal twin is apparent. Thus when one twin has a lethal anomaly such as anencephaly, the risk of reducing this twin should be weighed against the risk of endangering the normal fetus by preterm birth. Conversely, the risk of preterm delivery because of a large polyhydramnios surrounding an anomalous twin might be reduced after selective reduction.

Embryonic and Fetal Demise

From the early days of ultrasound, it was apparent that there are more twin pregnancies than twin deliveries. The early loss of one twin, the VTS, is considered by many as the natural equivalent of intentional multifetal pregnancy (numerical) reduction (MFPR). Obviously, the true frequency of VTS is unknown, as many twin pregnancies are unnoticed unless first-trimester sonography is performed (19). One estimate of VTS frequency comes from iatrogenic conceptions. Spontaneous reduction of one or more gestational sacs or embryos occurred before the 12th week of gestation in 36% of twin, 53% of triplet, and 65% of quadruplet pregnancies (20). Dickey also pointed out that spontaneous reduction of multiple gestational sacs occurs less frequently in iatrogenic pregnancies compared with spontaneously conceived multiples (21). La Sala and his co-workers (22) as well as Matias and her associates (23) demonstrate that loss rates of twin pregnancies after assisted reproduction have a two to five times lower miscarriage rate of the entire pregnancy compared with singletons. The source of this advantage of ART twins is unknown. Importantly, Pinborg et al. found that 1 in 10 in vitro fertilization (IVF) singletons originates from a twin gestation and is one reason for the higher risk of adverse obstetric outcome in IVF singletons (24).

Single fetal death beyond the first trimester is also said to be more common in multiples. In DC twins, it is believed that the risk to the surviving twin is extremely low and present only when an external insult such as maternal disease is the cause of death. By contrast, fetal death in MC twins is entirely different. In the past, some ill-defined thromboplastin-like material was assumed to be transfused from the dead to the live fetus—leading to the so-called twin embolization syndrome. The theory was that these emboli might either cause fetal death or result in end-organ damage, such as brain and kidney lesions. In the early 1990s, and following painstaking postmortem examinations of brains of survivors of the twin embolization syndrome, the embolic theory was abandoned because no emboli were found and the lesions were rather ischemic in nature.

The embolic theory was soon replaced by the ischemic theory, which postulates that blood is acutely shunted from the live twin to the low-resistance circulation of the demised fetus, causing acute hypovolemia, ischemia, and end-organ damage in the survivor. A meta-analysis found that 12% of the co-twins die very soon after death of a twin, 18% survive but with

a significant damage, and 70% enjoy an intact survival (25). Death of a co-twin in an MC pair is rarely noticed in real time. However, when single fetal death is a recent event (e.g., after laser photocoagulation), the peak systolic velocity of the middle cerebral artery (PSV-MCA) might demonstrate acute fetal anemia (associated with other signs of fetal anemia). In such a case, prompt delivery is a valid option when gestational age permits. Alternatively, percutaneous umbilical cord (rescue) blood transfusion can be offered. However, it is unknown whether rescue transfusion actually decreases brain damage because not enough evidence exists to suggest improving outcomes after such procedures. When the timing of fetal death is unknown, as is more often the case, the diagnosis of single fetal death is made some time after the event. Data indicate that acute blood loss probably occurs just before the time of death of the surviving twin, and therefore it is unlikely that immediate delivery of the surviving twin could decrease the associated high mortality and morbidity rates associated with severe premature birth (26). It is therefore prudent to suggest conservative management in such cases, especially remote from term, and to use ultrasound and magnetic resonance imaging (MRI) to exclude brain lesions. The latter is ideally performed after the end of neuromigration at 30 to 32 weeks, unless diffusion weighted MRI, where available, might demonstrate white matter lesions earlier after the event.

Twin–Twin Transfusion

One of the most interesting consequences of MC twinning is the TTTS. TTTS is seen mainly (or only) in the diamniotic variety. The extensive literature on TTTS may lead to the erroneous impression that the syndrome is very frequent. In fact, TTTS occurs in about 10% of MC twins, and about half are of mild severity. Nonetheless, early onset (before 20 weeks of gestation) severe TTTS, unless intensively treated, is associated with 100% mortality of both twins.

It is a transplacental arteriovenous anastomosis that enables blood shunting from one twin (the donor) to the other (the recipient). Since all MC placentas have inert-twin anastomoses, the syndrome probably occurs because of fewer compensating veno-venous and arterio-arterial connections. The hypovolemia of the donor is manifested by poor micturition (absent bladder and oligohydramnios on sonographic scan). Conversely, the hypervolemic recipient is surrounded by polyhydramnios and manifests signs of cardiac overload ranging from tricuspid regurgitation to cardiac insufficiency and hydrops fetalis (27).

TTTS should be excluded on each antenatal visit of an MC pregnancy by demonstrating adequate amount of amniotic fluid. By definition, the first sign of TTTS is the twin oligo-polyhydramnios sequence (TOPS) corresponding to combination of largest pocket >8 cm and <2 cm in the respective sacs before 20 weeks and >10 cm and <2 cm after 20 weeks. TOPS in MC twins is defined a Quintero's stage I and should initiate a series of targeted sonographic evaluations, including Doppler velocimetry of the umbilical artery, DV, and middle cerebral artery (MCA-PSV).

In general, TTTS means serious morbidity, but the specific outcome is related to the gestational age when TTTS developed and to the severity of the syndrome. Quintero's stages are

useful in comparing management of TTTS. At present, selective laser photocoagulation of the inter-twin anastomoses is the preferable treatment modality and should be performed in TTTS occurring between 16 and 28 weeks of gestation. A decision of “no treatment” after 28 weeks would thus invariably lead to very preterm delivery of affected twins and it seems just logical that preterm delivery of treated TTTS might be better than delivering an untreated pair with TTTS. However, laser interventions after 28 weeks are still at an investigational stage. Selective laser photocoagulation, when available, is indicated in Quintero’s stage II (invisible urinary bladder), stage III (pathologic umbilical artery Doppler values), and stage IV (*hydrops fetalis*). Selective laser photocoagulation might also be indicated in “symptomatic” stage I (TOPS, with uterine contractions and/or short cervix). Alternatively, Quintero’s stage I might be followed very closely, because a proportion of stage I cases do not progress and remain asymptomatic. Induction of labor is reasonable in cases with Quintero’s stage V and a double fetal death, whereas follow-up of the survivor seems appropriate after a single fetal demise.

Cervical length before selective laser photocoagulation bears a negative correlation with outcome following the procedure and should be considered during preoperative counseling.

Amnioreduction (amniodrainage), that is, removal of a large quantity of amniotic fluid, was used to treat symptomatic mothers suffering from respiratory problems related to TOPS. The best technique regarding how fast should the amniotic fluid be drained, how much fluid should be removed, and how frequent should the technique be repeated is not established.

Since it is currently unknown how amnioreduction works, many hold that this procedure should be reserved to symptomatic patients only and for indications such as refusal or when laser photocoagulation is not available, when laser photocoagulation is contraindicated or technically difficult to perform, or after 28 weeks of gestation in order to buy time to increase gestational age. Amnioreduction might impede laser photocoagulation thus decreasing success rates and should not be performed as an interval procedure. Other treatment methods such as creating a hole in the inter-twin septum (septostomy) are not indicated for the treatment of TTTS.

Discordance in MC Twins

In the classic definition of TTTS (28), the twins are supposed to be discordant in size (at least 20–25%) and in hemoglobin levels (at least 5 g/dL). This concept changed over time, and at present, neither hemoglobin difference nor size discordance is part of the definition of TTTS. At times, however, a difference in hemoglobin is present—the so-called twin anemia-polycythemia sequence. The anemic twin can manifest all signs of anemia, especially by measuring the MCA-PSV. At birth, the donor is usually pale and anemic, whereas the recipient is polycythemic. The donor twin might be acutely distressed, with severe anemia and hypovolemic shock necessitating transfusion or exchange of blood products, or both. The recipient occasionally requires partial dilution exchange and support for cardiac failure.

Size discordance, however, seems to develop more slowly. When a significant size disparity exists, the smaller twin is at

risk of intrauterine death. At present, follow-up with serial Doppler velocimetry of the umbilical artery is indicated. Three patterns are recognized: type I, normal (positive diastolic) Doppler flow; type II, absent/reversed-end diastolic flow; and type III, intermittent absent/reversed-end diastolic flow—in the same or in the subsequent sessions (29,30). Deterioration of the growth-restricted fetus occurred in 90% of type II cases, significantly higher compared with 0% and 10.8% of types I and III, respectively. Unexpected intrauterine fetal death of the smaller twin occurred in 15.4% of type III cases, significantly higher compared with 2.6% and 0% of types I and II respectively. And finally, parenchymal brain lesions in the larger twin were observed in 19.7% of type III cases and significantly less than 5% in the other groups (30).

Fetal Growth

As noted earlier, multiples grow in utero to the same extent as singletons until about 28 weeks. Thereafter, during the third trimester, a decelerating trend of the growth curves of multiples is clearly seen. Not surprisingly, the limited uterine capacity to nurture multiples leads to growth aberrations (31). The higher risk of delivering low-birth weight (LBW) infants in a multiple birth is well known, as is the advantage for the multiparous patient. For instance, analysis of population-based data related to 12,567 live-born twin pairs found that, overall, the risk of having at least one very LBW (VLBW, <1500 g) infant was 1:5 among nulliparous women and 1:12 among multiparous women. The risk of having two VLBW twins among nulliparas (1:11) was double that of multiparas (1:22) (32). A similar trend and similar frequencies, but for extremely LBW (<1000 g) babies, were found in the analysis of triplets (33).

The most common growth aberration in multiples is birth weight discordance, defined as a difference between the larger and the smaller infant of a multiple pregnancy set. In fact, it is quite rare to find that all members of the set have the same birth weight, and it is quite normal to find some variation between siblings. Discordance is usually defined by the percent difference, whereby the birth weight disparity is calculated as a percentage of the larger infant. However, this definition does not refer to the actual size of the twins, and the same degree of discordance (e.g., 20%) can be found in a twin pair weighing 1500 and 1200 g as well as in a pair weighing 3000 and 2400 g. The cumulative frequency (34) suggests that about 75% of twins exhibit less than 15% discordance, about 20% are 15% to 25% discordant, and about 5% are more than 25% discordant.

Birth weight discordance is even more complex in triplets. In a new approach, in which the relative birth weight of the middle triplet was defined, the set was considered symmetrical, low, or high skew (35). The frequencies of different types of triplet discordance (average values: 57%, 30%, and 13%, respectively) did not change with gestational age, suggesting three distinct types of discordant growth in triplets that are independent of gestational age (35).

Several important related issues should be considered. First, it has been determined that at lower levels of discordance, either twin can be the smaller but the likelihood of the second-born twin being the smaller increases with increasing discordance levels (36). At discordance levels greater than

25%, the smaller twin was three to six times more often the second born (36). Data also suggest that there are three levels of discordance whereby in the lowest levels (probably at less than 25%), discordance seems to be related to the normal variation expected from the natural dissimilarities between siblings whereas in the highest level (probably greater than 35%), discordance seems to be related to the exhausted uterine environment and reflects growth restriction (37). Consequently, observation or intervention is indicated for the lowest and highest degrees of discordance, respectively.

Mortality is 11 times higher among highly discordant smaller twins (>30%) compared with nondiscordant smaller twins. Risk estimates ranged from 1.1 among 15% to 19% discordant twins to 2.0 among highly discordant twins. After accounting for the association between fetal growth and discordance, mortality risk was substantially higher among smaller and larger twins who were highly discordant (30% or more) (38). After controlling for fetal growth, smaller and larger twins affected by higher levels of birth weight discordance (>25%) remain at disproportionate risk for neonatal mortality (38). Finally, when neonatal mortality rates were compared among three groups of discordant twins (>25%), distinguished by the birth weight of the smaller twin being in the lowest 10th percentile [i.e., small for gestational age (SGA), 62.4%], in the 10th to 50th percentile (32.9%), or above the 50th percentile (4.7%), the rate was significantly higher among pairs in which the smaller twin's birth weight was in the lowest 10th percentile (29% vs. 11.1% and 11/1000) (39). This difference results from the higher mortality rates among the smaller but not among the larger twins. Thus, in severely discordant twin pairs, about 40% do not comprise a growth-restricted fetus and identification of this group is an imperative step in the management of birth weight discordance in twin gestations and in avoiding unnecessary interventions that may lead to iatrogenic prematurity.

Controversy exists as to whether to use singleton or twin growth curves for assessing multiple pregnancies. Because most multiple pregnancies weigh less than singletons of the same gestational age, it seems that multiples grow differently than singletons do and therefore are frequently and erroneously defined as SGA by singleton standards. Before birth, sonographic assessment of individual fetal growth cannot establish a pattern of growth restriction unless the pregnancy is longitudinally followed by repeated scans. In addition, despite the relative accuracy of sonographic estimations of the individual fetal weight, the "plus or minus" situation that exists for each estimation can cause significant under- and overestimation of the weight difference between fetuses and to low positive predictive values of discordance (40).

Growth restriction in twins—genuine or relative—is usually managed conservatively unless signs of fetal compromise are seen. At times, especially with higher levels, discordant growth and discordant fetal well-being go hand in hand. Remote from term, a decision to save the ailing fetus is in clear conflict with the potential risks of extreme preterm birth imposed on the healthy fetus. Thus, whenever the clinical circumstance of one twin jeopardizes the other, care should be exercised to select a management plan that would optimize the outcome of both fetuses. The pregnant woman should be involved in such decision making. Obviously, when the risk for the unaffected

neonates is lower than the expected risk for the affected fetus, delivery is a clear option, as would be the case at greater than 32 weeks.

FETAL ASSESSMENT

Fetal surveillance before and during labor should be carried out on all fetuses. It follows that each fetus should be adequately and appropriately monitored. In fact, assessment in multiples is no different from assessment in singletons, although it might be more complicated. For instance, fetal heart rate should be traced for both twins at the same time and intrapartum dual tracing is as important as during pregnancy. Once the membranes are ruptured, the presenting twin might be traced with a scalp electrode while the nonpresenting twin is followed with an external Doppler electrode. The fetal biophysical profile is similarly assessed individually although the amniotic fluid volume is sometimes difficult to assess. Sophisticated technology, like Doppler velocimetry of the umbilical artery, DV, and MCA, three-dimensional or four-dimensional ultrasound, and MRI of the fetal brain should be reserved for special indications.

DELIVERY CONSIDERATIONS

Most twins and practically all high-order multiple pregnancies go into spontaneous labor before 38 weeks of gestation. Circumstantial evidence suggests that, at least for twins, delivery after 37 completed weeks might carry an increased risk of neonatal mortality (41) and morbidity (42), and that fetal systems of the multiple pregnancy are mature by this date.

Many reasons for a cesarean section could be indicated in most twins and all high-order multiple pregnancies (43). Because twin gestations often involve some complications and are considered "premium" pregnancies, many clinicians would deliver twins by cesarean section for many subtle reasons other than clear-cut, evidence-based indications. Vaginal birth is allowed in twins whenever the first twin is in vertex presentation. Breech delivery of the second twin or internal podalic version of a transverse-lying second twin is still permitted and clinicians await a Canadian randomized trial initiated in 2004, to evaluate the safety of such births. Otherwise, all pairs with a nonvertex presenting twin are likely to undergo a cesarean section. Nuances on this construct consider fetal size, discordance, prior uterine surgery, and—mainly—the experience and dexterity of the obstetrician. Delivery considerations should include the welfare of all fetuses and the mode of delivery should be based on medical considerations pertaining to each fetus, as well as on maternal health and preferences. Delivery of multiples should ideally take place in a center that is equipped with neonatal intensive care facilities available simultaneously for each infant, where a medical care provider certified in neonatal resuscitation is present for each neonate, and with facilities for a high-risk delivery (such as availability of an experienced obstetrician, 24-hour anesthesia coverage, blood availability, etc). If this is not possible, in utero transfer may be preferable to postpartum transfer.

When a multiple birth is expected, the main neonatal problem is logistic, rather than medical, because immediate neonatal treatment of an infant of a multiple pregnancy is not significantly different from treating a singleton, except that

twins come in pairs, and triplets come in sets of three. In practical terms, this means more staff in the delivery suite, more cribs available in the nursery, and more stations ready in the neonatal intensive care unit (NICU). At times, delivery of several very preterm sets in a short period may occupy the entire NICU for a relatively long period. It is clear that if the availability of NICU cribs lags behind the increased production of multiples, a serious public health situation may be created.

OUTCOME

Given the much-increased risk of maternal and fetal complications during a multiple pregnancy, the overall outcome for multiples is worse compared with the outcome for singletons. For example, the increased risk of cerebral palsy among multiples is clear: 28 to 45 for triplets, 7.3 to 12.6 for twins, and 1.6 to 2.3 for singletons per 1000 survivors, indicating that the greater the number of fetuses, the greater the prevalence of cerebral palsy. Moreover, the increase in cerebral palsy with the number of fetuses seems to be exponential (44). It is however unclear whether outcomes of multiples are poorer than outcomes of singletons matched for birth weight or gestational age. For example, the usual prophylactic dose of corticosteroids given to singletons does not have the same effect in multiples in terms of prevention of neonatal respiratory distress syndrome and intraventricular hemorrhage (45,46). A multivariate logistic regression analysis of a cohort of VLBW infants with similar background characteristics was done on 3717 singletons, 1394 twins, and 483 triplets. Respiratory distress syndrome was significantly more common in twins and triplets despite increased exposure to antenatal steroids (47). In addition, VLBW triplets were at increased risk of death, but VLBW twins and triplets had no increased risk of chronic lung disease or adverse neurologic findings compared with matched singletons (47).

PREVENTION VS. CURE

The epidemic dimensions of multiple births, and especially of high-order multiple pregnancies, became evident toward the end of the 1980s as an aftershock of effective infertility treatment. To amend this untoward consequence of infertility treatment, clinicians proposed to reduce the number of embryos during pregnancy (MFPR) (48). MFPR, considered by many as the ultimate paradox of medicine, soon became a popular “cure” of the side effects of infertility treatment. This procedure, performed during the early second trimester via the transvaginal or transabdominal route, carries a risk of about 5% to 8% total loss. However, MFPR is certainly associated with better outcomes simply because a lower plurality will always do better than a higher plurality pregnancy.

Interestingly, and somewhat disturbingly, clinicians were more busy in refining and mastering the technique of MFPR than in trying to reduce the number of iatrogenic high-order multiples. At present, it is believed that MFPR should be seriously considered with quadruplets or more and should rarely be considered with twins. The controversy remains regarding MFPR of triplets (49).

As always in medicine, prevention is better than cure. In terms of infertility treatment, this means transferring only one embryo in ART and canceling ovulation induction cycles

when more than one ripe follicle is visualized. Such preventive measures might somewhat reduce the overall success rates, although it is rarely debatable if a multiple pregnancy with three or four severely premature infants constitutes success. Put differently, the author of this chapter truly believes that if single-embryo transfer would have been the standard from the outset, it would never be possible to obtain ethical approval of a randomized trial for more than one embryo transfer.

6 Gestational hypertension and pre-eclampsia

Erol Amon and Erin Dickert

Hypertensive disorders are the most common medical complications of pregnancy. Approximately 7% to 10% of all pregnancies are complicated by hypertension. The two most common forms of hypertension are pregnancy-associated hypertensive disease, which accounts for 70% of hypertension during pregnancy, and pre-existing chronic hypertension, which is responsible for the remaining cases (1). Hypertensive disorders are associated with increased maternal and perinatal mortality and present as a wide spectrum of disorders, ranging from minimal elevation of blood pressure alone to severe hypertension with multiple organ dysfunction.

CLASSIFICATIONS

Multiple classifications have been proposed for the hypertensive disorders of pregnancy. In 2001, the National Institutes of Health Working Group on Hypertension in Pregnancy (2) defined five disorders (Table 1).

Gestational hypertension may be defined as elevated blood pressure appearing after the 20th week of pregnancy or in the first 24 hours postpartum without edema or proteinuria, and with a return to normotension within 10 days of delivery. In order to diagnose hypertension, blood pressures must be at least 140 mmHg systolic or 90 mmHg diastolic on at least two occasions 6 hours apart. This is the most frequent cause of hypertension during pregnancy, affecting 6% to 17% of nulliparous women and 2% to 4% of multiparous women. The majority of cases of gestational hypertension develop after 37 weeks of pregnancy. Outcomes are similar to normotensive controls if only mild elevations in blood pressure. Increased morbidities if severe blood pressure elevations.

Pre-eclampsia is defined as new-onset hypertension in the second half of pregnancy with new-onset proteinuria. In order to diagnose proteinuria, greater than 300 mg must be present on a 24-hour sample or 0.1 g/L in at least two random urine samples more than 4 hours apart. Often evidence of end-organ dysfunction is present. Development of convulsions or coma in patients with signs and symptoms or pre-eclampsia in the absence of other causes of convulsions is diagnostic of eclampsia.

Chronic hypertensive disease includes patients with pre-gestational hypertension, patients with pre-existent elevation of blood pressure to at least 140/90 mmHg on two occasions before 20 weeks of gestation, and patients with hypertension that persists for more than 6 weeks postpartum. Superimposed pre-eclampsia or eclampsia is defined as the development of pre-eclampsia or eclampsia in patients with diagnosed chronic hypertension. About 15% to 30% of chronically hypertensive women will develop superimposed pre-eclampsia.

The classifications and definitions of the hypertension disorders of pregnancy are frequently confusing. It is often difficult to differentiate between pre-eclampsia, chronic

hypertension, and chronic hypertension with superimposed pre-eclampsia. The normal mid-trimester fall in blood pressure may conceal the presence of underlying chronic hypertension; therefore, unless the patient presents in the first trimester or has a well-documented history of chronic hypertension, accurate classification may be impossible.

PRE-ECLAMPSIA

Pre-eclampsia is a disorder specific to human pregnancy. Reported incidences range from 2% to 10% depending on the diagnostic criteria used and the population studied. It is principally a disease of young primigravidas. The incidence is about 6% to 7% of all nulliparous pregnancies in the United States (3).

Geographic and racial differences in incidence have been reported. Several risk factors have been identified as predisposing to the development of pre-eclampsia in varied populations (4–11) (Table 2). For unknown reasons, the incidence appears reduced in women who smoke during pregnancy (12,13), as well as in those who have had previous abortions or miscarriages (14–16).

Pre-eclampsia may be classified as either mild or severe. Severe pre-eclampsia is diagnosed when any of the criteria listed in Table 3 is present; additional markers of organ dysfunction may indicate severe disease.

PHYSIOLOGY

In normal pregnancies, the diameters of the uterine spiral arteries increase in size. The endothelium and the internal elastic lamina are replaced by invading trophoblast tissue. These changes begin in the decidual layer and extend into the myometrium. These vascular changes are thought to be associated with increased perfusion. In women with pre-eclampsia, these changes may be localized to the decidual layer or absent altogether. The diameter of the spiral arteries in affected pregnancies is 40% of the diameter in normal pregnancies (17). This is a disease of poor perfusion and vasospasm. Placental changes associated with pre-eclampsia may be seen weeks to months prior to the development of symptoms of the disorder. The symptoms of pre-eclampsia are associated with maternal endothelial dysfunction. Abnormalities in the endothelial control of vascular tone lead to increased permeability across vessel walls leading to edema and proteinuria.

DIAGNOSIS

A spectrum of clinical signs and symptoms, presenting either alone or in combination, makes the diagnosis of pre-eclampsia a subject of great controversy. Historically, diagnosis included a relative increase in blood pressure as well as presence of edema. Neither of these criteria has proven to be reliable for

Table 1 Classification (2)

	Gestational hypertension	Pre-eclampsia		Eclampsia	Chronic hypertension	Superimposed pre-eclampsia
		Mild	Severe			
Onset	20 weeks of gestation or greater	20 weeks of gestation or greater	20 weeks of gestation or greater	After 20 weeks of gestation	Prior to 20 weeks of gestation	Worsening of chronic HTN after 20 weeks
Diagnosis	Elevated blood pressure (>140/90 on two occasions, at least two hr apart); no proteinuria	Elevated blood pressure (>140/90 on two occasions at least 6 hr apart), proteinuria (>300 mg/24 hr)	Elevated BP, proteinuria (>5 g/24 hr)	Seizures with other evidence of pre-eclampsia	Elevated blood pressure, proteinuria may be present	Worsening hypertension, worsening of proteinuria

Abbreviation: HTN, hypertension.

Table 2 Risk Factors for Pre-eclampsia

Nulliparity
 Multiple gestation
 Family history of pre-eclampsia/eclampsia
 Pre-existing hypertension/renal disease/vascular disease
 Personal history of pre-eclampsia/eclampsia
 Pre-existing diabetes (class B-F)
 Non-immune hydrops fetalis
 Molar pregnancy
 Obesity

diagnosis (2). A finding of abnormal blood pressure is subject to many errors; several variants may influence the readings: faulty equipment, cuff size, race, obesity, smoking, position, patient anxiety, or duration of the resting period (18).

The presence of proteinuria is usually determined by the use of dipsticks on random urine samples. The concentration of urinary protein is highly variable. It is influenced by several factors, including contamination with vaginal secretions, blood, or bacteria; urine specific gravity and pH; and exercise and posture. Moreover, studies have found that urinary dipstick determinations correlate very poorly with the amount of proteinuria found in 24-hour urine determinations in hypertensive pregnancies (19–21). Dipstick measurements in urine samples (+3) are not adequate for the diagnosis of severe pre-eclampsia (20). In addition, urinary protein-to-creatinine excretion is highly variable in patients with pre-eclampsia (22). Spot urinary protein-to-creatinine ratios are useful as a screening tool for pre-eclampsia. A result of less than 0.21 correlates to less than 300-mg protein on a 24-hour timed urine protein with a negative predictive value of 83.3% and sensitivity of 86.8% (23). Nevertheless, the definitive test for diagnosing proteinuria is a quantitative measurement of total protein excretion over a 24-hour period. An effort should be made to ensure an accurate collection by concurrently measuring the total 24-hour urine creatinine excretion. Significant proteinuria in pregnancy should be defined as >300 mg per 24-hour urine sample. For making the diagnosis of severe pre-eclampsia based on proteinuria only, it is recommended that a 24-hour urine sample with protein of >5 g be documented.

PREVENTION OF PRE-ECLAMPSIA

The likelihood of recurrence in subsequent pregnancies is such that numerous reports and clinical trials have focused on the

Table 3 Diagnostic Criteria for Severe Pre-eclampsia

Blood pressure (3)	160 mmHg systolic or 110 mmHg diastolic on two occasions at least 6 hr apart with the patient at rest
Proteinuria (3)	5 g in a 24-hr urine collection
Oliguria	<400 mL in 24 hr
Severe, persistent epigastric pain	Liver function test abnormalities may exist
Pulmonary edema or cyanosis	
Thrombocytopenia	<100,000/mm ³
Persistent cerebral symptoms	Headache, visual changes
Fetal growth restriction	<10th percentile

use of various methods to prevent or reduce the incidence of pre-eclampsia. In 2006, recurrence rates were examined in 896 Icelandic women as described in Table 4 (24). Almost three-fourths of women with a hypertensive disorder in a first pregnancy had a recurrence in the following pregnancy.

Since the etiology of the disease is unknown, various methods were used to correct the pathophysiologic abnormalities in the hopes of ameliorating the course of, or preventing, the disease. Some of the methods used are summarized in Table 5. To date, none of these methods have been shown conclusively to be effective in preventing the disease.

Alterations in diets (low salt, high protein, as well as restricted caloric intake) have been suggested as prevention for pre-eclampsia. In addition, the use of diuretics has been recommended to prevent pre-eclampsia (25). However, the efficacy of these measures has never been proven. Several epidemiologic studies and a few clinical supplementation trials have suggested a relationship between calcium, magnesium, zinc intake, and pregnancy-induced hypertension. The relationship between dietary calcium intake and hypertension has been the subject of several experimental and observational studies (26). It has been shown that there is an inverse association between calcium intake and maternal blood pressure and the incidences of pre-eclampsia and eclampsia in epidemiologic studies (27). The blood pressure-lowering effect of calcium was thought to be mediated by alterations in plasma renin activity and parathyroid hormone. In addition, calcium supplementation during pregnancy was shown to

Table 4 Recurrence Rates

First pregnancy	Second pregnancy					
	Normal	Gestational HTN	Pre-eclampsia	Chronic HTN	Superimposed pre-eclampsia	All recurrences
Gestational HTN (<i>n</i> = 511)	153 (29.9%)	239 (46.8%)	25 (4.9%)	82 (16%)	12 (2.3%)	358 (70.1%)
Pre-eclampsia/ eclampsia (<i>n</i> = 151)	63 (41.7%)	52 (34.4%)	17 (11.3%)	16 (10.6%)	3 (2%)	88 (58.3%)
Chronic HTN (<i>n</i> = 200)	24 (12%)	69 (34.5%)	17 (11.3%)	16 (10.6%)	3 (2%)	68 (58.3%)
Superimposed pre-eclampsia (<i>n</i> = 34)	2 (5.9%)	10 (29.4%)	4 (11.8%)	14 (41.2%)	4 (11.8%)	32 (94%)
Total (<i>n</i> = 896)	242 (27%)	370 (41.3%)	52 (5.8%)	203 (22.7%)	29 (3.2%)	654 (73%)

Table 5 Prevention of Pre-eclampsia

Dietary manipulation	Pharmacologic manipulation	Personal habit changes
Low-calorie diet	Diuretics	Frequent prenatal care
High-protein diet	Anti-hypertensives	Daily rest in lateral position
Low-salt diet	Beta-sympathomimetics	Keeping same partner
Nutritional supplementation	Anti-thrombotic agents	Avoiding/reducing coffee
Calcium	Low-dose aspirin	
Magnesium	Dipyridamole	
Zinc	Dazoxiben	
Fish oil	Heparin	
Evening primrose oil		
Vitamins C and E		

reduce angiotensin II vascular sensitivities in such pregnancies (28,29).

The findings of clinical studies comparing the use of calcium versus no treatment or placebo in pregnancy were reviewed in two meta-analyses (30–40). These trials differed by the population studied (low risk or high risk for hypertensive disorders of pregnancy), study design (randomization, double blind, or use of a placebo), gestational age at enrollment (20–32 weeks of gestation), sample size in each group (range 22–588), and dose of elemental calcium used (156–2000 mg/day). In addition, these studies differed regarding the definition of the hypertensive disorders of pregnancy. The findings suggest that calcium supplementation reduces the overall incidence of hypertensive disorders of pregnancy, with a trend toward reducing the incidence of pre-eclampsia.

A large, multicenter, randomized controlled trial to evaluate the benefits and side effects of calcium supplementation to prevent pre-eclampsia was performed in the United States. This trial randomized over 4500 healthy nulliparous women who were enrolled prior to 20 weeks of gestation. The results of this trial demonstrated *no* difference between those receiving 2 g of calcium as opposed to those receiving placebo in the incidence of either pre-eclampsia or gestational hypertension. In addition, calcium supplementation had no effect on maternal blood pressure throughout gestation or birth weight (40).

Pre-eclampsia is associated with vasospasm and an activation of the coagulation–hemostasis system. Enhanced platelet activation plays a central role in the above process with resultant abnormality in the thromboxane/prostacyclin balance. Aspirin inhibits the synthesis of prostaglandins by irreversibly acetylating and inactivating cyclooxygenase. *In vitro*, platelet cyclooxygenase is more sensitive to inhibition by very low doses of aspirin (<80 mg) than vascular endothelial cyclooxygenase. Therefore, treatment with low doses of aspirin could alter the balance between prostacyclin (vasodilation) and thromboxane (vasoconstriction) (41).

More than 35,000 women have participated in a variety of randomized control trial describing the effects of low-dose aspirin (60–81 mg/day) on pre-eclampsia (42). Some of these studies were conducted in healthy nulliparous women (43,44), whereas others included patients with various obstetric and medical complications (45–49).

Sibai and associates (44) reported a multicenter study in 2985 health nulliparous women who were randomized at 13–26 weeks of gestation to either receive 60 mg aspirin daily or a placebo. The incidence of pre-eclampsia was reduced by only 26% in the aspirin-treated women; however, there were no differences in mean gestational age at delivery, birth weight, or the frequency of fetal growth retardation or preterm delivery. Moreover, there was a significantly higher incidence of abruptio placentae in women receiving aspirin (0.7%) compared with those receiving placebo (0.1%).

Viinikka and colleagues (45) studied 197 women with pre-existing chronic hypertension or a history of severe pre-eclampsia in their previous pregnancies who were randomized at 15 weeks of gestation to receive 50 mg/day aspirin or a placebo. The incidences of exacerbation of hypertension as well as pre-eclampsia were similar in the two groups. In addition, the two groups had similar mean gestational age at delivery. However, patients receiving low-dose aspirin had a higher mean birth weight and lower frequency of fetal growth retardation.

An Italian multicenter trial evaluated the use of 50 mg/day of aspirin to no treatment at 16 to 32 weeks in a large group of pregnant women considered at risk for pre-eclampsia (46). There were no differences between the two groups regarding the incidences of hypertension only, pre-eclampsia, fetal growth retardation, preterm delivery, abruptio placentae, or perinatal death.

The CLASP (Collaborative Low-Dose Aspirin Study in Pregnancy) trial (47) was a multinational randomized trial of low-dose aspirin for the prevention and treatment of pre-eclampsia and fetal growth retardation. In the trial, 9364 women at risk for pre-eclampsia between 12 and 32 weeks took part. There were no differences between the two study groups regarding the incidences of pre-eclampsia, fetal growth retardation, abruptio placentae, or perinatal deaths. However, the aspirin-treated group had a lower incidence of preterm delivery. In addition, there was a significant trend ($p=0.004$) toward progressively greater reductions in pre-eclampsia (more in preterm delivery). The study group suggested that low-dose aspirin administration may be justified in women judged to be at risk for early-onset pre-eclampsia. In such women, the researchers recommended that low-dose aspirin be started before 20 weeks of gestation.

In a large multicenter clinical trial, pregnant women at 13 to 26 weeks of gestation with high-risk characteristics (previous pre-eclampsia–eclampsia, chronic hypertension, class B–F diabetes, or multifetal gestation) were randomized to either aspirin 60 mg/day or matching placebo. This trial was conducted at 11 centers in the United States and was sponsored by the National Institute of Child Health and Human Development. The results of this trial demonstrated minimal to no benefit from the use of low-dose aspirin in such women (50).

An additional meta-analysis of individual data the Perinatal Antiplatelet Review of International Studies attempted to differentiate the success of aspirin by maternal diagnosis, timing of initiation of therapy, and dosage of aspirin (51). A reduction in preterm birth and incidence of pre-eclampsia by 10% was noted in those treated with aspirin. No subgroups of women were found for which aspirin therapy was more effective. In addition, the number needed to treat was 500 low-risk pregnancies to prevent one preterm birth, while 50 high-risk pregnancies needed to be treated.

Oxidative stress has been suggested to play a role in the development of pre-eclampsia. Previous trials of the benefits of vitamins C and E have had disparate results. A recent trial evaluated the impact of antioxidant therapy on the prevention of pre-eclampsia (52). In the trial, 10,154 women were enrolled to participate, with 40% beginning while still in the first trimester. No differences were noted between women

Table 6 Hospital Management of Patients with Gestational HTN and Mild Pre-eclampsia

	Gilstrap et al. (53)	Sibai et al. (54)	Sibai et al. (56)
Patients (<i>n</i>)	576	200	200
Mean hospitalization (days)	24	21	12
Pregnancy prolongation (days)	24	21	22
Preterm delivery (<37 weeks)	23	–	41–49
Perinatal deaths	9/1000	5/1000	0/1000
Abruptio placentae (%)	0.9	1.7	

receiving vitamin supplementation and those receiving the placebo for the primary outcomes of severe pregnancy-associated hypertension or pre-eclampsia. Rates of adverse perinatal outcomes were similar between the groups.

Based on the data available at this time, no one specific therapy appears to be more efficacious in the prevention of pre-eclampsia in high-risk patients than no therapy.

MANAGEMENT OF MILD GESTATIONAL HYPERTENSION/PRE-ECLAMPSIA

The optimal management of mild pre-eclampsia remote from term is controversial. In general, there is considerable disagreement regarding the need for hospitalization as opposed to ambulatory management. Management of gestational hypertension–pre-eclampsia by hospitalization was based largely on clinical experience rather than being the result of controlled randomized trials. In theory, hospital admission for bed rest could delay or prevent progression to severe hypertension (53,54). Historically, admission to a hospital was an accepted practice worldwide and its rationale was to reduce eclampsia (55) and improve perinatal outcome (53). In some centers in the United States, management of these patients has included relative bed rest in the hospital for the duration of pregnancy. This approach has been reported to diminish the frequency of progression to severe disease and to enhance fetal survival (15,53). In fact, several studies (Table 6) noted the benefits of prolonged hospitalization for patients with mild gestational hypertension remote from term.

This practice was challenged by Matthews and associates (57), who found no differences in perinatal mortality in women with gestational hypertension between those who were hospitalized for the duration and those who were managed as outpatients. Further, Matthews and colleagues (58) studied 135 patients with gestational hypertension in a randomized trial. They showed that complete bed rest appeared to have no advantage over “ambulation as desired” in controlling the severity of maternal disease. Similarly, Crowther and coworkers (59) conducted a randomized controlled trial on 218 patients with gestational hypertension. They showed that bed rest in pregnancies complicated by gestational hypertension was not associated with an overall improvement in fetal growth or reduced neonatal morbidity. Instead, the recording of fetal kick count at home and continued outpatient antenatal care provided a safe alternative to hospital admission.

Management Alternatives

Obstetricians are increasingly utilizing outpatient management of gestational hypertension, especially with the increasing pressure to decrease medical expenses and use outpatient therapy. Outpatient management was addressed by the American College of Obstetricians and Gynecologists Practice Bulletin Number 33 (60), which noted that "Hospitalization is often initially recommended for women with new-onset preeclampsia. After maternal and fetal conditions are serially assessed, subsequent management may be continued in the hospital, at a day-care unit, or at home on the basis of the initial assessment... Hospitalization is recommended for noncompliant patients, those with logistical barriers, and those who show progressive disease as outpatients."

Randomized trials assessing the value of admission to hospital for bed rest found no benefits over outpatient management in women with mild gestational hypertension (56,61). With the introduction of outpatient management alternatives, evaluation of maternal and fetal status was similar to inpatient therapy. In fact, the incidence of both eclampsia and placental abruption and the perinatal mortality rates were almost the same in both hospitalized and non-hospitalized patients.

Home-Care Programs

In an attempt to provide a safe and less expensive alternative to hospital care for women with pre-eclampsia, some home-care programs were initiated in the mid-1980s. Helewa and associates (62) reported their experience with one such program. Patients eligible for home-care management included those with blood pressure of <150/100 mmHg, protein level of <0.6 g in a 24-hour collection of urine, absence of symptoms of severe pre-eclampsia, platelet count of >120,000/mm³ and liver enzymes of <50 U/L. Enrolled patients were visited at home by a trained nurse. The nurse measured the blood pressure and fetal heart rate, reviewed fetal movement counts, tested for the presence and amount of protein in the urine, and checked for signs and symptoms of pre-eclampsia. An assessment of the fetal biophysical profile and biochemical profile and a visit to the attending physician were carried out on a weekly basis. The program nurse contacted the physician if clinical deterioration was noted. Labor was induced electively at term when the patient had a favorable cervix or whenever pre-eclampsia became severe or there were signs of fetal distress. In this study, 321 patients met the criteria and were enrolled in the home-care program. A total of 141 patients (44%) were admitted to the antepartum unit for inpatient monitoring: nine had severe pre-eclampsia. The mean length of enrollment in the home-care program was 11.5 days (1–42 days). Hospital stay was reduced from 5.7 days to 3.7 days, and cost was reduced by 74%.

Day-Care Programs

Similarly, and in an attempt to decrease hospital bed occupancy, a fetal surveillance unit or day-care unit established within the hospital was described by some authors (63–67). The unit was established within the hospital and run by a nurse-midwife and staffed by an attending physician. Every visit included monitoring of maternal blood pressure, urine testing, with assessment of fetal heart rate, biophysical

profile, and uteroplacental circulation, as needed. The patient remained under the care of the referring physician unless there was need for immediate intervention. Soothill and coworkers (63) reported a decrease in the rate of antenatal bed occupancy by 22% with no significant change in the stillbirth rate. Similarly, Tuffnell and associates (64) reported an 80% reduction in hospital inpatient stay, and a reduction in the number of medical interventions. In addition, Dawson and colleagues (65) showed that telephonic monitoring of the fetal heart rate in such women was also associated with fewer hospital admissions and a smaller percentage of time spent in hospital. Turnbull and associates (67) reported no significant difference in fetal or maternal morbidities when compared with in-patient care.

Perinatal Outpatient Monitoring Service

There are outpatient monitoring services designed to monitor and record information associated with the major signs of obstetric hypertensive disease (blood pressure determination, weight, sleep/rest documentation, fetal movement count, and urinalysis) (57). Outpatient evaluation includes four times daily automated blood pressure and pulse measurement and daily assessment of weight, fetal kick counts, duration of rest/sleep periods, and proteinuria. Each data element is dated and time coded. Objective and subjective data are then transmitted by phone to a perinatal center daily or immediately (if elevated blood pressure or decreased fetal movements are observed). Patients receive twice weekly antenatal evaluation with nonstress testing and frequent amniotic fluid assessment. Barton and colleagues (57) evaluated the perinatal and maternal outcomes of this outpatient monitoring service in 592 patients with mild gestational hypertension at 24–36 weeks of gestation. The mean pregnancy prolongation was 27.4±3.3 days, whereas the mean antepartum hospitalization for management of similar patients was only 1.7 days. Maternal and perinatal outcome were similar to those reported by investigators using hospitalization for management of similar patients. In a subsequent report, Barton and associates (68) found that a similar program was safe and effective, even in young teenage patients with mild gestational hypertension remote from term.

The success rate of outpatient management depends primarily on maternal status (presence or absence of proteinuria, diastolic blood pressure, and gestational age) at the time of enrollment. Pregnancies complicated by pre-eclampsia are associated with a lower gestational age at delivery, shorter pregnancy prolongation, and an increased requirement for antepartum hospitalization as compared with pregnancies with gestational hypertension without proteinuria. Those women with gestational hypertension or pre-eclampsia at an earlier gestational age tend to have earlier gestational age at delivery and a worsening of the disease status and more unfavorable fetal outcome than those who develop the disease at term (56,61).

Management Protocol

Management plan for patients with mild gestational hypertension/pre-eclampsia is dependent on gestational age as well as maternal and fetal findings. A recent multicenter, randomized clinical trial described by Sibai compared induction of labor

with continued expectant management for patients with gestational hypertension/pre-eclampsia at 36 to 41 weeks (69). Once 37-week gestation was reached, there is an overall reduction in relative risk of maternal morbidity. Induction of labor was not associated with increased risk of cesarean delivery or neonatal morbidity. The principal maternal benefit of delivery is decreased disease progression. Additionally, HYPITAT study described by Koopmans (70) assessed whether induction of labor at term with mild hypertensive disease reduces maternal morbidity. This multicenter randomized trial divided patients with mild hypertensive disease at term into groups for induction of labor or expectant management. Those undergoing induction of labor had a relative risk 0.71 of worsening maternal disease. There was no statistical difference in cesarean rates or neonatal complications between the groups. An economic analysis of the HYPITAT study performed by Vijgen and colleagues demonstrated decreased cost with induction of labor as opposed to expectant management for patients with mild hypertensive disease at term (71). Based on these data, patients with gestational age beyond 37 weeks can reasonably be managed with induction of labor.

Patients who are less than 37 weeks of gestation are assigned to either ambulatory or inpatient management based on certain criteria: those who are unreliable, or have a diastolic blood pressure of >100 mmHg, proteinuria of >500 mg, abnormal laboratory tests, abnormal fetal testing, preterm labor, or bleeding are usually hospitalized. They are allowed to eat regular hospital diet without salt restriction, and their activity is not restricted to complete bed rest. Initially, antihypertensive drugs are not prescribed. Patients undergoing outpatient care are instructed to have daily urine dipstick measurements of proteinuria, blood pressure monitoring, daily assessment of weight gain, and daily recording of fetal kick counts. They are also educated to report any symptoms of impending eclampsia. The patient is then evaluated in the antepartum testing area for maternal and fetal well-being at least twice a week for patients with proteinuria (1+) and once a week for those without proteinuria (0 or trace). If there is any evidence of disease progression and if acute severe hypertension develops, then hospitalization is indicated. During expectant management, these women have periodic laboratory evaluation of platelet count and liver enzymes (one to two times a week), serial ultrasound examinations for estimated fetal weight (every 2–3 weeks), antenatal testing with the nonstress test (two times a week), and weekly umbilical artery Doppler studies, as well as amniotic fluid volume assessment.

In summary, management of women with mild gestational hypertension–pre-eclampsia must always put safety of the mother first and then aim at the delivery of a live, mature newborn that will not require intensive and prolonged neonatal care. The goal of management of mild gestational hypertension–pre-eclampsia should be to identify the development of severe disease prior to maternal seizure or fetal jeopardy. Therefore, requirements for outpatient management must include well-motivated patients, a perinatal outpatient monitoring service or other management alternative for close maternal and fetal evaluation, and guidelines for contacting the health-care provider (Table 7).

Table 7 Guidelines for Outpatient Management

Well-motivated patients
Well-trained nurses
Perinatal outpatient monitoring service or other management alternative
Close maternal and fetal evaluation
<i>Daily</i>
• Urine dipstick for proteinuria
• Blood pressure
• Weight
• Fetal kick count
<i>Two times per week</i>
• Platelet count and liver enzymes (1–2 times per week)
• Fetal antenatal testing with nonstress test or biophysical profile
<i>One time per week</i>
• Measure of amniotic fluid volume
• Platelet count and liver enzymes (1–2 times per week)
• Physician visit
<i>Every two to three weeks</i>
• Serial ultrasound examinations for estimated fetal growth
Guidelines for contacting health-care provider
• Labor or rupture of membranes
• Vaginal bleeding
• Decreased fetal movement
• Symptoms of impending eclampsia (CNS, visual disturbances)
• Symptoms of impending HELLP (epigastric pain, vomiting)
<i>Abbreviation:</i> HELLP, hemolysis, elevated liver enzymes, and low platelet count.

Antihypertensive Drugs in Mild Gestational Hypertension/Pre-eclampsia

There are several retrospective and prospective studies that have described the use of various antihypertensive drugs in women with mild gestational hypertension/mild pre-eclampsia (56,72–80). Drugs used in these studies included hydralazine, methyldopa, nifedipine, prazosin, diuretics, and beta-blockers. These studies included women with gestational hypertension (proteinuria absent) and mild pre-eclampsia. The purpose of using antihypertensive drugs in this group of women was not to improve blood pressure, but rather to improve perinatal outcome by prolonging the pregnancy in those who were remote from term. Some of these studies found that labetalol had some beneficial effects on the disease process (progression to severe hypertension, development of proteinuria), whereas other studies reported detrimental effects (higher frequency of fetal growth retardation) in the treated group. In general, none of these studies have reported a better perinatal outcome than those reported in studies using hospitalization alone. In summary, there are currently few data to support the use of antihypertensive drugs in the management of mild gestational hypertension–pre-eclampsia remote from term (81).

MANAGEMENT OF SEVERE PRE-ECLAMPSIA

Pre-eclampsia affects two patients—the mother and the fetus. Traditionally, women with severe pre-eclampsia have been delivered without delay, regardless of fetal considerations. Although delivery is appropriate therapy for the mother, aggressive management with immediate delivery of a fetus remote from term leads to high neonatal mortality and morbidity resulting from prematurity. Recent studies have

demonstrated favorable neonatal outcomes after conservative management of severe pre-eclampsia. Since 1990, randomized trials and several observational studies have evaluated expectant management of severe pre-eclampsia at less than 34 weeks of gestation. These studies included greater than 1700 women, with gestational age between 24 and 34 weeks of gestation. The results suggested that expectant treatment in a select group of women with severe pre-eclampsia between 24-0/7 and 32-6/7 weeks of gestation in a suitable hospital is safe and improves neonatal outcome (82). Candidates for conservative management should be carefully selected and managed with intensive maternal and fetal monitoring at a tertiary perinatal center.

The timing of delivery in women with severe pre-eclampsia in the second trimester is a difficult decision to make for mother and obstetrician. Aggressive management with immediate delivery will result in extremely high neonatal mortality and morbidity resulting from prematurity. Consequently, hospitalization in a neonatal intensive care unit is prolonged, and surviving infants may have long-term disabilities (83). Attempts to prolong pregnancy may improve perinatal outcome, but may expose the mother to potential morbidity (84).

Therefore, concerning expectant management, one must weigh risks and benefits to the mother and the fetus. Fetal gestational age, fetal condition, and maternal condition play important roles in reaching such a decision (83).

Maternal Indications

Because the pathophysiology of pre-eclampsia involves diffuse endothelial injury, patients may present with multiple-system involvement and differing degrees of severity. Some women with severe disease have marked improvement in blood pressure, protein excretion, and urine output shortly after hospitalization. However, others require immediate delivery because of signs of deterioration as seen in Table 8. Careful selection of patients with severe disease is important (84). Patients judged suitable for expectant management have one or more of the following clinical findings: controlled hypertension, proteinuria of >5 g/day, oliguria that resolves with routine fluid or food intake, elevated liver enzymes (aspartate aminotransferase or alanine aminotransferase greater than two times the upper normal value)

without epigastric pain or without right upper quadrant tenderness (84).

Visser and Wallenburg (93) rejected the general recommendation of prompt termination of pregnancy in pre-eclamptic patients with hemolysis, elevated liver enzymes, and low platelets [hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome] in the late second or early third trimester. In their study, 128 pre-eclamptic patients with HELLP syndrome were matched for gestational age with 128 pre-eclamptic patients without HELLP. Both groups were treated conservatively with volume expansion and pharmacologic vasodilatation with the aim of prolonging gestation and enhancing fetal maturity. Complete reversal of HELLP occurred in 43% of patients. Perinatal mortality was 14.1% in HELLP patients and 14.8% in patients without HELLP. Similarly, Magann and coworkers (94) demonstrated significant improvement in maternal platelet count, urinary output, lactic dehydrogenase, alanine aminotransferase, and postponement of delivery in women with HELLP syndrome who received high-dose antenatal dexamethasone (10 mg intravenously every 12 hours until delivery; average time of 41 hours).

Fetal Indications

Severe pre-eclampsia may affect the fetus in a negative way. Inadequate trophoblastic invasion causing abnormal placentation is one of the main features of pre-eclampsia. This can lead to decreased uteroplacental perfusion with a resulting increased incidence of intrauterine growth retardation, fetal hypoxia, and perinatal death. Therefore, careful selection and intensive monitoring of the fetus is essential. Patients judged suitable for conservative management have one or more of the following: biophysical profile >4, largest vertical amniotic fluid pocket of >2, ultrasound-estimated fetal weight above the 5th percentile.

It is commonly believed that maternal pre-eclampsia has a protective effect on neonatal outcome after delivery before 34 weeks of gestation. This protective effect is thought to be caused by the fact that fetuses of pre-eclamptic mothers are subjected to stress in utero and therefore have accelerated maturation and consequently a better prognosis than other preterm infants. However, in a well-designed retrospective study, Schiff and colleagues (95) studied fetal lung maturity by amniocentesis in 127 pre-eclamptic patients and a matched

Table 9 Indication for Delivery

Maternal	Fetal
Persistent severe headache or visual changes; eclampsia	Severe FGR (estimated fetal weight, 5 th percentile for gestational age)
Shortness of breath or chest tightness with rales and/or pulse oximetry of <93% on room air or pulmonary edema	Persistent severe oligohydramnios (amniotic fluid index, <2 cm) with fetal heart rate decelerations
Epigastric/right upper quadrant pain with AST or ALT >2 times the upper limits of normal	Repetitive late or variable fetal heart rate decelerations unresponsive to therapy
Uncontrolled severe hypertension, despite maximum doses of antihypertensive agents	Persistent biophysical profile, <4 (evaluations 6 hr apart)
Oliguria (<500 mL/24 hr) or a rising serum creatinine level of >1.5 mg/dL	Umbilical artery Doppler with reversed end-diastolic blood flow
Persistent platelet count, <100,000/mm	Fetal death
Suspected abruptio placentae, progressive labor, and/or rupture of membranes	

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; FGR, fetal growth restriction. *Source:* From Ref. 99.

control group of women with preterm labor. They found no significant difference in the incidence of an immature laboratory result between pre-eclamptic patients and their matched controls (39.4% vs. 38.6%). The incidence of respiratory distress syndrome was slightly, but not significantly, higher in the pre-eclamptic group. In addition, Friedman and associates (96) found no beneficial effect from pre-eclampsia on the postnatal course of infants born at 24–35 weeks of gestation.

The poor perinatal outcome associated with severe pre-eclampsia is believed to be related primarily to prematurity. However, severe pre-eclampsia is associated with increased vascular resistance and a decreased uteroplacental perfusion leading to an increased incidence of intrauterine growth retardation, fetal hypoxia, and perinatal death. Studies have demonstrated the efficacy of umbilical artery velocimetry in identifying fetal acidosis. Doppler ultrasound scanning is now common in the management of pregnancies complicated by hypertension and has become an indirect tool to assess fetal well-being. The absence or reversal of end-diastolic velocity in the umbilical artery has proved to be highly predictive of low birth weight or fetal death (97,98). Torres and coworkers (98) retrospectively investigated the relationship between abnormal umbilical artery velocimetry and fetal outcome in 172 hypertensive pregnant women. In their study, the absence of end-diastolic velocity predicted low birth weight in 100% of pregnancies and fetal death in 66.6%. All stillbirths in this study had absence of end-diastolic velocity (sensitivity 100%). However, the value of abnormal umbilical artery Doppler results (reversed or absent end-diastolic flow) in predicting poor fetal outcome in hypertensive pregnancies has been studied in only a small number of patients.

Table 9 provides a summary of guidelines for delivery. These indications should not be considered absolute, as exceptions may exist in allowing for individualization of patient care.

Management According to Gestational Age

In general, management of severe pre-eclampsia is dependent on gestational age. Patients with fetuses at a gestational age greater than 34 weeks are generally delivered after admission. Patients at 33 to 34 weeks of gestation with immature fetal lung maturity studies may receive steroids to accelerate fetal

lung maturity and may be delivered 24 hours after the last dose of steroids in the presence of any significant adverse change in maternal or fetal conditions. However, patients found eligible for conservative management should be counseled about the fact that gaining 2 more weeks could make the difference between having an infant admitted to the neonatal intensive care unit or having an infant admitted to the well-baby nursery.

Patients at 28 to 32 weeks of gestation are managed according to their clinical status during the observation period. Sibai and colleagues (83) published data from a randomized and well-controlled study comparing aggressive versus expectant management in patients with severe pre-eclampsia between 28 and 32 weeks of gestation. In this study, it was possible to prolong pregnancy by an average of 15.4 days in women assigned to expectant management without a significant increase in maternal morbidity. Additionally, the expectant management group had a lower incidence of admissions to the neonatal intensive care unit (76% vs. 100%), lower average number of days spent in that unit (20.2 vs. 36.6 days), reduced incidence of respiratory distress syndrome (22.4% vs. 50.0%), and a reduced incidence of necrotizing enterocolitis (0% vs. 10.9%). Similar findings were observed by Odendaal and coworkers (85) and by Fenakel and colleagues (100).

Patients with severe pre-eclampsia at a gestational age of < 27 weeks should receive extensive counseling regarding the risks and benefits of expectant management (Table 10). Sibai (86) reported a perinatal survival rate in conservative management of severe pre-eclampsia between 25 and 27 weeks of gestation of 76% compared with 35.5% in the group that had immediate delivery. In addition, the infants in the conservative management group had a lower incidence of intraventricular hemorrhage (41% vs. 71%) and a shorter length of stay in the neonatal intensive care unit (70 vs. 115 days). In the same study, a perinatal survival rate of 6.7% and a 27% incidence of maternal morbidity were reported in conservative management of severe pre-eclampsia at ≤ 24 weeks of gestation. Therefore, expectant management of patients between 25 and 27 weeks of gestation had a significantly higher perinatal survival and a lower acute and long-term neonatal morbidity compared with aggressive management. Maternal complications were infrequent in both

Table 10 Expectant management of severe pre-eclampsia at <25 weeks of gestation (101)

	Patients	Perinatal death (%)	Maternal complications (%)
Sibai et al. (83)	15	93	27
Moodley et al. (102)	10	100	50
Visser and Wallenberg (103)	25	84	Not reported
Gaugler-Senden et al. (104)	26	82	65
Hall et al. (82)	8	88	36
Budden et al. (105)	31	71	71

groups. Perinatal survival was low, morbidity was high, and maternal complications were also elevated. Therefore, for patients between 24 and 25 weeks of gestation, a gain of 1 or 2 weeks will markedly improve perinatal survival and reduce neonatal morbidity.

Any deterioration in the status of either the mother or the fetus may necessitate urgent delivery. Early detection of maternal or fetal complications or deterioration in their clinical status and prompt therapy and delivery may be responsible for infrequent maternal complications. Such management with frequent and daily monitoring of maternal and fetal status is essential and should be practiced only at a tertiary care center. Chari and colleagues (106) studied 68 women with severe pre-eclampsia remote from term who underwent expectant management with daily fetal testing until delivery. In this study, patients who had non-reassuring fetal testing were delivered. Neither stillbirths nor fetal compromise at birth occurred in patients undergoing daily antenatal testing; thus the authors recommended daily testing in patients with severe pre-eclampsia managed expectantly. Odendaal and associates (85) recommended performing the nonstress test at least three times daily in this group of patients. However, such evaluation must be individualized.

INTRAPARTUM MANAGEMENT

Once a decision for delivery is made, vaginal delivery is preferable if possible, and a trial of labor may be warranted.

It is generally accepted that pre-eclamptic women are at increased risk for convulsions during labor, compared with normotensive pregnant women. The risk for convulsions depends on the severity of the pre-eclamptic process. Women with gestational hypertension (absent proteinuria) are at a lower risk than those with proteinuric hypertension. The highest risk is usually in women with severe pre-eclampsia, particularly those remote from term, those with cerebral manifestations, and those with HELLP syndrome. The use of magnesium sulfate in patients with pre-eclampsia has been questioned for a long time. The incidence of eclampsia in pre-eclamptic women receiving magnesium sulfate is 0.15% to 0.3% vs. 1.2% in pre-eclamptic women not receiving magnesium sulfate (107). As a result, all women who are diagnosed to have pre-eclampsia should receive parental magnesium sulfate during labor. Magnesium sulfate has been the drug of choice for the prophylaxis of eclamptic seizures in the United States. Other agents (diazepam, clomethiazole,

barbiturates, and phenytoin) or no agent at all have been used for the same purpose in Europe and Australia. The most commonly used regimens of magnesium sulfate administration are the standard intramuscular regimen of Pritchard (4 g IV with 10 g IM load, 5 g IM every 4 hours) and the intravenous regimens of Zuspan (4 g load, 1–2 g/hr) and Sibai (6 g load, 2 g/hr). Phenytoin has proved to be an effective anticonvulsant in the setting of pre-eclampsia and eclampsia, and was considered by some to be a desirable alternative to magnesium sulfate, especially because phenytoin possesses certain advantages (more rapid cervical dilatation and a smaller drop in hematocrit) and fewer side effects (108). Lucas and colleagues (109) conducted a randomized study comparing the use of magnesium sulfate with phenytoin in the prevention of eclampsia. They found that magnesium sulfate was clearly superior to phenytoin when given prophylactically for eclamptic seizures to women with peripartum hypertension. In fact, 10 of the 1089 women randomly assigned to the phenytoin regimen had eclamptic convulsions, compared with none of the 1049 women assigned to magnesium sulfate. Phenytoin is an acceptable alternative to magnesium sulfate in patients with renal insufficiency, myasthenia gravis, or magnesium failure.

Patients should receive close monitoring during labor and delivery and postpartum, with special attention to fluid intake and output. Patients with severe disease and those with the HELLP syndrome are at an increased risk for the development of pulmonary edema from fluid overload and from acute renal failure from blood loss during delivery or from hemolysis, or from a combination of both. Urinary output needs to be monitored frequently, and fluid administration should not exceed 150 mL/hr. If the patient develops oliguria (<100 mL/4 hr), both the rate of fluid administered and the dose of magnesium sulfate may be adjusted appropriately.

Antihypertensive Drugs in Severe Pre-eclampsia

Empirically, antihypertensive therapy is recommended for systolic blood pressure exceeding 160 mmHg and diastolic blood pressure of >110 mmHg in order to protect the patient from the complications of severe hypertension, especially stroke. The aim of therapy is to maintain the blood pressure within the range of 140 to 150 mmHg systolic and 90 to 100 mmHg diastolic or to initially reduce mean arterial blood pressure by no more than 20% from baseline values. Antepartum diuretics are not needed, except in the presence of pulmonary edema. Irrespective of the antihypertensive drug used, care must be taken not to lower blood pressure excessively, as this may exacerbate maternal cerebral ischemia, decrease renal function, or jeopardize fetal well-being by decreasing cerebral, renal, and placental blood flow. Attempts should be made to reduce the blood pressure to a safe range within 4 hours of diagnosis. The doses are usually titrated to blood pressure response. Comparative trials have not shown one agent to be superior in the acute management of severe hypertension in pregnancy (101,110). (Table 11)

Hydralazine is given in sequential intravenous boluses of 5, 5, and 10 mg at intervals of 15 to 20 minutes until a satisfactory response is achieved. Hydralazine causes a direct relaxation of arterial smooth muscle, resulting in stimulation of the sympathetic nervous system and causing an increased reflex

Table 11 Treatment of Severe Hypertension

Class	Drug	Onset (min)	Peak (min)	Dose
Arterial dilator	Hydralazine	10–20	60	5–10 mg IV every 15–30 min
Calcium channel blocker	Nifedipine	10	60	10–20 mg orally every 30 min, max 120 mg/d
Alpha/beta-blocker	Labetalol	5	60	20–40–80 mg IV every 10–20 min up to 300 mg
Arterial/venous dilator	Sodium nitroprusside	0.5–5	5	0.2–5.0 mg/kg/min

heart rate and contractility. Maternal side effects include flushing, headache, palpitations, nausea, and vomiting. Uteroplacental perfusion may decrease following parenteral administration leading to fetal heart rate decelerations. The onset of drug effect may be 20 to 30 minutes, reaching a peak at 60 minutes from administration. Therefore, the drug may accumulate after continuous intravenous infusion, resulting in overshoot hypotension.

Nifedipine is started at an initial oral dose of 10 mg. It is then repeated in 20 to 30 minutes as necessary (10, 10, 20 mg). The total dose of short-acting nifedipine should not exceed 120 mg over a 24-hour period.

In a randomized clinical trial, Fenakel and colleagues (100) compared the effects of nifedipine with hydralazine in patients with severe pre-eclampsia. Nifedipine produced a more predictable reduction in blood pressure without being associated with sudden or excessive falls in blood pressure. This characteristic is an important factor in the avoidance of acute fetal distress from sudden hypotension in pre-eclamptic patients who frequently have compromised uteroplacental blood flow. Only one of the 24 nifedipine subjects developed signs of acute fetal distress, as opposed to 11 of the 25 hydralazine patients. The longer duration of action by nifedipine resulted in fewer doses necessary to achieve blood pressure control.

Labetalol is administered in repeated bolus intravenous injections. The starting dose is 20 mg, and if no improvement in blood pressure is noted, repeated doses of 20, 40, and 80 mg may be given every 10–20 minutes to a maximum total dose of 300 mg. When compared with hydralazine, labetalol has fewer side effects including less headache, quicker onset of action, and smoother reduction in blood pressure (101).

Sodium nitroprusside is a potent arterial and venous dilator. It is given in a continuous intravenous infusion beginning at a rate of 0.2 mg/kg/min. It has a rapid action, with short duration. Because of the potent hypotensive properties of the drug, invasive arterial pressure monitoring is recommended. It should be used only in extreme emergencies in pregnancy, because of the potential risks of fetal cyanide poisoning and metabolic acidosis (111).

Anesthesia

There is controversy about the use of epidural analgesia/anesthesia in women with pre-eclampsia. Some authors believe that the administration of epidural anesthesia in women with severe pre-eclampsia is detrimental to both the mother and the fetus, owing to possible profound hypotension. Other studies have demonstrated, however, that administration of epidural anesthesia in women with pre-eclampsia has a favorable effect on maternal hemodynamics, decreases catecholamine levels, and improves intervillous as well as umbilical blood flow (112–115). Ramanathan and colleagues

(115) prospectively compared the effects of lumbar epidural ($n=11$) and general ($n=10$) anesthesia on the hemodynamic and neuroendocrine stress response to cesarean delivery in 21 women with severe pre-eclampsia. The authors found that, in the epidural group, there was a decrease in mean arterial pressure, and the concentrations of adrenocorticotrophic hormone, beta-endorphin, and catecholamine decreased or remained unchanged during the procedure. By contrast, patients receiving general anesthesia demonstrated a significant increase in both mean blood pressure and the concentration of the various hormones studied. In addition, neonatal outcomes were similar in both groups. It is our opinion that the epidural is the anesthetic of choice in women with pre-eclampsia. Care must be taken to avoid fluid overload during pre-epidural fluid boluses. However, its use is contraindicated in patients with coagulopathy and/or acute fetal distress. For patients with the HELLP syndrome, the use of pudendal block is contraindicated.

Postpartum Management

Following delivery, the patient should continue to be closely monitored for 12 to 24 hours, during which time maternal vital signs including reflexes, and intake and output, should be monitored hourly. Twenty-five percent of cases of eclampsia are reported to occur postpartum; therefore, observation is mandatory. Salt restriction and diuretics are most often not needed. Most patients will show evidence of resolution of the disease process within 24 hours. The best sign of pre-eclampsia resolution is spontaneous diuresis.

Some, however, mainly those with severe disease in the mid-trimester, and those with HELLP syndrome, require intensive observation for greater than 24 hours. In such patients, magnesium sulfate may be needed for an extended period of time. In addition, these patients are at increased risk for the development of pulmonary edema from fluid overload, fluid mobilization, and compromised renal function (116).

If the patient develops severe hypertension during this time, the blood pressure may be controlled with oral nifedipine. In a double-blind study, Barton (117) evaluated the effect of nifedipine in postpartum patients with severe pre-eclampsia before delivery. They found oral nifedipine to be effective in the control of blood pressure as well as improving urine output during the 24 hours after delivery. In a subsequent report, Barton (118) studied the pharmacokinetic and pharmacodynamic parameters of oral nifedipine use in the immediate postpartum period. Based on the clinical pharmacology in this setting, they suggested that dosing should be every 3–4 hours. Most patients will be normotensive at the time of discharge from the hospital. A few patients may continue to have significant hypertension, and this can be controlled with additional oral blood pressure medications. Prophylactic anticonvulsive drugs such as phenobarbital are

not needed. The patient is then seen at weekly intervals until her blood pressure is in the normal range without the use of medication. If this change does not occur by 6 weeks, a workup to assess hypertension should be performed.

LONG-TERM IMPACT

The long-term effects of pre-eclampsia and gestational hypertension on maternal and fetal well-being are only now being realized.

Maternal

Multiple studies have demonstrated an increase in maternal cardiovascular morbidity following hypertensive disorders of pregnancy. Recently, Magnussen and colleagues (119) described a prospective study of 15,065 women to assess impact of hypertensive disease in pregnancy on maternal cardiovascular risk. The association of increased cardiovascular risk was stronger with hypertensive disease in more than one pregnancy or in whom it developed late in their reproductive career. For example, those with two episodes of pre-eclampsia were 10 times more likely to require medication to control blood pressure at follow-up. In addition, women with a history of pre-eclampsia were more likely to develop diabetes (adjusted odds ratio 2.8 after adjustment for current BMI.) In a 2010 case-control study comparing three groups of women (history of HELLP, history of pre-eclampsia, and normal pregnancy), Strobl (120) noted that 13 to 18 years after the affected pregnancy, those women in the HELLP and pre-eclampsia groups were more likely to have impaired cardiac function on echocardiogram. Additionally, there were more women in these groups on anti-hypertensive medications.

Child

The impact of hypertensive disease in pregnancy on the child is now a focus of increasing research. A prospective case-control trial by Tenhola and colleagues (121) compared 57 children of pre-eclamptic pregnancies with 57 born from gestational age-matched unaffected pregnancies. When comparing blood pressure as well as plasma catecholamines, those exposed to pre-eclampsia had higher blood pressure. Those children with hypertension were more likely to have been born small-for-gestational age. Additionally, a small increase in plasma epinephrine levels was noted in these children. There was no difference in the norepinephrine levels between groups. Palmsten and colleagues (122) examined a cohort that was followed from pregnancy into adulthood as a part of the Collaborative Perinatal Project and the New England Family Study. Adults born from hypertensive disorders of pregnancy were more likely to have increased blood pressure as adults. These findings remained after adjustment for gestational age at birth and birth weight. Exposure in utero of the fetus to oxidative stress is one possible explanation for these results.

The Helsinki Birth Cohort Study described by Kajantie and colleagues (123) included 6410 individuals born in the period 1934 to 1944. Of these pregnancies, 284 were complicated by pre-eclampsia and an additional 1592 complicated by gestational hypertension. While it was found that individuals born of these pregnancies are more likely to be at an increased risk for stroke (relative risk 1.4–1.9), no association with coronary heart disease was found. The elevation in risk of stroke is

hypothesized to be secondary to disordered local response of blood vessels as a result of impaired in utero growth.

9 Placenta previa and placental abruption

Ann K. Lal and William J. Watson

Antepartum hemorrhage can be divided into obstetric and non-obstetric causes. Frequent non-obstetric causes of antepartum vaginal hemorrhage include cervicitis, cervical polyps, cervical cancer, or vaginal lacerations. In the third trimester, the main clinically important causes of antepartum hemorrhage are placenta previa and placental abruption. When the clinician is evaluating a patient with antepartum hemorrhage, a precise diagnosis is needed so that proper management can be expeditiously implemented.

PLACENTA PREVIA

Placenta previa is defined as abnormal placental implantation over the cervical os. There are several variants of this definition. A low-lying placenta occurs when the placenta implants in the lower uterine segment; the placental edge lies near, but not over the cervical os. A low-lying placenta is not considered a category of placenta previa, but it is a form of irregular placentation, which may cause vaginal bleeding when the lower uterine segment develops during labor. When the edge of the placenta lies exactly at the internal cervical os, a marginal placenta previa is present. A complete placenta previa occurs when the internal cervical os is completely covered by the placenta. Clinicians refer to a “central previa” when the center of the placenta is covering the internal os of the cervix (Figs. 1 and 2). The term “partial placenta previa” in which part of the placenta covers the internal os of the cervix is not clinically useful, given the above definitions.

Epidemiology

Placenta previa is thought to be caused by an implantation abnormality. With increasing gravity and parity, for example, the underlying endometrium may be damaged, and in subsequent pregnancies, the embryo may implant in the lower uterine segment because it is a potentially more suitable site (1). The incidence of placenta previa complicating pregnancy is 0.26% to 1% (2,3). In gravidas with parity of five or greater, the incidence increases to 2.2% (4).

There are many known risk factors for placenta previa. One of the most significant risk factors is prior cesarean delivery. In a patient with two prior cesarean deliveries, the risk of previa is approximately 1.9%; this increases to 4.1% in those with three or more previous cesareans (5). If a patient with a prior cesarean section has a placenta previa in a subsequent pregnancy, the probability that the previa will persist until the term is increased (Table 1) (6).

A history of placenta previa confers an eightfold increased risk of previa in a subsequent pregnancy (7). A history of prior uterine curettage is a risk factor for previa, most likely due to the endometrial scarring from the surgical procedure (8). Advanced maternal age also increases the risk for the development of placenta previa. One report found that in

women of age 19, the risk of previa was 1/1500, but the incidence of previa increased to 1/100 in gravidas greater than 35 years old (3). Smoking poses a twofold elevated risk for the development of placenta previa. This is thought to be secondary to carbon monoxide-induced hypoxemia, which causes placental hypertrophy and impaired decidual vascularization (9). Likewise, an amplified risk is noted in patients who live at higher altitudes, most likely due to an increased placental surface area (10).

Clinical Presentation

The classic presentation of placenta previa is painless sudden vaginal bleeding. The first episode of bleeding is called the “sentinel bleed.” Most sentinel bleeds occur after the 28th week of gestation. About 70% of patients with placenta previa experiencing an antepartum hemorrhage will have this occur prior to 34 weeks of gestation (11). This painless hemorrhage usually has an onset without previous signs or symptoms. Fortunately, most initial bleeds are small and stop spontaneously. In patients with marginal placenta previa, it is more likely that the sentinel bleed will occur with the onset of labor. The cause of this bleeding is the development, or thinning, of the lower uterine segment and dilation of the cervix, which can cause dissociation of the placental connection to the uterus. This bleeding is augmented by the fact that the lower uterine segment has less contractile activity and is therefore impaired in its ability to constrict and stop ongoing hemorrhage. Bhide et al. studied 121 patients with low-lying placenta and placenta previa and noted that in cases of partial or marginal placenta previa, 57% had antepartum hemorrhage (12). The risk of bleeding with low-lying placenta was inversely related to the distance of the placental edge from the cervical os.

Diagnosis

The diagnosis of placenta previa is clinically important when a patient presents with antepartum hemorrhage. Among patients with placenta previa, specifically those with antepartum hemorrhage, the average gestational age at diagnosis is 32 weeks. Classical teaching is that pelvic exams are contraindicated in a patient with antepartum hemorrhage and unknown placental location. Before the availability of accurate real-time ultrasound, if a pelvic exam was to be performed in a patient with vaginal bleeding in the latter half of pregnancy, a double setup was required. A double setup is a digital cervical exam performed in the operating room with the necessary staff and equipment ready to perform an immediate cesarean delivery should heavy bleeding occur. Current ultrasound technology has made the double setup exam obsolete and relegated this procedure to the history books.

Initially, transabdominal ultrasound was used for diagnosis. Transabdominal ultrasonography, however, may be limited by

Figure 1 Abdominal ultrasound image of complete placenta previa, with a cervical length of 3.24 cm.

Figure 2 Transvaginal ultrasound image of complete placenta previa.

Table 1 Risk Factors for Placenta Previa

Prior uterine curettage	Multiparity
Cigarette smoking	Advanced maternal age

difficulty visualizing a posterior placenta, difficulty visualizing the lower uterine segment secondary to fetal positioning, and poor visualization in cases of maternal obesity (13). Although pelvic examination is contraindicated, clinical experience has shown that transvaginal ultrasound is safe to perform in patients with placenta previa (14). It has also been proven to be superior to abdominal ultrasound as diagnostic tool (15). Translabial ultrasounds can be of diagnostic assistance, but this technique does not appear to offer an advantage over transvaginal sonography. With the improved diagnostic accuracy of transvaginal ultrasound, in cases with a low-lying placenta, the ultrasound report should state the actual distance of the placental edge from the cervical os (13).

Natural History

If placenta previa is diagnosed at less than 24 weeks of gestation in an asymptomatic patient, a repeat ultrasound

should be performed at 32 weeks. This is done because 90% of placenta previas diagnosed at mid-trimester will resolve by term (16). The chance that the placenta previa will continue until term depends on whether it is marginal or complete. Zelop and colleagues found that complete placenta previa will persist at delivery 26% of the time, while a marginal placenta previa will persist only 2.5% of the time (17). If the placental edge is not touching the internal os at mid-trimester scan, the chance of a placenta previa at term is remote (15,18). Mustafa and colleagues, in a study of 337 gravidas examined by transvaginal ultrasound, found that in the general population, 42.3% had placenta previa at 11 to 14 weeks, 3.9% had previa at 20 to 24 weeks, and 1.9% had previa at term (19).

Because of the clinical observation that placenta previa diagnosed early in pregnancy often resolves later in pregnancy, the question of placental migration must be addressed. The phenomenon of placental migration can be attributed to two underlying causes (20). The first is trophotropism, which states that the placenta migrates toward areas of better endometrial vascularity. The second is that the placenta appears to migrate because it undergoes atrophy of the areas implanted over the cervical os, due to inadequate blood supply. Another hypothesis is that the placenta moves away from the cervical os as the lower uterine segment develops. The lower uterine segment extends during pregnancy and has been shown to change its total length from 0.5 cm at 20 weeks to 5 cm at term (21). It is noteworthy that the rate of placental migration appears to be variable (18).

Clinical Care

In patients with placenta previa, delivery occurs at a gestational age less than 36 weeks over 50% of the time. Because of this, careful management decisions must be made both in patients with a known diagnosis of previa and in those who present symptomatically with vaginal bleeding. The clinician must consider both maturity of the infant and maternal well-being.

In present-day obstetric practice, most cases of placenta previa are diagnosed early in pregnancy, and thus, management and delivery plans are started very early in pregnancy. No activity restrictions appear to be necessary in a stable patient without clinical symptoms prior to 28 weeks of gestation. Some clinicians advise against intercourse after the diagnosis is made early in pregnancy, but there is no objective data to guide the clinician. After 28 weeks of gestation in an asymptomatic patient, there are a few basic principles which are followed. Patients are counseled to present to the labor and delivery unit early with any sign of hemorrhage, and they are advised to avoid strenuous physical activity and sexual intercourse (8). Follow-up should include ultrasounds to assess the placental location. If the placenta previa resolves during this time of follow-up, no further evaluation is needed and the patient is free from activity restrictions. If, however, the placenta previa persists to the third trimester, the clinician should continue to follow serial ultrasounds and the patient should continue with activity restrictions.

In the clinical management of gravidas who present with preterm bleeding, the initial management should consist of admission to the labor and delivery unit with continuous fetal heart monitoring and monitoring of maternal vital signs. Large-bore intravenous access should be established in the mother.

Initial laboratory evaluation includes hemoglobin, hematocrit, platelet count, type and screen, and coagulation studies; Rh-immune globulin should be administered to Rh-negative gravidas. If the gestational age is <34 weeks, antenatal corticosteroids should be administered. Depending on the location of the institution and availability of neonatal care, transfer to a larger facility should be considered. Transfer of an actively bleeding patient may not be possible because of the maternal risk during transport. Of gravidas who present with an initial bleeding episode greater than 500 mL, 50% will not require immediate delivery (10). Only 5% who present initially with profuse vaginal bleeding need immediate delivery (22).

When patients with placenta previa present with a sentinel bleed, many experience uterine contractions or uterine irritability, which may augment the bleeding. Tocolytic therapy may decrease uterine irritability and decrease bleeding that is occurring secondary to uterine contractions (23). Depending on the clinical presentation, tocolysis can be utilized. Magnesium sulfate may be a better choice when compared with beta-mimetics, due to a lesser effect on the maternal cardiovascular status (24). In one retrospective study by Towers et al., 72% of patients diagnosed with placenta previa received tocolytic agents. The mean birth weight of infants born to mothers who had received tocolytics was 2276 versus 2076 g for those who did not receive tocolytic therapy (25). Neither the need for blood transfusion was increased in patients who received tocolytic therapy nor the maternal morbidity. Besinger et al. found that in the group of patients who received tocolysis, the mean birth weight was 2520 versus 2124 g in the no tocolytic group (26). Additionally, delivery was 39.2 days from admission in the group that received tocolytics versus the group that did not, where it was 26.9 days. In this study, both short-term and long-term tocolyses were used. In patients receiving only short-term intravenous magnesium sulfate treatment, the time until delivery was 15.3 days. In patients receiving longer term tocolysis, the delay until delivery was 40.9 and 47.4 days, respectively. This was statistically significant from the short-term application of tocolytics only (26). Similarly, a study by Sharma and colleagues using ritodrine as a tocolytic showed prolonged time to delivery, higher mean birth weight, no difference in bleeding episodes between the two groups, and an acceptable maternal and fetal safety profile (27).

The use of any tocolytic is controversial in modern obstetric practice. Specifically in the case of a stable patient with placenta previa and contractions, there are no prospective studies to guide the clinician. Tocolysis is appropriate to use during maternal transport. We think that tocolysis with a non-beta-mimetic is reasonable during the 48-hour window of steroid administration. There is no convincing evidence that use of long-term tocolysis in this clinical circumstance is beneficial. The use of a prophylactic tocolytic agent, such as 17-alpha-hydroxyprogesterone, to prevent the development of the lower uterine segment and possibly delay the onset of the sentinel bleed has not been investigated.

The conservative management of patients who are carrying preterm infants and are clinically stable after an initial antepartum hemorrhage includes expectant management with in-hospital bed rest. This in-hospital management includes daily fetal monitoring, fluid management, maternal blood

transfusion, if needed, and fetal lung maturity tests (25). Lam et al. assessed patients with known placenta previa and found that the overall incidence was 0.9%, with 60% of the patient experiencing antepartum hemorrhage (11). Between the patients who experienced an antepartum hemorrhage and those who did not, there was no difference in their age, parity, initial hemoglobin level, previous elective abortions, previous spontaneous abortions, previous dilation and curettages, prior cesarean sections, and history of placenta previa. In the group of patients presenting with antepartum hemorrhage, there was an increase in antenatal corticosteroid use, tocolytic administration, and an increase in emergency cesarean sections. With conservative management, this same study showed that the mean interval between bleeding and delivery via cesarean section was 3 weeks. Less than 25% of women had cesarean sections within 1 week of the initial presentation with bleeding.

In patients with previa who present with an initial bleeding episode and remain clinically stable without bleeding for 48 hours of observation, some might be eligible for outpatient management (20). For a patient to be eligible for outpatient care, she must understand her diagnosis and its implications. She should also live in close proximity to the hospital and have constant access to a telephone and transportation. In a randomized controlled trial by Wing and colleagues evaluating the significant differences in outcome between inpatient and outpatient management, there was no significant difference in mean time interval from enrollment to delivery, mean gestational age of the infant at delivery, birth weight, neonatal intensive care unit (NICU) admissions, and neonatal morbidity (22). Only 5 of 26 patients initially randomized to outpatient care had to be admitted for a third episode of bleeding, which was the criterion for changing groups in this study. Similar numbers of inpatients and outpatients had a second episode of vaginal bleeding (22). In Love's retrospective study assessing management strategy for placenta previa, the need for urgent delivery, defined as delivery within 4 hours of the presenting episode of vaginal bleeding, was unpredictable and showed no association with the number of bleeding incidents, the type of placenta previa, or outpatient management (28). Moreover, in women with placenta previa managed on an outpatient basis who needed an immediate delivery, there was no increase in maternal or neonatal morbidity and mortality (28). The decision for outpatient management needs to be individualized, with an emphasis on careful patient selection and education prior to discharge.

In most all patients with placenta previa, the mode of delivery must be cesarean section. Timing of delivery is a delicate balance between the risk of maternal bleeding and fetal prematurity. Without acute bleeding, delivery can be accomplished at 36 weeks with or without an amniocentesis. In a patient with any bleeding at a gestational age >34 weeks, it is reasonable to deliver her. In patients with a marginal placenta previa, greater than 2 cm from the internal cervical os, a vaginal delivery can be attempted; however, the facility and clinician must be prepared for immediate cesarean delivery. Additionally, there is an increased risk for postpartum hemorrhage in these patients (15).

During the cesarean delivery, two to four units of packed red blood cells should be readily available. The clinician should be prepared for significant postpartum hemorrhage. Ideally,

the placenta should not be disrupted with the hysterotomy. However, a transverse incision will most often extend through the placenta and, nonetheless, maternal and fetal outcomes remain good. The fetus should be delivered expeditiously when going through the placenta after hysterotomy. During the delivery, risk factors for blood transfusion include use of general anesthesia, history of cesarean delivery, and the need to perform a cesarean hysterectomy (29). In the case of previa with prior cesarean and suspected accreta, the incision should be made vertically, high on the uterus, above the placental implantation site.

Postpartum hemorrhage is a known risk that may occur after cesarean section for placenta previa. Hemostasis can be attempted with intravenous or intramuscular oxytocin, methylergonovine, carboprost, or uterine massage. These techniques may not be effective because the bleeding is coming from the lower uterine segment, which may not contract down well after delivery. If bleeding continues, the physician can try uterine artery ligation, bilateral ligation of the internal iliac artery, or cesarean hysterectomy as a last resort. Additional procedures to try during surgery include circular isthmic-cervical suture placement and parallel vertical compression sutures. Cervical isthmic sutures obstruct the site where the placenta was abnormally attached by interrupting the uterine blood flow below the placental implantation site (30). Dedes reported no complications from the suture placement; hysterectomy was not needed, and at ultrasonography performed 6 weeks after delivery, no abnormalities were demonstrated. Vertical compression sutures placed in the lower uterine segment can also help to achieve control of postpartum hemorrhage in patients with abnormal placentation (31). These sutures were found to effectively control bleeding in 14 women in whom they were placed, without intraoperative complications. Additionally, all women had a normal ultrasound 1 month postpartum and resumed normal menstrual flow after the conclusion of breastfeeding. If all other means for obtaining hemostasis have been attempted, and bleeding continues despite abnormal maternal coagulation status, cesarean hysterectomy can be performed. In one report, the most common cause for cesarean hysterectomy was placenta accreta (51.1%), followed by placenta previa at 26.7% (32).

PLACENTA ACCRETA

A significant risk associated with placenta previa is placenta accreta. Placenta accreta is abnormal attachment of the placenta, with an absence of deciduas basilas and an incomplete development of the fibrinoid layer. More severe variants are placenta increta and percreta, with placental extension into the myometrium and through the myometrium, respectively. Two significant risk factors for placenta accreta formation are history of a prior cesarean section and a diagnosis of placenta previa. In a patient with a placenta previa and no prior uterine scar, the risk of an accreta is 3%. However, in patients with one cesarean section and a previa, the accreta risk is 11% and increases to 67% in those with four prior cesareans (33). In the absence of a placenta previa, placenta accreta is rare (34). Because of the significant risk associated with placenta accreta, investigators have attempted to elucidate ultrasonographic signs to accurately diagnose this condition.

Multiple irregular vascular spaces in the placenta have been associated with accrete (Figure 3) (15). Other ultrasonographic signs include loss of the normal hypoechoic zone behind the placenta, focal exophytic masses in the placental bed, and a disturbed bladder-uterine connection (33,35). Doppler may also be helpful in making this diagnosis (33,35). MRI can also be used as an adjuvant tool to assess placental invasion. In one study when the placenta was implanted anteriorly overlying a previous cesarean section scar, 29% of cases were accreta (34). The major morbidity associated with accreta is postpartum hemorrhage and maternal blood loss; 55% of cases require blood transfusion, and in 15% of cases, there can be more than 5 liters of blood loss (34). Other surgical complications include ureteral transection, cystotomy, disseminated intravascular coagulation, hypotensive shock, and enterotomy.

VASA PREVIA

Vasa previa is defined as fetal blood vessels running through the membranes over the maternal cervix, unprotected by either the umbilical cord or the placenta (Figure 4). It is associated with velamentous umbilical cord insertion. With

Figure 3 Placenta previa and accreta seen on ultrasound with multiple vascular lacunae present.

Figure 4 Ultrasonographic depiction of vasa previa with fetal vessels, unprotected by umbilical cord, evident by Doppler ultrasound between fetal head and cervix.

the rupture of membranes, these fetal vessels can rupture and result in significant fetal bleeding. The fetus can lose a large portion of its blood volume; therefore, this condition is associated with a high fetal mortality rate (8). It is also noteworthy that vasa previa can be present after a low-lying placenta is visualized on a second-trimester ultrasound (15).

POST-DELIVERY COMPLICATIONS

The clinician also needs to be aware of post-delivery complications. Placenta previa is rarely associated with coagulopathy. Massive blood loss per se can be associated with coagulopathy (see chapter on postpartum hemorrhage). However, in a study by Wing and colleagues, fibrinogen was abnormal in only 1.1% of the cases, and prothrombin times were normal in all of the women with symptomatic placenta previa who were studied (36). In patients with placenta previa, there is a significant increased risk of postpartum hemorrhage, probably due to the poor contractility of the lower uterine segment. In one report, 8.3% of women with previa had postpartum hemorrhage, even without a diagnosis of placenta accreta (12). Hemoglobin and hematocrit are most likely to be abnormal of the initial laboratory studies (36). After massive blood loss, complications from hypotension can occur, including acute tubular necrosis and Sheehan syndrome.

FETAL RISKS

The most significant fetal complication is prematurity. The mean gestational age at delivery is 34 to 35 weeks of gestation. Lam et al. found that 60% of infants were born at less than 37 weeks, in 26% the infant was born at less than 34 weeks, and in 5% delivery occurred at less than 30 weeks (11). Because of this increase in premature birth rates, the neonatal mortality rate is increased threefold. Importantly, however, when controlled for gestational age at delivery, there is no association with intrauterine growth restriction. There is not a difference in the birth weight of term infants (11). There is a slightly elevated risk of fetal anemia. In women with placenta previa who experience antepartum hemorrhage, neonatal risks include respiratory distress syndrome, lower birth weight, lower Apgar scores, and an increase in NICU admission (11).

SPECIAL CIRCUMSTANCES

First-trimester bleeding is a common problem for an obstetrician. Typically, placenta previa is not associated with first-trimester bleeding; it has been shown, however, that threatened abortion is a 2.5-fold increased risk factor for placental abruption and placenta previa (37). Varma found that if a placenta previa is detected with ultrasound in the first trimester or early second trimester, it is linked to an increase in vaginal bleeding during pregnancy, an increased rate of spontaneous abortion, and an increased chance of a placenta previa persisting to a later gestational age (38). Obed and colleagues examined 374 patients with threatened abortion; they found that 2% had placenta previa, compared with a control group rate of 1% for the same diagnosis (37).

While second-trimester bleeding is less common than first-trimester bleeding, if bleeding does occur, it is necessary to elucidate the cause of the bleeding. Two common causes are placenta previa and non-previa bleeding that is most likely associated with placental abruption (39). Towers and Burkhart

found that in gravidas who bleed between 16 and 24 weeks, the best outcomes were associated with light bleeding, whether or not the patient was diagnosed with a placenta previa. The worst outcome was associated with a patient who presented with heavy vaginal bleeding, not attributed to a placenta previa; 50% of these pregnancies were lost prior to viability (39).

A patient with a known placenta previa and either an intrauterine fetal demise or a fetus with chromosomal or structural abnormalities diagnosed in the second trimester presents a special problem for the clinician. In these patients, the safest approach for termination of the pregnancy needs to be decided. Halperin retrospectively studied 306 gravidas; 2.6% had a complete placenta previa and underwent laminaria placement and subsequent dilation and evacuation (40). This study found no difference in operative time, the need for packed red blood cells, postoperative morbidity, duration of hospital stay or bleeding with laminaria placement, when comparing those with and without placenta previa. In Thomas's retrospective study, there was slight increase in blood loss in patients with placenta previa; however, there was no increase in blood transfusion, infection, or postoperative complications (41). Most patients with placenta previa have a previous cesarean section; however, it has been shown that even in patients with prior uterine surgery who undergo laminaria placement and subsequent dilation and evacuation, there is no increase in anesthetic complications, uterine perforation, mean operative time, or cervical lacerations (42).

In pregnancy complicated by placenta previa with fetal demise or fetal anencephaly after 22 weeks of gestation, hysterotomy is the generally accepted practice for delivery. It may be possible in rare cases, after fetal demise has occurred, to attempt vaginal delivery by expectantly managing the patient, allowing the vascularity of the placenta to decrease. There are risks of conservative management in such cases, which include bleeding and coagulopathy. Delivery must occur in a facility where immediate cesarean can be performed. In such cases, maternal care must be individualized.

PLACENTAL ABRUPTION

Placental abruption is defined as separation of the placenta from the maternal endometrium that occurs before birth. This leads to bleeding at the site of separation from local maternal blood vessels. Most often, the maternal blood then tracks downward between the fetal membranes and uterine wall and comes out of the cervix. If this bleeding remains trapped behind the placenta and is not clinically evident, then the abruption is "concealed." This occurs in approximately 10% of cases. This placental separation may occur secondary to an acute process, such as maternal trauma, or from a chronic process, such as maternal smoking.

The etiology of abruption is unknown. Some cases are associated with rapid changes in uterine size or shape. This is the case with maternal trauma or abruption that can occur after delivery of one fetus in a multifetal pregnancy or after reduction amniocentesis. Other cases may be related to acute vascular changes in the mother, such as that which may occur after maternal cocaine use. Abruption may also occur in association with chronic placental disease. It is known that

Table 2 Risk Factors for Placental Abruption

Maternal trauma	Cigarette smoking
Maternal cocaine use	Hypertension during pregnancy
Abruption in a previous pregnancy	Premature rupture of membranes
Reduction amniocentesis	Polyhydramnios
	Chorioamnionitis
Disorders of maternal fibrinogen	Advanced maternal age

abruption is increased, for example, in gravidas with elevated maternal serum alpha fetoprotein levels. Low Papp-A levels are similarly associated with abruption. Serum levels of placental growth factor are decreased in gravida who subsequently develop placental abruption (43). Thrombophilia disorders are common, and some studies have noted an association between thrombophilia and placental abruption (44–47). This association, however, does not establish thrombophilia as a cause of abruption. Newer prospective studies are finding little association between inherited thrombophilias and pregnancy complication such as placental abruption. Currently, there is no evidence that patients with a history of abruption and known thrombophilia should be treated with heparin during pregnancy for the prevention of abruption recurrence (48). It is reasonable to use folate to treat hyperhomocysteinemia in patients with prior abruption. Risk factors for abruption are shown in Table 2 (49–53).

Clinical evidence of abruption occurs in approximately 1% of pregnancies (49). The frequency is higher than this if one considers abnormal placental findings in asymptomatic gravidas. The spectrum of clinical disease ranges from mild bleeding with a stable mother and baby to fetal death with heavy maternal bleeding and coagulopathy. It is estimated that an abruption of 50% of the placental surface volume will cause fetal mortality. Abruption severe enough to cause fetal loss is estimated to occur with a frequency of 1 in 830 births (54). Clinical observation indicates that abruption occurs most frequently during the gestational age of 24 to 26 weeks, with a decreasing frequency as the pregnancy progresses to term (49). Abruption is important clinically because it can be a cause of premature birth, with consequent increased perinatal mortality.

The diagnosis of abruption is clinical. Clinical findings include uterine hypertonus with pain and vaginal bleeding. This helps the clinician to distinguish abruption from previa; with placenta previa, painless vaginal bleeding is most commonly seen. The diagnosis can be confounded because, as mentioned above, in some cases of abruption, bleeding is concealed and pain may be insignificant. Abruption should be suspected in a gravida who presents with abdominal or back pain, with vaginal bleeding, or even with symptoms of preterm labor. Typically the uterine contractions are described as high frequency/low amplitude. This pattern may occur as a focal uterine response to limit bleeding at the point of placental separation. The amount of vaginal bleeding observed may not correlate with the extent of abruption. Furthermore, the rate of progression or extension of abruption is unpredictable. Clinicians have noted “port-wine”-colored amniotic fluid in some cases of placental abruption.

The main usefulness of ultrasound lies in finding the placenta location and excluding placenta previa. It is well known that abruption may not be visible on ultrasound study, because the blood may be similar in appearance to the placenta. A retroplacental blood collection may also be hyperechoic or hypoechoic relative to the placenta. If a hyper- or hypoechoic mass is seen in a pregnant women with the classical presentation of abruption, then the sonographic accuracy for diagnosis of abruption is high. Sonography, however, cannot be used to exclude abruption. Nyberg et al. reviewed 57 cases of placental abruption sonographically and noted that acute hemorrhage was difficult to distinguish from the adjacent placenta and may be isoechoic with the placenta (55). Resolving hematomas became hypoechoic over 1 to 2 weeks of time period. Some cases were confused with other mass lesions. Glantz reported ultrasound findings on 149 patients with vaginal bleeding after 24 weeks of gestation and confirmed the poor sensitivity of ultrasound in the detection of placental abruption (56).

CLINICAL MANAGEMENT

Abruption can present as an acute or a chronic process. Acute abruption typically presents clinically with pain and bleeding. In a patient who presents with abdominal pain and vaginal bleeding after the period of fetal viability, the clinician must quickly assess maternal and fetal status. It is necessary to obtain IV access and to send blood for type and crossmatch, as well as coagulation studies. A Kleihauer-Betke test, to assess for fetal cells in the maternal circulation, may be indicated only in the Rh-negative mother. The most important parameter in the coagulation panel is maternal fibrinogen level. In normal pregnancy, fibrinogen levels increase. A fibrinogen level below 250 mg% is low during pregnancy and levels below 150 mg% are critically low. A clot (red top) tube can be used to rapidly estimate maternal coagulation status (see chapter on postpartum hemorrhage). If the fetus is alive (less than 50% abruption) and at a viable gestation age, then electronic fetal monitoring (EFM) is used to assess fetal status. After a bedside ultrasound excludes previa, a vaginal exam to assess cervical status is safe to do and is clinically indicated to assess the status of labor.

If fetal demise has occurred, the goal is to accomplish vaginal delivery while minimizing maternal morbidity. Maternal anemia and coagulopathy, if present, can be corrected by transfusion of packed red blood cells and fresh frozen plasma. Coagulopathy is more commonly seen with large abruptions, and it may be seen in up to 30% of cases where abruption causes fetal demise. Clinically, labor in most cases is rapid, and vaginal delivery can be accomplished despite maternal bleeding. In the case of massive bleeding in a mother remote from delivery, cesarean delivery may be needed for maternal indications, despite the fetal demise. When performing a cesarean section on a mother with coagulopathy, blood products to correct coagulopathy (fresh frozen plasma, platelets) should be infusing at the time of the initial skin incision, if possible.

Cesarean is also indicated in cases of abruption with a living fetus at a viable gestational age, if there is evidence of abnormal EFM. Ominous findings may include sustained fetal bradycardia or recurrent late decelerations. Rapid delivery in cases of fetal bradycardia may improve fetal outcome in pregnancy

complicated by abruption. The uterine incision at the time of cesarean is dictated by obstetric indications. A vertical incision may be needed if the fetus is a premature breech or back-down transverse lie. Bleeding will usually abate after delivery of the placenta and correction of coagulopathy, if present.

At the time of cesarean section, the obstetrician may note a dark purple discoloration of the uterus. This is called a Couvelaire uterus; it is caused by extravasation of blood into the myometrium. This was described by Alexandre Couvelaire, a French obstetrician, who wrote a classic paper on the subject in 1911 (57). He termed the condition "uterine apoplexy" and noted that blood from abruption could extravasate not only into the uterine muscle but also into the serosa of the uterus, the broad ligament, and the pelvic peritoneum. Initially it was thought that Couvelaire uterus was an indication for hysterectomy, but with the current therapy for coagulopathy, Couvelaire uterus per se is not considered an indication for hysterectomy.

Following delivery, bleeding may continue due to coagulopathy or uterine atony, and these conditions can be managed medically, as they would in a patient without abruption (see chapter on postpartum hemorrhage). After surgery, the patient should be monitored closely, and general parameters include transfusing packed red cells to keep the hematocrit at or near 30%, platelets above 50,000/ml, and fibrinogen above 150 mg%. Fluids are given to maintain urine output at >30 cc/hr. Serial assessments of complete blood count and coagulation parameters are needed.

Chronic abruption presents a clinical dilemma because there is no known way to predict recurrent bleeding or extension of abruption. Second-trimester bleeding in the absence of previa most commonly is from marginal placental abruption, and perinatal mortality is increased. In cases managed conservatively after fetal viability, steroids should be given to the mother to enhance fetal pulmonary maturity. If bleeding abates for 48 hours and the fetus has reassuring testing, the patient may be discharged to close outpatient follow-up. Since abruption is associated with growth restriction, it is important to perform serial ultrasound evaluation for growth.

RECURRENCE RISKS

Previous abruption is a known risk factor for recurrence in a subsequent pregnancy. The recurrence risk is estimated to be 5% to 15%. If the initial abruption was from a temporary risk factor such as trauma, then the recurrence risk may be lower. In abruption associated with modifiable risk factors, such as maternal smoking or cocaine use, quitting these activities will decrease the recurrence incidence. An interesting observation is that quitting smoking before pregnancy may not reduce the abruption recurrence risk to that of the general population. The abruption risk of former smokers remains elevated (58). In gravidas whose prior pregnancy was complicated by abruption, there is an increase in growth restriction, pre-eclampsia, and preterm birth in subsequent pregnancies, in addition to abruption. This suggests a common etiologic process of vasculopathy in these conditions.

10 Postpartum hemorrhage

Wade D. Schwendemann and William J. Watson

While the incidence of postpartum hemorrhage has not changed significantly in the past several years, the maternal mortality rate has decreased in developed countries because of better education regarding the issue and new treatment modalities (1,2). New therapies developed for the treatment of postpartum hemorrhage hold considerable promise in expanding the arsenal of the physician in conservatively treating cases refractory to standard therapy.

Developing countries still see a significant maternal mortality rate from this condition, enough to make hemorrhage the most common cause of maternal death worldwide (1,2). In addition to mortality, significant maternal morbidity can result.

DEFINITION AND EPIDEMIOLOGY

There are several different definitions of postpartum hemorrhage. The first is an estimated blood loss greater than 500 cc with vaginal delivery or greater than 1000 cc with a cesarean delivery (3). These definitions are the standard for most clinicians. However, obstetric texts quote a mean of 500 cc of blood loss for vaginal delivery and 1000 cc of blood loss for cesarean delivery. This confuses the issue, because the average blood loss cannot represent a pathologic condition. We believe that a more reasonable definition of a postpartum hemorrhage is 1000 cc or more with vaginal delivery or greater than 1500 cc with cesarean delivery.

A second definition is a 10% decrease in the hematocrit when comparing pre- and postdelivery blood counts. This definition has several limitations as well. In our current environment of medical cost containment, a predelivery hematocrit might not be obtained in low-risk cases. Furthermore, following acute blood loss, the hematocrit value may take hours to equilibrate.

These definitions also present a problem because clinicians have been shown to be very poor at estimating actual blood loss, consistently underestimating it (4–7). This difficulty is increased in the obstetric setting due to the presence of amniotic fluid at the time of delivery. Training and graded drapes have been shown to improve the accuracy of blood loss estimates (8,9) and should be implemented, particularly in areas where postpartum hemorrhage is more common.

Further subclassification of postpartum hemorrhage divides cases into early and late hemorrhage. Early postpartum hemorrhage is any hemorrhage that occurs up to 24 hours postdelivery. Postpartum hemorrhage that occurs from 24 hours to 12 weeks postdelivery is considered a late postpartum hemorrhage. This distinction is important to understand because the likelihood of a given diagnosis as a cause for the hemorrhage differs based on the timing.

The incidence of postpartum hemorrhage will vary based on the criteria used to define the condition. The best estimates available indicate that somewhere between 1% and 5% of deliveries will be complicated by postpartum hemorrhage (10).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of postpartum hemorrhage includes retained placental tissue, uterine atony, lacerations, uterine inversion, and defects in maternal coagulation. Women are at an increased risk of hemorrhage due to uterine atony if they have multiple gestation or polyhydramnios or have recently been administered any medications to reduce frequency of uterine contractions, such as terbutaline (11–14). Hemorrhage caused by laceration is increased in cases of operative vaginal delivery, large for gestational-age infants, and in women with a history of previous lacerations (11–14). Obstetric hemorrhage can also be the presenting symptom in women with a previously undiagnosed clotting disorder (15). Women with the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome are also at an increased risk for blood loss due to coagulation defects (16).

ASSESSMENT OF BLOOD LOSS/COAGULATION STATUS

The initial assessment of the status of the patient is crucial. This involves clinical examination, including vital signs, urine output, and laboratory testing. The signs and symptoms of clinically significant blood loss include vertigo, tachycardia, and hypotension. Other vasovagal syndromes can also be confused based on symptomatology alone. Immediate postpartum hemorrhage is rarely misdiagnosed, but a late hemorrhage, particularly in the setting of a cesarean delivery, can be missed if the clinician does not have a high index of suspicion. Blood loss of approximately 10% to 15% of the circulating blood volume (500–1000 cc) can cause tachycardia, while it generally takes at least 25% to 35% (1500–2000 cc) to cause hypotension (17). This is, of course, dependent on maternal body size and the rate of blood loss.

Changes in vital signs can provide some information regarding the degree of hemorrhage, but as the majority of obstetric patients are young and healthy, there can be a considerable amount of blood loss with compensation that can occur prior to a significant change in vital signs.

Initial laboratory evaluation should include a complete blood count (CBC) and coagulation studies including fibrinogen, prothrombin time, international normalized ratio, and activated partial thromboplastin time. It is important to remember that the initial CBC value may not reflect the true degree of anemia because it may not have yet equilibrated. In the delivery room, one method of rapid assessment of the maternal coagulation status is to collect a red top (non-heparinized) tube of the mother's blood. This blood should

clot within 6 minutes. If it does not, a diagnosis of a coagulation defect is suspected, and treatment can be instituted if clinically indicated without waiting for the results of a full coagulation panel.

THERAPY

Initial treatment after all deliveries includes removal of placental tissue, either expectantly or through the use of the Crede maneuver (18), as well as fundal massage. This also allows for assessment of uterine contraction. A fundus that is not firm should be vigorously massaged both abdominally and vaginally to increase uterine tone.

Further initial prophylaxis involves treatment with oxytocin (19), either 20 units in one liter of IV fluid or 10 units intramuscularly. The timing of this therapy remains a matter of some debate, and local practice methods often govern whether it is administered after cord clamp or following delivery of the placenta (20–22).

Upon recognition of an immediate (early) postpartum hemorrhage, several factors must be assessed virtually simultaneously. To accomplish this, it is recommended that help be requested immediately. Initial assessment should include an evaluation of uterine tone through bimanual examination, evaluation of the placenta and membranes for any evidence of incomplete removal, and inspection of the cervix, vagina, perineum, and rectum to evaluate for laceration.

Treatment for atony involves uterine massage, IV fluid resuscitation, and administration of uterotonic agents. In addition to the oxytocin recommended for prophylaxis, further oxytocin can be given. Doubling the previously mentioned dose is a recommended first step. Other medications can be provided as well. These are summarized in Table 1.

Treatment for retained placenta involves extraction of remaining placental tissue. This can be accomplished either through manual exploration or through surgical intervention. Prior to either intervention, care should be taken to ensure adequate anesthesia for the patient. Either IV narcotic medications or re-dosage of a previously placed epidural catheter can be safely performed in the patient with postpartum hemorrhage. Manual exploration and removal of retained placental tissue through curettage with a banjo curette can be safely performed in the delivery room. Bedside ultrasound can be invaluable in this clinical situation. Real-time ultrasound is used to assess for retained tissue and as a

guide for surgical procedures. In curettage for suspected retained placenta, the clinician should select the largest curette that can be safely passed through the cervix in order to minimize the risk of uterine perforation. Generally, a banjo curette can be easily passed through the dilated cervix in the immediate postpartum period.

A thorough inspection of all vaginal, cervical, and perineal tissues should be performed as quickly as possible. Lacerations should be repaired with absorbable suture, typically in a running, locked fashion. Repair of lacerations should be performed only under excellent visualization. Such visualization may require transport to an operating room for better lighting and equipment. Transfer to the operating suite should not be delayed due to hemorrhage. In addition, inspection can reveal the presence of a vaginal hematoma. Unless this hematoma is large, or expanding, it should not be opened and inspected due to the possibility of significant blood loss with the minimal chance for identification of a discrete source.

Rare causes of postpartum hemorrhage should not be discounted. During the pelvic examination following delivery, uterine inversion can be diagnosed. This condition often presents as a beefy-red mass at the introitus. Failure to visualize the cervix around this mass should arouse the clinical suspicion for this condition. The clinician may mistake this for a prolapsed leiomyoma. Once inversion is recognized, attempts at manual replacement should be made first (23,24). Should this fail to alleviate the problem, IV nitroglycerine can be administered in hopes of relaxing the uterus. If attempts at medical therapy also fail, a laparotomy should be performed; the uterus can then be reverted by progressive traction on the round ligaments or, if this fails, by incising the uterine contraction ring posteriorly. The vertical incision should then be repaired in layers, similar to the repair of any other vertical uterine incision (25).

If rare causes of postpartum hemorrhage have been ruled out and standard medical therapies have failed to relieve the bleeding, further intervention is required. Which method one chooses will be largely based on the method of delivery. In a vaginal delivery, if the patient has not been transported to the operating suite, this should be done. The room should be prepared for the possibility of an emergent laparotomy. Consideration should be given to the idea of uterine tamponade prior to surgical intervention. Packing of the uterus is one method (26–28), although newer techniques

Table 1 Medications Commonly used in the Treatment of Postpartum Hemorrhage Due to Uterine Atony, Including Dosage and Contraindications

Medication	Dosage and route of administration	Contraindicated in patients with
Pitocin (oxytocin)	20–40 Units IV Or 10 Units IM (including uterine injection during C/S or laparotomy)	
Methergine (methylergonovine)	0.2 mg IM (including uterine injection during C/S or laparotomy) every 2–4 hours	Hypertension
Hemabate (15-methyl prostaglandin F _{2α})	0.25 mg IM (including uterine injection during C/S or laparotomy) every 15–90 minutes	Asthma
Cytotec (misoprostol, prostaglandin E ₁)	Protocols vary, 800 mcg PR hourly	None, but monitor for maternal fever
Recombinant factor VIIA	Doses of 20–90 mcg/kg IV	Used for refractory coagulopathy. No known contraindication, but cost is a factor

have replaced it to a large extent. The Bakri balloon was developed specifically for this purpose (29). The balloon must be inserted completely into the uterine cavity and inflated with 300 to 500 cc of saline. Care should be taken to ensure that the balloon does not cross the cervical os, as this placement will not be effective and could cause cervical trauma.

In the clinical setting of ongoing bleeding refractory to standard medical therapy, after lacerations have been repaired and retained products ruled out, factor VIIa may be a useful adjunct to therapy. It has been shown to be effective in approximately 80% of cases during one recent review (30). Other case reports have also demonstrated its effectiveness as an adjunct therapy (31–34). There is not a known method to measure the effectiveness of factor VIIa therapy.

Some institutions will have the ability to perform a rapid arterial embolization for emergent treatment of postpartum hemorrhage. Embolization may be most appropriate for cases of postpartum hemorrhage secondary to laceration, if blood loss is ongoing. If an interventional radiologist is available and the patient is stable, she can be transferred to the radiology suite for evaluation and treatment as an acceptable alternative (35–37). Occasionally, a discrete vessel can be identified and embolized. Angiography of both uterine arteries can be performed and an embolization of a feeder vessel can be performed. The availability of this technique is limited, and its use should not delay definitive therapy in cases where the patient is not stable for transport. It is not a standard therapy for cases in which uterine atony is the primary cause of bleeding. Patients with high risk of bleeding, such as those with a suspected accreta or known previa with previous cesarean section, could have catheter sheaths placed prophylactically prior to a scheduled procedure to facilitate the embolization should it become necessary.

Should tamponade fail, and interventional radiology either fail or be unavailable, the next step is laparotomy. Subsequent steps can also be performed to treat hemorrhage at the time of cesarean section. Hemorrhage can be treated by ligation of the vessels supplying the uterus. First to be secured should be the uterine arteries bilaterally. Originally described by O'Leary (38–40), this involves placing an absorbable suture into the lateral aspect of the lower segment of the uterine corpus, then around the uterine vessels and secured lateral to these vessels. Care must be taken to identify and avoid the ureter. This procedure should be completed bilaterally. If this procedure does not completely cease bleeding, additional sutures can be placed to secure the uterine branches supplied by the ovarian arteries (41). The purpose of these therapies is to decrease the pulse pressure through their respective vessels and to decrease overall flow to the affected area in hopes of controlling the hemorrhage.

If these therapies are unsuccessful, the anterior division of the internal iliac (hypogastric) artery can be ligated (38,42–45). This dissection is considerably more complicated than either of the previous two described above. This procedure will ideally be performed with the assistance of a surgeon experienced in operating in the retro peritoneum. Care should be taken to avoid injury to local structures, particularly the ureter and the hypogastric veins.

Given the technical difficulties associated with ligation of the hypogastric arteries, techniques have been developed to treat uterine atony with compression rather than via decreased blood flow (46–49). The B-Lynch suture provides a degree of

compression similar to that done manually. This allows the practitioner to determine its effectiveness prior to placement. If manual compression does not decrease the bleeding to an acceptable level, then the suture is unlikely to do so. If manual compression does provide adequate hemostatic control, then the suture can be placed with a reasonable chance of success. Placement of the suture involves use of chromic gut placed entering the body of the uterus inferior to the hysterotomy and exiting superior to the incision. The suture is carried to the posterior aspect of the uterus (over the fundus) where it enters on one side of the lower uterine segment and exits on the other side. It is then carried over the fundus once more and entered into the uterus superior to the incision, then exits parallel to the initial suture placement. The suture is secured to compress the uterus (46–49). This is made considerably easier with surgical assistance. Case reports of pregnancy following compression sutures have been published, although there are no data to suggest any subfertility or increased rate of spontaneous pregnancy loss (49–51).

Hysterectomy should be employed only as a last resort, but should not be delayed in cases where it is necessary. The blood loss from a delay can result in significant maternal morbidity or even mortality and definitive treatment should be readily available. The technique does not differ significantly from the nonpregnant patient, but distortion of the normal anatomy of the pelvis presents challenges. The gravid uterus obstructs the operative view, and the increased blood flow to the area represents a potential for further blood loss. Physiologic dilation of the ureter can make this structure more difficult to avoid. The soft consistency of the cervix and its effacement can also make identification of the cervix more difficult and result in excess vaginal tissue being removed, leading to a foreshortening of the vagina. These changes, and others, make the procedure one fraught with morbidity (52). Surgeons with experience in this procedure should be consulted for assistance whenever available.

Late postpartum hemorrhage is much more likely to be related to retained products of conception than to any other cause (53). Ultrasound of the uterus can often identify these products (54,55). Curettage should be performed once these products are identified. Endomyometritis can also cause a delayed postpartum hemorrhage. In these cases, bleeding should be treated as necessary, primarily with medical therapy, but antibiotic therapy should be instituted once the diagnosis is made.

BLOOD AND BLOOD PRODUCT REPLACEMENT

The clinician must also pay continued attention to the hematologic status of the patient. Initial efforts at control should not be withheld during the attempts to obtain laboratory analysis on the patient, but once available, these laboratory values, particularly any abnormalities, must be addressed quickly. First among concerns in the bleeding patient is the red blood cell transfusion. Patients should receive two units of packed red blood cells as soon as deemed clinically appropriate by the attending clinician. Ideally this blood will be typed and crossmatched to the patient, but in cases where hemorrhage was not expected, uncrossmatched O negative blood may need to be infused. The degree of bleeding that

Table 2 Expected Results from Blood Product Transfusion

Blood product	Contains	Expected result
Packed red blood cells (1 unit = 200–250 mL)	Red blood cells only	Increase of 1 gm/dL hemoglobin or 3% hematocrit
Platelets (1 unit = 50 mL)	Platelets only	Increase of 5–10,000/dL
Fresh frozen plasma (1 unit = 200–300 mL)	All clotting factors	Increase fibrinogen 7–10 mg/dL
Cryoprecipitate (1 unit = 10–15 mL)	Fibrinogen, factors V, VIII, XIII, and vWF	Increase fibrinogen ~7 mg/dL

would necessitate the transfusion of uncrossmatched units depends upon the assessment of the patient and the timing of the availability of type-specific crossmatched blood. Clinicians should consider red cell transfusion in cases where the estimated blood loss exceeds 1000 cc during a vaginal delivery or 1500 cc during a cesarean delivery. The transfusion of one unit of packed red blood cells can be expected to raise the hemoglobin concentration by 1 gm/dL or the hematocrit by 3%. The decision to transfuse a patient depends on the amount of blood loss, any maternal comorbidities, and the risk of recurrent bleeding (Table 2).

During the initial treatment of hemorrhage, infusion of intravenous fluids should not be overlooked. Approximately 3 liters of IV fluid is required to replace 1 liter of blood loss. This fluid does not contain the necessary clotting factors or the oxygen-carrying capacity of the blood lost, so treatment with fluid does not replace treatment with blood products.

Once coagulation studies are available, or sooner if there is an abnormal clot tube, or if clinically indicated, clotting factors should be replaced as well. In order to replace platelets, platelet transfusion is performed. Most conventional blood banks will perform transfusion in terms of units of platelets, but some will still use the term “six pack,” which refers to six units of platelets. Transfusion of each unit of platelets can be expected to raise the platelet count by 5 to 10 K/dL. Correction of the underlying cause of platelet consumption is critical or these platelets may undergo the same consumption that initially caused the thrombocytopenia.

Fibrinogen should be replaced to keep the level above 100 mg/dL (56). Hemostasis can generally be achieved when the activity of coagulation factors is at least 25% of normal, and when the level of fibrinogen is 100 mg/dL. Since the plasma volume in adults is approximately 40 mL/kg, 10–15 mL/kg of fresh frozen plasma may be needed. This dose is approximately three to five units of FFP for adult patients with BMI in the normal range, and may lead to volume overload. Replacement of fibrinogen can be accomplished in two ways. Transfusion of FFP, one unit (200–300 mL), can be expected to increase the fibrinogen level 7 to 10 mg/dL. FFP also has the advantage of containing virtually all clotting factors, making its administration ideal in the treatment of disseminated intravascular coagulation. Cryoprecipitate contains fibrinogen as well as factors V, VIII, XIII, and vWF. One bag of cryoprecipitate will raise the fibrinogen of the patient by 7 mg/dL. The advantage of cryoprecipitate is the smaller volume that must be infused. This presents an advantage in patients where fluid overload is a concern, such as those with severe pre-eclampsia/HELLP syndrome.

In addition to the above, care must be taken to pay particular attention to the electrolyte component of blood loss. Replacement of four units of packed red blood cells should be

accompanied by one ampule of calcium intravenously to prevent derangements in calcium balance, particularly as it relates to the citrate binding of calcium and the potential for metabolic acidosis due to the citrate. Hepatic function should also be considered, as liver derangements common in pre-eclampsia may result in a decreased ability to process the citrate, leading to a greater risk for hypocalcemia in these patients. Older blood may contain a higher percentage of lysed red blood cells, and care must be taken to follow the patient’s potassium level in such cases and hyperkalemia should be treated if necessary. Transfused blood and blood products should be warmed to prevent hypothermia.

RECURRENCE

Risks for recurrent postpartum hemorrhage may be as high as 10%, depending on the previous cause (57). Patients with a history of postpartum hemorrhage should have a type and screen performed prior to scheduled induction of labor or cesarean delivery, and all obstetric team members should be aware of the patient’s history and should be prepared in case of a recurrent bleeding.

11 Septic shock

Bryan E. Freeman and Michael R. Foley

INTRODUCTION/EPIDEMIOLOGY

The idea that infectious etiologies underlie many complications related to illness and medical and surgical procedures is a relatively young area of interest and understanding in the medical profession. Throughout time, scientists have considered that toxins, miasmas, and “bad humors” may be the culprits behind various disease processes, but it was not until the last 300 years that a viable link between bacteria and infection, including sepsis, has been made.

Sir John Pringle’s work in the 1700s relating the ideas of septic and antiseptic conditions to systemic diseases such as fever and dysentery in jails and on the battlefield as relating was a step in the right direction, despite an incorrect mechanism of infection. Although he blamed “putrid air” as the source of disease, awareness of his ideas led to a decrease in the incidence of sepsis (1).

Further advances in medical understanding of the etiology behind infectious diseases were made in the 1800s. The French chemist, Louis Pasteur, discovered that microorganisms were responsible for disease, and Joseph Lister, the English surgeon, was responsible for the introduction of sterilization of surgical instruments and sterile technique. The 1900s brought Alexander Fleming’s discovery of penicillin to combat gram-positive bacteria.

Shock, also known as physiologic or circulatory shock, is an alteration in normal physiology that results in severe and potentially life-threatening changes in the circulatory system. There are various categories of shock, but the most common are cardiogenic, hypovolemic (hemorrhagic), and septic shock. While the etiologies behind these categories are different, the effect on the body is essentially the same. The result of shock is a cascade of events that includes hypoperfusion of tissues, cellular hypoxia, metabolic acidosis, and eventually cellular death.

The incidence of sepsis is difficult to determine due to a lack of use of appropriate terminology as well as inaccurate reporting. However, recent data in the United States regarding severe sepsis have shown an overall rate of three cases per 1000 population, with a substantial, directly proportional increase with increasing age. Outcomes are variable based upon the etiology and underlying comorbidities of the individual, as well as by location of infection. Annual national costs relating to sepsis are estimated to be \$16.7 billion per year in the United States alone (2).

Sepsis remains one of the most significant causes for medical morbidity and mortality worldwide. It was responsible for 9.3% of all deaths in the United States in 1995 and has been shown to have a 30% mortality rate, although this varies depending upon the patient population (2).

Septic shock affects an estimated one in 8338 deliveries (3). However, much of the data relating to sepsis and septic shock

deals with a non-obstetric population. Generally, since women of childbearing age are young, healthy women, without the serious comorbidities of the elderly populations that are usually studied, rates are significantly lower. In fact, a review of the percentage of total cases of sepsis in the United States demonstrated that pregnant patients comprised approximately 0.6% of all cases in 1979 to 1984, but 0.3% of cases in 1995 to 2000 (4).

Despite the fact that sepsis is such a concern worldwide, a surprising number of people have not heard of, much less understand, what sepsis is. A study performed using telephone interviews of 6021 citizens in Italy, Spain, the United Kingdom, France, and the United States revealed that public knowledge of simply the term “sepsis” was astonishingly low and that 58% of those surveyed did not know that sepsis is a leading cause of death (5). The implications of this alone may indicate why early sepsis and its significance may present challenges in the treatment of less severe disease.

ETIOLOGY

Causes of bacteremia in the obstetric population may be due to a single or multiple pathogens and may be made in patients with different illnesses. Blanco et al. found that the most common pathogens were *Escherichia coli* (32%), group B streptococcus (16%), and *Bacteriodes* spp. (15%), each of which led their respective categories of gram-negative, gram-positive, and anaerobic bacteria, respectively (6). The conditions that these infections were associated with were variable, but have been shown to be the most prominent etiologies in other studies. Of 176 patient studies, diagnoses included endometritis (70%), pyelonephritis (16%), chorioamnionitis (8%), and various other causes (6). Therefore, sepsis in the obstetric population is a concern both antepartum as well as postpartum.

Septic shock has been shown to be associated with the same conditions, but in a slightly different order of frequency according to recent studies. Mabie et al. in 1997 published an article that examined the outcomes of 18 women with septic shock in pregnancy. Their definition of septic shock conforms to the definition set forth by the 1992 American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM) Consensus Conference (7). The mortality rate was 28%, with etiologies for septic shock ranging from pyelonephritis (33%), chorioamnionitis (17%), toxic shock (11%), and postpartum endometritis (11%). The remaining causes included septic abortion, ruptured appendix, ruptured ovarian abscess, necrotizing fasciitis, and bacterial endocarditis (approximately 5% each). Etiology varied due to the clinical history of the patient and the presence of significant comorbidities. Other significant findings were that depressed left ventricular function was noted in 64% of survivors and

80% of those that died. Organisms isolated from cultures included *Escherichia coli*, group A streptococcus, group B streptococcus, *Klebsiella pneumoniae*, *Streptococcus viridans*, *Staphylococcus epidermidis*, and others. Of note, *E. coli* was present in 61% of patients, and there was one patient who was culture negative (3).

PATHOPHYSIOLOGY

Despite the continual discovery of new cytokines, intercellular relationships, and systemic changes that accompany the sepsis spectrum of diseases, the precise mechanisms behind severe sepsis and septic shock are not completely understood. Under normal conditions, the site of bacterial infection is targeted by the body's natural immune response. This involves an increase in inflammatory cytokines, activation of the clotting cascade, and decreased fibrinolysis in a localized fashion. In the setting of a normally functioning immune system, this leads to the body being able to effectively eliminate the invading pathogen, after which damage caused by the insult may be repaired.

Sepsis and septic shock, on the other hand, are exaggerations of the body's natural response to infection. Pro-inflammatory and anti-inflammatory mediators are upregulated, along with the natural immune response, but on a systemic scale, with effects far beyond the area in which it is needed. The precise mechanisms behind the regulation of a normal immune response and the lack of regulation in sepsis-related conditions are an area of ongoing research and interest. Understanding of the signaling pathways and resultant mediators produced has advanced greatly over recent years.

An extensive summary of current knowledge about the molecular biology behind inflammation and sepsis was published by Cinel and Opal in early 2009. The following are selections from this article that shed light on the mechanisms involved in these processes (8).

One popular area of sepsis research is the examination and elucidation of mechanisms behind the action of toll-like receptors (TLRs). Essentially, TLRs function to activate immune responses once the body's natural barriers (skin, vascular system, etc.) have been breached. Current research has shown that binding of TLRs causes activation of intracellular transcription activators including interferon regulator factors, phosphoinositide 3-kinase (PI3K), and cytosolic nuclear factor-kappa β (NF- β). NF- β then enters the nucleus and ultimately causes the activation of genes for acute phase proteins, inducible nitric oxide synthase, coagulation factors, and pro-inflammatory cytokines, among others (8).

The significance of PI3K is that it can either positively or negatively regulate TLRs in order to influence pro-inflammatory cytokine production. For instance, positive regulation of TLRs by PI3K leads to increased production of pro-inflammatory cytokines interleukin-1 β (IL-1 β), IL-6, and IL-8 (8).

Sepsis also leads to increased neutrophil activation. Normally, these proapoptotic neutrophils are responsible for the effective clearance of the invading pathogen while remaining well controlled so as not to damage healthy host cells. In sepsis, neutrophils have been found to evade the normal clearance by macrophages, which usually regulate their number and effect. This lack of regulation leads to increased

numbers of circulating neutrophils, which have a pro-inflammatory effect (8).

Along these same lines, macrophage migration inhibitory factor (MIF) is induced by glucocorticoids in sepsis and is probably involved in sepsis pathogenesis. Experiments in mice have found that inhibition of MIF leads to attenuation of inflammatory mediators such as TNF- α and IL-1 β (8).

Tumor necrosis factor α (TNF- α or cachectin), which is produced primarily by macrophages, and secondarily released from damaged endothelial cells, is a pro-inflammatory cytokine. It acts with other cytokines, such as IL-1 and IL-6, to cause various alterations in the function of multiple organs. In the setting of sepsis, insulin resistance and fever increased.

Activation of the clotting cascade is another mechanism by which the body fights infection and its effects. The formation of a clot (which serves as an intravascular barrier) and initiation of inflammation are attempts to isolate the area of infection and prevent systemic spread of the pathogen. However, this is not always held in check, resulting in sepsis and related conditions. In sepsis, the extrinsic (tissue factor) pathway is activated, leading to increased thrombin production. This is the target of action of activated protein C, which will be discussed later (8).

DIAGNOSIS

Initial diagnosis of septic shock and related conditions include a thorough history and physical examination, baseline laboratory tests, and blood cultures. The history can help to elucidate the etiology of the septic shock and to direct treatment. This is important as a simple clinical history can help elucidate a probable etiology for the condition.

In general, baseline laboratory tests that need to be obtained include a complete blood count, at least two blood cultures, coagulation studies, a complete metabolic panel, and any other cultures that are deemed clinically applicable. Specific recommendations are outlined in the following paragraphs.

In order to properly diagnose which entity is involved, understanding of the currently accepted definitions is essential. The terminology surrounding the sepsis spectrum of disorders has been inconsistently and incorrectly utilized, leading to misunderstanding of the disease process involved. This has led to a variety of terms being used for a spectrum of conditions related to sepsis such as bacteremia and septicemia. Other etiologies for conditions resembling sepsis exist, and it has not been until the past two decades that an attempt has been made to clarify the differences between these entities.

Therefore, it is more appropriate to think of sepsis and related conditions as a continuum of conditions that overlap to various degrees. They share the same etiologies, but have more serious implications the further they exist along this continuum.

In recognition of this, the ACCP/SCCM has established more firm definitions. In 1992, the members of the ACCP/SCCM Consensus Conference made four recommendations to create more precise terminology for sepsis-related entities. Along with this, they introduced the term "systemic inflammatory response syndrome" (SIRS). The goal of these formal definitions was to give clinicians the ability to

differentiate between illnesses in order to better direct patient care. The disease categories now include sepsis, severe sepsis, SIRS, septic shock, sepsis-induced hypotension, and multiple organ dysfunction syndrome (7).

SIRS can be the result of a variety of injuries (trauma, infection, burns, or sterile inflammatory processes such as pancreatitis) that lead to a series of complex findings. Assigning the diagnosis by 1992 criteria initially required at least two of the following:

1. Body temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$
2. HR >90 bpm
3. Tachypnea (RR $>20/\text{min}$) or hyperventilation (PaCO₂ <32 mmHg)
4. WBC count $>12,000$ cells/ μL or <4000 cells/ μL , or presence of bands (7)

Sepsis is the systemic inflammatory response that is due to an infection. More simply, it is SIRS that has occurred due to an infectious process. The clinical and laboratory criteria are therefore the same as listed for SIRS (7). This allows a differentiation to be made between the other potential etiologies that may lead to SIRS and clearly identifies a specific subdivision of SIRS.

In order to clarify other terms that are commonly used with sepsis, they proposed the following definitions. Infection is the invasion of a normally sterile host by an organism that leads to an inflammatory response. Bacteremia refers to viable bacteria in the blood. If the invading pathogen is not bacteria, the appropriate corresponding term should be employed (viremia, fungemia, etc.) (7).

Severe sepsis is sepsis complicated by organ dysfunction, hypoperfusion abnormality (lactic acidosis, oliguria, or altered mental status), or sepsis-induced hypotension (7). Sepsis-induced hypotension is systolic blood pressure <90 mmHg or a decrease in systolic blood pressure of ≥ 40 mmHg from baseline, without any other identifiable cause for hypotension (7).

Septic shock is a subdivision of severe sepsis and is defined as sepsis-induced hypotension (as defined above) that is unresponsive to fluid resuscitation, accompanied by hypoperfusion abnormalities or organ dysfunction. This definition still applies to patients who have been treated with vasopressors, as hypoperfusion abnormalities and organ dysfunction may not occur until after treatment (7).

Septicemia has been determined to be an inaccurate term, and the members of the ACCP/SCCM Consensus Conference have recommended its removal from sepsis vocabulary (7).

The definitions set forth at the 1992 ACCP/SCCM Consensus Conference were reevaluated after almost a decade of use. Representatives from Europe and the United States met at the 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference to discuss the efficacy and potential need for modification of the previously mentioned definitions.

Regarding the definition of SIRS, the committee felt that since the clinical signs of inflammation may be quite variable, a specific definition for SIRS was too difficult to formulate. The definition established by conference in 1992 remained unchanged, but with the acknowledgement that it is "overly sensitive and nonspecific" (9). Subcommittees had been

assigned to look at common markers found in sepsis, as well as other laboratory derangements brought about by this condition. Increased levels of IL-6, adrenomedullin, soluble CD14, soluble endothelial cell/leukocyte adhesion molecule 1, macrophage inflammatory protein 1 α , extracellular phospholipase A₂, procalcitonin, and C-reactive protein had been noted by committee members. Although these and other markers may be elevated during times of inflammation, there are no laboratory panels to create from these to function as a diagnostic tool for SIRS. However, understanding of the significance of the individual markers may aid in targeting specific treatment to a given organ, the coagulation cascade, and so on (9).

The definition of septic shock was expanded minimally to include a mean arterial pressure (MAP) <60 . The definitions for infection, sepsis, and severe sepsis remained essentially unchanged (9).

Aside from the reevaluation of definitions for the spectrum of sepsis conditions, the 2001 Committee developed a prototype classification tool for sepsis, called PIRO. This mnemonic represents

1. predisposing conditions,
2. insult (the nature and extent of the insult),
3. response (the nature and magnitude of the host response), and
4. organ (the degree of organ dysfunction).

Based upon the utility derived from this in subsequent studies, this tool may be of use in the future for assigning a prognosis or determining the appropriate treatment protocol for patients with sepsis (9).

Although pregnant women were excluded from the study, a group of researchers recently explored the possibility of utilizing a biomarker panel to predict serious outcomes for patients with suspected sepsis who were admitted through the emergency department. The primary outcome was to predict the probability of development of sepsis and the secondary outcomes included septic shock and inpatient mortality. Nine biomarkers were studied in all, but the combination of protein C, IL-1 receptor antagonist (IL-1ra), and neutrophil gelatinase-associated lipocalin (NGAL) was found to be the most predictive of identifying both primary and secondary outcomes. Protein C is a marker of activation of coagulation, IL-1ra indicates inflammation, and NGAL reflects renal dysfunction. This may be an area of future research to help direct physician intervention at the time of initial assessment. The results of these tests were used by the authors to arrive at a Sepsis Score (10). When this has undergone further testing, there may be utility for treating the obstetric population as well.

MANAGEMENT

Management recommendations are largely based upon work that has been done in the non-obstetric population. Therefore, there are not established protocols to deal with the pregnant patient with septic shock or that take into account the significant physiologic changes that accompany pregnancy and how these changes may alter the effectiveness of a given therapy. The basic goals of therapy, which have been used successfully, are based upon early detection and diagnosis of

the problem, aggressive fluid resuscitation and use of vasopressors, glycemic control, corticosteroids, and, more recently, the utilization of activated protein C (11).

Expanding upon this, in 2008, the Surviving Sepsis Campaign Committee published updated guidelines for the management of severe sepsis and shock. Extensive evaluation of each step of severe sepsis management was performed, and a grading system was then used to assign which interventions were either recommended or simply suggested, according to the strength of supporting evidence. Initial management was divided into 10 categories: initial resuscitation, diagnosis, antibiotic therapy, source control, fluid therapy, vasopressors, inotropic therapy, corticosteroids, activated protein C, and use of blood products, which are summarized below (12).

The Surviving Sepsis Campaign protocol for initial resuscitation should be initiated as soon as tissue hypoperfusion (persistent hypotension despite fluid administration or serum lactate concentration ≥ 4 mmol/L) is recognized. The goals during the first 6 hours of therapy are as follows:

1. Central venous pressure = 8 – 12 mmHg
2. MAP ≥ 65 mmHg
3. Urine output ≥ 0.5 mL/kg/hr
4. Central venous oxygen saturation $\geq 70\%$ or mixed venous oxygen saturation $\geq 65\%$

If these criteria are not able to be met within 6 hours, the committee suggests transfusing packed red blood cells until a hematocrit is $\geq 30\%$ is reached and/or administering dobutamine up to 20 $\mu\text{g}/\text{kg}/\text{min}$ (12).

Diagnostic studies should be performed quickly. If possible, prior to the administration of antibiotics, at least two blood cultures should be obtained, in addition to cultures of intravascular devices (and each lumen of these devices) greater than 48 hours old. Other areas representing potential sources of infection, such as urine, wounds, respiratory tract, and so on, should be cultured according to clinical suspicion. If, and only if, obtaining any of these cultures risks serious delay of initiation of antibiotic administration, antibiotics should be started first. The cultures must be collected soon thereafter to avoid the risk of sterilization of blood cultures, which may occur within a few hours of antibiotic administration. Additionally, imaging studies should be performed as soon as possible to help confirm a diagnosis (12).

Antibiotic therapy should be initiated as soon as possible with intravenous medications within the first hour of recognition of severe sepsis and septic shock. As previously stated, collection of cultures should ideally be performed prior to antibiotic administration, if possible. Since etiologies of sepsis and septic shock vary depending upon each patient's clinical history and underlying conditions, the choices of antibiotic are also variable and will be dictated by these factors. Recently used antibiotics should be avoided and the choice of a broad-spectrum antibiotic that would cover pathogens associated with the presumed source of infection should be chosen. Other considerations include awareness of the increasing prevalence of methicillin- and oxacillin-resistant *Staphylococcus aureus* (MRSA and ORSA) or whether candidemia is suspected, which would require appropriate antifungal coverage (12).

Additionally, loading doses of antibiotics should be used, but with the awareness of organ damage and large changes in

volume due to fluid resuscitation that may alter serum levels of any medication. Therefore, physicians and pharmacists need to carefully monitor serum levels to avoid toxicity. The recommended course of antibiotics should be at least 7 to 10 days and needs to be tailored to reflect the culture and sensitivity results (12).

Source control needs to be achieved within 6 hours of treatment. This includes establishing a diagnosis, locating the etiology of the infection, and taking steps to appropriately deal with the cause. In the case of an intravascular device being the culprit, it should be removed immediately after alternate intravascular access has been achieved (12).

Fluid therapy should include administration of either colloids or crystalloids. The SAFE study demonstrated no difference in efficacy between these two types (13). Goals of fluid resuscitation are initially to achieve a central venous pressure of ≥ 8 mmHg (or 12 mmHg if the patient is mechanically ventilated). Fluid challenges should be administered in the form of either at least 1000 mL of crystalloids or 300 to 500 mL of colloids over 30 minutes. As long as the patient responds to fluid challenges, they should continue. However, if central venous pressures or pulmonary artery pressures increase without simultaneous hemodynamic improvement, the rate of fluid administration should be substantially reduced (12).

Vasopressors should be utilized to maintain MAPs of at least 65 mmHg. The committee recommends that first-line vasopressor therapy should include norepinephrine or dopamine administered via a central line. Epinephrine, phenylephrine, and vasopressin should not be used as first-line therapy, although epinephrine may be used if initial efforts with norepinephrine or dopamine were unsuccessful in achieving the desired MAP. Additionally, low-dose dopamine for renal protection is not recommended (12).

Inotropic therapy with dobutamine may be utilized in patients with evidence of myocardial dysfunction (high cardiac filling pressures and low cardiac output).

Recommendations relating to the utility of corticosteroid treatment in septic shock are largely based upon results from the Corticosteroid Therapy of Septic Shock Study Group. Routine use of corticoid therapy as adjuvant treatment should not be employed in patients with septic shock. The ACTH test is not recommended to determine which patients should receive hydrocortisone treatment. Corticosteroid treatment should be reserved for patients with septic shock only if their hypotension is non-responsive to fluid therapy and vasopressors (12,14). Additionally, since etomidate is frequently used for sedation in the intensive care unit, including care for patients with severe sepsis, care should be taken to avoid performing an ACTH test for any reason in patients who have received etomidate, as it can adversely impact their survival (15).

Activated protein C therapy [also known as recombinant human activated protein C (rhAPC), drotrecogin alfa] should be based upon the diagnosis of the patient and their Acute Physiology and Chronic Health Evaluation (APACHE) II score. The APACHE II score is a tool used to assess the severity of disease in adults admitted to intensive care units and is based upon physical assessment of patients during the first 24 hours of their admission. Patients with severe sepsis, an

APACHE II score >25 or multiple organ failure, and who are deemed to be at high risk of death should receive rhAPC, assuming that they have no contraindications. On the other hand, patients with severe sepsis, an APACHE II score <20 or single organ failure, and who are at low risk for death should not receive rhAPC therapy (12). These recommendations are consistent with conclusions from the Administration of Drotrecogin Alfa (Activated) in Early Stage Severe Sepsis (ADDRESS) Study Group, published in 2005 (16).

Although the exact mechanism is unknown, activated protein C possesses both anti-thrombotic and anti-inflammatory properties. As mentioned before, sepsis involves activation of the extrinsic (tissue factor) pathway of the clotting cascade, which leads to overproduction of thrombin. This is the target of APC. Normally protein C, the zymogen of APC, is activated by thrombin. However, there are two aspects of sepsis that cause disruptions in this system. The first problem is that circulating levels of protein C, APC, and protein S (the cofactor for protein C) are decreased. The other issue is that the thrombin:thrombomodulin complex that is usually responsible for the conversion of protein C to APC is also disrupted, which leads to the unregulated production of thrombin. Administration of rhAPC compensates for the lack of naturally created APC and exerts an anti-thrombotic effect by blocking the conversion of factors VIIIa and Va to factors VIII and V, as well as by inhibiting plasminogen activator inhibitor-1 (PAI-1), thereby allowing fibrinolysis to occur. Other mechanisms may be involved as well (17).

After resolution of hypoperfusion, and in the absence of complicating factors such as myocardial infarction, acute hemorrhage, and so on, administration of blood products (not covered in recommendations for initial resuscitation) may be considered. Packed red blood cells should be transfused for hemoglobin levels <7.0 g/dL, with a target hemoglobin of 7.0 to 9.0 g/dL. The use of erythropoietin is not recommended in the treatment of severe sepsis unless there is another reason for its administration, such as renal failure (12).

Other blood products, such as fresh frozen plasma, may be utilized to correct coagulopathy. Platelet administration should be performed in severe sepsis when platelet counts are <5000/mm³, whether or not the patient is bleeding. For platelet counts in the range of 5000 to 30,000/mm³, platelet transfusion should be considered. Goals of platelet therapy are dependent upon future interventions that are to be made. In the event of anticipated surgery, platelet transfusion should be performed to reach a count of >50,000/mm³ (12).

One final area of management that has received recent attention is that of glucose control in patients with severe sepsis and septic shock. The Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP) is the most recent study to address this issue and their findings coincide with prior studies. The investigators randomized patients into groups of either conventional or intensive insulin therapy. The conventional insulin group was treated via insulin drip if blood glucose levels exceeded 200 mg/dL and were maintained in the range of 180 to 200 mg/dL. The intensive insulin therapy group received insulin via insulin drip once blood glucose levels exceeded 110 mg/dL and were maintained in the range of 80 to 110 mg/dL. No benefit was found to intensive insulin therapy. In fact, this treatment was

terminated early by the data and safety monitoring board at the time of the first safety analysis due to the high incidence of hypoglycemia (18).

The Surviving Sepsis Campaign Committee recommends that following patient stabilization, insulin therapy should be initiated. The goal is to maintain blood glucose levels <150 mg/dL, with levels checked every 1 to 2 hours until stable, then every 4 hours (12).

CONCLUSIONS

Fortunately, sepsis and septic shock in pregnancy is a rare entity. Normal pregnancy involves many physiologic changes that would present problems for any other patient due to the increased demands on the cardiovascular and other systems. As noted, the work and recommendations that currently exist for the treatment of the continuum of sepsis conditions are for non-obstetric populations and do not take into account the changes associated with pregnancy. Given the paucity of data that exist strictly in regard to septic shock in pregnancy, it is reasonable to proceed with septic shock management according to these guidelines. Definitions that specify the exact entity within the spectrum of sepsis-related diseases can help focus management and facilitate communication with colleagues. Until specific studies in the pregnant prove otherwise, quick assessment and diagnosis of this condition followed by critical care and emergency protocols should be followed.

12 Invasive hemodynamic monitoring in obstetrics

Luis D. Pacheco, Shannon Clark, and Gary D. V. Hankins

CENTRAL VENOUS ACCESS

Approximately 0.17% to 1.1% of all pregnant patients require admission to the intensive care unit (ICU) at some point during their pregnancies (1). Obstetric complications, including hemorrhage and hypertensive disorders (primarily pre-eclampsia and eclampsia), account for most of these ICU admissions comprising 47% to 93% of patients (2). Understanding the main hemodynamic changes associated with pregnancy is crucial when invasive monitoring is applied to the critically ill pregnant patients (Table 1). Central venous access is more commonly obtained through internal jugular (IJ) vein or subclavian vein catheterization, as seen in the nonpregnant population as well.

The main indications for central venous catheter (CVC) placement include administration of vasoactive medications such as norepinephrine or dopamine, infusion of caustic or hypertonic solutions such as potassium chloride or parenteral alimentation, administration of incompatible medicines through a multi-lumen catheter, requirement of acute or subacute renal replacement therapy, necessity of hemodynamic monitoring or transvenous cardiac pacing, and rapid infusion of fluids (3,4). Due to the emergent nature of most CVC placements and their lifesaving indications, there are truly no absolute contraindications to their placement. A few general contraindications do exist and include infection of the area overlying the target vein, thrombosis of the target vein, and coagulopathy (4).

Recent statistics show that approximately 5 million CVCs are placed each year in the United States with one or more complications occurring in >15% of catheter placements (5,6). The risk of complications increases with operator inexperience, emergent placement, patient obesity, history of difficult cannulation, and coagulopathy. Common mechanical complications include arterial puncture, hematoma formation, pneumothorax, hemothorax, arrhythmias, and improper location of the catheter (7,8). Venous thrombosis is another complication that occurs less frequently in the subclavian vein and more frequently with cannulation of the femoral vein (5,6). The risk of pneumothorax during CVC insertion increases with hyperinflation of the lungs associated with mechanical ventilation with large tidal volumes or with increased positive end-expiratory pressure. Inadvertent arterial puncture can usually be distinguished by the pulsatile nature of the flow and the red color of arterial blood (4). If in doubt, the operator may insert a small 18-gauge catheter over the guidewire and determine the waveform of the vessel to distinguish arterial from venous cannulation (4). Alternatively, the 18-gauge catheter may be connected to a regular intravenous tubing that is allowed to fill with blood, and when raised, the column of blood should drop if the catheter is inside a vein. Finally, a chest x-ray to confirm proper placement should be obtained

after central venous catheterization regardless of insertion site (except for the femoral vein placement).

In addition to mechanical complications, catheter-related infections pose a significant risk to the patient. Infection of the CVC may occur locally at the insertion site, from hub colonization and subsequent infection through the catheter lumen, or through hematogenous seeding of the catheter (5). The Centers for Disease Control and Prevention recommend the subclavian vein as the site of choice to reduce the risk of catheter-related sepsis (9). The Institute for Healthcare Improvement recommends five steps to reduce central-line infections: hand washing, maximal barrier precautions, chlorhexidine skin antisepsis, selection of an optimal catheter site, and prompt removal of the CVC when no longer needed. Antiseptic-containing hubs (chlorhexidine) and antimicrobial-impregnated catheters (minocycline and rifampin) have been shown to decrease the rate of catheter-related bloodstream infections when compared with non-impregnated catheters and should be considered in all CVC insertions when the institutional infection rate exceeds 2% (4,5).

The use of ultrasound guidance has been shown in various prospective/randomized trials and two meta-analyses since 1990 to reduce mechanical complications of CVC insertion into the IJ and improve first-pass success (10). Two-dimensional ultrasound can be used indirectly or directly. With indirect ultrasound guidance, the ultrasound is used for vessel localization, and the puncture site is identified. After this, puncture of the vein is performed without real-time ultrasound guidance. Direct ultrasound guidance allows visualization of the needle puncture in real time after localization of the vessel and can employ one or two operators.

In 2003, Hind et al. evaluated data from 18 studies in a meta-analysis that excluded Doppler studies (11). They found that two-dimensional ultrasound was significantly better for central venous access when compared with the traditional landmark methods and was more effective in avoiding failures in the first attempt of venous cannulation.

Particularly for IJ catheter placements, ultrasound guidance is now considered the standard of care.

Internal Jugular Vein

IJ cannulation has a lower risk of pneumothorax as compared with the subclavian approach. However, the risks of infection and thrombosis are higher with the IJ.

The anatomical landmarks commonly used to place a central line in the IJ consist of the triangle formed by the clavicle and the sternal and clavicular heads of the sternocleidomastoid muscle. The apex of this triangle corresponds to the separation of the two heads of the muscle. In the apex, the carotid pulse is felt, and the artery is gently retracted to the

Table 1 Hemodynamic Changes in Pregnancy

	Nonpregnant	Pregnant
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10.0	83 ± 10.0
Stroke volume (mL)	65	75–85
Systemic vascular resistance (dynes × s × cm ⁻⁵)	1530 ± 520	1210 ± 266
Pulmonary vascular resistance (dynes × s × cm ⁻⁵)	119 ± 47.0	78 ± 22.0
Colloid oncotic pressure (mmHg)	14.5 ± 2.5	10.5 ± 2.7
Mean arterial pressure (mmHg)	86.4 ± 7.5	90.3 ± 5.8
Pulmonary capillary wedge pressure (mmHg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mmHg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g × min × m ²)	41 ± 8	48 ± 6
Blood volume (L)	4.5	6.5
Plasma volume (L)	2.5	3.5–4.6

midline (the IJ usually is located lateral to the carotid pulse). The needle should be inserted at the apex level just lateral to the carotid pulse. The site is prepared and draped in a sterile fashion. The operator is gowned and gloved for gaining venous access and for positioning the catheter. The patient is positioned, and the head is tilted to the side opposite to the vessel selected for cannulation. The Trendelenburg position aids in distending the venous caliber. With the use of 1% xylocaine and a 21- or 22-gauge 2-inch needle, the skin is injected and a wheal is made over the planned cannulation site. The needle is then advanced with the bevel up at a 45° angle toward the ipsilateral nipple. Turning the patient's head to the opposite side will straighten the course of the vein and thus facilitate the procedure. The right side is usually preferred since it has a straighter course toward the superior vena cava. In most cases, the vein will be found at a depth of less than 2 cm. Often the vein walls will collapse against each other by the pressure of the needle, and the vessel is completely penetrated without blood return. Slow retraction of the needle while maintaining negative pressure on the syringe will overcome this problem, as during retraction, the needle will re-enter the vessel and blood return will be obtained. Once the vessel is located with this "finding needle," an 18-gauge needle is used to puncture the vein following the tract established with the initial small needle. After this, the syringe is detached from the needle (which should stay in place), and a guidewire is advanced through it. After the wire is passed into the vessel, the needle is withdrawn over the wire. A scalpel is used to make a 5-mm cut in the skin, following which the larger venous dilator is inserted to dilate the tract. After this, the dilator is removed, and the catheter is advanced over the guidewire. The wire is then withdrawn, and the catheter remains in place. This same principle (Seldinger) is applied for the placement of lines in the subclavian or femoral veins.

When using ultrasound guidance for IJ catheter insertion, blood is hypoechoic and appears dark on the ultrasound screen with the IJ typically seen anterior and lateral to the carotid artery. The IJ vein can be distinguished from the artery because it is compressible, nonpulsatile, and distended by Trendelenburg position or the Valsalva maneuver (10). There are several factors that must be considered when using the ultrasound for IJ catheter insertion: (i) excessive pressure applied to the transducer decreases IJ vein diameter, making it harder to access; (ii) extreme contralateral head rotation can

decrease IJ vein diameter and increase overlap onto the carotid artery; (iii) employing the Trendelenburg position and using correct head positioning can significantly increase IJ vein diameter and facilitate placement; and (iv) patient intravascular volume status can affect the size of the IJ.

Passage of a needle into the IJ can be done with either a transverse (short axis) view or a longitudinal (long axis) view. The transverse view is associated with a shorter learning curve and makes it easier to visualize smaller vessels (10). Using the longitudinal (long axis) view, as recommended by the American College of Emergency Physicians, allows better visualization of the advancing needle tip, which may reduce perforation of the posterior wall of the vessel and potential entry into the artery (10).

Figure 1 illustrates the placement of a CVC in the IJ site.

Subclavian Vein

Due to the low risk of thrombosis and infection, in addition to the patient's comfort and easy access, the subclavian vein is the preferred site for CVC placement in the ICU setting.

Coagulopathy is a relative contraindication since in the event of bleeding, the vessels (subclavian vein or artery) are not directly accessible for compression.

The subclavian vein lies just beneath the clavicle. Exposure of the vein may be improved by placing a small rolled towel between the shoulder blades. The right side is also preferred since the right lung apex is lower than the left, diminishing the chances of a pneumothorax when this side is chosen. Also injuries to the thoracic duct may happen (albeit infrequently) when attempting to access the left subclavian vein.

The head of the patient is turned to the opposite side, and Trendelenburg positioning is accomplished. The entry site is usually 2 to 3 cm caudal to the midpoint of the clavicle. The 18-gauge introducer needle is advanced with the bevel up toward the sternal notch and beneath the clavicle. Care should be taken to avoid directing the needle too caudally (risk of pneumothorax) or too cephalad (risk of subclavian artery puncture). Once blood flow is obtained, the bevel should be rotated 90° clockwise so that the wire, when advanced, will follow the direction toward the superior vena cava. The Seldinger technique is then followed to advance the catheter.

When considering the subclavian vein, several recent articles have suggested that ultrasound can increase the likelihood of successful placement of a subclavian catheter

Figure 1 Placement of a central venous catheter in the right internal jugular vein. Source: With permission from New England Journal of Medicine.

despite the presence of the clavicle (12). In addition, Doppler can also be used to distinguish artery from vein due to the difficulty in identifying the vein by compression alone (13).

Figure 2 illustrates the placement of a CVC in the subclavian site.

Femoral Vein

Placement of the femoral catheter begins with optimal exposure of the femoral region by externally rotating and abducting the leg away from the midline. The femoral vein is 1 to 2 cm medial to the artery and runs distal to the inguinal ligament. The vein can be located by palpating the pulsating femoral artery. The site must be prepped and draped and the insertion site must be anesthetized with local anesthesia. The introducer needle should then be inserted at a 45° angle directed along the course of the vein 2 cm below the inguinal ligament (2 cm below an imaginary line that connects the symphysis pubis and the superior–anterior iliac crest). Avoid puncturing above the inguinal ligament since retroperitoneal hemorrhage may ensue. The femoral artery should be palpated at all times while introducing and advancing the needle in an attempt to avoid femoral artery puncture.

When compared with the IJ and subclavian vein cannulations, femoral catheters are associated with higher risk of infection, thrombosis, and arterial puncture (5). Inadvertent puncture of the femoral artery can be resolved with direct pressure. As with the IJ and subclavian veins, ultrasound has been shown to increase success and reduce complications in femoral catheter placement (11).

ARTERIAL LINES

The preparation for arterial line (A-line) placement begins with sterile preparation of the site, local anesthesia of the insertion site, and positioning of the patient's wrist on a hand board in the dorsiflexed position (14). The radial artery is located 1 to 2 cm from the wrist, between the bony head of the distal radius and the flexor carpi radialis tendon. The two techniques for A-line placement (over-the-wire and over-the-needle) begin with palpation of the artery and location of the radial pulse followed by entry of the needle at a 30°–45° angle. In the over-the-wire technique, the catheter is advanced through the artery until a flash of blood is noted. At this point, both the needle and the catheter are advanced 1 cm deeper in order to completely transect the artery. After this, the needle is removed and the catheter is lowered until it is almost parallel with the skin. The catheter is pulled gently until pulsatile blood is noted. At this point, the guidewire is introduced, and then the catheter is advanced into the artery through the guidewire. Finally, pressure should be placed proximal to the catheter and the wire removed. For the over-the-needle technique, the needle is advanced slowly through the skin until a flash of blood is seen. The needle is then lowered 10°–15°, and the catheter is advanced into the artery. The catheter is then secured in place.

Continuous blood pressure monitoring is mandatory in patients requiring vasopressors.

Use of the radial artery is commonly employed due to the dual arterial supply of the hand by the ulnar artery (7). However, the radial artery is susceptible to vasospasm and hematoma formation after multiple cannulation attempts. In a

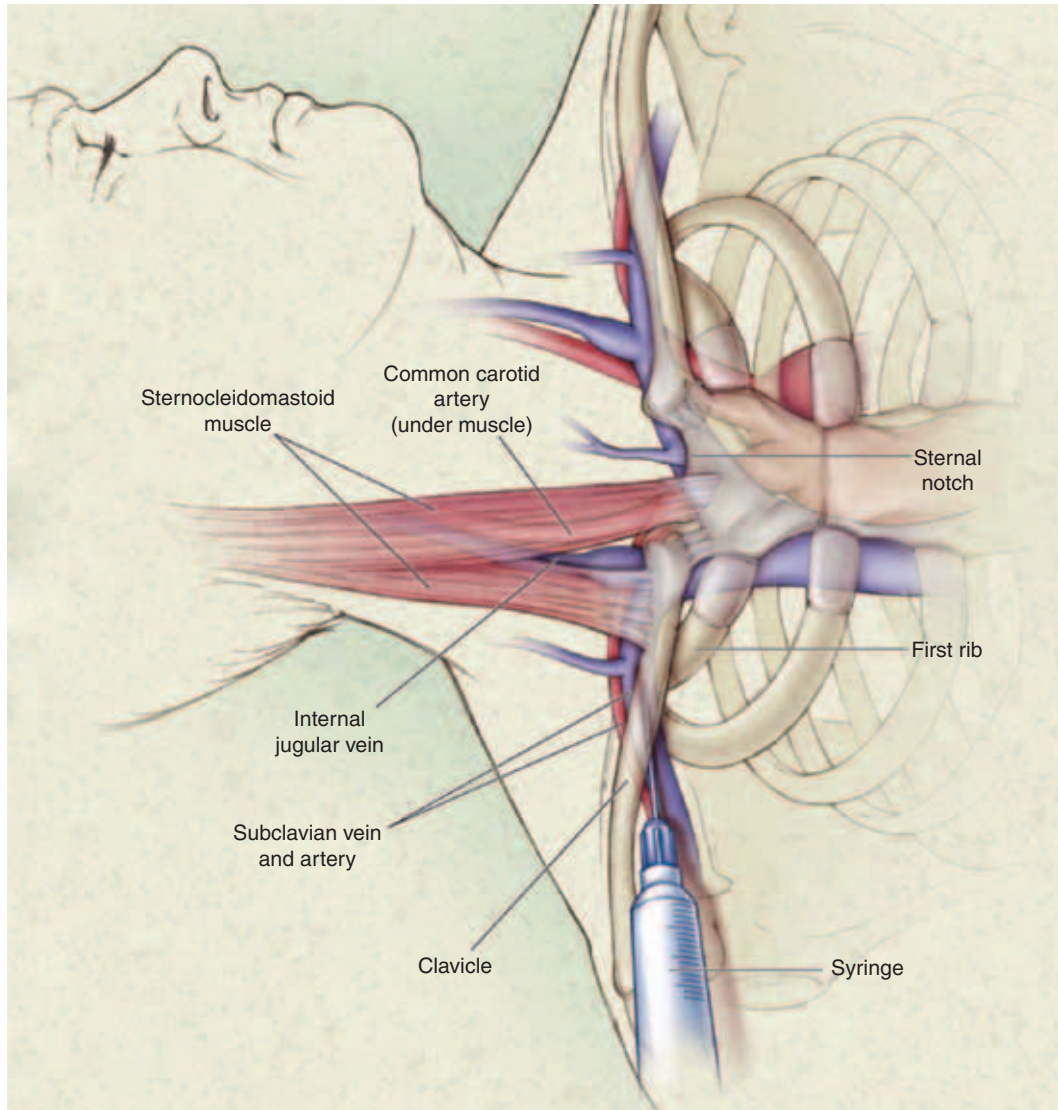

Figure 2 Placement of a central venous catheter in the right subclavian vein. Source: With permission from New England Journal of Medicine.

prospective randomized study by Levin et al. comparing ultrasound-guided radial artery cannulation versus the traditional palpation technique, two-dimensional ultrasound-guided catheterization was superior to palpation for first insertion attempt and overall total number of attempts (15).

CENTRAL VENOUS PRESSURE

One of the main goals of hemodynamic monitoring is to predict which patients will improve their hemodynamic conditions when a fluid bolus is given. This is of utmost importance since excessive fluid administration may lead to unwanted consequences such as cerebral edema, pulmonary edema, heart edema with diastolic dysfunction, bowel edema and intra-abdominal hypertension, and poor wound and anastomotic healing, among others. Obstetricians are faced with this challenge frequently when deciding to administer fluids to a pre-eclamptic patient.

Central venous pressure (CVP) is the pressure measured through a CVC placed with its distal tip at the junction of the superior vena cava and the right atrium. Such a catheter is attached to a fluid-filled system and a pressure transducer, producing a characteristic waveform in the monitor (Fig. 3).

Clinical use of CVP requires careful attention in order to achieve proper measurements (16). The anatomical site to “zero” the line should be 5 cm vertically below the sternal angle, which corresponds to the midpoint of the right atrium.

If one desires to estimate cardiac preload, the CVP measurement should be done at the base of the “c” wave (Fig. 3). This corresponds to the last pressure estimate prior to ventricular contraction, thus yielding the best estimate of cardiac preload. In cases where the “c” wave of the CVP tracing cannot be identified, the base of the “a” wave may be used. Alternatively, this point may be identified by tracing a vertical line from the Q wave of the continuous EKG tracing in the monitor (16). All estimates should be performed at the end of expiration (17). Simply reading the CVP value displaced in the monitor is inaccurate since this is an average of pressures taken over time irrespective of the diastolic cycle.

CVP variations during the respiratory cycle have classically been associated with hypovolemia. In spontaneously breathing patients and in mechanically ventilated patients with triggered efforts, an inspiratory fall in CVP (measured at the base of the “c” or “a” wave) greater than 1 mmHg may indicate fluid responsiveness.

Figure 3 Central venous pressure waveform. Wave “a” corresponds to atrial contraction and wave “c” is secondary to the closure of the tricuspid valve and the isovolumetric contraction of the right ventricle, which displaces the tricuspid leaflets upward, causing an increase in pressure in the right atrium. Wave “v” corresponds to passive right atrium filling during early diastole. The correct place to measure CVP is shown by the asterisks, which approximate the base of wave “c”

A CVP tracing with a prominent “y” descent usually indicates that cardiac output (CO) will not increase with fluid administration (16).

CVP has been used as a monitor of central blood volume and thus preload to the heart. This latter concept has been challenged during the last years as CVP is affected by multiple factors such as right ventricular compliance, tricuspid valve regurgitation, positive pressure ventilation, pericardial disease, vascular tone, and arrhythmias (18).

For example, patients with decreased right-sided CO secondary to a myocardial infarction or pulmonary hypertension or an acute pulmonary embolism will all have elevated CVP, and this will show no correlation with the overall volume status. The same situation is typical in patients with cardiac tamponade, where despite elevated CVP values, initial therapy includes aggressive fluid resuscitation.

The major pitfall of CVP in predicting fluid responsiveness is that it is a static preload measurement. The latter means that a specific value of CVP will not necessarily guarantee an increase in CO after a fluid challenge. A recent trial showed that among patients with a CVP of less than 8 mmHg, the positive predictive value for fluid responsiveness, defined as an increase in cardiac index of $\geq 15\%$, was only 47% (19).

A systematic review of the literature showed that there was no association between CVP values and circulating blood volume and that CVP does not predict fluid responsiveness (20). Furthermore, the receiver operator characteristic curve for CVP was only 0.56. This means that a low CVP will predict an increase in CO in only 56% of the cases. This is similar to flipping a coin!

Thus, a patient is equally likely to respond to fluid with a low or a high CVP (20). Despite lack of scientific evidence, the 2008 Surviving Sepsis Campaign still recommends utilizing CVP as an end point for fluid resuscitation in the setting of septic shock (21).

During early sepsis (first 6 hours of presentation), the use of a CVP-guided protocol of resuscitation as shown by Rivers et al. did improve outcomes (22). We believe that the use of CVP in these first hours of sepsis management is acceptable.

Most of the recent literature concurs in that CVP should not be used to guide fluid management. However, CVP may still be useful as a marker of right ventricular performance in cases of right-sided myocardial infarction, post heart transplant, pulmonary hypertension, and acute pulmonary embolism (20).

PULMONARY ARTERY OCCLUSION PRESSURE

The pulmonary artery catheter (PAC) allows one to measure multiple hemodynamic variables. The catheter is 110 cm long

and contains a variable amount of ports. An infusion port is usually present. The proximal port connects to the proximal lumen, which is located 30 cm proximal to the distal end of the catheter. This port, when connected to a fluid-filled system and a pressure transducer, permits continuous measurement of the CVP. The distal port allows continuous measurements of pulmonary artery pressures. An additional port allows a syringe (with 1.5 mL of air) to be connected to it. By inflating this port, one inflates the balloon present in the distal part of the catheter. When this happens, blood flow after that point will be interrupted due to vascular occlusion secondary to the inflated balloon. The pressure immediately distal to the balloon, when inflated, is the pulmonary artery occlusion pressure (PAOP). PAOP is also measured at the end of expiration. This, theoretically, is a surrogate of the left ventricular filling pressure at the end of diastole since a “column” of blood will be present between the site of balloon inflation (in a branch of the pulmonary arterial system), the pulmonary venous system, the left atrium, the mitral valve, and, finally, the left ventricle (LV).

The catheter also allows measuring the CO by the thermodilution method. Once the CO is calculated, the systemic vascular resistances (SVR) are also calculated as follows: $SVR = (MAP - CVP / CO) \times 80$, where MAP is the mean arterial pressure.

The PAC is advanced through a larger introducer, which is placed as any other central line with the Seldinger technique. The two preferred approaches to float a Swan-Ganz catheter are the right IJ vein and the left subclavian vein. As the catheter is advanced, characteristic waveform changes will occur as its tip enters the right atrium, right ventricle, and pulmonary artery as well as when the inflated balloon occludes the vessel completely (PAOP). Figure 4 depicts these waveform changes.

Complications with the use of the PAC include pneumothorax, hemothorax, arrhythmias, pulmonary infarcts and hemorrhages, and heparin-induced thrombocytopenia, among others. Extreme care is recommended when obtaining a PAOP value in the patient with severe pulmonary hypertension, where pulmonary hemorrhage may occur while obstructing blood flow with the inflated balloon.

Recent literature has questioned the benefit of the PAC in clinical practice. A recent trial involving patients with acute lung injury and adult respiratory distress syndrome (ARDS) showed that the PAC did not improve outcomes as compared with patients managed with a conventional CVP line (23). Another prospective cohort study including patients with severe sepsis also showed no benefit from the PAC (24). A randomized multicenter control study including patients with shock, ARDS, or both similarly showed no benefit from the PAC (25). Similar findings have been reported in the setting of

Figure 4 As the pulmonary artery catheter is advanced, the waveform analysis in the monitor will display typical patterns according to the anatomical site, where the tip is located. When the tip of the pulmonary artery catheter (PAC) is in the superior vena cava and right atrium, the waveform corresponds to the central venous pressure tracing. Entrance to the right ventricle leads to a sudden increase in the systolic pressure (15–30 mmHg) with the same diastolic pressure as on the right atrium (0–8 mmHg). As the PAC is advanced more deeply, the pulmonary artery is entered. The latter leads to an increase in diastolic pressure (6–12 mmHg) with the same previous systolic pressure seen in the right ventricle. Also the entrance to the pulmonary artery may be noticed by the appearance of a notch in the waveform caused by the closure of the pulmonary valve. If one keeps advancing the catheter, one will notice in the monitor the tracing of the pulmonary artery occlusion pressure (PAOP) when the balloon obstructs the flow distal to its position. This pressure should generally be less than the pulmonary artery diastolic pressure and is always measured at the end of expiration.

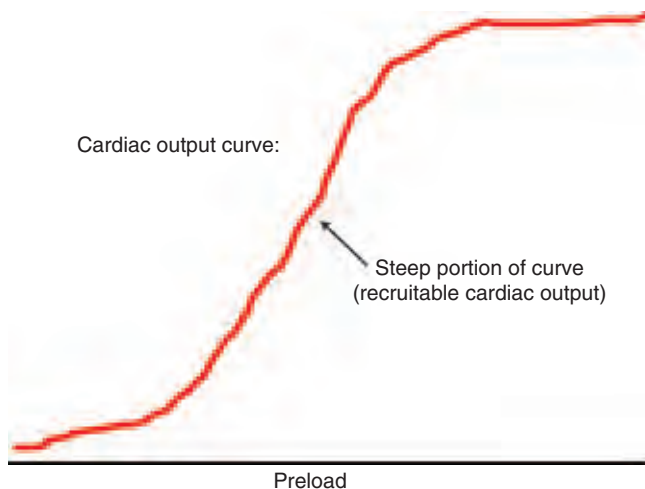

Figure 5 Frank–Starling curve. When the heart operates in the steep portion of this curve, it will respond by increasing stroke volume in the setting of a fluid bolus.

congestive heart failure, general critical illness, and high-risk perioperative patients (26). In trauma patients, most trials have shown no benefit with the use of the PAC to manage resuscitation. Only one trial, to our knowledge, showed a decrease in mortality in a subset of trauma patients (severely injured with severe shock and elderly patients with moderate shock) (27).

The use of PAOP to predict fluid responsiveness has the same limitations discussed previously for the CVP. It is a static measurement of preload and consequently does not predict fluid responsiveness (28). A PAOP of <12 mmHg predicted fluid responsiveness (defined as an increase in cardiac index of at least 15%) in only 54% of critically ill septic patients (19). This is not surprising since PAOP is not a reliable surrogate of the left ventricular filling pressure; it only reflects the internal pressure of the pulmonary veins relative to atmospheric pressure (18). This measurement is also widely affected by multiple factors. Positive end-expiratory pressure increases PAOP. Of particular concern in obstetrics, pre-eclamptic patients frequently have left ventricular diastolic dysfunction. The latter means that the ventricle will be unable to accommodate significant amounts of fluid. This will cause retrograde accumulation of blood, providing high values in PAOP despite a hypovolemic state.

Significant increases in afterload will diminish left ventricular stroke volume. This will also elevate PAOP despite no changes in total blood volume.

Again, the adequacy of intravascular volume cannot be assessed by one CVP or PAOP (29).

Classic obstetrical literature has attempted to provide a list of clinical scenarios where the PAC is usually indicated (e.g., severe pre-eclampsia not responsive to anti-hypertensive therapy, difficult to manage pulmonary edema, acute kidney injury in the setting of pre-eclampsia); however, it is our opinion that most of these patients can be managed safely without this device.

We favor dynamic measurements of preload responsiveness, where the hemodynamic effect after a fluid challenge can be assessed at the bedside, as will be discussed later in this chapter.

ECHOCARDIOGRAPHY AND FLUID STATUS

The use of transthoracic echocardiography (TTE) may be useful in evaluating hemodynamics. This is an attractive option due to the noninvasiveness of the technique.

Simple subjective assessment of the left ventricular volume by estimating the left ventricular size may aid in guiding fluid therapy (30). A small hyperdynamic LV is typical of hypovolemic patients. Also systolic obliteration of the left ventricular cavity is very suggestive of decreased blood volume (30).

Obviously, certain limitations exist. A large LV end-diastolic area does not always guarantee adequate preload as this may be secondary to LV dilation in the setting of heart failure. On the contrary, a small LV end-diastolic area (frequently suggestive of hypovolemia) may be present in patients with a significant drop in SVR (e.g., sepsis), which favor LV emptying.

Circulating volume status may also be evaluated indirectly by assessing the change in diameter of the inferior vena cava (IVC) during the respiratory cycle (31). During spontaneous breathing, the negative pressure generated in the thoracic cavity during inspiration will favor preload return to the right heart; this will decrease the caliber of the IVC. The more pronounced the respiratory variation in the IVC diameter, the more likely right atrial pressures will be low (and theoretically, the more likely the patient will respond to a fluid bolus). A dilated IVC (diameter more than 2 cm) that does not decrease caliber during spontaneous inspiration is indicative of high right atrial pressures (30).

Figure 6 Example of pulse pressure (PP) variation in an arterial line tracing. In this situation, the double line is the maximal PP, while single line corresponds to the minimal PP. This variation in PP in patients on mechanical ventilation predicts fluid responsiveness.

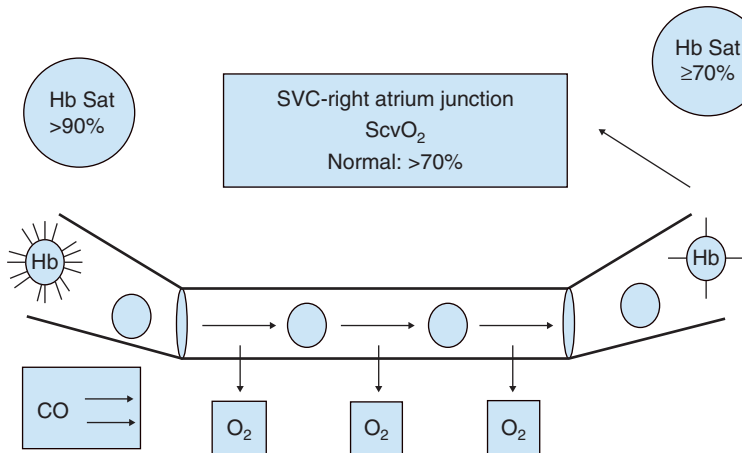

Figure 7 When oxygen delivery (DO_2) is compromised, tissues will increase extraction of O_2 from hemoglobin. As a consequence, evaluation in the central venous circulation will reveal low hemoglobin oxygen saturation. Abbreviations: CO, cardiac output; Hb, hemoglobin; SVC, superior vena cava.

Some data suggest that using a 12% cutoff in IVC diameter variation with respiration will predict fluid responsiveness with a positive predictive value of 93% (32).

The accuracy of the IVC diameter in predicting fluid responsiveness in patients mechanically ventilated is significantly decreased, as the increased intrathoracic pressures may prevent IVC collapse. Also the application of this method during pregnancy is unknown.

Other methods used to assess LV volume include left ventricular end-diastolic measurements. A left ventricular end-diastolic diameter smaller than 2.5 cm or an LV end-diastolic area less than 55 cm² is typically associated with hypovolemia (33).

Just like CVP and PAOP, most of these echocardiographic-based measurements are static measures of volume status and, as such, poorly predict fluid responsiveness (34).

PULSE PRESSURE VARIATION

Since static preload measurements (CVP, PAOP, LV end-diastolic measurements) are no better than random chance at predicting fluid responsiveness, other dynamic approaches have come into clinical practice.

Pulse pressure (PP) is the difference between systolic and diastolic pressures. The use of pulse pressure variation (PPV) to predict fluid responsiveness applies only to patients on mechanical ventilation, not triggering the ventilator, with tidal volumes of 8 to 10 mL/kg, and in sinus heart rhythm.

A recent prospective observational study found that PPV was still an adequate tool to predict fluid responsiveness despite the use of lower tidal volumes (6 mL/kg in setting of ARDS) (34,35).

During conventional mechanical ventilation, each time the ventilator delivers the tidal volume, right atrial pressure will increase. This increase in pressure will decrease preload to the right ventricle in patients who are preload responsive (28). By achieving this, there will be less leftward displacement of the interventricular septum, allowing more filling of the LV. Tidal volume delivery also squeezes the lungs, increasing volume return to the LV through the pulmonary venous system. In addition, during this inspiratory phase, the left ventricular afterload will be significantly decreased. All of the above will lead to an increase in LV stroke volume during inspiration (reversed pulsus paradoxus) (36). This means that during inspiration, PP will increase. If the variation in PP during inspiration and expiration is larger than 13%, patients will likely respond to fluids. Ventilator-induced cyclic changes in preload to both right and left ventricles are more pronounced when the ventricles operate on the steep portion of the Frank-Starling curve (Fig. 5).

In patients with an arterial line in place, the latter is relatively easy to identify at the bedside. The arterial line tracing is evaluated over a period of 30 to 60 seconds, and the maximal and minimal PPs are recorded (Fig. 6). The PPV is then calculated by using the following formula: $PPV = \frac{Max\ PP - min\ PP}{(max\ PP + min\ PP) \cdot 0.5} \times 100$. If PPV is >13%, patients will respond to a fluid bolus (28).

The latter concept may also be applied to the pulse oximetry plethysmographic curve (36). A sharp waveform with a clear dicrotic notch indicates adequate peripheral perfusion, while a sinus-shaped waveform reflects poor perfusion. Actually, the height of the pulse oximetry curve correlates well with PP (36). Consequently, in mechanically ventilated patients who meet

the same criteria cited above for PPV evaluation, respiratory-induced changes in the plethysmographic waveform is a useful method to predict fluid responsiveness.

PASSIVE LEG RAISING

Passive leg raising (PLR) is a useful method to predict fluid responsiveness. Unlike PPV, PLR may be used in patients who are spontaneously breathing or triggering the ventilator. It may also be used despite the presence of cardiac arrhythmias (34).

This test simply involves elevation of the lower extremities at a 30° to 45° angle for 1 minute. The maneuver causes a 300-mL blood bolus that will persist for up to 3 minutes before intravascular volume redistribution happens (28). Ideally, while doing PLR, some form of real-time measurement of blood flow should be available (e.g., esophageal Doppler monitoring allowing continuous measurement of both diameter and blood velocity in the aorta) in order to evaluate the immediate cardiovascular response to the maneuver. Patients who will respond to fluids (by increasing CO) will display an increase in aortic blood flow and diameter.

The latter technology is not widely available. A recent trial utilized TTE to evaluate response to PLR. A stroke volume increase higher than 13% after PLR predicted fluid responsiveness with a sensitivity of 77% and a specificity of 100% (37).

During pregnancy, mechanical compression by the uterus to the IVC may alter the response to this maneuver. No data are available about this issue.

SVO₂ AND SCVO₂

SvO₂ is the saturation of hemoglobin measured from a sample of blood obtained from the pulmonary circulation. This may be accomplished by sampling through the distal lumen of a PAC. The normal value is >65%.

ScvO₂ is the hemoglobin saturation of a sample obtained at the junction of the superior vena cava and the right atrium. Collecting this sample only requires the presence of a regular CVC. The normal value is >70%.

During pregnancy, there is an increase in basal metabolic rate of 20% as compared with an increase in CO of 40% to 50%. The higher the CO, the faster the red blood cell travels through the distal tissues. The latter will decrease the available time of perfused tissues to extract oxygen from hemoglobin, leading to higher hemoglobin saturation in the venous circulation. Consequently, one would expect that during pregnancy, SvO₂ (and probably ScvO₂) would be higher than nonpregnant values. However, Hankins and colleagues reported an SvO₂ of 72% in a group of normal pregnant women who received a PAC during the third trimester (38). This is not different from the values reported in healthy nonpregnant individuals.

Decreased values associate with poor oxygen delivery since hypoperfused tissues will extract more oxygen from hemoglobin, leading to low hemoglobin saturations in the venous pool (Fig. 7).

The clinician may attempt to correct low values by increasing resuscitation efforts including fluid resuscitation, blood transfusions, inotropic support, and decreasing

oxygen consumption through mechanical ventilation and sedation.

ScvO₂ monitoring has decreased mortality when used to guide resuscitation during early sepsis management (22).

No data exist on the use of these parameters to guide resuscitation during pregnancy.

13 Shoulder dystocia

Randall C. Floyd and James S. Smeltzer

One of the most frightening experiences in obstetrics is the failure of the shoulders to deliver spontaneously. This sequence, the cardinal sign of its occurrence, and the usual methods and frequently tragic consequences of its inappropriate management were described most vividly by Morris (1):

Antenatally, a careful observer may have recognized that the child was unusually large, though this is notoriously difficult to judge ... it may have been necessary to intervene in the second stage ... The hairy scalp slides out with reluctance. When the forehead has appeared it is necessary to press back the perineum to deliver the face. Fat cheeks eventually emerge. A double chin has to be hooked over the vulval commissure, to which it remains tightly opposed [Turtle sign] ... Time passes. The child's face becomes suffused ... Abdominal efforts by the mother or by her attendants produce no advance, gentle head traction is equally unavailing. Usually equanimity forsakes the attendants. They push, they pull. Alarm increases. Eventually "by greater strength of muscle or by some infernal juggle" the difficulty appears to be overcome ... It dawns on the attendants that their anxiety was not ill-founded, the baby lies limp and voiceless, and only too often remains so.

Such a disaster, not only the more common but also tragic result of fetal brachial plexus injury, can usually be averted by appropriate management. This management is based on a solid understanding of the biomechanics of normal shoulder delivery and of shoulder dystocia and the pathophysiology of excessive fetal growth. The steps in this management are prevention of the condition when it can be prevented prenatally, detection of the possibly large infant, and avoidance of operative vaginal delivery, preparation for the possible occurrence of shoulder dystocia when a large infant is anticipated, prompt recognition of the dystocia when it occurs, and employment of maneuvers with proven effectiveness, which are least likely to harm the fetus or mother.

THE MECHANISM OF SHOULDER DYSTOCIA

The mechanism of normal shoulder delivery can be partly verified by pelvic examination of a normal patient after delivery of the fetal head, if there is a generous episiotomy. During delivery of the head, one shoulder has entered the pelvis obliquely and is resting in the sciatic notch or hollow of the sacrum. This is the posterior shoulder on restitution. The identity of this shoulder, not any "memory" of previous attitude, determines the direction of "restitution" (1,2). This

position in the hollow of the sacrum or sacrosiatic notch provides room for the anterior shoulder to slide under the pubis or rotate from the obturator foramen. The *turtle sign* of fetal head retraction after delivery indicates that the above sequence has not occurred and that a shoulder dystocia exists.

The position of the shoulders in shoulder dystocia is anterior–posterior. In the more common high dystocia, the posterior shoulder is lodged at the inlet on the sacral promontory and the anterior shoulder is wedged against the pubis (1,3,4) (Fig. 1). The turtle sign is produced by traction between the delivered head and the posterior shoulder, and this traction locks the shoulders in an unfavorable position. As observed by Jacquemier (5) and by Woods (6) and demonstrated conclusively by Schwartz and Dixon (3), direct traction and pressure applied to such a "locked" position are likely to fail both to deliver the infant and to produce injury. This position will not let the posterior shoulder enter the pelvis, will not provide room for the anterior shoulder to slip under the pubis, and will stretch the cervical brachial plexus roots of the posterior arm, causing a greater chance of injury to this plexus (7).

This ominous situation occurs because the shoulders do not normally fit through the pelvic inlet together, and the shoulder destined to be the posterior must enter first. This fact is ignored by most writers on the subject, but is ascertainable by episiotomy and pelvic examination before performing maneuvers when the turtle sign is present. Most term infants have a minimum shoulder diameter that is greater than the maximum diameter of the normal maternal pelvic inlet and cannot traverse it together (8). The gynecoid pelvis, perfectly adapted to the delivery of the fetal head, has a higher relative risk for shoulder dystocia than other types, and maternal pelvic capacity is not an absolute factor in shoulder dystocia and fetal brachial plexus injury (9).

This situation can be made worse by ignorance and panic. The parturient wants to push the baby out, perhaps with the "help" from others by fundal pressure, further wedging the shoulders at the inlet. Attempting to push the anterior shoulder through the inlet with suprapubic pressure would further impact the posterior shoulder. The inclination of the novice accoucheur is to overcome the impaction by force, pulling the fetal head posteriorly, which stretches the brachial plexus of the anterior arm, or inferiorly, which further stretches the plexus of the posterior arm. The fetus is lucky if dystocia is mild or the obstruction is overcome by the fracture of a clavicle, either spontaneously or by the use of suprapubic pressure. The inclination to use suprapubic pressure is reinforced by many articles and texts on shoulder dystocia. It is usually ineffective in high dystocia (10) and should not be used until it is verified that the posterior shoulder is in the pelvis or in an attempt to fracture the clavicle. Once the

posterior shoulder is definitely in the pelvis, suprapubic pressure becomes rational, indicated, and likely to work.

The pelvic inlet, like the walls of Troy, cannot be breached by force without unacceptable loss (3,5,11,12). The posterior shoulder alone, like the Trojan horse, is small and mobile and can enter easily if permitted to do so. Once the posterior shoulder is in the pelvis, the anterior usually has room to traverse the pubis or can be persuaded to do so by other means. The mechanism of successful treatment of the normal high shoulder dystocia is to break the tie that occurs at the pelvic inlet and emulate the natural sequence of shoulder delivery. Successful treatments involve the following principles (Table 1):

1. Relieve the traction that is locking the posterior shoulder in an undeliverable position. This is the opposite of the pushing and pulling that is sometimes employed. Traction is relieved by a large episiotomy, McRoberts maneuver or supine squat (12), and the Hibbard maneuver or partial cephalic replacement (4).

Figure 1 Classic shoulder dystocia. The head is delivered, but retracted by the tension between the chin and the shoulder, which are at the inlet. Further progress for the anterior shoulder or fetus is not safe until the posterior enters the pelvis.

2. Rotate the posterior shoulder into an oblique diameter. Rock the anterior shoulder abdominally or push the posterior forward from behind (Rubin maneuver) (8), push the distal clavicle back from in front (Woods maneuver) (6), or do this while pushing the anterior shoulder in the opposite direction from behind above the pubis with the opposite hand (DeLee maneuver). If the shoulders rotate in either direction, the posterior shoulder will enter the pelvis.
3. If the posterior shoulder cannot be rotated, it will enter the pelvis over the sacral promontory when the posterior arm is delivered (Jacquemier maneuver) (3,5).
4. When there is insufficient room to deliver the anterior shoulder with the posterior shoulder in the pelvis (either turtle sign absent or after delivery of the posterior shoulder into the pelvis), the anterior arm can be delivered (Couder maneuver), which brings the anterior shoulder out under the pubis. This is the authors' choice. Alternatively, the shoulders can be rotated until the posterior is anterior and delivered under the pubis. This requires the posterior shoulder to be inferior to the spines (2,6). Once the posterior shoulder is delivered under the pubis, the anterior shoulder is now posterior, is in the pelvis, and can be spontaneously delivered.
5. If all these fail, relax the uterus, replace the head and perform a cesarean section (Zavanelli maneuver) (13), or perform a symphysiotomy (14).
6. If shoulder dystocia should occur during an in-bed delivery outside the delivery room, these maneuvers will be difficult or impossible in the supine position. If the McRoberts maneuver cannot be applied, or fails, the hands-and-knees position (15), the knee-chest position, or the squat (15) should be used. The first two positions give good access to the posterior shoulder and arm if necessary. These all give a favorable angulation of the pelvis, and gravity aids rather than impedes release of the posterior shoulder from the inlet.

Table 1 Sequence of Action When Shoulder Dystocia is Encountered

1	Recognize turtle sign: posterior shoulder is arrested at inlet or high in pelvis. Anterior shoulder is <i>not</i> deliverable and do not attempt to deliver it
2	Obtain help for McRoberts maneuver, neonatal resuscitation, and anesthesia
3	Perform McRoberts maneuver. Insure adequate flexion of hips (knees to shoulders). If it fails, reapply and continue
4	If turtle sign is released, attempt gentle delivery of anterior shoulder
5	If turtle sign is not released or anterior does not progress, cut generous episiotomy
6	Examine patient vaginally: Where is posterior shoulder? Is there a fetal tumor obstructing delivery?
7	Unlock locked shoulders with partial cephalic replacement
8	Rotate posterior shoulder off symphysis or under pubis symphysis if in pelvis
9	Deliver posterior arm across chest (Jacquemier maneuver) if posterior shoulder not in pelvis. This delivers posterior shoulder into pelvis
10	Deliver anterior arm (Couder maneuver) or use suprapubic pressure if posterior shoulder is in pelvis and anterior not delivered. This delivers the anterior shoulder under pubis symphysis
11	If this is not possible, rotate posterior shoulder to anterior (delivered position). Anterior will now be in mid-pelvis and deliverable (Woods maneuver)
12	Relax uterus, replace head, and perform cesarean section (Zavanelli maneuver) if above measures cannot be performed for some reason or fetus has a tumor obstructing delivery

PREVENTION

The incidence of shoulder dystocia is 0.2% to 0.8% and this risk increases directly with birth weight, especially among macrosomic infants. There is no way to predict with any confidence that a shoulder dystocia will occur in a particular delivery, however (16–19).

Shoulder dystocia cannot be strictly prevented because normal term fetuses, with shoulders wider than the fetal head, are at some risk for shoulder dystocia, and most infants of mothers without diabetes with shoulder dystocia are not macrosomic (16–20). The risk is increased by factors that increase the discrepancy between fetal body and shoulder size and head size. About two-thirds of fetuses with shoulder dystocia are male. The risks for macrosomia and shoulder dystocia are increased by a history of prior shoulder dystocia, prior large infant, and a large maternal birth weight. The mnemonic DOPE—diabetes, obesity, prolonged pregnancy, and excessive fetal size or maternal weight gain—indicates current pregnancy factors that should alert the clinician to an increased risk for shoulder dystocia (Table 2).

PROLONGED PREGNANCY

As body growth continues and head growth diminishes at term, shoulder dystocia risk increases with prolonged pregnancy and is negligible before term. The incidence of shoulder dystocia in pregnancies beyond 41 weeks is 1.5%, but the risks of macrosomia (5.2% >4500 g), birth trauma (0.7%), and shoulder dystocia were not reduced by routine induction of labor at 41 weeks versus observation and antenatal testing in one randomized study of 3407 pregnancies. However, cesarean section for fetal distress was reduced by routine induction using prostaglandin gel at 41 weeks (21), thus induction at term may be of use.

Fetal body and bone growth, unlike brain growth, are sensitive to fetal insulin, which in turn responds to a maternal–fetal glucose load. Maternal conditions such as diabetes, gestational glucose intolerance, excessive weight gain, and obesity can cause fetal overnutrition and are associated with an increased risk for macrosomia, operative delivery, and shoulder dystocia (16–20).

OBESITY

Maternal obesity is not preventable but is treatable. Past blanket proscriptions against excessive weight gain were obviously misguided. A woman who starts pregnancy 50 kg overweight already has caloric reserves that are the equivalent of 200 days of a normal diet. Her ideal weight gain is in the range of 5–10 kg. Moreover, fat exacerbates the normal gestational resistance to insulin and thus provides the fetus

excess glucose. A balanced diet emphasizing complex carbohydrates, moderate portion size, distribution of calories throughout the day, and high fiber intake (22) would seem prudent. These women should know that the objective is not to lose weight, but to limit heavy intake of simple sugars and provide the fetus with appropriate nutrition. The urine should be checked for ketones if weight gain is not adequate, and calories should be increased or distributed more favorably if ketonuria is present.

EXCESSIVE MATERNAL WEIGHT GAIN

Increased maternal weight gain is associated with shoulder dystocia, especially when the mother is already obese. Overall perinatal mortality is generally lower when weight gain during pregnancy is 10 to 20 kg for normal-weight women or over 20 kg for slim women. Caloric limitations would not be indicated for these women. Increased maternal weight gain and fundal height suggest the possibility of fetal macrosomia, however.

DIABETES

Infants of diabetic mothers have a greater risk for macrosomia and a greater risk of excess shoulder size (23) and shoulder dystocia for a given fetal weight (20,24). Glucose is the primary energy source for the fetus. It is absorbed by facilitated diffusion, with a rate regulated only by maternal serum glucose concentration. Fetal insulin responds to the fetal absorbed glucose, and it in turn acts as a trophic hormone on fetal liver, bone, muscles, and fat. Prevention of fetal overnutrition and macrosomia requires maternal glucose homeostasis.

Tight glucose control, with target fasting and preprandial glucose of 60–80 mg/dL and 2-hour postprandial glucose of <120 mg/dL, is associated with a significant reduction of the risk for macrosomia, shoulder dystocia, operative delivery, and, most importantly, perinatal mortality among diabetic women (25). It is also clear that recognition and control of hyperglycemia prior to 32 weeks is more successful than late control for reducing the risk of macrosomia (26). Obese women have insulin resistance, high insulin production, and delayed insulin secretion, rather than a lack of insulin. Thus, they may require large doses of insulin to achieve euglycemia, but have considerable range between adequate and oversupply of exogenous insulin because the endogenous insulin production moderates their response to exogenous insulin. Excellent glucose control can be readily accomplished with a balanced regular diet high in fiber and complex carbohydrates, with calories and carbohydrates distributed throughout the day.

The problem of hypoglycemia may limit the ability to meet these objectives in Type 1 diabetics who have little endogenous insulin production. For these women, “tight” control requires

Table 2 Prevention of Shoulder Dystocia and Injury

- 1 Offer cesarean section for high-risk vaginal deliveries: extremely large fetuses (over 5 kg), very large fetuses (over 4.5 kg) with maternal diabetes, large fetuses (over 4 kg) with a history of shoulder dystocia, second-stage protraction with large fetus
- 2 Identify and treat diabetes mellitus
- 3 Be prepared with a plan
- 4 Recognize the presence of dystocia before maternal pushing, staff assistance (fundal and suprapubic pressure), and traction have produced or contributed to injury
- 5 Note times and get help when shoulder dystocia is recognized. Help includes assistants for McRoberts, obstetric back-up, neonatal resuscitation, and anesthesia

close attention to regularization of calories, carbohydrates, and exercise; fiber is even more important. The risks of miscarriage and congenital anomalies are increased if maternal glucose is not controlled in the first trimester. In addition, early treatment of maternal hyperglycemia would better reduce the risk of macrosomia. Regular insulin or the newer rapid-onset insulins (humalog, novalog) administered at abdominal sites has more rapid and predictable absorption and can be taken before each meal, with small doses of long-acting insulin (NPH, Lantus, Levemir) provided at appropriate intervals to meet basal needs.

Women with possible gestational glucose intolerance, as evidenced by family history of diabetes, prior large infant, prior shoulder dystocia or stillbirth, should have a preconceptional glucose screen of fasting and 75 g 2-h determinations. These women should also have mid-pregnancy screening to exclude the possibility of overt diabetes. Nonobese patients without a suggestive history should undergo the regular early third-trimester screening (27).

The patient with type 2 diabetes controlled with oral agents or those pregnant with abnormal 3-hour glucose tolerance testing with normal fasting glucose but elevated postprandial glucose levels may benefit from treatment with appropriate doses of glyburide (28). The goals for fasting and postprandial capillary blood glucose levels are the same as those noted above. The use of metformin during pregnancy is under investigation but cannot be recommended at this time.

Untreated women with an abnormal screen but only one abnormal value on glucose tolerance test are at higher risk for macrosomia than women identified and treated as gestational diabetics (29). These patients should follow the same diet as those with an abnormal glucose tolerance test and have periodic screening for overt diabetes.

Optimal glycemic control reduces but cannot eliminate the risk of macrosomia. Maintaining maternal serum glucose at normal fasting levels during labor may alleviate fetal asphyxia if a difficult labor or delivery occurs (30,31) and decrease the risk of neonatal hypoglycemia.

Kjos and colleagues (32) found that induction of labor routinely at 38 to 39 weeks of gestation in insulin-requiring diabetes reduced the risk for macrosomia and shoulder dystocia versus conservative management and did not increase the cesarean section rate. It is currently our practice to deliver all patients with glucose intolerance at no later than 40 weeks of gestation. Those with poorly controlled diabetes as indicated by suspected macrosomia and/or persistently elevated capillary blood glucose monitoring are offered amniocentesis for evaluation of fetal lung maturity with delivery if maturity is documented secondary to concerns about increasing risk of fetal mortality and morbidity.

DETECTING FETAL MACROSOMIA AND PREDICTING SHOULDER DYSTOCIA

Most fetuses who experience shoulder dystocia but are not macrosomic have nondiabetic mothers, while most macrosomic fetuses with shoulder dystocia have diabetic mothers (17,20,23,24). Accurate prediction of the fetal weight could identify fetuses at increased risk for shoulder dystocia in this group. Unfortunately, error in predicting birth weight from ultrasonography is 10% to 20% of the actual birth weight with

the greater error seen at the extremes of estimated fetal weights. More babies are born at normal weights as opposed to very large weights; an infant predicted to be over 4000 g is as likely to be less than 4000 g as over 4000 g (20). With a predicted birth weight over 5000 g, the fetus is likely to be at least over 4000 g. This also means that some large fetuses will be missed.

Elective cesarean section for prevention of fetal injury has been proposed for macrosomic infants of nondiabetic and diabetic mothers with estimated fetal weights of above 5000 g and above 4500 g (or even above 4000 g), respectively. As large infants of diabetic mothers have a higher risk for shoulder dystocia and fetal trauma, weight for weight, elective cesarean section may be indicated if estimated fetal weight could be accurately identified (20).

Elliott and colleagues (33) described a sonographic finding of abdominal minus biparietal diameter difference of greater than 1.4 cm as predictive of an infant over 4000 g in diabetics, with a sensitivity of 87% and specificity of 72%. Using a similar difference measure for fetuses with an estimated weight of 3800 to 4200 also in diabetic mothers, Cohen and associates (34) found that a cutoff value of 2.6 cm identified 20 fetuses with a 30% incidence of shoulder dystocia.

Kitzmilller and coworkers (35) described detection of macrosomia by measurement of shoulder diameter in diabetics by computed tomography scan, with 14.5 cm as the cutoff level for macrosomia. Sensitivity was 100% and specificity was 87% for fetal weight over 4200 g.

The reported incidences of shoulder dystocia with a fetus over 4500 g vary from 2% to 35%, with most studies reporting incidences of 20% to 40% among infants of diabetic mothers delivering vaginally (20,24,36) and less than half that risk among nondiabetic patients (20,24). The risk for permanent brachial plexus neurologic injury arising from shoulder dystocia varies from 0.6% (19) to 27.5% (37). The risk for perinatal mortality varies between zero (36) and 28% (21). There appears to be considerable variation in the ability to diagnose and safely manage shoulder dystocia. The advocacy for elective cesarean section based on estimated weight by the various authors may be directly proportional to their own morbidity and mortality rates.

No rational cesarean section policy can completely prevent shoulder dystocia (9,11,12,16–20). Centers with high neonatal morbidity and mortality rates from shoulder dystocia would probably prevent more neonatal morbidity and mortality by meticulous treatment of diabetes in pregnancy and provision of formal training of staff in safe management of shoulder dystocia, rather than expending these resources on performing more elective cesarean sections.

Several studies have shown the benefit of simulation training with measurable improvement in outcomes and appropriate use of management techniques documented (15,21,25,38,39). These improvements have been demonstrated in providers at all levels of training. The use of simulation training appears demonstrably more effective than that of didactic training or didactic training combined with case review. Current simulation training with computerized simulators (such as the NOELLE) allows the provider the ability to practice various interventions in an extremely realistic situation with monitoring of the effectiveness of the

maneuvers. Various scenarios may be programmed by the proctor of the simulation and instantaneous feedback provided regarding the success or failure of the interventions performed.

The risk for a brachial plexus injury sustained at birth to become permanent is about 5%, based on the collaborative perinatal project data (9).

The recognition of the possibility of a large infant is definitely beneficial for management during labor. Labor disorders of all types are more common in pregnancies destined for shoulder dystocia (9,24,38). All studies with a significant number of operative vaginal delivery cases clearly indicate that there is a three- to sixfold increased risk for shoulder dystocia in association with abnormal labor curves. Infants over 4000 g with operative vaginal delivery, especially mid-pelvic delivery, have a several-fold increased risk (23%) for shoulder dystocia (9,38). Macrosomic infants of diabetic mothers have even a greater risk of shoulder dystocia (50%) and subsequent traumatic injury (24). It is uncertain whether operative vaginal delivery causes birth of the head when the shoulders are too large to follow or fails to give the shoulders time to follow the proper mechanism for birth. In any case, nonemergent operative vaginal delivery should be avoided in those patients with anticipated large infants. The mnemonic for the above becomes DODOPE (disordered labor, operative vaginal delivery, diabetes, obesity, prolonged pregnancy, and excessive fetal size or maternal weight gain), an association that is, hopefully, becoming extinct. The exceptions are cases of fetal distress and severe maternal disease, in which the actual risks of additional time to delivery or cesarean section must be weighed against the potential risk of shoulder dystocia individually.

PREPARATION

The delivery team has time physically, mentally, and psychologically to prepare themselves and the patient for the possibility of shoulder dystocia when a large infant is suspected. This permits review of maneuvers to be used and effective coordination of treatment if the problem is encountered. This physical and mental preparation is the antidote for the panic that can arise in a difficult shoulder delivery. It is helpful to have an anesthetist and a physician experienced in the treatment of shoulder dystocia available, and two people familiar with the McRoberts maneuver in the room. It may also help to have someone experienced in neonatal evaluation and resuscitation.

RECOGNITION

Usually the diagnosis is obvious, when the "turtle sign" of head retraction after final extension is found. Rarely, shoulder dystocia occurs when the posterior shoulder is in the pelvis and the turtle sign may not be present. These cases will become apparent when the anterior shoulder does not deliver easily with normal effort. Either situation calls for assistance, including all experienced help, anesthesia, and neonatal care.

Considerable force is often applied to the fetal head prior to the recognition and appropriate treatment of shoulder dystocia (40). Traction, neck twisting, and lateral head force are not only ineffective, but all stretch the cervical brachial

plexus roots and can avulse them leading to permanent damage.

TREATMENT

The McRoberts Maneuver

The McRoberts maneuver should be employed immediately. Assistants should be coached to use and continue the McRoberts maneuver. This accomplishes delivery in most cases and aids in delivery in others (41). It also provides assistants with a constructive alternative to fundal and downward suprapubic pressure, which only impacts the shoulders further. The McRoberts maneuver or supine squat flexes the lumbar spine and retracts the perineum (Fig. 2). The maneuver releases the traction that is locking and depressing the posterior shoulder against the sacral promontory. This spontaneous traction by itself can cause an Erb's palsy, especially if the parturient spontaneously extends rather than flexes the pelvis (42,43). The McRoberts maneuver also straightens out the lumbosacral lordosis and the sacral promontory and removes the compressive force of the delivery table on the sacrum. Radiologic studies evaluating the changes in the pelvis that occur have documented a significant increase in the size of the pelvic inlet with flattening of the sacral prominence (44). In addition, it pushes the anterior shoulder superiorly and places the pelvic inlet perpendicular to the axis of the fetus. These actions together usually place the posterior shoulder of the fetus in the maternal pelvis as the maneuver is being applied; it reduces the force necessary for delivery by 30% and produces less risk for injury of a simulated fetus (45).

As the posterior shoulder enters the pelvis, the baby's neck appears to get longer, usually as the maneuver is being applied. This "lengthening" should not be confused with the moderate release of tension that occurs with the McRoberts maneuver when the posterior shoulder is still at the inlet. If there is a good regional block and generous episiotomy, this maneuver should be applied with a hand in the pelvis to feel it work. If this succeeds, easy delivery of the anterior shoulder is to be anticipated without further maneuvers. If this fails, the legs can be relaxed somewhat and the maneuver repeated once, in conjunction with pressure on the fetal head toward the sacral promontory to free the shoulders (Hibbard maneuver) (4).

When the McRoberts maneuver is applied correctly, the patient's knees almost or actually touch her shoulders. An excited patient can make the maneuver difficult, as the hamstrings, gluteus, and low back muscles of a large patient are quite strong. Maternal pelvic extension should be avoided, however, as it can injure the fetus.

An average-sized assistant can effectively apply the maneuver with correct application of force and mass to mechanical advantage in the following fashion: (i) face the patient's head from near the stirrup, (ii) place her knee on your inboard shoulder, and (iii) lock your hands or forearms around the upper thigh and pull the upper thigh snugly against your hip and bend forward, using your mass to flex the hip. The McRoberts maneuver works most of the time if it is used in experienced hands (41) and over 80% of the time at many institutions.

(A)

(B)

Figure 2 The McRoberts maneuver (A and B) rotates the pelvis cephalad, straightens the lumbosacral lordosis, pushes the anterior shoulder back, and lifts the posterior off the sacral promontory. It also relieves the tension between the posterior shoulder and soft tissues by retracting them.

Episiotomy

If the McRoberts maneuver position has not affected release of the posterior shoulder and delivery, it can be continued through the other maneuvers, as it facilitates their action. This position should be relaxed during induction of anesthesia if general anesthesia is required at this time. It is imperative to determine the actual cause of the dystocia and to determine the position of the posterior shoulder and take appropriate action for a safe delivery. It is essential to release the tension between the fetal head and shoulders with minimum impediment and risk for serious fetal injury and extensive maternal vaginal lacerations. Some recommend a large mediolateral episiotomy. Others prefer a complete perineotomy. The simplest way to achieve the latter is a proctoepisiotomy. This is usually not necessary (19). The proper episiotomy depends on the clinical setting, the size of the fetus, and the size of the operator's hand. The only "wrong" episiotomy is the one that is not sufficient to permit the maneuvers needed to effect delivery without lasting fetal injury.

Examination

The next step is to verify the location of the posterior shoulder and to confirm the absence of dorsal tumors that would make further attempt at vaginal delivery either fruitless or dangerous. This can be accomplished with the hand toward the infant's back after restitution. This leads immediately to the Rubin maneuver.

The Rubin Maneuver

In the Rubin maneuver (8), the posterior shoulder is located, usually on the sacral promontory. The shoulder is rotated forward from behind, either by direct pressure or by hooking the scapula. The anterior shoulder can be rocked laterally to free it or rotated in the opposite direction with the heel of the free hand suprapubically. If the posterior shoulder is at the inlet, rotation will permit it to enter the pelvis and rest in

the sacrosiatic notch. If it is already in the pelvis while the anterior shoulder is undeliverable, rotation of the posterior shoulder should be continued until it is anterior and can be delivered under the pubis. Rotation using the fetal head has been described, but this may increase stretching of the brachial plexus, similar to direct and lateral traction on the fetal head (1). If the posterior shoulder does not rotate with moderate pressure, the operator should proceed immediately to the next maneuver.

The Woods Maneuver

In the Woods maneuver (6), the hand toward the fetal back is withdrawn, and the opposite hand is placed in the pelvis in front of the fetus. Although anterior fetal tumors are rarer than dorsal ones, if they obstruct further delivery, the operator should proceed to the Zavanelli maneuver. The posterior shoulder is rotated backward by pressure on the distal clavicle. This may be assisted by pressure with the opposite hand on the anterior shoulder to the front suprapubically (DeLee maneuver). If no rotation occurs with moderate pressure, the operator should proceed immediately to the next maneuver.

Delivery of the Posterior Arm (Jacquiemier Maneuver)

The most effective maneuver is delivery of the posterior arm (3,5,9,11,12). The main risks are vaginal lacerations and fetal humeral fracture. The latter risk can be minimized in the following way (Fig. 3): The operator's hand is extended further into the uterus to find the humerus attached to the posterior shoulder. The humerus is brought to the front along the side of the fetus. The elbow is flexed so that the forearm is brought across the body. The forearm is firmly grasped by the operator's entire hand and pulled out in a reverse Pinard sequence. The delivery of the arm causes the posterior shoulder to enter the pelvis. The anterior shoulder should now be easily deliverable under the pubis. Otherwise, an identical maneuver is performed on the anterior arm, except

Figure 3 The fetus in the pelvis revealed. (A) Even an average-sized fetus has shoulders too large to enter the pelvis together. (B) Delivery of the posterior arm (Jacquemier maneuver). The posterior forearm has been located and grasped. It will be pulled straight out. With this method, forearm fracture is less likely. (C) The posterior arm delivered. The posterior shoulder has entered the pelvis. There is still not sufficient room to deliver the anterior shoulder, and a low (turtle sign negative) shoulder dystocia exists. If the baby can be rotated, the posterior shoulder becomes the anterior and is delivered. (D) Delivery of the anterior arm (Coudere maneuver) relieves the impaction of the anterior shoulder. This time the pull is more downward.

that the traction on the forearm is more toward the mother's posterior (42) (Fig. 3C,D). This sequence of advance of the shoulders—the posterior one into the pelvis, the anterior one under the pubis, and the posterior one out of the pelvis—is exactly that of a normal delivery. The only difference is that this advance is accomplished by sequential delivery of the arms.

As an alternative, the posterior shoulder can be rotated forward to turn the fetus until it is anterior (6). The formerly anterior shoulder will be the posterior and in the pelvis. Unlike the sequential arm delivery, these may increase traction on the cervical brachial plexus with manipulation.

Potential problems encountered with arm delivery are (i) failure to get the operator's hand into the pelvis from inadequate episiotomy; (ii) difficulty in getting the operator's hand through the inlet, which can be facilitated by working the flat hand against the chest (which is compressible) and bringing the arm out through the deltopectoral triangle of the opposite shoulder; (iii) difficulty in finding the posterior arm, which can be corrected by starting at the shoulder; and (iv) difficulty in flexing the elbow, which can be corrected by freeing the forearm from the umbilical cord, the knees, and so on. Like the Pinard maneuver, it may be

necessary to start flexion by pushing the elbow toward the fetal back.

Hands-and-Knees Position

This position is difficult in the delivery room, but should be tried immediately during a delivery in bed if the McRoberts maneuver fails or immediately if the head is delivered with the mother not supine. It can be atraumatic and highly effective (15). It partially flexes the maternal pelvis, especially if the patient rocks back into a knee–chest position. Gravity aids rather than impedes maneuvers because it brings the fetal body in line with the pelvic inlet and disimpacts the anterior (now dependent) shoulder from the pubis, freeing the posterior from the sacrum. The position provides excellent access for episiotomy, examination, and delivery of the posterior arm from a position of comfort, if needed, in bed. The McRoberts maneuver brings the buttocks out of the mattress but requires the operator to assume truly awkward positions to try other maneuvers.

Anesthesia

All of these maneuvers can usually be accomplished within 5 minutes with no local or regional anesthesia and calm

instructions with the patient's cooperation. If things are not in order, then induction of general anesthesia, if immediately available, can provide time to restore calm, relax the patient, and get expert assistance.

The Zavanelli Maneuver

If the above maneuvers fail or cannot be performed, the fetal head can be replaced in the pelvis, with or without relaxing the uterus (with terbutaline, nitroglycerine, magnesium sulfate, or inhalation anesthetics). Replacement is accomplished by depressing the perineum and reversing the fetal head extension. Delivery can be completed by cesarean section, at a time indicated by fetal monitoring. This usually results in an intact infant, but possibilities of hypoxic ischemic encephalopathy or stillbirth and permanent brachial plexus injury still exist (13). The risks may be comparable with those associated with forceful vaginal delivery.

Symphiotomy and Other Maneuvers

The reader can find many other maneuvers that have been described for the treatment of shoulder dystocia, and other variations of those presented. The ones presented here have either been observed by the authors to be effective without injury or are theoretically likely to be effective biomechanically (hands-and-knees position) and have been reported to be safe and effective. The other maneuvers that may be safe and effective are (i) fracture of the clavicle, often the result of sharply applied suprapubic pressure but usually much more difficult to accomplish than anticipated and (ii) symphysiotomy, which is simple, rapid, and effective (14) though usually outside of the scope of practice of most providers.

Prognosis and Medicolegal Concerns

Stillbirth may occur if delivery is greatly prolonged. Unlike survivors of the Zavanelli maneuver, survivors of shoulder dystocia, even with brachial plexus injury, do not have excessive risk for cognitive deficit when compared with national norms (7) or appropriate controls (9).

Effective delivery with shoulder dystocia is therefore a life-saving treatment for the fetus. The most frequent severe disability for the fetus is Erb's palsy, usually of the posterior arm (7). This will resolve spontaneously in about 90% to 95% of cases (9,11,18,44). There may be some increase in speech dysfunction (7).

Many cases of neonatal brachial plexus injury are not associated with recognized shoulder dystocia, some not even with vaginal delivery (9,11,12,46,47). Indeed, Gherman et al. have published a report of six documented cases of brachial plexus injury in infants delivered by cesarean, five of whom were delivered for labor abnormalities but one in which delivery occurred in the absence of active labor (48). Brachial plexus injury has been observed by some (42,49) in the absence of any traction to effect delivery. It is likely that the traction between the locked head and posterior shoulder at the pelvic inlet is sufficient at times to cause harm, even when resolved spontaneously or by McRoberts maneuver.

Malpractice suits have been brought, by parents of children saved by the effective treatment of shoulder dystocia, for the brachial plexus injury sustained during that birth, which may or may not have actually resulted from the treatment. Most

shoulder dystocia suits have been successfully defended. Avoiding injury to the extent possible is the most effective prevention.

A fetus without previous compromise has at least 10 minutes from the time shoulder dystocia occurs until there is any risk of death from asphyxia. Previously compromised infants, or those exposed to high maternal serum glucose levels in the hours prior to delivery, may die or develop cerebral compromise after a shorter period of anoxia (30,31).

The best way to prevent potential lawsuits is a sincere attempt to render the best care possible, honest communication with the family, and adequate documentation of exactly what happened.

CONCLUSION

Shoulder dystocia risk increases with increasing fetal body size. There is no effective way to predict with confidence the occurrence of shoulder dystocia or even macrosomia. The only way to decrease the risk for shoulder dystocia may be early and adequate glucose screening and appropriate diet and insulin therapy.

An estimated weight of over 5 kg in nondiabetics, a bisacromial diameter of 14.5 cm by computed tomography or estimated fetal weight of 4.5 kg in diabetics, or estimated weight of over 4 kg with a history of shoulder dystocia (50) are situations that warrant a discussion of shoulder dystocia and the potential risks and benefits of elective cesarean section with the mother. When dystocia is encountered, planned orchestrated action is undertaken to unlock the locked fetal position and to deliver the fetus with procedures involving minimal invasion and least risk. These should emulate the natural mechanism of shoulder delivery. These are the McRoberts or hands-and-knees position, generous episiotomy and partial cephalic replacement to unlock the shoulders, delivery of the posterior shoulder into the pelvis by fetal rotation or delivery of the posterior arm, followed, if necessary, by delivery of the anterior shoulder by delivery of the anterior arm or rotation of the posterior shoulder into the anterior position.

Simulation training of obstetric residents in training and providers in active practice may significantly improve the approach to the management of shoulder dystocia. The opportunity to practice the required maneuvers in a simulated situation with immediate feedback can improve the ability to perform them in the stress of the real situation. This can significantly decrease the risk of injury to both the parturient and the infant during these deliveries.

It is important to have a health-care provider who is proficient in neonatal resuscitation present in the delivery room. Neurologic evaluation of the infant is indicated when maternal injury occurs. The delivery should be clearly and completely documented and discussed with the patient.

14 Breech presentation

Randall C. Floyd and Martin L. Gimovsky

Breech presentation is a significant obstetric event associated with dramatic increases in perinatal morbidity and mortality (1,2). The three areas of greatest risk for these infants are the often overlapping problems of preterm delivery, congenital anomalies, and birth trauma. More than one quarter of breech-presenting fetuses are premature. Concomitantly, severe or lethal anomalies further complicate up to 20% of such preterm deliveries and fully 6% to 7% of term breech deliveries (a relative risk of three- to fivefold), depending on gestational age. The outcome of vaginal breech delivery has always been noted to be associated with a higher risk of neonatal injury with both short-term and long-term morbidity as well as an increased risk of neonatal death. These risks have led to numerous attempts to evaluate the risk of vaginal breech delivery versus that of elective cesarean delivery for the persistent breech at term. The results of studies published prior to the Term Breech Trial (TBT) (3) in 2000 were inconclusive with some showing no increased risk of vaginal breech delivery and some showing an increased risk of fetal injury and death in those infants delivered vaginally. These studies were, for the most part, small and retrospective, which left room for error in their conclusions. In 2000 the publication of the TBT, a randomized, multinational multicenter trial that incorporated all levels of care in both advanced and developing countries, demonstrated a clear benefit to the delivery of the term fetus in a breech presentation by elective cesarean.

The TBT gathered information from 121 participating centers in 26 countries and included 2088 women randomized into two arms: planned vaginal delivery or planned cesarean delivery. The details of the study will not be reviewed here, but it is a publication of significant importance and should be read by all of those who are actively involved in the delivery of obstetric care. Other studies have supported the conclusions of the TBT (4–6). The study is not without its critics and there have been numerous reviews written questioning the methodology and the interpretation of the results (7–11); however, the study appears to be able to withstand the test of both time and these critics. Indeed, the American College of Obstetricians and Gynecologists, in a committee opinion, initially recommended that all deliveries of term infants from breech presentation be performed by cesarean; however, this has since been revised to state that the decision regarding mode of delivery should depend upon the experience of the health-care provider (12,13). Perhaps the decrease in vaginal breech deliveries is due to the willingness of those currently practicing obstetrics to accept a philosophy that is, to them, so apparent or possibly it is based upon a self-fulfillment of the decreasing numbers of providers with sufficient training to develop those skills required to perform an elective vaginal breech delivery (14). For whatever reason, the incidence of

elective vaginal breech deliveries continue to decrease and the option will likely fade into rarity.

The need to learn the maneuvers necessary to perform a breech delivery remains, however. Delivery of the breech infant by cesarean requires similar maneuvers in order to successfully extract the infant. Delivery of the nonvertex-presenting second twin following delivery of the cephalic-presenting first twin in an otherwise uncomplicated twin gestation concordant for weight also requires the ability to perform these maneuvers. Finally the rare patient who presents in active labor with the breech on the perineum would likely be poorly served by emergent cesarean delivery and providers should possess knowledge of the maneuvers necessary to successfully complete the delivery. The use of simulation training in teaching the skills necessary for vaginal breech delivery has been shown to be effective (15).

Any consideration of breech management involving either a trial of labor or cesarean delivery is bedeviled by issues of birth injury and medicolegal risk. External cephalic version has been championed as a means of avoiding the issue by converting breech into cephalic presentations. Unfortunately, the results of these major shifts in methodology of delivery have not resulted in the substantial reductions in fetal/neonatal injuries that were originally confidently predicted. Utilizing perinatal mortality as an endpoint, a review of the obstetric literature from the 1930s to the 1960s demonstrates a rough linear relationship—that is, the perinatal death rate for term-sized neonates was reduced as the cesarean delivery rate increased from 3% to 30% or more (Fig. 1). Fetal/neonatal injuries still occur at cesarean delivery to a surprising degree (2). In 1981, Green and coworkers (16) reported that, in a relatively controlled setting, that is, one department over a period of time, increasing the use of cesarean delivery for breech from 22% to 94% did not eliminate preventable trauma pointing up the need for the obstetric provider to have a fundamental understanding of those maneuvers necessary to decrease the risk of injury of the breech-presenting infant. The problem for the profession is to define which maneuvers can and should be taught, how to maintain a high level of competence in these, and how to present the options of trial of labor or cesarean delivery fairly to our patients.

SPECIAL ISSUES

External Cephalic Version

A potential technique for reducing the incidence of breech presentation is external cephalic version. External cephalic version performed at 37 weeks to term has decreased the rate of intrapartum breech presentation from 3–4% to 1–2% (17–21). Earlier groups of investigators had attempted version at 28 to 32 weeks (6) or 30 to 32 weeks (20), but failed to effect any change in the intrapartum rate of breech presentation. These

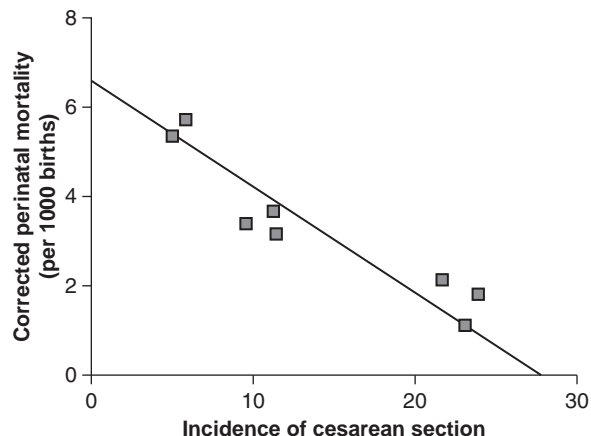

Figure 1 Correlation between cesarean delivery rates and decreased perinatal mortality in term breech infants in the 1940s and 1950s.

failures erroneously led clinicians to believe that the only versions that succeeded were those that would have occurred spontaneously. These “early” versions were probably unsuccessful because of the relatively large amount of amniotic fluid with respect to the size of the fetus, which therefore reverted to breech after the original procedure. Also anesthesia and analgesia were employed in a number of these trials. This allowed more forceful procedures, leading to occasional transplacental hemorrhage and isoimmunization, a substantial risk in the era prior to the availability of rhesus immune globulin.

Even in modern practice, version is not without risk, albeit small. Both umbilical cord complications and placental abruption have been described in conjunction with external version (22). The most common problem associated with version is failure to alter the fetal lie, despite manipulation. Currently, external cephalic version at 36–37 weeks gestation performed under tocolysis (terbutaline, IV nitroglycerine or oral glyceryl trinitrate spray (23,24), nifedipine (25), or intravenous magnesium sulfate) has a reasonable success rate (50–80%). Also the concomitant use of nonstress testing, real-time ultrasound, and the avoidance of analgesia/anesthesia has contributed to the overall safety of the procedure. An exception to the rule of no analgesia/anesthesia is the occasional use of epidural anesthesia for intrapartum version, a special application for selected cases (26,27).

There is a place for external cephalic version even in early labor. Depending on the stage of labor at which the patient is admitted and the time when breech presentation is diagnosed, immediate β -mimetic tocolysis is often successful in permitting manipulations. However, after rupture of the membranes and the onset of true labor, any attempt at version becomes both difficult and inherently dangerous, owing to the descent of the presenting part and the potential risk of cord prolapse.

Continued efforts at refinement of external cephalic version have revolved around the issues of tocolysis and anesthesia. Robertson and coworkers (27) found that the use of tocolytics for adjunctive treatment after a trial of external cephalic version without tocolytics did not improve success rates. Samuels (26) has described the successful use of regional anesthesia instead of tocolysis for version. No difficulty with sequelae of excessive force was described in his original report. Despite these interesting reports, brief treatment with

tocolytics prior to attempting manipulations remains popular, because of the inherent safety, minimal expense and ease of administration of these drugs, and their perceived utility. Most clinicians have found that the use of a tocolytic before version (usually 0.125 or 0.250 mg of terbutaline administered subcutaneously) reduces patient discomfort as well as the external force required for the procedure.

CLINICAL ISSUES

Despite a decision to submit all breeches to cesarean delivery, some instances of vaginal breech delivery cannot be avoided, owing to unforeseen events such as undiagnosed breech presentation or breech presentation diagnosed too late in labor. Regardless of their view toward vaginal trials or cesarean delivery, it is vital for all clinicians to develop experience in the management of both breech extraction at cesarean section and vaginal breech delivery. The routine resort to cesarean delivery does neither guarantee a perfect infant nor obviate the clinician's need for great care and substantial skill as an accoucheur in the operating room. Not surprisingly, measurable rates of the entire range of birth injuries occur in cesarean sections, although the incidence is low. The occurrence of these injuries at cesarean section underscores the need for full understanding of the manual maneuvers utilized for breech delivery. In the performance of safe cesarean section for breech presentation, the surgeon must possess facility with total breech extraction. Even with the exposure possible at laparotomy, breech extraction remains an inherently more dangerous procedure than the assisted breech delivery performed in the majority of vaginal breech births (28). Such procedures require thoughtful and judicious application of force. Commensurate with the increased use of abdominal operative delivery, maternal morbidity, both immediate and remote, is also increased, although the majority of these complications prove to be of trivial clinical consequence (29).

Selective Trial of Labor

Protocols for vaginal delivery of breech infants need critical review. An important consideration in determining best management is the type of breech presentation. The largest group of breech fetuses at term is in frank breech position. The best data reflect management protocols for these most favorable cases. Collea and coworkers (29) conducted a prospective randomized study that compared elective cesarean section with protocol-managed labor for fetuses with frank breech presentation at term. They reported significant maternal morbidity among patients delivered by cesarean section, without any dramatic improvement in neonatal outcome. Among 60 infants delivered vaginally, there were two instances of brachial plexus injury. O'Leary (30) performed a similar study at the University of South Alabama. Among term frank breech presentations screened by a protocol similar to that described by Collea and coworkers, O'Leary described one injury in 81 vaginal deliveries, and this occurred during a breech extraction performed for fetal distress. In this study, the comparison group was a cohort of breech deliveries managed without the specific requirements of protocol. In this non-protocol group, a similar number of infants were stillborn; however, one infant died of trauma, eight had low Apgar scores,

Table 1 Results by Delivery Type, Presentation, and Outcome

	Protocol group	Non-protocol group	Control group 1	Control group 2
Type of delivery	Vaginal	Vaginal	Spontaneous vaginal	Elective cesarean section
Presentation	Breech	Breech	Vertex	Vertex (95%), breech (5%)
Mean birth weight (g)	3125	3025	3170	2980
Range	2001–4080	2000–4210	2470–4010	2350–4100
Number of deliveries	130	78	130	130
Ward/private ratio	59/41	62/38	60/40	58/42
Mean 5-min Apgar score	8.6	8.1	8.7	8.6
Neonatal morbidity	4/130	12/78 ($p < 0.001$)	3/130 ($p < 0.50$)	2/130 ($p < 0.34$)
Intrapartum mortality	0	1	0	0
Perinatal mortality ^a	0	12.8	0	0

and four experienced birth injuries. The author concluded that the use of the protocol had significantly improved the outcome for the breech infants in the study.

In a study of all types of breech presentation (including non-frank or complete, incomplete, and footling breeches) at the Sloane Hospital for Women in New York, a protocol similar to that of O'Leary was followed by Gimovsky and coworkers (31). The authors found that selective management by protocol of term breech fetuses, even those non-frank in presentation, gave acceptable immediate neonatal performance in comparison with elective cesarean section (Table 1). The outcome for protocol-managed breech fetuses delivered vaginally was essentially identical to that of all patients delivered by elective cesarean section. The protocol in use at Columbia (32) has since been revised. In 1983, Gimovsky and coworkers (33) reported preliminary results of the new protocol that confirmed a similar outcome between patients with elective cesarean section and selected protocol-managed patients. In that prospective study of non-frank breech presentations at term, a rigorous protocol was employed for intrapartum management (Fig. 2). One fetus in the study group of 105 patients died during the intrapartum period, owing to an unusual complication that emphasized the complex problems of clinical medicine. This occurred when a woman became hysterical during a trial of vaginal delivery. Efforts to place her under anesthesia to affect safe vaginal delivery were prolonged and the infant eventually delivered could not be resuscitated, despite intensive efforts. The discussion of complex protocols to select appropriate candidates for a trial of breech vaginal delivery is likely to become moot. The results of the TBT will likely make the use of any protocol for the evaluation of the patient presenting with a persistent breech presentation outdated with the exception of the attempt at external version.

Informed Consent

In an area such as management of breech presentation that is rife with controversy, informed patient consent for any clinical approach is not only prudent, but it is also mandatory. The mother (and her spouse) must be advised of the facts necessary to make an informed, independent choice of either undergoing a trial of labor or of proceeding with cesarean delivery. This explanation needs to be simple, factual, balanced, and complete. Despite the complexities that attend such assessment and

obstetric decision making, the obstetrician has an obligation to make the essential and pivotal factors that are central to a clinical choice understandable to the patient. Ideally, the actual decision should be made by the patient and not simply surrendered to the obstetrician. To do otherwise invites the risk that a patient who experiences a sad or untoward result will respond with blame and feelings of betrayal.

The focus of the obstetrician's explanation should emphasize a detailed comparison of risks attendant on the alternatives: specifically trial of labor versus prompt cesarean delivery once labor begins or term has been reached. The issue of possible version should also be carefully discussed. The nature, purpose, and risks (to both mother and infant) should be outlined for both approaches. The obstetrician must explain and discuss the following.

1. The nature of breech presentation. In this review, the clinician explains how breech differs from cephalic presentation and factors that influence perinatal morbidity and mortality in breech delivery.
2. A comparison of the mechanics of cesarean section with vaginal delivery after a trial of labor, with emphasis on the increased risk of fetal injuries secondary to the dynamics of the delivery process. This explanation should include the observations that, with cephalic presentation, the largest and most unyielding part comes first and then the softer, more malleable parts follow. With breech presentation, the softer more malleable parts are received first, followed by the relatively larger and unyielding head. If the head proves too big for the pelvic outlet, and the rest of the baby is already delivered, there is a substantially increased risk for significant injury to the infant.
3. The nature of specific risks of cesarean section to the mother from hemorrhage, infection, or unanticipated lacerations versus the potential for genital tract lacerations and hemorrhage associated with breech delivery with or without the use of forceps.
4. Data on potential fetal injury, including the risks to the infants of intracranial hemorrhage and significant long-term neurologic injury, either by cesarean section or by vaginal incidental to breech delivery.

1. Verify breech presentation (fetal ultrasound)
Estimated gestational age: 36–42 weeks
Estimated fetal weight: 2–4 kg
2. Labor active? Advanced past 7 cm?
Consider tocolysis with terbutaline 0.25 mg subcutaneously
3. Prepare for expeditious cesarean section
4. Discuss potential alternatives, risks and benefits of each, with patient and family
5. Fetal and pelvic X-ray (CT scan where possible)
Rule out fetal hyperextension at the cervical spine (105°)
Maternal pelvic measurements:
inlet of the pelvis:
 >11 cm in the anteroposterior diameter
 >12 cm in the greatest transverse diameter
midpelvis
 >10 cm at the interspinous diameter
6. Patient elects trial of labor

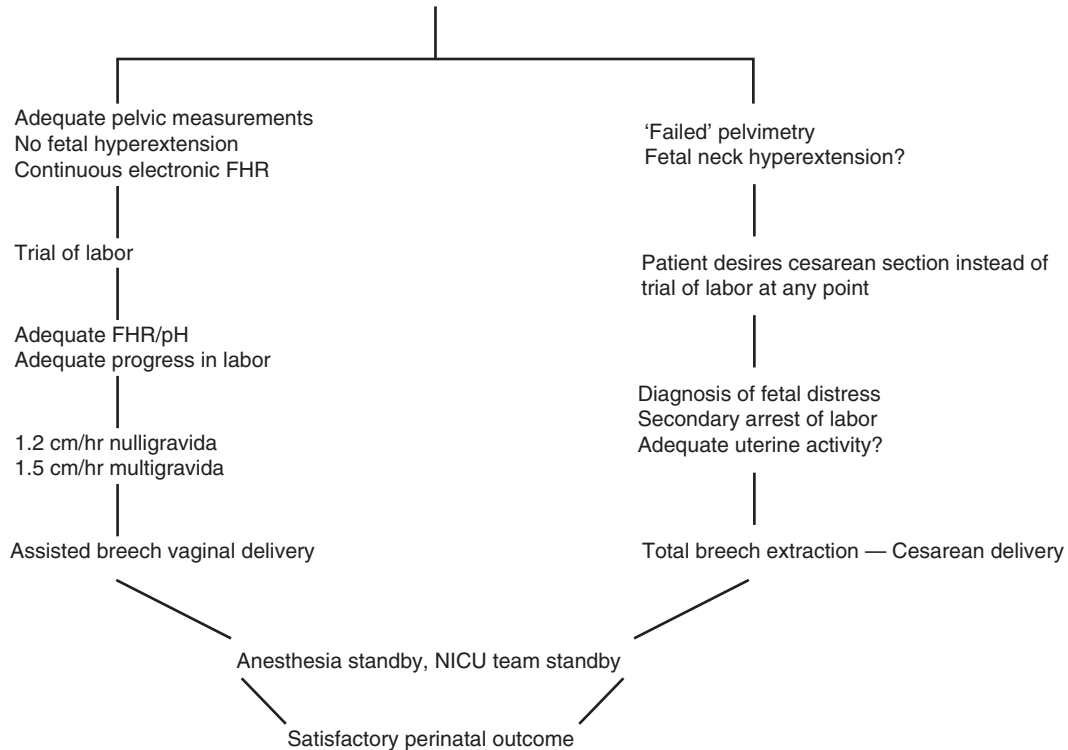

Figure 2 Selective management protocol for intrapartum breech management. Abbreviations: FHR, fetal heart rate; NICU, neonatal intensive care unit. Source: From Ref. 57.

5. The role of version. This discussion critically reviews the advantages versus the risks of external cephalic version and why this procedure should or should not be attempted in the patient’s specific case.

Because there is controversy surrounding the decision to recommend a trial of labor with breech presentation, as opposed to proceeding immediately to cesarean section, the obstetrician is well advised to make a balanced presentation of both views. The clinician must be prepared to explain that those who favor cesarean delivery in all cases rely on statistics, which suggest that three times as many fetal injuries occur with vaginal/breech delivery as compared with cesarean section. Those advocating trial of labor with a breech presentation will want to explain how a meticulously implemented protocol of surveillance may render the statistical difference between these procedures negligible. In making such explanations, the obstetrician should resist favoring the decision he/she wants by either exaggerating or underrating the risks of one

management plan over another. The use of dramatic overstatement or florid language will undoubtedly be long remembered by an apprehensive mother or an expectant father. If the decision is to be truly that of the patient, based upon information, the facts and just the facts should be presented in a logical and unemotional manner, as free from bias as possible. At the end of this discussion, an obstetrician is well advised to invite any questions the patient might have and make every effort to ensure that both she and her partner are satisfied with the explanation given.

In cases in which the breech presentation has been recognized prior to the onset of labor, such discussions will be likely to have occurred outside the hospital. It is prudent to review the same data briefly with the woman/family following admission for labor/delivery. These in-hospital conversations are best conducted in the presence of a nurse, who can then independently document in the medical record that the pertinent consent discussions have taken place.

Pelvic Measurement and Fetal Evaluation

When selecting patients as possible candidates for a trial of labor, careful, objective evaluation of the fetopelvic size is mandatory. Imaging studies can provide this information and also document that the fetal skull is normal in both general appearance and attitude. Ultrasound scanning has also been extensively employed in describing fetal size, structural normality, and head attitude and is useful in acute evaluation of the baby (34,35).

Ultrasound or other imaging studies are particularly useful in the diagnosis of hyperextension of the fetal head, a condition that occurs when an angle of more than 105° exists between the fetal mandible and the main axis of the cervical spine. This is an absolute contraindication to an attempt at vaginal delivery (36). Even at cesarean delivery with an adequate incision, meticulous attention to minimal force is required for safe delivery of a breech infant with cranial hyperextension. Experience suggests that up to 5% of term breech infants have this additional risk. Early diagnosis is important, as prolonged labor with hyperextended head may also result in cervical spine injury, even when delivery is ultimately accomplished by cesarean section (37).

The additional purpose of imaging assessment of the mother is to diagnose women with moderate degrees of pelvic disproportion prior to attempting delivery of the aftercoming head. Entrapment of the fetal head and/or difficult delivery may be largely avoided if such cases are taken to cesarean section without a trial of labor. Imaging studies can define patients with potential borderline pelvis; however, these studies are neither guarantors of perfect safety nor do they substitute for clinical expertise.

Radiographic pelvimetry first appeared in Europe in the late 19th century following Roentgen's discovery of the X-ray. Over its long history, the popularity of radiographic pelvimetry has waxed and waned, owing, in part, to its risks and to questions regarding its accuracy. Subsequently, there has been a shift to pelvic measurement by computerized tomography (CT). A pilot study in 1985 indicated the applicability of such management (38). In 1986, Kopelman and coworkers (39) assessed the reliability of this method in a breech protocol and reported favorable results. Standard pelvimetry techniques in use up to that time, with the radiation exposure to maternal and fetal gonads, were compared with the equally useful single CT scan (40). CT generates more accurate and more reproducible data than other techniques (38) (Fig. 3). Magnetic resonance imaging has also been used to evaluate obstetric pelvimetry and has the advantage of avoiding the use of ionizing radiation (41).

Taken alone, the measurement of pelvic diameters is not capable of reliably directing management, especially for women in labor. Experience has shown that minimal pelvic inlet measurements of 11 cm in the anteroposterior diameter and 12 cm at the transverse of the inlet, coupled with 10 cm at the mid-pelvic plane of the intraspinous diameter, are consistent with a normal bony pelvis (10, 11, 12 rule) (31–33,42). These recommended measurements should be used as a starting point in considering the labor of an average-sized fetus at term. A clinical consideration of fetal size is obviously a major issue in deciding upon the appropriateness of a labor trial. It may be helpful for the attending obstetrician to review the pelvimetry

directly. The use of the fetal head circumference obtained by ultrasonography in addition to the CT-derived pelvic inlet measurements has been evaluated as a more definitive guide to fetopelvic disproportion (43).

As maternal position during labor affects pelvic diameters, careful maternal placement and positioning during attempted vaginal delivery are important. Thorough evaluation of the fetus for structural abnormalities and position by real-time scanning is also critical prior to making decisions regarding management. When circumstances dictate an expeditious delivery by cesarean section, brief tocolysis lessens both operative and anesthetic risks by relaxing the uterus and permitting sufficient time for a proper discussion of informed consent (44). It should be noted that clinical pelvic examination is still important. Soft tissue resistance, which can create a significant problem for vaginal delivery, is not directly measurable but can be assessed by an experienced attendant. Although it is difficult to quantify, the slope of the pelvic sidewalls and the position of the sacrum also play a role in the estimated pelvic capacity and the likelihood of an uncomplicated vaginal delivery.

Fetal Surveillance

Continuous fetal surveillance is essential in intrapartum management of breech labor, as umbilical cord prolapse is a potential hazard in all breech presentations. Cord complications are most likely to occur in the second stage of labor, which should be conducted in the delivery room. In 1963, in the pre-electronic fetal monitoring era, Rovinsky and coworkers (45) showed that vertex fetuses had the same risk of intrapartum demise from overt cord prolapse as did frank breeches. It is of interest that both these presentations subject the fetus to a greater risk for compromise from cord accidents than do footling and complete breech presentations, probably because of the close clinical attention paid to the non-frank breech labor.

The usual criteria for interpreting intrapartum electronic fetal monitoring apply, regardless of fetal position. Nishijimi and colleagues (46) compared fetal heart rate patterns of nulliparas and multiparas in labor for breech and vertex presentations and found no essential difference.

Wheeler and Greene (47) have suggested that periodic fetal heart rate accelerations are more common in breech babies, presumably because of a difference in vaginal stimulation. Our experience, based upon umbilical cord gas studies at birth, confirms that the fetal acid–base status is normal when fetal heart rate patterns are normal during labor.

Vaginal breech delivery results in cord respiratory blood gas values and Apgar scores at birth that are similar to those observed at cesarean delivery. These data are consistent with the previously described findings concerning the similarity between both fetal heart rate monitoring patterns and capillary pH in breech-presenting fetuses, independent of the mode of delivery (46,47).

Anesthesia

Skilled anesthetic support is essential for safe breech management. In the past, practitioners commonly used pudendal nerve blocks in trials of labor, with a general anesthetic

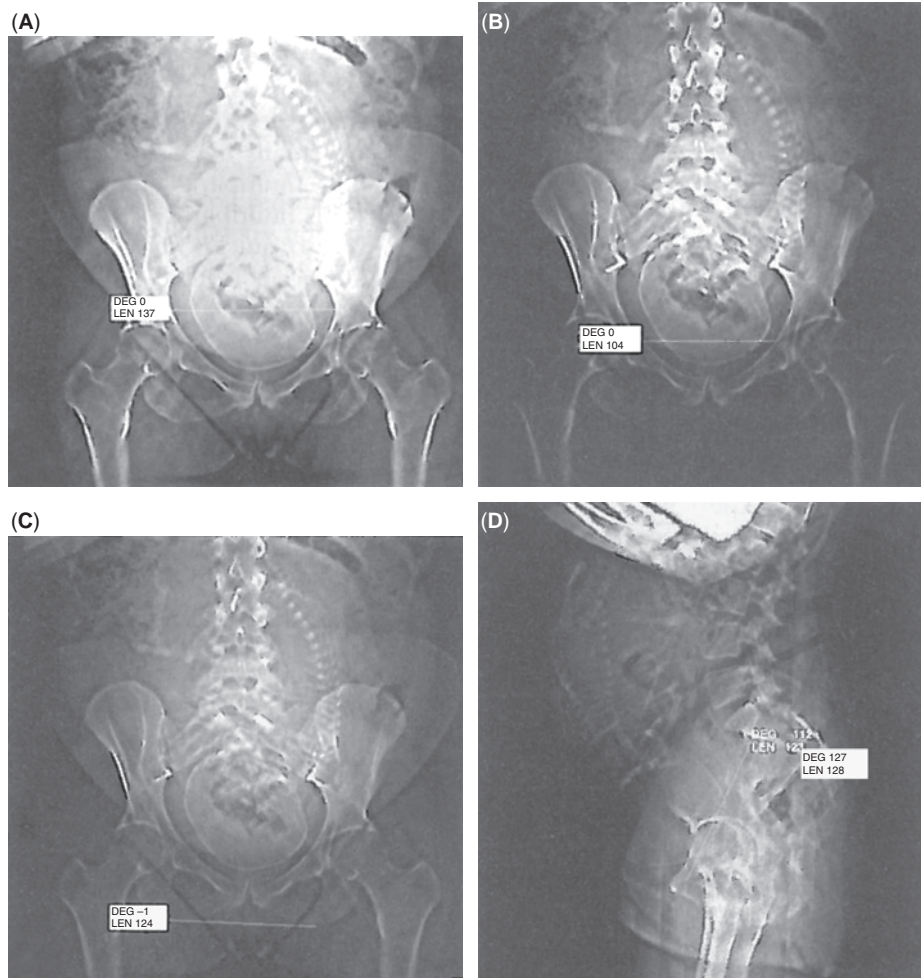

Figure 3 Computed tomography of the maternal pelvis and the flexed fetal head demonstrates (A) the transverse diameter of the pelvic inlet from an anterior-posterior view; (B) transverse diameter of the mid-pelvic plane from an anterior-posterior view; (C) the transverse diameter of the pelvic outlet from an anterior-posterior view; and (D) the anterior-posterior diameters of the pelvic outlet (123) and mid-pelvis (128) from a lateral view.

supplement in about 10% of cases, if required (2). Epidural anesthesia is by far the superior method and is the current first choice for many clinicians (48). For the small breech fetus or the footling breech presentation, adequate anesthesia helps to dampen maternal bearing-down efforts, retarding spontaneous membrane rupture and involuntary pushing. This also decreases the risk of umbilical cord or fetal body prolapse through an incompletely dilated cervix (48). The absence of such involuntary bearing-down efforts is also desirable when the clinician's intent is to deliver a markedly premature fetus *in caula*.

The anesthesiologist should be immediately available. Adequate anesthesia for either emergency cesarean section, should it be necessary, or vaginal manipulations is essential to a successful and safe trial of labor. Neonatal support is also important for a good outcome. Regardless of the delivery route, the breech presentation is a high-risk situation and neonatal resuscitation, when required, must be prompt, proper, and expeditious.

Dynamics of Labor

Parity plays little or no role in the outcome of trials of labor. In fact, despite the beliefs of many clinicians, there may actually be an increase in perinatal morbidity among multiparas

undergoing vaginal breech delivery (31). In multiparas, the aftercoming fetal head can deliver so quickly that acute and unpredictable fluctuations occur in fetal intracranial pressure, which presumably lowers Apgar scores.

The judicious use of oxytocin in selected cases is permissible and does not prejudice outcome (1,29,30,33). In their experience at Moffitt Hospital, Flanagan and coworkers (49) reported no difference in the perinatal outcome seen among patients with breech presentation given a trial of labor with or without the administration of oxytocin. In this study, almost 20% of the patients received oxytocin, primarily for labor induction.

Therefore, if the breech is engaged, the fetus is of normal size, the fetal head is flexed, and the radiographic measurements show the pelvis to be adequate and induction of labor by oxytocin is acceptable (42). However, oxytocin augmentation of breech labor is rarely indicated, given both the potential risks and the current medicolegal atmosphere. The experience at Los Angeles County, University of Southern California Medical Center, indicates that oxytocin augmentation rarely achieves safe vaginal delivery of a breech infant if a secondary arrest of active-phase labor has occurred (2). Therefore, great care is needed if normal progression in labor does not occur. These data tend to confirm an earlier observation of Friedman (50)

that fetopelvic disproportion is a frequent cause of secondary arrest in breech labor. There is also an association between larger infants and abnormalities in labor. Approximately three-fourths of women who deliver breech infants weighing more than 3500 g develop a dysfunctional labor pattern. An abnormal labor pattern is therefore a critical clue that a decision for vaginal trial should be carefully reasoned and that cesarean delivery may be indicated.

The authors consider that 3500–4000 g is the upper limit considered as a safe fetal size for vaginal breech delivery. Therefore, the practitioner must be careful to avoid “forcing” a trial of labor in the presence of a known or suspected large breech fetus. Both ultrasound and clinical weight estimates should be combined in judging fetal size. The lower limits of safe progress in labor are (16) 1.2 cm/hr for nulliparas and (16) 1.5 cm/hr for multiparas. In the presence of normal uterine activity, women failing to dilate at this rate should be taken to cesarean section without an attempt at oxytocin augmentation of labor.

Accouchement

If a vaginal trial is elected, the second stage of labor should be carried out in the delivery room with continuous fetal monitoring. Perhaps more than in any other obstetric setting, vaginal delivery of a breech fetus requires both watchful waiting and gentle manipulation. An experienced, gowned, and gloved assistant and a scrub nurse should be present for the delivery.

A safe assisted breech delivery requires that the accoucheur understands the judicious application of force. An 80-kg obstetrician can easily overpower a 3000-g neonate. However, excessive force alone is not necessarily the major cause of injury. Acute rotation of the fetal body for delivery of the arms or head exceeding 90° may compromise the vertebral blood supply to the central nervous system. In addition, maintaining flexion of the aftercoming head during the actual birth process is crucial. Gentle but firm and continuous suprapubic force needs to be judiciously applied by an assistant to the aftercoming head as the delivery proceeds. The accoucheur must also be prepared either to apply forceps or to reach for the face of the aftercoming fetal head during delivery. It is well to recall that Piper forceps were designed to act as a lever and not as a tractor in aiding the delivery of the head. Good results with forceps to the aftercoming head have been described by Milner (51) (Table 2). If forceps are not applied, the Mauriceau–Smellie–Veit (MSV) maneuver is the procedure of choice in completing the breech delivery. The purpose of the suprapubic pressure is not to effect delivery by *accouchement forcé* but simply to maintain cranial flexion during descent, thus facilitating the entry of the fetal skull into the pelvis by continuously presenting the smallest diameter. If the clinician fails to “follow” the fetal head by exerting gentle but continuous transabdominal pressure on the uterus, cranial extension can occur, resulting in a difficult delivery as a larger diameter of the cranium is presented to the maternal pelvis. Haste is dangerous in the management of breech delivery and almost always unnecessary. Slow, gentle manipulations are always best. Normal cord gases are seen even after a 6-min delay from emergence of the umbilicus to final delivery.

Table 2 Vaginal Breech Delivery: Impact of Forceps to Aftercoming Head

Birth weight (g)	Neonatal deaths (%)	
	No forceps	Forceps
1500–1999	22.3	11.0
2000–2499	7.8	0.0
2500–2999	3.5	0.5

A comparison of duration between the vaginal route of delivery and cesarean section is illuminating. We have found that, in two-thirds of cases, the duration of time during vaginal delivery is shorter than the incision-to-delivery time at cesarean section (52).

Documentation

Complete and accurate records are essential in the conduct of breech management, regardless of the mode of delivery chosen. Within the progress notes, the obstetrician should detail the discussions that are the foundation of patient informed consent. As has already been discussed, the obstetrician is well advised to have a knowledgeable labor and delivery nurse present at the time of these interactions who can, in his/her own nursing notes, confirm the nature and extent of the discussions.

The obstetrician should record in the progress notes the basis for the clinical judgments made in support of the decision to conduct a trial of labor. This note should stress the clinical and diagnostic factors that favor the choice that was made. If a trial of labor is planned, the note should make a statement of the specifics of the protocol to be followed, with emphasis on the elements of meticulous observation during the progress of labor, ongoing assessment of adequacy of descent, continuous fetal monitoring, and preparedness for immediate emergency cesarean delivery. The progress note recorded during the course of labor itself should set forth in detail the basis for all clinical decisions in response to significant changes in maternal/fetal status. This process may at first appear to be excessive, but it is nothing more than a plan for strict adherence to the usual standards for documentation of high-risk labor.

COMPLICATIONS

Prematurity and Low Birth Weight

The low-birth weight breech fetus, between 25 and 36 weeks of gestation, presents a clinical challenge (36,53,54). These fetuses have up to a one in five chance of having a major congenital malformation (2). Furthermore, such pregnancies are commonly complicated by significant obstetric problems including but not limited to placenta previa, abruptio placentae, and multiple gestations (55). Owing to the relative sizes of head and abdomen, the risk of cord prolapse (or body prolapse) through an incompletely dilated cervix is high.

The limits of ultrasound measurement are also a problem. Underestimation of fetal weight results in fetuses that are essentially dismissed as being too small to survive (56). Less likely is the overestimation of fetal weight, which can lead to heroic efforts for fetuses with limited chance for survival. In the growth-retarded fetus, the abdomen can be significantly

smaller than the head and thus more likely to prolapse through a partially dilated cervix, resulting in entrapment of the fetal head.

For the fetus between 34 and 38 weeks of gestation, there may be a crucial difference, based on the estimates of gestational age and fetal weight, in the likelihood of success and safety of a trial of labor versus cesarean delivery. By insisting on a clinically estimated fetal weight of *more* than 2000 g and a gestational age of >36 weeks, a reasonable margin of error is built into the protocol.

Untoward Results

In the event of an untoward result following either a vaginal trial or a cesarean delivery, the facts of the occurrence must be carefully documented. If the obstetrician has appropriately documented adherence to the originally decided protocol, and clinical decision making throughout the course of the trial of labor or cesarean delivery has followed this plan, there should be little need for lengthy commentary or explanation in the progress note. Protracted retrospective explanations entered into the medical record with the hope that subsequent medical/legal reviewers will be persuaded to exonerate a physician's conduct seldom prove effective, unless the remainder of the chart adequately documents a coherent *prospective* plan. In fact, many physicians find themselves compromised by their own "explanatory remarks," because such hastily formulated notations are frequently either incomplete or poorly articulated.

Initial discussions with the mother concerning the injury or death of her infant ought to be prompt. In these conversations, the clinician should frankly discuss the infant's status and/or prognosis, if it is accurately known. Imparting either falsely hopeful or falsely negative information is more harmful than simply stating that the baby's condition is uncertain or under evaluation. Because an atmosphere of

strong emotion often attends this initial communication, it is sometimes wise for the obstetrician to defer detailed discussion of the circumstances which led to the unpleasant result (if they are known) until a later time. Once the mother/family is calm and reasonably receptive to such discussion, the physician should explain what happened. Obstetricians who regularly pride themselves on their skill, knowledge, and professional acumen are at that moment met with a singularly demanding challenge: embracing their own human limitations and explaining in plain language why they were powerless to prevent this untoward result. Honest acknowledgment of both human and technical limitations is necessary and appropriate. If done properly, this should simply reinforce what the patient should have known before the delivery was ever undertaken. The gift of simple humanity on the part of the physician at this juncture will go a long way toward healing the loss experienced by both the patient and the doctor. It is good practice to have another observer (nurse, colleague, etc.) present during these discussions. Obviously, it is prudent to notify the hospital risk management service of such complications, as it is always uncertain whether formal legal proceedings will result from any complication and the lag time between the event and the legal complaint can be long indeed.

CONCLUSIONS

The results of the TBT have changed the approach to breech vaginal delivery by the majority of obstetric providers. This will eventually lead to the loss of the experience to provide safe vaginal delivery to those who present with the persistent breech-presenting infant. There currently remain some centers that provide vaginal breech delivery with a management program consisting of radiologic confirmation of pelvic adequacy in conjunction with careful assessment of labor and continuous fetal monitoring, which usually produces

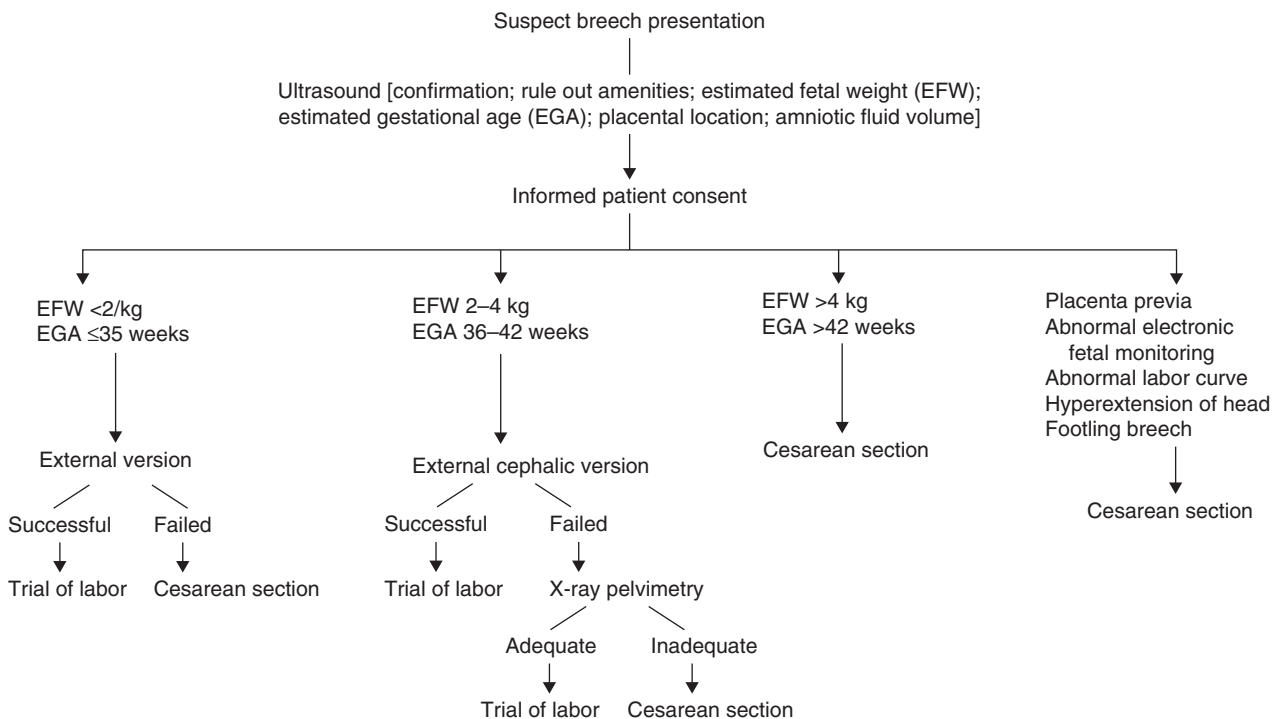

Figure 4 Overview and flow diagram of the management of breech presentation in early labor. Source: From Ref. 58.

outcomes in neonates born vaginally that are comparable with those delivered abdominally (29–33) (Fig. 4).

The liberal use of cesarean section reduces the potential for trauma and hypoxia in breech delivery, but it by no means eliminates it. In establishing any protocol and ultimately in reaching a management plan for any individual patient, it is necessary to balance the risks and benefits for both mother and neonate from cesarean section and vaginal delivery and to counsel families accordingly. Where facilities allow for expeditious cesarean section and a stringent protocol for evaluation, selected patients may safely be offered a trial of labor. However, to assure maternal and fetal safety, the obstetrician must be committed to thorough evaluation of the maternal pelvis and close attention to the course of labor. Furthermore, the clinician must know the mechanics of safe breech delivery, regardless of the delivery route initially chosen. At cesarean section, although the infant is being delivered through incisions in the abdominal wall, the mechanism of delivery by extraction has the potential for greatly traumatizing the infant unless extreme care is exercised. Even at cesarean section, peripheral nerve and bony injuries to the fetus are not only possible, but seen to occur with regularity (57). The obstetrician can minimize the risk of trauma to the breech fetus born by cesarean section or vaginally after a labor trial by close attention to detail with the application of the standard obstetric techniques for assisted delivery. The same approaches to delivery apply to both cesarean section and vaginal delivery: minimal force, careful pressure to the aftercoming head to prevent the loss of flexion, and judicious use of the MSV maneuver and/or Piper forceps for cranial extraction.

Based on the cumulative experience of many clinicians on multiple obstetric services, traumatic birth injuries to both the parturient and her fetus can often be avoided and always be minimized in the management of breech presentation. A program of antepartum external cephalic version offers the advantage of decreasing the incidence of breech presentation in labor, thus avoiding these dilemmas for the clinician. Cesarean section will be used to deliver the vast majority of breech infant, but a selective trial of labor employing strict protocol adherence can be satisfying to both physician and parturient and result in an equally good outcome.

15 Cesarean section and vaginal birth after cesarean section

Jessica Winn and Hung N. Winn

INTRODUCTION

In the United States, cesarean section was the most common surgical operation in 2006 (1) and about 31.8% of approximately 4.3 million infants born in 2007 were delivered by cesarean section (2). The rates of cesarean section increased dramatically from an annual rate of 5.5% in 1970 to 24.1% in 1986, stabilized between 1986 and 1989, then gradually declined to 21% in 1996, and finally steadily rose again to 31.8% in 2007 (2–5). Between 1996 and 2007, the overall cesarean section rate increased for all pregnant women, regardless of the maternal age, race, and the state of residence (5). The overall rate of cesarean section increased or decreased with the fall or rise in the rate of vaginal birth after previous cesarean section (VBAC), respectively. The overall rate of cesarean section increased by 53% between 1996 and 2007 while the rate of VBAC dramatically declined during the same period (5,6).

Cragin's dictum "once a cesarean, always a cesarean" dates back to 1916, when he suggested that uterine rupture following vaginal delivery after previous cesarean birth was so catastrophic an event that a repeat cesarean should be done prior to the onset of labor (7). This opinion was then cited in the fourth edition of *Williams' Obstetrics* (8) and the attitudes favoring repeat cesarean sections began to prevail. All this dates back to a pre-antibiotic, pre-transfusion era when cesarean section involved a classical uterine incision. In 1980, the *National Institutes of Health (NIH) Consensus Development Conference* pointed out that repeat cesarean was one of the major reasons for the rising cesarean rate. The literature was reviewed and the Consensus Development Task Force on Cesarean Childbirth concurred that labor following a low transverse uterine incision was associated with lower maternal morbidity and mortality, with equivalent infant outcomes. They concluded that VBAC was an appropriate option (9). Subsequently, the rate of VBAC steadily increased from 5% to 28.3% while the overall rate of cesarean section decreased from 25% to 21% between 1985 and 1996 (4). After peaking in 1996, the trend for VBAC was reversed with the rates of VBAC plummeted to 12.6% in 2002 and to 8.5% in 2006 with a concomitant rise of overall cesarean section to 31.1% in 2006 (10). The reverse trend in VBAC could be attributed to (i) the increased number of reports of maternal complications and perinatal morbidities and mortalities associated with VBAC (11–15) and (ii) professional liability concerns (16). The overall success rates of VBAC is about 74% with a range from 54% to 89% (5,6,17–19). The indications for the primary cesarean sections such as failure to progress, breech presentation, fetal distress, and genital herpes infection do not appear to influence the high success rate of VBAC delivery (17–19). Factors that are associated with a higher rate of successful

VBAC include spontaneous labor, birth weight of less than 4000 g, and a history of prior vaginal delivery especially a prior successful VBAC (1,5,6,20–23).

RISK OF UTERINE RUPTURES

Oxytocin

The risk of uterine rupture in patients undergoing trial of labor after cesarean section (TLCS) ranges from 0.4% to 0.5% with spontaneous labor and 0.8% to 1.1% with oxytocin induction of labor (24,25). The higher the maximum dose of oxytocin, the higher the risk of uterine rupture (26). Similarly, overuse of oxytocin to augment labor for prolonged latent phase in patients undergoing TLCS is associated with a risk of uterine rupture 2.7 times that of a control group (26,27). The risk of uterine rupture is not increased if uterine pressure is carefully monitored, preferably with an intrauterine pressure catheter (28).

Prostaglandin Use

The risk of uterine rupture in patients undergoing TLCS ranges from 0.4% to 0.5% with spontaneous labor and 1.4% to 2.2% with prostaglandin induction of labor (24,25). The increased risk of uterine rupture seems to exist only in the setting of sequential process of cervical ripening with prostaglandin E₂ then induction of labor with intravenous oxytocin (29). In addition, the use of prostaglandin E₁ (misoprostol) in patients with previous cesarean sections is consistently associated with a much higher risk of uterine rupture (30–33). Limited data suggest that cervical ripening with prostaglandin (PGE₂) gel alone in patients with a previous low transverse cervical cesarean section appears to be safe, without the increased risk of uterine rupture of maternal perinatal morbidity or mortality (29). Careful monitoring of uterine contraction and fetal heart rates (FHRs) is strongly recommended.

Induction of labor with prostaglandins including misoprostol during the second trimester for fetal demise in patients with previous cesarean sections is a reasonable option since it carries a uterine rupture risk of less than 1% that is comparable with that of unscarred uterus (34–36).

Epidural Anesthesia

The initial concern of epidural anesthesia for analgesia in masking the symptoms and signs of uterine rupture such as pain or hypotension in patients undergoing TLCS has not been supported by clinical data. Epidural anesthesia is not associated with an increased risk of uterine rupture in patients undergoing TLCS (27,37). The use of epidural anesthesia allows adequate pain relief during labor and ready access to safe anesthesia when cesarean section is required.

Fetal Macrosomia

Fetal macrosomia is defined as a fetus having an estimated weight of 4000 g or more (38). Trial of labor in patients with fetal macrosomia is not associated with an increased risk of uterine rupture and perinatal or maternal morbidity or mortality (27,39). It is uncertain whether fetal macrosomia affects the success rates of VBAC (40). One study showed VBAC success rates of 78% with infants having birth weights of <4000 g, 58% with birth weights between 4000 and 4499 g, and 26% with birth weights of >4500 g (41). Another study showed a lower VBAC success rate if the neonatal birth weight of the index pregnancy is larger than the one associated with a prior cesarean section done for cephalopelvic dystocia (42). Trial of labor should not be discouraged because of fetal macrosomia, in view of its safety and the inaccuracy of predicting fetal weight in macrosomic fetuses.

Breech Presentation

External version can be safely performed in patients with a previous cesarean section, followed by a trial of labor and vaginal delivery (43). Success rates of 82% for external cephalic version and 65% for subsequent vaginal delivery have been reported (44).

Twins

The management of patients with multiple gestations remains a topic of debate. There are inadequate data on the management of patients with previous cesarean sections who have multiple gestations (45–48).

Amnioinfusion

Amnioinfusion has been performed for indications such as oligohydramnios, meconium-stained amniotic fluid, and variable FHR decelerations in patients with previous cesarean sections. The success rates of VBAC range from 58% to 83% without a significant increase in the incidences of uterine rupture and maternal or perinatal morbidity/mortality (49,50). The incidence of uterine rupture is 0.8% (49). Amnioinfusion does not appear to be a contraindication for a trial of labor in patients with previous cesarean sections.

Multiple Previous Cesarean Sections

Patients undergoing a trial of labor after having more than one previous cesarean section have VBAC success rates ranging from 64% to 77% that were comparable with those with one previous cesarean section (17,18,51–56). Uterine wound separation appeared to be increased, even though not statistically significantly in patients with multiple previous cesarean sections compared with those with a single previous cesarean section (52). There was no increased perinatal morbidity or mortality that could be attributed to uterine separation or rupture (17,52). More recent studies demonstrated that the risk of uterine rupture was inconsistent, either about the same (0.9% for one previous cesarean section vs. 0.7% for multiple ones) or increased (0.9% for one previous cesarean section vs. 1.8% for two previous ones) (53,54). Thus, a trial of labor for patients with two previous cesarean sections is still a reasonable option in the presence of other favorable factors for successful VBAC.

A Previous Low Uterine Vertical Cesarean Section

Patients who undergo a trial of labor after a previous low uterine vertical cesarean section have VBAC success rates ranging from 83% to 85%, risks of uterine rupture ranging from 1.1% to 1.3%, and no maternal deaths. There is no significantly increased incidence of maternal or perinatal morbidity/mortality due to uterine rupture (57–59). Therefore, a trial of labor could be attempted in patients who had a previous low vertical uterine cesarean section with close maternal and fetal monitoring.

Unknown Uterine Scar

Documentation of the uterine incision in the previous cesarean section is one of the main criteria for undergoing a trial of labor. A dilemma occurs when the type of uterine incision is unknown. Limited data reveal that the rate of uterine rupture is 2.2% without a significant increase in maternal or perinatal mortality or morbidity (60). Augmentation of labor during the latent phase with intravenous oxytocin increased the incidence of uterine separation compared with that of patients who were managed expectantly without oxytocin (61).

In 1984, Beall and coworkers (62) reported on 451 women with unknown types of uterine scar. Ninety-seven patients labored with an 87% vaginal delivery rate. The rate of scar dehiscence in the women who labored was 1% that did not significantly differ from the one in women with unknown scar who did not labor. Perinatal mortality was similar in both groups.

CONCLUSIONS

The risk of uterine rupture in patients undergoing TLCS varies with the type of previous uterine incision and the number of previous cesarean sections. The risks of uterine rupture range from 0.6% to 0.9% with one previous low transverse uterine incision (19,28,53,54,63–66), 0.7% to 1.8% with more than one previous low transverse uterine incision (53,54,56,57), and is about 12% with a previous classical uterine incision (59). Other predisposing factors include excessive amount of intravenous oxytocin for augmentation or induction of labor, and dysfunctional labor. Fetal macrosomia and epidural anesthesia do not appear to increase the risk of uterine rupture (27). Signs of uterine rupture include abdominal pain, vaginal bleeding, abnormal labor, and abnormal FHR patterns such as sudden onset of prolonged fetal bradycardia and severe variable decelerations (18,67). Trial of labor in patients with previous cesarean sections does not increase maternal mortality compared with those undergoing elective cesarean section (59).

Despite the reassuring data, VBAC has been steadily decreased during the last decade. Undue concern from both obstetricians and patients about the potential maternal, fetal complications and legal issues associated with uterine rupture and the convenience of scheduled cesarean sections have contributed to the low rate of trial of labor. Patients with a previous low transverse cervical cesarean section should be encouraged to undergo a trial of labor. In addition to the low risk of uterine rupture, patients who have successful VBAC have significantly lower maternal morbidity in comparing with those undergoing elective repeat cesarean section (19,68). Trial

of labor may be offered to patients who have two previous low transverse cervical cesarean sections. Patients with a low vertical uterine cesarean section or unknown uterine scar should not be discouraged from a trial of labor after being informed of the slightly higher risk of uterine ruptures (up to 2%) and potential-associated maternal or perinatal complications. Fetal macrosomia is not a contraindication for a trial of labor. Epidural anesthesia for pain control may be offered to patients who undergo VBAC. Fetal heart rate, maternal labor and medical condition should be closely monitored during labor. The American College of Obstetricians and Gynecologists has recommended that the institution's resources and the medical staff should be *immediately available* to respond to maternal and perinatal emergencies including *emergency cesarean section delivery* if a trial of labor after a previous cesarean section is undertaken (69).

16 Diabetes in pregnancy

Donald. R. Coustan

EPIDEMIOLOGY OF DIABETES IN PREGNANCY

Preexisting diabetes mellitus complicates approximately 0.3% of all pregnancies in the United States (1), while gestational diabetes mellitus (GDM) complicates 5% to 10% (2). Type 2 diabetes, characterized by the typical clinical presentation of obesity and insulin resistance, is roughly 10 times more prevalent in the American population than type 1 diabetes; in recent years, as the nationwide epidemic of obesity and type 2 diabetes has impacted younger and younger individuals, type 2 diabetes is becoming proportionally more common in pregnancy. Individuals with type 1 diabetes are prone to ketoacidosis whereas those with type 2 diabetes rarely manifest this complication.

ETIOLOGY

Diabetes mellitus is a heterogeneous group of disorders all characterized by hyperglycemia. Type 2 diabetes, as described above, is commonly related to obesity and appears to be inherited in a polygenic manner. There are a number of less common forms of type 2 diabetes, formerly called "MODY" (maturity onset of diabetes in youth), which are inherited as single gene defects in an autosomal dominant manner (3). It is not yet clear whether insulin resistance alone is sufficient to cause type 2 diabetes or whether there must also be an element of relative insulinopenia. Type 1 diabetes, on the other hand, is an autoimmune disorder in which the immune system is directed against the islet cells in the pancreas. There is clearly a genetic predisposition toward such pancreatic destruction, as evidenced by the preponderance of specific HLA antigens in individuals with type 1 diabetes. However, the genetic predisposition is not sufficient to bring about the disease, as evidenced by the less than 50% concordance of identical twins for this disorder (3).

GDM is a condition of "carbohydrate intolerance of variable severity with onset or recognition during pregnancy" (4). Women with GDM are at increased risk, compared with the general population, for the subsequent development of type 2 diabetes, with 60% developing this condition within 20 years of the index pregnancy (5). One possible explanation is that the metabolic changes brought about by pregnancy induce transient carbohydrate intolerance in individuals whose metabolism is at some point along a continuum ultimately leading to diabetes (6).

PATHOPHYSIOLOGY

Pregnancy has profound effects on maternal metabolism. It is useful to think of these effects as being designed to assure a plentiful supply of fuel (glucose, gluconeogenic amino acids) and structural material (various amino acids) for the building of a fetus. When the gravida has fasted, circulating glucose and amino acid levels are lower than those in nonpregnant fasting

women (7). While it is tempting to speculate that this relative hypoglycemia is secondary to fetal consumption of fuel, the change occurs relatively early in pregnancy, when the fetus cannot yet utilize enough fuel to account for the observed phenomenon. The fall in glucose levels during fasting is associated with a rise in circulating levels of ketone bodies, to an extent greater than that observed in the nonpregnant state. This fall in glucose and rise in ketones has been termed "accelerated starvation," which is a useful concept. Insulin levels after an overnight fast are significantly higher than those in the nonpregnant individual, despite lower glucose values. Such apparent insulin resistance is believed by many to be the underlying cause of GDM, as will be discussed below.

When the pregnant woman ingests glucose, particularly after an overnight fast, her circulating glucose level increases somewhat more slowly, but to a greater amplitude, than in the nonpregnant state, despite the fact that her insulin level is quite a bit higher than that in nonpregnant women (7). This "insulin resistance" is present in both the liver and the periphery. Nevertheless, in the context of the usual day-to-day ingestion of mixed meals, it appears that normal pregnant women maintain their circulating glucose levels within a rather narrow range (7,8).

The insulin resistance mentioned above is most probably the cause of the appearance of GDM in 5% to 10% of women in the United States. Whether there is also a relative deficiency of insulin production in such individuals remains to be determined.

Individuals with preexisting diabetes who become pregnant are impacted dramatically by the increase in insulin resistance brought about by the pregnancy. Those with type 2 diabetes are likely to require markedly increased doses of insulin in order to maintain relative euglycemia. Those with type 1 diabetes generally experience a two- to threefold increase in insulin requirements as pregnancy progresses (9).

Most importantly, despite a tendency toward hypoglycemia during the first trimester, individuals with type 1 diabetes are significantly more likely to experience diabetic ketoacidosis (DKA) during the second half of pregnancy than at other times. This proclivity toward DKA appears to be related to the insulin resistance of pregnancy. The most important causes of DKA are absolute or relative insulinopenia and glucagon excess, resulting in hyperglycemia from hepatic glycogenolysis and gluconeogenesis and hyperketonemia due to uninhibited lipolysis and increased hepatic production of ketone bodies (10). When DKA is present, hepatic glucose production is increased as much as threefold, accounting for marked hyperglycemia even in patients who have not eaten for a considerable length of time. The maternal effects of hyperglycemia during DKA include osmotic diuresis, which may result in dehydration. The resultant hypovolemia can cause hypotension, renal dysfunction, mental

aberrations, and shock. Electrolytes, particularly total body sodium and potassium, become depleted. Because ketone bodies are moderately strong acids, the maternal pH falls, the serum bicarbonate level falls, and an anion gap [(serum sodium)–(serum bicarbonate + serum chloride)] > 10–15 mEq/L results, indicative of metabolic acidosis. The acidosis is the cause of the characteristic tachypnea and increased tidal volume known as Kussmaul's respirations. Nausea and vomiting frequently accompany the acidosis, further exacerbating the hypovolemia and electrolyte depletion. The fetus is particularly at risk, with fetal mortality rates historically reported to be in the range of 50% to 90% when maternal DKA occurs. Explanations for this high rate of fetal death include hypoxia due to uterine hypoperfusion resulting from maternal hypovolemia and the possible fetal effects of the rapid transport of hydrogen ions across the placenta. More recent studies (10) report lower perinatal mortality rates of between 9% and 35%, suggesting some improvement in the management of this complication over the years. During pregnancy, common causes of DKA appear to be similar to those seen in the nonpregnant state: intercurrent infection and omission of insulin injections. However, in addition, iatrogenic causes may contribute, including the use of betamimetic agents for tocolysis and corticosteroids for the enhancement of fetal pulmonary maturity. DKA is not caused by the administration of exogenous glucose unless there is simultaneous underinsulinization.

Even in the absence of DKA, hyperglycemia is associated with perinatal morbidity and mortality in diabetic pregnancy. In fact, according to the "Pedersen hypothesis" (11), all of the problems comprising "diabetic fetopathy" are related to fetal hyperinsulinemia, which results from hyperglycemia transmitted from the maternal to the fetal compartment. This concept was extended by Freinkel (12) as the "modified Pedersen hypothesis" to acknowledge the probable role of non-glucose secretagogues in stimulating fetal pancreatic insulin production and release.

There is a body of experimental evidence to support the Pedersen hypothesis with regard to both preexisting and GDM. Although a randomized, prospective trial of loose versus strict metabolic control in diabetic pregnancy has not been carried out, existing data on human pregnancy support the concept that near-normalization of maternal circulating glucose levels strongly predicts favorable perinatal outcome. Karlson and Kjellmer (13) demonstrated that diabetic women whose average blood glucose level in the third trimester exceeded 150 mg/dL manifested a 24% perinatal mortality rate, compared with 4% in those whose average third-trimester glucose level was less than 100 mg/dL. Virtually every series published since that time in which near-normalization of glucose levels was attempted has reported a perinatal mortality rate of less than 5%. The pathophysiology of the relationship between maternal hyperglycemia and perinatal death is yet to be determined. However, studies in laboratory animal models have demonstrated that fetal hyperinsulinemia can lead to hypoxia, acidosis, and fetal death (14). Morbidity, such as fetal macrosomia, neonatal hypoglycemia, respiratory distress syndrome, plethora, and jaundice, has likewise been linked to fetal hyperinsulinemia (14).

It has long been appreciated that infants of diabetic mothers suffer from birth defects at a rate of two to three times that in the general population. Because virtually all structural anomalies in infants of diabetic mothers have taken place by 8 to 10 weeks after the last menstrual period (15), the cause(s) of such anomalies in humans has been difficult to study. Laboratory investigations have demonstrated that maternal hyperglycemia during organogenesis can induce fetal anomalies in rodent embryos (16). In human pregnancies, first-trimester glycosylated hemoglobin levels have been positively correlated with the likelihood of anomalies, raising the possibility of a cause-and-effect relationship between hyperglycemia (or some other aspect of poor metabolic control) and birth defects (17–19). In the Diabetes in Early Pregnancy (DIEP) study, an observational study in which women were asked to perform multiple daily self glucose monitoring tests, an approximate halving of the rate of congenital anomalies (4.9%) was noted in diabetic individuals registering for care prior to conception or during very early pregnancy compared with those enrolled after 8 weeks (9%), even though no specific goals for glucose control were imposed (20). In this study, offspring of diabetic women registering early for care still had an approximate doubling of the malformation rate compared with control children of nondiabetic mothers. Furthermore, no correlation could be found between the level of glucose control and malformation rate, a finding possibly attributable to the paucity of pregnancies with either very good or very poor control in the series. In an interventional study, Fuhrmann and coworkers (21) demonstrated a malformation rate of 2% to 3% in the offspring of diabetic mothers who were given intensive prepregnancy and early pregnancy care, a rate similar to that in the general population and considerably lower than the 8% rate among offspring of mothers registering for care after the eighth week of gestation. Kitzmiller and colleagues (22) reported a major malformation rate of 1.2% among the offspring of 84 diabetic women who entered a preconception care program, compared with 10.9% among the offspring of 110 diabetic women presenting for prenatal care at 6 weeks of gestation or later. Average ambient glucose levels during organogenesis were considerably lower in the preconception care group than in the women participating in the DIEP study cited above. Poor maternal metabolic control has also been linked to spontaneous abortion in diabetic pregnancy (19,23,24). It therefore seems likely that there exists a continuum of reproductive damage related to aberrations of metabolism in early diabetic pregnancy. This ranges from spontaneous abortion when poor control is very early and/or severe, to anomalies when it comes somewhat later, is less severe, or happens at a critical time. As described above, aberrations of metabolic control occurring later in pregnancy, after organogenesis has been completed, appear capable of inducing a wide range of problems which may be called, collectively, "diabetic fetopathy."

The above pathophysiological mechanisms appear to be operative in gestational diabetic pregnancy, as well as in pregnancy complicated by overt diabetes, albeit to a lesser degree. Because the metabolic alterations seen in GDM are generally, but not always, less severe than those of preexisting diabetes, perinatal mortality is distinctly less likely with the milder forms of diabetes, particularly if the condition is

identified and treated in some way. However, studies of *undiagnosed* and *untreated* GDM suggest a marked increase in the perinatal mortality rate (25,26). Even in gestational diabetic pregnancies maintained in reasonably good metabolic control, there is an excess of fetal macrosomia (27). Furthermore, childhood and young adult obesity has been reported in infants of gestational diabetic mothers (28–30), suggesting the possibility that the intrauterine milieu may have profound and long-lasting effects on adipose tissue formation. Strengthening this hypothesis is the finding of a significant relationship between maternal response to a glucose challenge during pregnancy and the likelihood of the offspring developing diabetes and of the female offspring developing GDM (31).

DIAGNOSIS

By definition, preexisting or overt diabetes has already been diagnosed prior to pregnancy; it is GDM, therefore, that is the subject of this section. The diagnostic criteria currently accepted in the United States utilize a 100-g, 3-hour oral glucose tolerance test (OGTT) and are based on the work of O'Sullivan and Mahan (32), in which normative data were collected for 752 consecutive prenatal patients. Various thresholds derived from these data were then applied to a separate group of subjects who underwent the test during pregnancy and then were followed for 7 years. The criteria recommended were the most efficient predictors of subsequent diabetes. According to these criteria, GDM is diagnosed if at least two of the four glucose tolerance test values meet or exceed thresholds two standard deviations above the means for their respective specific time intervals. In O'Sullivan's original study (32), venous samples of whole blood were utilized, and the Somogyi–Nelson technology was applied for glucose measurement. The resultant thresholds were fasting 90 mg/dL, 1 hour 165 mg/dL, 2 hours 143 mg/dL, and 3 hours 127 mg/dL. These were rounded off to the nearest 5 mg/dL for ease of recall.

In the 1970s most clinical laboratories switched to venous plasma or serum, which yield values approximately 15% higher than whole blood samples. Accordingly, in 1979, the National Diabetes Data Group (NDDG) (33) attempted to convert the O'Sullivan and Mahan criteria to plasma values by adding approximately 15% to each threshold. The resultant criteria were at one time recommended by the American Diabetes Association (ADA) (34) and the American College of Obstetricians and Gynecologists (ACOG) (35) and were widely utilized in the United States. The recommended thresholds for plasma or serum glucose samples were fasting 105 mg/dL, 1 hour 190 mg/dL, 2 hours 165 mg/dL, and 3 hours 145 mg/dL for the 100-g, 3-hour OGTT; GDM was diagnosed if two or more samples meet or exceed the above thresholds.

In addition to the change from whole blood to plasma or serum samples, another alteration in glucose testing occurred in the 1970s. The Somogyi–Nelson method, which measures approximately 5 mg/dL of reducing substances other than glucose, was replaced by more specific enzymatic methods such as glucose oxidase and hexokinase. Consequently, in 1982 (36), our group published suggested thresholds to take into account both methodological advances: fasting 95 mg/dL, 1 hour 180 mg/dL, 2 hours 155 mg/dL, and 3 hours 140 mg/dL. One study (37), in which the original methodology of

O'Sullivan and Mahan was compared directly with the current technology, found that the NDDG criteria were above the 95% confidence limits of the O'Sullivan criteria at three of the four glucose tolerance testing intervals, whereas the criteria of Carpenter and Coustan were within such confidence intervals at all times. Subsequently, the ADA (38) recommended the use of these lower thresholds, and ACOG (39) recommends using either set of thresholds.

It is important to point out that the relationship between glucose intolerance and perinatal morbidity and mortality is, in all likelihood, continuous. Magee and colleagues (40) found a similar level of perinatal morbidity in pregnancies in which GDM diagnosed by the Carpenter and Coustan conversion of O'Sullivan and Mahan's criteria, but not the NDDG conversion criteria, were met; both groups manifested significantly more morbidity than did the general population. Naylor and associates (41) compared patients known to their caregivers to have GDM (NDDG criteria), patients whose caregivers were blinded to the diagnosis of GDM (Carpenter and Coustan criteria), and normoglycemic controls. Both groups of patients with GDM had a greater likelihood of delivering by cesarean section than did normal controls. However, in the patients with undiagnosed, milder GDM, cesarean section was related to an increased likelihood of macrosomia. In the patients with known GDM, the treatment apparently lowered the macrosomia rate to that of the normal controls, but high cesarean section rates persisted, possibly because of the caregivers' expectations of macrosomia (42).

The 3-hour, 100-g OGTT was considered too time consuming and expensive to be universally applied. Therefore, a screening procedure was deemed necessary in order to choose which patients should be tested. It was at one time traditional to use the taking of a history as the screening test. Patients who reported the presence of certain risk factors (e.g., family history of diabetes, previous macrosomic baby or stillbirth, etc.) would undergo glucose tolerance testing. Unfortunately, this method of screening is too insensitive for clinical use, identifying only approximately 50% of women with GDM (43). For this reason, both the ADA (38) and the ACOG (39) have recommended the use of a 50-g, 1-hour glucose challenge, administered without respect to the time of the last meal, as a screening test for GDM. The test is administered at 24 to 28 weeks, and a plasma or serum glucose level at or above 130 or 140 mg/dL is considered by these two organizations to be an indication for the full 3-hour, 100-g OGTT. In our center, we use a threshold of 130 mg/dL, since we have determined that 10% of women with GDM manifest screening test values of 130 to 139 mg/dL (43). Currently, the ACOG (39) acknowledges that the benefits to a population of screening for GDM have not been proven, but suggests that if screening is to be performed, it be done universally. Exceptions would be populations in which the prevalence is unusually high or low. In high-prevalence populations, such as the Pima Indians, it may make the most sense to omit the screening test and go right to the full 3-hour OGTT, since the likelihood of having GDM by virtue of being a Pima is higher than that imparted by a positive screening test. In low-prevalence populations, such as attendees to an adolescent pregnancy clinic, screening based on risk factors may be appropriate. The ADA made similar recommendations (44).

The original O'Sullivan criteria for GDM, as well as the NDDG and Carpenter and Coustan adaptations of those criteria to more modern methodology, were validated by their predictive value for subsequent diabetes in the mother. It would be much preferable to use criteria that are based upon pregnancy outcomes. Furthermore, the criteria described above are used in the United States, whereas other sets of criteria and other glucose challenges, such as 50 and 75 g, are in use at various places around the world. How much better it would be if there were diagnostic criteria accepted worldwide. Recently, the Hyperglycemia and Adverse Pregnancy Outcomes study was carried out in an attempt to define the relationship between hyperglycemia less severe than diabetes and adverse pregnancy outcomes (45). Over 23,000 pregnant women in 15 centers in nine countries participated in a blinded 75-g, 2-hour OGTT. Each of the three OGTT values (fasting, 1 and 2 hours) was linearly and significantly related to the four primary outcomes studied (birth weight above the 90th centile, primary cesarean section, cord blood C-peptide above the 90th centile, and clinical neonatal hypoglycemia) as well as a number of secondary outcomes such as preterm delivery and pre-eclampsia. Based upon these results, the International Association of Diabetes and Pregnancy Study Group (IADPSG) convened a consensus panel to make recommendations for the diagnosis and classification of hyperglycemia in pregnancy (46). That group recommended that a 75-g, 2-hour OGTT be used and that GDM be diagnosed if any one or more of the following thresholds are met or exceeded: fasting plasma glucose 92 mg/dL, 1-hour plasma glucose 180 mg/dL, and 2-hour plasma glucose 153 mg/dL. If these recommendations are adopted by professional organizations in various countries, the goal of universal diagnostic thresholds based upon pregnancy outcomes will have been realized. The IADPSG consensus panel also recommended that if women are considered to be at high risk for preexisting diabetes, they may be tested at the first prenatal visit with either a fasting plasma glucose (values at or above 126 mg/dL indicate overt diabetes), hemoglobin A_{1c} (values of 6.5% or more indicate overt diabetes), or random plasma glucose (values of 200 mg/dL or more indicate overt diabetes if confirmed by fasting plasma glucose or Hb A_{1c}). The American Diabetes Association endorsed these recommendations in January 2011 (92).

MANAGEMENT

The management of diabetes in pregnancy brings together advances in internal medicine, obstetrics, pediatrics, physiology, and metabolism. Although there are marked similarities in the management of pregnancies complicated by preexisting diabetes and those complicated by GDM, the differences in the degree of risk and maternal glycemic stability make it most convenient to consider each separately.

Preexisting Diabetes—Medical Management

Preconception Care

As discussed above, diabetic pregnancy presents a rare opportunity to prevent congenital anomalies. Preconception care should begin at the time diabetes mellitus is diagnosed in any female prior to or during the age of reproduction.

Pediatricians, internists, family doctors, and others caring for such patients should educate young diabetic women about the need for planning prior to pregnancy, and the increased risk of congenital anomalies when a pregnancy begins prior to the institution of reasonable metabolic control. Various approaches to contraception should be discussed (47) in order to minimize the likelihood of inadvertent pregnancy.

Once the individual with diabetes has decided to attempt pregnancy, a thorough evaluation of her medical status should be undertaken (48,49). This should include renal function tests, cardiac assessment, hemogram, immunity testing for hepatitis and rubella, blood type, Rh and antibody testing, and HIV testing. A thorough physical examination is appropriate, as is an expert ophthalmologic examination in patients whose diabetes is not of recent onset. Once risk factors have been assessed, the patient should be counseled as to their significance. The patient's list of medications should be reviewed, since drugs such as statins, angiotensin converting–enzyme inhibitors, and angiotensin-II receptor blockers are contraindicated in pregnancy. If pregnancy is to be initiated, intensive management aimed at near-normalization of circulating glucose levels should be instituted. There is not widespread agreement as to the most appropriate goals for glycemic control during the preconception period and during the time of organogenesis in early pregnancy, but the ADA recommends that hemoglobin A_{1c} be reduced to 1% or less above the normal range prior to conception, in order to reduce the risk of congenital malformations (49). In our center, we attempt to maintain fasting and 2-hour postprandial glucose levels, measured at least four times a day, at under 150 mg/dL during this time period. Although we strive for tighter glucose control later in pregnancy, the periconceptional period is of uncertain duration and hypoglycemic reactions appear to be more likely than that in the second half of pregnancy. Glycosylated hemoglobin levels are followed at 1- to 2-month intervals. Once they fall within 1% above the normal range for the method being employed, and glucose control appears to be stable, we inform the patient that it is reasonable to discontinue contraception and attempt pregnancy. Preconception care has been shown to be cost effective (50), and an outline of its contents has been published by the ADA (49,51).

Care During Early Pregnancy

Unfortunately, the majority of diabetic women do not present for care until after conception. Furthermore, most of those presenting when already pregnant are not in optimum metabolic control. Because organogenesis has been virtually completed by the 8th to 10th week after the last menstrual period (15), patients who register prior to this time may benefit from attempts to normalize glycemia as rapidly as possible. Often, this means a brief period of hospitalization. Patients who commence care after organogenesis has been completed will also benefit from near-normalization of circulating glucose levels, but the degree of urgency is less and outpatient management can usually accomplish the needed improvement in glycemia without unnecessarily interrupting the patient's life style.

If the patient has not had the benefit of preconception care, the baseline evaluation described earlier should be carried out at the time of the first visit in pregnancy. Patients with preexisting diabetes will benefit from a team approach to the

management of diabetic pregnancy, including physicians with special expertise in diabetes management and high-risk pregnancy management, as well as dietitians, nurse educators, social workers, and subspecialists as needed. Frequent contact with the health-care team is essential in order to respond to problems as they arise.

Blood Glucose Monitoring

Glycemic control can best be assessed by daily self blood glucose monitoring, using glucose oxidase-impregnated test strips and reflectance meters. There are a number of different approaches, including measuring fasting and preprandial glucose prior to each meal, 1-hour postprandial glucose measurements, and 2-hour postprandial measurements. In one study of gravidas with type 1 diabetes, postprandial glucose values were more predictive of fetal macrosomia than preprandial values (52). A randomized trial of preprandial versus postprandial glucose measurements in insulin-requiring gestational diabetic women demonstrated that preprandial measurements were more effective in preventing adverse outcomes (53). In our center, we advise our patients to measure glucose in the morning prior to breakfast and 2 hours after each meal, at a minimum. Depending upon the clinical circumstances, glucose may be measured at other times, including the middle of the night if the Somogyi effect or the “dawn phenomenon” is suspected (54).

Goals for metabolic control utilized in our center include the maintenance of fasting values below 95 mg/dL, 1-hour values below 130–140 mg/dL, and 2-hour postprandial values below 120 mg/dL, with glucose levels under 60 mg/dL being viewed as unnecessarily low. All pregnant patients with preexisting diabetes, and their significant support persons, should be familiar with the appropriate responses to hypoglycemia, including the use of glucagon injections. While hypoglycemia has not yet been demonstrated to be clearly harmful to the fetus, it carries risk enough for the mother that its frequency and severity should be minimized to the extent possible, compatible with the achievement of good metabolic control during pregnancy.

Insulin Management

A number of different approaches to insulin administration have been used successfully (55) during pregnancy. Rarely, if ever, does a single daily injection of intermediate-acting insulin suffice to establish and maintain near-normoglycemia. In our center, we tend to start with simpler regimens and increase the complexity if the need arises. Based upon the insulin secretion patterns of normal pregnant women in the third trimester (56), we begin with twice-daily injections of mixed intermediate- and short-acting insulins. The morning total dose, administered before breakfast, is twice the evening total dose, administered before dinner. The proportion of intermediate- to short-acting insulins is 2:1 in the morning and 1:1 in the evening (57). Once a patient has been started on this “split, mixed” regimen, the various doses can be adjusted to improve the appropriate glucose measurement. Many patients require the evening dose to be divided so that the intermediate insulin is given at bedtime to avoid morning hyperglycemia. Another approach is the use of short-acting insulin before each meal, with long-acting insulin given daily

at bedtime, or in the morning, or at both times. In some centers, the subcutaneous insulin infusion pump is used by pregnant women with diabetes, although a randomized trial has demonstrated no distinct advantage for this approach compared with intensive conventional therapy (58). The specific regimen is probably less important than the degree of familiarity, understanding, and comfort of both the caregiver and the patient.

A number of insulin analogs have come on the market. Insulin lispro and insulin aspart are short-acting insulins, with a more rapid onset of action than that of regular insulin. Each differs from natural human insulin by a single amino acid. They can be given immediately before a meal, which increases flexibility of lifestyle. Insulin lispro does not cross the placenta to any great extent (59), and insulin aspart appears to have similar properties (60,61). Insulin glargine and insulin detemir are long-acting insulins with at least 24 hours of duration of action. Their absorption curve appears to be flat with no peak, and so their use can mimic basal insulin production by the pancreas or that of a continuous subcutaneous insulin infusion pump. In isolated placental perfusion models, insulin glargine at therapeutic concentrations on the maternal side did not reach detectable levels in the fetus, and even at very high levels, the rate of transfer was low (62). No published studies regarding transplacental passage of insulin detemir were found. If long-acting insulin analogs are used in pregnancy, insulin glargine is preferred to insulin detemir at the present time.

Dietary Management

Approaches to dietary management of diabetic pregnancy have varied greatly over the years (63), and there is no single generally accepted dietary prescription. Research is ongoing as to the advisability of caloric restriction in obese women with type 2 diabetes in pregnancy, but there is concern about the possible adverse fetal effects of ketonemia induced by relative starvation (64). The ADA has published a set of recommendations for dietary management of diabetes during pregnancy that emphasize individualization of the prescription for medical nutrition therapy (65). The most important aspect of the diet is the consistency with which it is followed. Dietitians should take into account the ethnic and cultural food preferences of their patients.

Vascular Complications

Women with diabetes are at risk for a number of vascular complications, including nephropathy, retinopathy, neuropathy, coronary heart disease, and macrovascular disease. A detailed discussion of these specific problems is beyond the scope of the present chapter, but may be found elsewhere (66–68). It is not clear whether pregnancy has an independent effect on vascular complications of diabetes. Although one prospective study has demonstrated an independent effect of pregnancy on worsening retinopathy (69), it is possible that the adverse effect was due not to pregnancy itself, but to the rapid institution of tight metabolic control coincident with pregnancy. It is important that these complications be diagnosed and managed promptly and effectively even in the nonpregnant individual and appropriate care becomes even more important when pregnancy coexists. For example,

patients with diabetic nephropathy generally manifest increasing hypertension and almost invariably develop increasing proteinuria as pregnancy progresses (70). It may be exceedingly difficult to distinguish nephropathy from preeclampsia. In our center, the worsening of hypertension, or its new appearance, are considered grave complications in diabetic pregnancy and necessitate hospitalization and intensive monitoring of mother and fetus. While proliferative retinopathy does not pose a particular threat to the fetus, it poses a serious risk of maternal blindness. Laser photocoagulation is safe to perform during pregnancy and should be applied using the usual ophthalmologic indications.

Preexisting Diabetes—Obstetric Management

Obstetric and Neonatal Complications

In addition to perinatal mortality as described earlier, a number of obstetric complications occur with greater frequency in diabetic than nondiabetic pregnancies (14,71). Among these are hypertensive disorders, urinary tract infections, hydramnios, and preterm delivery. Particular care should be exercised in treating diabetic women with betamimetic agonist tocolysis and/or corticosteroids because of the possibility of severe hyperglycemia and ketoacidosis developing (72). Cesarean section is more common in diabetic pregnancies, and respiratory distress syndrome occurs with greater frequency at any given gestational age, possibly related to poor metabolic control. Neonatal hypoglycemia, plethora, jaundice, and hypocalcemia are also more common than in the offspring of nondiabetic mothers.

Fetal Surveillance

Because of the increased perinatal mortality and morbidity risks described above, a number of different modalities of fetal surveillance are brought to bear on diabetic pregnancy. The increased risk for congenital malformations, particularly in cases registering for care after pregnancy has been established and among those whose metabolic control is suboptimal, merits screening for birth defects. Maternal serum multiple marker testing is generally recommended in diabetic pregnancy. The laboratory performing the alpha-fetoprotein and other screening tests should be informed of the patient's diabetic status, as adjustments in interpretation are sometimes necessary. Furthermore, directed ultrasound examination is appropriate, particularly when metabolic control during organogenesis has been poor or undocumented, even in the presence of normal alpha-fetoprotein levels. Many of the major malformations can be diagnosed (73), and families can be offered options for the management of affected pregnancies.

Serial ultrasound examinations for fetal growth and amniotic fluid volume may be helpful during the third trimester. Antepartum testing is usually performed, but there is no agreement as to which test is ideal, what gestational age is appropriate for the commencement of testing, and with what frequency testing should be carried out (74). In our center, we use the modified biophysical profile (nonstress test plus amniotic fluid index) as our primary approach because of its simplicity of application. In patients with clear high risk for fetal death, such as those with vascular disease and known

growth restriction and oligohydramnios, we may commence testing as early as 24 to 26 weeks, although the danger of a false-positive test is magnified in such early gestations in which delivery has a high inherent perinatal mortality and morbidity risk. Patients with new or worsening hypertensive disorders likewise may be started on early testing. On the other hand, patients with excellent metabolic control and no other complications may delay the onset of testing until as late as 34 to 35 weeks, particularly if daily fetal movement determinations are made. We generally perform surveillance twice weekly or even more often, depending upon the circumstances.

Timing of Delivery

Although diabetic pregnancies formerly were routinely delivered as early as 4 to 6 weeks prior to term, owing to concern about the possibility of unanticipated fetal death, current surveillance practices have improved the identification of fetuses in jeopardy. In addition, improvements in metabolic control appear to be effective in preventing fetal death (75). Therefore, automatic early delivery is no longer necessary. However, it may be appropriate to deliver those patients whose metabolic control is poor or undocumented prior to term. In most cases, we await the spontaneous onset of labor. If the cervix is “ripe,” consideration may be given to inducing labor at 39 weeks or beyond in order to diminish the inconvenience and expense of continued testing, as well as the anxiety inherent in such high-risk pregnancies. This timing is based upon the increasing evidence that delivery prior to 39 weeks of gestation is associated with greater neonatal morbidity (76). In our center, we attempt to document pulmonary maturity by amniocentesis on those rare occasions when totally elective delivery by induction of labor or cesarean section is planned prior to 39 weeks, provided that the amniotic fluid is abundant and accessible (77). We have allowed diabetic pregnancies to proceed past 40 weeks, but only rarely.

Mode of Delivery

Maternal diabetes is not an indication for cesarean section, but its complications may be (78). Complications such as hypertensive disorders may require early delivery, increasing the likelihood of unsuccessful labor. Fetal macrosomia may also make cesarean section more likely. Problems such as shoulder dystocia appear to occur more frequently in diabetic pregnancies than in others. Although there is no general agreement on the subject, we tend to deliver by primary cesarean section without a trial of labor in cases of diabetic pregnancy in which the estimated fetal weight is 4500 g or more (78). If the estimate is between 4000 and 4499 g, we individualize the decision based upon past obstetric history, clinical pelvimetry, and events during labor. Unfortunately, our ability to estimate fetal weight by ultrasound is less than ideal, rendering any rigid protocol problematic.

Management of GDM

The maternal and fetal implications of GDM differ from those of preexisting diabetes only by degree. There has been controversy as to whether GDM should be treated at all. As recently as 2008, the U.S. Preventive Services Task Force stated that the evidence is insufficient to recommend for or

against the screening for GDM (79). However, a randomized trial of screening for and treatment of GDM has now demonstrated a benefit in terms of decreased perinatal mortality and morbidity (80). Furthermore, a randomized double-blind trial of intervention for mild GDM versus standard obstetric care also demonstrated a reduction in morbidity with identification and treatment (81). Glucose control is generally accomplished more easily in GDM, and many patients can be managed with dietary intervention alone. The recommendations of ACOG (39) are that fasting glucose values be maintained below 95 mg/dL and 2-hour postprandial values be below 120 mg/dL. Most women with GDM perform self glucose monitoring. In our center, each woman with GDM tests her blood glucose fasting and 2 hours after breakfast, lunch, and dinner. If the fasting values exceed 95 mg/dL or the postprandial value exceeds 120 mg/dL during the third trimester, insulin therapy is begun in a dose of 20 units NPH mixed with 10 units short acting insulin each morning prior to breakfast. A number of studies (52,82), including one randomized trial (53), have demonstrated that postprandial glucose measurements are better predictors of macrosomia and perinatal morbidity than are fasting or preprandial values.

Oral antidiabetic agents are gaining favor in the treatment of GDM. While first-generation sulfonylureas were originally considered to be contraindicated because of potential fetal effects, initial placental perfusion studies of glyburide, a second-generation sulfonylurea, demonstrated that very little reached the fetal circulation (83). Subsequently, a randomized trial of glyburide, in doses up to 20 mg/day, compared with insulin, in patients with GDM who required treatment, demonstrated similar outcomes in both groups (84). Following publication of this report, glyburide was increasingly utilized in patients with GDM. In June 2009, a report from the National Institute of Child Health & Human Development Obstetric-Fetal Pharmacology Research Units Network demonstrated that fetal levels of glyburide average 70% of maternal levels (85). Although no harmful effects of glyburide on the fetus have been demonstrated to date, little is known about the possible long-term effects of fetal exposure to a drug that increases pancreatic insulin secretion. Metformin is a biguanide insulin sensitizer, which was demonstrated to be similarly effective to insulin in a randomized trial among gestational diabetic women needing treatment (86). However, close to 50% of patients randomized to metformin required supplemental insulin to control their blood glucose levels. Of greater concern, metformin has been shown to cross the placenta to a significant degree (87). For these reasons, insulin remains the first-line drug for treating GDM when medical nutrition therapy is not effective enough. If oral agents are prescribed to pregnant women, there should be thorough counseling and documentation of the unknown risk of these drugs for the fetus.

Although there are data to suggest that women with uncomplicated diet treated GDM do not require fetal surveillance other than fetal movement determinations until term (88), in our center, we institute weekly nonstress testing at 36 weeks in order to avoid inadvertently missing gestational diabetic women with risk factors being discovered retrospectively. We prefer to document fetal pulmonary maturity prior to elective delivery at less than 39 weeks, as in preexisting diabetes.

It should be remembered that fetal macrosomia can complicate gestational diabetic pregnancy despite apparently near-normal blood glucose levels (27). A number of possible explanations exist, primarily centering around the likelihood that our definitions of “near-normoglycemia” are not really normal, but rather approximately two standard deviations above the mean. Various approaches to preventing macrosomia have been developed (89). One randomized trial (90) demonstrated that ultrasonographic demonstration of a large fetal abdominal circumference at 29 to 33 weeks could select fetuses that would benefit from maternal insulin therapy, decreasing the likelihood of neonatal macrosomia, even though the maternal fasting serum glucose level was below 105 mg/dL. A randomized trial (91) of induction versus expectant management at 38 weeks of gestation in women with insulin-treated GDM demonstrated similar cesarean section rates, but fewer large-for-date infants with induction of labor.

As mentioned early in this chapter, GDM is clearly a risk factor for the subsequent development of diabetes. For this reason, it is important that each patient with GDM be counseled to undergo a 75-g, 2-hour glucose tolerance test for the diagnosis of diabetes in the nonpregnant state at around the time of the 6-week postpartum checkup and ideally annually thereafter. Such women should attempt to avoid obesity as they mature. There is no reason to counsel women with GDM not to have further pregnancies, although they should be informed of the approximately 50% risk of recurrence.

17 Chronic hypertension and acute hypertensive crisis

William F. Rayburn and Lauren Plante

INTRODUCTION

Chronic hypertension occurs in up to 5% of pregnant women (1,2). Rates vary, however, according to the population studied and the criteria used for confirming the diagnosis. Terminology and criteria used to diagnose this complication can be confusing, as well as the benefit and potential harm of treatment during pregnancy. Chronic hypertension may result in maternal, fetal, or neonatal morbidity or mortality. These complications have significant economic impact, including costs of treating sick mothers and neonates and costs of intensive antenatal monitoring. The purposes of this chapter are to review the effects of chronic hypertension on pregnancy, clarify the terminology and criteria used to define and diagnose it during pregnancy, and review evidence about treatment options.

HYPERTENSION IN REPRODUCTIVE-AGE WOMEN

Young hypertensive women who are *not* pregnant are generally active individuals with increased sympathetic tone and elevated plasma renin activity. Extracellular fluid volumes are usually normal or decreased. More than 80% of hypertensive adults have primary or essential hypertension of unknown etiology, that is, without an identifiable cause (3). Most have mild hypertension, defined as a diastolic blood pressure of 90 to 104 mmHg.

Arguments have been made both for and against treating mild elevations of diastolic pressure in young adults. Antihypertensive therapy reduces morbidity and mortality from stroke, coronary artery disease, heart failure, and renal failure for all degrees of hypertension, but the benefit is modest for mild hypertension and is concentrated primarily on those with hypercholesterolemia, glucose intolerance, left ventricular hypertrophy, and cigarette smoking (4).

In the United States, nonpregnant patients with systolic pressure above 140 mmHg or diastolic pressures above 90 mmHg who have not responded to lifestyle modifications are considered to be the candidates for drug intervention. Current European recommendations for drug therapy suggest that both blood pressure and total cardiovascular risk be factored into the decision to begin pharmacotherapy (5). These specific cardiovascular risk factors include abdominal obesity, smoking, dyslipidemia, diabetes, or family history of premature cardiovascular disease.

In the past, a traditional “step-care” approach to pharmacologic treatment of hypertension involved the patient being first given a single commonly used drug such as a beta blocker, calcium channel antagonist, angiotensin-converting enzyme (ACE) inhibitor, or diuretic. The blood pressure response usually is consistent within a given class of agents; therefore, if a drug fails to control blood pressure, another agent from the same class is unlikely to be effective. At times, however, a

change within drug class may be useful in reducing adverse effects. The lowest possible effective dosage should be used to control blood pressure, adjusted every 1 to 3 months as needed. Many patients with stage 1 (mild) hypertension can attain adequate blood pressure control with single-drug therapy (3). The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial suggested that a diuretic was the best initial choice of agent for nonpregnant adults, being equally efficacious and less expensive than the alternatives (6).

When a second drug is needed, it can generally be chosen from among the other first-line agents. A diuretic should be added first, as doing so may enhance effectiveness of the first drug, yielding more than a simple additive effect (7). In considering a modification of therapy because of inadequate response to the current regimen, the physician should investigate other possible contributing factors. Poor patient compliance, use of antagonistic drugs (i.e., sympathomimetics, antidepressants, steroids, nonsteroidal anti-inflammatory drugs, caffeine, thyroid hormones, and cocaine), inappropriately high sodium intake, or increased alcohol consumption should be considered before antihypertensive drug therapy is modified (3).

Preconception Counseling and Early Prenatal Care

Generally, isolated elevated blood pressure or, less commonly, headaches are the only signs or symptoms in women with chronic hypertension. The history should seek to discover secondary causes of hypertension and note the presence of medications that can affect blood pressure (see above.)

Ideally, hypertensive women considering pregnancy should be counseled before conception. They should be informed of the potential for superimposed pre-eclampsia and worsening of renal disease or systemic illness. Valuable baseline data are provided from laboratory tests performed when hypertensive patients are first seen before conception or in early gestation. Tests to help identify target-organ damage and provide a baseline for assessing adverse effects of therapy would include the following: urinalysis, hematocrit, plasma glucose, serum potassium, serum creatinine, calcium uric acid, fasting serum cholesterol and triglyceride level, and electrocardiogram. Baseline determination of renal function (24-hour proteinuria and creatinine clearance), uric acid, transaminase levels, and platelet count are useful for comparison with values in later pregnancy to help determine if increases in blood pressure during pregnancy represent usual physiologic increases or the onset of pre-eclampsia.

Because of the risk of fetal growth restriction, an early sonogram for accurate dating is encouraged. Depending on the circumstance, other various specialized clinical tests at the initial visit may include echocardiography (for left ventricular

hypertrophy), ophthalmologic examination, and renal ultrasonography. Sleep apnea is increasingly recognized as a treatable cause of hypertension, and a screening questionnaire or sleep study may be appropriate.

Normotensive patients with intrinsic renal disease but minimal renal dysfunction usually do well in pregnancy (8). Women with significant renal disease (serum creatinine >1.4 mg/dL) may experience deterioration of renal function. Those with a serum creatinine >2.0 mg/dL and hypertension should be advised of a high incidence of superimposed pre-eclampsia, perinatal morbidity and mortality, and deteriorating renal function (8,9).

Many women with chronic hypertension are under the care of a primary care physician and already have been evaluated for causes of secondary hypertension, such as primary aldosteronism, pheochromocytoma, or Cushing's disease (3). Women with paroxysmal hypertension, frequent "hypertensive crisis," seizure disorders, or anxiety attacks should be evaluated for pheochromocytoma with measurements of 24-hour urine vanillylmandelic acid, metanephrines, or unconjugated catecholamines (10). Primary aldosteronism is rare in pregnancy, but may present with hypokalemia. Imaging studies (magnetic resonance imaging or computed tomography) may be helpful in demonstrating or localizing an adrenal tumor. Doppler flow studies or magnetic resonance angiography can reveal renal artery stenosis (3).

Nonpharmacologic Therapy

Borderline or mildly elevated blood pressures can often be controlled without medication. Diastolic blood pressures from 90 to 99 mmHg are not difficult to attain, because pressures fall during the first and second trimesters in most pregnant women (1). Lifestyle modifications should be encouraged in all hypertensive patients regardless of whether they require medication. These changes may have beneficial effects on other cardiovascular risk factors. Some standard methods of treating hypertension must be changed in pregnancy. For example, weight reduction is not encouraged during gestation, although it is advisable before pregnancy for those who are obese. Saturated fats, alcohol, and smoking should be avoided. Data are insufficient to routinely recommend additional dietary calcium supplementation for the treatment of pregnant women with chronic hypertension.

The severity of hypertension correlates with the extent of plasma volume contraction and that pregnant women with chronic hypertension have lower plasma volumes than normotensive women (11). Thus, sodium is generally not restricted during pregnancy, except for the rare pregnant woman with chronic hypertension who is salt sensitive or whose creatinine clearance is reduced.

Although exercise has not been sufficiently studied in hypertensive pregnant women, theoretic concerns exist about the role of uteroplacental blood flow in the pathogenesis of pre-eclampsia. Strict bed rest is seldom necessary, but despite a lack of formal research on the subject, rest is often prescribed to lower blood pressure and promote diuresis (1). Adjustments may be necessary in child care and employment.

We encourage patients to take their blood pressures outside the physician's office and keep a record of readings (12). Self-monitoring of blood pressure is often helpful in determining

whether borderline or mildly elevated blood pressures remain elevated at home or in the work setting and whether limitation of activity is necessary to better control the blood pressures. Adjustments of drug therapy or withdrawal are more plausible with the knowledge of frequent blood pressure recordings. The patient should have formal instruction on the correct technique for applying the appropriately sized cuff, measuring the blood pressures while sitting. The patient is also to be instructed to notify the office if the blood pressure rises significantly before the next scheduled visit.

Two readings should be taken, separated by 2 minutes. Systolic blood pressure should be noted with the appearance of Korotkoff sounds (phase I) and diastolic blood pressure with the disappearance of sounds (phase V). In certain patients, the Korotkoff sounds do not disappear but are present to 0 mmHg. In this case, the initial muffling of Korotkoff sounds (phase IV) should be taken as the diastolic blood pressure. In order to reduce inaccurate readings, an appropriately sized cuff should be used (length 1.5 times upper arm circumference or a cuff with a bladder that encircles 80% or more of the arm). The appropriate position in which to measure blood pressure is sitting, with the arm at the level of the heart. Measuring BP in the "up" arm with the patient side lying gives an artifactually lower reading, which does not represent a true decrease in BP.

Mild Chronic Hypertension

The goal of treating a pregnant woman with chronic hypertension is to reduce cardiovascular risks to the mother while avoiding compromise of fetal well-being (13). Since most pregnant women with chronic hypertension have only borderline or mild elevations in blood pressure, the risk of acute cardiovascular complication is extremely low.

Pharmacotherapy of mild hypertension at diastolic levels of 90 to 99 mmHg must be undertaken cautiously because of the possibilities that medication may reduce placental blood flow or cross the placenta to directly affect the fetus (1,13). Although the literature is conflicting, many obstetricians do not prescribe drugs for chronic hypertension in pregnancy unless the mother's blood pressure remains above 150/100 mmHg or her hypertension was well controlled by medication before the pregnancy (13). Clinical trials and experience have not shown whether long-term treatment of chronic hypertension prevents pre-eclampsia.

Pharmacologic management of chronic hypertension during pregnancy is too small to either prove or disprove moderate to large benefits (>20% improvements). A paucity of scientific data exists regarding the most appropriate management of women with well-controlled or mild hypertension already taking antihypertensive medications at the time of pregnancy. Although therapy may offer long-term benefits to the mother, such therapy is of unproven short-term benefit and could interfere with uteroplacental blood flow and fetal growth. In a meta-analysis of 623 women with mild chronic hypertension from seven trials comparing antihypertensives with no therapy, drug treatment was associated with a decrease in the incidence of severe hypertension but no improvement in perinatal outcomes (14).

A systematic review of chronic hypertension management during pregnancy revealed that this condition alone doubles

the risk for placental abruption (OR, 2.1; 95% CI, 1.1, 3.9) and triples the risk for perinatal mortality (OR, 3.4; 95% CI, 3.0, 3.7) (13). Several studies in this review demonstrated an association between chronic hypertension and pre-eclampsia (variously defined) and preterm, small-for-gestational age (SGA), or low-birth weight infants when compared with normotensive women or the general obstetric population. The risk of these complications was increased even in the absence of superimposed pre-eclampsia, although the absolute increased risk from mild hypertension could not be calculated (13). In the largest clinical trial, which demonstrated a reduction in perinatal deaths, most women took methyldopa beginning before or during the second trimester. In a review of 263 women with mild hypertension randomized to methyldopa, labetalol, or no treatment at 6 to 13 weeks of gestation, treatment with antihypertensive medications did not decrease the incidence of complications such as intrauterine growth restriction, superimposed pre-eclampsia, placental abruption, or perinatal mortality (13).

Data are inconclusive about the benefits and potential adverse fetal effects from treatment of mild chronic hypertension during pregnancy. It would seem reasonable to defer antihypertensive therapy in women with mild hypertension who become pregnant unless they have other complicating factors (e.g., cardiovascular or renal disease) and to either stop or reduce medication in women who are already taking antihypertensive therapy (1). Adjusting or withdrawing any drug therapy should be undertaken cautiously. A conservative approach is necessary to avoid excessive reductions or rises in blood pressure. As suggested by the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy, therapy could be increased or reinstated for women with blood pressures exceeding 150 to 160 mmHg systolic or 100 to 110 mmHg diastolic (15).

Since the evidence for the efficacy of antihypertensive treatment for mild hypertension during pregnancy is lacking, safety considerations are paramount for clinicians who elect to prescribe antihypertensive medication in this indication. The following areas have been suggested by Ferrer et al. for further research: (i) a better understanding of current practice, (ii) benefits and harms of commonly-used, unproven therapies to be tested in large collaborative multicenter and population-based studies among women with clearly established mild chronic hypertension, (iii) comparison between pharmacologic therapy begun early in the course of pregnancy with a placebo and commonly used alternative therapies, (iv) better surveillance systems that routinely monitor adverse events, and (v) large trials that compare alternative strategies and use clinically important outcomes to establish appropriate and cost-effective methods for monitoring (13).

DRUG THERAPY DURING PREGNANCY

Table 1 lists drugs commonly used to treat chronic hypertension before or during pregnancy (3). Standard oral dose regimens and adverse effects to mother and fetus are shown for each medication. The prescribing clinician should know the efficacy of at least a few of these drugs and their acute and long-range effects on fetal well-being.

Nearly all nonpregnant women can achieve adequate blood pressure control with many of these medications. Considerations

about safety during pregnancy are as important as the patient's hemodynamic status. Experience has shown that, except for the ACE inhibitors, the drugs currently prescribed do not alone pose any additional risk of perinatal morbidity or mortality. A detailed description of the different classes of antihypertensive drugs is presented elsewhere, but experience with their use during pregnancy is summarized below (3).

Centrally Acting Adrenergic Inhibitors

Methyldopa was the first antihypertensive used during pregnancy and remains the most commonly prescribed central adrenergic antagonist for pregnant women. Because of its long-term safety, methyldopa is considered by many authorities to be the initial drug of choice for pregnant women with chronic hypertension and the standard by which other drugs are measured (15). Long-term follow-up evaluations of outcomes are reassuring, and studies of children exposed in utero to methyldopa reported normal mental and physical development at 7¹/₂ years of age (16).

Beta-adrenergic Blocking Agents

Many women with chronic hypertension are treated with labetalol (an alpha and beta blocker) or a pure beta₁-adrenergic blocker (e.g., atenolol, metoprolol). Most studies of these drugs include relatively small numbers of cases with gestational ages at entry usually being at 29 to 33 weeks (17). Beta-blocking agents cross the placenta easily; they may interfere with interpretation of the fetal heart rate (FHR) pattern and, in theory, may compromise the fetus's ability to withstand hypoxic stress. A search for growth restriction is recommended after long-term exposure to beta blockers.

Labetalol causes a decrease in maternal blood pressure without diminishing blood flow through the fetal aorta, umbilical vein, or intervillous space (18,19). Based on experimental animal studies and human reports, labetalol therapy does not appear to increase the risk of congenital anomalies (20). This agent compares favorably with other antihypertensive medications for use during pregnancy.

In a meta-analysis of beta-receptor blockers prescribed for pregnancies complicated by hypertension, there was an increase in SGA infants born to those women who took oral beta blockers for mild hypertension (OR, 2.46; 95% CI, 1.02, 5.92) (21). In randomized trials comparing oral atenolol with metoprolol, no adverse fetal effects were demonstrated with either drug (22).

Calcium Channel Blockers

The most experience with calcium channel blockers has been during the second half of pregnancy as a treatment for hypertension or arrhythmias (23–26) or for tocolysis (27–29). Nifedipine, the best known calcium channel blocker, exerts a greater effect on vascular smooth muscle than on the myocardium (30,31). A review on 102 women who received oral nifedipine for tocolysis concluded that therapy appeared safe for mother and fetus (32). A human investigation that utilized Doppler ultrasound techniques to assess fetal and uteroplacental circulation did not uncover any significant effects after short-term nifedipine therapy (33). Oral nifedipine is rapid acting and has been used without complications; however, long-term trials of calcium channel blockers during

Table 1 Standard Oral Doses and Maternal and Fetal Adverse Effects of Antihypertensive Drugs

Drug	Initial oraldose (mg)(usual range)	Maternal adverse effects ^a	Fetal adverse effects
<i>Central adrenergic antagonists</i>			
Methyldopa	250 bid (250–2000)	Sedation, decreased mental acuity, fatigue, sodium retention, hepatic dysfunction, drug fever, positive antinuclear antibody Coombs test, hemolytic anemia, galactorrhea and postural hypotension	None reported
<i>Beta blocker agents</i>			
Metoprolol	50–100 (50–450)	Sodium retention, aggravation of heart failure, bradycardia, depression, aggravation of bronchoconstrictor disease, vivid dreams, interference of diabetic control, CNS disturbances (headache, tremulous)	Intrauterine growth retardation, hypoglycemia, respiratory depression, bradycardia
Atenolol	50 (25–100)		
Labetalol	100 bid (200–1200)		
<i>Vasodilators</i>			
Hydralazine	10 qid (30–300)	Tachycardia, palpitations, flushing, headache, sodium retention, aggravation of angina, lupus syndrome, neuropathy, dizziness	None reported on long-term use; fetal heart rate changes when given acutely at term
<i>Calcium channel blockers</i>			
Nifedipine	10 tid (30–120)	Palpations, flushing, headache, orthostatic hypotension	None reported but chance for reduced placental perfusion
<i>Diuretic</i>			
Hydrochlorothiazide	25 (12.5–50)	Decreased renal blood flow and cardiac output initially	None reported but chance for reduced placental perfusion
Furosemide	10–20 (20–320)	Electrolyte depletion, thrombocytopenia hyperuricemia	
^a Maternal adverse effects are usually dose dependent, and low doses are most commonly prescribed during pregnancy. <i>Abbreviation:</i> CNS, central nervous system.			

pregnancy are necessary (29). A comparison of nifedipine and atenolol reported no differences with either agent (34). Fetoplacental hemodynamics, birth weights, and Apgar scores were similar between the two groups.

ACE Inhibitors and Angiotensin II Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors, such as captopril and enalapril, are commonly prescribed to reproductive-age women. Side effects are minimal, and the drugs have considerable appeal for patients with renal disease. First-trimester effects were suggested by one study but have not been established (35). Women who inadvertently become pregnant on these medications can be switched to an alternative antihypertensive agent.

The U.S. Food and Drug Administration has issued a Public Health Advisory about ACE inhibitors in pregnancy. Use in the second and third trimesters is discouraged because of multiple risks to the fetus, including oligohydramnios, hypoplasia of the calvarium, possible death, and patent ductus arteriosus or anuria in the neonate. Hypoplasia of the fetal calvarium may result from uterine pressure, oligohydramnios, or decreased perfusion to the developing head (36). The teratogenic risk appears to be similar for the entire drug class (37).

Angiotensin receptor blockers are not used in pregnancy by extrapolation from the effects of ACE inhibitors.

Vasodilators

Hydralazine, a peripheral vasodilator, is ineffective when used orally as a sole agent (3). In pregnant women with chronic hypertension, it should be limited to use as a second- or third-line drug. Hydralazine is most often prescribed with methyldopa in treating preexisting hypertension in pregnancy. When hydralazine is combined with a beta-adrenergic blocking agent, reflex tachycardia is lessened and blood pressures are reduced.

It is considered safe for both mother and fetus, although one survey in Scandinavia reported fetal thrombocytopenia (38). Use of the parenteral form is discussed in the section on hypertensive crisis.

Diuretics

Diuretics reduce intravascular volume, and women who use diuretics from early in pregnancy do not develop the expanded blood volume normal in pregnancy (39). Based on experimental animal studies and human experience, hydrochlorothiazide use during pregnancy is not expected to

increase the risk of congenital malformations (37). Theoretically, use during pregnancy might produce fetal biochemical abnormalities and decreased uteroplacental perfusion, but these problems are not believed to occur in women treated chronically with thiazide diuretics beginning prior to conception.

A meta-analysis of nine randomized trials involving more than 7000 patients revealed a tendency toward less edema or hypertension with no increase in adverse fetal effects (40). The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy concluded, "If diuretics are indicated, they are safe and efficacious agents that can markedly potentiate the response to other antihypertensive agents and are not contraindicated in pregnancy except in settings in which uteroplacental perfusion is already reduced" (15).

Aspirin

Small doses of aspirin (60–100 mg) by women at high risk of pre-eclampsia may reduce the incidence of pregnancy-induced hypertension (41). Conclusions from a multinational study of more than 90,000 women indicated that low-dose aspirin begun before 20 weeks reduced fetal morbidity in a select population (42). These women had preexisting disorders, such as chronic hypertension or renal disease, or had developed pre-eclampsia before 32 weeks of gestation in a previous pregnancy.

No fetal complications attributable to the aspirin have been identified. Low-dose aspirin therapy during pregnancy does not alter fetal cardiovascular wave forms, decrease fetal urine excretion, or increase neonatal bleeding complications (43–45).

WORSENING HYPERTENSION

Risks to women with diastolic blood pressures of 100 mmHg or greater are sufficient to warrant drug therapy. Hospitalization is sometimes necessary. Methyldopa and labetalol are commonly the initial drugs of choice (46). If neither is successful or the patient does not tolerate it, reasonable alternatives are dual therapy, diuretics, or calcium channel blockers.

No evidence exists to show that antihypertensive therapy improves fetal well-being or reduces risks of placental abruption, disseminated intravascular coagulation, seizures, or other maternal complications: (15) with or without drug therapy, both fetus and mother should receive frequent assessments, with special alertness for signs of renal disease or superimposed pre-eclampsia.

It is often difficult, if not impossible, to distinguish worsening chronic hypertension from superimposed pre-eclampsia. The prevalence of superimposed pre-eclampsia averages 15% to 25% among women with chronic hypertension (1). Some studies have shown that infants of chronically hypertensive women who do not develop superimposed pre-eclampsia do as well as those born to normotensive women (1). *However, other studies reported higher perinatal loss rates in otherwise uncomplicated hypertensive pregnancies than those without hypertension.* Coexisting conditions such as renal disease, diabetes, and obesity also affect the risk of perinatal loss.

Signs of superimposed pre-eclampsia may mimic worsening primary renal disease. Conversely, pre-eclampsia may be disguised by pre-existing proteinuria or antihypertensive medications. Some investigators suggest that the diagnosis can be improved by monitoring for decreasing platelet counts and increasing serum uric acid levels. A sudden rise in blood pressure complicated by proteinuria or symptoms of central nervous system irritability should strongly raise the suspicion of superimposed pre-eclampsia. With either superimposed pre-eclampsia or eclampsia, the outlook for both infant and mother can be grave, unless the pregnancy is terminated.

INDICATIONS FOR DELIVERY

Delivery is recommended, even preterm, if superimposed pre-eclampsia develops, renal function deteriorates, severe fetal growth restriction is confirmed, or fetal compromise is suspected on biophysical assessment. The most common techniques of antepartum fetal surveillance are fetal movement counting, nonstress testing, and biophysical profiles. Daily fetal movement charting can begin early in the third trimester. Weekly FHR testing is typically recommended, beginning by the 32nd gestational week. Earlier or more intensive surveillance is probably appropriate if hypertension is more difficult to control or if placental insufficiency is suspected (47).

Serial ultrasound examinations to assess fetal growth are commonly recommended every 3 to 4 weeks during the second half of pregnancy. As long as the fetus continues to grow appropriately and the quantity of amniotic fluid is adequate, it can be inferred that placental function and uterine blood flow are adequate at that time. Oligohydramnios may signify less effective placental perfusion and is associated with umbilical cord compression before and during labor. Doppler assessment of the fetal arterial or venous system is often used as an adjunct.

Hospitalization is indicated when systolic and diastolic values are persistently above 170 and 110 mmHg respectively (despite medication adjustment), the clinician suspects superimposed pre-eclampsia or fetal growth restriction, or antenatal fetal surveillance warrants. Hospitalization allows for intensified maternal and fetal surveillance, for ancillary therapies such as antenatal steroids, and for additional consultation if needed. If maternal condition deteriorates rapidly or fetal compromise persists in the hospital, delivery is indicated. The predictive value of fetal surveillance testing may be invalidated by rapid changes in the maternal health. Evidence of reduced perfusion should be sought periodically in the brain, kidneys, liver, and placenta.

Fetal considerations often dictate the timing of delivery. The physician should reconsider delivery as soon as fetal lungs are documented mature, if control of blood pressure remains problematic, if fetal growth is suboptimal, or if maternal or fetal complications could be ameliorated by delivery. When delivery is anticipated before 34 weeks, corticosteroids are to be given to enhance fetal lung maturity if the mother's condition is stable, and delivery can be delayed at least 24 hours (48). Amniocentesis may be done if determination of pulmonary maturity would influence decision-making.

Whether these plans of action improve perinatal outcome is unclear. Despite good intentions, the approach toward

delivering a very premature but surviving perinate who requires intensive care and faces the attendant risk of long-range developmental disability is open to debate. Such an approach is probably best attempted at tertiary care centers staffed by specialized personnel.

INTRAPARTUM CARE

Vaginal delivery is preferable to cesarean delivery, regardless of gestational age. If the condition permits, an induction of labor should be attempted regardless of cervical condition. A clear endpoint is encouraged from the onset, with delivery usually being expedited within 24 to 48 hours after the decision to induce labor (49). If vaginal delivery cannot be effected within a reasonable time, a cesarean may be preferable. Regional anesthesia is preferred to general anesthesia because of the risk of provoking uncontrolled hypertension when the airway is instrumented.

Although intrapartum analgesia with narcotics may be used, attempting to manage or prevent eclampsia with profound maternal sedation is dangerous and ineffective. Epidural anesthesia is permissible when an experienced anesthesiologist is available and no coagulopathies are present. Hazards include the possibility of extensive symptholysis with resultant decreased cardiac output, maternal hypotension, and impairment of an already compromised uteroplacental perfusion (1). The advantage, of course, is that epidural anesthesia blunts the sympathetic response to pain, which may be exaggerated in women with preexisting hypertension. Women with chronic hypertension complicated by significant cardiovascular or renal disease require special attention to intake and urine output, because they may be susceptible to fluid overload with resultant pulmonary edema.

POSTPARTUM CONSIDERATIONS

Acute hypertensive changes usually dissipate within the first few days after delivery. The likelihood of underlying chronic hypertension is greatly increased if hypertension persists more than 3 days after delivery. In such cases, oral antihypertensive therapy is often begun before discharge and the women are reevaluated in the next week. Hypertension that persists longer than the postpartum period (12 weeks post delivery) is classified as chronic (1).

Reinstituting the prepregnancy regimen treatment is often appropriate for women who were previously well controlled. As an alternative, either oral nifedipine or labetalol is commonly prescribed, using the lower doses shown in Table 1. Self-blood pressure monitoring at home or work is helpful in determining the need to continue any antihypertensive agent. If prepregnancy blood pressures were normal or unknown, it is reasonable to stop medications after 3 to 4 weeks and observe.

Many chronically hypertensive women wish to breastfeed. When hypertension is mild, medication may be withheld and the blood pressure should be observed closely. For a breastfeeding mother with more elevated recordings, the clinician should continue drug therapy at the lowest effective dose. All agents have low but measurable amounts in the milk, and no clinical trials have studied the cardiovascular effects of an antihypertensive agent on the breast-fed infant (50). Most antihypertensive drugs, including ACE inhibitors, are

considered “compatible with breastfeeding” by the American Academy of Pediatrics.

Postpartum contraception is advisable to reduce the risk of an unplanned pregnancy. Oral contraceptives, depot medroxyprogesterone acetate (Depo Provera), and other hormonal contraception are not contraindicated in chronically hypertensive patients who are under 35 and do not smoke, as long as the blood pressure is controlled and monitored (51).

HYPERTENSIVE CRISIS

Hypertensive emergencies still occur, albeit less frequently: in the years before the availability of antihypertensive drugs, 7% of individuals with hypertension could expect to develop a hypertensive emergency (with an associated 1-year mortality risk nearly 80%); the figure is now 1% to 2% (52,53). Most patients who develop a hypertensive crisis have a history of hypertension, often inadequately treated. This may not be the case in pregnancy, however, where hypertensive crisis may manifest against a background of either chronic hypertension or pre-eclampsia.

Incidence and Definition

Hypertensive crisis can occur at any time before or after delivery. There are no reliable data on the incidence of hypertensive crisis complicating pregnancy. A query of the National Hospital Discharge Survey for severe maternal morbidity included 50 million deliveries and reported 36,000 cases of eclampsia and 6000 cerebrovascular accidents in the United States across the time period from 1991 to 2003 (54). This excludes those pregnant women whose hypertensive crisis did not result in one of those diagnoses, but it would appear that in the United States at least 3500 women per year develop a hypertensive crisis during pregnancy, which is roughly 1 per 1000 live births. Figures from Canada appear to be about half of that (55).

The clinical entity of hypertensive crisis is poorly defined, but this term has replaced earlier terms such as “malignant hypertension” and “accelerated hypertension.” While it seems intuitively obvious that it refers to a state of severe hypertension, there is no consensus as to the degree of hypertension involved. The Joint National Committee (JNC) on Detection, Evaluation, and Treatment of High Blood Pressure (JNC) reports of 1993 and 1997 divided acute severe hypertension into categories of “hypertensive emergency” and “hypertensive urgency” (56,57). The distinction between the two related not to blood pressure measurement but to the presence of end-organ damage. The most recent iteration, JNC 7, does not address hypertensive emergency specifically but refers to stage 1 (systolic BP 140–159 mmHg or diastolic 90–99 mmHg) and stage 2 (systolic \geq 160 mmHg or diastolic \geq 100 mmHg) hypertension, largely for the purposes of initiating outpatient drug therapy (7). JNC 8 is scheduled for release in 2010 and may redress this flaw (58).

Pathophysiology

The pathophysiology of hypertensive crisis is still inadequately understood. Because blood pressure is determined by cardiac output and peripheral vascular resistance, and cardiac output itself is a product of heart rate and stroke volume, there are several possible triggers, but it appears that an abrupt increase

in systemic vascular resistance is most commonly involved (53). Mechanical stress causes vascular endothelial damage, which in turn provokes increased permeability, activation of the coagulation cascade, and fibrin deposition. Fibrinoid necrosis of the arterioles can further decrease vascular perfusion and thus activate the mediators commonly associated with ischemia, further worsening injury. In many (but not all) hypertensive crises, the renin–angiotensin system is activated, forcing further vasoconstriction and production of inflammatory cytokines (59). Because of pressure natriuresis, effective circulating volume is decreased: this stimulates the kidney to produce vasoconstrictive mediators. A feed-forward loop or vicious circle becomes difficult to break.

Hypertensive Crisis: Emergency Vs. Urgency

Individuals with systolic blood pressure ≥ 180 mmHg, or diastolic ≥ 110 mmHg, are commonly considered to be in a state of hypertensive crisis (53). If evidence exists for acute target-organ involvement (Table 2), then pressures must emergently be reduced, within the next 1 to 2 hours, to limit damage or prevent further organ failure: this qualifies as a hypertensive *emergency*. In the absence of end-organ findings, while it is certainly prudent to begin measures to lower blood pressures, the process can be allowed to take 24 hours or longer, and the situation is hypertensive *urgency*.

This cutoff point, admittedly arbitrary, is even less well defended in the case of hypertension in pregnancy. Current guidelines from the American College of Obstetricians and Gynecologists allow a diagnosis of severe pre-eclampsia if a systolic pressure of ≥ 160 mmHg is achieved or any of the criteria in Table 3 is met (60). Comparing these with the standard list of clinical syndromes, which defines hypertensive emergency, CNS findings, pulmonary edema, and thrombocytopenia or microangiopathic hemolytic anemia are common to both. Martin et al. have suggested that systolic blood pressure in pre-eclampsia is far more important than diastolic and reported that in 96% cases of stroke related to pre-eclampsia, systolic pressure was greater than 160 mmHg immediately preceding the event (61).

While nonpregnant patients with hypertensive crisis most commonly present to emergency care with symptoms related to target-organ involvement, this may not be true for pregnant patients, who have many interactions with the health-care system during pregnancy. The pregnant patient with hypertensive crisis (e.g., hypertensive urgency rather than emergency) may be asymptomatic and be admitted for evaluation after hypertension is noted in the office. As a rule, the patient with abnormally high blood pressure but no signs or symptoms of target-organ damage is considered to have a hypertensive *urgency* rather than *emergency*. Unlike true hypertensive emergency, hypertensive urgency allows 24 to 48 hours to normalize blood pressure: oral agents are acceptable. It is prudent to lower mean arterial pressure gradually so that the limits of autoregulation are not exceeded.

Initial Evaluation and Management

If a hypertensive crisis is suspected, then diagnosis, assessment, and therapy should proceed at equal pace. In the setting of hypertensive emergency, speed of intervention is important in limiting complications. A history should be obtained, focusing

Table 2 Hypertensive Emergency: Organ System and Clinical Manifestation

Cerebral	Hypertensive encephalopathy Stroke
Cardiovascular	Acute aortic dissection Acute myocardial infarction Acute left ventricular failure
Renal	Acute renal failure
Hematologic	Microangiopathic hemolytic anemia
Placental	Severe pre-eclampsia (?) Eclampsia HELLP syndrome
<i>Abbreviation:</i> HELLP, hemolysis, elevated liver enzymes, and low platelet count.	

Table 3 Criteria for Diagnosis of Severe Pre-eclampsia (One or More of the Following)

BP ≥ 160 mmHg systolic <i>or</i> ≥ 110 diastolic (two occasions, at least 6 hr apart)
Proteinuria ≥ 5 g in 24 hr
Oliguria (<500 ml in 24 hr)
Cerebral or visual disturbances
Pulmonary edema or cyanosis
Epigastric or right upper quadrant pain
Impaired liver function
Thrombocytopenia
Fetal growth restriction

on any known history of hypertension, medications (prescribed, over-the-counter, and illicit), obstetric history, and symptoms. Blood pressure should be measured in each arm, with the patient sitting, using the correctly sized cuff. The remainder of the physical examination should incorporate assessment for pulmonary edema, peripheral pulses, and neurologic evaluation. In the nonpregnant patient with hypertensive crisis, fundoscopic examination of the retinas and auscultation of the flanks for bruits in the renal arteries are recommended as well (53), but in the hands of an obstetrician–gynecologist inexperienced in these examinations, they are likely to be of low yield.

Blood should be sent for electrolytes, blood urea nitrogen, serum creatinine, hepatic function, complete blood count, and coagulation profile. If a specific concern exists (illicit drug use, pheochromocytoma), additional laboratory testing should be ordered as relevant. Fetal assessment is important. Fetal cardiac activity should be confirmed or excluded immediately upon admission. Ultrasound assessment for fetal growth, amniotic fluid, Doppler, and the like should be deferred until after the maternal condition is stabilized. The utility of electronic fetal monitoring is discussed below.

Once diagnosed with a hypertensive *emergency* (abnormally high BP plus evidence of target-organ damage), the patient must be treated immediately with the goal of reducing BP within 1 to 2 hours. This will require parenteral medication and high-acuity nursing care. It will often require minute-to-minute evaluation, so the threshold for intra-arterial monitoring should be low. There are no good clinical trials that could

Table 4 Drug Therapy for Acute Hypertensive Crisis

Drug	Drug classification	FDA pregnancy category	Dose (initial)	Dose adjustment	Onset	Duration	Side effect profile	Notes
Clevidipine	Calcium channel blocker (dihydropyridine)	C	1–2 mg/hr iv infusion	Initially, double dose q 90 sec; as target BP approached, lengthen interval to 5–10 min, decrease to less than doubling, based on patient response; max 16 mg/hr	2–4 min	5–15 min after stopping infusion	Atrial fibrillation, nausea, headache, tachycardia	Lipid emulsion; cannot use if allergic to soy or eggs; adverse effects on lipid profile
Enalaprilat	Angiotensin-converting enzyme inhibitor	C (first trimester)	1.25 mg iv	Repeat q 6 hr, max 5 mg			Nausea, vomiting, headache	
Esmolol	Beta ₁ blocker	C	500 mcg/kg/min load over 1 minute, followed by 50 mcg/kg/min × 4 min	May repeat loading dose (500 mcg/kg/min), then increase infusion rate by 50 mcg/kg/min, q 5 min; as target approached, lengthen interval or decrease increment	Immediate	<10 min	Bradycardia, injection site pain, nausea	Metabolized by red blood cell esterases; independent of hepatic or renal function
Fenoldopam	Dopamine (D1) receptor agonist	B	No bolus dose; begin infusion at 0.03–0.1 mcg/kg/min	Increase q 15 min by 0.05–0.1 mcg/kg/min, max dose 1.6 mcg/kg/min		5 min	Flushing, nausea, headache, tachyarrhythmia	
Hydralazine	Peripheral vasodilator (arteriolar)	C	5 mg IV bolus	10 mg, 20 mg	15–20 min	3–6 hr	Tachyarrhythmia, headache, nausea, dyspnea	Rarely: hepatotoxicity, lupus. Promotes salt/water retention. Tachyphylaxis common
Ketanserin	Serotonin receptor blocker	n/a	5–10 mg IV bolus followed by 4 mg/hr	Repeat bolus, increase infusion rate by 2 mg/hr; dose may be adjusted at 20-min intervals, max infusion rate 14 mg/hr	10–20 min	13–16 hr	May inhibit uterine contractions. Failure rate appears to be high. Q–T prolongation	Not FDA approved; used in Europe, South Africa

Labetalol	Mixed alpha and beta blocker (beta predominates, 7:1)	C	10–20 mg IV bolus	Repeat q 5–10 min, doubling the dose to max bolus 80 mg. Continuous infusion 1–2 mg/min is an alternate to bolus dosing	2–5 min	3–6 hr	Bradycardia, dizziness, GI effects, abnormal liver function, hypoglycemia	
Nicardipine	Calcium channel blocker (dihydropyridine)	C	Initial rate 5 mg/hr	Increase rate by 2.5 mg/hr q 5–15 min; max 15 mg/hr	5–10 min	1–4 hr	Tachycardia, dizziness, headache, edema	
Nitroglycerin	Nitrate, vasodilator (venous and arteriolar)	C	Initial rate 5 mcg/min	Increase rate by 5 mcg/min q 3–5 min, max 100 mcg/min	2–5 min	3–5 min	Tachyarrhythmia, headache, nausea, dizziness, visual disturbance; rare hematologic	
Sodium nitroprusside	Vasodilator (venous and arteriolar)	C	No bolus; begin at 0.2–0.3 mcg/kg/min	Increase by 0.2–0.5 mcg/kg/min (q 5 min) to usual max 2 mcg/kg/min; rarely as high as 5 mcg/kg/min. Use lowest dose possible, shortest time possible	Instant	~1 min	Bradyarrhythmia, tachyarrhythmia, rash, sweating, dizziness, headache, altered mental status, restlessness, azotemia	Metabolic acidosis, cyanide toxicity, thiocyanate toxicity. Therapeutic and toxic ranges may overlap. No quick lab test for cyanide level exists
Phentolamine	Alpha blocker	C	1–5 mg iv bolus		1–2 min	5–15 min	Dysrhythmia, nasal congestion	
Trimethaphan	Ganglionic blocker	D	Initial rate 0.5–1 mg/min	Increase by 0.5–1 mg/min, max 15 mg/min	1–5 min	10 min	Tachyarrhythmia, hyperglycemia, hypokalemia, GI symptoms, diplopia, pupillary dilation, paralytic ileus, urinary retention	

form the basis for the management of hypertensive emergencies, let alone hypertensive emergencies in the setting of pregnancy. Management as currently recommended is driven largely by expert and consensus opinion. Given these caveats, the recommendation is to aim for a reduction in mean arterial pressure of 15% to 25% over 1 to 2 hours (53,62,63). While the presence of symptoms is a clear indicator that blood pressure is dangerously high, a too-rapid or too-acute lowering risks worsening the ischemia, which already accompanies hypertensive crisis and may exceed the threshold of autoregulation, particularly in the cerebral circulation. At this time, it seems appropriate to remark upon the sensitivity of the uteroplacental circulation to perfusion pressure and to note that an exaggerated drop in blood pressure is frequently reflected in decelerations in the FHR tracing.

Drug Therapy

The ideal agent for use would be easily administered, have a rapid time to both onset and offset, be easily titratable, free of side effects, and well tested in pregnancy. Unfortunately, none of the agents currently available meet these criteria. Hydralazine and labetalol are the drugs most commonly used in obstetrics for hypertensive crises. Hydralazine, contrary to popularly held opinion, has a number of factors that render it unsuitable in the setting of hypertensive crisis (53). Its onset of action can be delayed by as long as 20 minutes after bolus injection, its effect is unpredictable (especially in the common scenario of volume depletion), and its duration is unacceptably long (up to 6 hours). It has been shown in a meta-analysis to produce far higher rates of maternal hypotension than other antihypertensives, more adverse effects on the FHR, and more maternal side effects: these side effects are commonly headache and nausea, which are easily confused with deterioration of the clinical condition (64). While labetalol shares with hydralazine a long duration of effect, the response to labetalol is typically seen within 5 minutes, so the risk of overshoot is lower.

Other drugs that have been used to treat hypertensive crisis include sodium nitroprusside, nitroglycerin, nicardipine, esmolol, clevidipine, fenoldopam, phentolamine, trimethaphan, enalaprilat, ketanserin, and diazoxide (Table 4). Because of their immediate effects, they are best given when the patient has an arterial line in place. Most of these are given by continuous infusion and must be titrated to effect. Depending on local protocol, the use of vasoactive infusions may require the patient be admitted to an intensive care unit. The intravenous form of diazoxide is no longer manufactured, and so it is of historical interest only. Enalaprilat has occasionally been used for hypertensive crisis in nonpregnant patients, but like all ACE inhibitors, it should not be used in pregnancy.

Data in pregnancy are limited for most of these drugs: nicardipine, nitroglycerin, sodium nitroprusside, and esmolol have been reported. Nicardipine is developing a track record in pregnancy. It has been used successfully as a second-line treatment for pre-eclampsia after failure of ketanserin, labetalol, or hydralazine (65). In a small randomized trial, intravenous nicardipine was just as efficacious as labetalol for controlling blood pressure in hypertensive emergency during pregnancy (66). It has definite advantages over hydralazine, being a more predictable and titratable drug, with a much shorter time to onset and quicker disappearance once discontinued.

Trimethaphan and phentolamine have largely been replaced by other drugs of better efficacy and greater predictability, and ketanserin is not available in the United States. There are, as yet, no data on fenoldopam or clevidipine in pregnancy.

Whichever drug is chosen, the goal is to reduce mean arterial pressure by 15% to 25% within 1 to 2 hours and then gradually lower BP into the range of 160/100 over the next 2 to 6 hours (67). During this period of time, judicious volume repletion should also occur, since the majority of patients in hypertensive crisis will be significantly volume depleted because of pressure natriuresis. Precipitating factors should be corrected if identified (i.e., conditions of catecholamine excess, drugs that may contribute to hypertension, etc.). The FHR should be monitored both as a sign of uteroplacental perfusion and as a sign of fetal status: placental abruption is an ongoing concern in severe hypertension, and fetal growth restriction, a common complication of pre-eclampsia, signifies a tenuous fetal status that may require intervention. It is inappropriate, however, to rush to delivery before maternal status is stabilized. In cases in which fetal compromise is thought to exist, if delivery is contemplated, it will usually be by cesarean, and both anesthesia and surgery entail risks in the unstable patient. Stroke is an especially feared complication when a patient with inadequately controlled hypertension requires laryngoscopy and intubation for a general anesthetic.

Once blood pressure control has been achieved with parenteral agents, oral medications can generally be started while the parenteral drug is being tapered (68). However, in case of pregnancy, hypertensive crisis often means a commitment to delivery. Absorption of oral medications may be unpredictable in labor, and is not feasible during abdominal surgery, and therefore the plan is often to defer oral agents until after delivery, whether vaginal or cesarean. Oral agents should be started at a low dose and increased as necessary to the desired effect. Agents that have been used in pregnancy include nifedipine, clonidine, and labetalol; postpartum, the ACE inhibitors can also be used. There is no good role for methyldopa or oral hydralazine as a follow-up agent after hypertensive crisis in pregnancy, because adequate blood pressure control is crucial in preventing another episode.

18 Rheumatologic diseases and antiphospholipid syndrome

Thomas J. Santoro, Michiyo Tomita, and Alfonse T. Masi

Rheumatic diseases and associated autoimmune phenomena occur frequently in women of childbearing age (1). Many of these disorders occur in women who are pregnant or desire to become so. In pregnancy, complications arising from coexisting autoimmune diseases may be minor (e.g., exacerbations of low back pain in women with HLA-B27-related spondyloarthropathy syndromes) or life-threatening [e.g., progressive glomerulonephropathy, in patients with flare of renal involvement from systemic lupus erythematosus (SLE) or systemic sclerosis (SSc), or serious pregnancy-related thromboembolic events in patients with antiphospholipid (aPL) syndromes (APS)] (2–4).

GENERAL CONSIDERATIONS

Strategies for managing certain of these patients are controversial. Although all pregnancies in women with diffuse connective tissue disorders (CTDs), e.g., SLE or SSc, should be considered high risk, little effect from pregnancy may occur in such patients with remitted or mild disease. The obstetrician and internist/rheumatologist team should construct a well-planned assessment and management strategy in anticipation of pregnancy in the setting of autoimmunity. The plan should be aimed at

1. surveillance for disease activity,
2. provision of fully adequate therapy for maternal disease, and
3. assessment of fetal growth and well-being.

Diligent search for indications of maternal or fetal compromise is required, if prompt and effective therapy is to be provided.

Management decisions should consider both the effects of pregnancy on maternal disease and the effects of the disease on the developing fetus. Active management of the pregnancy might include

1. monitored progression to delivery (5),
2. interruption by early delivery and immediate specialized neonatal care (6), or
3. therapeutic abortion, if maternal survival is jeopardized.

The optimal goal is to attain a healthy term outcome for both mother and baby.

EFFECTS OF ANTIRHEUMATIC MEDICATIONS ON THE FETUS AND PREGNANCY

Ethical considerations mandate that most of the information that is used to assess the relative risk of maternal use of a drug on the viability of a pregnancy and/or fetus is based on developmental toxicity and reproductive studies done in animal models. The results of such studies may contribute

significantly to placing a drug in U.S. Food and Drug Administration Pregnancy Category A, B, C, D, or X. Such classification exists despite the fact that extrapolating data derived from teratogenicity studies done in animals to the human situation frequently requires assumptions that may not, in certain cases, be entirely valid. “Hard” human pregnancy safety data are available for only approximately 20% of the drugs currently marketed in the United States (7). With these limitations in mind, this section will provide a summary of our current understanding of the risks associated with the use of the more common antirheumatic drugs (i.e., anti-inflammatory agents, corticosteroids, small molecules, and biologics) in the setting of pregnancy.

Nonsteroidal Anti-inflammatory Agents (reviewed in ref. (8))

Nonsteroidal anti-inflammatory agents (NSAIDs), such as celecoxib, diclofenac, and ketorolac, are FDA category C drugs. This category derives from animal reproduction studies in which an adverse effect was shown on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant the use of the drug in pregnant women despite potential risks. However, all other NSAIDs, including ibuprofen, are category B drugs. For these drugs, animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women. The D category drugs have shown positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans. However, potential benefits may warrant the use of the drug in pregnant women despite potential risks.

Results from a number of studies have indicated that NSAIDs may, although rarely, be associated with congenital malformations (9,10) and, possibly, increase the risk of spontaneous abortions (11,12). These untoward effects discourage the use of NSAIDs during the third trimester and just prior to delivery (10). Whether maternal use of selective cyclooxygenase (COX) inhibitors such as celecoxib reduces the potential risk of congenital defects in the fetus compared with NSAIDs that target both COX-1 and COX-2 is currently unclear.

Glucocorticoids

Fetal regulation of glucocorticoid exposure is achieved by the placental glucocorticoid “barrier,” which involves glucocorticoid inactivation within the labyrinth zone by 11-beta-hydroxysteroid dehydrogenase 2 (11beta-HSD2) (13). Data from Murphy et al. (14) indicate that placental 11beta-HSD2 also has the capacity to metabolize a number of synthetic corticosteroids, including beclomethasone dipropionate, betamethasone, dexamethasone, and prednisolone, but not others, such as budesonide and fluticasone propionate. In a

series of 34 pregnancies in 30 women, prednisolone use was associated with increased placental insufficiency, fetal distress, and/or stillbirths (15). Overall, however, the available data suggest that the risk associated with prenatal exposure to corticosteroids, although real, is relatively small.

Small Molecules (Slow-Acting Antirheumatic Drugs; Disease-Modifying Agents)

Among the commonly used slow-acting antirheumatic drugs (SAARDs), or small molecules, methotrexate and leflunomide have been classified as FDA pregnancy category X drugs. Animal or human studies of these drugs have demonstrated fetal abnormalities and/or investigational or marketing data have indicated human fetal risk. The risk involved in use of these drugs in pregnancy clearly outweighs the potential benefits.

Methotrexate is considered the “anchor” drug in the treatment of rheumatoid arthritis (RA). It is an abortifacient (16) that may induce a pattern of congenital abnormalities, referred to as the fetal aminopterin/methotrexate syndrome (17). This condition consists of growth retardation, and craniofacial, limb, and neurologic developmental anomalies, which may be dose dependent. In planning conception, it is important to realize that it takes approximately 20 weeks for cell-associated methotrexate to become undetectable (18). In contrast to methotrexate, there are minimal data on the effects of leflunomide on human pregnancy, and the FDA’s pregnancy category X classification of this small molecule is largely based on the drug’s known inhibitory effects on transcription and translation (19) and its demonstrated teratogenicity and embryotoxicity in animal reproductive studies. Women who become pregnant while undergoing treatment with leflunomide are advised to reduce fetal exposure to the drug by undergoing cholestyramine elimination procedure. In a study of 64 pregnant women with RA who were treated with leflunomide during pregnancy (61 of whom received cholestyramine), no increase in adverse pregnancy outcomes was found relative to 108 pregnant women with RA not treated with leflunomide and 78 healthy pregnant women (20).

The antimalarial, hydroxychloroquine, a pregnancy category C drug, has not been associated with growth or developmental abnormalities. However, it has known potential untoward effects of retinal or ototoxicity following maternal exposure to the drug in the first trimester for the treatment of a variety of connective tissue diseases (21,22). In a randomized, controlled trial of nonpregnant lupus patients, discontinuation of hydroxychloroquine doubled the risk of an SLE flare within the subsequent 6 months (23). Taken together, the data suggest that hydroxychloroquine use in pregnant patients with connective tissue diseases is relatively safe, although not without risk. It may be prudent to continue such therapy in some SLE patients who unexpectedly become pregnant.

D-penicillamine traverses the placental barrier and can probably decrease molecular cross-linking of collagen in the fetus. Two reports describe congenital cutis laxa and associated connective tissue birth defects, probably due to D-penicillamine treatment during pregnancy (24,25). Discontinuation of

this drug is recommended prior to conception as well as during pregnancy and lactation (26,27).

Sulfasalazine is FDA approved for the treatment of RA. Isolated case reports of fetal malformations exist in the setting of maternal sulfasalazine use (28). However, a population-based case-control study (29) together with two observational studies (30,31) revealed no evidence of teratogenicity in the offspring of pregnant women with inflammatory bowel disease who had been treated with sulfasalazine. Similarly, no increase in the rate of birth defects compared with the general population was found in two more recent studies when sulfasalazine was used during pregnancy (29,32). Accordingly, sulfasalazine enjoys an FDA pregnancy category B classification. If used in a pregnant patient with an autoimmune disease (e.g., RA), it should be administered with folic acid supplementation, since this drug impairs folate absorption and metabolism (29,32).

Immunosuppressive Agents

Chlorambucil and cyclophosphamide are FDA pregnancy category D drugs. They should be discontinued during pregnancy and lactation based on their teratogenic potential (33,34). Mycophenolate mofetil is used in the treatment of lupus and in refractory RA. Although initially given pregnancy category C status, use of this drug has been associated with recurrent pregnancy loss and congenital malformations and it is now classified as a category D drug (available from: <http://www.fda.gov/downloads/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm093675.pdf>). Cyclosporin A is FDA approved for the treatment of RA and is used as an immunosuppressive agent in a variety of other autoimmune diseases as well. Based on the transplantation literature, the observed rate of birth defects and neonatal deaths after cyclosporine A treatment in doses of 2.5 to 5 mg/kg/day during pregnancy does not exceed that seen in the general population (35,36).

Azathioprine was not infrequently employed in the treatment of refractory RA prior to the widespread use of biologics. Azathioprine is currently used in the treatment of pregnant patients with active SLE, where toxicity concerns for the fetus obviate the use of cyclophosphamide. Solid evidence linking congenital abnormalities to azathioprine and its more active metabolite, 6-mercaptopurine (6-MP), does not exist (16,37,38). In this connection, a recent study showed no increase in the rate of birth defects in 160 children of women who were exposed to azathioprine in doses of 50 to 100 mg/day (39). This notwithstanding, it is prudent to discontinue the use of azathioprine, 6-MP, or cyclosporine A prior to conception and to avoid the use of these drugs during pregnancy, if possible, especially in the first trimester and during lactation (16,37,38).

Biologics

Inhibitors of tumor necrosis factor- α (TNF- α) have become a mainstay in the treatment of aggressive and refractory RA. Over 300 women have been exposed to the anti-TNF- α agents, infliximab, etanercept, and adalimumab during pregnancy, most during the first trimester (40). Approximately 10% of such women were treated with TNF- α inhibitors throughout pregnancy. Overall, the numbers are

too small to draw definitive conclusions. Two prospective controlled studies have shown comparable rates of malformation and miscarriage rates in women treated or not with anti-TNF- α agents (41). However, the monoclonal anti-TNF- α agents (infliximab, adalimumab) do not cross the placenta and achieve significant plasma level in cord blood (42), and the role of TNF- α in embryogenesis remains incompletely understood. As of 2005, 61 congenital anomalies in 41 children born to mothers taking TNF- α inhibitors have been reported to the FDA (43). The data provided by the FDA do not permit drawing a conclusion of the actual rate of birth defects with the use of such agents, but tend to argue against the use of TNF- α inhibitors in pregnancy.

Rituximab is a monoclonal antibody, which is directed against a receptor expressed on a broad lineage of B cells that is FDA approved for the treatment of RA. Anecdotal reports indicated that rituximab can suppress neonatal B cell development and the manufacturer recommends the drug be discontinued 12 months before pregnancy (44).

Bisphosphonates

Bisphosphonates are frequently used to prevent glucocorticoid-induced osteoporosis in a number of autoimmune diseases. In a small study ($n=21$), exposure to these drugs during the first trimester did not increase the risk of abortion, birth defects, or growth retardation relative to controls (45). This notwithstanding, bisphosphonates have a half-life of approximately 10 years (in bone), may be mobilized during pregnancy, and have been shown in experimental studies to cross the placenta and accumulate in the fetus. Given the limited amount of data available on this class of drugs, use of bisphosphonates in pregnancy is not advised.

DRUGS DURING LACTATION (REVIEWED IN REF. (38))

Effects of NSAIDs on the infant are largely unknown. Aspirin is generally considered safe for nursing mothers. However, the American Academy of Pediatrics recommends that aspirin should be used cautiously by the mother during lactation because of potential adverse effects in the nursing infant (38). The SAARDs, particularly cytotoxic agents, biologics, and bisphosphonates, are not recommended during lactation (16,38,46).

RA AND PREGNANCY

Clinical Profile of RA

RA is a chronic systemic disease characterized by inflammatory changes in the synovial membranes that primarily affect small joints of the extremities in a symmetrical fashion (47). The untreated pathologic process often extends beyond the synovial tissue and can erode adjacent joint cartilage and bone, leading to deformities and disability. The underlying mechanisms preceding symptomatic onset that predispose to this disease are unknown (48), although inflammatory pathways predominate in the clinical phase. Women are affected about three times as often as men or to an even greater preponderance during childbearing ages. This sex predisposition and increasing incidence with age in adults are important clues to predisposing mechanisms (48).

Course of RA in Pregnancy

The course of this disease often improves during pregnancy, usually beginning in the first trimester, although a full remission occurs only in the minority of patients (49,50). About a quarter of patients do not improve or can worsen during the course of pregnancy. Clinically, the features of pain, objective swelling, and systemic inflammatory markers tend to diminish. Aggravating or stressor factors can increase both symptoms and objective manifestations of RA in pregnancy, as with other patients. The ameliorating influence usually diminishes within weeks following delivery and the course may even rebound, unless actively treated (49,50).

Theories of Pregnancy—Amelioration of RA

Multiple hypotheses have been advanced to explain gestational improvement in RA, as recently reviewed (49,50). Interactions in the core hormonal, immunologic, and microvascular endothelial (MVE) systems are believed to be important determinants of RA (51). These alterations may be favorably influenced during pregnancy, but reverse postpartum (52). The glucocorticoid and reproductive hormone physiology of normal pregnancy and postpartum have been described (53). However, their influences upon the neuroendocrine immune (NEI) and MVE systems have been less well documented (47). During pregnancy, the placenta produces increasing amounts of corticotrophin-releasing hormone (CRH) (54,55). A state of *physiologic* hypercortisolism with increased production and secretion of cortisol thereby results during pregnancy from placental CRH-induced hypothalamic–pituitary–adrenal (HPA) activation (53–55). The placental CRH induces HPA stimulation and also causes adrenal gland hypertrophy during pregnancy (55).

Generalized immunosuppression is not evident during pregnancy, as recently reviewed (49,50). However, the increased adrenal and ovarian hormones produced during pregnancy are believed to suppress T helper type 1 (Th1) activity, which is a pathway implicated in the pathogenesis of RA (56,57). Moreover, concentrations of estradiol (E2), as found during pregnancy, promoted proliferation of T regulatory (Treg) cells exposed to an activating stimulus (58).

The above NEI interactions favor a shift from Th1 to Th2 immunity during pregnancy that is believed to have a salutary effect on RA activity (49,50). However, recent research has called greater attention to the roles of natural killer (NK) and NK-T cells in local immune responses of pregnancy and in the production of pro-inflammatory cytokines (49,50,59). Insufficient studies have been performed of cytokine levels during normal pregnancy or in those with RA. Critical sequential (repeated) multivariate analytic techniques are needed to uncover independent predictors of inflammatory mediators and clinical features of RA activity status during pregnancy (49).

In normal pregnancies, syncytiotrophoblast microvilli, fetal cells, and cell-free fetal nucleic acids are found circulating in maternal blood and in even significantly higher levels in pre-eclamptic states (60,61). These microparticles are scavenged by antigen-presenting cells and are believed to influence cytokine production (59). Serum levels of fetal DNA correlated with arthritis improvement during pregnancy in one study (62). Microchimerism, that is, two genetically distinct and

separately derived populations of cells, can occur during pregnancy from placental release of fetal cells into the maternal circulation. Incompatibility of HLA-class II antigens between mother and fetus is suspected to influence the maternal course of RA (63). This area of HLA antigens, maternal–fetal incompatibility, and microchimerism were recently reviewed (49,50).

RA and Fertility, and Fetal Outcome in Patients

Biologic fertility is not believed to be diminished in RA, but data are few. Before the onset of RA, the length of time of unprotected intercourse until first pregnancy (fecundity) was reported to be longer in one study (64), but not in a more recent investigation (65). Fertility following the onset of RA may be influenced by lessened sexual desire in active disease, but firm data are lacking. Fetal outcome of RA patients is believed to be comparable with healthy controls (66).

Effects of Pregnancy on Risk of Developing RA

The timing of pregnancy history was studied in relation to RA onset compared with age-matched normal control women (67). The risk of developing RA was about 30% of expected incidence during the pregnancy period, but was about fivefold greater during the first 3 months postpartum. These data mirror the previously described suppression of disease activity during pregnancy and postpartum flare in women with RA. The postpartum flare was suspected to be explained by breastfeeding during that period (68), but the risk ratio of developing RA while breast-feeding for 3 months or less was not excessive in another study (69).

ANKYLOSING SPONDYLITIS AND PREGNANCY

Clinical Profile of AS

Ankylosing spondylitis (AS) mainly affects the spine and sacroiliac joints (SIJs) and also those of the girdles as well as *lower* extremities to a lesser degree (70). A striking (circa 80-fold) association occurs with the genetic factor HLA-B27 and familial aggregation is strong. The typical spinal and peripheral lesions are localized at attachments of ligaments, tendons, or joint capsules to bone, that is, enthesopathy sites. The SIJ lesions in AS are also unique, characterized by joint space narrowing, erosions, bony bridging, and late-stage intra-articular bony fusion. Underlying disease mechanisms remain obscure, but the enthesopathy feature and SIJ pathology suggest that biomechanical stresses could predispose to onset and also activate inflammatory pathways in its physiopathogenesis (70). Unlike RA, AS occurs in opposite male to female preponderance (circa 2–3M:1F), and has disease onset mainly during adolescence or early adulthood (70).

In early disease, pain and stiffness of the spine and other affected areas are the typical symptoms. In later disease, symptomatology is accompanied by restricted motion or spinal deformities and arthritis of the hips or other lower extremity joints. Disease course tends to be less progressive in women than men, and fertility is not adversely affected.

Course of AS in Pregnancy and Outcomes

Pregnancy does not improve manifestations of primary AS, that is, without associated ulcerative colitis or psoriasis (71–73). However, postpartum flares can occur during the

first 3 months after delivery up to about 90% of the AS pregnancies (73). Nevertheless, no substantial change was observed in the overall course of disease (71,72). Rather, the chronic low back, sacroiliac area, or other pain sites were aggravated during a flare. Available data indicate that AS does not adversely affect pregnancy (71,72). Worsening of symptoms in AS patients during pregnancy or postpartum may require additional rest or physical measures, for example, non-straining and stretching activities, hot showers or baths, and avoidance of impacts or undue fatigue. Lowest effective dosages of anti-inflammatory medication are advisable for limited time periods, until discontinuation in the last month of pregnancy (72).

POLYMYOSITIS DERMATOMYOSITIS AND PREGNANCY

Clinical Profile of PM–DM

Polymyositis (PM) and dermatomyositis (DM) are acquired degenerative and inflammatory myopathies of striated muscles that belong to a spectrum of CTDs (74,75). Proximal, rather than distal, muscle weakness is the typical early feature, with skin involvement of the face, neck, and extensor articular surfaces occurring in dermatomyositis. The onset of these disorders is bimodal in age, with peaks occurring in the juvenile and middle ages. Associated malignancy occurs in a minority of adults, particularly in those older than 40 years, circa 10% to 15%.

Active PM–DM is rarely seen in association with pregnancy (76,77), due to the low incidence of this disease in childbearing ages, less than one-tenth of SLE. However, a greater number of remitted patients with prior history of juvenile-onset PM–DM may present in pregnancy or for pre-pregnancy counseling (76,77). Only rarely does PM–DM first develop during pregnancy. Overall, the prognosis for the mother is good (78), and the chances of fetal loss reflect the level of maternal disease (76,77). The pregnancy with PM–DM should be considered high risk for both the mother and the baby, with monitoring of disease activity in the mother and of the growth and well-being of the fetus (79).

Onset of PM–DM in Pregnancy

As stated, onset of PM–DM during pregnancy is rare, but has the poorest prognosis for the fetus (77,78,80,81). Increasing corticosteroid dosage is a standard treatment for active dermatomyositis in pregnancy, but can have deleterious maternal effects. Intravenous immunoglobulin monotherapy was successful for the outcome of mother and infant in managing a primigravida who presented with dermatomyositis in the first trimester of pregnancy (81).

PM–DM Antedating Pregnancy

A preceding history of PM–DM occurs more frequently than new disease in pregnant patients, due to the juvenile onset of this disease (78,80). One study (78) reported 10 pregnancies in 6 juvenile-onset PM–DM women. The six pregnancies without exacerbation of PM–DM resulted in term births, whereas the four pregnancies with exacerbations were associated with two abortions. Although the disease is often controlled before the onset of pregnancy, management of such patients is guided by the activity of the PM–DM. The dosage of corticosteroids should be sufficient to control disease, since exacerbation may increase fetal loss or prematurity (77,78). No neonatal effects

of PM-DM were reported in one study of surviving children nor have placental abnormalities been reported (78)).

SSC AND PREGNANCY

Clinical Profile of Systemic Sclerosis

SSc or scleroderma is an uncommon multisystem CTD that encompasses a broad spectrum of clinical entities (82). The spectrum of skin involvement ranges from the most limited form of tightening and hardening that affects only the fingers (sclerodactyly) to a diffuse form that affects proximal extremities and the trunk. Raynaud's phenomenon, or the discoloration of skin on exposure to cold or increased emotion, occurs typically before or during the earliest skin manifestations of scleroderma. An example of a limited form of SSc is the CREST syndrome (calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias).

The systemic manifestations are also broad and depend upon the degree of the three main pathologic features of this disease: (i) increased deposition of collagen in tissues, which contributes to the skin hardening; (ii) microvascular damage and dysfunction, which contribute to skin atrophy and ischemia of parenchymal tissues of the gastrointestinal tract and circulatory organs (heart, lungs, and kidneys); and (iii) immune activation leading to multiple autoantibodies (83,84). A number of other scleroderma-like fibrosing conditions can also present with clinically hard skin and tissue fibrosis, which should be differentiated from SSc (85). Such conditions and subsets of SSc can be differentiated by their clinical features and occurrence of specific autoantibodies (83,84).

Effect of Pregnancy on SSc

Pregnancy in SSc may be uneventful, with good outcomes in mother and fetus (86). Those women who have diffuse scleroderma could be at higher risk for developing cardiopulmonary or renal problems for which they should be carefully monitored. In one study of 59 women with SSc who had 91 pregnancies (87), miscarriage was increased only in those with long-standing diffuse scleroderma. Three cases of renal crisis during pregnancy occurred in that subset. Preterm births occurred in almost one-third (29%) of pregnancies, and all but one of the infants survived.

Effect of SSc on Pregnancy and Fertility

In a case-control study of women with self-reported scleroderma, spontaneous abortion was twice as high in the cases than controls (88). Pregnancy loss was also high (44%) in another series of 28 SSc patients, even though the majority (78%) of the 81 gestations had occurred before clinical disease onset (89). In another case-control study of 46 women with SSc, the odds ratio of pregnancy (abortive or completed) was lower than that in controls (90), suggesting lower fertility. In another study of 100 consecutive women with SSc (91), those with limited disease had significantly more children than those with diffuse disease, again suggesting subfertility in the latter group.

SLE AND PREGNANCY

Clinical Profile of SLE

SLE, or lupus, is distinguished from other diffuse CTD by its characteristic multiple organ system and serologic abnormal-

ities (1,4,92). Erythematous malar rash, discoid skin lesions, photosensitivity, and painless oral or nasopharyngeal ulcers are characteristic mucocutaneous features. The arthritis of SLE is non-erosive, but may show deformities, such as ulnar deviation of the fingers. Pleuritis, pericarditis, and abnormalities in renal (proteinuria or cellular casts), neurologic (seizures or psychosis), and hematologic (hemolytic anemia, leukopenia, or thrombopenia) function are also clinically typical of SLE and contribute to its classification criteria (92).

Lupus predominantly affects younger adult women, having a F:M sex ratio in the child-bearing ages of approximately 8:1. The disease is more common in non-Caucasians (1). The clinical presentation, degree of severity, and course of disease are all highly variable (4).

Diagnosis depends upon characteristic clinical manifestations together with confirmation by typical laboratory abnormalities (1-4,93). The antinuclear antibody (ANA) test is positive in essentially all SLE patients. However, it also occurs frequently in other CTD. The ANA has greater diagnostic import when either absent (tending to exclude SLE) or when present in high titers, especially with homogeneous or peripheral-staining nuclear patterns (typical of SLE). An isolated low-titer ANA lacks association with SLE or adverse pregnancy outcome, compared with high-titer ANA or the more specific antibodies that correlate with this disorder. The specific and confirmatory immunologic abnormalities of SLE include anti-native (double-stranded) DNA (nDNA) or anti-Smith (Sm) antibody. Positive lupus erythematosus (LE) cell preparation, a test that is rarely performed today, or chronic (at least 6 months) biologic false-positive test for syphilis supports, but does not confirm the diagnosis, since these serologic findings are typical but are not specific for SLE (1).

Course of SLE in Pregnancy

The outcome for pregnant women with SLE has substantially improved over the last four decades as evidenced by the decline in fetal loss from 40% in 1960 to 1965 to 17% in 2000 to 2003 (94). However, pregnancy in women with lupus can still be associated with significant maternal and fetal complications. A recent study reported that the incidence of spontaneous abortion, stillbirth, intrauterine growth retardation (IUGR), and prematurity are increased at least twofold among SLE patients compared with the normal population (95). Following the diagnosis of SLE, a greater than fourfold increase was observed in pregnancy loss compared with an individual's reproductive history before the diagnosis of lupus was made (96). Similarly, a cross-sectional analysis of adverse outcomes in 1029 pregnancies of Afro-Caribbean women in Trinidad found that SLE pregnancies were more than twice as likely to end in fetal death than non-SLE pregnancies (97). In a study of 16.7 million pregnancies, which included 13,555 lupus patients, an increased maternal mortality of more than 20-fold, 325 per 100,000 live births, was observed in SLE patients (98). The latter rate is lower than that reported in the Hopkins Cohort Study (1130 maternal deaths per 100,000 live births) (99).

There is general agreement that increased lupus activity at the time of conception increases the likelihood of a flare during gestation (99-102). Hence the recommendation: pregnancy

should be planned when SLE is in remission. In support of this recommendation, a number of reports indicate that pregnancy may not increase the risk of lupus flares in the inactive or well-controlled patient (94,98,99) and that frequency of flares may not be greater in the well-controlled lupus patient in pregnant state than in the nonpregnant state (4,93,103–105).

Exacerbation of disease has been reported in up to 50% of SLE pregnancies. In a recent case-control study, flares were observed in 18% of SLE pregnancies (106), a rate that agrees favorably with another recently published report in Argentina (107). Apart from glomerulonephritis and, less commonly, neuropsychiatric SLE, flares during pregnancy and in the postpartum period are generally mild or moderate, with a predominance of cutaneous, articular, and minor hematologic manifestations (98,100,107). Of the 309 pregnancies cited in the review by Moroni and Ponticelli (102), only 12% of SLE flares were associated with renal insufficiency. Active lupus nephritis was found to result in greater fetal loss compared with pregnancies in women without lupus nephritis and in more frequent preterm delivery in the study by Wagner et al. (108). By contrast, active renal disease had no effect on pregnancy outcome (save for low birth rate) in the study by Gladman et al. (109).

A high rate of adverse fetal events can occur in pregnant woman with lupus independent of the presence of lupus nephritis (2–4,110,111). Published data have identified several risk factors for poor pregnancy outcomes, including the presence of hypertension, the presence of lupus nephritis, the presence and degree of proteinuria (112,113), and the presence of high-titer aPL antibodies. Most American physicians do not believe that routine “prophylactic” steroid therapy to suppress disease activity during pregnancy reduces risk for maternal flare or decreases fetal wastage, unless needed to control intercurrent disease flare.

Decidual vasculopathy with necrotizing inflammatory lesions and “acute atherosclerosis” occurs in placentas from lupus patients (114,115) as well as in those with the aPL syndrome (115,116), irrespective of whether the pregnancies resulted in fetal deaths (115) or in live-born SGA infants (117). Placental size is reduced in SLE patients compared with both healthy and diabetic controls (118). Most later pregnancy losses may be attributable to placental dysfunction (114–116,118).

NEONATAL LUPUS SYNDROME AND CONGENITAL HEART BLOCK

Neonatal lupus is characterized by transient hematologic and cutaneous disorders and permanent incomplete or complete congenital heart block (CCHB). It occurs in less than 1% of the offspring of SLE patients (3,4,119–123) and only in pregnancies associated with maternal antibodies to SSA (i.e., Sjögren’s syndrome A/Ro) or SSB/La (124). These auto-antibodies are present in 25% to 32% of pregnant SLE patients (122). In one prospective study of sequential pregnancies, none of 38 infants of lupus mothers with anti-SSA (Ro) antibody had children with heart block (122). In another prospective study of 100 women with anti-Ro/SSA antibodies, 2 had infants who developed CCHB in utero. Among the 53 lupus mothers who harbored such antibodies, no case of CCHB occurred (125). Thus, most infants with this syndrome are born of asymptomatic mothers with such

antibodies who rarely develop a lupus-like disorder later in life (121,124,126).

CCHB

Substantial morbidity and mortality are associated with CCHB (123). This rare, potentially fatal complication (120,122,124,126,127) is more problematic than the non-cardiac transient abnormalities in the neonatal lupus syndrome. The CCHB is associated with myocarditis and with simultaneously present maternal anti-Ro (SSA) and anti-La (SSB) antibodies (120–122,124,126,127). If cardiac conduction defects are detected by antepartum fetal heart rate monitoring, a fetal echocardiogram should be obtained for detection of other cardiac anomalies (120–122,128). Appropriate fetal monitoring and management procedures should be employed (128).

Effects of SLE on Fertility

There are insufficient data to support a deleterious effect of SLE on fertility (129–132). Generally, fertility is not considered to be impaired in women with SLE (127,133) except in those with severe renal disease (i.e., creatinine clearance <50 ml/min) (3,119) or those exposed to cyclophosphamide or chlorambucil.

MANAGEMENT OF PREGNANT WOMEN WITH SLE

Initial Assessment and Monitoring

Management of pregnant women with SLE should be a collaborative effort between the obstetrician and the rheumatologist. The initial intake should consist of a careful history, including duration of lupus, an assessment of the patient’s current disease activity, the patient’s past obstetric history, and the timing of past pregnancies with regard to onset of lupus. If the patient is in remission, the duration of remission should be noted. Physical examination should include blood pressure measurement, cardiovascular assessment, and accurate pregnancy dating with confirmation by early obstetrical sonogram. Laboratory testing is suggested to include a complete blood count with quantitative assessment of platelets; serum creatinine (and measurement of creatinine clearance if indicated); complement 3 (C3), C4, and total complement levels; the presence of anti-dsDNA, anticardiolipin antibodies (aCLs), lupus anticoagulant (LAC), anti-SSA (Ro), and anti-SSB (La) (96). In pregnancy, baseline values of C3 and C4 are higher secondary to the permissive effect of estrogen on complement synthesis. Thus, normal levels of C3 and/or C4 do not necessarily mean that a pregnant SLE patient’s disease is quiescent.

Monitoring During Pregnancies

The complete blood count, creatinine, serum complements, anti-dsDNA, and urine with microscopic analysis should be repeated at 1- to 2-month intervals, as appropriate, during pregnancy and for 3 months postpartum (112). Beginning at 20 weeks of gestation, obstetrical visits are increased to every 2 weeks, because pre-eclampsia may occur at this point. At 28 weeks, visits should be weekly (96). aCL Should be repeated if initially negative, each trimester. The other laboratory parameter to indicate lupus flares are increases in erythrocyte sedimentation rate, lower hemoglobin, and increased activity

indices such as Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), European Consensus Lupus Activity Measure (ECLAM), and Lupus Activity Index (LAI). The SLEDAI and LAI have been validated as indicators of flares in pregnant SLE patients with a sensitivity of 93% and a specificity of 98% (134). Clinical and laboratory measures of disease activity are used to distinguish kidney involvement in lupus from superimposed pre-eclampsia. Early detection and aggressive management of lupus activity is the approach recommended by most rheumatologists, although determination of lupus activity during the pregnancy may be challenging (96,101,112).

Fetal Surveillance

Surveillance for fetal growth can be conducted by serial obstetrical sonography (96,135–138). This is especially important in patients with chronic hypertension in whom pre-eclampsia has developed, and in SLE mothers with aPL antibodies and a history of prior unexplained pregnancy losses (139,140). Interestingly, although spontaneous abortions were somewhat higher among those with (20.6%) than without (11.3%) renal involvement, the presence of nephropathy did not significantly alter fetal outcome overall among patients in the Mexico City study (110).

In those patients at risk for fetal congenital heart block associated with anti-SSA (Ro) and anti-SSB (La) antibodies, additional testing is required (127). This fetal condition occurs after 16 weeks of gestation. Screening by m-mode echocardiography should be started at 16 weeks and should continue weekly until delivery (127).

Treatment

(See also Effects of Antirheumatic Medications on the Fetus and Pregnancy above). The reader is referred to a number of recent reviews for a discussion of treatment of SLE in pregnancy (96,101,102).

Route and Timing of Delivery

For SLE patients, route and timing of delivery should be based upon results of fetal studies with attention to the maternal condition, especially renal and blood pressure status. The need for neonatologist attendance should be determined prior to labor by both maternal and fetal statuses. If necessary, transport should be arranged to a facility equipped for care of complicated premature infants.

APS

Definition of APS

Antibodies to anionic (negatively charged) phospholipids or phospholipid-binding proteins (aPL antibodies) are associated with recurrent, usually mid-trimester, spontaneous abortions, autoimmune thrombocytopenia, arterial and deep venous thromboses, and livedo reticularis (141–145). The definition of recurrent miscarriage has varied in the literature, with implications as to prognosis of the untreated pregnancy. The standard obstetrical definition is three or more consecutive losses. However, the definition used for most rheumatologic patients has been two or more losses (sometimes even one). Incidence of pregnancy loss increases with greater number of

preceding miscarriages, which has implications in evaluating efficacy of one or another therapeutic approach.

aPL Antibodies and Laboratory Tests for Measuring aPL Antibodies

The aPL antibodies are heterogeneous, polyclonal and may vary in titer over the course of follow-up. LACs are aPL antibodies that block phospholipid surfaces and reduce the coagulant potential of plasma, thereby prolonging the clotting time in coagulation tests based on the activated partial thromboplastin time (146). The presence of LAC is determined functionally by (i) a failure to correct the prolonged clotting time after mixing with normal platelet-free plasma and (ii) the dilute Russell's viper venom time (147). aCL Are IgG, IgM, or IgA antibodies that bind to the phospholipid cardiolipin. They do not prolong functional assessments of clotting (i.e., coagulation assays). Detection of aCL is done using an enzyme-linked immunosorbent assay (148). It is generally believed that aCL antibodies are significant only when present in the context of a thrombotic event and that anti-IgG antibodies carry greater pathogenetic significance than do those of the IgM isotype (149). The aCL antibodies are sensitive, being present in ~80% of patients with APS, but not as specific as that of LAC and have been reported in numerous infectious diseases (150–153). False-positive tests for syphilis occur with increased frequency in individuals with LAC and aCL activities using a variety of tests (e.g., the rapid plasma reagin and Venereal Disease Research Laboratories tests). These tests are not reliable indicators of clinically important outcomes. In patients with false-positive syphilis tests secondary to aPL antibodies, the fluorescent treponema antibody test remains negative (154).

Beta-2-glycoprotein I (beta2GPI) (155) is a naturally occurring anticoagulant and potential antigenic target for some aPL antibodies that are detected by solid-phase assay (156). It is thought that aPL-associated thrombosis occurs when anti-beta2GPI antibodies bind and promote dimerization of beta2GPI, which increases binding affinity for phospholipids and induces activation of complement, platelets, endothelial cells, and monocytes (157). The revised Sapporo criteria (158) for diagnosing APS (159) include the presence of LAC, or IgG or IgM aCL, or anti-beta2GPI antibodies (measured on two occasions 12 weeks apart) together with vascular thrombosis or pregnancy morbidity.

Primary and Secondary APS

aPL Antibodies without clinical symptoms may be found in otherwise healthy persons (144). Those with symptoms who do not have SLE or previously recognized clinical disorders are designated as having a "primary" APS (160). Persons with SLE or other rheumatic disorders (143–145,161,162) are designated as having "secondary" APS. Close to 50% of patients who have APS also have SLE; however, less than 10% of SLE patients have an APS (163). In lupus, APS seems to correlate with increased fetal loss (115,139,140,164) and appears to be part of the disease, rather than a separate, associated condition (162). That said, there may be a negative correlation of aPL antibodies with active lupus (115), nephrotic syndrome, and certain cutaneous forms of lupus (162). Secondary and primary APS patients have similar overall clinical and

laboratory profiles (165), although lupus patients with APS have more hemolytic anemia, endocardial valve disease, neutropenia, and lower C4 levels (165). In pregnancy, lupus disease activity and associated APS, when present, behave independently. A patient with remitted lupus and secondary aPL syndrome behaves like one with primary APS. A patient with active lupus and APS develops complications of, and needs treatment for, both diseases.

Do aPL Antibodies Predispose to Fetal Wastage?

A literature review concluded that there was an association between the prevalence of aPL antibodies in women with SLE and history of fetal loss (60%), but remained inconclusive about the relationship between aPL antibodies and miscarriages in women without SLE (4–13% losses) (144). Most studies, however, do find an association between high-level aPL antibodies and repeated, but not first, fetal loss (4,139,140,161,164,166). In one study, aCL titers remained high in aborting patients (167), which is not uncommon (142,164,168). aPL Antibodies have been detected in 5% to 15% of otherwise healthy women with a history of unexplained recurrent abortions (144).

Frequencies of aCL antibodies are low (<5%) in consecutive samples of healthy pregnant women without prior pregnancy losses, and there is no significant correlation with fetal or maternal complications (169). Moderate to high levels of aCL antibodies, of the IgG isotype, do correlate with fetal wastage, in referral, high-risk (142,164) and general obstetric (168,170) populations.

Antibodies to beta2GPI–CL complex were significantly associated with fetal complications in a large cohort of apparently healthy pregnant women followed prospectively in Japan (171). It is not known whether women with positive titers have other primary risk factors for increased fetal wastage such as clinically inactive lupus (114–116,118,166).

Fetal Complications Reported with aPL Antibodies

APS is the most common association of recurrent miscarriage syndrome, a condition that affects more than 500,000 women in the United States annually (172,173). Recurrent fetal losses due to intrauterine death at any stage of pregnancy, but particularly in the second and third trimesters of gestation, and fetal growth restriction, are characteristic complications associated with aPL antibodies (168,170,174). Recurrent, late first-trimester fetal loss after detection of fetal heart activity has also been associated with aPL antibodies (175). No fetal pathology can explain the spontaneous abortions and stillbirths. Instead, the placentas invariably show scattered areas of infarction, intervillous thrombosis, and fibrin deposition (114–118,174).

Few published data are available on the aPL antibody status of live-born infants of mothers positive for these antibodies. Most infants in whom antibody can be detected are well, except for the effects of prematurity and IUGR, although reports are anecdotal.

Maternal Complications Reported with aPL Syndromes

Maternal complications of pregnancies associated with APS can be life-threatening or fatal (172,173) and include severe pre-eclampsia (176), arterial or venous thromboses (177,178),

pulmonary hypertension (179), and the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP) (163). Although aPL antibodies are not present in the majority of individuals with pre-eclampsia (180), a systematic review indicates that positivity for aPL antibodies is a highly significant risk factor for the development of pre-eclampsia (181). Over half of women presenting with obstetrical problems in the setting of APS have not had a previously recognized autoimmune disease (166) although a minority go on to develop SLE. The majority experience thrombotic vascular complications of APS (165). There may also be an increased risk of cardiopulmonary complications associated with delivery (159,160,166,167) and an increased risk of stroke in the postpartum period (176).

Treatment of Pregnancy-Related Complications Associated with aPL Antibodies

Patients with aPL antibodies should have consultations with maternal–fetal specialists, either on a preconception basis or immediately following verification of pregnancy. Patients with prior complicated aPL-related gestations should be managed by a maternal–fetal medicine team familiar with the illness and skilled in critical care. Infants of such gestations should be delivered in facilities experienced in the care of premature small infants (500–1500 g birth weight). Careful monitoring of fetal growth and uteroplacental function (5), beginning as early as the second trimester, may detect impending fetal compromise and necessitate early delivery (6).

Anticoagulation plus Low-Dose Aspirin

In an earlier uncontrolled study, fetal wastage was prevented with heparin therapy in most women with aCL and LAC antibodies who had recurrent losses or previous abnormal outcomes (182). However, successful pregnancy has been observed in SLE patients with untreated LAC (183). Full-dose heparin plus low-dose aspirin was found to provide significantly better pregnancy outcome than low-dose aspirin alone in women who had at least three consecutive pregnancy losses, without causing increased complications (184). By contrast, ongoing studies (185) indicate that treatment of aPL antibody-associated pregnancy loss with lower dose heparin and aspirin is equivalent to full-dose anticoagulation (184). As recently pointed out (186), the optimal dose of heparin to maximize benefit and minimize harm is currently unknown.

Based on controlled clinical trials (184,185,187,188), aspirin (81 mg/day) plus heparin, either unfractionated heparin or low–molecular weight heparin, is the preferred treatment for repeated fetal losses associated with aPL antibodies (172). However, a Cochrane collaboration review on the therapy of miscarriage in women with aPL recommends aspirin (81 mg/day) and unfractionated heparin (186). Therapy with aspirin and heparin should be begun immediately postconception and should be taken throughout the pregnancy (172).

Prednisone Suppression of Maternal LAC

Initial reports in the 1980s (166) suggested that high-dose prednisone therapy (e.g., 40–60 mg/day, orally) promotes fetal survival in pregnancies of women with recurrent abortions associated with LAC; however, more recent experience argues against glucocorticoid prophylaxis (4,139,189) in favor of

anticoagulation therapy as noted above (184–188,190). Importantly, lupus patients will likely need to be treated with sufficient prednisone for suppression of disease activity in pregnancy. However, there is no compelling evidence to indicate that higher doses of steroids intended for immunosuppression of aPL antibodies per se are beneficial. Furthermore, since pre-eclampsia may be associated with the presence of LAC (176,191), the indication of fluid retention and hypertension argues against the use of high-dose prednisone (189,192). Finally, the use of high-dose prednisone increases the risk of long-term complications, especially osteonecrosis and osteoporosis.

Intravenous Gamma-globulin Therapy

Anecdotal reports comprising a small number of patients have suggested improved pregnancy outcomes with experimental gamma-globulin therapy (193,194) in patients with recurrent miscarriages due to APS. However, The Pregnancy Loss Study Group reported that gamma-globulin therapy had no beneficial effect in such patients in a double-blinded randomized trial (195). Also it has been shown that immunoglobulin therapy is inferior to aspirin plus heparin in the treatment of recurrent fetal loss associated with aPL antibodies (196).

Low-Dose Aspirin

Although mini-dose aspirin (e.g., 60–100 mg daily) has been recommended for treatment in pregnant women with primary APS and history of recurrent abortions (190), recent studies suggest that aspirin therapy in the absence of anticoagulation is not sufficient to prevent fetal loss in high-risk pregnancies (184).

19 Sickle cell disease

Marc R. Parrish and John C. Morrison

INTRODUCTION

Hemoglobinopathies complicating pregnancy number in the hundreds, but fortunately most of them are very rare (1). These inherited disorders usually result from structural abnormalities such as additions, deletions, or substitutions in the amino acids that comprise the two pairs of polypeptide chains common to each hemoglobin molecule (Table 1). These amino acid linkages contain either 141 or 147 amino acids, are responsible for the nomenclature, and comprise the common types of hemoglobin such as A, A₂, F, and so on (2).

Sickle cell disease (SCD) refers to a group of autosomal recessive disorders involving abnormal hemoglobin (hemoglobin S). Hemoglobin S differs from the normal Hb A because of a single nucleotide substitution of thymine for adenine in the globin gene. This alteration causes a substitution of valine for glutamic acid in the number six position of the globin polypeptide. Asymptomatic individuals with heterozygous Hb S genotypes (carriers) are said to have sickle cell trait. The most severe form of the disease, Hb S-S (homozygous Hb S), is called sickle cell anemia (3).

Sickle cell crisis occurring at any time during gestation is a medical emergency (4). Vaso-occlusive sickle cell crisis is the most common maternal complication noted in gestations complicated by sickle hemoglobinopathies (5). Crisis is associated with increased maternal and perinatal morbidity and mortality (6). Severity as well as frequency of crises among pregnant women is extremely variable and may occur during the prenatal or intrapartum period as well as the puerperium (7). Improvements in management over the last two decades have resulted in improved outcome for such women and their progeny. Nevertheless, providers who care for these high-risk patients must be prepared to practice preventive medicine, recognize the early signs of crisis, and respond rapidly with a well-founded perinatal management plan.

EPIDEMIOLOGY

In the United States, sickle cell anemia affects about 70,000 people (8). It mainly affects African-Americans. The disease occurs in about 1 out of every 500 African-American births. Sickle cell anemia also affects Hispanic Americans. The disease occurs in 1 out of every 36,000 Hispanic American births (8,9). Patients with Hb S-S, as well as with other variants, such as hemoglobin S-C (Hb S-C) and hemoglobin S- β thalassemia (Hb S- β Thal), are said to have SCD and this is most often responsible for adverse effects on the mother, the fetus, and the newborn (3). These are also the disorders most likely to be associated with sickle cell crisis. Other sickle hemoglobinopathies such as Hb S-D, Hb A-S, and Hb S-E are unlikely to result in sickling episodes.

SICKLE CELL TRAIT

About 2 million Americans have sickle cell trait. The condition occurs in about 1 in 12 African-Americans (8). Sickle cell trait has been considered to be an essentially benign condition during pregnancy, with few exceptions (10,11). A common problem tends to be an increased rate of urinary tract infections, thought to be associated with an inability to concentrate urine and asymptomatic bacteriuria among patients with sickle cell trait. There is some literature that contradicts the benign nature of the carrier state revealing an increased risk of intrauterine fetal demise, spontaneous miscarriage, and intrauterine growth restriction (12,13). However, due to a lack of sufficient evidence, routine obstetrical management with monthly urinalysis is the only recommendation in this group of patients at this time.

MORBIDITY AND MORTALITY

Patients with Hb S-S or Hb S-C have no hemoglobin A, therefore the predominant hemoglobin is Hb S, 90% to 95%, with the remainder being Hb F. Patients with this disorder have been shown to have a shorter life span, more common infections, and when pregnant, a higher maternal as well as perinatal mortality/morbidity (1). The fertility rate does not appear to be decreased unless there are frequent crises and disseminated disease affecting many systems. Due to improvements in modern medicine, the maternal death rate has been reduced to less than 2%, and many women are now electing to proceed with pregnancies (14).

Women with SCD are at an increased risk to experience both medical complications (such as infections, thromboembolic events, and stroke) and pregnancy-related complications (such as pre-eclampsia, eclampsia, preterm labor, placental abruption, and fetal growth restriction). The risk for experiencing these complications is significantly higher than that in other women (15,16). Decreased placental blood flow due to sickling in the tortuous, arcuate vessels of the myometrium has been associated with poor perinatal outcomes (2). More than one-third of pregnancies in women with SCD terminate in miscarriage, stillbirth, or neonatal death, according to the National Institutes of Health Cooperative Study of Sickle Cell Disease (17). The neonatal mortality rates are not increased in patients with SCD per se but may appear to increase due to preterm deliveries.

These women are also more likely to experience pneumonia, pyelonephritis, postpartum infection, sepsis, and systemic inflammatory response syndrome compared with women without SCD. At the time of delivery, these women are also more likely to have asymptomatic bacteriuria and genitourinary infections (15). Severe cardiopulmonary ailments may be observed in those women with long-standing disease. Cardiovascular sequelae are often a consequence of chronically

Table 1 Normal/Abnormal Hemoglobin

high cardiac output due to anemia, although these women rarely die of heart disease, but almost all eventually have some degree of ventricular dysfunction from hypertrophy and diastolic dysfunction. These underlying changes make affected women less tolerant of the additional increase in cardiac output noted in pregnancy (18). Pulmonary hypertension is acknowledged increasingly as a complication of SCD. It has been described in up to 30% of this population and is associated with a high mortality rate (19). The statistically significant presence of pulmonary hypertension at delivery supports the previous observation and warrants the need for appropriate evaluation and management.

Although neonates are asymptomatic at birth because of a higher concentration of hemoglobin F, the incidence of neonatal mortality increases after about 6 months with 20% of overall deaths from SCD occurring in the first 2 years, 10% between the ages of 2 and 5 years, and the remainder between 5 and 30 years (20). During pregnancy, severe anemia is the rule among patients with SCD and rarely does the hematocrit rise above 25%. Infections are also common and usually involve the urinary tract, pulmonary system, and orthopedic system.

Diminished oxygenation in the intravascular compartment in patients with SCD converts the normal oval red blood cells

into the classic sickle-shaped erythrocytes noted in subjects undergoing crisis (Fig. 1). These sickle cells lodge in the microvasculature of many organs and result in a decreased life span of red blood cells as well as the maternal and perinatal complications mentioned above. Any event leading to deoxygenation can initiate a sickle cell crisis. For instance, infections from viruses or bacteria, acidosis, dehydration, trauma, blood loss, severe stress, strenuous physical activity, high altitude, and hypothermia have been incriminated.

There are several different kinds of sickle cell crisis. The most common is the vaso-occlusive crisis, which is most frequently noted in pregnant women and adults. The less common hematologic type of crisis is more often seen, but not exclusively so, in children (Table 2). The clinical expressions of the vaso-occlusive crises are extremely variable in their presentation but usually follow a characteristic pattern in each patient. These recurrent and sudden attacks of pain most often involve the abdomen, extremities, central nervous system, and chest although no body area is immune from these attacks (21). Some patients exhibit generalized pain and malaise, while others have more localized syndromes involving a compromised microcirculation in various areas of the body.

Table 2 Sickle Cell Crisis Classification

<i>Vaso-occlusive</i>

Central nervous system
<i>Hematologic</i>
Aplastic
Hemolytic
Megaloblastic
Splenic sequestration

On the other hand, hematologic crises are infrequent among pregnant women, but if they occur, aplastic crisis is the most common type. Fortunately, this type of crisis is usually self-limited and most often associated with infection. Hemolytic crises, in general, are most commonly related to concomitant spherocytosis or glucose-6-phosphate dehydrogenase deficiency. Megaloblastic crises are usually secondary to folate depletion and are remedial to supplementation. Finally, splenic sequestration crises are usually limited to childhood. As a group, hematologic crises are characterized by sudden anemia without icterus, pale conjunctiva, malaise, reticulocytopenia, and cardiopulmonary failure.

ETIOLOGY

In a patient with SCD, the symptom constellation of the chronic, severe anemia and frequent pain leads one to suspect a vaso-occlusive crisis. Most commonly, this event in the pregnant adult is associated with apparent or occult infection (20–33%) (21). Pneumonia, urinary tract infection, and puerperal endomyometritis, as well as osteomyelitis, are the infectious sites commonly encountered with sickle cell crisis. *Pneumococcal pneumonia* or meningitis is particularly frequent in adolescent pregnant patients with SCD (22). Gram-negative bacteria, such as *Escherichia coli* or *Salmonella*, are the most common organisms noted in the third decade of life (4). These organisms are particularly likely to attack the renal and gastrointestinal (gallbladder) systems, respectively. During the second decade of life, *Mycoplasma pneumoniae* is also common.

Factors other than infection have been associated with vaso-occlusive crisis in these patients. Acidosis from dehydration and hypotension has been noted to initiate such crises (1). Strenuous activity, as well as drug overdose and hypothermia, have likewise been associated with these events (2). Therefore, when confronted with a suspected vaso-occlusive crisis in a parturient with SCD, one should suspect infection first but rule out other factors during intensive assessment.

PATHOPHYSIOLOGY

The variable clinical symptoms with which these patients present is not fully explained. There is evidence to suggest that this variability may be related to the presence of linked and unlinked genes, which modify the disease expression (23). Another theory has been that of incomplete penetrance. As previously noted, the molecular basis for sickle cell crisis can be traced to the single amino acid substitution in the sickle hemoglobin molecule, which distinguishes it from hemoglobin A. During deoxygenation or under conditions of acidosis

as well as hypoxia, the molecules of Hb S aggregate in a process called nucleation.

Hydrophobic bonding occurs between the abnormally substituted valine, owing to the change in electromagnetic charge. These hydrophobic bonds lead to the formation of polymerized hemoglobin strands, which become tactoids and microcables that eventually transform the cell into the half-moon or crescent shape (Fig. 1) (24). This overall process of gelation of the sickle hemoglobin is enhanced by increasing levels of sickle hemoglobin and/or 2,3-diphosphoglycerate levels. It is reduced by lowering the oxygenation or pH (25).

Repetitive cycles of gelation during the red blood cell life cycle distort the cellular membrane, with resultant potassium and water reduction as well as calcium accumulation and membrane fragmentation (24). This leads to an increase in the intracellular hemoglobin concentration with a concomitant increase in membrane rigidity to form discocytes or irreversibly sickled (26). The irreversibly sickled cells retain the half-moon shape despite oxygenation. These irreversibly sickled cells constitute up to 50% of the red cell mass in such parturients. However, the index of reversible/irreversible sickle cells does not appear to correlate well with vaso-occlusive crisis or its severity, but does have a positive relationship to the degree of anemia.

These abnormalities of the red cells themselves do not, alone, explain the pathophysiology of the sickle cell crisis. It is currently felt that there exists a combination of the erythrocyte abnormalities, plasma flow alterations, and vessel wall interactions that are associated with sequestration and destruction of abnormal red cells in the microcirculation (Fig. 2) (27). This would explain patient variability noted in the clinical expression of a sickle crisis. Another factor involved in the pathophysiology of sickle cell crisis appears to be the large oscillation in blood flow in the microcirculation (28). With the use of laser-Doppler velocimetry, rather large changes in blood flow in factors of 7–10 s with peak/trough magnitudes measured at 50% of mean flow were noted. These findings would suggest that during sickle cell crisis, there is periodic flow in the microcirculation with synchronized rhythmic oscillations versus the continuous even-flow pattern observed in patients with normal hemoglobin.

Therefore, although the environmental factors may stimulate deoxygenation resulting in aggregation, polymerization, and subsequent formation of sickled red cells, flow dynamics and also microcirculation factors are important determinants of the crisis cycle (Fig. 2). These factors combine to increase whole blood viscosity and, thus, alter vasomotion in the microcapillaries. This would lead to sludging and destruction of red cells in the microcirculation. This promotes further deoxygenation, which leads to vascular injury via ischemic necrosis, which results in pain and the other symptoms expressed during vaso-occlusive crises.

The marked susceptibility of parturients with sickle hemoglobinopathies to infection is related to functional hyposplenism, defective activation of complement fixation, decreased serum IgM, impaired serum opsonizing capacity, and defective granulocyte phagocytosis (29). There does not appear to be any difference in the percentage of helper or suppressor T cells or B cells in subjects in crisis (30). This finding is compatible with the observation that patients with sickle hemoglobinopathies did not show increased susceptibility to those infections that are normally associated with depressed cell-mediated immunity (31).

DIAGNOSIS

The diagnosis of hemoglobinopathies, including sickle cell disorders, is made by hemoglobin electrophoresis. In the homozygous form, nearly all the hemoglobin is Hb S with small amounts of Hb A₂ and Hb F. Heterozygous sickle cell trait (Hb AS) is identified by a larger percentage of Hb A and an asymptomatic course. Solubility tests (Sickledex) alone are inadequate for the diagnosis of sickle cell disorders because they cannot distinguish between the heterozygous AS and homozygous SS genotypes. In addition, they fail to detect other pathologic variants such as Hb C trait, thalassemia trait, Hb E trait, Hb B trait, and Hb D trait (3).

Although some tests for crisis are helpful, the diagnosis is largely a clinical experience and basically one of exclusion. Fortunately, most women with sickle hemoglobinopathies are known prior to pregnancy. For patients with SCD, the first step is to confirm the diagnosis with hemoglobin electrophoresis. Once the diagnosis is documented, surgical/medical/obstetric conditions associated with a similar symptom complex or even malingering must be ruled out (Table 3). Because a parturient may have any one of many medical, surgical, or obstetric complications, pain in a pregnant woman with SCD does not always result from vaso-occlusive crisis.

Infection and crisis are usually associated with an increase in the segmented neutrophil counts as well as the presence of bands. A hemolytic crisis with anemia is presumed in the presence of an elevated lactate dehydrogenase, a reticulocyte count of 3% to 15%, an elevation in unconjugated bilirubin, and a low serum haptoglobin.

MANAGEMENT

General

Pregnant patients with SCD need increased prenatal folic acid supplementation. The standard 1 mg of folate in prenatal vitamins is not adequate for patients with hemoglobinopa-

thies; 4 mg/day of folic acid should be prescribed because of the continual turnover of red blood cells (3). Supplemental iron is not usually recommended due to the risk of iron overload that accompanies chronic hemolysis and transfusions. Its administration can be considered if serum iron and

ferritin are found to be diminished. Routine prenatal labs including evaluation for the hepatitis B antigen and HIV should be performed at the patient's initial visit. Other labs to consider would be serum uric acid, creatinine, liver function tests, and a 24-hour urine collection for protein and creatinine to assess for the presence of preexisting vascular disease. If not already accomplished, the patient should be immunized with both the pneumococcal and meningococcal vaccines due to the likelihood of autosplenectomy during childhood and their susceptibility to encapsulated organisms. Neither vaccine is contraindicated in pregnancy.

Intrauterine growth restriction, reduced birth weight, and lower placental weights are common with this disease and may be due to vascular changes within the uteroplacental unit as well as preterm delivery (32,33). It is likely that chronic vascular occlusion, even in the absence of clinically overt pain crisis or acute chest syndrome, contributes to placental injury and adversely affects fetal growth. Altered vascular flow rather than anemia may account for low birth weights in infants of women with Hb S-S, which does not appear to improve with transfusion support (14). Starting at 24 to 28 weeks, monthly ultrasonography is recommended to assess fetal growth, and patients should be instructed in daily fetal movement counts. Nonstress testing and biophysical profile testing should be considered weekly beginning at 32 to 34 weeks. Doppler ultrasound, performed at 28 to 30 weeks to assess umbilical artery flow and systolic/diastolic ratios as a predictor of intrauterine growth restriction, may be a useful adjunct.

Despite advances during the past 20 years and the appreciation of the molecular basis of sickle cell crisis, there is no specific therapy available. However, an understanding of the pathophysiology involved in vaso-occlusive crisis allows the provider to address those aspects of this event that can be treated. Such therapeutic regimens generally include (i) adding fluids to reduce intracellular hemoglobin concentration, (ii) correcting acidosis when present, (iii) treating infection, and (iv) increasing oxygen concentration.

Antepartum

During the prenatal period when the patient in crisis is not in labor and is remote from term, hospitalization in a quiet area where bed rest, analgesia, and hydration can be carried out is optimal. Because of the risk of fetal loss, health assessment via biophysical profile and/or fetal heart rate monitoring is carried out during crisis treatment if gestational age is sufficient to consider intervention for fetal distress. In addition, continuous fetal heart rate monitoring is helpful, because resolution of worrisome signs, such as late decelerations, has been demonstrated during the treatment of sickle cell crisis with blood infusion (34).

Initial medical assessment should focus on detection of the following medical complications requiring specific therapy: infection, dehydration, acute chest syndrome (fever, tachypnea, chest pain, hypoxia, radiologic chest infiltrates), severe anemia, cholecystitis, splenic enlargement, abdominal crisis, and neurologic events (cerebral infarct, cerebral hemorrhage, transient ischemic attack, seizure). Vigorous rehydration is useful, particularly in crisis patients who are febrile (4). In the absence of cardiopulmonary disease, infusion of a liter of Ringer's lactate or isotonic saline during the first 2-hour period with continuing replacement at 125 mL/hr is undertaken.

Careful monitoring of intake and output is essential, but invasive hemodynamic monitoring and urinary catheterization are usually avoided, because of the risk of infection. The administration of alkali during the hydration process has not been found to be helpful (35). For analgesia, opiates are superior to nonsteroidal agents in the presence of severe pain. Opiates are not associated with teratogenicity, congenital malformations, or toxic effects other than transient suppression of movement and variability in fetal heart tones. Chronic exposure to opiates, such as that in women who require methadone or other medications to control severe chronic pain, can result in neonatal abstinence syndrome after birth. Acetaminophen is preferable if mild analgesia is required. As soon as the pain begins to regress, nonnarcotic agents are recommended. It is important to recognize that assessment of fetal well-being during a pain episode may be complicated by the use of opiates to treat sickle cell crisis pain, which transiently affect nonstress testing and biophysical profile scores (36). Caution must be used when interpreting the results of these tests during an acute pain episode, because they may not be predictive of increased perinatal morbidity and mortality in the absence of other findings (14).

Although the utility of oxygen therapy is unproven, it is often employed during crisis. Oxygen is administered at 3–6 L/min by tight face mask or nasal cannula. Arterial blood gas assessment is usually recommended if hypoxemia is suspected. Because infection is present in up to one-third of patients with vaso-occlusive crisis and since it is frequently associated with maternal death occurring in sickle cell crisis, attempts to detect occult infection are undertaken immediately. If an infection is suspected, then broad-spectrum antibiotic therapy is begun after appropriate cultures are obtained. Prophylactic antibiotic use, however, is not generally recommended.

BLOOD TRANSFUSION

Controversy exists regarding the role of prophylactic blood transfusion in the management of SCD in pregnancy (37–41). In the only randomized controlled trial published to date, prophylactic transfusion was associated with a decreased risk for painful crisis and severe anemia, but no difference was observed for pregnancy outcome (38). By limiting transfusion to situations in which it is clinically indicated, patients are not subjected to the increased risk for blood-borne infections, iron overload, and alloimmunization. The rate of alloimmunization in sickle cell patients is estimated to be between 18% and 36% (42). It is estimated that six to eight deaths per year in the United States occur as a result of delayed transfusion reactions (43). It appears from the available evidence that the reduction in morbidity and mortality of SCD in pregnancy may be attributable to improvements in general management of pregnancy rather than prophylactic transfusion per se (3).

However, prophylactic transfusions may be indicated in patients who have particularly severe disease manifestations or for symptomatic patients who are unresponsive to conservative management (44). Major complications (e.g., worsening anemia; intrapartum complications such as hemorrhage, septicemia, and cesarean delivery; painful crisis; chest syndrome) may require intervention with an exchange transfusion. There is no consensus regarding the exact hematocrit value below which transfusion should be considered. However, when a transfusion is clinically indicated in the patient with SCD, the

Table 4 Manual Partial Exchange Transfusion

Measure hemoglobin A level and hematocrit
Type and match six units packed red blood cells
Start intravenous administration of 1L normal saline (200–400mL in the first hour) then 150–250mL/hr
Phlebotomize 500mL blood from opposite arm over 30 min
Give two units leukocyte-poor washed red cells (under pressure and warmed) over 1–2 hours
Repeat procedure after 4 hours
If hematocrit 35% and hemoglobin A 50%, discharge home
If hemoglobin A <50%, repeat procedure

objective is to lower the percentage of Hb S to approximately 40% while simultaneously raising the total hemoglobin concentration to about 10g/dL (3).

Exchange transfusion, also known as erythrocytapheresis, allows the Hb S-containing cells and irreversibly sickled cells to be removed by extracorporeal, differential centrifugation. It affords the simultaneous return by venous access in the other arm of the patient's own plasma, leukocytes, platelets, and clotting factors along with donor, leukocyte-poor washed Hb A-containing red cells. This type of transfusion occurs via a machine that allows for automated continuous erythrocytapheresis. In addition, this method maintains isovolemia at all times and allows the provider to accurately monitor the patient's hematologic indices such as hemoglobin levels and hematocrit. It also has the advantage of administration on an outpatient basis. If such a device is not available, the manual "push-pull" mechanism can be considered (Table 4) (45).

Generally, six units of donor packed red cells are exchanged by this process and there is rapid resolution of crisis symptomatology and ongoing sickling. In addition to being more isovolemic, automated continuous erythrocytapheresis requires less transfusion time than the manual method (46).

Obviously, most of the complications associated with this approach are related to the risk of the blood products. Blood products given to these patients should be from cytomegalovirus-seronegative donors or leukoreduced. Careful cross-matching to minimize minor blood incompatibilities and alloimmunization is critical in avoiding problems later for these patients who may need blood products at various points during their life. The use of blood from family members or friends matched for recipient and donor red cell antigens are clinically helpful in reducing the number of post-transfusion crises. Such episodes are known as delayed hemolytic transfusion reactions. The exact mechanism of hemolytic transfusion reaction is not well understood, and the pathophysiology seems to be far more complex because it involves the destruction of both patient and donor RBCs. A subcategory of this problem is known as a delayed transfusion reaction. It is classically characterized by a clinical triad of fever, hyperbilirubinemia, and anemia occurring 3–10 days after transfusion. Laboratory tests that aid diagnosis include increased reticulocyte count, free hemoglobin in the urine, fragmented RBCs on peripheral smear, decreased post-transfusion Hb A on electrophoresis, or discovery of previously undetected alloantibodies (47).

Intrapartum

The occurrence of a vaso-occlusive crisis during labor offers additional challenges to the provider. Obviously, with painful

uterine contractions, the diagnosis of a vaso-occlusive crisis may be more difficult. If delivery is expected within a short time, a simple transfusion of two units of leukocyte-reduced washed red cells can be considered. During labor, patients should remain in the lateral recumbent position and receive oxygen by tight-fitting face mask. Careful monitoring of maternal and fetal vital signs is essential. Usually, when crisis has been diagnosed during labor and late decelerations appear, infusion of blood products has been associated with resolution of suspected fetal hypoxemia. Maternal blood gas assessment, if necessary, is carried out, but invasive hemodynamic monitoring is avoided unless other concomitant disease processes such as pre-eclampsia, and so on, are present. Urinary catheters, as well as intrauterine catheters, are discouraged, because of their association with increased infection.

No consensus exists concerning the anesthetic care of parturients with SCD (48–50). It appears that the use of general anesthesia can result in a significant increase in postpartum sickling complications (51). We feel that epidural analgesia/anesthesia is ideal if the vaso-occlusive crisis is mild or can be aborted with blood infusion. If not, intermittent intravenous analgesia with pudendal block for vaginal delivery may be appropriate. Continuous epidural morphine has also been utilized with success in these patients. If cesarean delivery is indicated, the choice of regional or general anesthesia depends on the patient's general condition and the preference of the anesthesiologist. Careful monitoring of the patient's vital signs is important during anesthesia so that hypoxemia and acidosis are obviated. Avoidance of hypothermia and hypoxia during labor, as well as in the delivery room, is critical. Persons skilled at neonatal resuscitation should be present at delivery. Consultation with anesthesia and neonatology during labor is important. The use of oxytocic agents for induction/augmentation or an ecbolic agent during the third stage of labor is not contraindicated.

Postpartum

Crises in Hb S-S women after delivery usually do not develop unless hypovolemia, acidosis, or infection occurs. On the other hand, patients with Hb S-C are more likely to experience crises postpartum than during pregnancy. The same pitfalls of management applied during the antepartum period are also prudent after birth. Both urinary tract infection and endometritis are common and are frequently associated with crises. There is also a substantial increased risk of pulmonary edema and thromboembolic disease in these patients. Maintenance of isovolemia and high Hb A levels (>20%) appear to be important points in management.

SUMMARY

Overall, pregnant women with SCD appear to be more likely to experience antepartum, intrapartum, and postpartum complications when compared with unaffected women. Access to high-risk obstetric care, patient education, and close follow-up are important to minimize maternal morbidity and mortality.

In the absence of consistent data supporting a reduction in adverse obstetric or fetal outcomes, the use of transfusion therapy is generally limited to patients who experience a significant increase in SCD activity with severe complications, including acute chest syndrome, acute severe anemia (Hb <5.0–6.0 g/dL), severe, or refractory pre-eclampsia, and those

who are in anticipation of surgery (14,52). A high index of suspicion and good diagnostic acumen is necessary to obtain optimal results in the pregnant patient with SCD.

20 Cardiac diseases in pregnancy

Saravanan Kuppuswamy and Sudarshan Balla

INTRODUCTION

Major hemodynamic alterations in the cardiovascular system occur during normal pregnancy, labor, and delivery. With advances in surgical techniques and improved diagnostic and therapeutic alternatives, greater numbers of women with congenital and acquired heart disease are surviving to the childbearing years. Therefore, management of the pregnant patient, especially those with underlying cardiovascular disease, requires a thorough understanding of both the normal cardiovascular adjustments to pregnancy and the predicted response of the abnormal cardiovascular system to the hemodynamic stresses of pregnancy.

NORMAL CARDIOPULMONARY ADJUSTMENTS DURING PREGNANCY

Symptoms and Signs

Table 1 summarizes the cardiovascular symptoms and signs in normal pregnancy and findings that need further investigations.

Cardiovascular Hemodynamics in Pregnancy

Table 1 Normal and Pathologic Findings in Pregnancy

<i>Normal findings seen in pregnancy</i>	
Fatigue, dyspnea, and decreased exercise tolerance	
Peripheral edema	
Apical impulse will be laterally displaced	
First heart sound (S1) will have an increased amplitude and wide splitting of the two components (mitral and tricuspid) due to early closure of the mitral valve	
The second heart sound (S2) is little affected	
Majority of patients (84%) will develop a third heart sound (S3)	
Continuous murmurs due to cervical venous hum and mammary soufflé	
<i>Pathologic findings warranting evaluation (1)</i>	
Paroxysmal nocturnal dyspnea	
Hemoptysis	
Diastolic murmurs	
Continuous murmurs	
Loud systolic murmurs (louder than grade 2 on the six-point scale)	
Pansystolic murmurs	
Murmurs associated with symptoms or an abnormal electrocardiogram	

Table 2 Cardiovascular Changes in Pregnancy

Parameter	Modification	Magnitude	Peak
Oxygen consumption (VO ₂)	Increases	+20% +40–60%	Term
Oxygen delivery (DO ₂)	↔ ↑	700–1400 mL/min	Term
Plasma volume	↑ ↑	+45–50% ^a	32 weeks
Red blood cell volume	↑	+25–32%	30–32 weeks
Total body water	↑	+6–8 L	Term
Systemic vascular resistance	↓	–20%	16–24 weeks
Pulmonary vascular resistance	↓	–34%	34 weeks
Blood pressure			
Systolic	↓	–9% ^b	28 weeks
Diastolic	↓	(slightly more on diastolic)	
Heart rate	↑	+20–30%	Term ^c
Contractility (SV)	↑	+11–32%	Term
Cardiac output	↑	+30–50%	Term ^c
Uteroplacental circulation	↑	+>1000%	Term

^aCorrelates positively with the number of fetuses. ^bPosition dependent; lower for systolic and diastolic in left lateral decubitus. ^cIf measured in left lateral decubitus; otherwise peaks between 28 and 32 weeks. Abbreviation: SV, stroke volume. Source: From Ref. 2.

Alterations During Normal Labor and Delivery

Numerous cardiovascular changes take place during labor and delivery, and these changes are affected by a wide range of variables including anesthesia, analgesia, pain sensation, and mode of delivery.

During labor, transient increases in cardiac output occur with each uterine contraction, as well as increases in blood pressure, both systolic and diastolic. These changes are attenuated by anesthesia, with the minimum alterations occurring with spinal or epidural anesthesia, and with the greatest alterations seen during balanced general anesthesia.

Changes in blood volume during delivery are primarily a function of blood loss, with greater loss occurring after cesarean section rather than vaginal delivery. After delivery of the fetus, preload may increase dramatically due to the decompression of the vena cava and the return of uterine blood into the systemic circulation.

The point at which cardiac changes regress to preconception levels is debatable; normal levels have been reported from 5 to over 12 weeks postpartum (3,4).

PRECONCEPTIONAL CARE

The woman with heart disease should be considered a high-risk patient even before she becomes pregnant (5). Thorough planning, beginning even before conception, is the key for a successful pregnancy. Ideally, the timing of pregnancy should be a decision that the woman should decide after a detailed discussion with her obstetrician and the cardiologist. The following are the key points to be discussed before conception:

1. The natural history of the patient's disease. Pregnancy may be postponed for the medical treatment of a condition, for example, remission in the case of lupus or acute phase of myocarditis or for the surgical repair of structural abnormalities, such as valvular disease or shunts (2).
2. The expected outcomes of pregnancy in terms of maternal and perinatal morbidity and possible mortality of these conditions (6,7). Table 3 summarizes the maternal risk in commonly encountered heart diseases in pregnancy and can serve as a guide for counseling.
3. The frequency of office visits, multiple specialty consultations, medications, and peripartum management should also be discussed. This discussion prepares the patient or the couple for economic and other social issues (10).
4. The risk for transmitting the cardiac condition or syndrome to offspring (11–13). Accurate estimates of the risk for cardiovascular defects in the offspring of affected parents are difficult to obtain. Frequently, the risk is quoted as approximately 5%, which is six times higher than the risk in the general population (14). More recent studies have observed risks in the range of 13% to 16% (Table 4) (12,15,16).

Preconceptional Risk Stratification

Risk stratification is based on three main factors: (i) the cardiac lesion, (ii) the baseline functional compromise, and (iii) the possibility and probability of complications during gestation based on the published literature. The spectrum of risk ranges from small to prohibitive. Table 5 summarizes some of the conditions that are indications for strong consideration of termination of pregnancy, and patients with these conditions should be strongly advised against pregnancy.

A thorough discussion and informed decision before conception minimize the need for a difficult decision like termination of pregnancy. After conception, the decision to terminate or continue the pregnancy is that of the woman. For some of these patients, there may be only one chance for a

successful pregnancy (19). The team should provide the patient with the best information possible and to continue to assist her regardless of her decision (20).

PRENATAL CARE

Management of the pregnant woman with heart disease should be coordinated by an obstetrician experienced in high-risk cases, with a multidisciplinary team of cardiology and anesthesia (21).

Most patients with cardiac disease are aware of their cardiac condition, but in some, cardiac disease is suspected and confirmed subsequently (22). Between 16% and 25% of the patients referred for the suspicion of cardiac disease have significant structural heart disease (23). The reasons for referrals are for the evaluation of murmurs (43%), arrhythmias (35%), and congenital (15.6%) and acquired heart disease (7%) (23,24). A previous successful obstetric outcome does not exclude a significant cardiac pathology, for example, rheumatic heart disease may not manifest until second or third pregnancy (25). In addition, patients with already diagnosed heart disease may have acquired new lesions that may complicate their usual symptomatology (Table 6) (26).

A targeted ultrasound to evaluate for fetal congenital anomalies (the fetal heart and major vessels) should be scheduled between 16 and 20 weeks of gestation in women with defined clinical syndromes at risk for complications and in women with a history of congenital heart disease (16,27).

Prenatal Risk Stratification

Assessing the risk of maternal and fetal mortality and morbidity is a continuous process throughout the pregnancy. A clinically relevant tool to assess the risk would be to use Cardiac Disease in Pregnancy (CARPREG) risk index. A retrospective study examined the risks and predictors of pregnancy-related cardiac complications in women with heart disease (28). The findings were then validated by the CARPREG investigators in a prospective study (29).

Four predictors of cardiac events were identified as follows:

- Poor functional class [New York Heart Association (NYHA) class III or IV] or cyanosis
- Previous cardiac event (e.g., heart failure (HF), transient ischemic attack, stroke) or arrhythmia
- Left heart obstruction (mitral valve area of $<2\text{ cm}^2$, aortic valve area of $<1.5\text{ cm}^2$, peak left ventricular outflow gradient $>30\text{ mmHg}$)
- Left ventricular systolic dysfunction (ejection fraction $<40\%$)

The presence of none, one, or more than one risk factor was associated with 3%, 30%, and 66% rates of cardiac events (pulmonary edema, arrhythmia requiring treatment, stroke, cardiac arrest, or death) during gestation, respectively. In the presence of one or more risk factors, the score was 91% sensitive and 61% specific for the occurrence of cardiac events (28).

GENERAL PRINCIPLES FOR MANAGEMENT OF CARDIAC DISEASE DURING PREGNANCY

A multidisciplinary approach is key to a successful outcome. The frequency of assessment and the types of investigations needed depend on individual conditions. High-risk pregnancies

Table 3 Maternal Mortality Risk Groups of Cardiac Disease Associated with Pregnancy

Risk group	Conditions	Mortality
Low	Atrial septal defect Ventricular septal defect (uncomplicated) Patent ductus arteriosus (uncomplicated) Pulmonic/tricuspid disease Corrected tetralogy of Fallot Bioprosthetic valve Asymptomatic AS with low mean gradient (less than 25mmHg and valve area greater than 1.5cm ²) in presence of normal LV systolic function (EF greater than 0.50) NYHA functional class I or II AR with normal LV systolic function NYHA functional class I or II MR with normal LV systolic function MVP with no MR or with mild to moderate MR with normal LV systolic function Mild MS (MVA greater than 1.5cm ² , gradient less than 5mmHg) without severe pulmonary hypertension	<1%
Moderate	Mild to moderate pulmonary valve stenosis Mitral stenosis with atrial fibrillation Artificial valve Coarctation of the aorta (uncomplicated) Uncorrected tetralogy of Fallot Previous myocardial infarction	5–15%
High	Mitral stenosis, NYHA II, III, and IV Severe aortic stenosis with or without symptoms AR with NYHA functional class III–IV symptoms MR with NYHA functional class III–IV symptoms Aortic and/or mitral valve disease with severe LV dysfunction (EF less than 0.40) Marfan syndrome with normal aorta Pulmonary hypertension Coarctation of the aorta Marfan syndrome with aortic involvement	25–50%

Abbreviations: NYHA, New York Heart Association; AR, aortic regurgitation; MR, mitral regurgitation; EF, ejection fraction; LV, left ventricular; AS, aortic stenosis; MS, mitral stenosis. *Source:* From Ref. 8,9 ACC guideline document does not have moderate risk category.

should be managed in a tertiary care center, where immediate access to specialists is readily available. The following pages summarize the management of the different conditions.

SPECIFIC CARDIOVASCULAR ABNORMALITIES OF LOW RISK TO THE PREGNANT PATIENT (FIG 1)

Atrial Septal Defect

Ostium secundum atrial septal defect (ASD) is the most common congenital cardiovascular defect seen in pregnancy. Most women are asymptomatic and pregnancy is usually well tolerated in the pregnant patient with an ASD.

Numerous reports suggest that pregnancy is safe (30), although there are reports of the development of congestive HF and arrhythmias in these patients (31). If circumstances allow, ASDs should be closed before pregnancy. For a secundum defect, catheter device closure can be performed during pregnancy if necessary (with transesophageal or intracardiac echocardiographic guidance). In most instances, in pregnant women diagnosed with an ASD during pregnancy, closure can be deferred for 6 months after delivery (32).

A small proportion of patients with an ASD may develop Eisenmenger syndrome and should be considered as high-risk pregnancy. The management of high-risk patients is discussed below.

Ventricular Septal Defect

Women who reach childbearing years with an uncorrected ventricular septal defect (VSD) generally have smaller defects

that are well tolerated, since the clinical picture is largely determined by the size of the defect; larger defects often require repair in childhood. Physical exam is characterized by a harsh holosystolic murmur.

Pregnancy is usually very well tolerated in women with a VSD (33). Morbidity and mortality is related to the presence of pulmonary hypertension, with a higher complication rate in those patients with Eisenmenger's physiology (31). Management of Eisenmenger syndrome is discussed below.

Patent Ductus Arteriosus

With improved pediatric surgical techniques, most patients with a patent ductus arteriosus (PDA) are surgically corrected during infancy and childhood, so it is a rare finding in pregnancy. Many patients are asymptomatic unless there is associated pulmonary hypertension. The physical examination is characterized by a "machinery" or continuous murmur in the second intercostal space. As with other shunt lesions, echocardiography is useful in defining chamber dimensions and shunt detection.

The patient with a PDA generally tolerates pregnancy well, whether surgically corrected (34) or uncorrected (30,31), but the presence of pulmonary hypertension increases the morbidity and mortality.

Mitral Regurgitation

The causes of mitral regurgitation (MR) are myriad, but in young women of childbearing age, the most common

Table 4 Maternal and Fetal Outcomes in Cardiac Lesions

Maternal lesion	Number of pregnancies	Number of abortions	Maternal mortality (%)	Maternal cardiovascular complications (%)	Live births (%)

Table 5 Indications for Pregnancy Termination

Pulmonary arterial hypertension of any cause
Severe ventricular systolic dysfunction
NYHA III–IV symptom class or LVEF <30%
Previous peripartum cardiomyopathy with any residual impairment of left ventricular function
Severe left heart obstruction defined as mitral stenosis: mitral valve area <1.0cm ² Aortic stenosis: aortic valve area <1.0cm ² or (nonpregnant) mean gradient >50mmHg
Marfan syndrome with aorta dilated >40mm
<i>Abbreviations:</i> LVEF, left ventricular ejection fraction; NYHA, New York Heart Association. <i>Source:</i> From Ref. 17,18.

etiologies are rheumatic (almost always seen in association with mitral stenosis) and as a component of Barlow’s syndrome (click–murmur or mitral valve prolapse syndrome).

The characteristic finding on examination is a holosystolic murmur at the apex, which radiates to the axilla. Echocardiography provides a comprehensive assessment of the etiology and the severity of the MR. In general, pregnancy is very well tolerated. Mitral valve surgery, preferably repair for

symptomatic MR, may be indicated before conception (35). However, any associated left ventricular dysfunction is unlikely to improve after surgery (36) and will increase maternal risk during pregnancy (37). Severe MR may lead to HF during pregnancy or labor. The management of HF is discussed separately.

Aortic Insufficiency

Aortic insufficiency is seen infrequently in women of child-bearing age, and the usual etiology is rheumatic, bicuspid aortic valve, previous endocarditis, and Marfan syndrome.

Physical findings include widened pulse pressure, and a diastolic murmur (blow) heard at the upper sternal border and the diagnosis is confirmed by echo. Aortic insufficiency without HF is generally well tolerated during pregnancy, and these patients remain essentially asymptomatic. Patients with NYHA class III–IV are at increased risk.

Tricuspid and Pulmonary Valve Lesions

Tricuspid regurgitation is an extremely common finding in normal pregnancy (38) and is rarely clinically important. The

exception is tricuspid regurgitation seen in association with Ebstein's anomaly, which increases the morbidity of pregnancy. Tricuspid stenosis and pulmonary insufficiency are uncommon findings in pregnancy, and there are few published data on the outcome of pregnancy in these patients.

Pulmonary stenosis (PS) represents a common congenital cardiac defect and is seen both alone and as part of the syndrome of tetralogy of Fallot. Isolated PS is usually detected in childhood; both surgical and nonsurgical (with balloon valvuloplasty) repairs are often curative. Patients with all but the severest forms of PS often tolerate pregnancy well (31,39,40). The incidence of inherited cardiac defects in the offspring of these patients appears to be high (41). Balloon valvuloplasty is recommended before conception if the gradient across the right ventricular outflow track is >50 mmHg at rest (42) or if the patient is symptomatic. The procedure is rarely indicated during pregnancy in patients who are either asymptomatic or mildly symptomatic before pregnancy. Vaginal delivery is tolerated well and can be permitted in the great majority of patients with PS.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is a common cardiac condition, seen in up to 2.4 % of the general population (43).

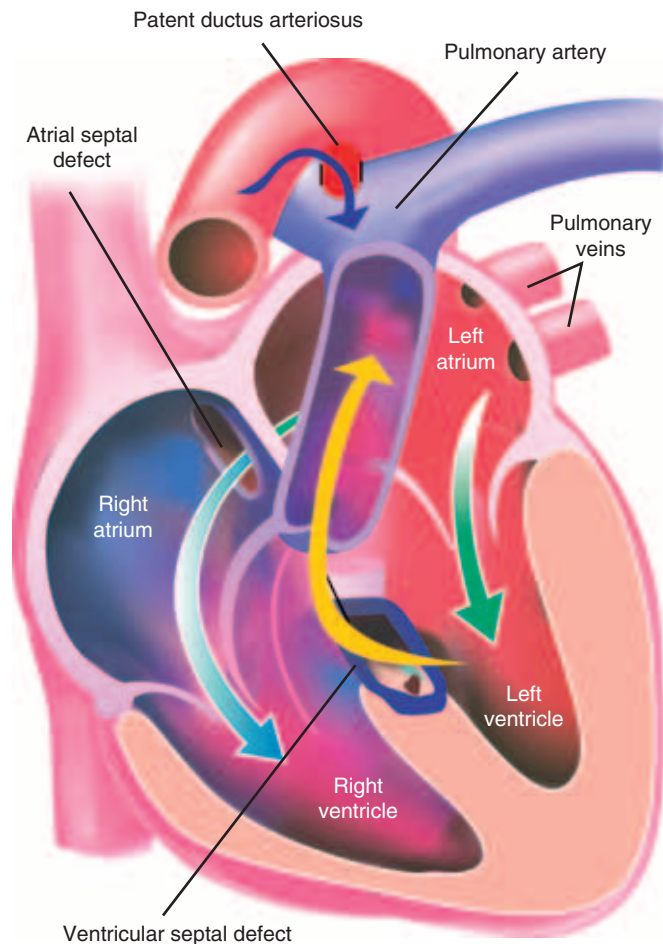

Figure 1 Anatomic locations of left-to-right shunts.

Although the majority of patients with mitral valve prolapse are asymptomatic, some patients may experience palpitations, fatigue, and chest pain. On physical examination, mid-systolic ejection click and a murmur of MR may be heard. Management of MVP is similar to patients with MR. Infective endocarditis prophylaxis is no longer recommended (44) (see section on antibiotic prophylaxis below).

SPECIFIC CARDIOVASCULAR ABNORMALITIES OF MODERATE RISK TO THE PREGNANT PATIENT (FIG. 2) Mitral Stenosis

A common etiology for mitral stenosis in a woman of childbearing years is rheumatic heart disease, and mitral stenosis represents the most common rheumatic valvular lesion. Physiologic changes in pregnancy and atrial fibrillation can result in pulmonary edema.

These patients may have symptoms of fatigue and dyspnea. Physical examination may reveal evidence of pulmonary congestion and a diastolic murmur at the apex associated with an opening snap. Echo can assess the severity, suggest etiology, and guide in the management of mitral stenosis.

It is not uncommon for women with occult mitral stenosis to become symptomatic during pregnancy, usually by mid-pregnancy, when the pregnancy-induced hemodynamic changes are at the maximum. The risk of pulmonary edema exists from this period until several days after delivery.

Predictors of adverse maternal outcomes in these patients include a reduced mitral valve area (less than 1.5 cm²) and the NYHA functional class before pregnancy (45). Mortality among pregnant women with minimal symptoms is less than 1% (15). Severe mitral stenosis with NYHA class III–IV symptoms has a 4% to 5% maternal mortality and 30% fetal mortality (46). The mortality is even higher if atrial fibrillation is present (47). Improved diagnostic techniques,

better prenatal management, and effective cardiac drugs have improved the outcome of these patients. Development of atrial fibrillation requires prompt treatment, including cardioversion. Beta blockers and digoxin can be safely used for rate control. Antiarrhythmic drugs preferred are beta blockers (sotalol, atenolol) or flecainide. Procainamide is another safe alternative, while mexiletine and amiodarone have also been used with success in small numbers of patients in the acute setting with success (48). Anticoagulant therapy is indicated in patients with mitral stenosis and atrial fibrillation to decrease the risk of systemic embolism (49,50). Anticoagulation in pregnancy is discussed separately. In patients who present with severe symptoms during pregnancy, successful percutaneous balloon mitral valvuloplasty, performed during the second trimester, has been associated with normal subsequent deliveries and excellent fetal outcomes (51). The maternal and perinatal benefits of the procedure probably outweigh the small risk of fetal exposure to the radiation. Open cardiac surgery has been performed during pregnancy for severe mitral stenosis. Maternal outcomes are approximately the same as those among nonpregnant, but there is fetal loss in 10% to 30% of cases (52). See also Figure 3.

Aortic Stenosis

Aortic stenosis is not a commonly seen valvular abnormality in pregnancy, because it is usually prevalent in an older population. However, patients with aortic stenosis who have a bicuspid aortic valve may become symptomatic in their twenties and thirties. Patients may present with symptoms of angina, syncope, and HF. The physical examination reveals a crescendo–decrescendo systolic murmur at the upper sternal border, and in severe cases, a single or absent second heart

Black arrows indicate abnormal direction of flow

Figure 2 Normal and diseased aortic and mitral valve states.

sound may be present. EKG may show left ventricular hypertrophy. Echo assesses the severity of stenosis and left ventricular (LV) systolic function.

Pregnancy can usually be successfully carried to term in all but the most severe cases of aortic stenosis; reported maternal mortality in severe aortic stenosis is 17% (53). A more recent review of 12 studies demonstrated an average maternal mortality of 6.6% and an average perinatal mortality of 4% (54). The fetal risks of congenital heart diseases range from 17% to 26% (12,55). Complications arise when the already low forward output is compromised further by reduced preload from either hypovolemia or peripheral vasodilatation.

Patients who are symptomatic or who have a peak outflow gradient of more than 50mmHg are advised to delay conception until after surgical correction (56). Termination of pregnancy should be strongly considered if the patient is symptomatic before the end of the first trimester. Aortic valve replacement and palliative aortic balloon valvuloplasty have been performed during pregnancy with some associated maternal and fetal risk (52,57–59).

Coarctation of the Aorta, Uncomplicated

Coarctation of the aorta is a stenosis of the aorta, usually located just distal to the left subclavian artery at the ligamentum arteriosum (fetal ductus arteriosus). The lesion may be associated PDA, congenital bicuspid aortic valve, and aneurysms of the circle of Willis.

The hallmark of coarctation is an asymmetry of upper and lower limb blood pressures with a markedly decreased pressure in the lower extremities. Patients who have had coarctation of the aorta corrected prior to pregnancy and no other associated anomalies usually tolerate the pregnancy well. These patients, however, are still at a higher risk for cardiovascular compromise compared with nonpregnant patients.

Complications associated with uncorrected coarctation of the aorta include hypertension, HF, and aortic dissection. The mainstay of therapy is control of hypertension and avoidance of hypovolemia during the peripartum period. In cases of

aortic dissection or severe HF unresponsive to medical therapy, surgical repair has been successfully attempted during pregnancy (60,61). Fetal morbidity and mortality are high because of decreased placental blood flow from hypertension or reduced cardiac output and increased incidence of fetal cardiac anomalies (34).

Marfan Syndrome, Normal Aortic Root

Marfan syndrome is an autosomal dominant condition with defective collagen synthesis affecting the ocular, skeletal, and cardiovascular abnormalities with variable severity. The cardiovascular manifestations include mitral valve prolapse with MR and aneurysmal dilatation of the proximal aorta; the latter may be occasionally associated with aortic regurgitation and dissection.

Pregnancy seems to increase the risk of aortic rupture in patients with Marfan syndrome. The maternal morbidity and mortality depends on whether there are aortic root dilatation or valvular abnormalities (62,63). Maternal mortality from aortic rupture or dissection may be up to 50% when the aortic root diameter is greater than 40mm (63). On the other hand, pregnancy in patients who have aortic root diameter less than 40mm and no valvular involvements can be successfully carried to term with minimal maternal mortality or morbidity. Patients should be advised of the risk and should be closely followed for signs and symptoms of aortic dissection. Serial echocardiograms during pregnancy are recommended to assess the size of the aortic root and the presence of valvular regurgitation. In selected patients, beta beta blockers may lower the risk of progressive aortic dilatation (64,65).

Prior History of Myocardial Infarction

Coronary artery disease is rare in women of childbearing years, and there are only a few reports of pregnancies in women who have sustained myocardial infarctions prior to pregnancy. The pregnancy outcome of these patients is related to left ventricular function. Myocardial infarction during pregnancy poses a much higher risk (see section below).

SPECIFIC CARDIOVASCULAR ABNORMALITIES OF HIGH RISK TO THE PREGNANT PATIENT

Considering the high morbidity and mortality of pregnancy in patients with lesions in this category, counseling should be directed toward the avoidance of pregnancy. If pregnancy occurs, elective termination during the first trimester may be offered. If the pregnancy has to be continued, it is imperative that the patient is followed up closely in a tertiary care center with a multidisciplinary team including obstetrician, cardiologist, anesthesiologist, and neonatologist with experience in high-risk pregnancies (66–68). Frequent visits are recommended, and hospitalization during the third trimester may facilitate management. Detailed plans including timing and mode of delivery should be discussed with the patient in advance (66). Maternal safety needs to be weighed against the risk of premature delivery, intrauterine growth retardation, and the need for neonatal care, when decisions about timing and type of delivery are made.

These conditions are associated with a very high maternal mortality (23–50%), which may occur during the pregnancy or the postpartum period (33,69). The patient should be

Figure 3 Relation between severity of multiple sclerosis (MS) and frequency of adverse maternal cardiac, fetal, or neonatal events. Any event refers to cardiac, fetal, or neonatal events. White bars indicate pregnancies in women who have mild MS; gray bars indicate pregnancies in women who have moderate MS, and black bars indicate pregnancies in women who have severe MS. Source: From Ref. 138.

informed about the risk and offered the option of termination of pregnancy.

If the patient continues the pregnancy, careful monitoring of arterial oxygen saturation, cardiac rhythm, and blood pressure is recommended in the peripartum period. The management also includes oxygen supplementation to prevent fetal hypoxemia, invasive hemodynamic monitoring in select cases, and shortening of the second stage of labor with low or outlet forceps delivery. Hospitalization is necessary. Since the incidence of intrauterine growth retardation and fetal death is high (69), close fetal monitoring with serial ultrasound examinations and nonstress tests and/or biophysical profiles is recommended.

Eisenmenger's Syndrome

In patients with left-to-right shunts (e.g., PDA, VSD, ASD), worsening pulmonary hypertension, approaching systemic levels, results in a reversal of shunting (Eisenmenger physiology) and causes hypoxemia and death. These patients may present with peripheral cyanosis, HF, and hemoptysis.

General principles of management are discussed above. Other measures include maintaining maternal PaO₂ above 70% to ensure adequate fetal oxygenation (70). There is no standard thromboprophylaxis for pregnant women with Eisenmenger (71). However, anticoagulation is needed if patient has documented pulmonary artery thrombosis.

The peripartum period is a precarious time, owing to a rapid shift in blood volume and chance of hemorrhage. Measures should be taken to avoid a reduction in preload such as hypotension or hemorrhage, since severe hypoxemia and death may ensue from decreased cardiac output. The patients should be closely monitored in the hospital setting for at least several days after delivery, since the significantly increased risk of maternal mortality still persists during this period.

Idiopathic Pulmonary Artery Hypertension

Idiopathic pulmonary artery hypertension (IPAH) is a disease of unknown etiology, primarily seen in young women and results in a progressive increase in pulmonary artery pressures. Presenting symptoms include dyspnea, fatigue, palpitations, and occasional syncope.

Right ventricular failure (elevation of jugular venous pressure, hepatomegaly, and peripheral edema) may be present.

Echocardiography remains the key diagnostic test in pulmonary hypertension, and a right heart catheterization may be needed to confirm the diagnosis of pulmonary arterial hypertension and, if needed, for the assessment of response to therapy. Right heart catheterization can be done without exposure to any radiation.

Pregnancy is poorly tolerated in patients with IPAH, with maternal mortality in excess of 40% (72). This excess mortality appears to be present even in patients who were asymptomatic or only mildly symptomatic prior to becoming pregnant. In addition, there appears to be a high incidence of fetal and neonatal death associated with maternal IPAH. Patients with IPAH often come to clinical attention during the second trimester, when the hemodynamic changes of pregnancy are maximum and the presenting symptoms are often those of right ventricular failure.

General principles of management are discussed above. Over the past decade, advanced therapies (prostacyclin analogs, phosphodiesterase inhibitors, and endothelin-receptor antagonists) have revolutionized PAH management considered before patients decompensate or thrombotic complications ensue. The effect of advanced therapies in pregnancy with PAH is unknown.

Bosentan may have teratogenic effects (73) and is, thus, contraindicated during pregnancy; limited data on sildenafil suggest no deleterious effects on the mother or offspring (74). Calcium channel blockers are safe during pregnancy (75) and may prevent preterm labor (76), a common complication in patients with PAH. However, calcium channel blockers may be beneficial only in responders to vasoreactivity tests, and only 6.8% are reported to have a long-term benefit (77).

Inhaled nitric oxide (NO) has been shown to decrease the pulmonary vascular resistance in IPAH, in Eisenmenger syndrome, and in chronic pulmonary thromboembolic disease. The effect of NO during pregnancy or labor on outcomes remains uncertain (78).

Low-dose subcutaneous heparin prophylaxis is generally recommended in pregnant women with PAH, but some patients may require higher levels of anticoagulation (e.g., patients with a history of thromboembolic events or atrial fibrillation) (68).

The optimal mode of delivery (vaginal vs. caesarean section) in patients with PAH remains a matter of debate (29). Invasive pulmonary arterial pressure monitoring remains controversial and the lack of evidence that it improves outcomes in these patients (79).

Complex Cyanotic Congenital Heart Disease

Many children with complex cyanotic congenital heart disease die during infancy and childhood, and do not reach child-bearing age, but with greatly improved surgical techniques, a larger number of these patients are surviving into adulthood. Specific congenital lesions of interest include (i) tetralogy of Fallot (PS, VSD, overriding aorta, and right ventricular hypertrophy); (ii) Ebstein's anomaly (displacement of the tricuspid valve into the right ventricular cavity, resulting in a small right ventricle and poor forward output, often associated with right-to-left shunting through an ASD); (iii) truncus arteriosus (single outflow tract and outflow valve distal to both ventricles, often associated with a VSD); (iv) transposition of the great vessels (separate pulmonary and systemic circulations operating in parallel with communication via a VSD); and (v) tricuspid atresia (absent tricuspid orifice, small non-functional right ventricle, and a connection between the pulmonary and systemic circulations). These lesions represent many of the important cyanotic congenital heart lesions, and individual lesions may be variable in severity.

In general, patients with uncorrected cyanotic congenital heart defects do not survive long enough to become pregnant; those who do survive should be counseled against pregnancy. Despite the high morbidity and mortality of pregnancy in these patients, there are case reports of successful completion of pregnancy in patients with these congenital lesions (72). If the cardiac abnormality has been surgically corrected, maternal morbidity and mortality during pregnancy appears to be related to residual cardiac defects, with a marked improvement

in prognosis for those who have undergone successful complete correction. Infective endocarditis prophylaxis is discussed below.

Marfan Syndrome Associated with an Abnormal Aortic Root

Marfan syndrome, discussed earlier in this chapter, markedly increases maternal and fetal mortality if there is evidence of a dilated aortic root, valvular regurgitation, or dissection. Transesophageal echocardiography is superior to transthoracic echocardiography in diagnosing aortic root dilatation and aortic dissection. Preventive replacement of the ascending aorta with a graft has been recommended in patients with the aortic root diameter of at least 60mm prior to pregnancy (80). Patients who contemplate pregnancy may consider preventive replacement of the ascending aorta when the aortic root dilatation is progressive and approaching 55mm in diameter (64). If pregnancy occurs in patients with significant aortic root dilatation, therapeutic termination during the first trimester may be offered. If the patient chooses to continue the pregnancy, careful assessment of the patient throughout pregnancy should include evaluation for aortic dissection and use of beta blockers during pregnancy to reduce the incidence of dissection. The patient should be encouraged to avoid strenuous physical activity. Urgent delivery and vascular repair should be undertaken if clinical evidence of dissection occurs, regardless of the viability of the fetus.

Myocardial Infarction During Pregnancy

The epidemiology of coronary artery disease is such that myocardial infarction is extremely rare in women of childbearing years, estimated to occur in 1 in 10,000 pregnancies (81). Risk factors for coronary heart disease in pregnant women are the same as those for the general population and include cigarette smoking, hyperlipidemia, diabetes mellitus, and hypertension. The causes of occlusion or stenosis of the coronary arteries include thrombus and atherosclerosis; uncommon etiology includes dissection and vasospasm (82–86).

In ST elevation myocardial infarction (STEMI) in the general population, primary PCI (percutaneous coronary intervention) is the recommended therapy, if the infarct-related artery can be opened within 90 minutes of presentation (commonly referred to as door to balloon time). Treatment with thrombolytics is relatively contraindicated in pregnancy (87).

In selected group of pregnant patients with myocardial infarction, including patient with STEMI and high-risk non-ST elevation myocardial infarction (NSTEMI), PCI may be the therapy of choice during pregnancy. However, before completion of major organogenesis (before 15 weeks after menses), radiation exposure must, whenever possible, be avoided.

Cardiac catheterization offers the advantage of diagnosing and treating, in addition to thromboembolic disease, other causes such as coronary artery dissection.

All reported stenting during the acute phase of MI during pregnancy were performed with bare metal stents. The safety of drug-eluting stents in pregnant woman is therefore still unknown. Because drug-eluting stents require prolonged antiplatelet therapy with aspirin and thienopyridine, and the incidence of cesarean section deliveries in patients with heart

disease is relatively high, the use of drug-eluting stent during pregnancy should be avoided if possible. Although animal experiments do not demonstrate teratogenic effect, there are no studies in pregnant women and should be used in pregnancy only if clearly needed.

Successful vaginal deliveries without further myocardial injury have been reported (82,84–86). Therefore, myocardial infarction is not a contraindication for a vaginal delivery.

HEART FAILURE (HF) SYNDROMES

Peripartum Cardiomyopathy

This entity involves the development of HF during the last month of pregnancy or in the first five postpartum months, without obvious etiology. In the United States, the incidences vary from 1 in 4000 deliveries to 1 in 1500 deliveries, peak during the second postpartum month and increase among older, multiparous black females. The overall maternal mortality ranges from 25% to 50% (88,89).

Although the etiology of peripartum cardiomyopathy is not known, various factors have been suggested to play a role in its development, including hypertension (90), viral illness (91), an immunologic reaction (92), and vitamin deficiency (93).

Presenting clinical symptoms include those of left-sided HF (orthopnea, dyspnea, weakness) as well as peripheral edema, palpitations, and occasionally hemoptysis. On physical examination, these patients may have pulmonary rales, cardiomegaly, a gallop rhythm, distended neck veins, and peripheral edema. Cardiomegaly and pulmonary venous congestion are typical chest X-ray findings.

The diagnosis of PPCM has been based upon four clinical criteria (94–96):

- Development of cardiac failure in the last month of pregnancy or within 5 months of delivery.
- Absence of an identifiable cause for the cardiac failures (see “Causes of dilated cardiomyopathy”).
- Absence of recognizable heart disease prior to the last month of pregnancy.
- LV systolic dysfunction (e.g., LVEF<45% or a reduced shortening fraction).

Echocardiography is helpful in ruling out a valvular or pericardial etiology for the clinical presentation, assessing cardiac chamber size and overall left ventricular function.

Treatment is directed toward managing HF, which is discussed below. These patients are at risk for thromboembolic disease, so prophylactic anticoagulation with heparin should be considered. If HF is refractory to medical management, early delivery should be considered.

The prognosis appears to be related to the course following pregnancy. Patients who have persistent cardiomegaly have a poor prognosis (97), whereas a return to normal heart size within 6–12 months postpartum predicts a more favorable outcome (94). Women with persistent LV dysfunction should be advised to avoid pregnancy due to the risk of HF progression and death (98). Successful subsequent pregnancies have been reported in patients who have a return to normal heart size (99,100). For patients who have a refractory downhill course following the diagnosis of peripartum cardiomyopathy, cardiac transplantation should be considered. Case reports of successful completion of pregnancy following

cardiac transplantation have been published (101–105). Patients in whom left ventricular dysfunction develops as a result of peripartum cardiomyopathy require echocardiographic follow-up of ventricular function. Improvement in systolic function beyond that assessed at 6 months after delivery is uncommon.

Heart Failure

The etiology of the HF could be ischemic or non-ischemic. Ischemia is an uncommon etiology in this population. Non-ischemic causes include peripartum cardiomyopathy, viral illness, and valvular heart disease among the many. Presenting symptoms include fatigue, dyspnea, orthopnea, and pedal edema. Prognosis depends on the etiology for congestive HF (Table 7).

In patients with stable HF, initial evaluation includes careful history and physical examination, assessment of NYHA functional class, and echocardiogram. In addition, medication adjustments and serial echocardiography during each trimester is recommended. The goals of therapy include relief of symptoms and continuation of the chronic therapy if possible, and treat precipitating causes such as anemia, arrhythmia, and thyroid disorders.

Angiotensin-converting enzyme inhibitors (ACEI), and angiotensin receptor blockers (ARB), and aldosterone antagonists like spironolactone are contraindicated throughout pregnancy. Due to the risks of embryopathy associated with ACE inhibitor use in the first trimester, ACEI should be discontinued when the woman with chronic stable HF is attempting conception. Beta blockers are generally safe and effective during pregnancy, although some adverse effects have been reported (106).

In patients with moderate symptoms of HF, in addition to sodium restriction, diuretics such as furosemide and afterload-reducing agents like hydralazine should be considered. Digitalis is safe during pregnancy and may be used to maximize contractility and control heart rate, but improved survival rates have not been shown.

In decompensated HF, positive inotropes like dobutamine and dopamine and, in select patients, intravenous nitroglycerin may be needed.

Table 7 New York Heart Association Classification of Heart Failure

NYHA class	Symptoms
I	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea (shortness of breath)
II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea
III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea
IV	Unable to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency at rest. If any physical activity is undertaken, discomfort is increased

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy has an autosomal dominant inheritance pattern with a widely variable penetrance, but sporadic cases occur as well.

The clinical presentation is characterized by dyspnea, chest pain, angina, dizziness, and syncope, although many patients may remain asymptomatic. Occasionally, sudden death is the presenting symptom. In patients with outflow obstruction, a loud systolic murmur and thrill can be detected along the left sternal border. Maneuvers that increase venous return or chamber size (handgrip, squatting) decrease the intensity of the murmur and Valsalva maneuver increases the intensity of the murmur.

The echocardiogram provides comprehensive assessment of the thickness of the left ventricular wall, dynamic outflow tract obstruction with different maneuvers, and valvular regurgitation.

In a study of 82 pregnancies, Kumar and Elkayam (107) concluded that the outcome of pregnancy is generally favorable, although worsening of symptoms may occur.

In asymptomatic patients, management involves avoiding situations that increase the outflow tract obstruction such as hypovolemia, vasodilatation, and medications like digoxin, inotropes, and diuretics (Table 8). For symptomatic pregnant patients, treatment should be aimed at alleviating symptoms with beta blockers or non-dihydropyridine calcium channel blockers. Arrhythmias, both atrial and ventricular, occur frequently in patients with hypertrophic cardiomyopathy. General measures during labor and delivery in these patients include laboring in the left lateral decubitus position to maximize venous return to the heart, avoidance of hypovolemia, and a shortened second stage of labor. Prostaglandins, such as PGE₂ (because of their vasodilatory effect), and beta-adrenergic stimulants should be avoided in these patients.

OTHER CONDITIONS WITH VARIABLE RISKS:

ARRHYTHMIAS

Tachyarrhythmias

Cardiac arrhythmias may be classified as supraventricular or ventricular and may occur during pregnancy either spontaneously or related to preexisting heart disease. Sinus tachycardia is a frequent occurrence during pregnancy, as are premature atrial and ventricular contractions. The hormonal and hemodynamic changes of pregnancy may predispose women, even those with normal cardiovascular systems, to frequent ectopic beats. Although the essentials of treatment of the arrhythmias in pregnant women are similar to those for nonpregnant women, the treatment has to be individualized depending on the stage of pregnancy and the risk–benefit ratio of exposing the fetus to the drugs. The principle is to avoid maternal hypotension and fetal hypoperfusion.

Atrial fibrillation in pregnancy is usually seen in the setting of rheumatic mitral stenosis. Two important considerations in pregnancy are the following: (i) If the ventricular rate is rapid, the diastolic filling time shortens, resulting in a fall in both stroke volume and forward output. This can cause decreased placental perfusion and fetal compromise. For this reason, women who are at risk for developing atrial fibrillation during pregnancy should be maintained on prophylactic digoxin or a beta blocker to prevent the rapid ventricular response, should atrial fibrillation develop. (ii) Atrial fibrillation in mitral

Table 8 Cardiovascular Drugs in Pregnancy

Drug	Use in pregnancy	Potential side effects	Breast feeding	Risk factors
Adenosine	Maternal and fetal arrhythmias	No side effects reported; data on use during first trimester are limited	Data NA	C
Amiodarone	Maternal arrhythmias	IUGR, prematurity, congenital goiter, hypothyroidism and hyperthyroidism, transient bradycardia, and prolonged QT in the newborn	Not recommended	C
Angiotensin-converting enzyme inhibitors	Hypertension	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, death, skull ossification defect, limb contractures, patent ductus arteriosus	Compatible	First trimester: C Second and third trimester: D
Aldomet	Hypertension			C
Beta blockers	Hypertension, maternal arrhythmias, myocardial ischemia, mitral stenosis, hypertrophic cardiomyopathy, hyperthyroidism, Marfan syndrome	Fetal bradycardia, low placental weight, possible IUGR, hypoglycemia, no information on carvedilol	Compatible, monitoring of infant's heart rate recommended	Acebutolol: B Labetalol: C Metoprolol: C Propranolol: C Atenolol: D
Digoxin	Maternal and fetal arrhythmias, heart failure	No evidence for unfavorable effects on the fetus	Compatible	C
Diltiazem	Myocardial ischemia, tocolysis	Limited data; increased incidence of major birth defects	Compatible	C
Disopyramide	Maternal arrhythmias	Limited data; may induce uterine contraction and premature delivery	Compatible	C
Diuretics	Hypertension, congestive heart failure	Hypovolemia leads to reduced uteroplacental perfusion, fetal hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia; thiazide diuretics can inhibit labor and suppress lactation	Compatible	C
Flecainide	Maternal and fetal arrhythmias	Limited data; two cases of fetal death after successful treatment of fetal SVT reported, but relation to flecainide uncertain	Compatible	C

(Continued)

Table 8 (Continued) Cardiovascular Drugs in Pregnancy

Drug	Use in pregnancy	Potential side effects	Breast feeding	Risk factors
Heparin	Anticoagulation	None reported	Compatible	C
Hydralazine	Hypertension, hypertensive emergencies	None reported	Compatible	C
Lidocaine	Local anesthesia, maternal arrhythmias	No evidence for unfavorable fetal effects; high serum levels may cause central nervous depression at birth	Compatible	C
Mexiletine	Maternal arrhythmias	Limited data	Not recommended	C
Nifedipine	Hypertension, tocolysis	Fetal distress related to maternal hypotension reported	Compatible	C
Nitrates	Myocardial infarction and ischemia, hypertension, pulmonary edema, tocolysis	Limited data; use is generally safe, few cases of fetal heart rate deceleration and bradycardia have been reported	Data NA	C
Procainamide	Maternal and fetal arrhythmias	Limited data; no fetal side effects reported	Compatible	C
Propafenone	Fetal arrhythmias	Limited data; fetal death reported after direct intrauterine administration in fetuses with fetal hydrops	Data NA	C
Quinidine	Maternal and fetal arrhythmias	Minimal oxytocic effect, high doses may cause premature labor or abortion; transient neonatal thrombocytopenia and damage to eighth nerve reported	Compatible	C
Sodium nitroprusside	Hypertension, aortic dissection, hypertensive emergencies	Limited data; potential thiocyanate fetal toxicity, fetal mortality reported in animals	Data NA	C
Sotalol	Maternal arrhythmias, hypertension, fetal tachycardia	Limited data; two cases of fetal death and two cases of significant neurologic morbidity in newborns reported, as well as bradycardia in newborns	Compatible, monitoring of infant's heart rate recommended	B
Verapamil	Maternal and fetal arrhythmias, hypertension, tocolysis	Limited data; other than a single case of fetal death of uncertain cause, no adverse fetal or newborn effects have been reported	Compatible	C

(Continued)

Warfarin	Anticoagulation	Crosses placental barrier; fetal hemorrhage in utero, embryopathy, central nervous system abnormalities	Compatible	X
Aspirin	Antiplatelet	Increased maternal and fetal hemorrhage, increased perinatal mortality, intrauterine growth retardation, and premature closure of the ductus arteriosus. Chronic high-dose use not recommended. Low-dose use (<150mg/day) safe	Cautious use of aspirin during lactation	High dose in third trimester: D
Thienopyridine derivatives		Very limited data	Not recommended	B
Glycoprotein IIb/IIIa inhibitors		Data NA, cesarean section should be considered as the method of delivery to avoid the risk of fetal intracranial hemorrhage	Data NA	(Risk category B: eptifibatide, tirofiban; risk category C: abciximab)
HMG-CoA reductase inhibitors (statins)		Skeletal abnormalities maternal, fetal, and neonatal mortality in animal studies. Post marketing surveillance—no adverse outcome	Not recommended	X
<p>FDA classification: Category B: Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect that was not confirmed in controlled studies in women. Category C: Either studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if potential benefits justify the potential risk to the fetus. Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant woman may be acceptable despite the risk. Category X: Studies in animals or human beings have demonstrated fetal abnormalities. The risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant. <i>Abbreviations:</i> NA, not available; SVT, supraventricular tachycardia; IUGR, intrauterine growth retardation. <i>Source:</i> From Refs. 9,87.</p>				

stenosis carries a higher risk of systemic embolization. Anticoagulation in pregnancy is described below.

Supraventricular tachycardias can be terminated by vagal maneuvers such as carotid sinus massage, splashing the face with cold water, or a Valsalva maneuver. If these vagal maneuvers are unsuccessful, intravenous adenosine or verapamil should be tried. Electrical cardioversion has been used successfully during pregnancy for reversion to sinus rhythm (108).

Ventricular tachycardia is rare during pregnancy and often accompanies structural heart disease. If the ventricular tachycardia is slow (<100–120 beats/min) or non-sustained (self-terminating within 30 seconds), and there is no apparent structural heart disease, the prognosis is excellent and further therapy with antiarrhythmic drugs is usually not necessary. Patients with ventricular tachycardia who have structural heart disease or those with symptomatic episodes of ventricular tachycardia warrant treatment. The urgency of treatment depends on the presenting symptoms. Rapid ventricular tachycardia in the pregnant patient who is demonstrating significant hemodynamic compromise should be treated urgently with electrical cardioversion, to maintain the fetal blood supply. Patients who are hemodynamically stable can be treated with intravenous procainamide or lidocaine, both of which have been shown to be safe for the fetus. Once sinus rhythm has been reestablished, a thorough evaluation should be undertaken to determine the cause of the ventricular tachycardia before long-term therapy is initiated.

Bradyarrhythmias, Conduction Blocks

Despite the fact that sinus bradycardia and Wenckebach atrioventricular (AV) block (type I second-degree AV block) have been observed during pregnancy, labor, and delivery (109), conduction blocks are not a normal finding in pregnancy. Type II second-degree AV block and third-degree AV block are associated with an increased incidence of sudden death, and permanent pacemaker should be considered. The exception to this is congenital complete heart block, which is generally well tolerated and, because it carries a good prognosis, usually does not need to be treated with a pacemaker, unless it is symptomatic.

MANAGEMENT DURING LABOR AND DELIVERY

As discussed elsewhere in this chapter, a number of profound cardiovascular changes take place during labor and delivery, and these changes are affected by numerous variables including type of delivery (vaginal vs. cesarean), level of pain, and anesthesia.

Labor and Delivery

Timing of Delivery

The main factors considered in deciding the time for delivery are as follows:

- The current NYHA functional status (hemodynamic compensation)
- The presence or absence of fetal compromise (intrauterine growth restriction, oligohydramnios, or nonreassuring fetal testing)
- The functional status trend over time

- The possibility of improving or relieving the current functional status through optimization of treatment (e.g., evaluation of compliance, adjustment of medication doses or additional medications, additional rest)

Women in functional classes NYHA I and II and without fetal indications for delivery are allowed to go into labor spontaneously. Women in functional classes III and IV or in high risk are electively delivered. If the maternal and fetal conditions allow, the induction of labor is scheduled between 38 and 39 weeks of gestation (110). Patients in functional class III or IV are best managed in an obstetric intensive care unit, if available, or in an alternative intensive care unit.

Route of Delivery

Considering the hemodynamic changes of an uncomplicated vaginal delivery in comparison with an abdominal delivery, the vast majority of these women better tolerate a vaginal delivery (12,64,110,111). Cesarean delivery increases the risk of hemorrhage, postpartum infection, pulmonary morbidity, and the fluid shifts and metabolic demands of these women during the period of recovery (13).

The indications for cesarean delivery are the same for women with cardiac disease and the general population (112). There are a few exceptions to this principle. Some women with heart disease may benefit from proceeding directly to cesarean delivery including women with endocarditis needing an emergency valve replacement at or near term; women with severe intrauterine growth restriction and Eisenmenger's reaction and unripe cervical conditions; and women with severe aortic stenosis, aortic dilatation, or dissection (2). Similarly, acute severe cardiovascular decompensation during labor might prompt the performance of a cesarean delivery (2).

Induction and Augmentation

General guidelines for the management of pregnant cardiac patients include induction of labor at term with favorable cervix and laboring in the lateral position. Women in higher functional classes may need cervical ripening procedures before induction. Mechanical methods (e.g., Foley catheter) have the advantage of avoiding hemodynamic effects and are associated with lower rates of uterine hyperstimulation and fetal bradycardia. They are the method of choice in higher functional classes and patients with cyanotic lesions. Prostaglandin-based ripening can be used in patients with lower functional classes without tachycardia or a history of asthma.

Maternal and Fetal Monitoring Considerations

Continuous EKG and pulse oximetry monitoring is recommended to monitor for hypotension, hypoxemia, myocardial ischemia, and arrhythmias. The role of pulmonary artery catheter is controversial and should be decided on a case-by-case basis. Women in functional class IV and selected cases in functional class III, pulmonary hypertension, may benefit from a pulmonary artery catheter insertion before the process of labor and delivery is started (8). In some conditions, such as mitral stenosis, controlling the heart rate with a beta blocker infusion may be indicated to avoid tachycardia and decrease in cardiac output (113).

Continuous fetal heart rate monitoring is indicated throughout labor. The fetus is an excellent parameter of maternal perfusion. If cervical conditions allow, internal monitoring is preferable. In the presence of nonreassuring fetal patterns (e.g., nonreactive fetal strip, fetal tachycardia, repetitive late decelerations), prompt evaluation of the maternal hemodynamic parameters and oxygenation is indicated.

Analgesic and Anesthetic Considerations

Anaesthesia can alleviate anxiety and pain, which are associated with tachycardia, increased oxygen consumption and increase in cardiac workload. Cardiovascular hemodynamics is also affected by the type and amount of anesthesia.

An anesthesiologist with experience in managing these patients is pivotal to a successful maternal and fetal outcome. The combination of intrathecal and epidural analgesia (combined spinal–epidural technique or coaxial anesthesia) provides excellent analgesic control, minimizing the patient's anxiety and tachycardia. Epidural anesthesia should be used with caution in patients with hypertrophic cardiomyopathy, in other conditions with low or fixed cardiac outputs such as aortic stenosis, and in potential or actual right-to-left shunts (114). Epidural anesthesia may be contraindicated in patients with Eisenmenger's physiology because it can increase the right-to-left shunt (115). Alternatively, parenteral administration of meperidine or morphine can be used to achieve patient comfort, with the combined use of a pudendal block for analgesic relief of the second stage (114). For vaginal delivery, the second stage of labor is routinely shortened with outlet forceps or vacuum extractor (2).

Postpartum Considerations

It is important to remember that the majority of deaths in this group of patients occur during the puerperium (110). Specifically, the risks of pulmonary edema persist 24 to 72 hours postpartum (2).

Some studies have reported a significantly higher incidence of postpartum hemorrhage among patients with Marfan syndrome, higher functional classes (NYHA III or IV), or cyanosis (2). Postpartum hemorrhage should be managed promptly. Patients who have Eisenmenger syndrome may sustain an increase in the right-to-left shunt during the immediate postpartum period secondary to a decrease in systemic vascular resistance due to blood loss or relief of aortic compression by the fetus (13). In this subset of patients, vasopressors like norepinephrine may be started at the time of delivery to prevent the increase in right-to-left shunting (16).

Early assisted ambulation, use of elastic support stockings, and prophylactic anticoagulation, if needed, will minimize the risk of thromboembolism and are encouraged. If the patient has a need for prolonged anticoagulation, warfarin can be started the day after delivery with an overlap with heparin for 1 or 2 more days after reaching goal INR (116).

Prolonged postpartum admissions are recommended for patients with Eisenmenger syndrome and those with IPAH because most deaths occur during the first month after delivery (68).

Breastfeeding

No specific contraindications for breastfeeding exist provided that an adequate state of hydration is maintained. It is important to consider the fetal risks from the drugs that may be excreted in the breast milk.

Follow-Up

Cardiovascular responses do not completely normalize until 7 months after delivery. These patients should be closely followed by the cardiologists, in addition to the obstetrician.

SPECIAL CONSIDERATION

Cardiac Surgery

Cardiac Surgery During Pregnancy

Certain patients with heart disease may develop refractory symptoms during pregnancy that necessitate cardiac surgical procedures. In some cases, surgery may be lifesaving for the mother, albeit resulting in increased fetal mortality. The outcome of cardiovascular surgery performed during pregnancy is affected by numerous variables, such as the indication, maternal condition, the timing of the surgery relative to the duration of the pregnancy, the interval between admission and surgery, and the use of duration of cardiopulmonary bypass. These factors should be reviewed with the patient on an individual basis.

With the advances in knowledge and technology, the maternal and fetal outcome has improved significantly. Numerous pregnant patients with mitral stenosis have undergone valve replacement for both aortic and mitral valve diseases (92,117,118). Although this procedure has been shown to be relatively safe and effective, it carries a high fetal mortality and should be reserved for patients refractory to medical management. In selected patients, closed mitral valvotomy offers excellent results, comparable with those of nonsurgical treatments (119). Other successful intracardiac procedures during pregnancy include pulmonary valvuloplasty, ASD and VSD repair, excision of left atrial myxomas, and, as an emergency, repair of an aortic dissection. In addition, there have been several successful coronary artery bypass graft procedures carried out during pregnancy (92,117). The chief concerns in the optimal management of pregnant patients who are undergoing cardiopulmonary bypass (CPB) are the control of temperature, perfusion pressure, and the nature of the bypass flow. Current evidence favors maintaining normothermic CPB instead of the hypothermic CPB. The role of off pump coronary artery bypass grafting is a safe and accepted technique for coronary revascularization; however, its role in pregnancy needs further evaluation.

Pregnancy Following Cardiac Surgery

The outcome of pregnancy in women with corrected congenital heart disease depends on many factors including the success of the surgical repair, the extent of residual cardiac lesions, and the need for cardiovascular medications such as Coumadin. In addition, some maternal cardiac defects are associated with an increased incidence of congenital fetal cardiac and noncardiac defects that may affect fetal prognosis. Pregnancies following a heart transplant are usually not complicated (101,102,104,105). Peripartum cardiomyopathy may not recur after the heart transplant (102).

Patients with successfully corrected cardiac lesions without sequelae have a good prognosis during pregnancy and can

often be managed in the same way as a noncardiac patient. Patients with residual stenosis, or residual pulmonary hypertension, are at an increased risk.

Women who have had valve replacement with a mechanical prosthesis pose a special problem, owing to the need for anticoagulation. Anticoagulation in pregnancy is discussed below. Management of the pregnant patient with a bioprosthetic valve is not markedly different from that of patients with native valves, because the valve does not require anticoagulation.

Devices

With the expanding indications for implantable cardioverter defibrillators (ICDs), there are increasing number of pregnant patients with ICD. The mere presence of an ICD should not deter women from becoming pregnant and that pregnancy does not increase the risk of major ICD-related complications or result in high number of ICD discharges (120). For those pregnant women with ongoing malignant arrhythmias despite pharmacologic treatment, an ICD may be a safe alternative (48). It is recommended that ICD should remain activated during labor and should be switched off during cesarean section due to the interference with electrocautery and promptly reprogrammed after the surgery.

Medications

Anticoagulation

Certain medical conditions such as venous thrombosis of the proximal venous system, or certain types of prosthetic valves, necessitate anticoagulation during pregnancy. As with other therapy during pregnancy, the risks arising from the untreated condition must be weighed against the risks and side effects of the treatment. For conditions such as mechanical prosthetic valve, anticoagulation is a necessity.

Warfarin

Warfarin, a vitamin K antagonist, crosses the placenta and has been associated with increased risk of spontaneous abortion and “warfarin embryopathy.” This condition is characterized by hypoplasia of the nasal bone and a wide variety of central nervous system abnormalities including optic atrophy, mental retardation, deafness, and microcephaly (121–123). The risk is higher in the second half of first trimester. In addition, warfarin predisposes both the mother and her fetus to hemorrhagic complications including fetal intracranial hemorrhage (124–127).

Heparin

Unfractionated heparin (UFH) is a large molecule that does not cross the placenta and has little effect on the fetus. Heparin can be administered by continuous intravenous infusion or by intermittent subcutaneous doses (every 8–12 hours).

Low–Molecular Weight Heparins

Low–molecular weight heparins (LMWHs) have potential advantages over UFH during pregnancy. They do not cross the placenta and are safe for the fetus (128). Plasma anti-Xa levels 4 to 6 hours after the morning dose may be used to guide therapy with LMWH. Dosage of LMWH is adjusted to achieve an anti-Xa level of approximately 0.7 to 1.2 units/LmL (129).

Although LMWHs have been used successfully to treat deep venous thrombosis in pregnant patients, there are no data to guide their use in the management of patients with mechanical heart valves (130). Reports of LMWH use in pregnant women with prosthetic heart valves are becoming more frequent, and many physicians now prescribe these agents during pregnancy in women with mechanical valves, but treatment failures have been reported.

The 2008 ACCP Guidelines for antithrombotic therapy recommended one of three approaches for anticoagulation during pregnancy: (131)

- Adjusted-dose bid LMWH throughout pregnancy. Dosing to be adjusted to achieve the manufacturer’s peak anti-Xa LMWH 4 hours after subcutaneous injection.
- Adjusted-dose UFH throughout pregnancy administered subcutaneously q12 hours in doses adjusted to keep the mid-interval activated partial thromboplastin time at least twice control or attain an anti-Xa heparin level of 0.35 to 0.70 U/mL.
- UFH or LMWH (as above) until the 13th week with warfarin substitution until close to delivery when UFH or LMWH is resumed.

Antibiotic Prophylaxis

Per most recently updated American Heart Association guidelines (44), prophylactic antibiotics solely to prevent endocarditis are not recommended for patients who undergo gastrointestinal (GI) or genitourinary (GU) tract procedures. In general, the incidence of infective endocarditis is relatively low during uncomplicated vaginal delivery and antibiotic prophylaxis is not recommended.

Patients with infections of the GI or GU tract may have intermittent or sustained enterococcal bacteremia. For patients with the conditions listed in Table 9, with an established GI or GU tract infection, or for those who receive antibiotic therapy to prevent wound infection or sepsis associated with a GI or GU tract procedure, it may be

Table 9 Conditions Requiring Infective Endocarditis (IE) Prophylaxis

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous IE
Congenital heart disease (CHD) ^a
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure ^b
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

^aExcept for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD. ^bProphylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure. Prevention of infective endocarditis: guidelines from the American Heart Association (44).

reasonable that the antibiotic regimen includes an agent active against enterococci, such as penicillin, ampicillin, piperacillin, or vancomycin (44).

Cardiac Diagnostic Testing During Pregnancy

Tests Not Involving Ionizing Radiation

Electrocardiogram

The EKG can be enormously helpful in diagnosing a wide variety of abnormalities, including arrhythmias, and poses no risk to either the mother or the fetus. Premature atrial and ventricular complexes are usually benign and seen frequently, and a wide variety of brady- and tachyarrhythmias have been documented during labor (132).

Echocardiography

Echocardiography has been widely used and poses no risk to either the mother or the fetus. An echocardiographic evaluation would be appropriate in instances of systolic murmurs in the presence of symptoms, systolic murmurs with associated thrill, pansystolic murmurs, diastolic murmurs, or murmurs accompanied by arrhythmias or gallop.

Transesophageal echocardiography has been reported to be well tolerated during pregnancy and is helpful to further elucidate structural and functional changes not well defined on transthoracic echocardiography, such as endocarditis vegetations, prosthetic valves, and the severity of valvular disease (16,64,133).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been studied in detail and no apparent long-term adverse effects have been demonstrated on the fetuses of pregnant mice. The safety of fetal MRI has not been fully evaluated. Fetal MRI using 1.5-T magnets may be performed in any trimester (134). However, because of limited data, MRI in the first trimester is currently avoided whenever feasible.

Cardiac Diagnostic Tests Involving Ionizing Radiation

Ionizing radiation, depending on the dose and the gestational age, may pose risks to the fetus. During the first few weeks after conception, a maternal dose of 0.1 Gy results in a 0.1% increase in abortions over the naturally occurring spontaneous abortion rate of 25% to 50%. The period of organogenesis (2–8 weeks) is critically important. A dose of 0.1 Gy is estimated to produce a 1% increase in the frequency of congenital fetal abnormalities (135). After 8 weeks of gestation, the primary effect of radiation exposure is an increased incidence of childhood leukemia. A dose of 0.01 Gy may increase the frequency of malignant disease by up to 11 cases per 1,000,000 live births (135).

Fetal exposure of 0.1 Gy or greater may increase the rise of childhood leukemia and fetal abnormalities such as microcephaly (136). Some limit the safe fetal dose to 5 mGy. Occasionally, the need arises during pregnancy for cardiac diagnostic testing that involves ionizing radiation. If the information obtained is crucial for the management of the patient, the test should be performed in such a way as to minimize exposure to the fetus.

Chest Radiograph

A chest X-ray delivers approximately 0–0.05 mGy to the fetus, which is considered a negligible amount. In addition, the abdomen of the pregnant patient can often be shielded during

the test to minimize exposure by scattered radiation. An inadvertent chest X-ray during early pregnancy poses little, if any, risk to the fetus, but should be performed only if the benefits outweigh the very small risk.

Myocardial Perfusion Imaging and Radionuclide

Ventriculogram

Radionuclide imaging using ^{99m}technetium-labeled sestamibi or ²⁰¹thallium is expected to yield <1 rad of radiation to the conceptus (87). These tests are rarely needed in pregnancy and can be substituted by echocardiography if indicated.

Cardiac Catheterization

There are cardiac events during pregnancy that require cardiac catheterization and obligate exposure to ionizing radiation. The classic example would be acute myocardial infarction, where the risk of fetal exposure to ionizing radiation may be less than the benefits of immediate revascularization and prevention of complications.

The amount of fetal exposure to radiation during chest radiography in PCI results in a mean exposure of 0.02 mSv and a maximum of 0.1 mSv in difficult PCI procedures (National Council of Radiation Protection and Measurements 1998). Radiation that scattered from the directly irradiated area reaches the fetus. Shielding the abdomen and pelvis will not intercept the scattered irradiation. Catheterization through the radial artery will keep fetal radiation exposure to a minimum.

As with other tests, catheterization should be avoided unless the critical information cannot be obtained in other ways. Before completion of major organogenesis (before 15 weeks after menses), radiation exposure must, whenever possible, be avoided. Doses in excess of 50 to 100 mSv increase the incidence of fetal malformation and may warrant termination of pregnancy (137).

Pregnancy in cardiac patients poses multitude of challenges to the multidisciplinary team taking care of these patients. With meticulous planning, education, counseling, and advances in technology, the maternal and fetal outcome continues to improve.

21 Dermatologic diseases and pregnancy

Holly Edmonds, Dana Ward, Ann G. Martin, and Susana Leal-Khoury

DERMATOLOGIC DISEASES AND PREGNANCY

The skin during pregnancy undergoes profound changes that are associated with multiple endocrine, metabolic, and immunologic adjustments to this state. Pregnant patients develop physiologic or endocrine-induced skin changes, dermatoses specifically related to pregnancy, and skin diseases seen in the nonpregnant state. The physiologic changes occur with such regularity during pregnancy that they are considered virtually normal, but these changes sometimes become pathologic when severe. The physiologic changes often occur in the general population but are increased in frequency among pregnant women, and most regress postpartum. The most common physiologic changes affect pigmentation, striae formation, the vascular system, the pilosebaceous unit, oral mucosa, and sweat glands (Table 1).

The specific dermatoses of pregnancy include pemphigoid gestationis (herpes gestationis), pruritic urticarial papules and plaques of pregnancy (PUPPP), pustular psoriasis of pregnancy (impetigo herpetiformis), cholestasis of pregnancy (CP; prurigo gravidarum), prurigo of pregnancy (PP; papular dermatitis of pregnancy), and pruritic folliculitis of pregnancy (PFP) (Table 2). These diseases are discussed later in the chapter.

PHYSIOLOGIC CHANGES ASSOCIATED WITH PREGNANCY

Pigmentary Changes

Ninety percent of pregnant patients develop hyperpigmentation, usually mild and generalized. There is accentuation of normally hyperpigmented regions such as the areolae, nipples, axillae, genitalia, perineum, anus, and inner thighs (1–3). Generally, hyperpigmentation appears during the first trimester, progresses until delivery, and regresses postpartum. However, anatomic sites already hyperpigmented (areola, nipples, and genitalia) usually do not return to their previous color. The cause of hyperpigmentation is controversial. Most investigators agree that an increase in the production of pituitary, placental, and ovarian hormones is responsible (4–6). Melanocyte-stimulating hormone (MSH), estrogen, and progesterone are strong melanogenic stimulants and may play an important role. MSH is increased during pregnancy and decreases postpartum (7–9). Studies have also shown that the placenta contains other bioactive molecules that stimulate melanocytes by upregulating tyrosinase activity (10).

Pigmentary changes during pregnancy include darkening of the areolae, producing what is known as secondary areolae. This is usually seen as pigmentation between the two areolae. Areolar pigmentation is readily distinguished from nevoid hyperkeratosis of the nipple and areola, a rare condition which also develops during pregnancy (11). The linea alba often darkens and is renamed the linea nigra; this is most notable in

dark-skinned women. Linea nigra is often accompanied by the shifting of the umbilicus to the right side of the patient at term, known as the “ligamentum teres sign,” which persists postpartum until the abdominal muscles redevelop normal tone (11,12). Pigmentary demarcation lines, seen as borders of abrupt transition between more deeply pigmented skin and that of lighter pigmentation, may occur on the lower limbs during pregnancy (13). Severe generalized hypermelanosis is rare and its occurrence suggests hyperthyroidism.

Melasma (chloasma), or the “mask of pregnancy,” presents as blotchy, irregularly shaped, usually sharply demarcated patches of light to dark brown pigmentation of the face. It occurs in greater than 50%, with some studies reporting up to 75%, of pregnant women and in up to 34% of women taking oral contraceptives (14,15). Melasma usually begins during the second trimester and is more common in dark-skinned (skin types IV–VI) women (16). The most commonly affected sites are the nose and cheeks followed by the upper lips, forehead, chin, and eyebrows (17). Three clinical patterns exist, which can be distinguishable by examination with the Wood’s lamp. The causative agent for melasma is unknown. Contributing factors, aside from pregnancy and oral contraceptives, include genetics, skin type, exposure to UV radiation, nutrition, hepatic diseases, thyroid dysfunction, drugs, and cosmetics (16). Preventive measures such as avoidance of sun, usage of broad-spectrum sunscreens, and non-allergenic cosmetics are recommended. Treatment is frequently deferred until after delivery, since gestational melasma usually regresses within a year postpartum but may persist in less than 10% of patients (11). If melasma does persist, treatment options (in addition to consistent daily use of broad-spectrum SPF 30 sunscreen and sun protective hats) include topical hydroquinone products, or hydroquinone in combination with tretinoin and topical steroid creams, azelaic acid topical preparations, laser therapy, and chemical peels.

Freckles, melanocytic nevi, and recent scars may also darken. Although melanocytic nevi may appear somewhat darker during pregnancy, an increase in size, significant change, or variation in color, or irregular shape of a nevus is always of concern and therefore warrants an excisional biopsy. Data support the finding that women with previously diagnosed dysplastic nevus syndrome demonstrate an increased rate of changing nevi during pregnancy compared with their nonpregnant counterparts (18). Other studies have demonstrated that women who are pregnant or on oral contraceptives have an increased number of estrogen and progesterone receptors on their nevi cells similar to those observed in malignant melanoma and severely dysplastic nevi (19). Histopathologic evaluation of malignant melanoma diagnosed during pregnancy shows an increased tumor thickness. This may be associated with growth factor accelerating tumor growth

or may reflect a delay in diagnosis. However, there has been no study that has shown a difference in anatomic location or histologic type when comparing malignant melanoma in the pregnant and nonpregnant patients (18).

Striae Distensae

Striae distensae, or stretch marks, are linear violaceous bands, which progress over time to pink or white atrophic lines. Striae develop opposite to skin tension lines on the abdomen, breast, upper arms, lower back, buttocks, thighs, and groin and are reported to occur in 55% to 90% of pregnant women during the 6th and 7th months (1–3,20–22).

The exact etiology is unknown, but several contributing factors include hormonal changes (adrenocorticotropicins, relaxin, and estrogens) affecting connective tissue formation, maternal weight gain, degree of abdominal distension, and genetic predisposition (11). A recent study by Atwal et al. showed that the most significant risk factor for developing striae is low maternal age (due to increased fragility of fibrillin), followed by BMI greater than 26, maternal weight gain greater than 15 kg, and high neonatal birth weight (23). Postpartum, the purplish striae improve cosmetically, becoming flesh-colored or hypopigmented, although striae generally do not disappear entirely. No treatment has proven definitive to prevent or decrease the occurrence of striae; topical agents have been tried (11) with minimal success.

Hair and Nail Changes

Some degree of hirsutism develops in many women early in pregnancy and is most pronounced in women with preexisting abundant body hair or dark hair. Excessive hair growth is most pronounced on the face (upper lip, chin, and cheeks); however, the arms, legs, back, and suprapubic areas may be affected. Within 6 months postpartum, excess vellus-type hairs disappear, but coarse terminal hairs may remain.

The cause of hirsutism is unknown, but it is thought to be due to increased ovarian androgen secretion or increased adrenocorticotropic hormone secretion (24,25). Patients with marked persistent hirsutism should have an appropriate evaluation to exclude virilizing tumors. Therapy consists of reassuring the patient, although when hirsutism persists more than 6 months postpartum, cosmetic treatment (hair removal lasers or electrolysis) may be considered.

Lynfield reported an increased proportion of anagen hair follicles (growth phase) during pregnancy, which is thought to be secondary to a decreased rate of conversion of anagen to telogen hairs (resting phase), producing a thicker than normal growth (26). This increased proportion of anagen to telogen hairs is due to the increased estrogen levels during pregnancy, which prolong the anagen phase (4). The mean percentage of anagen hairs in the first trimester is comparable with the nonpregnant state at 85% and is increased to 95% by the second trimester (26). Postpartum, a greater than usual number of hairs enter the telogen phase manifesting clinically as a sudden increased shedding of telogen hairs, known as telogen effluvium. Telogen effluvium begins classically 3 months after delivery, but may start 1 to 5 months postpartum and usually persists for approximately 1 year with complete regrowth by 15 months. The causes of telogen effluvium include the stress of delivery and changes in postpartum hormone balance. There is an abrupt decrease in estrogen after delivery probably leading to the dramatic shift from anagen to telogen phase. Lynfield found the percentage of anagen hairs dropped from 95% to 76% shortly after delivery. Therapy involves reassurance, with most patients returning to baseline hair growth and thickness within 1 to 2 years.

A mild degree of frontoparietal recession in a male pattern distribution may develop toward the end of pregnancy. This may not be fully reversible postpartum (11). Diffuse thinning of the hair during the last trimester is also seen. The causes of male pattern frontal recession and hypotrichosis are unknown, but inhibition of gonadotropic activity secondary to high steroid levels occurring late in pregnancy may play an important role.

Nail changes seen during pregnancy include Beau's lines (transverse grooving), brittleness or softening, distal onycholysis, subungual keratosis, and accelerated nail growth (1–3, 24,27). The pathogenesis of these pregnancy nail changes is unclear. It is important to consider nail changes associated with psoriasis, lichen planus, and onychomycosis. Treatment consists of careful nail trimming and avoidance of external sensitizers and infections.

Vascular and Hematologic Changes

Vascular changes occur during pregnancy and are related to distention, fragility, and proliferation of vessels. Elevated

levels of circulating estrogens and angiogenesis factors are believed to be important in the pathogenesis of "spider" angiomas, palmar erythema, hemangiomas, and pyogenic granulomas.

A spider angioma is a bright red macule or papule, with a telangiectatic puncta, radiating branches, and surrounding erythema, easily blanchable with pressure. Spider angiomas appear most commonly in areas drained by the superior vena cava (neck, throat, periorbital, and arms) (28). These changes appear in 67% of white and 11% of black women between the 2nd and 5th months of pregnancy and regress within 3 months postpartum in 75% of cases (29). Persistent spider angiomas may be best treated for cosmetic purposes with electrodesiccation or vascular lasers (28). Treatment is usually deferred until after delivery.

Palmar erythema may be localized to the thenar or hypothenar area or can present as a diffuse mottling of the hand with cyanosis and pallor. It is seen in 66% of white and 33% of black women beginning in the first trimester (1–3). The erythema may be accompanied by a burning sensation and therefore mistaken for erythromelalgia (12). Palmar erythema usually resolves 1 week postpartum. Diffuse palmar erythema is indistinguishable from that seen in hyperthyroidism and hepatic cirrhosis.

Varicosities involving the saphenous, vulvar, and hemorrhoidal veins appear in 40% of women starting from the 3rd month of pregnancy (2,3,21). A familial tendency for increased elastic tissue fragility in conjunction with increased venous pressure may account for varicosities. However, because most varicosities develop toward the end of the first trimester when intrapelvic pressure is not significant, vascular fragility may be the more important factor (28). Partial regression tends to occur postpartum. Prevention or minimizing the risk of development of varicosities is the focus of therapy. Leg elevation, lying in the left lateral decubitus position, sleeping in Trendelenburg position, compression stockings, and avoidance of tight-fitting clothes are recommended but no studies definitively show their efficacy (28).

Other vascular changes occur less commonly in pregnancy. Cutis marmorata and livedo reticularis of the legs, facial flushing, and pallor are presumably due to vasomotor instability secondary to increased estrogens. Patients with preexisting Raynaud's phenomena may improve because of vasomotor relaxation. Non-pitting edema of the eyelids, face, hands, and feet is common during the third trimester. The edema tends to decrease during the day and is due to sodium and water retention in conjunction with increased capillary permeability. Small purpuric lesions on the legs secondary to increased capillary permeability are common during the last half of pregnancy.

Mucous Membrane Changes

Gingival hyperemia is present in up to 80% of pregnant women with an increased incidence of gingivitis beginning in the 2nd month of pregnancy (1–3,30). The gingivae enlarge, darken, become red, swollen, and may bleed spontaneously. The causes are unclear, although poor oral hygiene, local gingival irritation, nutritional deficiencies, and progesterone-induced vascular proliferation are thought to be important in the pathogenesis.

Cutaneous Tumors

Proliferation of capillaries in hypertrophied gingivae results in granuloma gravidarum (pyogenic granuloma of pregnancy or pregnancy tumor). In 27% of women, it appears as a deep-red friable nodule arising from the gingiva during the 2nd to 5th month of pregnancy (30). Clinically and histologically, it is identical to pyogenic granuloma in nonpregnant women, but tends to regress postpartum. If regression does not occur, surgical removal of the nodule is a reasonable therapy.

Molluscum gravidarum (skin tags) may appear on the neck, chest, axillae, and inframammary areas in the latter stages of pregnancy and may spontaneously regress after delivery. Persistent bothersome skin tags are easily removed by simple scissoring, cryotherapy, or electrodesiccation if desired.

Hemangiomas, hemangioendotheliomas, glomangiomas, glomus tumors, neurofibromas, dermatofibromas, and leiomyomas may arise during gestation. Except for neurofibromas, these tumors tend to regress postpartum, but may recur during subsequent pregnancies. Keloids may grow rapidly and desmoid tumors may also develop during pregnancy. Desmoid tumors should be treated by wide local excision if there is rapid enlargement and resultant local tissue destruction.

Glandular Activity

Eccrine sweating progressively increases during the third trimester accounting for occasional hyperhidrosis and increased incidence of miliaria rubra (heat rash). The cause is unknown, but it is believed that these changes are due to increased thyroid activity. By contrast, palmar sweating is decreased, which may be secondary to increased adrenocortical activity. If eccrine sweating is significantly increased, topical treatment with a solution of 20% aluminum chloride hexahydrate in ethyl alcohol applied every night for 1 week may be helpful and then as necessary. Careful application to dry skin reduces potential irritation.

Apocrine gland activity decreases during pregnancy, improving preexisting Fox–Fordyce disease and hidradenitis suppurativa, but there may be a rebound postpartum. Sebaceous gland activity increases in some patients during the third trimester. Acne and oily skin may develop, but the effects of pregnancy on acne are unpredictable. Sebaceous glands are associated with lactiferous ducts on the areolae hypertrophy in 30% to 50% of women, beginning during the 6th week of gestation, and appear as elevated brown papules called Montgomery's tubercles (1–3,13,25). The cause of the glandular changes is not well understood, but estrogen, progesterone, and cortisol are implicated. Breast changes during pregnancy include enlargement, tenderness, erect nipples, hyperpigmentation of nipples and areolae, prominence of veins, striae, and Montgomery's tubercles. Most of these changes regress postpartum.

DERMATOSES OF PREGNANCY

The dermatoses of pregnancy can be divided into two main categories: dermatoses without fetal risk and dermatoses with fetal risk. Terminology of the disease processes continues to be an ongoing controversy. The newest terminology will be used to discuss each entity. Fetal risk is associated with pemphigoid gestationis, pustular psoriasis of pregnancy, and CP.

Pemphigoid Gestationis

Pemphigoid gestationis is the least common, but best characterized disease of pregnancy and the puerperium. It is an autoimmune disease characterized by an intensely pruritic, urticarial eruption, which rapidly progresses to bullae. The disease is most commonly associated with pregnancy, although rare occurrences have been reported with hydatidiform mole and choriocarcinoma (31,32). The incidences of pemphigoid gestationis range from 1:1700 deliveries to 1:50,000 deliveries (33–35). The older term “herpes gestationis” is a misnomer, reflecting the “herpetic” clinical appearance reported by JL Milton in 1872 (36), although the condition is not related to any known viral infection. Mayou and colleagues have proposed that the term “pemphigoid gestationis” is more appropriate given its clinical and histologic resemblance to bullous pemphigoid (37). Both names can be found in the literature.

The etiology of pemphigoid gestationis appears to be autoimmune in pathogenesis, and it is associated with C4Q0 allele in 90% of affected patients. However, the clinical relevance of the presence of a C4Q0 allele remains to be elucidated (38). All women with a history of pemphigoid gestationis have anti-HLA antibodies, with 50% exhibiting both HLA-DR3 and HLA-DR4 (38–40). Circulating maternal autoantibodies react with an “antigenic” constituent of the cutaneous basement membrane as well as the chorionic epithelium and amnion of the placenta. This antigen is a normal constituent of the basement membrane and may be found in the placenta as early as the second trimester. Subepidermal blisters develop from tissue damage incurred by this antigen–antibody reaction with resultant complement activation. A recent finding of abnormal expression of paternal major histocompatibility complex (MHC) II region molecules in the placenta suggests that the maternal immune system evokes an allogeneic reaction (41). This has been theorized to be the etiology for the production of maternal antibodies to the amniotic basement membrane. The amniotic basement membrane is antigenically similar to skin thus leading to a cross-reaction causing maternal and occasional newborn disease (38).

The pemphigoid gestationis antigen has been characterized as a 180-kDa glycoprotein found in the lamina lucida of the basement membrane of skin and placenta (42,43). It is an interesting observation that pemphigoid gestationis antigen may first appear in the placenta during the second trimester of pregnancy, coinciding with the time course of the development of pemphigoid gestationis (44). This 180-kDa antigen is also known as bullous pemphigoid antigen 2 and most recently as type XVII collagen. This is a transcellular glycoprotein in the hemidesmosome with both a cytoplasmic and extracellular domain. The function of the hemidesmosome is to anchor the basal cells of the epidermis to the basement membrane thus keeping it attached to the dermis. The NC16A segment of the 180-kDa antigen is the immunoreactive site in the majority of affected patients (38).

Pemphigoid gestationis presents as an extremely pruritic, urticarial, and bullous eruption that may begin at any time during the pregnancy, but most commonly occurs during the second and third trimesters. It frequently begins during the first pregnancy and has a tendency to recur earlier and with

greater severity in subsequent pregnancies. Initial onset in the postpartum period has also been well documented in up to 25% of patients and is often explosive, occurring within hours of delivering. A frequent observation is a relative remission in the weeks prior to delivery followed by a postpartum flare.

Early lesions of pemphigoid gestationis begin as erythematous, edematous papules and plaques, which rapidly develop into vesicles and tense bullae (Fig. 1). The vesicles and bullae may be grouped, hence the historical description of “herpetic,” and develop into erosions with crusting. The eruption begins in and around the umbilicus in the majority (50%) of patients and then spreads to involve the abdomen and thighs (Fig. 2). The back, breast, palms, and soles are frequently affected. The head and mucosa are involved less frequently (<20%). A constant feature of pemphigoid gestationis is pruritus. Itching is often extreme and may begin days or weeks prior to the appearance of clinical lesions.

Two skin biopsies are needed to establish the diagnosis: one punch biopsy of an intact bullous lesion for routine H & E histology and a second punch biopsy taken from perilesional skin for direct immunofluorescence. Histology of an early urticarial lesion shows a perivascular infiltrate consisting of lymphocytes and many eosinophils. Papillary dermal edema with spongiosis and intracellular edema of the overlying

Figure 1 Early lesions of herpes gestationis.

Figure 2 Periumbilical distribution of herpes gestationis.

epidermis are seen. Histology of a bulla reveals basal cell necrosis with a resultant subepidermal bulla. There is a pronounced inflammatory infiltrate containing many eosinophils. The presence of eosinophils is the most constant feature of pemphigoid gestationis (45).

Using a direct immunofluorescence assay, patients with pemphigoid gestationis have a linear deposition of complement 3 (C3) along the basement membrane zone in clinically normal and involved skin (46). This finding traditionally is the hallmark of the disease, remaining the most sensitive and specific test for pemphigoid gestationis (45). Immunoglobulin G (IgG) deposition is seen as well (30–40% of patients), and less frequently IgA and IgM.

The sera of patients with pemphigoid gestationis contain an antibody to a basement membrane constituent of normal skin. This antibody, known as “herpes gestationis factor,” avidly binds complement and is an IgG1 molecule (47). Using conventional indirect immunofluorescence, only 25% of patients show evidence of “herpes gestationis factor,” and usually in low titers. However, complement added indirect immunofluorescence reveals the circulating anti-basement membrane zone IgG in nearly all patients, thus this technique is much more sensitive (38). Salt split skin studies reveal the immunoreactants to localize in the epidermal side of the lamina lucida, a finding similar to that seen in bullous pemphigoid (48). Placental studies reveal a similar deposition of C3 and immunoglobulin along the amniotic basement membrane. As in lesional skin and plasma, IgG1 is the most frequently found immunoglobulin (49).

Laboratory evaluation is not necessary for the diagnosis of pemphigoid gestationis, although there is an increase in incidence of antithyroid antibodies detected in affected patients but clinically apparent thyroid dysfunction is rare (38,50). ELISA testing is now available and will potentially replace direct immunofluorescence for diagnosis in the future.

The primary disease entity in the differential diagnosis of pemphigoid gestationis is PUPPP. There is clinical overlap between the two diseases in that they are both pruritic dermatoses of pregnancy presenting with urticarial plaques, wheals, and vesicles. Pemphigoid gestationis is distinctive, however, in developing grouped bullae (PUPPP occasionally is vesicular), in its initial periumbilical distribution (PUPPP classically arises in abdominal and thigh striae), and its earlier appearance within the second trimester (PUPPP usually begins in the third trimester). On H & E histology, one cannot definitively differentiate them. However, direct immunofluorescence of pemphigoid gestationis is consistently positive for linear deposits of C3 at the basement membrane, while PUPPP shows nonspecific direct immunofluorescence. Indirect immunofluorescence studies in PUPPP are negative (51).

Other vesiculobullous diseases, such as dermatitis herpetiformis, bullous pemphigoid, and bullous erythema multiforme, are easily differentiated from pemphigoid gestationis by clinical presentation and routine immunofluorescence. Bullous pemphigoid has many similarities to pemphigoid gestationis both in its clinical appearance and in its ultrastructural findings. However, bullous pemphigoid is a disease of the elderly and would rarely be seen in the reproductive years. The dominant Ig subclass in bullous pemphigoid is IgG4 compared with IgG1 in pemphigoid gestationis (45).

Systemic steroids are the mainstay of therapy for moderate to severe pemphigoid gestationis. Recommended prednisone dosing is 0.5 mg/kg/day. One can frequently taper to a daily prednisone dose of 10 mg. Fortunately, the use of low-dose systemic steroids in the second and third trimester of pregnancy is not associated with increased risk of congenital anomalies, although careful monitoring is needed for gestational diabetes and hypertension (52). Mild cases are often treated with mid- to high-potency topical glucocorticoids and oral antihistamines (some studies have shown these medications to be ineffective, but they may offer symptomatic relief) (38). Alternative therapies include dapsone, cyclosporine, plasmapheresis, and cyclophosphamide, each variably effective at best, and all with significant potential for morbidity (38,53,54).

The usual course of pemphigoid gestationis is extremely variable. Many experience complete remission several weeks after delivery and mild flaring with resumption of menses. Rarely, severe cases of pemphigoid gestationis will persist far beyond the postpartum period and require corticosteroid therapy. Recurrent disease flares are reported from 2 weeks up to 12 years postpartum (38,45). Monthly perimenstrual flares, ovulatory flares, and flares with the use of birth control pills or estrogen therapy have all been reported in up to 25% of patients. These reports support the contention that once pemphigoid gestationis is initiated, it is hormonally mediated. Once a patient has pemphigoid gestationis, there is a clear tendency for it to recur in subsequent pregnancies (there are also reports of “skip pregnancies” in 5–10% of cases) with an earlier onset and more severe disease, but there are no good data to support this (38,55).

The impact of pemphigoid gestationis on perinatal morbidity and mortality is controversial. While Lawley and colleagues noted an increase in fetal morbidity and mortality, Shornick and coworkers found no increase in maternal or fetal complications (34,56). More recent data suggested an increase in preterm delivery and fetal growth retardation (57,58). No studies show that treatment with systemic steroids alters the risk of preterm delivery in these patients (38). In any case, good obstetrical and perinatal care gives a favorable outcome in the great majority of cases. Rarely do infants born to mothers with pemphigoid gestationis have vesicles or bullae (<10%). When present, the eruption is mild and transient. There appear to be no ill effects on the child nor evidence of increased incidence of other autoimmune diseases (46). Women with a history of pemphigoid gestationis have an increased risk for the development of Grave’s disease (38).

Pruritic Urticarial Papules and Plaques of Pregnancy

PUPPP is the most common of the dermatoses of pregnancy with an incidence varying from 1 in 160 to 1 in 300 pregnancies (50,59). In the first report of PUPPP, a woman was described with all the clinical features: a pruritic, urticarial eruption developing within abdominal striae during the third trimester and generalizing to the thighs and buttocks. While it was termed toxemic rash of pregnancy, there is no association of PUPPP with pre-eclampsia, and this terminology was not accepted (60). In 1979, Lawley and colleagues (61) reported seven cases in which they carefully defined the clinical features of PUPPP and gave it its widely accepted, yet controversial, name of pruritic urticarial papules and plaques of pregnancy.

Later Holmes and Black suggested the name polymorphic eruption of pregnancy based on the varying morphology of the lesions (62). Both names are now found in the literature.

While the etiology remains unknown, there are several current theories, one of which involves an inflammatory reaction to connective tissue damaged within striae secondary to late abdominal wall distension (63,64). Hormonal modulation may be involved as evidenced by patients with PUPPP having higher prevalence of multiple gestations compared with the general population. One study found a 13% incidence of PUPPP in multiple gestational pregnancies compared with 1% incidence in single gestational pregnancies (65). Other theories include maternal weight gain, fetal weight, infant sex (males more common), and fetal DNA (66,67).

The onset of PUPPP varies from as early as 17 weeks to 1 week postpartum, with the majority of patients presenting within the third trimester (mean onset 35 weeks) (38). The mean duration of the disease is 6 weeks, but it may persist as long as 16 weeks. Severe symptoms usually last 1 week. PUPPP classically presents with erythematous urticarial plaques on the abdomen usually in association with striae and always sparing the periumbilical region (Fig. 3) (38,65). Other presentations include vesicular, purpuric, targetoid, or polycyclic lesions, hence the polymorphous nature. This cutaneous eruption then spreads rapidly to involve the thighs, buttocks, breasts, and arms while the face, palms, and soles are rarely involved. Pruritus is localized to the involved skin.

Histopathologic findings of an early urticarial lesion reveal epidermal and upper dermal edema with a superficial lymphohistiocytic perivascular infiltrate. Eosinophils often are present in the infiltrate. However, blood eosinophilia is a less common feature. Vesicles are present in the most florid examples, in which case intense focal spongiosis is seen in the epidermis. Direct immunofluorescence studies are nonspecific, and indirect immunofluorescence studies are negative, which helps differentiate PUPPP from pemphigoid gestationis.

Treatment of PUPPP is symptomatic due to its self-limiting course and lack of serious outcomes. Management of pruritus, often very intense and unremitting, is usually accomplished with medium-potency topical steroid preparations and oral antihistamines. Systemic corticosteroids are sometimes used. Reassurance to the patient about this common cutaneous

Figure 3 Pruritic urticarial papules and plaques of pregnancy developing in striae.

disease of pregnancy is important, because it usually resolves within a few weeks without risk to the fetus.

Maternal and fetal prognosis is excellent (68). Recurrence during subsequent pregnancies, with menses, or oral contraceptives is uncommon. If it does recur, the disease tends to be attenuated.

Pustular Psoriasis of Pregnancy (Impetigo Herpetiformis)

Pustular psoriasis of pregnancy is rare, with fewer than 350 cases reported. It was first described by Von Hebra in 1872, and it consists of an acute pustular eruption resembling pustular psoriasis arising suddenly in a patient without prior history of psoriasis (69). Pustular psoriasis of pregnancy continues to be debated as to whether this disease is a variant of pustular psoriasis or a distinct clinical entity truly specific to pregnancy. Several factors favor a pregnancy-specific dermatosis. These include the absence of a positive family history of psoriasis, abrupt cessation of symptoms after delivery, and the tendency for recurrence with subsequent pregnancies and oral contraceptives (38).

The onset of pustular psoriasis of pregnancy is usually during the last trimester of pregnancy, but it may occur as early as the third month. Skin lesions begin as circinate erythematous macules or plaques, with 1 to 3 mm pustules advancing along the peripheral edge, preferentially occurring in intertriginous areas. It may spread to mucous membranes as well as to the entire integument, sparing only the face, hands, and feet. Pruritus is usually not present or very mild. The lesions heal with non-scarring post-inflammatory hyperpigmentation. Systemic symptoms are common including fever, chills, malaise, nausea, diarrhea, and arthralgias. Rarely does the patient present with tetany, delirium, and seizures secondary to hypocalcemia. Other potential lab abnormalities include leukocytosis with neutrophilia, elevated erythrocyte sedimentation rate, hypoalbuminemia, and iron deficiency anemia (70–72).

Histologically, pustular psoriasis of pregnancy is identical to pustular psoriasis and is characterized by parakeratosis, elongation of the rete ridges, and subcorneal collections of neutrophils. Immunofluorescence studies are all negative. It is important to remember that these pustules are sterile unless the skin becomes secondarily bacterially infected.

Early recognition of pustular psoriasis of pregnancy is crucial, with both maternal and fetal morbidity and mortality increased (73). Maternal complications may include profound hypocalcemia and the risk of bacterial sepsis, due to failure of skin barrier function. Fetal complications include placental insufficiency with sequelae such as miscarriage, fetal growth restriction, and possible stillbirth (73,74). Fetal well-being should be monitored with nonstress tests, biophysical profiles, and ultrasound studies as indicated (70).

First-line treatment during pregnancy is oral corticosteroids. A prednisone dose as high as 60 mg/day may be required, with a careful slow taper to prevent a rebound phenomenon. Therapeutic consideration may be given to cyclosporine (class C), depending on the severity of the clinical situation (38,73). After delivery, treatment options are broader with oral retinoids (isotretinoin or etretinate), narrowband ultraviolet B phototherapy, and methotrexate more commonly used (71).

CP

CP, also known as prurigo of pregnancy and prurigo gravidarum, is characterized by sudden onset of intense pruritus in the absence of primary cutaneous lesions, although secondary excoriations may occur (Fig. 4). It classically presents during the third trimester in 80% of cases (with 10–20% during first and second trimesters). Symptoms remit within 2 to 4 weeks after delivery but can recur with successive pregnancies (38,51). The incidence of this disorder ranges from 0.02% to 3% depending on the region, with the highest incidence in Chile at 14% to 16% (4,38,75).

The etiology of CP is secondary to maternal intrahepatic bile secretory dysfunction with the pathogenesis remaining unclear. Hormonal alterations most likely play a large role in CP. Increased levels of estrogen and progesterone during pregnancy have been shown to inhibit the enzyme glucuronyl transferase, resulting in impaired bilirubin conjugation and excretion leading to intrahepatic cholestasis. Disease onset and resolution correlating with elevation and reduction of hormones also favor hormonal alterations. However, several other factors including genetic, environmental, and alimentary etiologies may play a role in inducing cholestasis, which results in elevated levels of bile acids in serum and skin in genetically predisposed women (76).

Clinical presentation is moderate to severe pruritus, which may be intermittent initially, occurring only at night. Pruritus may be localized to the palms and soles, but tends to become generalized. Occasionally, patients may have anorexia, nausea, vomiting, and diarrhea. The progression to jaundice occurs in approximately one in five patients (38). Jaundice is usually mild and may be associated with dark urine and light-colored stools. It becomes detectable 1 to 4 weeks after the onset of pruritus. The symptoms resolve rapidly postpartum (within 2 to 4 weeks), but may recur in subsequent pregnancies or with the use of oral contraceptives in 45% to 70% of patients (38).

CP should be highly suspected in a patient who presents in the third trimester with the complaint of pruritus, but with few or absent skin findings. Skin biopsy is of little benefit. Laboratory evaluation is necessary for diagnosis, with elevation of bile acid the most sensitive indicator of CP (levels greater than 11.0 M are significant) (77). The degree of pruritus tends to correlate with the bile acid level. Other liver function tests may be elevated including transaminases, alkaline phosphatase, and bilirubin (76). It is also important to rule out other causes of liver abnormalities, jaundice, and pruritus.

Maternal and fetal risks are associated with CP. Maternal outcomes are generally favorable, but severe cases may lead to postpartum hemorrhage secondary to low vitamin K (38). Other complications include an increased tendency toward cholelithiasis and cholecystitis. Fetal risk includes fetal distress in 20% to 30% of cases, premature birth in 20% to 60% of cases, and stillbirth in 1% to 2% of cases. Fetal risks are thought to be due to the result of placental anoxia secondary to decreased fetal elimination of toxic bile acids (38,51,76).

Medical management of CP is twofold: fetal monitoring and treating maternal symptoms. Fetal monitoring should begin around the 34th week of gestation. Delivery may need to be induced depending on the severity of fetal distress. Topical therapy with steroid preparations, emollients, and oral antihistamines provides some relief to mild pruritus. In

patients with intense pruritus, ursodeoxycholic acid has replaced cholestyramine as first-line therapy. Ursodeoxycholic acid treatment is the only medical therapy shown to decrease both maternal pruritus and fetal mortality (38,51,78). Doses range from 450 to 1200 mg/day (38).

PP and PFP

In the past, these two dermatoses of pregnancy were viewed as separate entities by the majority, but recently Ambros-Rudolph et al. have proposed the term “atopic eruption of

Figure 4 Excoriations in pruritus gravidarum.

Figure 5 Allergic contact dermatitis, a common dermatosis, which also occurs in pregnant patients.

pregnancy” (51). This term encompasses PP, PFP, and eczema in pregnancy. Though discussed separately, PP and PFP may best be considered part of a spectrum.

PP has an incidence of 1 in 450. It tends to manifest during the second or third trimester. Clinically, the patient presents with erythematous, excoriated papules or nodules along the extensor surfaces most commonly. The lesions can appear eczematous or crusted. This is more common in patients with a history of atopy (79). A laboratory workup is usually not necessary. PP resolves postpartum, but may persist for up to 3 months. Fetal and maternal prognoses are excellent. It may recur in subsequent pregnancies (79). Treatment for pruritus is symptomatic including topical steroids and antihistamines.

PFP has an incidence of approximately 1 in 3000 (79). Clinical presentation occurs during the second or third trimester with pruritic, follicular, monomorphous papules and occasionally pustules. The skin findings tend to be on the trunk but may become generalized. PFP is a sterile folliculitis; however, evaluation to rule out other infectious etiologies is warranted. Fetal and maternal outcomes appear to be unaltered. One study reported decreased birth weight and a male to female ratio of 2:1 (80). Treatment is aimed at symptomatic relief. Topical medium potency steroids and narrowband ultraviolet B phototherapy have proven beneficial (38).

CONCLUSION

Pregnancy affects the majority of the biologic systems, and the skin is not an exception. It is important to remember that many common dermatoses also occur in pregnant patients (Fig. 5) as well as significant dermatoses specific to pregnancy. Risks to both mother and fetus, associated with specific dermatoses of pregnancy, may be identified quickly and treated appropriately with accurate dermatologic diagnosis.

22 Endocrine diseases and pregnancy

Stephen A. Brietzke

INTRODUCTION

The epidemiology and natural history of endocrine diseases are such that they commonly occur in women of childbearing age. While major endocrinopathies often adversely affect fertility, and thereby in effect prevent pregnancy, the innate resilience of the human reproductive system, and the fundamental good health of most endocrine patients, assures that incidental pregnancies will frequently be encountered in patients with established endocrine disease. Pregnancy profoundly affects many of the endocrine systems and the laboratory testing upon which confirmation of disease relies; thus, physicians who treat pregnant patients are well advised to have familiarity with these alterations. Endocrine diseases may have adverse consequences for maternal, fetal, and neonatal health; likewise, the pregnancy may alter the expression of endocrine disease and as well may alter the interpretation of diagnostic laboratory testing commonly performed in non-gravid patients. Additionally, pregnancy alters choice of pharmacotherapy and diagnostic modalities and reagents.

THYROID DISORDERS

Physiologic Adaptations of Pregnancy

In the normal woman, serum thyroxine (T₄) and triiodothyronine (T₃) concentrations increase by approximately 50% because of expansion of the protein-bound pool of thyroid hormones. This in turn is due to marked increase in plasma thyroxine-binding globulin (TBG), a consequence of reduced hepatic clearance owing to estrogen-induced sialylation of TBG (1). In addition to the expansion of the total circulating pool of thyroid hormones, renal clearance of iodide increases, due to the increase in glomerular filtration rate accompanying pregnancy-related volume expansion. Finally, early in gestation, maternal thyroid hormones are passed via the placenta to the fetus, and throughout pregnancy, iodide is transferred to the fetus transplacentally (2). To meet the expanded requirement for total serum thyroxine and to offset increased loss of iodide in the urine and to the fetus, maternal thyroid synthesis and secretion of T₄ and T₃ increases throughout gestation. Accurately assessing the adequacy of circulating maternal thyroid hormones is challenging. Clinical laboratory measurement of free T₄ is increasingly available and has largely supplanted older methodology wherein total T₄ ("free" plus TBG-bound T₄) was measured. However, at this time, free T₄ normal ranges have not been benchmarked well for each trimester of pregnancy, and there are inconsistent data reporting values of free T₄ lower, the same, or higher than that in nonpregnant patients (1,3). At the present time, it is prudent to request measurement of total serum T₄ and adjust the normal reference range to 1.5 times the nonpregnant adult normal range (4).

Thyroidal iodide transport, synthesis of thyroid hormone, and release of stored thyroid hormone are all controlled by the secretion of thyroid-stimulating hormone (TSH) from the

pituitary gland. In turn, TSH is stimulated by hypothalamic thyrotropin-releasing hormone (TRH). TRH and TSH secretion is inhibited in negative feedback fashion by rise in serum T₄ and T₃ to the equilibrium set point. During the first trimester of pregnancy, TSH levels consistently fall below the non-gravid baseline. Since this change accompanies the rise in serum human chorionic gonadotropin (beta-hCG), and since hCG has considerable structural homology to TSH, it has been assumed that in the first trimester, hCG transiently supplants TSH as the primary stimulator of maternal thyroid function. As hCG concentrations wane from gestational weeks 10 to 20, serum TSH returns toward its usual baseline value (1). In the first trimester, to allow for partial replacement of TSH function by hCG, it has been suggested that the normal upper limit for maternal TSH be adjusted to no more than 2.5 mU/L (5). With this caveat, TSH is an excellent screening test for thyroid disease in pregnancy and is generally recommended as the test of first choice.

Normal Fetal and Neonatal Thyroid Physiology

The fetal thyroid begins to take up iodine and synthesize T₄ at 10 weeks of gestation. Fetal T₃ is low throughout gestation (6). Normally, only a small amount of maternal thyroid hormone traverses the placenta to reach the fetal circulation, but may be vital for fetal brain development (7), particularly in athyrotic fetuses (8). Iodides, antithyroid drugs, and thyroid-stimulating immunoglobulins (TSIs) cross the placenta maternal-to-fetus readily and affect fetal thyroid function. In the immediate postpartum period, neonatal plasma TSH peaks at approximately 30 mU/mL several hours after birth, accompanied by increased plasma T₄ and T₃. Thereafter, plasma TSH falls to the adult reference range within a few days, and plasma T₄ and T₃ fall to the adult reference range within 1 month.

Hypothyroidism

Primary hypothyroidism is defined by elevated serum TSH above the normal reference range, and this finding occurs in about 2.5% of pregnancies (3,9). Severity of the thyroid deficiency is further characterized by the magnitude of TSH elevation ("mild" disease = TSH 2.5–10 mU/L; "moderate" disease = TSH 10 to <20 mU/L; "severe" disease = TSH >20 mU/L and T₄ below the lower limit of the pregnancy-adjusted reference range). Secondary hypothyroidism due to pituitary insufficiency is far less common (unless the patient is known to have pituitary or hypothalamic disease), since anterior pituitary insufficiency commonly adversely affects pulsatile gonadotropin secretion to a profound degree, with the result that unassisted conception is unusual in such patients. Secondary hypothyroidism is defined by subnormal plasma T₄ without an appropriate degree of TSH elevation.

Unless the patient has a history of radioactive iodine treatment or thyroid surgery, primary hypothyroidism is

overwhelmingly due to chronic lymphocytic thyroiditis (Hashimoto's thyroiditis). Postablation hypothyroidism or post-thyroidectomy hypothyroidism, stemming from radioactive iodine or surgical treatment of hyperthyroidism, goiter, or thyroid nodular disease (including thyroid cancer), is the other principal cause of hypothyroidism encountered in pregnant women. In most instances, the patient will be known hypothyroid prior to pregnancy, although of course exceptions will be encountered in clinical practice.

Symptoms of hypothyroidism in pregnant women are subtle and often attributed to the pregnancy itself. Cold intolerance, mild weight gain, fatigue, somnolence, depression, dry skin, constipation, and myalgias are some of the "classic" symptoms. There may have been a history of anovulation, dysfunctional uterine bleeding, or infertility pre-dating the pregnancy. Physical signs offering clues to diagnosis include goiter (Hashimoto's thyroiditis glands are often of palpably firm consistency), pretibial myxedema (rare), and delayed return phase of deep tendon reflexes, particularly at the ankle. Untreated maternal hypothyroidism increases the risks of gestational hypertension (up to 36%) (10), caesarean section due to fetal distress (up to 56%) (11), placental abruption (threefold increased risk vs. euthyroid pregnancies) (12), and pre-term labor (approximately twofold increased risk vs. euthyroid pregnancies) (12). Neonatal consequences of maternal hypothyroidism include a two- to threefold increased risk for low birth weight and delayed mental and motor developmental milestone attainment. There is also concern that ultimate cognitive attainment of offspring of hypothyroid mothers is slightly less than offspring of euthyroid mothers (5).

Hypothyroidism in pregnancy should be treated with levothyroxine (13). Owing to the increased TBG-bound pool of circulating T4, higher levothyroxine doses are prescribed for pregnant than for nonpregnant patients. For the patient newly diagnosed and not previously treated, if the serum TSH is >10 mU/L, a starting levothyroxine dose of 2 mcg/kg/day is prudent (4), whereas for TSH <10 mU/L, a starting levothyroxine dose of 1 mcg/kg/day may be sufficient (2). For women already receiving levothyroxine treatment at the time of conception, the dose requirement increases predictably by 25% to 50%. Functionally athyrotic patients (those with postablation hypothyroidism or post-thyroidectomy hypothyroidism) have a larger dose increase than patients with primary hypothyroidism due to Hashimoto's thyroiditis, probably because in the latter condition, the thyroid is still capable of some T4 generation albeit to a subnormal extent (14). Conservatively, a serum TSH <2.5 mU/L should be targeted as goal for therapy; dose of levothyroxine should be increased for values >2.5 mU/L and TSH retested monthly with further dose titration until stable. A suggested formula for dose increase based on TSH is to increase levothyroxine by 50 mcg/day for TSH <10 mU/L; by 75 mcg/day for TSH 10 to 20 mU/L; and by 100 mcg/day for TSH >20 mU/L (2,14).

Congenital Hypothyroidism

Approximately 1 in 5000 live births is associated with congenital hypothyroidism, most usually due to thyroid agenesis or dysgenesis (15). Other causes include genetic defects of hormone synthesis, maternal treatment with

antithyroid drugs or radioactive iodine, and placental transfer of maternal TSH receptor inhibitory antibodies. Antithyroid drugs and iodides may induce fetal goiter large enough to produce tracheal obstruction (16). Hypothyroid infants appear normal at birth, but develop mental retardation due to the syndrome of cretinism unless treated soon after birth. Neonatal screening of TSH is essential for early diagnosis and prevention of irreversible neurologic damage and has become a universal practice in the United States.

Thyrotoxicosis (Hyperthyroidism)

The term "thyrotoxicosis" distinguishes excessive serum T4 and/or T3 from all causes (including, importantly, excessive ingestion of levothyroxine, liothyronine, or desiccated thyroid hormone), from "hyperthyroidism," which specifically implies excessive active production of thyroid hormones by the native thyroid gland. In practice, the term "hyperthyroidism" is generally used interchangeably with "thyrotoxicosis." Hormonally, the syndrome is defined by suppressed serum TSH (usually <0.1 mU/L); if T4 and/or T3 are not elevated beyond the normal range but the TSH is suppressed, the condition is referred to as "subclinical hyperthyroidism." Prevalence of hyperthyroidism in pregnancy is in the range of 0.1% to 0.5%, and 85% to 90% of cases are due to diffuse toxic goiter (Graves' disease). As the name suggests, Graves' disease is usually accompanied by a fleshy-consistency goiter ranging from minimally enlarged to three to four times that of the normal thyroid. Graves' disease is caused by an autoantibody, TSI, which binds to and activates the thyroidal TSH receptor, usurping the normal function of TSH in unregulated fashion (17). Other than Graves' disease, possible causes of hyperthyroidism in pregnancy include toxic adenoma (a solitary, usually large, thyroid nodule with autonomous, TSH-independent production of T4 and/or T3), toxic multinodular goiter (typically with multiple thyroidal nodules or regions autonomously producing T4 and/or T3), subacute thyroiditis (painless lymphocytic thyroiditis), and excessive ingestion of thyroid hormones either prescribed or obtained surreptitiously. Trophoblastic tumors associated with very high levels of beta-hCG (typically $>100,000$ IU/L) can cause hyperthyroidism due to activation of the TSH receptor by hCG (18,19). In the first trimester, some patients with hyperemesis gravidarum have elevation of T4 and non-suppression of T3, in contrast to other conditions with nausea, vomiting, and poor oral intake, wherein T3 levels are invariably low (20). Sixty percent of patients with hyperemesis have serum TSH <0.4 mU/L and approximately half have a serum free T4 elevated above the normal range. TSH and T4 normalize as hCG serum levels decline beyond week 20 of gestation.

Symptoms of thyrotoxicosis include heat intolerance, weight loss, anxiety, palpitations, tachycardia, and excessive sweating, along with poor exertional tolerance and easy fatigability. Not surprisingly, in many instances, the symptoms will be erroneously attributed to those of normal pregnancy. Physical clues to the possibility of thyrotoxicosis include goiter, proptosis, lid lag, stare, a fine resting hand tremor, warm moist palmar skin, and generalized hyperreflexia.

Maternal–Fetal Risks of Hyperthyroidism

Untreated maternal hyperthyroidism is associated with several adverse outcomes of the pregnancy. Preterm labor occurs in up to 88% of untreated mothers, compared with 8% whose hyperthyroidism is optimally treated (21). Pre-eclampsia in untreated or poorly controlled hyperthyroid mothers occurs at approximately twice the frequency as in well-controlled hyperthyroid mothers (22), and stillbirth may occur in up to 50% of untreated mothers, compared with a 0% to 16% risk in optimally treated mothers (21). Small-for-gestational age and various congenital malformations may occur at increased frequency in the neonates of untreated or poorly controlled hyperthyroid mothers (17).

Treatment

Thionamide drugs are the only treatment, which can be recommended with respect to both maternal and fetal health during the course of pregnancy and can be used to treat hyperthyroidism due to Graves' disease, toxic adenoma, or toxic multinodular goiter. Due to the mechanism of action of this class of drug and the pathophysiology of subacute thyroiditis (passive leakage of pre-formed T4 and T3 from a damaged gland, rather than excess production), thionamides are ineffective in the treatment of subacute thyroiditis. Propylthiouracil (PTU) and methimazole (MMI) are the available thionamides in the United States. The mechanism of action of thionamides is interference with the key steps of thyroid hormone synthesis (thyroidal organification of iodine and coupling of iodotyrosines), by serving as a competitive substrate for the thyroid peroxidase enzyme. Accumulation of thionamide in the thyroid gland, rather than serum levels of drug, is required for optimal effect. Thus, 7 to 8 weeks of treatment is usually required before a euthyroid state can be expected clinically (23). Both drugs cross the placenta and have potential to cause fetal hypothyroidism and, for this reason, can be used to treat fetal hyperthyroidism. Historically, PTU is preferred over MMI in pregnancy because MMI is thought to be associated with a rare congenital scalp defect, aplasia cutis. The association is, however, very weak and has not been observed in several well-done case-control series. Therefore, for patients who do not tolerate PTU, MMI could be considered as alternative therapy and is probably far preferable to the alternative of no treatment of severe maternal hyperthyroidism (2). PTU is given in a dose range of 50 to 150 mg/day orally three times; doses >600 mg/day pose high risk of fetal/neonatal hypothyroidism. Even at a maternal dose of PTU <100 mg/day, about one in five neonates have above-normal serum TSH at birth (24). To minimize the risk of significant neonatal hypothyroidism, the general recommendation is to titrate treatment of maternal hyperthyroidism so as to minimize symptoms, but maintain T4 levels in the upper third of the normal range for pregnancy and not necessarily normalize serum TSH during the pregnancy (25). The lowest possible dose of PTU, which attains these goals of treatment, should be maintained if at all possible. Adequacy of treatment can be reassessed at 2- to 4-week intervals throughout gestation, with adjustment of the PTU dose at about that frequency (2). Most authorities recommend not exceeding a dose of 450 to 600 mg/day PTU. If MMI is used as an alternative to PTU, the dose should not exceed 30 to 40 mg/day.

Unlike PTU, MMI can be effectively administered as a single daily dose, which may be of value in patients who have difficulty fully adhering to a thrice-daily medication schedule. Adverse effects of thionamides include, commonly, skin rashes, most characteristically, urticaria. Serious drug-related hepatitis (due to PTU) and cholestasis (due to MMI) are possible, and periodic monitoring of hepatic transaminases (aspartate aminotransferase and alanine aminotransferase) is recommended. Approximately 1 in 200 users of PTU or 1 in 300 users of MMI develop agranulocytosis, which usually declares as neutropenic fever. Standard recommendation to patients is to seek prompt care and have a complete blood count with differential for any febrile illness, while they are taking a thionamide drug (26).

A beta blocker drug can be used during pregnancy as an adjunct to thionamide therapy and is especially useful to quickly gain control of tachycardia, extreme nervousness, and tremor in extremely symptomatic patients. The best-studied drug in pregnancy is propranolol, which can be given in a dose range of 10 – 40 mg/day orally four times. The dose is titrated to subjective symptomatic improvement and to heart rate <90 beats/min. Curtailing the dose to the minimum necessary to attenuate symptoms is prudent, as beta blockers may cause fetal growth retardation in dose-dependent fashion. If possible, delaying the initiation of propranolol until the second trimester may also be prudent, because of evidence from one study that combined use of thionamide and propranolol was associated with a 24% risk of first-trimester miscarriage, versus 5.5% miscarriage rate when thionamide alone was used (27). Beyond the first trimester, the only significant risk of propranolol has been low birth weight.

Stable low-dose iodide used for 1 to 2 weeks in conjunction with thionamide therapy appears safe, as long as the dose is limited to 6 to 40 mg/day of potassium iodide or equivalent (28). The major practical usage of iodide therapy would be in short-term preparation of a patient for thyroid surgery in pregnancy or to rapidly reduce circulating T4 and T3 in a patient with severe hyperthyroid illness. Radioactive iodine, which is a popular treatment for Graves' disease, toxic adenoma, and toxic multinodular goiter in non-gravid patients, is strictly contraindicated in pregnancy, due to concern not only for fetal thyroid ablation but also for possible induction of various congenital defects.

For very severe maternal hyperthyroidism that cannot be controlled by PTU or MMI, or for patients unable to take thionamides due to serious adverse drug reactions, or for large maternal goiter threatening airway obstruction, subtotal thyroidectomy prior to gestational week 24 in the second trimester is a reasonable consideration (29). Preparation of the patient for surgery can include PTU or MMI, if tolerated, plus a beta blocker and potassium iodide 6 to 40 mg/day beginning 10 to 14 days preoperatively. The role of iodide in this setting is to reduce the vascularity of the thyroid prior to surgery, thereby limiting operative blood loss (2).

Fetal and Neonatal Hyperthyroidism

Fetal and neonatal hyperthyroidism is caused by placental transfer of maternal TSI to the fetus (30). Fetal disease is heralded by tachycardia (>160/min), growth retardation, goiter, craniosynostosis, and increased perinatal mortality (31). Fetal hyperthyroidism can be treated in utero by prescribing

PTU 50 to 150mg/day orally three times to the mother, anticipating that the drug will cross the placenta and be incorporated into fetal thyroid, thereby inhibiting synthesis of T4 and T3. Active previously untreated Graves' disease obligates PTU treatment in the mother as well as in the fetus. However, a common dilemma involves a mother previously treated with radioactive iodine (less commonly, with subtotal thyroidectomy) prior to gestation for Graves' disease who now has postablation hypothyroidism, is euthyroid on replacement levothyroxine, but who continues to have high-titer TSI. In such pregnancies, there is still a finite risk of fetal and neonatal hyperthyroidism due to placental transmission of TSI to the fetus. A strategy for the detection and treatment of fetal disease, and prevention of neonatal disease, is to measure maternal TSI titer during the second trimester in mothers who have a history of Graves' disease. A highly positive TSI test leads to careful surveillance of fetal growth and heart rate (2). For poor growth or excessive tachycardia, the mother continues to receive her usual levothyroxine dose but is concurrently treated with PTU 50 to 150mg/day three times, titrating the dose to fetal heart rate and goiter size as assessed by ultrasound at 2-week intervals (31). Neonatal hyperthyroidism complicates 1% to 2% of pregnancies in women with Graves' disease (32) and manifests as irritability, tachycardia, poor weight gain, goiter, and, potentially, heart failure and death. T4 and TSH should be measured in cord blood if the mother has a history of Graves' disease. Neonatal hyperthyroidism is treated with PTU, iodine, and propranolol and usually resolves within 1–3 months, as TSIs are cleared from plasma.

POSTPARTUM THYROID DISORDERS

Graves' disease commonly spontaneously improves during the third trimester and flares in the postpartum period, and may first become evident then. The differential diagnosis of postpartum thyrotoxicosis is principally between Graves' disease and postpartum subacute thyroiditis (also known as painless lymphocytic thyroiditis), which affects about 5% of postpartum women (33). It occurs within the first 3 postpartum months and produces mild or moderate thyrotoxicosis that lasts up to 3 months, and then either resolves or is followed by transient hypothyroidism, which lasts for several months and then spontaneously resolves. In up to one-third of affected patients, permanent hypothyroidism ensues; such cases are difficult to distinguish from Hashimoto's thyroiditis and are usually accompanied by high levels of thyroid peroxidase autoantibody. Distinguishing postpartum Graves' disease from postpartum thyroiditis can be difficult. Graves' disease is very likely to be associated with a significant goiter, which may be accompanied by a bruit over the thyroid or supraclavicular fossa, while postpartum thyroiditis is associated with normal thyroid or minimal goiter, and no bruit. Proptosis is not seen in postpartum thyroiditis, so if present implies Graves' disease. Measurement of radioactive iodine uptake (RAIU) can be performed if the patient is not nursing; uptake is always nearly undetectable (<5% 24-hour RAIU) in thyroiditis and is elevated (>30% 24-hour RAIU) in Graves' disease. TSI would only be positive in Graves' disease, but is an expensive and usually unnecessary test. The pathophysiology of postpartum thyroiditis involves leakage of T4 and T3 from a

damaged gland; thus, thyroid hormones are not being actively synthesized, and antithyroid drug therapy with thionamides has no rational role. Treatment of postpartum thyroiditis is limited to beta blocker for control of symptoms, including heart rate, nervousness, and tremor. Close follow-up with measurement of TSH and T4 every 1 to 2 months is desirable. If hypothyroidism occurs and is bothersome to the patient, treatment with levothyroxine can be entertained for up to 6 months. Hypothyroidism persisting beyond 6 months postpartum is likely to be permanent, and levothyroxine titrated to normalization of TSH is desirable at that time. Women who experience postpartum thyroiditis during one pregnancy are likely to experience recurrences with subsequent pregnancy and can be counseled and monitored accordingly (33).

Thyroid Nodules

Solitary thyroid nodules occur in up to 15% of women in the first trimester and in up to 24% of women in the first 3 months postpartum (34). Upward of 90% of such nodules represent benign disease (follicular or colloid adenomas), but deserve cytologic diagnosis to exclude the possibility of thyroid carcinoma. As in non-gravid patients, women in the first two trimesters of pregnancy can be evaluated by ultrasound-guided fine needle biopsy (35). If cytology confirms papillary thyroid carcinoma, the patient could undergo thyroidectomy during the second trimester. Alternatively, the size of the lesion may be followed by repeat ultrasound at midtrimester. A known cancer, which has enlarged significantly, can be referred for surgery; if it has remained stable in size, surgery is deferred until the patient is postpartum (2). Conversely, if cytology is read as "consistent with follicular neoplasm" (which conveys an approximately 20% risk of malignancy), it is a reasonable practice to delay thyroidectomy until the postpartum period. Conclusively benign cytologic findings in euthyroid patients provide excellent reassurance, and simple long-term clinical follow-up is sufficient.

ANTERIOR PITUITARY DISORDERS

Normal Physiology

Thyrotropin (TSH), corticotropin (ACTH), the gonadotropins [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], prolactin, and growth hormone (GH) comprise the hormonal products of the anterior pituitary gland. With one key exception, the secretion of anterior pituitary hormones is governed by secretion of stimulatory hypothalamic releasing hormones, which traverse the pituitary stalk via the portal veins. The known hypothalamic releasing hormones specific for each of the anterior pituitary are TRH, corticotrophin-releasing hormone (CRH), gonadotropin-releasing hormone (GnRH, for both LH and FSH), and growth hormone–releasing hormone (GHRH) for GH. Control of prolactin secretion, in contrast to the other trophic hormones, is primarily inhibitory, with the inhibitory signal hormone being dopamine of hypothalamic origin, circulated to the anterior pituitary via the hypothalamic–hypophyseal portal veins in the pituitary stalk. Knowledge of the normal hypothalamic stimulatory and inhibitory control of anterior pituitary hormone secretion explains common patterns of disease. Hypothalamic lesions are frequently heralded by deficiency of GH, ACTH, TSH, LH, and FSH and concurrently

by hyperprolactinemia. Anatomically large secretory tumors of one discrete cell type of anterior pituitary origin usually overexpress one hormonal product (ACTH, TSH, or GH) producing a clinically recognizable syndrome; compression of the pituitary stalk by the tumor may impede communication of releasing hormones and dopamine, and therefore such large tumors commonly are accompanied by partial hypopituitarism and modest hyperprolactinemia.

Pituitary Adaptations in Normal Pregnancy

Beginning soon after conception, under the influence of rising estrogen concentration, hypertrophy and hyperplasia of lactotroph cells result in an approximately 40% increase in pituitary volume by term (36,37). In accord with the gain in lactotroph cell numbers, serum prolactin increases, usually peaking at approximately 200 ng/mL during the third trimester of pregnancy. Pituitary LH and FSH secretion are inhibited by prolactin, due to feedback inhibition of GnRH secretion by hyperprolactinemia (38).

Placental production of a variant GH stimulates elevated serum levels of somatomedin-C during the third trimester, which in turn inhibits GHRH and native GH of pituitary origin secretion in the third trimester (39,40).

Throughout gestation, serum cortisol levels progressively increase, reaching two to three times the non-gravid baseline value by term. Some of the increase is accounted for by the expansion of the serum pool of protein-bound, biologically inactive cortisol due to estrogen-stimulated hepatic synthesis of cortisol-binding globulin. However, plasma free cortisol is also approximately three times elevated versus the non-gravid baseline value and is reflected by 24-hour urinary free cortisol values of the same magnitude.

Because rising concentrations of human chorionic gonadotropin early in gestation transiently usurp control of thyroid hormone secretion from TSH, TSH levels normally decline in the first trimester, gradually returning to baseline values by the third trimester (3,40).

Pituitary Tumors

Pituitary tumors, which are most frequently benign adenomas of a single cell type, are classified as microadenomas if <1 cm in diameter, and as macroadenomas if >1 cm in diameter. They may be either clinically nonfunctional (in which case, immunostaining is commonly positive for FSH), or secretory, with prolactin, GH, or ACTH excess. Microadenomas produce clinical effects only through hormone excess or hormone deficiency caused by feedback signaling, whereas macroadenomas can cause hypopituitarism by either stalk compression or displacement of normal anterior pituitary cells and can produce symptoms due to mass effect, with headaches due to dural stretch, and/or visual field defects due to encroachment of optic chiasm (40,41).

Clinically important pituitary hormone deficiencies during pregnancy are secondary hypothyroidism and secondary adrenal insufficiency, caused respectively by TSH and ACTH deficiency. Prolactin deficiency poses no significant hazard to the viability of the pregnancy or to maternal-fetal health; however, prolactin deficiency would declare in the postpartum period as failure to lactate. Evaluation of suspected hypopituitarism or pituitary tumor during pregnancy should include

measurement of serum free T4 measurement, assessment of cortisol response to injected cosyntropin (synthetic ACTH), and magnetic resonance imaging (MRI) (without gadolinium contrast) of the sellar region. If there is suspicion of visual field compromise based on clinical exam, or if the MRI shows encroachment of the optic chiasm, formal visual field assessment (Goldman fields) by an ophthalmologist is recommended (40). If adenoma resection is required, the vast majority can be removed by a transsphenoidal approach (31).

Hyperprolactinemia

Hyperprolactinemia is a common endocrine disorder in young women and may be responsible for up to one-third of cases of infertility. Because hyperprolactinemia suppresses GnRH, which in turn results in diminished gonadotropin pulsatility, disruption of ovulation and consequent anovulatory bleeding, amenorrhea, or luteal phase defects can all occur, and the hyperprolactinemia may also produce galactorrhea. Significant and persistent hyperprolactinemia may be due to either micro- or macro-sized prolactinomas. Modest hyperprolactinemia (serum prolactin, 20–50 ng/mL) may be due to microprolactinoma, pituitary stalk compression by a non-prolactinoma pituitary tumor, hypothalamic lesions, or a variety of dopamine antagonist medications (40).

Prolactin levels >200 ng/mL are virtually certainly due to prolactinoma; however, since physiologic hyperprolactinemia of pregnancy approaches 200 ng/mL, and since lactotroph hyperplasia and hypertrophy of normal pregnancy may mimic pituitary adenoma, it is rare that prolactinoma would be suspected or confirmed during pregnancy (40).

Because medical therapy or surgical therapy of prolactinoma can be highly effective in restoring ovulatory function to formerly infertile hyperprolactinemic women, intended or unintended pregnancy in such patients is an entirely likely outcome. Drugs used to treat prolactinoma are bromocriptine, pergolide, quinagolide (not approved for use in the United States), and cabergoline; commonly, when pregnancy is recognized, the patient with prolactinoma will be receiving one of these agents. What is known about this class of drugs during pregnancy is largely reassuring. Bromocriptine and cabergoline are classified by the U.S. Food and Drug Administration as class B (no definite evidence of harm; available information and reported experience indicates probably safe for use) in pregnancy. Once pregnancy is recognized, a decision about how to manage dopamine agonist drug therapy for the duration of pregnancy should be based on the tumor size, symptoms, and the natural history of prolactinomas during pregnancy. Pooled reported experience with 376 patients suggests that only 1.3% of microprolactinomas enlarge sufficiently during pregnancy so as to produce clinical symptoms of mass effect (visual compromise or intractable headache) (40,42). Given the favorable prognosis, recommendation is that drug therapy for microprolactinoma be discontinued as soon as pregnancy is confirmed. Neuroimaging during the pregnancy would be recommended only if symptoms of visual field defect or intractable headache were to occur. Monitoring of serum prolactin during pregnancy is not helpful and not advised. Of the previously untreated patients with macroprolactinoma, 20% to 25% may develop symptomatic tumor enlargement during pregnancy, but if

the macroprolactinoma has been previously treated with surgery, the risk of symptomatic enlargement is only 2% to 3%. For the patient who has previously undergone transsphenoidal resection of macroprolactinoma, and who is not receiving medication therapy at the time of conception, careful follow-up during the pregnancy, with monthly visits emphasizing symptoms of headache or visual compromise, is a prudent recommendation. Women with macroprolactinoma treated with primary medication treatment (no surgery) often respond with considerable size reduction of the tumor, are able to conceive, and constitute the most problematic group of hyperprolactinemic patients in pregnancy for whom generic recommendations are made. Consideration is given to simply continuing bromocriptine or cabergoline throughout the pregnancy, as rapid enlargement of macroadenomas is a risk when medication therapy is discontinued. At a minimum, careful surveillance and monthly office visits to elicit symptoms, and reinstatement of medical therapy or transsphenoidal tumor debulking should be pursued if symptomatic tumor enlargement occurs. Formal testing of visual fields in each trimester of pregnancy is commonly advised (40,42).

Acromegaly

Maternal Effects

Infertility or hypogonadotropic hypogonadism frequently accompany acromegaly, and pregnancy is an unusual enough occurrence that there have been fewer than 100 cases of pregnant acromegalics reported in the literature. Acromegaly is caused by GH excess and is most commonly due to a pituitary adenoma. Approximately 80% of recognized acromegalic pituitary tumors are >1 cm in size (macroadenomas), with the remainder being microadenomas. Characteristic clinical findings include enlargement of hands (particularly broadening of the digits) and feet, with increased glove, ring, and shoe size often reported by patients. Characteristic facial features include wide spacing between teeth and prognathism, consequent to enlargement of the mandible, frontal bossing consequent to the enlargement of frontal sinuses, thick lips and broad fleshy nose consequent to soft-tissue expansion, and prominent nasolabial folds. Carpal tunnel syndrome, hypertension, and diabetes mellitus occur with increased frequency in actively acromegalic patients (40).

Confirmation of acromegaly suspected for the first time during pregnancy is complicated by the normal increase in serum IGF-1 in late pregnancy, and by the GH variant of placental origin, which cannot be easily distinguished from GH of pituitary origin. Early in pregnancy, a very high serum IGF-1 would be suggestive of acromegaly, and the diagnosis can be confirmed by documenting failure of GH suppressibility (<2 ng/mL) during a 75-g oral glucose suppression test. MRI of the sella and suprasellar region should be performed to identify and assess the size of the responsible pituitary adenoma. By the third trimester, definitive diagnosis of acromegaly may reasonably be deferred until after delivery (40).

Fetal Effects

The limited reported clinical experience with acromegalic pregnancies suggests no ill effect on fetal development directly attributable to maternal GH and IGF-1 excess. Rather, the major fetal risks are likely related to acromegaly-linked

complications of diabetes mellitus (which can occur in up to 20% of acromegalic pregnancies) and hypertension (up to 35% of acromegalic pregnancies) (43). If observed, these complications are managed in usual fashion for the duration of the pregnancy.

Management of the Pregnant Acromegalic Woman

The most likely clinical scenario involving acromegaly and pregnancy is pregnancy in a woman previously diagnosed and treated for the disease. She may in fact have been cured by transsphenoidal resection of an adenoma; confirmation of cure rests with sustained suppressibility of GH to oral glucose challenge and normalization of serum IGF-1. If so, pregnancy should be managed as a normal pregnancy. For patients not surgically cured, the most conventional and effective long-term management involves use of a long-acting somatostatin analog, either octreotide or lanreotide. Frequently, treatment with a somatostatin analog normalizes IGF-1 and restores fertility; consequently, pregnancy can occur. The available information about pregnancies occurring in treated women identifies no adverse fetal consequences (44–46). However, because octreotide and lanreotide do cross the placenta (47) and because experience with continuation of these drugs throughout pregnancy is extremely limited, a conservative and mainstream recommendation is to discontinue the somatostatin analog once pregnancy is recognized (40). Symptomatic enlargement of acromegalic pituitary adenomas during pregnancy is an uncommon complication (one reported case) (48); should this be encountered in the first two trimesters, consideration could be given to transsphenoidal resection or to reinstatement of somatostatin analog therapy.

Lymphocytic Hypophysitis

Late in the third trimester or early in the postpartum period, lymphocytic hypophysitis represents a rare cause of hypopituitarism or visual field defects. Anatomically, the disorder may be suspected by thickening of the pituitary stalk or by sellar mass, which cannot be distinguished from a pituitary tumor. The diagnosis is definitively established by surgical resection or biopsy demonstrating absence of tumor cells and diffuse lymphocytic infiltration (40). Clinically, lymphocytic hypophysitis is distinguished from Sheehan's syndrome by the absence of obstetric hemorrhage in the former and its presence in the latter (49). If surgical biopsy is not undertaken, spontaneous resolution may occur (50,51), and attention should be given to treatment of hypopituitarism. The limited available experience suggests that ACTH deficiency is especially common (49), so assessment of the hypothalamic–pituitary–cortisol axis is especially important; identified deficiency should be treated with a cortisol agonist in standard physiologic replacement dose (e.g., hydrocortisone 20 mg orally in the morning and 10 mg in the late afternoon or equivalent).

Sheehan's Syndrome

Postpartum pituitary necrosis (Sheehan's syndrome) results from an ischemic insult to the pituitary as a complication of peripartum hemorrhage (52) and is distinctly rare in modern obstetric practice (53). Physiologic enlargement of the pituitary in late gestation, consequent to the physiologic

expansion of lactotrophs, seems to render the gland especially sensitive to hemodynamic insult. In the setting of known obstetric hemorrhage or maternal hypotension during the labor and delivery process, Sheehan's syndrome is suspected if postpartum lactation fails to occur. Lactation failure heralds possible loss of other critical pituitary hormonal function, including ACTH and TSH, which should be assessed through appropriate testing. Diagnosis is confirmed by MRI, typically demonstrating the absence of a pituitary tumor and possibly demonstrating an edematous or hemorrhagic gland. Frequently, deficiencies of ACTH and TSH are not evident for years, so long-term follow-up of affected women is essential (40).

POSTERIOR PITUITARY DISORDERS

In normal pregnancy, the osmotic thresholds for vasopressin [arginine vasopressin (AVP), also known as antidiuretic hormone (ADH)] release and thirst are lowered, resulting in plasma osmolality about 10mOsm/kg lower than that in nonpregnant women (54). The metabolic clearance of AVP is markedly accelerated by mid-pregnancy, probably owing to circulating placental vasopressinase, which degrades AVP.

Diabetes Insipidus

Diabetes insipidus (DI) is the inability to concentrate urine, owing to AVP deficiency [central or neurogenic diabetes insipidus (CDI)] or renal tubular resistance to AVP (nephrogenic diabetes insipidus) (55). Causes of CDI include head trauma and hypothalamic tumors and other anatomic lesions; many cases are idiopathic. Transient forms of CDI may occur in pregnancy, owing to unmasking of subclinical disease by circulating vasopressinase (56) or to excessive circulating vasopressinase in the setting of hepatic dysfunction (57). Other causes of polyuria should be excluded by appropriate and pragmatic patient assessment. Diabetes mellitus causes polyuria, but if so, it is always accompanied by glycosuria. Urine dipstick consistently negative for glucose excludes this possibility. So long as thirst sensation is intact, plasma osmolality remains normal if patients are able to drink and have access to water. In the presence of CDI or nephrogenic DI, nonavailability of water or inability of the patient to drink because of nausea, vomiting, or impaired cognition will quickly result in dehydration and hyperosmolar hyponatremia. Various forms of dipsogenic DI also occur, but since AVP secretion and response are typically normal, a strong clinical clue suggestive of dipsogenic DI is significant hypoosmolar hyponatremia (as opposed to slight hyponatremia or normal serum sodium concentration, which is expected in either CDI or nephrogenic DI). Dipsogenic DI is commonly due to a primary psychiatric disorder—notably, schizophrenia—or may be due to hypothalamic disorders (e.g., neurosarcooidosis), which reset the “osmostat” for thirst.

Cardinal symptoms of DI are polyuria and polydipsia. Polyuria must not be confused with increased frequency of voiding, which is a common symptom of normal pregnancy. Actual polyuria is defined by increased urine volume (more than 2.5liters/24hours), in the absence of glycosuria. A water deprivation test (55), which includes hourly measurement of urine volume and osmolality, body weight, and vital signs, and measurement of plasma sodium every 3–4hours, is the “gold

standard” traditional method of establishing the diagnosis of DI, but may be unnecessary if matched serum and urinary sodium, osmolality, and urine volumes reconcile with the clinical history. If a water deprivation test is performed, the patient should be seated or standing throughout the test, since urinary concentrating capacity is compromised during pregnancy by the lateral recumbent position. Water deprivation is achieved by enforced withholding of beverages and food, until a clinical endpoint is reached during the test. Endpoints justifying termination of water deprivation include (i) 3% decrease in baseline (time 0) body weight, (ii) urine osmolality rise <30mOsm/kg/hr for 3consecutive hours, or (iii) plasma sodium > upper limit of normal reference range. Upon attainment of an endpoint, the AVP analog desmopressin (DDAVP) 0.1mL is administered intranasally, and urine osmolality is measured again after 1 to 2hours. In severe CDI, maximal urine osmolality increases more than 50% after administration of DDAVP. In nephrogenic DI, maximal urine osmolality increases significantly less than 50%, and often not at all following administration of DDAVP.

Pregnant women with severe CDI may be treated with maintenance dosing of DDAVP, which is not degraded by placental vasopressinase. The usual dose is 0.1 to 0.2mL (10–20mg) intranasally once daily at bedtime or else twice daily. The major clinical risk of DDAVP treatment is excessive dosing, with the potential for seizures due to water intoxication (severe plasma hypoosmolar hyponatremia). In the authors' experience, this risk is minimized by limiting therapy to once-daily dosing, administered at bedtime, deliberately allowing a late-day period of breakthrough polyuria. Some patients with preexisting CDI may require an increase in the dose of DDAVP during pregnancy; therapy can be titrated by clinical response of symptoms and further guided by matched urine and serum sodium and osmolality.

ADRENAL DISORDERS

Normal Glucocorticoid Physiology

The adrenal cortex produces two hormones of biologic importance, cortisol and aldosterone. If cortisol or aldosterone production is biologically inefficient due to defective steroidogenic enzymes, androgenic precursor steroids may accumulate to a physiologically significant degree. Important roles of cortisol include sustainment of blood glucose under physiologically stressful or fasting conditions via facilitation of gluconeogenesis, modulation of the systemic inflammatory response, sustainment of blood pressure, and facilitation of renal free water excretion and promotion of renal sodium conservation and potassium excretion. Cortisol circulates in plasmas in both free and protein-bound forms; the free form is biologically active and the protein-bound form represents a slow-release reservoir pool. Cortisol-binding globulin (CBG) is the predominant binding protein for cortisol, and CBG production can be reduced or increased in disease states and under a variety of physiologic conditions. Cortisol secretion is controlled by circadian pulses of ACTH (in synergy with ADH). Normal circadian ACTH fluctuation results in peak secretion during the nocturnal hours after midnight, resulting in peak serum cortisol between 0600 and 0800hours. Throughout the day, ACTH secretion wanes toward nadir between 2200hours and midnight, at which time serum

cortisol normally does not exceed 5 mcg/dL. Signals for ACTH release include hypothalamic CRH as well as ADH. CRH and ADH secretion is stimulated by physiologic stress and hypoglycemia, and CRH and ACTH secretion is inhibited by rising concentrations of serum cortisol (negative feedback inhibition).

The other major adrenal cortical steroid hormone, aldosterone, is a mineralocorticoid promoting renal sodium reabsorption and potassium excretion, and maintenance of extracellular fluid volume and blood pressure. Although ACTH stimulates aldosterone secretion, the primary regulation of aldosterone secretion is via the renin–angiotensin signal pathway. Decreased delivery of sodium to glomeruli via afferent arterioles in the nephron stimulates renin secretion by juxtaglomerular cells. Renin in turn activates the angiotensin-converting enzyme, resulting to conversion of inactive angiotensin-1 to active angiotensin-2 in the lung; angiotensin-2 is the major stimulant of aldosterone synthesis and secretion by the adrenal. Aldosterone in turn promotes renal sodium conservation and extracellular fluid volume expansion, resulting in rising arterial pressure and increasing delivery of water and sodium to the proximal nephron. Renin secretion is inhibited by increased sodium delivery to the afferent renal arteriole, thereby completing the feedback loop of the renin–angiotensin–aldosterone axis.

In pregnancy, total plasma cortisol is increased, not only because of estrogen-stimulated increased CBG but also because of increased free cortisol. These changes occur early and progressively during gestation, increase further during labor, and persist for several days postpartum. Suppression of CRH and ACTH by exogenous glucocorticoids such as dexamethasone is impaired during pregnancy (58). It is possible that tissue responsiveness to cortisol is reduced, as normal pregnant women do not show physiologic consequences of cortisol excess. Maternal plasma renin and aldosterone are increased throughout pregnancy. The fetal adrenal gland (with a large fetal zone) contributes substantial dehydroepiandrosterone sulfate, which is converted by the placenta to estrogens (59).

Adrenal Insufficiency

Adrenal insufficiency in pregnancy has an estimated frequency of 1 per 300 births (60). Recognition and treatment of adrenal insufficiency has virtually eliminated maternal mortality, and the miscarriage rate may be as low as 15% (61). However, primary adrenal insufficiency due to autoimmune adrenalitis (Addison's disease) is frequently associated with other autoimmune disorders, including antiphospholipid antibody syndrome and systemic lupus erythematosus, which independently confer hazard to the pregnancy (62).

Adrenal failure can result in either disease of the adrenocortical tissue itself (primary adrenal insufficiency), due to autoimmune-mediated destruction of adrenocortical tissue (Addison's disease), or replacement of normal adrenocortical elements by metastatic tumor or granulomatous tissue, or from loss of trophic stimulation of the adrenal cortex by ACTH (secondary adrenal insufficiency). Secondary adrenal failure may be caused by any anatomic hypothalamic or pituitary lesion, including lymphocytic hypophysitis (49). In most cases, adrenal insufficiency will have been diagnosed

prior to pregnancy, which will then usually be uneventful provided maternal therapy is not interrupted. New-onset adrenal insufficiency in a pregnant woman may be heralded by symptoms such as malaise, salt-craving, orthostatic faintness, persistent vomiting, and weight loss (63). Significant hyponatremia is present in over 90% of cases, but may be difficult to distinguish from the "physiologic" hyponatremia of normal pregnancy. Hyperkalemia, present in about two-thirds of non-gravid patients with untreated primary adrenal insufficiency, is usually absent in the pregnant patient (64). Definitive diagnosis of adrenal insufficiency rests with measurement of plasma ACTH and cortisol, and performance of a cosyntropin (synthetic ACTH; Cortrosyn) stimulation test. A very low early morning (0600–0800hr) plasma cortisol (≤ 3.0 mcg/dL) accompanied by a plasma ACTH > 100 pg/mL is adequate to establish the diagnosis of primary adrenal insufficiency at any stage of gestation (65,66). After drawing basal blood samples for ACTH and cortisol, the cosyntropin stimulation test is performed by administering cosyntropin 250 mcg intramuscularly or intravenously, and drawing blood samples for cortisol 30 and 60 minutes post-cosyntropin. While cutoff points for "normal" and "abnormal" have not been formally established for pregnant patients, there is general agreement that maximum stimulated cortisol > 30 mcg/dL, even in the late third trimester, is adequate to exclude the diagnosis of adrenal insufficiency (66). Likewise, a maximum stimulated cortisol < 18 mcg/dL is adequate to establish the diagnosis of adrenal insufficiency with confidence (63). Additional testing of patients found to have adrenal insufficiency may include measurement of serum 21-hydroxylase autoantibodies (positive in 90% of patients with Addison's disease), and plasma renin-to-aldosterone ratio, which will be markedly elevated in primary adrenal insufficiency (63). Patients with "normal" or "suppressed" ACTH can be evaluated with pituitary imaging via non-gadolinium-enhanced MRI, whereas those with primary adrenal insufficiency who test negative for 21-hydroxylase antibodies can be assessed with MRI of the adrenals. Adrenal insufficiency caused by neoplastic or granulomatous disease is most usually associated with adrenal enlargement, whereas autoimmune disease causes adrenal atrophy.

Treatment of adrenal insufficiency is straightforward and largely empiric. Primary adrenal insufficiency obligates hormone replacement for both cortisol and aldosterone, whereas secondary adrenal insufficiency obligates replacement only for cortisol (since the renin–angiotensin–aldosterone axis is preserved). For cortisol replacement, a physiologically sound surrogate regimen is hydrocortisone 20 mg orally in the morning and 10 mg orally in the late afternoon; a pharmacologically equivalent alternative glucocorticoid such as cortisone acetate or prednisone may be substituted. As aldosterone surrogate, the synthetic mineralocorticoid fludrocortisone (Florinef) is used in a dose averaging 0.1 mg (range 0.05–0.2 mg) orally each morning (67). The dose of fludrocortisone can be adjusted to maintain blood pressure and plasma potassium within the normal range. During labor and delivery, surgery, or severe intercurrent illness, supplemental glucocorticoid in doses intended to mimic natural stress-stimulated hypercortisolemia is prescribed. A traditional "stress" regimen is hydrocortisone 50 mg intravenously every 8 hours (63). At

this dosage, hydrocortisone exhibits sufficient mineralocorticoid agonism that fludrocortisone is unnecessary.

Cushing's Syndrome

Cushing's syndrome is the consequence of hypercortisolism (68). When diagnosed in pregnancy, the predominant cause (60% of total) is an adrenal tumor (benign or malignant) (69). Other causes include ACTH-dependent Cushing's syndrome from a pituitary adenoma or from an ectopic source, or hypercortisolism of an iatrogenic or surreptitious source from exogenous glucocorticoids.

Clinical manifestations of Cushing's syndrome include central obesity, moon-like plethoric face, dorsal cervical and supraclavicular fat pads, thin skin with easy bruising and wide, deeply recessed, reddish or violaceous striae, proximal muscle wasting and weakness, osteoporosis, and hirsutism. Hypokalemia, hypertension, and diabetes mellitus commonly complicate Cushing's syndrome, but are not invariably present. Anovulatory oligomenorrhea and infertility frequently prevent pregnancy, so Cushing's syndrome during pregnancy is an unusual occurrence. However, the presence of gonadotropin receptors in pigmented nodular hyperplasia and in some adrenal adenomas may account for first expression of Cushing's syndrome manifestations during pregnancy (69). When pregnancy does accompany Cushing's syndrome, pre-eclampsia, hypertension, miscarriage, premature labor, intrauterine growth retardation, and stillbirth are distinct risks (58,70). However, neonatal ACTH suppression and adrenal insufficiency are rare, and fetal virilization does not occur. Thus, most therapeutic attention and diagnostic efforts are directed toward maternal health during the pregnancy.

Accurate diagnosis of Cushing's syndrome during pregnancy is difficult based on physiologic changes in cortisol secretion in normal pregnancy. Ascertaining whether or not the hypercortisolism is ACTH-dependent is an important first step, and plasma ACTH < 10 pg/mL establishes ACTH independence (63). In the first trimester, daily cortisol production is comparable with the non-gravid state, and 24-hour urine free cortisol reflects this. Thus, in the first trimester, 24-hour urine free cortisol values distinctly above the normal range establish the diagnosis with some confidence. As pregnancy progresses into the second and third trimesters, cortisol production normally increases, peaking at about three times the non-gravid normal range in the third trimester; thus, to confirm hypercortisolism in the third trimester, one would need to observe 24-hour urine free cortisol well in excess of three times the normal upper limit to diagnose Cushing's syndrome with confidence. Salivary cortisol can be collected at home by patients and reflects production of cortisol on an hour-to-hour basis. Cushing's syndrome eliminates the normal diurnal fluctuation of cortisol production, such that the secretory trough normally observed at 2200 to 2400 hours is lost. Hence, salivary cortisol at midnight significantly above the upper limit of the normal range confirms loss of diurnal fluctuation and is consistent with Cushing's syndrome. The combination of 24-hour urine free cortisol > three times the upper limit of the normal range and elevated midnight salivary cortisol possibly represents the optimal means of confirming Cushing's syndrome in patients in the second and third trimesters (63,71).

If Cushing's syndrome is confirmed by 24-hour urine free cortisol and midnight salivary cortisol, appropriate adrenal or pituitary imaging is performed, based on whether plasma ACTH is suppressed or non-suppressed. If the ACTH is < 10 pg/mL, the adrenals should be imaged by non-gadolinium-enhanced MRI. For non-suppressed ACTH, the pituitary should be assessed by MRI (63).

Because of the hazards posed by hypercortisolism to the pregnancy and to maternal health, treatment during the pregnancy is recommended. Adrenal tumors can be resected by flank incision, since up to 20% may be malignant. For patients with ACTH-producing pituitary adenoma (Cushing's disease), transsphenoidal adenoma resection has been successfully performed in pregnancy (72). If imaging does not localize the site of disease with confidence, medical therapy can be entertained, although experience with effective drugs in pregnancy is very limited. Metyrapone and ketoconazole are categorized as FDA class C agents and represent the best available alternative treatments for patients whose Cushing's syndrome cannot be treated surgically (63,73).

Fetal Virilizing Disorders

Fetal virilization from maternal androgen excess is uncommon in pregnancy, since hyperandrogenemia suppresses GnRH and gonadotropins and thus is far more likely to cause oligomenorrheic infertility or amenorrhea. Rarely, virilizing adrenal (74) or ovarian tumors (75) can occur and are generally heralded by signs of maternal virilization, including hirsutism, male-pattern balding, increasing skin seborrhea, and deepening of the voice.

A more commonly encountered scenario in pregnancy is in couples with a prior history of a virilized newborn with 21-hydroxylase deficiency, the most common form of virilizing congenital adrenal hyperplasia. For couples with a personal or family history of 21-hydroxylase deficiency, genetic screening is available through GYP21 genotyping. The couple genetically at risk may elect prenatal treatment of the mother with dexamethasone, at a dose of 20 mcg/kg/day of non-gravid baseline maternal weight. Chorionic villous sampling performed at 9 to 11 weeks of gestation is performed to establish fetal sex and presence of fetal CYP21 gene (76). Maternal treatment is unnecessary for a male fetus or if fetal CYP21 is negative. Dexamethasone treatment of the pregnant woman is not without risk, as excessive weight gain, edema, impaired glucose tolerance or frank diabetes mellitus, or hypertension occurs in up to 50% of treated patients (63).

Primary Hyperaldosteronism

Just over 30 cases of primary aldosteronism in pregnancy have been reported in the past 40 years (77). Aldosteronism is characterized by suppressed plasma renin accompanied by autonomous adrenal secretion of aldosterone, with clinical consequences of hypertension, metabolic alkalosis, and frequently (but not invariably) hypokalemia. Plasma renin activity increases in the first trimester, and steadily throughout gestation, reaching levels three to seven times non-gravid baseline values by the late third trimester. Likewise, plasma aldosterone increases 5- to 20-fold during pregnancy (63). Normally, despite high levels of these hormones, maneuvers such as plasma volume expansion with saline or administra-

tion of synthetic mineralocorticoid result in appropriate suppression of the renin–angiotensin–aldosterone axis. Rising plasma progesterone throughout gestation is an important physiologic antagonist of mineralocorticoids and offers protection against maternal hypertension, despite markedly elevated levels of renin, angiotensin, and aldosterone. Very low levels of plasma renin (approaching undetectable), accompanied by elevated plasma aldosterone in a pregnant woman with hypertension or hypokalemia, would establish the diagnosis of primary aldosteronism with some accuracy. Adrenal imaging with non-gadolinium-enhanced MRI would then represent the next step in evaluation; identification of a unilateral adrenal nodule would be consistent with aldosterone-producing adenoma. In nonpregnant patients, catheterization of adrenal veins for measurement of aldosterone and cortisol is frequently performed. Such invasive testing would be difficult and largely contraindicated in a pregnant patient, so consideration may be given to medical management until after delivery (78). Amiloride is an FDA class C antagonist of aldosterone and may be the drug of choice for treatment of a pregnant patient with hyperaldosteronism (79).

Pheochromocytoma

Pheochromocytoma is a tumor of the adrenal medulla or extra-adrenal chromaffin tissue that hypersecretes catecholamines (80). Prevalence in pregnancy is estimated to be approximately 1 in 54,000, and over 200 cases have been reported in the literature (81). Typical clinical manifestations include sustained or paroxysmal hypertension, pallor, headache, palpitations, and diaphoresis. Hypertensive crisis can occur and is a feared complication. Serious sequelae include chest or abdominal pain, which can mimic acute myocardial infarction or acute surgical abdomen, seizures, hemodynamic shock (due to volume contraction induced by the excessive vasoconstricted state, when catecholamine secretory troughs occur), and death. Approximately 10% of pheochromocytomas are familial, including the multiple endocrine neoplasia (MEN) 2a and 2b syndromes (with pheochromocytoma about half as prevalent as medullary thyroid carcinoma), von Hippel–Lindau, and neurofibromatosis syndromes. Timely evaluation and definitive treatment of pheochromocytoma in pregnancy is essential, as untreated maternal mortality may exceed 15%, and if treated, mortality may be as low as 1% (82). Abdominal palpation and labor are known provocateurs of catecholamine secretion by pheochromocytoma tumors, and hypertensive crisis may accompany a secretory surge of adrenomedullary hormones.

Pheochromocytoma is generally suspected based on the presence of maternal symptoms, hypertension, or identification of a family history of MEN, von Hippel–Lindau, or neurofibromatosis. Elevated plasma catecholamines and metanephrines are strikingly elevated and are reflected in 24-hour urinary samples for catecholamines (epinephrine and norepinephrine) and metanephrines (metanephrine and normetanephrine). Most surgically confirmed pheochromocytomas have been associated with 24-hour urinary secretion three or more times the upper limit of normal for one or more of these hormones (83). When clinical suspicion is heightened by the finding of one or more extremely elevated urinary

catecholamines or metanephrines (epinephrine, norepinephrine, metanephrine, or normetanephrine), adrenal imaging with non-gadolinium-enhanced MRI is accomplished, to investigate whether there is a unilateral adrenal tumor. Characteristically, pheochromocytomas image very bright on T2-weighted MRI and may be very helpful in the pregnant patient, for whom imaging modality options are limited (84).

Confirmation of a pheochromocytoma prior to the third trimester should lead to expedited surgical evaluation, to optimally perform adrenalectomy during the second trimester. In the third trimester, surgery is usually deferred until postpartum, but the patient is treated medically for the pheochromocytoma, and caesarian section is usually planned so that the hypertensive crises associated with vaginal delivery can be avoided (63). Prior to surgery, or otherwise if the patient cannot be treated surgically, drug treatment emphasizes alpha blocker and later beta blockers. The traditional alpha blocker drug is phenoxybenzamine 10 to 20mg/day orally twice; the drug may be titrated to a maximum dose of 1 mg/kg/day until symptoms and hypotension are controlled (82). After several days of phenoxybenzamine therapy, a beta blocker is added, titrating to heart rate control, with two caveats. First, because pheochromocytoma hypertension is a profoundly vasoconstricted state, successful vasodilation may unmask clinical hypovolemia with orthostatic hypotension. Orthostatic blood pressure and symptoms should be routinely checked in the drug-treated patient. Second, alpha blocker drugs are always used first, for several days, to avoid theoretically catastrophic unopposed beta blockade, exacerbating vasoconstriction and potentially provoking a hypertensive crisis (63). After successful surgical resection of a pheochromocytoma, 24-hour urinary metanephrines and catecholamines should normalize, and medication therapy can be gradually tapered to complete withdrawal.

CALCIUM DISORDERS

Physiologic Adaptations of Maternal Calcium Metabolism in Pregnancy

Approximately 50% of circulating plasma calcium is ionized (free), and the remainder is complexed with plasma protein, most significantly albumin. Parathyroid hormone (PTH) is the most important determinant of plasma calcium, directly or indirectly controlling all routes of calcium intake and egress. Direct effects of PTH are on bone, the body's largest endogenous reservoir of calcium, and on kidney, which can up- or downregulate calcium egress. In bone, PTH induces osteoblasts to release cytokines stimulating osteoclastic resorption of calcium and phosphorus from bone, into the circulation. In the proximal nephron, PTH induces active reclamation of calcium from glomerular filtrate to interstitial fluid and from thence to the circulation. Indirectly, PTH also promotes absorption of calcium and phosphorus from the gut, by inducing the 1-alpha-hydroxylase enzyme in renal epithelium to convert comparatively inactive calcidiol (25-hydroxy-vitamin D3) to calcitriol (1,25 dihydroxy-vitamin D3), which directly activates gut absorption of calcium and phosphorus. PTH is exquisitely sensitive to serum-ionized calcium; slight decrement in ionized plasma calcium rapidly results in increased PTH secretion; conversely, slight increment in ionized plasma calcium inhibits PTH synthesis and secretion.

Mineralization of the fetal skeleton requires approximately 30g of calcium by term, about 80% of which accrues during the third trimester of pregnancy. This need is met by increased maternal absorption of calcium from the gut, mediated by calcitriol (1,25 dihydroxy-vitamin D3), as opposed to hyperresorption of calcium salts from the maternal skeleton. Compared with the non-gravid state, maternal adaptations of calcium homeostasis to pregnancy include decreased serum PTH, increased PTH-related peptide (PTHrP), and increased calcitriol. It is presumed that PTHrP is largely responsible for increased calcitriol production. Maternal serum calcitonin also increases, but its physiologic significance is unknown (85).

Hypercalcemia

Primary hyperparathyroidism (PHP) is the most common cause of hypercalcemia and is rare in pregnancy, with about 150 reported cases (86,87). The only entirely satisfactory treatment for this disease is surgical resection of a solitary parathyroid adenoma (the most common culprit) or debulking of diffuse parathyroid hyperplastic glands; about 0.8% of large surgical series of parathyroidectomies were performed in pregnant patients (88). While PHP in pregnancy is rare, recognition and treatment are important, as maternal complications occur in about 67% and fetal or neonatal complications in 80% (89). Approximately 80% of pregnant women with PHP will have at least one symptom; these include nausea, vomiting, abdominal pain, renal colic, muscle weakness, mental sluggishness, depression, and bone pain (90). Additionally, hyperemesis gravidarum, weight loss, seizures, and pancreatitis may occur more frequently in women with PHP than in unaffected women (87,88). Fetal complications of maternal PHP include stillbirth (approximately 2%), neonatal death (approximately 2%), and neonatal tetany (approximately 15%) (91). Neonatal tetany results from profound suppression of the neonatal parathyroid function by maternal hypercalcemia, which is unmasked at the time of delivery, when the previous continuous milieu of hypercalcemia is rapidly lost. The condition commonly persists for 3 to 5 months, but permanent neonatal hypoparathyroidism can rarely be permanent (91).

Optimal management of PHP recognized during pregnancy is parathyroidectomy performed during the second trimester (89). Risk of all neonatal complications was reduced by 53% as compared with surgically untreated patients, in one large reported series (87). Premature labor is a distinct risk when parathyroidectomy is delayed until the third trimester, occurring in four of seven treated cases in one reported series (92). Influencing the decision of whether or not to perform surgery should be the awareness that there are no evidence-based medical therapies to offer patients as a surgical alternative; treatments would be limited to saline hydration and high-dose magnesium infusions (93). Neonates suffering from hypocalcemic tetany are treated with oral or parenteral calcium, and calcitriol, as needed until the condition resolves.

Hypercalcemic disorders other than PHP are very rarely encountered in pregnancy. Familial hypocalciuric hypercalcemia, also known as familial benign hypercalcemia, was first characterized in the early 1970s as an autosomal dominant

genetic disorder notable for mild to moderate hypercalcemia accompanied by extremely low fractional excretion of calcium (ratio of calcium to creatinine clearance <0.01). It is now known to result from a mutation of the calcium-sensing receptor in both parathyroid and renal tubular tissues. There are no maternal consequences of this disorder, but neonatal hypocalcemic tetany can occur, with management similar as in maternal hyperparathyroidism (85). It is important to recognize the disorder for what it is so that maternal parathyroidectomy is not attempted. Malignancy-related hypercalcemia has only been reported in two pregnant patients, with maternal demise occurring within 4 months postpartum in both cases (94,95).

Hypocalcemic Disorders

Apparent hypocalcemia in pregnant patients may simply represent physiologic dilutional hypoalbuminemia. If necessary, measurement of serum ionized calcium can confirm this possibility, which is otherwise usually inferred by the concurrent findings of slight hypocalcemia and hypoalbuminemia. The traditional estimate of total serum calcium for hypoalbuminemia is to add 0.8mg/dL to measured serum calcium for every decrement of serum albumin of 1.0mg/dL below the lower limit of the normal laboratory range. True hypocalcemia (low serum ionized calcium) is most often consequent to hypoparathyroidism (which can be idiopathic, but is more often secondary to a complication of thyroid or parathyroid surgery) or pseudohypoparathyroidism (hereditary resistance to PTH). Most often, a pregnant woman with these disorders will have come to clinical attention prior to becoming pregnant and is likely to already be receiving chronic therapeutic intervention. Maternal consequences of severe hypocalcemia include oral and acral paresthesias, carpopedal spasms, and potentially fatal laryngospasm; fetal consequences include skeletal demineralization and possibly hypercalcemia due to neonatal hyperparathyroidism. Because maternal PTH normally declines during pregnancy, and calcitriol increases under the influence of PTHrP, maternal hypocalcemia is sometimes ameliorated by pregnancy, and need for oral calcium supplements and exogenous calcitriol is reduced (85,96). However, this is by no means universal, and careful monitoring of maternal serum calcium is important throughout the pregnancy.

Emergent therapy of symptomatic hypocalcemia (seizures or carpopedal or laryngospasm) should be treated with intravenous infusion of 10% calcium gluconate, 20mL intravenously over 10 minutes, followed by continuous intravenous drip infusion of calcium 0.5 to 2mg/kg/hr, adjusted to keep the plasma calcium level at 8 to 9mg/dL (97). Oral maintenance therapy of chronic hypocalcemic disorders is usually accomplished with synthetic calcitriol (Rocaltrol), 0.25 to 0.5mg orally daily to three times daily, and calcium carbonate 1 to 2g orally three times a day with meals. The dose of calcitriol is titrated as needed at 2- to 4-week intervals to maintain plasma serum calcium of 8 to 9mg/dL. As noted, pregnancy may either decrease or increase the non-gravid maintenance dose, and frequent (every 2–4 weeks) measurement of serum calcium throughout the gestational period is recommended.

23 Gastrointestinal diseases and pregnancy

Murtaza Arif, Anjana Sathyamurthy, Jessica Winn, and Jamal A. Ibdah

INTRODUCTION

Pregnancy has a significant effect on the normal physiology of the gastrointestinal tract, and gut-related symptoms are extremely common during gestation. In this chapter, a review is presented of the common gastrointestinal disorders in pregnancy, which may present difficult management problems. The treatment of these disorders in the nonpregnant as well as the pregnant patient is discussed, so that the reader will become familiar with the special diagnostic and therapeutic considerations during pregnancy.

GASTROESOPHAGEAL REFLUX DISEASE AND REFLUX ESOPHAGITIS

Gastroesophageal reflux disease (GERD) results from the inappropriate backwash of gastric contents into the esophagus. Although this process occurs frequently in asymptomatic individuals, it can also result in heartburn and regurgitation. Reflux esophagitis is defined as the presence of typical symptoms of GERD in conjunction with endoscopic and pathologic changes in the esophagus.

Epidemiology

The prevalence of symptoms of GERD is quite high in the general population. Large-scale surveys have revealed that approximately 33% to 44% of adult Americans experience reflux symptoms on a twice weekly to monthly basis (1). However, the great majority of this group does not seek medical attention. Of those individuals who go to a doctor, 40% to 70% will show endoscopic evidence of esophagitis. Gastroesophageal reflux symptoms are extremely common during pregnancy and are an important cause of morbidity in pregnancy. Reflux symptoms are reported by 40% to 85% women during pregnancy (2,3). The incidence of true reflux esophagitis is difficult to determine, because large-scale endoscopic studies of pregnant women have not been performed.

Defense Mechanisms for Prevention of Gastroesophageal Reflux

There are several defense mechanisms that act to limit contact with and damage to the esophagus by gastric contents (Table 1).

1. *Lower esophageal sphincter (LES)*: The LES is probably the major protective barrier, preventing reflux of food, acid, and secretions from the stomach into the esophagus. The LES relaxes in response to hormones, foods, and drugs. Some patients with reflux esophagitis have decreased resting LES pressures or a completely incompetent

LES; reflux events also occur in patients with normal LES pressures, presumably owing to transient LES relaxation (4,5).

2. *Esophageal motility and gravity*: Contact of the esophageal mucosa with damaging substances is limited by esophageal peristalsis and gravity, which promote clearing. Aperistalsis, as found in scleroderma, contributes substantially to the development of esophagitis in these patients (in addition to an incompetent LES).
3. *Saliva*: Saliva has also been shown to neutralize acid.
4. *Intrinsic epithelial defense*: The esophageal epithelial layer has intrinsic defense systems including cell membrane and intercellular components, which prevent influx of hydrogen ions as well as intracellular proteins, which function as buffers.

Pathophysiology

The pathophysiology of GERD and reflux esophagitis in pregnant patients is incompletely understood. It may be multifactorial, involving both mechanical and hormonal factors.

1. *LES*: Some analyses have shown that resting LES pressure decreases in pregnancy, in both early and late gestations (6,7). In other studies, LES pressure was normal in early pregnancy but hypofunction of the LES was detected, as measured by decreased responsiveness to drugs that increase sphincter pressure (8). Decreased LES pressure probably results from elevated serum estrogen and especially progesterone levels during pregnancy (6).
2. *Intra-abdominal pressure*: Although increased intra-abdominal pressure has been postulated to produce reflux, a study of men with tense ascites as a model of pregnancy (9) showed an increase in LES pressure and no demonstrable acid reflux. Thus, the contribution of increased abdominal girth in reflux esophagitis is unclear, but the relevance of this model may be questioned. Intra-gastric pressures appear to be increased even in early pregnancy, and patients with heartburn have lower mean barrier pressures (LES pressure–gastric pressure) than asymptomatic pregnant individuals (10).
3. *Esophageal motility*: Normal esophageal motility, which helps clear potentially damaging material from the esophagus, is altered in pregnancy; peristaltic wave speed and amplitude are both reduced (11).

Table 1 Esophageal Mucosal Defense Mechanisms

Mechanism	Effect
Lower esophageal sphincter	Barrier
Esophageal motility	Promotes clearing
Gravity (when upright)	Promotes clearing
Saliva	Acid neutralization
Intrinsic epithelial defense	Cell membrane, inter- and intracellular components

Clinical Features

The clinical features of GERD during pregnancy do not differ from those in the general adult population. Classic symptoms of GERD include heartburn (retrosternal burning pain) and regurgitation. In patients with long-standing reflux esophagitis, strictures may result, producing dysphagia or difficulty swallowing. Severe reflux esophagitis may produce painful swallowing (odynophagia), although this is more likely to be associated with infectious causes of esophagitis. Acid reflux may lead to esophageal dysmotility and atypical noncardiac chest pain. Extra-esophageal symptoms may include hoarseness, chronic cough, laryngitis, asthma, and recurrent aspiration.

Complications

A variety of complications can result from reflux esophagitis:

1. Stricture formation
2. Bleeding
3. Pulmonary aspiration
4. Barrett's esophagus—Chronic esophageal inflammation is thought to lead to Barrett's esophagus, in which the normal squamous esophageal epithelium is replaced by specialized columnar epithelium. This diagnosis is made by endoscopy with biopsy; routine surveillance with periodic endoscopic examination and biopsies is indicated because of an increased risk of esophageal cancer.

Diagnosis

During pregnancy, initial diagnosis of GERD is based on symptoms, and an empiric trial of therapy may be initiated.

1. *Barium radiography*: Barium studies are less sensitive compared with upper endoscopy for diagnosis of reflux esophagitis. They should be avoided during pregnancy because of risk of radiation exposure to the fetus.
2. *Upper endoscopy*: Endoscopy allows direct visualization of the epithelium, and biopsies can be taken for histologic analysis. Endoscopy can be safely performed during pregnancy for evaluation of intractable symptoms refractory to a trial of standard medical therapy or complications such as gastrointestinal bleeding. Please refer to the section on "Endoscopy and procedural sedation in pregnancy" for further discussion.
3. *Esophageal manometry and pH monitoring*: These studies are rarely used in patients with atypical or refractory symptoms to detect reflux and correlate symptoms with reflux events.

Table 2 Medications Used in Pregnancy for Gastroesophageal Reflux Disease

Drug name	FDA category
<i>Antacids</i>	
Aluminum-, calcium-, or magnesium-containing antacids	None
<i>H2RAs</i>	
Cimetidine	B
Ranitidine (preferred)	B
Famotidine	B
Nizatidine	B
<i>Mucosal protectant</i>	
Sucralfate	B
<i>Proton pump inhibitors</i>	
Omeprazole	C
Lansoprazole (preferred)	B
Rabeprazole	B
Pantoprazole	B
Esomeprazole	B
<i>Promotility agents</i>	
Metoclopramide	B

Abbreviations: FDA, Food and Drug Administration; H2RAs, histamine-2 receptor antagonists.

Management with Maternal–Fetal Consideration

1. *Lifestyle modifications*: Initial management of GERD usually consists of conservative measures such as lifestyle modifications and dietary changes. Avoidance of smoking, late-night meals, and substances that decrease LES pressure such as high-fat foods, caffeine, alcohol, and chocolate often provide some relief. Patients should remain upright after meals to minimize reflux of acidic contents, allowing gravity to aid esophageal clearance. Elevation of the head of the bed by shock blocks helps maintain the beneficial effect of gravity at night.
2. *Medications*: Various medications are used for the management of GERD (Table 2).

Antacids: Antacids are generally considered safe in pregnancy (12) and are used by 30% to 50% of women for relief of reflux symptoms during pregnancy (13). Magnesium-, aluminum-, or calcium-containing antacids are not teratogenic in animal studies (13). There are limited data on the safety and efficacy of antacids during pregnancy. A large retrospective study showed an increased incidence of birth defects in women who used antacids along with many other medications in the first trimester (14); however, no particular antacid was specified, and these data have not been verified in another study. More recent analyses of pregnant women in both the United States and the Netherlands (15,16) indicate that antacid use is common; although no obvious increase in rare birth defects has been noted, small increases in common abnormalities such as spontaneous abortion, cleft palate, or low birth weight would be difficult to detect (15). The major immediate side effects of large doses of antacids include constipation induced by aluminum-containing antacids and diarrhea caused by magnesium-based preparations. The use of a combination of these medications usually resolves

bowel-related problems. Antacids containing sodium bicarbonate should be avoided because it can precipitate metabolic alkalosis and volume overload (17).

Sucralfate. Sucralfate is FDA pregnancy category B. It is a polysulfated salt of sucrose, which binds to exposed proteins found in the base of ulcerated mucosa and produces a protective coating of the ulcer site. In a randomized controlled study, sucralfate-treated pregnant patients (1g three times daily) had a higher frequency of remission of heartburn (90% vs. 43%) and regurgitation (83% vs. 27%) compared with lifestyle and dietary modifications (18). In animal studies, sucralfate was not teratogenic with doses up to 50 times those used in humans (19).

Histamine-2 receptor antagonists: All histamine-2 receptor antagonists (H2RAs) including cimetidine, ranitidine, famotidine, and nizatidine are classified as FDA pregnancy category B. H2RAs have been recently replaced by proton pump inhibitors for treatment of reflux esophagitis in nonpregnant patients; however, in pregnant patients with GERD, H2RAs are the most commonly used and safest medications for those not responding to lifestyle modifications and antacids. Generally, 8 or more weeks of therapy is required to produce complete healing, and recurrences are frequent when medication is discontinued. In a study, efficacy of ranitidine once or twice daily was compared with placebo in pregnant women (20). Only ranitidine 150mg twice daily demonstrated significant relief in symptoms and reduction in the use of antacids. No adverse pregnancy or fetal outcomes were noted. A surveillance study in the United States found no increase in the incidence of congenital anomalies among infants exposed to various H2RAs including ranitidine, cimetidine, and famotidine (21). Ranitidine is usually the preferred H2RA during pregnancy because of the absence of teratogenicity in animal studies and documented efficacy in pregnancy.

Proton pump inhibitors: Proton pump inhibitors (PPIs) including lansoprazole, rabeprazole, pantoprazole, and esomeprazole are classified as FDA pregnancy category B drugs. Omeprazole is the only PPI, which is classified as FDA pregnancy category C because of dose-related embryonic and fetal mortality observed in animal studies. PPIs act as inhibitors of parietal cell H^+/K^+ ATPase (the proton pump responsible for hydrogen ion secretion) and are the most effective inhibitors of gastric acid secretion. These are the drugs of choice in nonpregnant patients for treatment of severe erosive reflux esophagitis and can heal esophageal lesions that are refractory to treatment with H2RAs. However, PPIs have not been extensively used in pregnancy and limited safety data are available for their use during pregnancy. A recent meta-analysis showed no significant increase in the risk of congenital anomalies in pregnant women exposed to various PPIs (22). PPIs should be used only in pregnant women with refractory symptoms who are not responding to H2RAs. Lansoprazole may be the preferred PPI because of its lack of teratogenicity in animal studies and limited safety reports during pregnancy.

Conclusion

GERD and reflux esophagitis in pregnancy should be managed in a step-up approach starting with lifestyle modifications. Medical therapy should be initiated for those who do not

respond to lifestyle and dietary modifications. Antacids and sucralfate are considered as first-line medical agents for GERD and/or reflux esophagitis. H2RAs should be introduced if symptoms persist despite the use of antacids. PPIs should be reserved for pregnant patients with refractory symptoms or complications secondary to GERD. Antireflux surgery is avoided during pregnancy because the symptoms usually resolve after delivery.

PEPTIC ULCER DISEASE

An ulcer is an injury to or interruption of the mucosal lining of the gastrointestinal tract extending through the muscularis mucosa. Peptic ulcer disease (PUD) is an important cause of morbidity and mortality in the general population; however, severity of symptoms and frequency of complications associated with PUD decrease during pregnancy (23–25).

Epidemiology

The incidence of PUD is low in pregnant women (23–25). It is difficult to ascertain the true incidence of PUD in pregnancy because diagnostic testing is generally avoided. Symptoms of PUD may be attributed to GERD or nausea and vomiting of pregnancy with resolution of symptoms upon treatment, thereby precluding further testing (26). Patients may also avoid medical attention by self-treatment with nonprescription medications for mild to moderate gastrointestinal symptoms.

A number of hypotheses have been proposed for the low incidence of PUD in pregnancy. Plasma levels of histaminases are increased during pregnancy due to placental synthesis. The histaminases can metabolize maternal histamine leading to decreased gastric acid secretion during pregnancy (27). Increased estrogen levels can result in hypochlorhydria, and gestational progesterone may increase synthesis of the protective gastric mucous layer (28). Immunologic tolerance during pregnancy may permit growth and colonization of *Helicobacter pylori* without immunologic response and mucosal injury (29,30). Maternal avoidance of ulcerogenic factors, such as smoking, alcohol, and nonsteroidal anti-inflammatory drug (NSAID) use, and reduced psychologic stress may also play a role in the decreased incidence of PUD during pregnancy (31,32).

Etiology and Pathophysiology

The etiology of PUD is complex and multifactorial. The two most common causes of PUD are *H. pylori* infection and use of NSAIDs. *H. pylori* has been implicated in the pathogenesis of PUD. Patients who are colonized with *H. pylori* have histologic evidence of antral gastritis, and eradication of infection leads to resolution of gastritis. *H. pylori* survives in the harsh gastric environment by the production of urease, which neutralizes acid by the generation of ammonia. *H. pylori* also produces protease, which thins the mucous layer and allows penetration and damage of the initial layer of mucosal defense. Almost all patients with duodenal ulcers, and gastric ulcers unassociated with the use of NSAIDs, are infected with *H. pylori*. The healing of ulcers occurs when *H. pylori* is eradicated and, most importantly, relapse of ulcer disease is prevented (33).

Gastric mucosal defenses, including a thick mucous layer and the ability of the mucosa to secrete bicarbonate, can

resist damage by acid, pepsin, and biliary reflux. Impairment or disruption of these protective mechanisms occurs because of inhibition of cyclooxygenase, prostaglandin synthesis, and mucosal mucous and bicarbonate secretion, leading to superficial gastric mucosal injury or gastric ulcer, predominantly in the gastric antrum. NSAIDs, including aspirin, increase the risk of PUD by inhibiting cyclooxygenase and a direct toxic effect on the gastric mucosa. There are several factors that influence the risk of developing PUD in patients using NSAIDs. The risk is more in patients taking higher doses of NSAIDs for a prolonged duration. Other risk factors for PUD include cigarette smoking and alcohol consumption (34). Cigarette smoking has been shown to slow ulcer healing and is associated with a higher rate of ulcer recurrence (35) in smokers compared with nonsmokers.

Clinical Features

Typical symptoms of PUD include epigastric pain, which is relieved by food or antacids. Patients often describe a dull “gnawing” or burning sensation, which may awaken them at night or may occur in the morning before eating or after meals. Because the abdominal pain is often relieved by eating, patients with PUD may gain weight. Other symptoms arise when duodenal or gastric ulcer is complicated by hemorrhage, perforation, penetration, or obstruction (Table 3). If the ulcer bleeds, the patient may develop black or tarry stools (melena) or hematemesis. Ulcer penetration into an arterial blood vessel can lead to massive, brisk bleeding with rapid transit of blood through the gastrointestinal tract and bright red blood per rectum (hematochezia). Abdominal pain that radiates to the back indicates possible penetration of the ulcer posteriorly through the wall of the stomach or duodenal bulb into surrounding organs. Duodenal bulb ulcers may penetrate into the pancreas, whereas gastric ulcers can erode into the liver or colon. The sudden onset of severe pain in conjunction with physical findings of an acute abdomen (rebound tenderness, guarding, absent bowel sounds, and distention) is associated with free perforation of the ulcer, which is a surgical emergency. Finally, prolonged nausea and vomiting can result from gastric outlet obstruction caused by edema and inflammation surrounding an ulcer crater located in the prepyloric or pyloric region. It is important to note that complicated ulcer disease may present with no antecedent history of abdominal pain or other symptoms.

In pregnancy, the signs and symptoms of PUD and its complications may be obscured. First, symptoms that are consistent with PUD may also be associated with GERD, which is quite common in pregnancy. Nausea and vomiting indicating the presence of an obstructing ulcer may be mistakenly considered to be “normal” pregnancy-related symptoms. Because of the morbidity and mortality associated with complicated PUD during gestation, a high index of suspicion should be maintained for those patients who develop nausea, vomiting, and abdominal pain in the second and third trimesters. Finally, in the immediate postdelivery period, signs of perforation such as abdominal rebound or guarding may be absent or decreased due to muscular relaxation, leading to delayed or misdiagnosis.

Diagnosis

During pregnancy, barium radiography is contraindicated because of risk of radiation teratogenesis. Upper endoscopy (esophagogastroduodenoscopy, EGD) is preferred for the diagnosis of PUD in both pregnant and nonpregnant patients because of a higher sensitivity and specificity when compared with barium radiography (30). EGD also has the ability to obtain histologic specimens to test for *H. pylori* infection and to exclude malignant gastric ulcer. In pregnant patients, EGD should be reserved only for patients with symptoms refractory to intensive medical therapy or PUD-related complications such as hemorrhage or gastric outlet obstruction. Since duodenal ulcers are benign, follow-up endoscopy to document complete healing is unnecessary. A significant although small percentage of gastric ulcers are malignant. Therefore, EGD and biopsy of gastric ulcers with follow-up until complete healing is documented is recommended.

In all patients with documented PUD, the presence of *H. pylori* infection should be determined. Upper endoscopy with gastric biopsy for histologic examination is considered the “gold standard” for the detection of active *H. pylori* infection. Histologic examination may also reveal changes in the gastric mucosa indicative of *H. pylori* infection, such as intestinal metaplasia or dysplasia. Gastric biopsy for detection of urease activity (Clotest), an enzyme produced in abundance by *H. pylori*, can also be used for the detection of active infection. Noninvasive methods include serologic detection of IgG antibodies to *H. pylori*, stool antigen assay for *H. pylori*, and urease breath test. Antibiotics, bismuth, and PPIs can affect the sensitivity of the test results. It is recommended to discontinue antibiotics for 4 weeks and hold PPIs for at least 2 weeks prior to testing for *H. pylori* infection.

Management of PUD

Acid secretion by the parietal cell is controlled by neural, paracrine, and endocrine influences. Receptors for histamine (H₂ receptors) and gastrin are present on the surface of the parietal cell; exposure to either histamine or gastrin leads to acid secretion. Cholinergic neural signals interact with muscarinic receptors to produce acid secretion. In response to these and other stimuli, vesicles containing the proton pump, or H⁺/K⁺ ATPase, fuse to the cell membrane and H⁺ ions are secreted into the gastric lumen. Treatment of PUD in the general population is primarily directed at blocking the interaction of histamine with its receptor. The treatment of PUD focuses on (i) healing of the ulcer crater and (ii) permanently eradicating *H. pylori* if present. Healing of the ulcer crater can be achieved by 4 to 8 weeks of therapy with antacids, H₂RAs, or PPIs.

Table 3 Complications of Peptic Ulcer Disease

Gastrointestinal bleeding (melena, hematemesis, hematochezia if brisk bleeding)
Perforation (acute abdomen with abdominal distention, rebound, guarding, absent bowel sounds)
Penetration (intractable abdominal pain, pancreatitis, gastrocolic fistula)
Obstruction (nausea, vomiting, early satiety)

Management with Maternal–Fetal Consideration

Antacids are preferred as the first line of therapy for PUD during gestation. Most antacids are considered safe in pregnancy, particularly those containing magnesium or aluminum, because they are not well absorbed systemically after oral ingestion. Recommended doses of antacids are 15 to 30 mL 1 hour after meals and at bedtime. Iron malabsorption may result from antacids, and because iron deficiency is common during pregnancy, antacids should be administered at a different time than iron supplements to avoid this possible drug complication (36).

Sucralfate is FDA pregnancy category B and is a good alternative to antacids in pregnancy. It is a preferred drug for PUD during pregnancy because it is not absorbed systemically and has not been shown to be teratogenic in animal studies (12).

H2RAs are highly effective in the treatment of PUD. About 80% of duodenal ulcers in the general population heal after treatment with H2RAs (37). All H2RAs including cimetidine, ranitidine, famotidine, and nizatidine are classified as FDA pregnancy category B. A recent meta-analysis revealed that H2RAs are not associated with an increased risk of congenital malformations (38). Use of H2RAs in pregnancy is recommended for refractory PUD, which does not respond to antacids or sucralfate, and for complicated ulcer disease (e.g., gastrointestinal bleeding, obstruction). Ranitidine is the preferred H2RA because of a better documented safety profile in humans.

PPIs effectively suppress gastric acid secretion by inhibiting the H^+/K^+ ATPase on the surface of the parietal cell. PPIs are highly effective in the treatment of PUD. Omeprazole is rated as category C during pregnancy because of embryotoxicity without teratogenicity in animal studies (19). All other PPIs, including lansoprazole, rabeprazole, pantoprazole, and esomeprazole, are classified as FDA pregnancy category B drugs. Lansoprazole is the preferred PPI during pregnancy because of lack of clinical data regarding the safety of newer PPIs. Treatment with PPIs during pregnancy should be reserved only for patients with refractory or complicated PUD, which does not respond to alternative medical therapies, including H2RAs.

Eradication of *H. pylori* Infection

Treatment of *H. pylori* infection is recommended in the general population because the risk of ulcer recurrence is lower after *H. pylori* eradication (39). Triple drug regimen consisting of antibiotics and PPI therapy is usually used for treatment of *H. pylori* infection. The recommended antibiotics for eradication of *H. pylori* infection during pregnancy include amoxicillin (FDA category B), clarithromycin (FDA category C), and metronidazole (FDA category B). However, administration of antibiotics for treatment of *H. pylori* infection should be avoided during pregnancy. Therapy is usually deferred until postpartum because of low risk of complications from untreated *H. pylori* infection during pregnancy and to avoid potential fetal risk from exposure to antibiotics.

HYPEREMESIS GRAVIDARUM

Definition

Hyperemesis gravidarum (HG) is a severe and disabling condition with potentially life-threatening complications. One of the most widely quoted definitions of HG is that proposed by Fairweather (40) in 1968, who described this syndrome as

“vomiting occurring in pregnancy, appearing for the first time before the twentieth week of gestation and of such severity as to require the patient’s admission to the hospital, the vomiting being unassociated with such coincidental conditions as appendicitis, pyelitis, etc.” HG is defined as nausea and vomiting in pregnancy, typically in the first trimester, resulting in dehydration, weight loss, and electrolyte imbalances severe enough to interfere with the nutritional and metabolic status of the patient and requiring admission.

Epidemiology

Nausea or vomiting is a common symptom occurring in up to 80% of women during pregnancy (41). HG is a much rarer disorder, affecting only 0.3% to 1.5% of pregnancies (42). HG is the most common cause of hospitalization during the first half of pregnancy. There is an increased risk of recurrence, with the risk of HG about 15% in a woman with a previous history of HG during pregnancy, compared with 0.7% with no prior history of HG (43). Several epidemiologic risk factors have been identified (Table 4).

Pathophysiology

Although nausea and vomiting in pregnancy and hyperemesis have been studied for many years, the etiology of these disorders remains obscure. A variety of pathophysiologic mechanisms for HG have been proposed. Etiology of HG is probably multifactorial, with both physiologic and psychologic components.

Hormonal

Because of its presentation early in the first trimester, a hormonal etiology has been suggested. Serum and urinary human chorionic gonadotropin (hCG) levels have been compared in emetic, hyperemetic, and non-emetic pregnancies; the results of these studies are inconsistent. Some groups have found no correlation between hCG levels and nausea and vomiting (44,45), whereas others report higher levels in emetic vs. non-emetic patients (46). However, increased free beta subunit of hCG has been found in the sera of hyperemetic patients compared with normal pregnant controls (47).

Analyses of serum estradiol levels also conflict. Depue and coworkers (44) found that estradiol levels and sex hormone binding globulin capacity were elevated in hyperemetic patients in the first trimester. Others did not show a correlation between

Table 4 Epidemiologic Risk Factors and Associated Conditions in Hyperemesis Gravidarum (HG)

HG is more common in Western countries
Ethnicity: Higher incidence in Asians and Africans
Young age (<20 years): HG is more common in younger maternal age
Family history of HG: Increased likelihood of HG
Parity and multiple gestations: HG is more common in nulliparous and multiple pregnancy
Body mass index (BMI): Low prepregnancy BMI is associated with HG
Coexisting medical conditions: HG is associated with molar pregnancy, hyperthyroidism, psychiatric illness, diabetes, and asthma
Prior history of HG: 15% recurrence risk

estradiol levels and nausea and vomiting, but these analyses did not include many hyperemetic patients (46).

There is a strong association between HG and abnormal thyroid function tests. Transient hyperthyroidism is frequently observed in hyperemetic patients (48). In one series, 73% of hyperemetic pregnant patients showed an increased free thyroxine (T4) index (48). Hyperthyroxinemic patients demonstrated tachycardia and weight loss but no other symptoms of Graves' disease. The hyperthyroid state tends to be short-lived, resolving by the third trimester, and usually does not require treatment. The mechanisms underlying transient hyperthyroidism in patients with hyperemesis are unknown. hCG has been implicated due to the structural similarity between hCG and thyroid-stimulating hormone (TSH), which may lead to hCG stimulating thyroid activity. Thyroxine and TSH levels in early pregnancy have been correlated with the severity of HG symptoms and electrolyte abnormalities (49).

Gastric Dysmotility

Decreased gastric motility is found to cause nausea. Measurement of gastric myoelectric activity in women with and without nausea in pregnancy revealed a much higher incidence of abnormal electrical patterns in nauseated patients compared with non-nauseated pregnant women (50); the physiologic significance of these findings is unclear.

Psychogenic

Psychologic factors have been considered for many years in the pathogenesis of hyperemesis. Analyses of the maternal relationships of pregnant hyperemetic women have revealed a variety of disturbances including over-strong maternal attachments (51) or negative maternal relationships (52). Persistence of hyperemesis into the third trimester was significantly associated with psychiatric symptoms (52).

Clinical Signs and Symptoms

Although vomiting may begin before the first missed menstrual period, persistent vomiting requiring hospitalization usually peaks between 8 and 12 weeks of gestation (40,51). Majority of the symptoms resolve by 20 weeks. Patients usually describe typical "morning sickness," which then becomes more severe and persists throughout the day. Intractable vomiting may lead to development of complications including dehydration and oliguria. Weight loss of more than 5% of prepregnancy weight is usually one of the diagnostic criteria. Physical examination may reveal signs of dehydration with poor skin turgor and tachycardia. Jaundice is occasionally present and the odor of ketones may be noted in the patient's breath. Neurologic symptoms include changes in mental status ranging from drowsiness to coma, and evidence of peripheral neuropathy due to vitamin B₆ or B₁₂ deficiency.

Diagnosis

The diagnosis of HG is based on the presence of symptoms of intractable nausea and vomiting, and any of the several indicators of severity including weight loss of more than 5%, ketonuria, signs of dehydration, and serum electrolyte imbalances. Evidence of major organ dysfunction may be present in more severe cases, including neurologic symptoms (Wernicke's

encephalopathy (53) and peripheral neuropathy (54)), renal failure, liver dysfunction, or retinal hemorrhage.

Elevated levels of blood urea nitrogen and creatinine, abnormal thyroid and liver function tests, ketosis and ketonuria, hyponatremia, hypochloremia, and hypokalemia are common laboratory abnormalities. HG is a diagnosis of exclusion. It is important to exclude other causes of nausea and vomiting such as pyelonephritis, gastroenteritis, and acute intra-abdominal conditions including pancreatitis, appendicitis, and cholecystitis (51).

Management

Treatment for HG is supportive because the condition is mostly self-limiting. The principles of management of HG include control of nausea and vomiting, correction of dehydration and electrolyte abnormalities, psychologic support, and prevention and treatment of complications.

Control of Nausea and Vomiting

Because of reluctance to use medications, especially in the first trimester, patients with uncomplicated nausea and vomiting are generally advised lifestyle modifications including small meals and avoid ingesting large amounts of liquid; specific therapy is usually not required. By contrast, the management of HG is challenging and often frustrating. Recurrent admissions are common and occur more often in nulliparous women (55).

Antiemetics are commonly used for the management of nausea and vomiting during pregnancy, but there are little data regarding their safety and efficacy in HG (Table 5). Antihistamines and phenothiazines are considered the most effective antiemetic medications. In general, antihistamines are considered to have the lowest teratogenic risk. A meta-analysis showed no evidence of teratogenicity or other serious maternal or fetal adverse outcomes associated with the use of antihistamines for nausea and vomiting during pregnancy (56). Phenothiazines include prochlorperazine and chlorpromazine. Isolated case reports have reported cleft palate, skeletal, limb, and cardiac abnormalities in association with

Table 5 Common Antiemetics Used in Nausea and Vomiting of Pregnancy

Drug class	Dosage
<i>Antihistamines</i>	
Promethazine	12.5–25 mg orally, i.m., or rectally every 4 hours
Dimenhydrinate	50–100 mg orally every 4–6 hours or 50 mg i.m. or i.v. every 4–6 hours (total dose should not exceed 400 mg/day, 200 mg/day if also taking doxylamine)
Doxylamine	12.5 mg orally three to four times daily
<i>Dopamine antagonists</i>	
Prochlorperazine	5–10 mg orally or i.v. every 6 hours (Max dose 40 mg/day)
Metoclopramide	5–10 mg orally, i.m., or i.v. every 8 hours
<i>5HT₃ antagonist</i>	
Ondansetron	4–8 mg orally or i.v. every 8 hours

Abbreviations: i.m., intramuscularly; i.v., intravenously.

the use of phenothiazines; however, there is no evidence of adverse fetal effects in clinical studies (57). No adverse fetal outcomes have been found with the use of metoclopramide in animals or humans (57). Recently 5HT₃ antagonists (ondansetron) have been shown to have efficacy for nausea and vomiting during pregnancy, and their use seems to be increasing (58). No adverse effects in animal studies and no reported increase in birth defects have been found with the use of ondansetron during pregnancy (58).

Correction of Dehydration and Electrolyte Abnormalities

Initial therapy should focus on repletion of fluids, usually by an intravenous route, and resolution of electrolyte imbalances. Chronic or severe hyponatremia must be corrected slowly and cautiously to avoid the complication of cerebral pontine myelinolysis (54,59). An increase in serum sodium of no more than 12mmol/L/day is recommended.

Repletion of vitamin deficiencies including thiamine is critical since prolonged vomiting may lead to severe depletion. Thiamine deficiency resulting in Wernicke's encephalopathy should be considered in pregnant patients with mental status changes and other neurologic symptoms. All women with HG symptoms should be prescribed thiamine supplementation (thiamine 50mg orally or 100mg intravenously daily) if their symptoms are prolonged for 3 weeks or more. Women with HG should take folic acid 5mg daily, once oral intake has resumed because of deficiency induced by vomiting.

When nausea and vomiting have resolved after treatment with intravenous fluids, oral hydration is begun slowly and diet is advanced from liquid to solid as tolerated (51,60). The cessation of vomiting and commencement of normal weight gain are the therapeutic endpoints to be achieved. In severe cases, in-hospital and even home-based parenteral hyperalimentation can be used if nutrition cannot be maintained orally (61).

Psychologic Support

Psychologic support is offered by nursing staff and physicians depending upon the needs of the patient. Intervention by a psychiatrist is recommended if there is evidence of an obvious psychiatric disorder (51) or occasionally for patients with third-trimester vomiting, which may indicate more serious psychologic problems (52).

Management of Complications

In the past, HG was regarded as a dreaded complication of pregnancy. Maternal mortality was high and primarily caused by severe metabolic disturbances. Improvements in fluid and electrolyte management have dramatically reduced the mortality rate of HG to virtually zero (51). Although uncomplicated nausea and vomiting in pregnancy may be an indicator of a favorable fetal outcome (62), the effects of hyperemesis on the fetus are unclear. A study of hyperemetic pregnancies associated with abnormal thyroid function indicated a higher than expected rate of premature labor and an increased incidence of low birth weight (49). Whether these effects were due to hyperemesis or hyperthyroxinemia is unclear. Analyses of the birth weights of babies born to hyperemetic mothers have been confounded by a varied patient population. Fairweather (40) found no change in birth weight when he reviewed birth records of a large group of

women with hyperemesis. However, others (62,63) have subclassified hyperemetic patients into mild versus severe disease based on maternal weight loss, heavy ketonuria, elevated urea nitrogen or creatinine, and electrolyte disturbances; those with severe hyperemesis gave birth to babies with significantly lower weights. Also more growth-retarded babies were found in the groups of mothers with hyperemesis and weight loss, or hyperemesis requiring multiple admissions (55). The risk of congenital anomalies may also be increased. One study suggested an increase in minor integumentary defects including webbed toes and an extra finger, and skin tags. However, the number of patients was small and the possible influence of anti-emetic medication was not clarified.

INFLAMMATORY BOWEL DISEASE

The inflammatory bowel diseases (IBDs) include two disorders, Crohn's disease (CD) and ulcerative colitis (UC). Both illnesses are characterized by inflammation of the gastrointestinal tract. Clinical manifestations commonly include diarrhea and abdominal pain, and patients may suffer multiple exacerbations and remissions. In CD, a transmural inflammatory process occurs, which can affect any part of the gastrointestinal tract from mouth to anus. On the other hand, the inflammatory process of UC is mucosal and is limited to the colon and rectum. IBD commonly affects women during the childbearing years; therefore, problems in the management of these disorders during pregnancy are frequently encountered by both the obstetrician and the gastroenterologist. In this section, the effect of IBD on fertility and pregnancy outcome, and the impact that pregnancy has on the course of IBD are discussed, and an approach to the management of these disorders in pregnancy is presented.

Epidemiology

The incidence of CD is now approximately equivalent to UC in North America and Europe. In North America, incidence rates range from 2.2 to 14.3 cases per 100,000 person years for UC and 3.1 to 14.6 cases per 100,000 person years for CD (64). Combined prevalence of CD and UC is approximately 100 per 100,000 population. The incidence of IBD has a bimodal distribution, with the peak age of onset between 15 and 30 years of age (65). A second peak in the incidence of IBD occurs between the ages of 50 and 80. There is marked geographic variation in the incidence of IBD. IBD is more common in developed nations compared with countries with poor sanitation. The regions with the highest incidence of UC include the United States, Northern Europe, and Israel. There is no gender specificity; however, within the United States, there is racial and ethnic variation. Incidence rates are increased in Jews and in white versus non-white populations, although the incidence in black populations may in fact be increasing (66).

Etiology

The etiology of IBD is at present unknown, but is thought to be multifactorial (67). A number of infectious agents have been postulated to be pathogenic. A bacterium similar to *Mycobacterium paratuberculosis* was isolated from the intestine of patients who underwent surgical resection for active CD, yet in the majority of patients, this organism cannot be cultured. Other potential agents involved in eliciting an immune

response have been postulated to include cow's milk proteins, other foods, water, viruses, and smoking, yet none has been definitively linked to either disease. Intestinal permeability has been shown to be altered in CD; a "leaky bowel" may allow translocation of antigens that elicit an immune response. Although the antigen that triggers the gut's immunologic response is unknown, there is active research directed at understanding the intestinal mucosal immune system in normal and affected individuals. The contribution of autoimmunity, cytokines, mucosal B and T cells, as well as neutrophil function is being actively examined in IBD.

Genetic factors play an important role as indicated by family studies. First-degree relatives of patients with IBD are approximately 3 to 20 times more likely to develop the disease than the general population (68). In one report, children in whom both parents had IBD (CD or UC) had up to a 33% chance of developing IBD by age 28 (68). Stronger familial association has been shown for CD than for UC. Twin studies showing disease concordance in monozygotic but not dizygotic twins further strengthen the evidence that genetic influences play a role in the pathogenesis of CD (67). In a study that included 80 twins with IBD, the concordance rate for monozygotic twins was markedly higher in CD than UC (58% vs. 6%) (69).

The inflammatory process of UC is confined to the colon. This disease may affect the rectum alone, the rectum plus the left colon, or it may be pancolonic. By contrast, in CD, inflammation can be found anywhere throughout the gastrointestinal tract, from mouth to anus. The commonest sites of involvement are small bowel alone (predominantly distal ileum) (30%), colon alone (15–25%), or ileocolon (40–55%). Perianal and perirectal disease is commonly encountered, manifested by fissures, fistulae, and abscesses.

In UC, mucosal lesions predominate; the muscularis propria is rarely involved. Crypt abscesses, in which collections of neutrophils invade crypt epithelium and may even be present in the crypt lumen, are characteristic of UC, yet may also be seen in CD. Evidence of chronic inflammation is also apparent with lymphocytic, plasma cell, and eosinophilic involvement of the lamina propria. Marked edema, hemorrhage, and pseudopolyps are often found in active UC. By contrast, the presence of granulomas and transmural inflammation with deep ulcerations that extend to the muscularis propria are more characteristic of CD. "Skip areas" (intervening normal mucosa) or rectal sparing are consistent with CD.

Clinical Signs and Symptoms

There are both similarities and differences in the presentation of UC and CD. Patients afflicted with either disorder may present with abdominal pain, diarrhea, weight loss, fevers, and malaise. Multiple extraintestinal manifestations accompany both illnesses.

UC

The inflammatory process characteristic of UC is confined to the colon. Some patients initially present with inflammation confined to the rectum (ulcerative proctitis); the disease may progress during subsequent exacerbations to other areas of the colon or may remain in the rectum. Other patients suffer from more extensive colitis and may have disease up to and

including the cecum. Due to rectal involvement, patients often complain of urgency and frequency of bowel movements as well as tenesmus. Rectal bleeding and diarrhea are the hallmarks of this disease. Abdominal pain is usually mild but may be severe in fulminant colitis. In mild cases, physical examination may be unremarkable, whereas patients with more active disease develop fevers, tachycardia, diffuse abdominal tenderness, and occasionally distention. A serious complication of acute UC, which may be heralded by the appearance of abdominal distention, is toxic megacolon. Massive dilatation of the inflamed colon may progress to perforation; this is a surgical emergency and requires immediate colectomy. A significant long-term complication of UC is the development of colon cancer. Patients are at an increased risk for carcinoma after 8 to 10 years of disease and are screened with yearly colonoscopy.

CD

CD is a chronic indolent disorder characterized by multiple remissions and exacerbations. Patients commonly present with abdominal pain, diarrhea, weight loss, anal pain, and drainage. On physical examination, abdominal tenderness and inflammatory masses particularly in the right lower quadrant and pelvis can be palpated. Because the inflammatory lesion is transmural, perianal fissures, internal fistulae between the bowel and skin, bladder, or vagina, as well as free perforation with abscess formation are common complications.

Extraintestinal Manifestations

Both UC and CD are associated with a wide variety of extraintestinal manifestations. The "colitis-related" manifestations include skin, eye, and joint diseases, which present in parallel with recrudescence disease activity. Skin manifestations such as erythema nodosum and pyoderma gangrenosum, and oral lesions including diffuse aphthous ulcerations may be severe enough to require treatment with corticosteroids. Arthritic complaints include ankylosing spondylitis, sacroiliitis, and peripheral large joint arthritis. Ocular diseases such as uveitis, iritis, and episcleritis may be present in approximately 15% to 20% of patients and may be the initial symptom that prompts a visit to a physician. Nonspecific complications of CD include a variety of liver diseases such as fatty liver, pericholangitis, primary sclerosing cholangitis, hepatic granulomas, and abscesses. In patients who have had extensive small bowel resection, malabsorption may result in deficiency of vitamin D and calcium, leading to osteoporosis. Increased absorption of oxalate from the gut lumen may lead to enhanced urinary excretion and the development of oxalate stones.

Diagnosis in the Nonpregnant Patient

In the nonpregnant patient, endoscopy has a pivotal role in establishing a diagnosis of IBD. The presence and extent of disease tend to be underestimated when radiographic studies are compared with direct endoscopic visualization, since subtle mucosal abnormalities can only be detected with endoscopy. The addition of biopsy adds considerably to the sensitivity and specificity of endoscopy in the diagnosis of IBD. Radiographic studies are now considered an adjunctive rather than a primary diagnostic tool. Small bowel barium radiograms may demonstrate terminal ileal narrowing, strictures, and enteric fistulae.

This may be useful in the evaluation of stricturing or fistulizing CD, and if patients are unable to undergo colonoscopy due to medical comorbidities. However, other imaging modalities such as small bowel wireless capsule endoscopy, CT, or MRI have supplanted the barium radiographic studies for evaluation of small bowel involvement in CD.

Endoscopic evaluation including upper endoscopy (for patients who have upper abdominal symptoms suggestive of CD), flexible sigmoidoscopy, and colonoscopy provides direct visualization of the gut's mucosa. Characteristic findings of ulcerative and Crohn's colitis include erythema, edema, granularity, ulceration, and friability of the colonic epithelium. Strictures may result from chronic inflammation. However, it is important to emphasize that these findings, while consistent with IBD, are not diagnostic, since they may also be found in a variety of infectious and other colitides. Abnormalities such as aphthous ulcerations and erythema may also be found in the upper gastrointestinal tract in CD. Biopsies taken during endoscopy may show the presence of granulomas or crypt abscesses and may help confirm the clinical impression.

Diagnosis in Pregnancy

There are limited data regarding the safety of endoscopic procedures during pregnancy. In those patients with undiagnosed abdominal pain, diarrhea, or rectal bleeding in whom IBD is suspected, flexible sigmoidoscopy under either minimal or no sedation appears to be safe (70). Complete colonoscopy usually requires a greater degree of sedation and is avoided when possible, although it is safe with appropriate monitoring of vital signs and oxygenation. In the pregnant patient, all efforts should of course be made to avoid fetal exposure to radiation, and radiologic procedures are not recommended. However, in emergent situations (when bowel perforation, abscess, or toxic megacolon are being considered), radiologic examinations may be necessary; there is some evidence to suggest that a very low dose of irradiation may have no long-term harmful effects (71).

Stool studies for routine bacterial pathogens (including *Clostridium difficile*) are extremely important in the initial evaluation of a patient in whom IBD is suspected. Infectious colitides such as those caused by salmonella, shigella, yersinia, *Campylobacter fetus*, *Giardia lamblia*, and amebae may present with an identical picture and demonstrate similar endoscopic findings. In patients infected with human immunodeficiency virus, organisms such as *Mycobacterium avium-intracellulare*, cryptosporidiosis, isospora, and cytomegalovirus can be ruled out with stool cultures and histologic examination of biopsies.

Management with Maternal–Fetal Consideration

Critical issues in the management of IBD during pregnancy include (i) the effects of pregnancy on the course of IBD and (ii) the impact of IBD and its therapy on fertility, pregnancy, and fetal outcome.

Effects of Pregnancy on the Course of IBD

Early studies in the 1950s and 1960s indicated that pregnancy had an adverse effect on the course of UC, yet more recent studies dispute these findings. Part of the reason for this discrepancy is the realization that the spontaneous risk of exacerbation of UC in the nonpregnant patient is similar to the

rate of relapse reported for pregnant patients with this illness. Pregnant women with IBD are as likely to flare (34% per year) as nonpregnant women with UC (32% per year) (72). With the advent of more effective medical therapy for UC, it has become apparent that pregnancy does not adversely affect the course of this disease. Those patients with quiescent disease will usually remain inactive (73,74), whereas those with active colitis will demonstrate persistent disease or worsen during pregnancy (75).

Patients with quiescent CD are probably not at increased risk for precipitating active disease when pregnant (76,77). Again, in those patients who are already active, approximately two out of three will continue to be ill or will worsen during pregnancy (75,77,78). Therefore, patients with IBD are usually counseled to avoid pregnancy when in a phase of moderate to severe disease activity.

Effects of IBD on Fertility, Pregnancy, and Fetal Outcome

Patients with UC demonstrate fertility rates that are comparable with those of the general population (76,78), although there are few case-controlled studies. In considering CD, there are conflicting reports; some groups have shown that as many as 50% of women of child-bearing age are subfertile, correlating with disease activity, whereas others have shown no difference in fertility rates when compared with the general population (76,79–81). Many studies did not account for disease activity, the patient's desire to become pregnant, or other risk factors that could decrease fertility. In fact, a recent report revealed that fertility may not be impaired in women who wished to conceive; there was a voluntary decrease in the number of pregnancies, arising from a desire to avoid pregnancy because of illness (79). Men with IBD who take sulfasalazine may show diminished fertility due to direct toxic effect on sperms (82).

The risk of spontaneous abortion in patients with quiescent CD or UC is probably no higher than that in the general population (75), but in several studies it has been shown to be increased as much as twofold in those patients with active disease (72,83,84). Reports indicate that IBD predisposes patients to a significant risk of preterm delivery (79), as defined by birth before 37 weeks of gestation. Therefore, vigilant monitoring of patients in the third trimester is recommended. Fortunately, once pregnancy occurs, the likelihood of a normal fetal outcome is identical to that in the general population. In almost all studies, the incidence of small-for-gestational-age babies and congenital defects was not increased, even in those patients on multiple medications such as steroids and sulfasalazine.

Management of IBD in Pregnancy

To improve the likelihood of a favorable outcome, patients are generally encouraged to avoid pregnancy during periods of disease activity if this is at all possible. Numerous retrospective analyses have ascertained that patients with IBD can be successfully treated without adverse effect to the mother or fetus. Medications should be reduced to the minimal amount required. In reports in which low birth weight or congenital anomalies were detected, it was often difficult to ascertain whether the severity of the bowel disease or the medications used were the major contributor.

Aminosalicylates are one of the cornerstones of medical therapy of IBD and are considered low risk for use in pregnancy. Most are pregnancy category B (sulfasalazine, mesalamine, and balsalazide) with the exception of olsalazine, which is category C. Sulfasalazine contains a sulfapyridine residue linked to 5-aminosalicylic acid (5-ASA), the active moiety. Its mechanism of action is unknown, but it has been shown to inhibit production of leukotriene B₄, an important mediator of inflammation, block prostaglandin production, and inhibit immunoglobulin secretion by mononuclear cells. Sulfasalazine crosses the placenta (85) and is found in breast milk, although in low concentrations. Serum levels of sulfasalazine in newborns are the same as in the mother (86). This drug is thought to be safe during pregnancy (87). There are a few case reports of congenital defects in infants of treated patients; however, a population-based study did not find a significant increase in congenital abnormalities in children of women treated with sulfasalazine (88). Its efficacy in maintaining remission in UC makes its continuation during pregnancy an important consideration. Patients are usually tapered to the lowest dose that is effective in suppressing disease activity. Sulfasalazine has anti-folate effects, and it is recommended that women take folate supplementation of at least 2 mg daily during the prenatal period and pregnancy.

Because of multiple side effects associated with the presumably inactive sulfapyridine moiety, both topical and oral agents that contain only 5-ASA have been developed. Topical therapy with 5-ASA (mesalamine) enemas is an effective treatment for acute proctitis or proctitis with left-sided colitis. In addition, several oral forms of 5-ASA (Pentasa®, Asacol®, and Dipentum®) have been released for treatment of both CD and UC. These drugs contain 5-ASA in formulations that prevent their premature absorption from the gastrointestinal tract. A number of studies have established the safety of oral and topical aminosalicylates in pregnancy (89–91). A meta-analysis of mesalamine formulations used during pregnancy demonstrated no increased risk for congenital malformations, stillbirths, spontaneous abortions, preterm delivery, or low birth weight with the use of mesalamine (92). Thus sulfasalazine and 5-ASA drugs can be used during pregnancy as in nonpregnant women with IBD.

Corticosteroids, including budesonide, are pregnancy category C. Steroid therapy is frequently used in the treatment of moderate to severe and fulminant UC, and moderate to severe active CD. In severely ill, hospitalized patients, high doses of intravenous steroids are employed to control bowel inflammation. Corticosteroid enemas are important topical agents for the treatment of proctitis and left-sided colitis. The major side effects associated with long-term corticosteroid therapy (such as cataracts, osteoporosis, diabetes, and hypertension) make it imperative that patients be tapered off this medication as soon as possible. Unfortunately, some patients with IBD require long-term corticosteroid use to treat persistently active disease; in these patients, a trial of an immunosuppressive agent such as 6-mercaptopurine (6-MP) or azathioprine (AZA) may be used to facilitate steroid tapering.

Evidence suggests that steroids should be used with caution in the first trimester because of an association with an increased risk of oral clefts (93). A number of studies showed no adverse effects on fetal outcome in women who took

corticosteroids during pregnancy (94,95). A meta-analysis of five studies of oral corticosteroid use did not reveal a major teratogenic risk of major malformations in the offspring of exposed patients at therapeutic doses (95). A significant increase was noted in risk of oral clefts (OR 3.69; 95% CI, 2.15–6.32); however, the increased risk appeared to be in women taking steroids for non-IBD diseases such as asthma. A case series of eight patients receiving budesonide during pregnancy demonstrated no increase in maternal adverse events (96). Corticosteroids also appear to be safe during breast-feeding (97). As in their nonpregnant counterparts, pregnant patients should be taken off steroids if at all possible, yet treatment during pregnancy can be safely initiated or continued as needed to control disease activity.

Immunosuppressive agents such as 6-MP and its prodrug AZA are primarily used to maintain remission in UC and CD. These agents are often used as steroid-sparing agents to facilitate discontinuation or dose reduction of steroids. 6-MP and AZA are pregnancy category D. Animal studies show teratogenicity with increased rates of cleft palate and skeletal anomalies (98). However, in these studies, animals were exposed to significantly higher doses than those used in humans. Limited data exist regarding the long-term adverse effects that may result from the use of these medications in IBD. However, regarding usage in pregnancy, there is a large body of data from the transplant population, which indicate that treatment with these agents is surprisingly well tolerated. The doses used for treatment of UC and CD are much lower than that used in transplant patients. Few studies also indicate their relative safety in pregnant IBD patients (99,100). It is reasonable to continue these drugs during pregnancy in patients who cannot be managed with other alternative medications.

AZA and 6-MP are detectable at low levels in breast milk. 6-MP excretion in breast milk occurs within the first 4 hours after intake (101). Mothers taking these medications should be discouraged from nursing; however, there is no absolute contraindication to breast-feeding. Lactating mothers are advised to wait 4 hours after dosing to feed.

Methotrexate is a pregnancy category X drug. Methotrexate is a folic acid antagonist and should not be used in women considering conception. It is contraindicated in pregnancy because of its mutagenic and teratogenic effects. Methotrexate is associated with multiple congenital anomalies including craniofacial malformations and central nervous system abnormalities, including anencephaly and mental retardation (102).

Antibiotics are frequently used in the treatment of CD. Particularly, metronidazole is useful in the treatment of perianal complications such as fistulae or abscesses. Metronidazole is pregnancy category B. A number of studies have demonstrated that metronidazole is not associated with an increased risk of birth defects or cancer in humans (103,104). However, long-term use in pregnancy remains controversial due to its teratogenic and carcinogenic potential. Breast-feeding should be withheld for 12 to 24 hours if a single dose of metronidazole is given. Long-term use of metronidazole should be avoided during breast-feeding due to potential toxic effects.

Biologic therapy has opened a new era in the treatment of IBD. All three biologic agents including infliximab, adalimumab, and certolizumab are pregnancy category B. These agents inhibit

the activity of tumor necrosis factor and are used for induction and maintenance of remission in IBD patients. Data on the safety of infliximab in pregnancy are limited; however, no maternal toxicity, embryotoxicity, or teratogenicity to infliximab has been observed. The two largest studies are the Crohn's Therapy, Resource, Evaluation, and Assessment Tool (TREAT) registry and the Infliximab Safety Database (105,106). The TREAT registry is a prospective, multicenter study of CD patients. Of more than 6200 patients enrolled, 117 of 168 pregnancies were exposed to infliximab. No fetal malformations were seen. Miscarriage and neonatal complication rates were not statistically significant between the infliximab-exposed and unexposed group (105). The Infliximab Safety Database is a retrospective database that records voluntary adverse event reports associated with infliximab use. The expected versus observed outcomes among women exposed to infliximab were reported no different than those of the general population (106). In a recent case series, infliximab remained undetectable in breast milk while maternal levels remained in the therapeutic range (107). Case reports have also described successful use of adalimumab in women with CD and pregnancy (108–110).

Special Considerations—Surgical Management, Pregnancy with Ileostomy, or Ileoanal Anastomosis

Despite advances in the medical management of IBD and improved therapy during pregnancy, surgical treatment is occasionally necessary. Emergent colectomy may be indicated for fulminant colitis unresponsive to medical therapy or for complications of UC such as toxic megacolon and colonic perforation. Morbidity and mortality rates for both fetus and mother are unknown; although there are scattered case studies of successful surgical intervention, fetal deaths have been reported.

Fertility and fecundity (rate of conception per menstrual cycle) are decreased after surgery for CD and colectomy with ileal pouch anal anastomosis for UC (111,112). Ileostomy may predispose to intestinal obstruction, which may be difficult to recognize, since abdominal pain may be mistakenly attributed to uterine contractions. An increased frequency of nocturnal stooling was noted in patients with ileoanal pouches (113). Patients may undergo vaginal or cesarean delivery and fetal outcome seems unaffected by the presence of an ileostomy or ileoanal anastomosis.

PANCREATITIS

Acute inflammation of the pancreas, or pancreatitis, is rare in pregnancy, ranging in incidence from 1 case per 1000 to 1 in 10,000 pregnancies occurring usually late in the third trimester or early in the postpartum period (114–116). Acute pancreatitis can cause significant fetal and maternal morbidity and mortality including premature delivery, shock, sepsis, and multiorgan dysfunction syndrome. Management of this disorder in pregnancy is often complicated and requires careful monitoring of the mother and fetus.

Etiology and Pathogenesis

The etiology and pathogenesis of acute pancreatitis are similar to those in the nonpregnant population (Table 6). Cholelithiasis is the most frequent cause of acute pancreatitis during pregnancy accounting for more than 70% cases (117). Weight gain and hormonal changes during pregnancy predispose to

Table 6 Etiologies of Pancreatitis

Gallstones (most common)
Hypertriglyceridemia
Alcohol
Obstruction (tumors, strictures)
Drugs (diuretics, azathioprine, sulfonamides, metronidazole, estrogens, valproic acid)
Trauma (blunt or penetrating abdominal injury, ERCP, surgery)
Viruses (mumps, hepatitis B, Coxsackie)
Metabolic (hypercalcemia, hyperparathyroidism)
Pre-eclampsia/eclampsia
Idiopathic (20% cases)

gallstone formation (118). Cholesterol secretion in bile increases during pregnancy leading to a supersaturated bile. Changes in serum hormonal levels may also result in bile stasis, which in turn favor stone development. Acute pancreatitis may be precipitated when gallstones become impacted at the ampulla of Vater or pass into the duodenum initiating premature activation of intracinar trypsinogen to trypsin (119). Release of activated digestive enzymes into the pancreatic parenchyma may result in autodigestion and injury.

Hypertriglyceridemia (serum triglyceride levels >1000mg/dL) is the second most common cause of acute pancreatitis during pregnancy. Hyperlipidemic pancreatitis accounts for 4% to 6% of cases with the majority of cases being associated with either type I or V familial hyperlipoproteinemia (117). During pregnancy, triglyceride levels elevate due to increase in estrogen-induced synthesis (120). In women with familial hyperlipidemias, further elevation of serum lipid levels during pregnancy leads to an even higher risk of pancreatitis. In patients with hypertriglyceridemia, it is postulated that pancreatic lipase becomes activated and releases fatty acids into the pancreas, producing inflammation, or that vascular obstruction results from blockage of vessels by fat globules (121).

Alcohol causes pancreatitis probably due to a direct toxic effect. Patients who have pancreatic duct obstruction from strictures, tumors, or other lesions may develop pancreatitis because of backflow of pancreatic juices into the gland, although the mechanism of enzyme activation in the pancreas is unclear. Pre-eclampsia or eclampsia is a rare cause of pancreatitis with its microvascular abnormalities that may affect the hepatic, splanchnic, renal, and placental circulation (117).

Clinical Signs and Symptoms

Acute pancreatitis can be divided into mild and severe or necrotizing pancreatitis. The presenting signs and symptoms of pancreatitis in pregnant patients are similar to those in the nonpregnant population. Characteristic symptoms include acute abdominal pain radiating to the back and associated with nausea and vomiting. Abdominal pain may worsen while lying flat or improve after assuming a forward or fetal position. Obstruction of the common bile duct as it courses through the head of the pancreas can lead to jaundice. Fever, pleuritic pain, and shock may result from peripancreatic fluid collection and pancreatic parenchymal hemorrhage. Physical examination may reveal epigastric tenderness, guarding and rebound, decreased, or absent bowel sounds, ecchymosis of the flank (Grey-Turner's sign) or periumbilical region (Cullen's sign) and ascites. Several other diseases such as duodenal ulcer

perforation, cholecystitis, hepatitis, bowel obstruction, diabetic ketoacidosis, and pre-eclampsia may share a similar presentation (122).

Diagnosis

Typical symptoms of severe acute epigastric pain radiating to the back, nausea, and vomiting in conjunction with elevated serum amylase and/or lipase levels strongly suggest the diagnosis of pancreatitis. Pregnancy does not affect serum amylase or lipase levels; therefore, marked elevations in amylase and lipase levels are reliable markers of acute pancreatitis during pregnancy (117). However, there are many other pathologic states in which these enzymes may be elevated, since organs other than the pancreas synthesize and release amylase. Bowel ischemia or obstruction, perforated viscus, ovarian/tubal diseases such as salpingitis or ruptured ectopic pregnancy, cholecystitis, and a variety of salivary gland and pulmonary diseases (mumps, pneumonia) may also lead to elevations in serum amylase and lipase. Elevation of serum alanine aminotransferase to more than three times the upper limit of normal is a high sensitivity for biliary pancreatitis (123).

The severity of pancreatitis can be predicted to a certain extent by using Ranson's criteria, a series of biochemical parameters (124). Poor prognostic signs include (at presentation) age greater than 55 years, white blood cell count greater than $16,000/\text{mm}^3$, glucose concentration greater than 200mg/dL , lactate dehydrogenase level greater than 350IU/L , and serum glutamic-oxaloacetic transaminase level greater than 250IU/L . Within 48 hours of presentation, a decrease in hematocrit of more than 10%, a drop in serum Ca^{++} level below 8mg/dL , arterial oxygen pressure less than 60mmHg , base deficit greater than 4mEq/L , rise in blood urea nitrogen level of greater than 5mg/dL , or fluid sequestration of more than 6 liters may also indicate more severe disease.

Ultrasonography, without fetal radiation, is the initial test of choice to detect gallstones with a high accuracy during pregnancy. However, if common bile duct stones or biliary sludge are suspected based on ultrasound examination or biochemical abnormalities, a more invasive test may be required such as endoscopic ultrasonography (EUS) or magnetic resonance cholangiopancreatography (MRCP), which can provide an adequate view of the bilio-pancreatic duct anatomy. EUS and MRCP do not involve radiation and are often the tests of choice for detecting CBD stones. Computer tomography (CT) scan is not recommended during pregnancy as it carries a small radiation risk to the fetus. Endoscopic retrograde cholangiopancreatography (ERCP) is no longer widely used as a diagnostic study due to its post-procedure pancreatitis risk, radiation exposure, and the availability of newer and safer techniques such as EUS and MRCP (119). Performing diagnostic EUS or MRCP helps to identify patients who require therapeutic ERCP.

Complications

Maternal Complications

Patients with pancreatitis may develop hypovolemia and shock due to fluid sequestration and prolonged nausea and vomiting. Hypocalcemia may occur, possibly owing to entrapment of calcium in necrotic pancreatic tissue. Other metabolic abnormalities include hypochloremic alkalosis resulting from

vomiting. Severe pancreatitis may result in disseminated intravascular coagulation and adult respiratory distress syndrome.

Pancreatic pseudocyst is a collection of pancreatic fluid within a fibrous cavity; its presence may be heralded by persistent abdominal pain or chronically elevated amylase levels. Infected pancreatic necrosis must be considered if patient develops fever and leukocytosis. A CT scan or ultrasonogram (the latter is preferable in the pregnant patient) may reveal the presence of fluid and necrosis in the pancreas, but cannot determine whether or not there is concomitant infection. The diagnosis of infected pancreatic necrosis is therefore usually made on clinical grounds. Hemorrhagic pancreatitis due to necrosis and blood vessel rupture may lead to massive bleeding. Pancreatic ascites results from rupture of pancreatic ducts with leakage of amylase-rich fluid into the peritoneum.

Over the years, the maternal mortality rate associated with pancreatitis has significantly decreased. Older reviews reported a very high mortality rate of up to 37% (125); however, more recent studies have shown no maternal mortality attributed to acute pancreatitis (126,127). The improvement in the outcome of pregnant patients with pancreatitis is mainly due to earlier diagnosis with better imaging and less invasive therapeutic options including ERCP and laparoscopic cholecystectomy.

Fetal Complications

Premature labor is the main cause of adverse fetal outcomes in pancreatitis during late pregnancy (116). The rates of preterm delivery ranged between 15% and 19% (128). Fetal growth restriction can occur but may in part be avoided by the use of total parenteral nutrition (TPN). Fetal loss rate of 4.7% has also been reported (119).

Management with Maternal–Fetal Consideration

The treatment of acute pancreatitis in pregnancy follows the same guidelines as in the nonpregnant patient. The management is primarily supportive and aimed at correcting any underlying predisposing factors. Close observation is imperative, keeping in mind that multiple organ systems may be affected. The treatment of gallstone and hyperlipidemic pancreatitis in pregnancy deserves special consideration and is discussed separately.

General Measures

The general management of uncomplicated acute pancreatitis is mainly supportive including bowel rest, fluid resuscitation, correction of electrolyte and metabolic abnormalities, and pain control. Volume depletion is frequently encountered due to vomiting and fluid sequestration into the retroperitoneum. Aggressive intravenous fluid replacement is necessary to prevent pancreatic necrosis and systemic complications. Patients are given nothing by mouth for bowel rest. Fluid and electrolyte balance is closely observed; in particular, correction of hypocalcemia and hypomagnesemia may be necessary. Abdominal pain is a prominent feature in acute pancreatitis and may be severe requiring analgesics. Intravenous opiates may be used cautiously for pain control during pregnancy. Meperidine and fentanyl are the preferred analgesics during pregnancy (129).

Prophylactic antibiotics are not routinely recommended in uncomplicated pancreatitis if there is no evidence of infection (130). Although therapeutic delivery has been considered in the past, recent literature suggests that termination of pregnancy does not affect the outcome of acute pancreatitis and is not recommended (131).

Nutrition

In mild pancreatitis, oral intake should be initiated when pain subsides and advanced as tolerated. Patients with a prolonged course due to severe pancreatitis or its complications may be unable to eat even after several days of hospitalization. To ensure adequate fetal growth and maintenance of maternal nutrition, TPN can be instituted (132–134). Most of the reported complications of TPN in pregnancy are the same as those found in the nonpregnant patients and are mainly catheter related, including sepsis and thrombosis. The rate of maternal complications such as septic complications secondary to centrally inserted central venous catheters for TPN is greater than that in the nonpregnant patients. Thus, peripherally inserted central venous catheters may be preferable for parenteral nutrition during pregnancy (119,129). There are no reports of adverse fetal outcomes related to TPN in pregnant patients. Enteral nutrition (EN) via nasojejunal feeding is preferable compared with TPN (129). EN has been shown to be associated with fewer infectious complications, shorter hospital stay, and reduced surgical interventions in patients with acute pancreatitis (135). EN helps to maintain intestinal barrier and prevents bacterial translocation. Monitoring fetal growth with serial ultrasonograms is generally recommended (132) to ensure that fetal nutritional demands are met.

Management of Complications of Acute Pancreatitis

Patients with *pancreatic pseudocysts* should be monitored with serial ultrasonograms to document resolution of the cysts. Patients should be closely monitored for new symptoms such as abdominal pain, fever, chills, gastric outlet obstruction, or obstructive jaundice. Drainage of pseudocysts should be considered in patients who are symptomatic or have an infected pseudocyst. Endoscopic, percutaneous, or surgical drainage of the pseudocysts may be considered.

The occurrence of *infected pancreatic necrosis* is a leading cause of morbidity and mortality in severe pancreatitis. Infected pancreatic necrosis should be suspected if patient develops unexplained fever, leukocytosis, and/or signs of sepsis in conjunction with a CT scan, which reveals necrosis in the pancreas. Antibiotic therapy with broad-spectrum antibiotics such as imipenem should be initiated if pancreatic infection is suspected. Radiologic-guided fine-needle aspiration of the necrotic area is recommended to determine whether it is sterile or infected. Sterile necrosis is usually managed conservatively; however, infected pancreatic necrosis requires surgical debridement (necrosectomy).

Gallstone Pancreatitis

Because of the risk of recurrent pancreatitis due to cholelithiasis, indications for cholecystectomy during pregnancy should be the same as in the nonpregnant patient. Once pancreatitis resolves, laparoscopic cholecystectomy is ideally

performed in the second trimester because during this period organogenesis is complete and technical problems due to an enlarging uterus are limited (131). A laparoscopic approach is preferable over open cholecystectomy because it is associated with shorter hospital stay, decreased narcotic use, and an earlier resumption of oral intake without affecting maternal or fetal mortality (119). In patients with onset of pancreatitis in the third trimester, postpartum cholecystectomy may be performed. ERCP with sphincterotomy may be useful in patients with severe acute pancreatitis, cholangitis, persistent biliary obstruction, and in those who are not ideal surgical candidates during the first and third trimesters of pregnancy (119). Fetal radiation exposure during ERCP can be kept below the teratogenic doses by limiting fluoroscopy times and shielding the pelvis.

Hyperlipidemic Pancreatitis

The management of hyperlipidemic pancreatitis poses a challenging problem. Attempts at refeeding patients after symptoms of pancreatitis subside may be difficult since even low-fat diets may lead to elevation of triglycerides and recurrent symptomatology (133). In these situations, particularly in patients who are not near term, adequate nutrition must be maintained. TPN has proven to be an efficacious method for delivering an appropriate calorie load without supplementation with fats, leading to improved regulation of triglyceride levels. Other supportive therapies include low-fat diet, antihyperlipidemic therapy, insulin, heparin, and plasmapheresis (134). Planned delivery of patients at term who have pancreatitis due to hyperlipidemia is recommended by some authors (136), and preterm delivery may be considered only in patients whose clinical status deteriorates, since lipid abnormalities are clearly worsened by pregnancy.

ENDOSCOPY AND PROCEDURAL SEDATION IN PREGNANCY

Endoscopy during pregnancy appears to be safe provided the indication for endoscopy is appropriate and adequate precautions are taken. A multidisciplinary team involving an endoscopist, obstetrician, and anesthesiologist may be required for the management of gastrointestinal diseases in pregnancy requiring endoscopic diagnosis and intervention. Potential risks associated with endoscopy during pregnancy include the following:

1. Fetal hypoxia: Caused by maternal hypotension and hypoxia due to oversedation and may lead to fatal consequences.
2. Exposure of the fetus to potentially teratogenic drugs and radiation.
3. Maternal positioning during endoscopy can cause inferior vena caval obstruction by the pregnant uterus, which can lead to decreased uterine blood flow and fetal hypoxia.

According to the guidelines issued by the American Society for Gastrointestinal Endoscopy for endoscopy in pregnant women (137):

1. Always have a strong indication, particularly in high-risk pregnancies,

2. Defer endoscopy to the second trimester whenever possible,
3. Use the lowest dose of sedative medication,
4. Minimize procedure time,
5. Position the pregnant patient in the left pelvic tilt or left lateral position to avoid vena caval or aortic compression,
6. Presence of fetal heart sounds should be confirmed before sedation is begun and after the endoscopic procedure is completed,
7. Obstetric support should be available in the event of a pregnancy-related complication, and
8. Endoscopy is contraindicated in obstetric complications such as placental abruption, imminent delivery, ruptured membranes, or pre-eclampsia.

EGD

EGD appears to be safe during pregnancy. The indications for considering EGD during pregnancy include significant upper gastrointestinal bleed, dysphagia, odynophagia, severe abdominal pain, and refractory nausea and vomiting. In one study, the diagnostic yield of EGD for upper gastrointestinal bleed was reported to be 95% (138). There were no cases of premature labor or congenital fetal malformation.

Flexible Sigmoidoscopy/Colonoscopy

The common indications for flexible sigmoidoscopy and/or colonoscopy during pregnancy are rectal bleeding, diarrhea with negative evaluation, and strong indication for a colon mass. Sigmoidoscopy may establish diagnosis in majority of patients and should be considered first. Colonoscopy may be required if refractory lower gastrointestinal symptoms persist and sigmoidoscopy was not diagnostic. The safety and efficacy of flexible sigmoidoscopy and colonoscopy were reported in a study in which 48 sigmoidoscopies (46 patients) and 8 colonoscopies (8 patients) were safely performed during pregnancy (70). There were no adverse fetal outcomes, and no evidence that sigmoidoscopy or colonoscopy precipitated the onset of labor. The safety of polyethylene glycol (PEG) electrolyte solutions has not been studied in pregnancy. PEG solutions are classified as category C. Tap water enemas may be used for bowel preparation for flexible sigmoidoscopy. Removal of majority of colon polyps should be deferred until the postpartum period.

ERCP

Pregnancy is associated with an increased risk of gallstone formation due to alterations in the bile composition (139). Therefore, the usual indications for ERCP in pregnant patients include complications related to gallstones including cholelithiasis, cholangitis, and gallstone pancreatitis. Several studies have reported safety of ERCP during pregnancy with no adverse fetal effects (140,141); however, ERCP should be performed only by an experienced endoscopist preferably at a higher volume tertiary care center. ERCP should be avoided during the first trimester due to radiation exposure. Fluoroscopy and procedure times should be minimized. Radiation exposure should be kept to a minimum by placing lead sheets under the pelvis and lower abdomen. Other diagnostic modalities that do not involve radiation such as MRCP and

Table 7 Common Sedation Medications for Endoscopic Procedures

Drug name	FDA category
Meperidine	B
Fentanyl	C
Midazolam	D
Propofol	B
Glucagon (antiperistaltic agent)	B
Naloxone (opioid reversal agent)	B
Flumazenil (benzodiazepine reversal agent)	C

endoscopic ultrasonography (EUS) should be considered if probability of choledocholithiasis requiring therapeutic intervention is low.

General Precautions

Patient Positioning

Pregnant patients should not be placed in the decubitus or prone position during endoscopic procedures. Position pregnant patients in left pelvic tilt or left lateral position to avoid vena caval or aortic compression. External abdominal pressure should be avoided. If pressure is required, it should be minimal and directed away from the uterus.

Medications for Sedation During Pregnancy and Lactation

EGDs and flexible sigmoidoscopies may be performed without sedation. However, if sedation is required, it should be kept to a minimum. For procedural sedation during pregnancy, meperidine (category B) is preferred. Small doses of midazolam (category D) may be used as needed. If deep sedation is required, then propofol administered by an anesthesiologist should be the preferred choice (Table 7).

Fentanyl is preferred to meperidine for procedural sedation in women who are breast-feeding. The concentrations of fentanyl in breast milk are low, and lactation may be continued after fentanyl administration. Infants should not be breast-fed for at least 4 hours after midazolam administration. After 4 hours, breast milk should be pumped and discarded before reinitiating breast-feeding. Continued breast-feeding after propofol exposure is not recommended, although the period of prohibition is not known (137).

24 Hepatic disorders in pregnancy

Ghassan M. Hammoud and Jamal A. Ibdah

Liver disease in pregnancy is uncommon, and in the majority of cases, there is no need for a change in the management of liver disorder till pregnancy ceases. Most often, abnormalities in liver tests are related to conditions not specific to pregnancy. The liver is affected both physiologically and anatomically during the course of pregnancy. As pregnancy progresses, the liver is squeezed toward the chest and, therefore, a palpable liver below the right subcostal region is indicative of underlying hepatic disorder.

Liver diseases in pregnancy are classified into those not specific to pregnancy and those unique to pregnancy. Furthermore, liver diseases unique to pregnancy are classified according to their onset during pregnancy and their association with pre-eclampsia. In this chapter, we will review changes in liver anatomy and function during pregnancy, liver diseases not specific, and liver diseases unique to pregnancy.

LIVER ANATOMY, HISTOLOGY, AND FUNCTION IN PREGNANCY

Anatomically, the liver is generally not palpable below the right costal margin secondary to the enlarging gravid uterus. Both liver size and gross appearance do not change during pregnancy. Furthermore, minimal histologic changes occur in pregnancy. These include cellular and nuclear pleomorphism, increased numbers of binucleate cells, steatosis, increased cellular and nuclear glycogen, hypertrophied Kupffer cells, and some lymphocytic infiltration of the portal tracts. During normal pregnancy, plasma volume is increased by 50% to 70% and reaches its maximum by 32 to 34 weeks of pregnancy. This results in hemodilution of all serum protein concentrations. Serum albumin concentration decreases, but the rates of albumin synthesis and catabolism are not affected. Hypoalbuminemia can occur in the third trimester regardless of liver disease. However, prolongation of prothrombin time (PT) and hyperbilirubinemia would raise the concern of significant liver disease. Other serum protein concentrations such as alpha-2-macroglobulin, alpha-1-antitrypsin, and ceruloplasmin are increased. Pregnancy is characterized by a hypercoagulable state and increased risks of deep venous thrombosis. Almost all coagulation factors increase during pregnancy except protein S. Moreover, fibrinolysis is inhibited. This physiologic state tends to decrease the risk of bleeding during delivery; however, it increases the risk of maternal venous thrombosis. Indeed, PT is generally not affected during pregnancy and any changes in PT should be considered abnormal and justify further investigation. Serum lipid concentrations increase in late pregnancy secondary to increased levels of estrogen and progesterone. Elevations in estrogen and progesterone levels enhance cholestasis and production of lithogenic bile and reduce gallbladder motility. These alterations predispose pregnant women for gallstone and biliary sludge formation. Measurement of serum lipids in

pregnancy is rarely useful unless in the setting of acute pancreatitis. During pregnancy, the total red cell mass is actually increased but rapidly decreases as pregnancy ceases. The cardiac output increases but the absolute hepatic blood flow remains unchanged. Plasma volume increases specially during the second trimester resulting in falling hemoglobin levels due to hemodilution. Serum aminotransferases [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)] are not altered by pregnancy and are considered the most useful test indicative of hepatocellular injury. Serum alkaline phosphatase activity levels rise during the third trimester as a result of increased production of placental and bone isoenzymes. Indeed, measurement of serum alkaline phosphatase activity is not a suitable test for the diagnosis of cholestasis during pregnancy. Total and free bilirubin concentrations are decreased during pregnancy partly due to hemodilution (Table 1). Gilbert's syndrome is characterized by an increase in unconjugated hyperbilirubinemia with absolute normal aminotransferases. The management of pregnant women with Gilbert's syndrome is not any different than those who are not pregnant, and medical reassurance should be provided. The syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP) is associated with indirect hyperbilirubinemia and should be differentiated from Gilbert's syndrome. Pregnancy is also associated with mild increase in serum bile acids secondary to reduced bile salt transport. Measurement of serum bile acid concentrations may be useful for the diagnosis of cholestasis during pregnancy.

PHYSICAL EXAMINATION DURING NORMAL PREGNANCY

Spider naevi and palmar erythema are commonly observed during pregnancy and in oral contraceptive receivers. Spider naevi consist of a central arterial vessel from which small capillaries lead off radially. These are found in 53% by the 9 months of pregnancy (1) and tend to be more common among white women. Palmar erythema is frequently observed in patients with chronic liver disease and in pregnancy. It manifests itself as a diffuse patchy erythema of the palms up to the start of the wrist joint. Occasionally, the soles of the feet are also affected, hence the name plantar erythema. Palmar erythema is observed in 63% of white women and 35% of black women during pregnancy (2). Scratch marks and pruritus are found in cases with cholestasis and biliary cirrhosis. Pregnancy is considered a pruritogenic state. The cause of this unbearable itching is deemed to be due to a decrease in bile salt transport secondary to a reduction in both sinusoidal and canalicular bile salt transporters. The concentration of bile salts in blood is within normal range in most pregnant women, but levels of unconjugated chenodeoxycholic acid are higher in late pregnancy. Anatomically, the liver

is displaced toward the chest by an enlarging uterus and palpable liver is considered abnormal in pregnancy. It is important to screen for cirrhosis in the physical examination of pregnant women with viral hepatitis. Detection of cirrhosis may not always be easy because spider angioma and palmar erythema can be seen in both cirrhotic and pregnant states. However, evidence for splenomegaly is suggestive of cirrhosis.

LIVER DISEASE NOT SPECIFIC TO PREGNANCY

Viral Hepatitis

Viral hepatitis is the most common cause of jaundice in pregnancy. The hepatotropic viruses (hepatitis A, B, C, D, E, non-A, and non-B) are responsible for the majority of these infections and accounts for 40% of jaundice in pregnant women in the United States (3). The course and outcome of viral hepatitis is no different in pregnant patients than in other individuals except in the case of hepatitis E, which has been associated with a higher morbidity and mortality in pregnant women in the third trimester (4).

Table 1 Biochemical Changes During Normal Pregnancy

Test	Change
White cell count	↑
Hemoglobin	↓
Platelets	–
Albumin	↓
Aminotransferases	–
Alkaline phosphatase	↑
GGT	–
Bilirubin	–/↓
Prothrombin time	–
Fibrinogen	↑
Globulins	↑ in α and β globulins and ↓ in γ globulin
Glucose	–
Creatinine	–
Uric acid	–
Bile acids	–
Cholesterol	↑
Triglycerides	↑
Alpha-fetoprotein	↑
Ceruloplasmin	↑
Ferritin	↑

Abbreviation: GGT, gamma glutamyl transpeptidase.

Herpes hepatitis is an extremely rare disease in immunocompetent adults with an associated mortality of 39% (5). Most infections occur in the third trimester of pregnancy. Altered CD4/CD8 lymphocyte ratio and impaired natural killer cell function are blamed for the development of systemic herpes virus infection. Hepatitis manifests with coagulopathy, markedly elevated liver transaminases (>1000IU), and low bilirubin. Liver biopsy reveals coagulative necrosis, multinucleated cells with ground-glass intranuclear inclusions, and peripheral chromatin condensation (6). Early treatment with intravenous acyclovir is lifesaving.

The diagnosis of viral hepatitis is usually made on the basis of serologic testing (Table 2). Although viral hepatitis is not associated with teratogenicity, transmission of viral infection to the fetus may occur, which may result in premature labor. Transmission of infection is believed to occur primarily during the peripartum. For some infections, measures can be taken to prevent or lessen the severity of hepatitis in the newborn.

Hepatitis A

Hepatitis A virus (HAV) is a small, spherical RNA virus that usually causes a self-limiting clinical hepatitis. The virus is transmitted by the fecal–oral route and replicates exclusively within the hepatocytes and is excreted in bile. HAV infection does not lead to chronic hepatitis but relapsing cholestatic hepatitis have been described (7). The average incubation period is about 28 days (range 15–50 days). Fecal shedding occurs for about 2 weeks after infection. The overall case-fatality ratio is less than 1%. Intrauterine transmission of HAV is very rare but perinatal infection could occur. Acute HAV infection during pregnancy is associated with high risk of maternal complications and preterm labor (8). Serologic diagnosis of acute HAV is made by the presence of anti-HAV IgM. Anti-HAV IgM is typically present for several weeks but may be present for up to 1 year. The presence of anti-HAV IgG antibody denotes immunity either by previous infection or vaccination and confers long-lasting immunity. Intrauterine transmission of HAV is very rare; however, perinatal transmission can occur. Neonates of mothers who acquire HAV in the last trimester should receive immune globulin (IG) at the time of delivery (9). Pregnant women who travel to an endemic area should receive prophylactic IG. Individuals who are exposed to acute HAV should receive IG within 10 days of exposure. Studies show that post-exposure prophylaxis can prevent

Table 2 Serologic Diagnosis of Common Viral Hepatitis in Pregnancy

Virus	Acute	Chronic	Recovered	Immunity
Hepatitis A	Anti-HAV IgM	Not applicable	Anti-HAV IgG	Anti-HAV IgG
Hepatitis B	Anti-HBc IgM	Anti-HBc total	Anti-HBc total	Anti-HBs Ag
Hepatitis C	HBs Ag	HBs Ag		
	HBe Ag	HBe Ag ^a /e Ab	Anti-HBs Ag	
Hepatitis D	HCV RNA	Anti-HCV Ab	Anti-HCV Ab	Not applicable
	Anti-HCV Ab +/-	HCV RNA	HCV RNA -	
Hepatitis E	Anti-HDV IgM	Anti-HDV	Anti-HDV Total ^b	Not applicable ^c
	HD Ag ^b	HD Ag ^b		
	HBs Ag	HBs Ag		
Hepatitis E	Anti-HEV IgM	Anti-HEV IgG	Anti-HEV IgG	Not applicable

^aHBeAg will be present during periods of high replication. ^bMarkers of hepatitis B infection will also be present because HDV cannot replicate without HBV. ^cAlthough no specific vaccine for hepatitis D exists, individuals vaccinated for HBV will be protected from infection with HDV. Abbreviations: HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus.

infection or lessen its severity in those who become infected. Mothers infected with HAV are encouraged to breast-feed and HAV infection is not a contraindication for breast-feeding (10).

Hepatitis B

Hepatitis B virus (HBV) is a 3.2kb, circular, partially double-stranded deoxyribonucleic acid (DNA) virus belongs to the Hepadnavirus group. HBV can result in both acute and chronic infections. Carriers with chronic HBV are at risk for the development of liver cirrhosis, hepatic decompensation, and hepatocellular carcinoma (HCC) (11). A person is said to be a hepatitis B surface antigen (HBsAg) carrier if serum HBsAg has persisted for more than 6 months; if the clinical and chemical findings fail to show any signs of acute hepatitis; and if no or minimal histologic changes are detectable. HBV is generally noncytolytic but liver injury is attributed to host immune response. In contrast to HCV that replicates in the cytoplasm of the hepatocytes, HBV (dsDNA) enters into the nucleus and is converted to covalently closed circular form known as cccDNA (12). This is remarkably a stable species from which all viral mRNAs are transcribed and is resistant to antiviral therapy. The virus is transmitted by perinatal, percutaneous, and sexual exposure, as well as by close person-to-person contact. Vertical transmission is very infrequent in the first and second trimesters, yet prevails in the third trimester. With the coexistence of HBsAg, HBeAg, and high HBV DNA in the third trimester, the child is nearly always infected. Perinatal transmission of HBV infection represents the single largest cause of chronically infected individuals worldwide (13). An estimated 350 million persons worldwide are chronically infected with HBV (14). North America, Northern Europe, and the Oceanic areas are low prevalence areas (<2%) (15,16). In the United States, there are an estimated 1.25 million hepatitis B carriers, defined as persons positive for HBsAg for more than 6 months (16). The incubation period is 25 to 180 days. The age at which HBV infection occurs is an important factor affecting the outcome. The earlier the infection occurs, the higher is the risk for chronicity. The risk of developing chronic HBV infection after acute exposure ranges from 90% in newborns of HBeAg-positive mothers to 25% to 30% in infants and children under 5 and to less than 5% in adults. The diagnosis of acute HBV infection is established by the presence of positive serum HBsAg and the IgM fraction of the antibody to hepatitis B core (anti-HBc IgM). Pregnant women who had an immediate exposure to hepatitis B virus may be given injection of hepatitis B immunoglobulin (HBIG) ideally within 72 hours of exposure and hepatitis B vaccine within 7 days of exposure (17). Hepatitis B vaccine is generally safe in all trimesters of pregnancy. The current HBV screening guidelines from the Centers for Disease Control and Prevention, the American College of Obstetrics and Gynecology, and the Immunization Practices Advisory Committee recommend that all pregnant women be tested for HBsAg during each pregnancy and that women at high risk for chronic hepatitis B be screened on admission for delivery, even if they previously have been tested or vaccinated (18). HBsAg-positive women who are pregnant should be counseled and make sure that their providers are informed so hepatitis B immune globulin (HBIG) and hepatitis B vaccine can be administered to their newborn immediately after delivery.

Immunization with HBIG and vaccine starting at birth reduces the risk of transmission to less than 10% among infants born to HBsAg/HBeAg-positive mothers (19). One such immunization schedule includes three intramuscular injections, the first one given between the time of birth and before the hospital discharge, and the second and third injections given at 1 and 6 months of age, respectively (18). The standard vaccination strategy for infants born to mothers who test positive for HBsAg includes the administration of 100IU HBIG (human hepatitis B Immunoglobulin-VF, CSL Bioplasma) and hepatitis B vaccine [Recombivax HB (5mg), Merck, or Engerix-B (10mg), GlaxoSmithKline] within 12 hours of birth (20). HBIG is given intramuscularly and at a different site from that used for vaccination. Immediate household contacts should also be given HBIG and vaccination. The current vaccines contain noninfectious HBsAg and should cause no potential risk to the fetus.

The current (2009) Federal Drug Administration (FDA)-approved therapy for HBV in nonpregnant patients include subcutaneous injection of interferon/pegylated interferon alpha and orally administered nucleoside/tide analogs such as Lamivudine, Adefovir, Entecavir, Telbivudine, and Tenofovir (21). Interferon is considered FDA category C drug in pregnancy and is not recommended. Lamivudine, an oral nucleoside analog, classified as FDA category C drug in terms of safety, is given to mothers with high HBV DNA during the second and third trimesters to reduce the risk of transmission at the time of delivery. It is generally not recommended for use against HBV in the first trimester of pregnancy. However, potential benefits may justify the potential risk. The data on adefovir, entecavir, telbivudine, and tenofovir safety are limited in pregnancy. Although HBV may be found in breast milk, a study comparing breast-fed versus non-breast-fed babies of seropositive mothers demonstrated no difference in the infection rate.

Hepatitis C

Hepatitis C virus (HCV) is a hepatotropic positive single-stranded RNA virus of the *Hepacivirus* genus and a member of the Flaviviridae family. HCV infection is one of the major causes for development of liver cirrhosis and end-stage liver disease in the world. The prevalence of HCV antibody in pregnant women is equivalent to that of the general population (0.5%) (22). The most remarkable feature of hepatitis C virus is its ability to establish chronic infection in 55% to 85% of acute cases. Approximately 20% of chronically infected patients go on to develop cirrhosis, hepatic decompensation, and HCC after 20 to 30 years of infection (23). Chronic HCV infection is estimated to affect 180 million people worldwide, including 2 to 3 million Americans (1.6% of the general population) (24). There are six HCV genotypes (1, 2, 3, 4, 5, and 6), and a large number of subtypes (1a, 1b, 1c, etc.) have been identified (25). Currently, injection drug use is the primary mode of HCV transmission in the United States. Other risk factors include clotting factor therapy prior to the year 1987, blood transfusion prior to the year 1992, contaminated therapeutic equipment, occupational needlestick, and sexual and perinatal transmission. The average rate of perinatal transmission is 5% to 6% (26). Infants born to mothers with HCV and human immunodeficiency virus coinfection have increased rate of HCV transmission (14–17%) (27). The risk of perinatal HCV transmission is related to HCV RNA titer and is

unrelated to delivery mode (vaginal vs. cesarean). Factors associated with increased risk of perinatal transmission are prolonged rupture of the membrane for more than 6 hours, amniocentesis, and perineal lacerations. Although HCV can be transmitted intrapartum, prevention by cesarean delivery is not generally indicated. Studies have evaluated breast-feeding of infants born to HCV-infected women, which indicate that the average rate of infection is 4% in both breast-fed and bottle-fed infants (28), and most experts do not consider breast-feeding a mode of transmission. The prevalence of hepatitis C in pregnancy does not differ significantly from that of hepatitis C in the age- and sex-matched general population. Routine prenatal HCV screening is not recommended; however, women with significant risk factors for infection should be offered antibody screening.

Fetal outcomes, such as birth weight, American Pediatric Gross Assessment Record score, and umbilical pH, have not been found to be different in children born to hepatitis C-infected mothers. Similarly, maternal outcome and obstetric complications are not greater in mothers chronically infected with hepatitis C in the absence of cirrhosis and portal hypertension. The diagnosis of acute or chronic HCV infection generally requires testing of serum for both antibody to HCV (anti-HCV) and for HCV RNA with a sensitive quantitative HCV RNA assay (Table 3). Anti-HCV is passively acquired by the infant and may persist for up to 18 months. Moreover, the rate of spontaneous clearance in the perinatal transmission of HCV is high. Infants born to mothers with HCV should not be tested for HCV till 18 months of age (29).

The course of hepatitis C can be affected by pregnancy. Some studies have reported an increase in HCV RNA levels in the third trimester of pregnancy, but others have not. On the contrary, serum ALT levels tend to be lower in the third trimester and return to normal by 6 months after delivery.

The currently recommended therapy of chronic HCV infection in nonpregnant patients is the combination of a pegylated interferon- α and ribavirin. This regimen has been shown to be effective in 40% to 70% of patients (30–32). In mid 2011, two new direct-acting antiviral agents have been approved in combination with pegylated interferon and ribavirin for hepatitis C therapy in non-pregnant genotype 1 patients. HCV treatment success is measured by sustained virologic response (SVR) (defined as undetectable HCV RNA by a sensitive assay 6 months following discontinuation of treatment). Interferon is classified by the FDA as a category C drug while ribavirin is a category X product, indicating that its use is contraindicated in women who are pregnant. Interferon monotherapy is far less effective than combined therapy with ribavirin and is associated with low SVR rates, and hence the risk of HCV therapy outweighs its benefit during pregnancy.

Hepatitis E

Hepatitis E virus (HEV) is a positive-stranded RNA virus that belongs to the Hepeviridae family. The virus is transmitted via the fecal–oral route, commonly by contaminated water supplies. Vertical transmission of hepatitis E virus ranged between 33% and 50% (33,34). The virus is endemic in the Middle East, India, Southeast Asia, Central Asia, Central America, and South America. Hepatitis E is an acute disease that does not progress to chronicity, although reports of chronic HEV have been described in liver transplant recipients (35,36). The clinical presentation is basically the same as that for HAV. HEV infection is known to cause severe hepatitis, fulminant liver failure, preterm labor, and increased mortality in pregnant women especially in their third trimester with reported maternal mortality rates as high as 20% to 31.1% (4,37). The incubation period is 3–8 weeks, with a mean of 40 days. Cholestatic hepatitis is common. Acute hepatitis E infection is diagnosed by detection of IgM anti-HEV or a rising titer of IgG anti-HEV. The treatment is supportive therapy. A proved effective vaccine against HEV is currently not available. There is no current evidence that HEV infection is transmitted in breast milk.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) is a syndrome of progressive hepatocellular inflammation and necrosis of unknown cause, frequently leading to cirrhosis (38). The disease is characterized by loss of tolerance to hepatic autoantigens. AIH occurs predominantly among women, particularly in their younger years, and may influence their fertility and pregnancy. Pregnant women with AIH have a reduced fertility rate secondary to amenorrhea and anovulation, which might be related to hypothalamic–pituitary dysfunction. Serious maternal complications can occur in 9% of cases with a high rate (52%) of postpartum flares (39). In one large review by Candia et al. analyzing 101 pregnancies, fetal death rate was observed in 19% with a perinatal mortality of 4% (40). Most fetal deaths occurred before the 20th week of pregnancy.

In the United States, AIH affects 100,000 to 200,000 patients with an incidence of 1.9 per 100,000 per year and a point prevalence of 16.9 per 100,000 persons per year (41). AIH occurs at two age peaks, one in adolescence and young adulthood and the other in the sixth or seventh decade. About 70% of cases involve females, and there is a frequent association with other autoimmune disorders such as thyroiditis.

The diagnosis is based on histologic abnormalities (portal tract inflammation with moderate infiltration with lymphocytes, plasma cells, and piecemeal necrosis), characteristic clinical and laboratory findings (absence of other causes of

Table 3 Interpretation of Serum Hepatitis C Virus (HCV) Antibody and HCV RNA

Anti-HCV	HCV RNA	Interpretation
Negative	Negative	No previous or current exposure to HCV
Positive	Positive	Acute or chronic HCV infection
Positive	Negative	Resolution of HCV either spontaneously or after response to treatment, false positive ELISA test
Negative	Positive	Acute HCV infection; chronic HCV in setting of immunosuppressed state; false-positive HCV RNA test

liver injury and abnormal aminotransferases), abnormal levels of serum globulins, and the presence of one or more characteristic autoantibodies (42). Immunosuppressive therapy with azathioprine (AZA) and corticosteroids are the principal therapy of AIH. Corticosteroid therapy induces clinical, laboratory, and histologic improvements in 80% of patients with AIH (43). Corticosteroids and AZA are generally safe during pregnancy but birth defects have been described (44). Pregnant women with AIH need careful monitoring during pregnancy and for several months postpartum.

Wilson's Disease

Wilson's disease (WD) is a rare autosomal recessive disorder of hepatic copper metabolism caused by defective copper transporting ATPase in the liver causing a decrease in biliary excretion of copper and abnormal accumulation of copper in many tissues, notably the liver, brain, kidneys, and cornea. The most common gene mutation described in WD is ATP7B. WD is a rare disorder with a worldwide prevalence of 1:30,000. Clinical manifestations depend on the affected organs and include acute or chronic hepatitis, cirrhosis, hemolysis, chorea, tremors, spasticity, and psychiatric changes. A Kayser–Fleischer ring is often observed once neurologic or psychiatric symptoms develop. The diagnosis is made by a low serum level of ceruloplasmin and an elevated concentration of copper in the liver tissue. Women with WD have high rates of infertility due to menstrual irregularities and recurrent miscarriages (45,46). The former is the result of hormonal changes caused by hepatic failure and copper toxicity and the latter is caused probably by increased copper deposition in the uterus. Hemolysis can be a presenting feature in some cases.

The current available anticopper agents are penicillamine, zinc, trientine, and tetrathiomolybdate. The main therapy is penicillamine, a copper-chelating agent. Although this agent has been used in pregnancy without teratogenic effect, transient goitrous hypothyroidism in infants born to mothers with WD on penicillamine has been reported (47). Cessation of therapy can lead to fulminant liver failure and death during pregnancy. Zinc intake at a dose of 25 to 50mg three times daily in pregnancy appears to be safe with very minimal teratogenicity (48). Since penicillamine has an antipyridoxine effect, supplementation with vitamin B₆ is recommended.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune cholestatic liver disease characterized by progressive destruction of intrahepatic bile ducts, predominantly seen in middle-aged women. Typical symptoms are fatigue, pruritus, and abdominal pain. Jaundice develops in advanced liver disease. At presentation, about 40% of the patients are asymptomatic, but 30% to 50% already have hepatomegaly and 15% present with splenomegaly. PBC is associated with a large variety of other diseases, such as Sjogren's syndrome, arthropathy, CREST (calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome, and autoimmune thyroiditis. The characteristic serologic hallmark of PBC is the anti-mitochondrial antibody, a highly disease-specific autoantibody found in 90% to 95% of patients (49). Up to now, it is not known whether pregnancy was harmful in PBC patients. Previous reports suggested

increased rates of infertility and preterm labor. Ursodeoxycholic acid (UDCA, 10–15 mg/kg/day) is regarded as the first-line treatment for PBC. UDCA appears to be safe and is considered FDA class B in pregnancy. UDCA may improve pruritus and serum liver tests.

Portal Vein Thrombosis

Portal vein thrombosis (PVT) is a rare occurrence during pregnancy. Malignant tumors, cirrhosis, and other causes of intra-abdominal inflammation such as pancreatitis, appendicitis, cholecystitis, duodenal ulcer, and inflammatory bowel disease are the leading local risk factors (50). Management differs in acute and chronic PVT in pregnancy. The goal of treatment of acute PVT is to recanalize the obstructed veins, which may prevent intestinal infarction and subsequent portal hypertension. Correction of the causal factors should be achieved as soon as possible. Anticoagulation should be given for at least 3 months and that a permanent anticoagulation therapy is considered for patients with prothrombotic conditions (51). Pregnant patients with chronic PVT should be offered screening for gastroesophageal varices. In patients with extrahepatic portal hypertension without gastroesophageal varices, labor and vaginal delivery are preferable and less morbid, with a passive second stage of labor in order to avoid increased intra-abdominal pressure. Elective cesarean section is advisable in patients with gastroesophageal varices. Portal vein cavernoma is a rare disease resulting from extrahepatic PVT and development of collateral venous circulation (51). This disease is often accompanied by splenomegaly, portal hypertension, esophageal, gastric, or jejunal varices, and thrombocytopenia. Early diagnosis and treatment of gastroesophageal varices before pregnancy are recommended, which can be accomplished by screening upper endoscopy and therapy with sclerotherapy or esophageal band ligation of esophageal varices and/or institution of nonselective β -blocker therapy is warranted.

Budd–Chiari Syndrome

Budd–Chiari syndrome (BCS), also known as hepatic venous outflow tract obstruction, is characterized by occluded hepatic venous outflow tract at various levels from small hepatic veins to inferior vena cava, resulting from thrombosis or its fibrous sequelae (51,52). Most patients with BCS have a “primary” disorder and share one or more prothrombotic risk factors, mainly myeloproliferative disorders (MPD), oral contraceptive use, factor V Leiden mutation, and antiphospholipid syndrome. MPD, particularly polycythemia vera, are observed in approximately half of the cases of BCS, but fewer than 10% of the subjects with overt MPD develop BCS. The characteristic clinical triad of acute BCS is right upper quadrant pain, hepatomegaly, and ascites (53,54). The diagnosis of BCS is established with Doppler sonography of the hepatic vessels. MRI can provide detailed examination of the hepatic and splanchnic vessels. Chronic thrombosis may evolve to precipitate portal hypertension with the formation of ascites, porto-systemic encephalopathy, and gastroesophageal varices. Women with BCS who desire to become pregnant should be screened for gastroesophageal varices with upper endoscopy, and if found, treatment should be offered preferably with esophageal band ligation or sclerotherapy. Most patients are placed on long-term warfarin therapy if nonpregnant and on

low–molecular weight heparin if pregnant as soon as possible, and preferably before conception.

Cirrhosis and Portal Hypertension

Pregnancy is uncommon in the setting of cirrhosis possibly due to altered sex hormones and hepatocellular injury. The rates of spontaneous abortion, premature birth, and perinatal death are all increased in women with cirrhosis. The incidence of cirrhosis in pregnancy is estimated to be approximately 1 in 5950 pregnancies (55). Maternal morbidity and mortality is high during pregnancy in cirrhotic patients (10.3–18%). Maternal deaths are due primarily to gastrointestinal hemorrhage from varices (56). During pregnancy, a hypervolemic state develops leading to an increase in portal flow and elevation of portal pressure transmitted to the collateral veins with increased risk of variceal bleeding. Esophageal variceal bleeding has been reported in 18% to 32% of pregnant women with cirrhosis and in up to 50% of those with known portal hypertension. Those with preexisting varices, 78% will have gastrointestinal bleeding during pregnancy, with a mortality rate of 18% to 50% (57). The outcome of pregnancy in women with cirrhosis is influenced by the underlying etiology of liver disease. AIH and alcoholic liver disease tend to have a favorable outcome in comparison with those with viral hepatitis. Endoscopic surveillance and banding of esophageal varices are recommended during pregnancy. Upper endoscopy in general appears to be safe during pregnancy. Primary prophylaxis with nonselective beta blockers is recommended. Propranolol and/or nadolol are considered FDA category C. The risks of nonselective beta blockers include fetal bradycardia, hypotension, hypoglycemia, and intrauterine growth retardation. Endoscopic band ligation seems to be a safe procedure in pregnancy. Termination of pregnancy is warranted in the presence of progressive hepatic decompensation. Vaginal delivery is usually safe and early forceps delivery or vacuum extraction should be considered to prevent any rise in portal pressure due to prolonged straining during labor. Cesarean section with general anesthesia is preferable in high-risk patients to avoid increase in portal pressure during labor.

Gall Stones and Biliary Tract Disease

The incidence of gallstones during pregnancy is estimated to be 3% to 12%; however, symptomatic gallstones occur in only 1.2% of these pregnancies (58). Hormonal changes during pregnancy, altered gallbladder motility, and increased cholesterol secretion are major predisposing factors for the development of gallstones and biliary sludge. The commonest clinical presentations are biliary pain and gallstone pancreatitis and the least common is acute cholecystitis. The management of symptomatic uncomplicated biliary tract disease is usually conservative. In patients with symptomatic choledocholithiasis, endoscopic management using endoscopic retrograde cholangiopancreatography (ERCP) is an alternative option. Since fluoroscopy poses a radiation risk to the fetus, abdominal shield to the pregnant patient should be provided. Laparoscopic cholecystectomy can be performed safely during pregnancy with no maternal mortality, although spontaneous abortions and preterm labor have been reported.

Table 4 Classification of Liver Diseases Unique to Pregnancy According to Their Onset in Pregnancy and Association with Pre-eclampsia/Eclampsia

Liver diseases associated with pre-eclampsia/eclampsia	Liver diseases not associated with pre-eclampsia/eclampsia
HELLP syndrome (occurs in second/third trimester)	Hyperemesis gravidarum (occurs mainly in first trimester)
Acute fatty liver disease of pregnancy (occurs mainly in second/third trimester)	Intrahepatic cholestasis of pregnancy (occurs in second and third trimesters)

Abbreviation: HELLP, hemolysis, elevated liver enzymes, and low platelets.

LIVER DISEASES UNIQUE TO PREGNANCY

Four unique disorders of liver dysfunction have been recognized during pregnancy. These include (i) hepatic involvement in hyperemesis gravidarum (HG), (ii) intrahepatic cholestasis of pregnancy (ICP), (iii) the syndrome of HELLP, and (iv) acute fatty liver of pregnancy (AFLP) (Table 4).

Hyperemesis Gravidarum

During pregnancy, nausea and vomiting are common; however, in some instances, the entity is protracted and may result in hospitalization. Intense nausea and vomiting in the first trimester associated with 5% weight loss, dehydration, ketonuria and electrolytes imbalance, and metabolic alkalosis are highly suggestive of HG. Risk factors include previous history of HG, previous molar pregnancy, preexisting diabetes, gastrointestinal disorders, asthma, singleton female pregnancy, pregnancy with multiple male fetuses, multiple gestations, hyperthyroid disorders, psychiatric illness, and small pre-pregnancy body weight (59). Maternal smoking prior to pregnancy appears to be protective (60). The most common hepatic abnormality associated with HG is mild elevation of liver transaminases (usually <300IU), and it is thought to be associated with a temporary impairment of mitochondrial fatty acid oxidation (61). Jaundice is infrequent and total bilirubin is generally <4mg/dL. These liver abnormalities are seen only in 20% to 30% of patients. Liver biopsy is generally not indicated unless to rule out other etiologies and, if performed, may show bland cholestasis. Maternal complications include Mallory–Weiss tears, preterm labor, and low birth weight (62). Treatment is supportive and directed at symptomatic relief with intravenous fluid and electrolytes replacement, thiamine and pyridoxine supplementation, and use of antiemetics. Hyperemesis with hepatic abnormalities has been reported to recur in subsequent pregnancies.

Intrahepatic Cholestasis of Pregnancy

ICP is characterized by pruritus and biochemical cholestasis typically presenting in the third trimester. This condition accounts for approximately 20% of jaundice during pregnancy. Although this is an uncommon disorder, it frequently recurs with subsequent pregnancies or the administration of synthetic estrogen compounds. Pruritus gravidarum is a term applied to patients with pruritus and biochemical cholestasis, whereas cholestasis of pregnancy is generally reserved for those patients with jaundice. The prevalence of ICP in the United States is estimated to be around 1/1000 to 1/10,000 pregnancies.

The highest prevalence is seen among the Araucanian (27.6%) and Aymara (11.8%) Indians of Chile (63). Although the exact etiology is unknown, genetic and hormonal factors play a role. Genetic factors have been implicated owing to the frequent history of cholestasis in female family members of index patients. Heterozygous non-sense mutation of the multidrug resistance-associated protein 3 (MDR3) gene has been implicated in familial ICP (64). Estrogens produce lithogenic bile because estrogens decrease bile salt-independent flow and increase diffusion of water from bile to plasma. Pruritus generally involves the palms of the hands and the soles of the feet. Skin examination should be performed to rule out other skin disorders of pruritus. Jaundice may or may not be present. Some patients will have subclinical steatorrhea that may affect nutritional status. The diagnosis is established by the presence of typical history of generalized intractable pruritus in the second or third trimester of pregnancy with elevated maternal serum bile acids in the absence of radiologic evidence of biliary obstruction. Laboratory abnormalities are cholestatic with elevations in alkaline phosphatase up to 10-fold and modest hyperbilirubinemia, typically less than 5mg/dL. Serum aminotransferases are usually elevated but <1000U/L. Cholestatic enzymes such as alkaline phosphatase are also elevated; however, serum gamma glutamyl transpeptidase is normal or slightly elevated. Elevated maternal serum bile acids are the hallmark of cholestasis and are usually 10 $\mu\text{mol/L}$ (65). A cutoff level of serum bile acids 40 $\mu\text{mol/L}$ is associated with impaired fetal outcome (66). Currently, genetic tests are performed in research laboratories only and are not applicable for diagnosis or risk stratification. However, mutation analysis of ABCB4 might be considered. Maternal outcome is favorable with prompt resolution of symptoms postpartum. Women with ICP have an increased incidence of gallstones due to lithogenic bile. Liver biopsy is unnecessary for diagnosis; however, if performed, it shows canalicular bile plugs with centrilobular cholestasis and intact parenchymal architecture. ICP recurs in about 70% of patients. Fetal outcome is not so favorable. Premature delivery occurs in 10% to 20%, meconium staining in 35% to 60%, and fetal distress in 19% to 60%.

Treatment of ICP is largely symptomatic. UDCA, a tertiary bile acid, is the main treatment to alleviate pruritus and cholestasis. The recommended dose is 15mg/kg/day in divided doses. UDCA improves liver transaminases, lower serum bile acids, and improve pruritus (67,68). Other treatment such as hydroxyzine, Ondansetron, and S-adenosyl-L-methionine (SAMe) has shown to be of some benefit (69). Fat-soluble vitamins should also be administered. In addition to the symptomatic relief of pruritus, a strict fetal monitoring must be carried out especially during the last few weeks of pregnancy, where rates of fetal morbidity and mortality are increased.

HELLP

Pre-eclampsia develops in 5% to 11% of all pregnancy and is characterized by the triad of proteinuria (greater than 300 mg in 24 hours), edema, and hypertension (>140/90 mmHg) after 20 weeks of gestation and/or within 48 hours after delivery. If the central nervous system becomes involved, for example, seizures or coma, the disorder is termed eclampsia. Hepatic involvement is a sign of advanced pre-eclampsia/eclampsia and may manifest as HELLP syndrome or hepatic rupture. The incidence

of HELLP syndrome is approximately 0.6% of pregnancies and 3.1% to 12% of patients with pre-eclampsia (70). HELLP syndrome occurs mainly in the antepartum period in 70% to 92% of cases and postpartum in 8% to 30%.

The symptoms include right upper quadrant abdominal pain, headache, malaise, nausea, and vomiting. Concomitant signs and symptoms of pre-eclampsia (hypertension, proteinuria, and edema) may or may not be present. Jaundice and bleeding, due to thrombocytopenia, are a very uncommon mode of presentation. Severe right upper quadrant abdominal pain that is radiated to the neck or shoulder may herald impending hepatic rupture or presence of hepatic hematoma. Serum aminotransferases range from 300 to 3000U/L and serum bilirubin is usually less than 5mg/dL, but higher values have been reported. Hepatic parenchymal injury results from microangiopathic hemolytic anemia, thrombocytopenia, and localized segmental vasospasm and may lead to hepatic infarction, hematoma, and rupture resulting in maternal death. Disseminated intravascular coagulation (DIC) is found in 8% to 21% of patients. If hepatic parenchymal injury is severe, hypoglycemia may be observed. Liver biopsies or autopsy specimens show periportal fibrin deposition and hemorrhage; portal tracts are usually involved but in some cases lesions may be focal. More recently, hepatic microvesicular fat similar to that seen in AFLP has been observed in histologic specimens, leading to speculation that pre-eclampsia and AFLP may be different presentations of the same process. Physicians should be aware of other causes that may resemble HELLP such as acute viral hepatitis, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, antiphospholipid syndrome, and AFLP. Both HELLP syndrome and AFLP occur in the third trimester and have similar presentations, but liver dysfunction is usually more pronounced in the latter and is more frequently associated with coagulopathy, hypoglycemia, and renal failure (Table 5). The coagulopathy of the AFLP is due to liver failure, whereas in HELLP syndrome, coagulopathy develops as a part of DIC syndrome.

Initial therapy is directed at control of hypertension and prevention of seizures, and optimal management includes prompt delivery. Frequent monitoring of serum glucose is warranted and intravenous dextrose solution is infused as needed. Maternal outcomes are generally favorable with mortality ranges from 2% to 4% in reported cases. Corticosteroids have been shown to improve maternal laboratory values but did not affect overall outcome. Platelet transfusion is recommended in the case of bleeding or severe thrombocytopenia (platelet count <20 $\times 10^9/L$).

Liver rupture is a rare, life-threatening complication of HELLP that carries a very high maternal mortality. It is usually preceded by an intraparenchymal hemorrhage progressing to a contained subcapsular hematoma in the right hepatic lobe in patients with severe thrombocytopenia. Hepatic rupture usually requires immediate laparotomy with evacuation of the hematoma with pressure packing and drainage, followed by consideration of hepatic artery embolization or ligation, partial hepatectomy, or oversewing of the laceration.

AFLP

AFLP is a rare disorder (1 per 13,000 deliveries) unique to pregnancy, which occurs in the third trimester or peripartum (71).

Table 5 Features of Liver Diseases Unique to Pregnancy

Disease/features	HG	ICP	HELLP	AFLP
Incidence	0.3–2%	0.1–0.01%	0.2–0.6%	0.005–0.01%
Onset (trimester)	first trimester	second/third	second/third	third
Presence of pre-eclampsia	No	No	Yes	>50%
Clinical features	Nausea, vomiting, weight loss, dehydration	Generalized pruritus, jaundice, elevated maternal serum bile acids	Abdominal pain, edema, hypertension, hemolysis, thrombocytopenia	Liver failure with coagulopathy, encephalopathy hypoglycemia, and DIC
Aminotransferases	Usually <300 U/L	Mild to 20-fold increase	Typically >500 U/L	Typically 300–500 U/L
Bilirubin	Usually <4 mg/dL	<5 mg/dL	<5 mg/dL	<5 mg/dL
Imaging	Normal	Normal	May show hepatic rupture or infarction	May show fatty infiltrate
Histology	Normal/bland cholestasis	Cholestasis	Periportal necrosis, hemorrhage	Microvesicular steatosis in zone 3
Outcome	Preterm, low birth weight	Preterm, low birth weight, meconium staining	Prematurity, fetal death	Fetal death

Abbreviations: HG, hyperemesis gravidarum; ICP, intrahepatic cholestasis of pregnancy; HELLP, hemolysis, elevated liver aminotransferases, and low platelets; AFLP, acute fatty liver disease of pregnancy; DIC, disseminated intravascular coagulation.

This was first described by Sheehan in 1940, who termed it obstetric acute yellow atrophy. The disorder is more common in primigravidas, twin gestations, and those with a male fetus. The disease occurs at any age in the childbearing period. Characteristically, it develops in the last 10 weeks and usually in the last 4 weeks of pregnancy.

Typically patients present with nausea and vomiting for several days, followed by jaundice and then progressive encephalopathy. Right upper quadrant pain and epigastric abdominal pain are common (50–80%) (72). Fever, headache, diarrhea, back pain suggestive of acute pancreatitis, and myalgias are occasionally initial presentation. Hepatic failure may ensue. Approximately 50% of patients may also have features of pre-eclampsia. Physical examination may reveal only right upper quadrant tenderness. Laboratory abnormalities include elevated serum aminotransferases usually 300 to 500 U/L, moderate increase in serum bilirubin 5 mg/dL and variable degrees of leukocytosis (73), DIC, hypoglycemia, hyperuricemia, and bacteremia. Patients may develop gastrointestinal hemorrhage, pancreatitis, and renal failure. Radiographic evaluations may suggest the diagnosis from steatosis seen by ultrasound, computerized tomography, or magnetic resonance imaging. However, this finding may not be universally present and normal studies do not exclude the diagnosis.

AFLP is characterized by a microvesicular fatty infiltration of the hepatocytes involving perivenular and mid-zones (74). Extensive hepatocellular necrosis, a common histologic feature of HELLP syndrome, is absent in AFLP, while microvesicular fatty infiltration, the predominant feature of AFLP, is generally absent in HELLP syndrome (72).

There is a strong association between AFLP and a deficiency of the enzyme long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) in the fetus, a disorder of mitochondrial fatty acid beta-oxidation (75). In a study by Ibdah and colleagues, 79% of women who carried LCHAD-deficient fetuses developed AFLP (76). Infants born to mothers with AFLP may exhibit immediate or delayed nonketotic hypoglycemia, hepatic encephalopathy, cardiomyopathy, slowly progressing

peripheral neuropathy, skeletal myopathy, or sudden unexpected death (77,78). Other studies reported involvement of fetal hepatic carnitine palmitoyltransferase (CPT I) deficiency and maternal medium-chain acyl-CoA dehydrogenase deficiency in AFLP (79,80). It is recommended that neonates born to pregnancies complicated by AFLP be tested for the common LCHAD G1528C mutation (81) and that this testing when done early after birth can be lifesaving as it may identify LCHAD-deficient children before they manifest the disease allowing early dietary intervention by institution of a diet low in fat and high in carbohydrate, and by substitution of the long-chain fatty acids with medium-chain fatty acids. This strong association between AFLP and the common G1528C mutation in the fetus is significant (82,83), and hence screening the offspring of women who develop AFLP at birth for this mutation can be lifesaving.

Successful management of AFLP is dependent upon prompt delivery and supportive care. Overall previous reported maternal and fetal mortality is 26% and 32% respectively, but more recent series suggest improving maternal and fetal mortality with prompt delivery. Fetal mortality is believed to occur as a result of rapid maternal decompensation, a high rate of premature delivery, and the maternal DIC resulting in fibrin deposition in the placenta, culminating in uteroplacental insufficiency, infarct, and fetal asphyxia (84). Immediate delivery would therefore be expected to improve fetal outcome, since basic organ systems are developed. AFLP may recur in subsequent pregnancy, particularly in mothers with a fatty acid oxidation defect in the offspring (72).

Liver Transplantation and Pregnancy

Since the first pregnancy in a transplant recipient in 1958, pregnancy in recipients of solid organ transplants has become increasingly common. The first successful pregnancy in a liver graft recipient was reported in 1978 (85). Given the improving success of liver transplantation over the past two decades and decreasing levels of immunosuppression, most organ transplant recipients lead happy and healthy lives with an average

1-year survival rate of >85% at better transplant programs. As of January 2007, there were 1595 pregnancies in female transplant recipients reported to the National Transplantation Pregnancy Registry (NTPR). In 131 liver transplant recipients in the NTPR, 219 pregnancies and 223 outcomes were reported (86,87). Children born to female liver recipients have a greater risk of prematurity and low birth weight than the general population; however, no congenital malformation patterns have been observed. Majority of women after liver transplantation will deliver a healthy baby. In a large single-center experience that evaluated the outcome of 71 pregnancies after liver transplantation, pregnancy-induced hypertension was seen in 20%, pre-eclampsia in 13%, acute cellular rejection in 17%, and renal impairment in 11% (88). Pregnancies occurring within 1-year post-transplantation had an increased incidence of prematurity (58% vs. 29%), low birth weight, and acute cellular rejection (33% vs. 14%) compared with those occurring later than 1 year (88). Although no statistically significant differences in outcome were identified, rates of acute rejection and graft loss are similar to nonpregnant liver recipients. An NTPR analysis of liver recipients noted that those who reported rejection during pregnancy had poorer newborn outcomes and graft survival (89). If desired, pregnancy should be deferred for 1 year after liver transplantation. This recommendation is supported by NTPR data. Immunosuppression regimens typically include cyclosporin (CyA) or FK506, mycophenolate mofetil, and prednisone with or without AZA. Additional medications for liver transplant recipients may include prophylaxis for *Pneumocystis carinii* infection with trimethoprim/sulfamethoxazole or pentamidine, and for herpes virus infection with acyclovir. Every effort should be exercised to avoid teratogenic medications during pregnancy. Family planning and multidisciplinary team involvement are optimum. Breast-feeding is discouraged while women are on immunosuppressant medication.

25 Neurologic disorders in pregnancy

Robert Burger, Terry Rolan, David Lardizabal, Upinder Dhand, Aarti Sarwal, and Pradeep Sahota

From headache to neuromuscular disease to stroke and movement disorders, neurologic disorders are common. They occur in men and women. Pregnancy is no exception. In fact, pregnancy may have an effect on neurologic condition; in turn, neurologic disorders may have an effect on pregnancy or outcome of pregnancy. Treatment of neurologic disorders is another important aspect whereby knowledge of teratogenicity is important for the physician treating a pregnant woman. While this is an extensive area, an attempt will be made to cover some key areas. The coverage will include headache, multiple sclerosis (MS), neuromuscular disorders (NMDs), epilepsy, movement disorders, and stroke.

HEADACHES IN PREGNANCY

Headache is perhaps the most common complaint in medicine and is a common complaint during pregnancy. Most headaches during pregnancy are due to primary headache disorders (migraine, tension-type, and cluster headaches). Although these may be debilitating, they are almost always benign. Secondary headache disorders are those in which an underlying cause can be identified for the headache. These include headaches due to infection, trauma, vascular disorders, pre-eclampsia, or cerebrospinal fluid (CSF) derangement. This chapter will attempt to look at the diagnosis and treatment of the major primary and secondary headaches during pregnancy.

Primary Headaches

Migraine

Migraine headaches are usually a moderate or severe unilateral or bilateral throbbing or pulsating headache with associated increased sensitivity to light, noise, or physical movement and may be accompanied by nausea and vomiting. Migraine pain also commonly involves the neck and medial shoulders in addition to the head. The usual duration of a migraine headache is 4 to 72 hours. Up to 25% of migraine headaches may be preceded or accompanied by an aura. The aura is due to neuronal dysfunction that is thought to move through the cortex and is accompanied by decreased regional blood flow (1).

The most common migraine auras are visual and sensory. Visual auras may produce positive visual phenomena such as seeing lights, stars, shimmering lights (scintillating scotoma), and pixilated or mosaic vision. The visual dysfunction may gradually spread across the visual field. Negative visual phenomena may also occur such as dark visual scotoma. Somatosensory migraine auras may produce numbness in the face or arm and hand that may slowly travel over the affected

area. Less commonly, patients may report dysarthria or aphasia as a form of aura accompanying a migraine attack.

The typical migraine aura builds up over 10 to 20 minutes and usually completely resolves in 60 minutes. The conclusion of the migraine attack usually coincides with the onset of the migraine headache.

In most women, migraine usually improves during pregnancy. Migraine improves in up to 50% to 80% of women during pregnancy (2,3). Migraine may recur in the first postpartum week in up to 50% of migraineurs (4).

Treatment of Migraine During Pregnancy

Migraine headaches affect up to 18% of women during their lifetime and are common during the childbearing years. Treatment of migraine during pregnancy is geared toward providing headache relief for the mother and avoiding potential adverse effects on the developing fetus. Acetaminophen (650–1000mg po), codeine (30–60mg po with acetaminophen), and hydrocodone (5.0–7.5mg with acetaminophen) are considered safe to use for acute pain relief. Narcotics should be avoided in the third trimester because of the risk of neonatal dependence and withdrawal following delivery. Narcotic use should be restricted to several days a week to avoid development of medication overuse headache. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen are considered safe (pregnancy class B) in the first and second trimesters but should be avoided in the third trimester due to potential risks of inhibiting labor or premature closure of the ductus arteriosus. The jury is still out on use of triptans (pregnancy class C) such as sumatriptan during pregnancy (5). At this time, it is difficult to recommend triptan usage during pregnancy unless felt absolutely essential for the well-being of the mother.

Ergotamine and dihydroergotamine (pregnancy class X) are contraindicated in pregnancy as they are considered potential abortifacients.

Antiemetics such as prochlorperazine (10mg IV), metoclopramide (10mg IV or PO), or ondansetron (4mg IV) are considered relatively safe in pregnancy and are particularly useful in women who have significant nausea, vomiting, and dehydration accompanying their migraines. Metoclopramide and ondansetron are pregnancy class B.

Women who have prolonged, recurrent, or severe migraines, particularly when resistant to acute treatment, should be considered for preventative migraine treatment. Beta blockers (atenolol, nadolol, propranolol, and timolol), some tricyclic antidepressants (doxepin and protriptyline), fluoxetine [a selective serotonin reuptake inhibitor (SSRI)], verapamil (a calcium channel blocker) are all class C

pregnancy drugs. Tricyclic antidepressants should be stopped at least 2 weeks before delivery due to the potential of neonatal respiratory distress.

There is inadequate information regarding use of the newer anticonvulsants [lamotrigine, gabapentin (GBP), topiramate (TPM), oxcarbazepine and levetiracetam (LEV)] for migraine prophylaxis in pregnancy (6). Valproic acid (VPA; pregnancy category D) should be avoided in women actively seeking to become pregnant or in early pregnancy due to reports of risks of neural tube defects (NTDs) when taken early in pregnancy (7).

The safest migraine treatment in pregnancy encompasses good headache hygiene—regular meals and sleep, avoidance of known migraine triggers for a particular patient, and the avoidance of stress when possible. Behavioral therapy such as focused relaxation techniques and stress management when available can also provide safe alternatives to pharmacologic treatment. The same modalities can be beneficial for tension-type headache sufferers.

Tension-Type Headaches

Tension-type headaches are the most common recurring headaches during pregnancy. The headache pain is usually described as mild to moderate (less severe than the usual moderate to severe pain of a migraine headache). The pain quality is dull and aching and located diffusely throughout the head or in a band-like encircling pattern. They are not typically associated with increased sensitivity to light, noise, or physical movement and are not accompanied by nausea and vomiting. The duration of tension-type headaches is variable, but most last less than a day. Like migraines, they may be triggered by stress. The most common variety of tension-type headaches is those that occur episodically (1–10 episodes less than 15 days a month). Chronic tension-type headaches (more than 15 days a month) occur in a small percentage of patients and may be associated with medication overuse.

Tension-type headaches in pregnancy can be treated pharmacologically with acetaminophen or NSAIDs (ibuprofen or naproxen in the first or second trimesters). Mild tension-type headaches often respond to rest, relaxation, cold or hot packs, physical therapy, or even acupuncture. Chronic tension-type headaches, especially if associated with depression, can be treated with an SSRI such as fluoxetine.

Cluster Headaches

Cluster headaches are more common in men than women (3–5:1) and are seen uncommonly in pregnancy. The typical cluster headache is a unilateral orbital, supraorbital, or temporal head pain of rapid onset (5–15 minutes to reach peak severity) that lasts from 15 to 180 minutes and subsides rapidly and completely. The pain is very severe and is usually described as boring, claw-like, or exploding. Cluster headaches are usually accompanied by ipsilateral autonomic symptoms with some combination of ptosis, conjunctival injection, tearing, rhinorrhea, or forehead sweating. Cluster headaches may occur several times a day and may be triggered by the onset of rapid eye movement sleep, awakening patients within an hour after going to sleep. Patients are usually very restless during a cluster attack and frequently rock back and forth or pace. Lying down (as opposed to migraine) may

aggravate the pain. Patients may have one or more attacks a day for 1 to 3 months during a cluster period and then have a period of complete remission for one to several years. Cluster headaches can usually be treated effectively with O₂ inhalation at 7L/min for 10 minutes by a non-rebreathing face mask. Up to two of three patients may obtain significant relief in 5 to 10 minutes (8).

Breast-Feeding Following Delivery

Drugs that are safe during pregnancy are safe to use in breast-feeding mothers. Acetaminophen and NSAIDs are considered safe for acute migraine and tension-type headaches. Short-acting triptans such as sumatriptan (half-life 2.5 hours) can be used by women who pump and store breast milk prior to triptan use. Beta blockers, verapamil, and narcotics (codeine and morphine) are also relatively safe.

Secondary Headaches

Secondary headaches in pregnancy include a number of disease states with potentially serious morbidity of the mother. These include subarachnoid hemorrhage, cerebral venous thrombosis (CVT) and stroke, pre-eclampsia, central nervous system (CNS) infections, and pseudotumor cerebri.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage usually presents with a sudden onset, severe headache that patients frequently describe as the “worst of their life.” Pregnancy does appear to increase the risk of aneurysmal and arteriovenous malformation (AVM) rupture with the greatest risk later in pregnancy, at the time of delivery, and in the puerperium (9). Most subarachnoid hemorrhages can be diagnosed with the use of MRI or CT scanning. A small percentage however may have negative cranial imaging and require analysis of CSF for detection of the hemorrhage. The risk of subarachnoid hemorrhage is estimated at 1 to 2 per 10,000 pregnancies.

CVT and Stroke

The risk of CVT is increased both during pregnancy and in the puerperium. Many conditions such as thrombophilias (factor V Leiden and prothrombin gene mutations, deficiencies of protein C or S, or presence of high titers of antiphospholipid antibodies), red blood cell disorders such as sickle-cell anemia or polycythemia, local infections (meningitis, cerebral abscess, sinus or inner ear infections), and dehydration among others can predispose to CVT. When the superior sagittal sinus is involved by thrombosis, the intracranial pressure may be raised producing headaches and papilledema. If the cerebral cortical veins are involved, cerebral hemorrhages, strokes, and seizures may occur. Diagnosis of CVT is made by magnetic resonance imaging (MRI) and MR venography (MRV). Treatment of CVT is anticoagulation with heparin. Warfarin is contraindicated in pregnancy due to the risk of fetal hemorrhage and malformation.

The risk of stroke appears to be increased in pregnancy. The exact risk is not known but is estimated to be at least several fold (10). Most strokes in pregnancy are due to arterial occlusions and be accompanied by headache in up to 29% of patients (11). Hemorrhagic strokes can also occur in pregnancy and may be accompanied by headache in up to

57% of patients (11). Pregnancy itself appears to be accompanied by a hypercoagulable state predisposing to both arterial and venous thrombosis. Cardiac embolic disease, systemic or cerebral vasculitis, hematologic disorders, and thrombophilias are the common causes of secondary strokes, although in up to a third of cases, no clear cause can be identified. A reasonable diagnostic approach to a stroke in pregnancy includes cerebral imaging with an MRI of the brain, a carotid and cerebral MR angiogram, a transthoracic echocardiogram with saline contrast injection to look for a right to left cardiac shunt, and blood work to help rule out hematologic, metabolic, infectious, and inflammatory causes. Treatment of stroke in pregnancy must be individualized.

Pre-eclampsia

Pre-eclampsia usually occurs in the third trimester and may be seen in up to 7% of pregnancies (12). Pre-eclampsia may present with headache and may at times be the only symptom of the condition. Other signs and symptoms of pre-eclampsia include hypertension (BP of 140/90 or greater), proteinuria of greater than 300 mg/dL, and blurred vision or non-formed visual hallucinations. If left untreated, pre-eclampsia may lead to a seizure (eclampsia), due to small cortical or subcortical hemorrhages. Treatment of pre-eclampsia consists of antihypertensives to control the hypertension, and if seizures are present, use of anticonvulsants (fosphenytoin or possibly LEV) to control the seizures.

CNS Infections

CNS infections may present with headache, fever, and neck stiffness, but are relatively uncommon during pregnancy. Suspected CNS infections should be evaluated with MRI brain imaging, followed by an analysis of spinal fluid obtained by lumbar puncture. CSF analysis should include cultures for bacteria, fungi, and acid-fast bacillus, and herpes simplex virus polymerase chain reaction.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Women may present with raised intracranial pressure (idiopathic intracranial hypertension—IIH) during pregnancy. The risk is higher in obese women. The usual clinical manifestations are pressure like or dull, throbbing, generalized headache, blurred vision, or tinnitus. The optic disc margins may be blurred or frank papilledema may be present. Following an MRI brain, a lumbar puncture shows an opening pressure of 20 to 25 cm or higher. Treatment consists of serial lumbar punctures or treatment with acetazolamide (500–2000 mg a day). Acetazolamide may be used in the second half of pregnancy. Occasionally optic nerve sheath decompression may be necessary to help preserve vision (13).

Diagnostic Evaluation of Headache in Pregnancy

Evaluation of a pregnant patient with the complaint of headache starts with a detailed history and thorough physical examination. The history should include a full characterization of the headache, any history of previous headaches, any history of recent trauma, a general medical history, and a history of concomitant drug use (including prescription, nonprescription, and illicit drugs). Both a careful neurologic examination and a physical examination should be

performed with attention to vital signs, the cranial nerves (especially the eyes), the motor and sensory systems, and the cardiovascular system. If the fetus is of viable age (24 weeks or greater), fetal monitoring should be performed. Appropriate blood work would include a complete blood count and differential, comprehensive metabolic profile, erythrocyte sedimentation rate, and thyroid function studies. MRI procedures (MRI brain, MR angiogram of the cerebral and cervical circulation, and MRV) for visualization of the venous sinuses with gadolinium are the procedures of choice for suspected cerebral or cerebrovascular pathology. If MRI is not readily available, noncontrast CT scanning with abdominal shielding poses very limited risk to the developing fetus. As noted above, lumbar puncture should be considered for pregnant patients with suspected CNS infection, suspected subarachnoid hemorrhage with negative neuroimaging, or idiopathic intracranial hypertension.

In summary, the diagnosis and treatment approach to headaches during pregnancy should be directed toward providing relief and comfort for the mother and safety for the developing fetus.

MS IN PREGNANCY

MS is an immune-mediated demyelinating disease of the CNS. Up to twice as many women are affected by MS compared with men. Up to 80% of women affected by MS develop clinical evidence of the disease between the ages of 20 and 40, the prime childbearing years.

Epidemiology of MS

There is extensive literature on the epidemiology and genetics of MS, which can be briefly summarized as follows:

- **Gender:** As noted above, MS is more common in females by a 2:1 margin. Women tend to present earlier than men. Women also tend to have less severe disease course overall compared with men.
- **Race:** Caucasians have the highest rates of MS, particularly those of Northern European ancestry (especially those of Scandinavian descent). The risk of African-Americans is about half of that of Caucasians in the same geographic area. In the United States, Asians and Native Americans have the lowest rates of MS.
- **Geographic distribution:** The prevalence of MS is the greatest in temperate climates and increases with increasing distance from the equator. The areas of greatest prevalence contain a proportionally higher Caucasian population.
- **Migration:** Epidemiologic studies have shown migration affects the development of MS, especially if immigration occurs from a low-risk to a high-risk area before the age of 15. When migration occurs after the age of 15, people tend to maintain the risk of their native country. Children of immigrants from low-risk to high-risk areas (or vice versa) tend to acquire the risk of their new homeland (14).
- **Familial occurrence:** First-degree family members of MS patients have a significantly increased risk (10–15 times) of development of the disease. The risk of

development of MS for children with one affected parent is 1.8%. The concordance rate for the development of MS is at least six times higher in monozygotic twins compared with dizygotic twins (31% compared with 5%) (15).

- **Genetics:** Numerous genes have been evaluated as possible causes or markers for MS. The strongest association with MS has been found in individuals who possess certain HLA (human leukocyte antigens) genes found on chromosome 6. Specifically, the presence of HLA-DW2 haplotype is found in up to 50% to 70% of northern Europeans with MS. The presence of these genes is currently thought to confer an increased susceptibility for the development of MS. Multiple other sites on the human genome involved in immune function and modulation are being examined for their possible role in MS (16).

Types of MS

Several different subtypes of MS have been identified.

- **Relapsing–remitting MS (RRMS):** The most common type of MS accounting for up to 60% of patients. RRMS patients have discrete attacks of neurologic dysfunction (relapses or exacerbations) lasting weeks to a few months. Recovery from relapses may be incomplete and patients may accumulate increasing disability over time. Patients tend to have relative stability of disease between relapses.
- **Secondary progressive MS (SPMS):** Many patients with RRMS develop a gradually progressive course although they may continue to have occasional relapses. SPMS may account for up to 30% of MS cases.
- **Primary progressive MS (PPMS):** Accounting for up to 9% to 10% of MS cases, patients with PPMS have a continuous downhill course from onset of the disease without relapses.
- **Progressive relapsing MS (PRMS):** These patients have a progressive course from onset with intermittent relapses with continuing progression between relapses. This pattern can be seen in up to 5% of MS cases.

Clinical Features of MS

The clinical manifestations of MS are due to lesions in the CNS, from lesions in the brain, or spinal cord. Although the initial lesions are due to demyelination and may be reversible, demyelinating lesions may progress to axonal loss and gliosis producing permanent neurologic deficits. MS can produce a wide range of neurologic dysfunction. The most common clinical manifestations are reviewed below.

- **Motor symptoms:** Muscle weakness is common in MS and may be a major source of disability. Muscle weakness in MS usually involves the legs to a greater degree than the arms or hands and may be the greatest in the proximal legs. Hyperreflexia,

ankle clonus, and extensor plantar responses (Babinski signs) are frequently seen in the legs. Spasticity (increased muscle tone) is common in the legs and patients may have both flexor and extensor spasms in the legs. The motor symptoms of MS are frequently worsened after exposure to increased environmental temperature and worsen later in the day.

- **Sensory symptoms:** Patients with MS often complain of numbness, tingling, or burning sensations. The distribution of symptoms usually does not correspond to a particular nerve root or dermatomal pattern. Shock-like or electric-type sensations may occur in the neck or back with neck flexion (Lhermitte's symptom). On examination, patients may have areas of impaired sensation to light touch, temperature, vibration, or position sense. Bilateral leg pain is another common complaint in MS.
- **Brainstem symptoms:** Cranial nerve dysfunction is commonly seen in MS. Patients may complain of blurred vision or diplopia and, on examination, may have horizontal, vertical, or rotary nystagmus. Many patients have an internuclear ophthalmoplegia due to a lesion of the medial longitudinal fasciculus in the brainstem. In this condition, examination reveals an ipsilateral adduction paralysis with nystagmus of the contralateral eye. Dysarthria and dysphagia may be seen in MS, particularly late in the disease. Although hearing loss is unusual in MS, vertigo is a fairly common complaint. Trigeminal neuralgia and both central and peripheral (Bell's palsy) facial palsy may also be seen.
- **Fatigue:** Fatigue is one of the most common complaints in MS patients and at times may be a major source of disability (17). Sleep complaints are also common in MS and poor-quality sleep may contribute to fatigue.
- **Cognitive and psychiatric dysfunction:** Many patients with MS complain of difficulty with memory, thinking, and concentration. Formal neuropsychologic testing may reveal deficits that patients are unaware of. Depression may be seen in up to 75% of patients at some time during the disease (18).
- **Autonomic disturbance:** Many MS patients complain of difficulty with bowel and bladder or sexual dysfunction. Most patients have constipation but bowel incontinence and fecal urgency may occur. Bladder frequency and urgency is also common in MS. Urodynamic studies may be necessary to define bladder dysfunction. Up to 50% of female MS patients may report sexual dysfunction, which may be due to decreased libido, vaginal dryness, or impaired perineal sensation.

Diagnosis of MS

The diagnosis of MS can be challenging. As with all medical conditions, a careful history is mandatory and should focus on current neurologic symptoms, any history of previous neurologic dysfunction (possibly indicating a previous unrecognized relapse), and inquiry as to other significant medical

conditions. A thorough physical examination should be performed with a full neurologic examination with emphasis on the mental status, visual system, motor and sensory systems, gait and balance, and reflexes.

- **Neuroimaging:** MRI of the CNS is the most sensitive test for determining the presence of demyelinating lesions. As up to 10% of MS lesions occur in the spinal cord, the cervical and thoracic spinal cord should be imaged in addition to the brain. Unless contraindicated, MRI imaging should be performed with gadolinium enhancement to look for evidence of active or acute demyelinating lesions. MRI is positive in at least 95% of patients with clinically definite MS. Typical MRI lesions in MS are seen in the periventricular regions, in the corpus callosum, and in the brainstem. Spinal cord MRI lesions in MS are often ovoid and involve two or less spinal segments. Spinal cord atrophy may also be seen.
- **CSF:** CSF analysis provides important information in MS and should be considered to help confirm a diagnosis of MS. The CSF may be abnormal in up to at least 80% of MS patients, although a normal CSF examination does not rule out the disease. Immunoglobulin G (IgG) in the CSF can be compared with levels in the serum and may be elevated in the CSF of patients with MS (IgG index and IgG synthesis rate). CSF electrophoresis may also reveal the presence of oligoclonal bands, which are due to IgG synthesis in the CNS. Elevated levels of myelin basic protein indicating myelin damage may also be seen in MS. None of the above CSF abnormalities are specific for MS although their presence in the setting of a typical clinical history can aid in making a diagnosis.
- **Evoked potentials:** Visual evoked potential (VEP) and brainstem auditory evoked potentials (BAEP) studies are useful at times in the diagnosis of MS as they can show subclinical lesions in the visual (VEP) and auditory (BAEP) pathways.

Ultimately, the diagnosis of MS is clinically based and usually rests on a clinical history of attacks of neurologic dysfunction in different areas of the brain or spinal cord at different times supported by evidence of positive findings on MRI, in the CSF, or on evoked potential testing.

Treatment of MS

Currently, a number of drugs have been shown to modify the natural history of MS and are approved to treat both the relapsing–remitting and the secondary progressive form of the disease. The interferons, glatiramer acetate, and natalizumab are approved for the relapsing forms of the disease. These drugs alter immune responses and have been shown to decrease relapse rates by up to 30% to 50% and are thought to retard disease progression over the long term. None of the drugs are indicated for use during pregnancy, and it is recommended that these drugs be stopped when a woman becomes pregnant or ideally 3 months prior to attempting to become pregnant.

The Course of MS in Pregnancy

Currently, pregnancy is not thought to impact the long-term progression of MS. Multiple studies have shown no adverse effects on pregnancy outcome in women with MS (19,20). Studies have also shown a significantly reduced rate of relapses during pregnancy (by 60–70%). Following pregnancy, there appears to be an increase in the relapse rate up to 3 months postpartum (21). Additionally, breast-feeding has not been shown to have a significant impact on exacerbation rates (22). In short, pregnancy does not appear to influence long-term disability in MS and a woman with MS who desires pregnancy should not be discouraged from pregnancy if her general health is adequate.

Finally, a woman who does have a significant MS exacerbation during pregnancy can be considered for treatment with glucocorticoids (methylprednisolone—pregnancy class C) only if the potential benefit to the mother outweighs potential risk to the fetus. Mild or moderate exacerbations are probably left best untreated in pregnancy.

In summary, women with MS who are contemplating pregnancy or who have become pregnant should be reassured that pregnancy does not adversely affect their long-term course of the disease.

NEUROMUSCULAR DISEASES (NMDs) IN PREGNANCY

NMDs are traditionally divided into diseases of anterior horn cell, peripheral nerves, neuromuscular junction, and skeletal muscles. In a pregnant woman, these may be approached as two categories: (i) pregnancy-related NMD including disorders with increased incidence or occurring as specific complications during pregnancy, delivery, or postpartum period, and (ii) chronic NMD that may influence maternal morbidity and mortality as well as fetal outcome. Following discussion focuses on the common NMDs encountered during pregnancy and puerperium.

Pregnancy-Related NMDs

Carpal Tunnel Syndrome

Incidence of carpal tunnel syndrome (CTS) is two to three times in pregnant women as compared with nonpregnant women of childbearing age (23). Gestational CTS is more common during third trimester. Various factors such as edema, weight gain, and abnormal hand position with need to sleep on side may contribute to increased incidence (24,25). Symptoms of burning pain and paresthesia in median nerve distribution or whole hand are typically worse at night and may be bilateral in 60% of patients. Loss of sensation or weakness in median nerve distribution, and Tinel or Phalen signs may be seen. Electrodiagnostic testing helps to confirm the diagnosis and distinguish it from nonspecific paresthesia of hands during pregnancy. Spontaneous resolution of symptoms occurs in majority in the immediate postpartum period, and therefore conservative treatment with wrist brace, physical therapy, and modification of activity is recommended (23,24). Patients with severe symptoms may benefit from corticosteroid injection. Women with the onset of symptoms in early part of pregnancy may be more likely to fail conservative treatment and need decompressive surgery on follow-up (24,26).

Lumbar Radiculopathy

Low back pain affects about 50% of pregnant women. Incidence of sciatica-type pain, however, is only 1% and clinical signs of radiculopathy are rare, occurring in 1:10,000 pregnancies (27). Women with prior history of back pain and sciatica are more prone to have recurrence during pregnancy. Lumbar lordosis, laxity of ligaments due to relaxin hormone, and pressure of gravid uterus may contribute to high incidence of lumbar pain (24). Lateral disc herniation commonly affects L5 or S1 nerve root and central disc herniation may cause cauda equina compression. MRI without the use of contrast agent is the investigation of choice, but care should be taken to interpret MRI abnormality in relation to clinical deficits. Most women respond to conservative treatment with analgesics and physical therapy (24,27). Decompressive surgery may be indicated for uncontrolled pain and neurologic deficits, and has been safely performed during pregnancy (28).

Meralgia Paresthetica

Lateral femoral cutaneous nerve is prone to entrapment or stretch during third trimester due to expanding abdominal wall and lordosis (23,29). Symptoms of pain, tingling, and numbness over lateral aspect of thigh may be unilateral or bilateral. Compression may also occur due to thigh flexion during delivery or pressure from the retractor during caesarian section. Treatment consists of reassurance for spontaneous resolution, and topical Lidoderm patches or local anesthetic injection in severe cases (24). Use of GBP or amitriptyline is preferably avoided during pregnancy. Intercostal neuralgias may also occur due to stretch injury and lead to chest or abdominal wall pain in a dermatomal pattern (23).

Bell's Palsy

Risk for Bell's palsy is three times higher during late pregnancy and early puerperium, probably related to increased tendency for reactivation of herpes virus infection. Corresponding incidence is lower in early pregnancy and therefore overall frequency of Bell's palsy is unaffected during pregnancy (30). Typical presentation is unilateral acute facial weakness, which progresses over 3 to 7 days. Increased lacrimation, alteration of taste, or hyperacusis may be present. There is no increase in recurrence rate during subsequent pregnancies. Gestational facial palsy is associated with increased occurrence of hypertension and pre-eclampsia, and close monitoring of affected women is recommended (30,31). Standard treatment with short course of prednisone, 1 mg/kg for 5 days and acyclovir 400 mg five times daily for 10 days, is recommended except in the first trimester of pregnancy. Lubricating eye drops and eye patching are used to prevent corneal injury. Prognosis for recovery is excellent in patients with incomplete facial weakness; however, worse prognosis during pregnancy, noted in some reports, may reflect higher chance of severe facial palsy in third trimester.

Neuralgic Amyotrophy

Predilection for occurrence of brachial neuritis (neuralgic amyotrophy or Parsonage–Turner syndrome) in immediate postpartum period is well recognized (32). Clinically, acute onset of shoulder/upper arm pain is followed by patchy weakness and wasting commonly in the distribution of upper

and middle trunks. The disorder may be sporadic or hereditary (autosomal dominant) and has possible immunologic basis. Bilateral and recurrent episodes are common in familial type. The onset may be within a few hours to weeks after the childbirth. Mode of delivery does not seem to impact the susceptibility. Spontaneous improvement with good motor function over 1 to 2 years is reported in 80% (27). Management in acute phase includes pain control, range of movement, and active physical therapy as tolerated. Intravenous methylprednisolone or intravenous human immunoglobulin (IVIG) may reduce the intractable pain but do not affect the course of the disease (33).

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is an acute or subacute predominantly motor, immune-mediated demyelinating polyneuropathy. Increase in risk for GBS is noted in postpartum period although overall incidence during pregnancy is similar to general population (27). Diagnosis is based on clinical features of generalized weakness, areflexia, elevated protein in CSF without pleocytosis, and abnormal electrophysiologic studies. Antecedent infection is seen in about two-thirds of patients. Significant association with *Campylobacter jejuni*, cytomegalovirus, and human immunodeficiency virus is described, and recognition of these infections in pregnancy may have important implications for maternal and fetal health. Pregnant women with GBS may be more prone to respiratory compromise due to elevated diaphragm and about 35% may need ventilatory support (34). Preterm labor may be more frequent, and caution should be exercised in the use of tocolytic agents to avoid autonomic complications. Vaginal delivery is possible, and caesarian section is performed for obstetric indications only (24). Efficacy and safety of plasmapheresis and intravenous immunoglobulin therapy for GBS during pregnancy are similar to nonpregnant population. General management includes respiratory and hemodynamic monitoring, prevention of thromboembolic complications, adequate nutrition, and physical therapy.

Maternal Obstetric Nerve Injuries

Lumbosacral plexus and its branching nerves are susceptible to injury during labor and delivery. The overall incidence of intrapartum nerve injuries has declined with present-day obstetric care, but is still fairly significant at 1% of live births (29). The predisposing factors include primiparity, short stature, dystocia, prolonged labor, and improper positioning (29). Injury to the components of lower plexus (L4–5, S1) presents as postpartum foot drop, while injury to the upper plexus (L2–4) causes mainly femoral and/or obturator nerve palsy. Pudendal nerve injuries are related to pelvic floor trauma.

Lumbosacral Plexus Injury

Lumbosacral trunk is unprotected as it crosses the pelvic brim to enter the true pelvis and is prone to compression by the fetal head or forceps. Rarely sciatic nerve itself may be compressed. Injury to lumbosacral plexus or sciatic nerve predominantly affects the peroneal nerve component. Foot drop is noted immediately postpartum. There is weakness of dorsiflexion, inversion and eversion of the foot, and

sensory impairment corresponding to L5 dermatome. Ankle reflex is preserved with L4–5 trunk lesion but is absent with sciatic nerve injury. Differential diagnosis is from lumbar radiculopathy and peroneal nerve compression at the fibular neck. Electrophysiologic studies help distinguish by findings of denervation in paraspinal muscles in lumbar radiculopathy and focal nerve conduction abnormality at fibular head in peroneal neuropathy. When difficult to distinguish from lumbar radiculopathy, MRI of lumbar spine is warranted.

The lesion is usually neurapraxic with variable axonal involvement. Significant spontaneous improvement is seen within 3 to 6 months. Patients with more than 50% axonal injury show slower and incomplete recovery. Treatment is symptomatic with physical therapy and ankle-foot orthosis. Caesarian section should be considered in subsequent pregnancies to avoid further compromise (23,29). Rarely, idiopathic or inherited lumbosacral plexopathy akin to brachial neuritis may occur in postpartum period.

Peroneal Neuropathy

External compression of peroneal nerve at fibular head is uncommon during labor and may be due to improper positioning in stirrups, manual pressure, or prolonged squatting. Women who receive epidural anesthesia may be more prone as they are not aware of pain and fail to change position to prevent prolonged pressure (35). Patients report pain and paresthesia over the anterior–lateral aspect of leg and dorsum of foot. Foot drop, weakness of dorsiflexion, eversion, and toe extension are noted. Normal inversion strength distinguishes from L5 radiculopathy and lumbosacral plexopathy. Nerve conduction demonstrates focal slowing and conduction block of peroneal nerve at the fibular head. Prognosis for recovery is good.

Femoral and Obturator Neuropathy

Incidence of femoral neuropathy in parturients has considerably declined with modern obstetric care. Branches of the lumbar plexus (L2–4) do not enter the true pelvis; the compression of femoral nerve therefore usually occurs at the inguinal ligament due to prolonged lithotomy position (29). Findings include difficulty walking and knee buckling, weakness of quadriceps femoris, absent patellar reflex, and impaired sensation in saphenous nerve distribution. Weakness of iliopsoas when present indicates a more proximal lesion due to nerve stretch from abduction and external rotation of hip or injury from instrumentation. Proximal part of femoral nerve has poor blood supply and is also prone to ischemia. Prognosis is favorable in majority of patients consistent with neurapraxic injury.

Obturator neuropathy is much less frequent as the nerve is deep within the pelvis and medial thigh. There is weakness of thigh adduction and sensory deficit over the medial thigh. A combined lesion of femoral and obturator nerves points to lumbar plexus involvement. Imaging of pelvis with computed tomography or MRI should be performed if intrapelvic pathology such as hematoma is suspected.

Various strategies that may help prevent nerve injuries in a parturient include avoiding prolonged thigh flexion and

extreme abduction and external rotation, frequent changing of the position of lower extremities, and reducing the active pushing time (29,35).

Pregnancy and Chronic NMDs

Motor Neuron Diseases

Late-onset spinal muscular atrophy (SMA), poliomyelitis/post-polio syndrome, and amyotrophic lateral sclerosis (ALS) may affect women of childbearing age. Pregnancy is rare in ALS, but severe exacerbation of ALS and respiratory failure are likely during pregnancy. Respiratory function should be closely monitored. Patients with severe SMA may be advised to avoid pregnancy. Presence of kyphoscoliosis and respiratory compromise are the major concerns in pregnant SMA patients. There may be increased incidence of premature labor in SMA and ALS, but fetal outcome is reported to be satisfactory (24,36,37).

For female survivors of poliomyelitis, spine deformity and cephalopelvic disproportion pose risks in pregnancy and parturition. Study of a large cohort of women with old poliomyelitis showed higher risk of complications during pregnancy and delivery, higher rate of caesarian section, and low birth weight of infants (38).

Peripheral Neuropathies

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is autoimmune acquired demyelinating polyneuropathy presenting as relapsing or chronic progressive forms. CIDP is three times more likely to relapse in pregnancy particularly during third trimester and early postpartum period (23,27). This is attributed to relative suppression of cellular immunity and stimulation of humoral immunity during gestation. Fetal outcome is not affected (39). Treatment with prednisone can be maintained, but other immunosuppressive agents should be avoided. Exacerbation is treated with plasmapheresis or IVIG.

Hereditary Neuropathy

Charcot–Marie–Tooth disease (CMT) is the most common hereditary NMD. Worsening of disease is noted in 50% of affected pregnant women, especially in those with childhood onset of CMT. Endoneurial edema and local pressure from gravid uterus may be the contributory factors (24). Some resolution of worsening may occur in about one-third of patients after delivery, but remaining continue to have progressive course. Women with CMT may have increased risk for fetal malpresentation, postpartum bleeding, and higher incidence of assisted delivery or caesarian section (40).

Myasthenia Gravis

Myasthenia gravis (MG) occurs predominantly in women of reproductive years with peak incidence in third decade (41). Management of MG in a pregnant woman is a unique challenge needing many therapeutic decisions at different stages. The course of MG during pregnancy is unpredictable with exacerbation in about 40%, remission in 30%, and no change in the remaining (24,42,43). The risk of worsening is the greatest during first trimester and early puerperium, and in

women with recent diagnosis of MG (31). Women with MG who are considering pregnancy should be instructed on optimal disease control, minimizing oral immunosuppressants, and risks to mother and fetus. Elective thymectomy if being considered should be done before pregnancy as the benefit of thymectomy is delayed (24,41). Treatment with acetylcholinesterase inhibitors (pyridostigmine, edrophonium) and prednisone is safe during pregnancy. Immunosuppressive agents such as azathioprine and mycophenolate mofetil are contraindicated (41,43). Aggressive treatment is needed in patients with bulbar or respiratory involvement. Plasmapheresis or intravenous immunoglobulin therapy can be used for control of severe symptoms and in myasthenic crisis (41). Maintenance IVIG therapy can help to avoid the use of immunosuppressive agents. There is higher risk of maternal mortality in myasthenic women especially within 1 year of diagnosis (42). It is advisable for MG women to delay childbirth for 2 years after the onset of illness.

MG has no significant effect on fertility, course of pregnancy, or mode of delivery (31,43). During labor, MG does not affect the uterine contraction; however, myasthenic weakness may limit active pushing necessitating assisted delivery. Parenteral cholinesterase inhibitors can be used during labor to tide over the myasthenic fatigue. Neostigmine 1.5 mg intramuscularly or 0.5 mg intravenously is equivalent to 60 mg oral dose of pyridostigmine. Magnesium sulfate as well as neuromuscular blocking agents should be avoided as these can aggravate weakness or precipitate myasthenic crisis (43). Care is also needed while managing pain, infection, and hypertension to avoid medications that may potentiate muscle weakness in MG.

Fetal/neonatal complications in myasthenic pregnancies include higher perinatal mortality (6–8%), stillbirth (2%), pulmonary hypoplasia, polyhydramnios, neonatal MG (10–20%), and arthrogryposis multiplex congenita (AMC) (31,41,42). Neonatal MG is related to placental transfer of acetylcholine receptor antibody. The neonate may develop hypotonia, poor sucking and swallowing, and respiratory difficulties. The onset is within 1 to 4 days and weakness resolves over 4 to 6 weeks. Intrauterine exposure to acetylcholine receptor antibody is also the basis for poor fetal movement and consequent AMC (27). There is a high risk of recurrence of AMC in subsequent pregnancies.

Muscle Diseases

Myotonic Dystrophy Type 1

An autosomal dominant, trinucleotide (CTG) repeat disorder is the most common muscular dystrophy of adulthood (24). Pregnancy in DM1 carries multiple risks for mother and fetus. The course of disease may be accelerated with increasing muscle weakness, congestive heart failure, and respiratory compromise. There is increased risk of spontaneous abortion, polyhydramnios, preterm labor, uterine atony, and postpartum hemorrhage (27,44). Perinatal loss may be up to 15%. Congenital myotonic dystrophy is a maternally transmitted condition and is reported in 6% to 20% of infants (24,44). Prenatal diagnostic testing is available. At times, the mother is first diagnosed with DM1 when she delivers an affected child. During pregnancy and delivery, use of tocolytic agents,

pentobarbital, and neuromuscular blocking agents should be avoided.

DM Type 2

This follows a more benign course than DM1 (45,46). Pregnancy may unmask or exacerbate the symptoms of DM2 in affected women. There may be predisposition to pre-term labor but no increase in fetal or perinatal loss is reported. Congenital myotonic dystrophy does not occur with DM2.

Other Rare Inherited Muscle Diseases

Some of these are likely to be encountered in a pregnant woman: facioscapulohumeral muscular dystrophy and various forms of congenital and metabolic myopathies. Vaginal delivery is possible in majority of the affected women. Increased muscle weakness during pregnancy, low birth weight, need for operative delivery, and presence of AMC are variably reported (24,27,47). Inhaled anesthetics are contraindicated as these may precipitate malignant hyperthermia (48).

Inflammatory Myopathy

Polymyositis and Dermatomyositis

This can affect women of childbearing age. Pregnancy may worsen the disease course. Women in clinical remission of polymyositis/dermatomyositis (PM/DM) carry no increased risk for obstetric complications. Active disease during pregnancy, however, is linked to poor outcome with almost 50% chance of fetal death and 33% incidence of intrauterine growth retardation (49). Corticosteroids are the mainstay of treatment. IVIG has been used for exacerbation or as maintenance treatment (50). Caution is needed while using chemotherapeutic agents. Assisted vaginal delivery or caesarian section is recommended to avoid maternal exhaustion and to reduce the risk of rhabdomyolysis.

EPILEPSY AND PREGNANCY

Epilepsy is a neurologic disorder that causes recurrent unprovoked seizures. There are an estimated 50 million people with epilepsy worldwide. Many issues in the treatment of epilepsy are sex specific. In women, this is not only related to maternity issues such as pregnancy and delivery, but also to puberty, menstruation, and contraception. The care of women with epilepsy (WWE) requires an understanding of anti-epileptic drug (AED) pharmacology, and the neuroendocrine changes during the menstrual cycle and pregnancy. This review will be divided into three parts: WWE before pregnancy (preconceptional), pregnancy and epilepsy, and postpartum care of WWE.

WWE Before Pregnancy (Preconceptional)

Every woman with childbearing capability should receive preconceptional care and counseling with her neurologist. The woman should be asked about her seizure type and frequency and response to AED therapy, as well as side effects. Additional information should include the menstrual cycle, method of contraception, plans for pregnancy, and history of birth defects or major malformation. This section will discuss the basic principles of AED therapy before pregnancy, oral

contraception, the interaction of AEDs, sex steroid hormones and seizures, and teratogenicity of AEDs.

Seizure Management Before Pregnancy

In every epilepsy patient, the first goal is the optimization of AED treatment with no seizures and side effects (51–53). It is advisable to give the lowest possible AED dose or sub-toxic dose. The appropriate drug is based on the epilepsy syndrome and seizure type (generalized vs. partial seizures). Each epilepsy patient is different in their dosage requirement, tolerance, and side effects. Preferably, AED monotherapy should be used. When seizures are controlled, it is important to obtain a baseline preconceptual (or prepregnancy) AED level. A trough or pre-dose AED level, which is before the first morning dose, should be measured. This AED serum level will serve the *individual's* therapeutic level and this may be within or outside the therapeutic range reported by the laboratory. This can also serve as an important marker for drug compliance, and to monitor serum drug fluctuations during menstruation, pregnancy, or hormonal contraception. Poorly controlled seizures despite multiple AED therapy should prompt a referral to an epilepsy center for comprehensive evaluation.

If a woman with epilepsy plans to become pregnant and is taking a drug with high teratogenic potential, attempts can be made to switch her to a drug with a more favorable teratogenic profile. However, these medication changes should be completed at least 6 months before a planned conception, if possible, to avoid fetal damage from a breakthrough seizure. When the seizures are controlled, the woman should be advised not to discontinue or lower the dose of the AED if she desires to become pregnant or if she discovers to be pregnant. WWE are also advised not to switch an AED indiscriminately without notifying their neurologist or family physician. Discontinuation of AEDs is appropriate if the patient is seizure free for 2 to 5 years, has a normal EEG, normal neurologic examination, and with a single seizure type. Some women who have not satisfied all these conditions may also wish to try discontinuing AEDs because of concerns about teratogenic effects or interference with hormonal contraception. Before doing so, the risk of seizures must be carefully considered. The risk of seizure recurrence is the greatest within the first 6 months after discontinuation (51).

Oral Contraception and Antiepileptic Medications

Beginning in adolescence, it is important to be sure that all female patients have full information regarding effective contraception (54–56). Contraceptive management requires careful consideration and is closely tied to epilepsy management. However, only 3% of pregnant women saw an obstetrician in the 3 months before conception, whereas another survey found that one-third had never been counseled regarding the issues of pregnancy and seizures. A number of safe and effective methods of contraception are available. Like all women, WWE must carefully consider their best contraceptive option; however, they need additional information regarding the possible interaction of their epilepsy medication and contraceptive choice. Most studies have shown that estrogen-based contraceptives do not affect seizure frequency. Most current guidelines suggest that the combination oral

contraceptive (COC) pills give a sufficient dose of estrogen to inhibit ovulation, generally 35 µg or greater. It is the progestin component that prevents breakthrough bleeding and is only indirectly involved in contraceptive efficacy. In the ideal situation, oral contraceptive (OC) is highly reliable with an annual failure rate of <1%. The annual failure rate of OC with AED use is about 6%. Enzyme-inducing AEDs (EIAEDs) affect the efficacy of COC. The EIAEDs include phenytoin (PHT), primidone (PMD), phenobarbital (PB), carbamazepine (CBZ), TPM, felbamate, and oxcarbazepine. They do this by inducing enzymes, that is, CYP3A4 component of the hepatic cytochrome P450, leading to faster clearance of steroid hormones and by increasing the production of sex hormone-binding globulin (SHBG) (51,55). For WWE taking EIAEDs, COCs containing 1 mg of norethindrone, 0.150 mg of levonorgestrel, or 0.300 mg of norgestrel are recommended. COCs with at least 50 µg of the estrogen component are recommended. If there is breakthrough bleeding, the estrogen dose may be increased to 75 to 100 µg daily. Other methods of contraception are barrier methods (e.g., condom, diaphragm, cervical cap). EIAEDs reduce the contraceptive efficacy of levonorgestrel implant but not with intramuscular medroxyprogesterone. It is recommended that injections be administered every 10 weeks instead of the usual 12 weeks for WWE. If the “morning after pill” containing levonorgestrel postcoital contraception is used after unprotected sexual activity, some practitioners recommend that the first dose should be doubled to two pills. IUDs that contain progestin or Mirena coil that secrete levonorgestrel hormone locally and copper IUDs are not known to be affected by EIAEDs. The rhythm method is not a reliable method of birth control for WWE. EIAEDs also affect the efficacy of transdermal contraception. There is no additional risk of OC failure with non-EIAEDs. AEDs that do not induce cytochrome P450 3A4 enzymes include VPA, GBP, LEV, tiagabine (TG), vigabatrin (VG), zonisamide (ZON), and pregabalin (PG). Vagal nerve stimulators, which are used in refractory epilepsy, have no effect on sex hormone metabolism.

There is a special situation where seizure exacerbation may occur among women taking lamotrigine and OCs (55). It has been found that lamotrigine levels, when adjusted for dose and body weight, were found to be reduced by 50% in a group of 22 women taking lamotrigine and an OC that combined ethinyl estradiol and levonorgestrel compared with women taking lamotrigine alone. Further evaluation of this interaction has shown that it is the ethinyl estradiol component that produces the interaction; the progestin component has no effect on lamotrigine levels. The mechanism of this interaction is the induction of uridine diphosphate-glucuronyl-transferase 1A4 by ethinyl estradiol, which is the main metabolic enzyme for lamotrigine. The lamotrigine–OC interaction is further complicated by the risk that lamotrigine levels will increase during the OC placebo or pill-free week, which in most regimens occurs every fourth week. There are reported increase in lamotrigine levels of 27% on the 3rd placebo day, 63% on the 5th, and 116% on the 7th placebo day relative to lamotrigine levels during OC administration. There is also a bidirectional interaction for OCs and lamotrigine, in which lamotrigine was associated with a small decrease in levels of progestin, levonorgestrel, by 12% (54–56).

Sex Hormones, Reproductive Function, and Seizures

To understand the far-reaching effects of epilepsy and AEDs on hormones and vice versa, the reader must review the normal physiologic mechanisms of the hypothalamic–pituitary–gonadal axis (HPGA). In the female, the gonadotropin-releasing hormone (GnRH) is secreted by the hypothalamus. This stimulates the anterior lobe of the pituitary leading to the release of the follicle-stimulating hormone (FSH) and the luteinizing hormone (LH). FSH and LH, in turn, stimulate the formation of ovarian follicles, hence stimulating the release of estrogen (estradiol). This phase is the follicular or preovulatory phase; the phase occurs when LH stimulates the preovulatory follicular theca cells to secrete androstenedione, which aromatizes into estradiol. Estradiol binds to the SHBG, a glycoprotein that acts as a carrier in the bloodstream. This feeds back to the hypothalamus with high levels of estrogen; the hypothalamus increases the release of GnRH, which increases the amount of LH and FSH. A spike of FSH and LH from the pituitary results in ovulation and the follicle transforms into the corpus luteum. This marks the luteal phase in which the corpus luteum produces both estrogen and progesterone. Progesterone feeds back to the hypothalamus and inhibits GnRH secretion and thus the decrease in FSH and LH from the anterior pituitary. As the corpus luteum breaks down, the inhibition of the hypothalamus lessens and the cycle begins again (57).

There is an interaction between steroid sex hormones (estradiol, progesterone) and neurons. Estrogen is known as a proconvulsant and progesterone, a potent anticonvulsant. Overall, the ovarian sex steroids act at the level of the neuron in the CNS and alter the frequency and severity of seizures. It has been shown in WWE that intravenous administration of conjugated estrogens activates epileptiform discharges and may result in seizures. Estradiol also potentiates glutamate receptor-mediated excitatory post-synaptic potentials and excitatory post-synaptic currents on hippocampal CA1 pyramidal cells. Progesterone exerts an inhibitory effect via metabolites such as allopregnanolone, which is a GABA-A-receptor-modulating neurosteroid. Progesterone increases seizure threshold and also has anti-anxiety and sedating effect. The effect of sex hormones and neuronal excitability may explain the pattern of seizure exacerbation during menstruation. Seizures have been reported to occur in a cyclic pattern in between 5% and 70% of WWE, for example, catamenial epilepsy. About 35% of WWE will have significant (> two times) increase in seizure frequency around menstruation. Women with localization-related epilepsies may have an increase in seizures at the time of menarche. Treatment with progesterone may be helpful and the average decline in seizure frequency is about 55%. The possible side effects of progesterone treatment include sedation, depression, weight gain, breast tenderness, and breakthrough vaginal bleeding. This is managed by discontinuing the progesterone or lowering the dose (57).

WWE are at risk for altered neuroendocrine regulation (56,57). Epilepsy can affect the various aspects of sexual and reproductive functioning. The most common symptoms are hyperandrogenism, menstrual disorders, ovarian failure, polycystic ovary syndrome (PCOS) with or without divalproex (VPA) therapy, hyperinsulinemia, and weight gain especially with VPA therapy. An unusually high number of WWE will

have some degree of sexual or reproductive dysfunction, which can include difficulty with libido, arousal, orgasm, and menstrual irregularities. Menstrual disturbances are more frequent with epilepsy as compared with women without epilepsy. This is particularly common with temporal lobe epilepsy. About 30% to 50% of women will have menstrual irregularities, reduced fertility, irregular bleeding, and anovulation. Aside from catamenial epilepsy, another reproductive hormone-related disorder in WWE is PCOS. It is characterized by polycystic ovaries on ultrasound, hirsutism, obesity, acne, endocrine disturbance, elevated LH/FSH ratio, chronic anovulation, and increased risk of endometrial cancer and breast cancer (54). The prevalence of PCOS in the general population is approximately 17% to 22% of women. Up to 15% of females with primary generalized or partial seizures may exhibit features of PCOS. With the frequent disruption of the normal function of the HPGA caused by ictal and interictal epileptiform discharges, a whole cascade of events happens. The LH/FSH rates are elevated, and follicular maturation is disrupted leading to elevation in androgens, leading to hyperandrogenism. The fertility rate of WWE is about 60% to 80% of the normal population, the major contributing factor being PCOS. Anovulatory cycles are more frequent in women with idiopathic generalized epilepsy and those taking VPA. The management of PCOS should be symptom focused and individualized, such as encouraging weight loss if body mass index $>25\text{kg/m}^3$ or fasting glucose tolerance is above normal and the insulin level is elevated. Hirsutism can be managed by laser treatments, electrolysis, waxing, and bleaching to improve hair growth. Hyperandrogenism can be treated with a combination of estrogen only and combined contraceptives, which are used in the first 21 days of the menstrual cycle and antiandrogen acetate (50–100mg), used for the first 10 days of menstruation. OCs are useful in adolescents to prevent unwanted pregnancy but may worsen insulin resistance associated with PCOS. Spironolactone with antiandrogenic properties can be tried in young women where oral contraception is contraindicated (54).

AEDs and Teratogenicity

Rates of congenital malformations range from 2.3% to 18.6% (combined risk about 7%) in infants of WWE versus 2% to 3% in the general population (58–65). Estimates of risk vary, but a recent study indicates 4.5% frequency for AED monotherapy in utero exposure and 8.6% for AED polytherapy. The most common major congenital malformations are heart malformations (e.g., ventricular septal defect), urologic defects Z (e.g., hypospadias), skeletal abnormalities (e.g., radial ray defects, phalangeal hypoplasia), and NTDs (e.g., spina bifida) (58–65). Congenital malformations are physical defects that warrant medical or surgical intervention and cause major functional problems. Most major and minor malformations have been reported with the older AEDs such as PHT, CBZ, PB, and VPA largely because they are the most widely used AEDs globally. Exposure in the first trimester poses the highest risk. Barbiturates have been found to be associated with major congenital malformations. PHT has been associated with facial clefts, congenital heart defects, and urogenital defects. There have also been reports of dysmorphic facial features and distal phalangeal hypoplasia with PHT. CBZ has been associated

with NTDs, heart defects, hypospadias, hip dislocations, and inguinal hernia. PHT, CBZ, and PB are folic acid antagonist, so their teratogenicity may be attributable to their folate deficiency. VPA has been shown to carry a high risk of spina bifida aperta, cardiovascular complications, urogenital malformations, and skeletal defects. Association of VPA with congenital defects is dose dependent and is most likely when VPA is used with polytherapy and monotherapy above the doses of 1000mg/day. Minor anomalies are deviations from the normal morphology, but do not threaten health, impair function, or require intervention. Examples include hypertelorism (widely spaced eyes), low set ears, and distal phalangeal hypoplasia. Minor anomalies occur at a rate of up to 30% in the offspring of WVE taking AEDs versus 15% in newborns of matched controls without epilepsy.

Knowledge of the effects of newer generation AEDs is incomplete. Data on GBP, OXC, PG, TG, and TPM are very limited. One study did find an association between OXC and a major malformation. LTG has the most data available at this time, primarily from the Lamotrigine Registry and the UK Epilepsy and Pregnancy Registry. When LTG and VPA are given together, there is a higher frequency of major malformations. Emerging data from a pregnancy registry suggest an association between LTG and nonsyndromic oral cleft lip/palate 24 times greater than expected. Data on ZON are quite limited. Very few pregnancy outcomes have been reported with LEV, but it has been speculated that LEV may have a favorable profile for pregnant women because it has <10% protein binding and is eliminated primarily via renal excretion and extrahepatic hydrolysis. Renal blood flow increases in early pregnancy and persists throughout; LEV elimination has been found to be enhanced with this increased renal blood flow. Preliminary studies have noted a good pregnancy safety profile with LEV; however, more data are needed before it can be said to be non-teratogenic.

There are different pregnancy registries in epilepsy with varying results in the rate of major malformations (58). The North American Registry with over 3000 women enrolled while having AED during pregnancy has reported that PB (6.5%) and valproate (10.7%) have increased rates for major malformations. There is also a specific risk for cleft lip/palate (0.89%) for lamotrigine and CBZ (0.57%). The UK registry with 3607 pregnancy outcomes found higher major malformation rate for valproate (6.2%) and increased risk for lamotrigine at higher dose. LEV was associated with major malformation in 2.7%. The Australian Registry with 555 outcomes reported malformations in 5% of live births and additional 1% in induced abortions. Valproate monotherapy in the first trimester at doses above 1100mg/day was associated with significantly higher risk (38.5%) of malformations than other AEDs, which were 3.8% for CBZ, 0% for lamotrigine, and 5.9% for PHT. Both the Swedish and Finnish Birth Registries reported higher malformation rates for valproate. Valproate effect was dose dependent in the Finnish study. The International Lamotrigine Pregnancy Registry reported 2.9% risk for malformation, which was not dose dependent.

Animal studies have demonstrated that in utero AED exposure can produce behavioral defects at dosages lower than those required to produce somatic malformation (59,61,63,65). Cognitive studies in humans are less clear.

There has been no evidence that children exposed to CBZ produced IQ impairment or autistic spectrum disorder. By contrast, valproate in utero exposure was associated with lower IQ scores and impairment of verbal/language skills. The effect of valproate was dose dependent. Prospective population-based studies give no definite evidence that CBZ or PHT fetal exposure impair intelligence. Data on fetal PB exposure are insufficient. AED polytherapy in utero exposure results in higher risk for cognitive/behavioral teratogenesis. There is no information to suggest whether some combination would be safer or more hazardous than others, except that polytherapies with valproate appear to be at higher risk. Overall, polytherapy is associated with more negative effects on cognitive functioning than monotherapy.

The mechanism underlying adverse AED effects on development is uncertain. Teratogens interact with genotype to produce both anatomic and behavioral defects (59). Whether a defect occurs depends on susceptible genotype and may involve interaction of multiple liability genes. Proposed mechanisms underlying teratogenicity of AEDs include folate, ischemia, neuronal suppression, reactive intermediates (e.g., epoxides or free radicals), and AED-induced neuronal apoptosis. Neuronal dysfunction short of apoptosis or migration disorders may also contribute. Mechanisms of anatomic and behavioral teratogenesis may well differ since it appears that anatomic defects result from first-trimester AED exposure while behavioral defects arise from third-trimester exposure. A leading hypothesis of anatomic teratogenesis involves oxidative macromolecular damage from free radicals formed as reactive intermediates of AED metabolism. AED-induced apoptosis has been proposed as a possible mechanism for the behavioral deficits. Widespread neuronal apoptosis in animals occurs as a result of exposure to clonazepam, diazepam, PB, PHT, VG, or valproate in neonatal rats. The effect is dose dependent, occurs at therapeutically relevant blood levels, requires only a relatively brief exposure, and can be synergistic suggesting possible increased polytherapy risk. Similar apoptotic effects were not seen at therapeutic dosages for CBZ, LEV, lamotrigine, or TPM monotherapy. Further, fetal exposure of GABAergic AEDs such as valproate and VG can result in hippocampal and cortical dysplasia secondary to impaired migration and neuronal death.

Folate Supplementation

Folate is a water-soluble coenzyme that occurs naturally in food (e.g., green leafy vegetable, dried beans, fruits). In addition, fortified foods like ready-to-eat cereals are fortified with 100% of the recommended daily allowance for folate. Even so, most women do not consume enough folate that is provided in supplements and added to fortified foods. Folate helps produce and maintain new blood cells and is necessary for proper CNS development. This is especially important during periods of rapid cell division and growth as early in the first trimester of pregnancy. Folate-deficient women who become pregnant are at greater risk of giving birth to lower birth weight premature infants. Folate deficiencies have been implicated in the development of certain birth defects, particularly NTDs. Neural tube closure occurs at about day 26 of pregnancy, often before a woman is aware that she is

pregnant. Neural tube and cardiac defects occur in the first 28 days following conception, so folate supplementation should begin before conception is attempted and continue throughout the pregnancy. If folate supplement is begun more than 30 days after conception, it will not provide protection against NTD. About 40% to 50% of pregnancies with epilepsy are not planned and, hence, it is reasonable to recommend routine use of folate supplement for any women of child-bearing age considered to be at risk for pregnancy. Evidence is mounting that folic acid protects developing fetuses against NTDs. There have been studies that have failed to demonstrate a neuroprotective effect for periconceptual folate supplementation. Folic acid supplementation may enhance PHT metabolism and thus lower PHT blood levels, placing women at risk for breakthrough seizures. EIAEDs have been shown to decrease serum folic acid levels by increasing the metabolism of circulating folic acid. The appropriate dosage for folate is probably dependent on a variety of factors including AED/no AED therapy, whether AED is taken, maternal age, and other concurrent medication. For any sexually active woman of childbearing potential, recommended daily allowances of folic acid have been increased to 400 µg/day for nonpregnant women, 600 µg/day for pregnant women, 600 µg/day for pregnant women and those contemplating pregnancy, and 500 µg/day for lactating women. Many epileptologists recommend higher doses (800 µg/day to 4 mg/day) for WWE. In most cases, folate intake should not exceed 1000 µg daily to avoid provoking seizures or masking the hematologic effects of B₁₂ deficiency and pernicious anemia. However, for women with a family history of NTDs, 4 mg/day is the recommended dosage and vitamin B₁₂ levels should be checked (54).

Epilepsy Care During Pregnancy

WWE can be reassured that having epilepsy should not prevent them from having children. About 1 million WWE in the United States are of childbearing age, and about 20,000 babies are born to WWE each year. It is probably not helpful to change an AED during pregnancy with the goal of using a less teratogenic drug, because of the critical phases of embryologic development occur very early in pregnancy. Despite the increased risk of maternal and fetal complications, around 90% of pregnant WWE deliver healthy newborns. Close medical care, however, is essential. A multidisciplinary approach is recommended, involving a patient's primary care, an obstetrician who specializes in high-risk pregnancies, and a neurologist (60).

EPILEPTIC SEIZURES DURING PREGNANCY

Epilepsy per se does not pose a teratogenic risk. Most WWE have no change in seizure frequency during pregnancy or even develop fewer seizures. Only 15% to 33% have more seizures during pregnancy (51,66–68). AED pharmacokinetics is altered during pregnancy. Serum drug concentrations are reduced by increasing maternal blood volume, a phenomenon that reaches its nadir at term (69,70). However, seizure frequency increases as early as the first trimester and not necessarily around term, so reduced AED levels only partially explain the phenomenon. Hormonal changes may also contribute: the ratio of estrogen (which lowers seizure threshold) to progesterone (which raises seizure threshold)

increases during pregnancy reaching its peak between weeks 8 and 16. Other factors that may contribute to a lower seizure threshold include stress, anxiety, and sleep deprivation. Also some women stop therapy because of the fear of teratogenic effects. Generalized tonic clonic seizure during pregnancy can result in fetal intracranial hemorrhage, transient fetal bradycardia, heart beat variability, fetal hypoxia, and stillbirth. Status epilepticus resulted in 30% maternal mortality and 50% infant mortality. There is no evidence that non-convulsive seizures during pregnancy adversely affect outcome apart from trauma.

Therapeutic Drug Monitoring During Pregnancy

Several published guidelines recommend monitoring serum AED concentration at the beginning of every trimester and 1 month after delivery (69,70). Monitoring *free* drug concentration has been recommended for both highly and moderately protein bound drugs such as PHT, PB, CBZ, and sodium valproate. Additional monitoring should be considered if adverse effects or poor seizure control are seen, or if non-adherence is suspected. In view of the large inter- and intra-individual variation of drug concentrations, some have recommended monthly serum AED concentration monitoring, particularly for lamotrigine. Since well-defined therapeutic ranges have not been established for the newer AEDs, including lamotrigine, it is suggested that an optimal therapeutic range should be established for each particular individual before conception and that this be used to guide dosage adjustment during pregnancy. Identifying an individual therapeutic range prior to pregnancy is similarly useful for older AEDs, as the clinical response to similar doses and serum drug concentrations can be highly variable. If AED doses have been increased during pregnancy, they should be readjusted after delivery, as concentrations normalize quickly in the postpartum period. At this time, AED toxicity may occur and serum concentrations may be a useful guide for reestablishing the correct dose.

By contrast, the unpredictability and variability of serum drug concentration have prompted others to recommend a more conservative approach, with alterations in dosage being made on clinical grounds. The practical limitations of free drug concentration monitoring and lack of a population target range make adjustments made on clinical grounds a more attractive and pragmatic approach. In fact, current evidence has failed to show that routine adjustment of AED doses during pregnancy based on serum concentration improves seizure control. There are no studies comparing seizure control in pregnancy in those with serum monitoring and those without. Additionally, increases in dose may potentially harm the fetus. While most changes in the dose are made in the second and third trimesters of pregnancy, when organogenesis is complete, there is concern that the potential longer term adverse effects of AED exposure in utero may be more likely to be related to exposure in the latter half of pregnancy. Women should have the opportunity to discuss the pros and cons of routine AED dose adjustment, and their views of the relative risk of seizures and potential adverse fetal outcomes should be taken into account. In practical terms, routine monitoring of serum AED concentration in pregnancy is not useful unless directed at answering a specific clinical question.

For example, if seizures increase or are likely to increase, serum AED concentrations may be useful to plan or anticipate the extent of the change (69).

Prenatal Screening for Fetal Malformations

All WWE should be offered prenatal screening for fetal malformation: maternal serum alpha-fetoprotein testing at 14 to 16 weeks of gestation and structural ultrasonography at 16 to 20 weeks of gestation (51). Performed together, these tests have more than 95% sensitivity in detecting open NTDs. Patients with equivocal results should undergo amniocentesis, which increases the sensitivity to more than 99%. Cardiac anomalies can also be diagnosed prenatally with detailed sonographic imaging of the fetal heart (18–20 weeks of gestation), which is 85% sensitive. The accuracy of ultrasonography for the prenatal diagnosis of cleft lip is less well established. The screening test has inherent ethical implications and may lead to difficult choices if a problem appears to be present.

Vitamin K Supplementation

Some case series have found that newborns exposed to EIAEDs have a higher risk of hemorrhagic disease of the newborn, a condition that has a mortality rate of up to 30%. When it occurs, bleeding usually happens within the first day of life and affects internal organs such as the lungs, abdomen, and brain. It is not clear whether the alteration of vitamin K metabolism caused by some AEDs is the only mechanism at work.

It is suggested that oral vitamin K supplementation at 10 to 20 mg/day be prescribed during the last month of pregnancy and 0.5 mg administered intramuscularly immediately after delivery for WWE. This is particularly important for women taking EIAEDs. Vitamin K is recommended for all neonates at birth; however, neonates born to WWE should be monitored for bleeding. The recommended dosage for neonates is 1 mg intramuscularly or intravenously at birth. If a woman has not taken vitamin K before beginning labor, it can still be administered during labor (51,53).

Labor and Delivery

About 95% of WWE have a safe vaginal delivery, without a seizure during, or in the 24 hour following, delivery (51,53). Women with generalized epilepsy are more at risk for seizures during delivery than are those with partial epilepsy. It is important to remind WWE to bring their AEDs to the hospital during labor and to take regular doses during this period under the supervision of hospital staff. Subtherapeutic or barely therapeutic AED concentrations can be a cause of seizures during labor and delivery. Intravenous or intramuscular AEDs may be needed if the woman is not able to keep down oral medication. Sleep deprivation can provoke a seizure, so in some cases, obstetric anesthesia may be indicated prior to delivery. WWE are more likely than the general population to have labor induced, although epilepsy is not an indication for induction. Cesarean sections and mechanically assisted delivery are also more common in WWE.

Epilepsy Care After Pregnancy

Postpartum Care and Breast-Feeding

New mothers with epilepsy should be encouraged to breast-feed their babies. Most experts believe that the benefits to the mother and baby outweigh the risk (54,67). All AEDs cross into breast milk, but only the free fraction—that which is not bound to maternal serum binding proteins—is available to cross. Breast-feeding conveys substantial benefits to the infant, and these benefits to the mother and infant outweigh any risk from AED exposure. AED concentrations in breast milk are far less than maternal serum levels; however, serum half-life of AEDs is longer in the neonate than in the mother. Nevertheless, the American Academy of Neurology supports breast-feeding for infants whose mothers are taking AEDs. Caution is advised if the mother is treated with PB, ESM, or PRM. For infants of women taking high-dose LTG, drug levels and adverse events in the infant should be monitored. Parents should alert their pediatricians if increased lethargy is noted. When the baby is born, an appointment for a neurologic evaluation should be made for age 4 to 6 weeks (67).

AED levels should be monitored closely in the weeks following delivery. During this period, AED levels may increase gradually. The increase in postpartum plasma levels of EIAEDs starts about 10 to 14 days postpartum. The levels of drugs that are excreted renally such as LEV, OXC, and LTG increase within days of delivery. Thus, some women require dose adjustment immediately following delivery.

Parenting Issues and Safety

WWE need to organize their lives to minimize fatigue in the weeks following delivery in order to minimize the occurrence of seizures precipitated by fatigue. They may also have an increased risk for breakthrough seizures due to stress. Napping is encouraged and asking help from other adults to do nighttime feedings can help with fatigue. For women who are breast-feeding, this can be accomplished either with expressed breast milk or with supplementary formula.

Each woman needs to assess her particular seizure pattern and to make appropriate arrangements for her own safety and that of her baby. For example, if her seizures make her fall, she may wish to rely on a stroller or carriage in the house rather than carrying the infant. If she tends to drop things, perhaps a baby harness is appropriate. Baby care such as changing diapers and clothing can be done on a blanket on the floor rather than on a high changing table, especially during the immediate postpartum period when AED levels fluctuate. A second person should be present during baths to avoid the danger than even a momentary lapse in alertness can pose (54).

MOVEMENT DISORDERS AND PREGNANCY

Disorders of human motor control are common neurologic problems. Although the majority of these disorders are more common in the older postmenopausal age groups, a few can be seen in women of childbearing age. Human motor control is achieved through complex interactions of many CNS regions but intimately involve regions of the brain known as the basal ganglia. The basal ganglia utilize a variety of neurotransmitters to achieve the desired sequencing of motor activity and

production of normal movement. The effects of progesterone and estrogen on the basal ganglia are unclear as experiments with rat models have produced improvement in dopamine function, whereas in humans either no effect or deleterious effects have been reported (71,75).

Rarely, abnormal movements known as choreas appear during gestation, typically following the first trimester known as chorea gravidarum. The chorea is generally seen only on half of the body and is known as a hemichorea. The incidence is said to be 1:139,000 pregnancies (76). It was previously associated with rheumatic fever; however, in the United States, the virtual elimination of this disorder has made this association less likely. More often now, it is linked to systemic lupus erythematosus or anti-phospholipid antibody syndrome (77,78). The chorea typically resolves spontaneously, often after delivery. Rarely, the movements are so severe as to induce rhabdomyolysis and hyperthermia (79). Treatment is typically by using dopamine receptor blockers. Due to concerns involving the fetus, haloperidol is preferred since of all of the medications available, it is the least likely to cause harm (80). Similar choreiform movements may occur following institution of birth control pills as well. These typically resolve after discontinuation of OC pills.

Dystonias

Dystonias are uncommon disorders that involve sustained muscle contraction and abnormal posturing. They can be associated with twisting and repetitive movements as well (81). Only very rare cases of dystonias being induced by pregnancy exist (authors' personal experience). More often, a preexisting dystonia may be seen to complicate pregnancy or delivery. The majority of medications used to treat dystonias have a high probability of being associated with fetal malformation; however, the exception to this is dopa-responsive dystonias treated with levodopa. Although experience with this levodopa in pregnancy is limited, small series and case reports published to date do not suggest any fetal malformations occurring while the mother is taking this medication (75). More recently, botulinum toxin injections have been used, and occasional case reports (82) suggest that this treatment is effective for the mother, and not harmful to the fetus.

Essential Tremor

Essential tremor is the most common movement disorder in the general population and is frequently seen in younger patients. This movement disorder more likely than any others to be encountered by a treating obstetrician. It involves action tremors of the hands, head, voice, and occasionally legs or trunk, and frequently runs in families. The tremor occurs when the patient is using the extremity; however, the head tremor occurs with any upright posture. There is no other impairment of neurologic function or cognition. The disorder follows a benign course and is generally only socially disabling; however, in more severe cases, it can be very difficult to eat or write. The most effective treatment for this disorder involves the use of PMD and propranolol. Other medications have been used with varying success. Given the unclear danger to the fetus of these medications, as well as the benign nature of the disorder, it is probably wise to counsel the mother to take no

medication for this condition while she is pregnant or breast-feeding. If the mother's tremor is so severe that it precludes reasonable normal daily function, the choice of medications should be discussed between the obstetrician and the neurologist to determine which medication is felt to be least likely, at that time, to cause harm to the fetus and most effective for that patient.

Tourette's Syndrome

Tourette's syndrome is also quite common, and since it begins in childhood, this disorder will be frequently seen in the obstetric population. Tourette's syndrome involves the combination of motor and vocal tics, which evolve and fluctuate over time. A tic is a brief un-voluntary movement or sound that can include throat clearing, coughing, sighing, or making sounds or words. The tics can be suppressed voluntarily but take a great deal of effort from the patient to do so. For this reason, they are called un-voluntary rather than involuntary. Patients with Tourette's syndrome also frequently have attention deficit disorder and obsessive–compulsive disorder. The tics typically respond to dopamine receptor blockade, and haloperidol is a very effective treatment. As discussed previously, this medication is felt to be the safest choice for the fetus (80).

Huntington's Disease

Huntington's disease occasionally presents during child-bearing years, although classically presents in the patients' 30s or 40s at a time when many women have already had children. Although not caused or necessarily exacerbated by pregnancy, the Huntington's patient presents several unique challenges. The first is treatment of a pregnant patient with significant symptoms. The symptoms of Huntington's disease include chorea, dementia, and psychiatric disorders. All treatment is symptomatic, as no neuroprotective or preventive therapies currently exist. The safest option for treatment of chorea or psychosis is dopamine blockade using haloperidol and the treatment for depression felt to be least harmful for the fetus is fluoxetine (80). A more common scenario is that a woman who has already delivered children will later develop the symptoms of Huntington's disease. The disorder is an autosomal dominant genetic disease that can be predicted by an expanded CAG repeat in the region that codes for the Huntington protein on chromosome four. Adult patients with symptomatic parents have the option of genetic testing to determine whether they will develop this disease, although not all will choose to do so. Genetic testing should not be carried out lightly, and the physician ordering this test must be prepared to properly counsel the asymptomatic adult patient. This responsibility is usually best carried out by a neurologist with expertise in Huntington's disease or a geneticist. The children of an affected parent have a 50% chance of developing the disorder, and some parents choose to proceed with pregnancy whether or not they expect to develop the disease themselves (83). For the affected patients who choose not to conceive naturally, techniques for artificial insemination or in vitro fertilization of donor ova could be considered as appropriate.

Parkinson's Disease

Because Parkinson's disease is more common over age 50, it is only rarely found in the age group likely to conceive children. Very little experience exists with this condition in the reproductive age group, although a small series (84) of patients suggests that levodopa is not associated with any significant fetal malformations or birth problems. Other anti-parkinsonian medications appear to be associated with variable risks to the fetus in many cases and probably should be avoided if at all possible (80). Parkinson's disease is a neurodegenerative disorder that generally begins with increased muscle tone or resting tremor on one side of the body progressing to the other side over a variable length of time. Gait problems and significant problems with activities of daily living and self-care are later findings. Young people with Parkinson's disease often have a more aggressive progression of disease, but hopefully would be able to be adequately maintained throughout pregnancy on levodopa monotherapy. Consultation with a movement disorder neurologist would be very helpful with this patient group.

Wilson's Disease

Wilson's disease is a very rare disorder involving disordered copper metabolism. Clinically, there is a wide variability in the age of onset as well as presentation. In children, it more commonly presents with symptoms of liver disease, but in young adults psychiatric or movement disorders tend to predominate. The clinical picture consists of liver cirrhosis, a wide variety of abnormal involuntary movements, and psychiatric illnesses. The most common treatment for this disorder is the copper chelator penicillamine, which is known to be teratogenic. Trientine is another chelating agent sometimes used, but may also be associated with fetal malformations. More recently, the therapy with zinc acetate has been shown to be effective in the treatment of Wilson's disease (85), and a small case series suggests only a mildly elevated birth defect rate compared with the general population (86). The authors of that paper conclude that zinc acetate is a preferable treatment for Wilson's disease in pregnant women.

In this section, we have reviewed movement disorders that appear to have a direct link with sex hormones as well as those that are preexisting and may change their manifestations during pregnancy or otherwise complicate pregnancy in some fashion. Movement disorders induced by pregnancy are rarely seen, and the majority of experience is from cumulative case reports from many authors. The rarity of these disorders in the childbearing age group makes it unlikely that any single physician will have much experience with the management of these conditions during pregnancy, and referral to a movement disorder neurologist would be appropriate.

STROKE AND PREGNANCY

Cerebrovascular disorders, which include ischemic and hemorrhagic stroke, are an uncommon but feared complication of pregnancy contributing to 5% to 12% of all maternal deaths (87). Eclampsia occasionally shares presentation similar to stroke but importance of prompt recognition of either cannot be overemphasized. For the sake of clinical management, the issue of stroke in pregnancy has been divided into

cerebrovascular risk factors before pregnancy, during pregnancy, and in immediate puerperium.

Stroke Risk Before Pregnancy*Contraception in Relation to Stroke*

Contraceptives containing more than 80µg of estrogen are linked to increased risk of stroke. This risk increases for hemorrhagic stroke if smoking is combined with estrogen intake.

Stroke Risk During Pregnancy

Incidence: Though studies have shown variable rates, most agree (88) that risk of cerebral infarction is the same in pregnancy as compared with age-matched controls though risk of intracranial hemorrhage is about 2.5 times higher during pregnancy. Witlin et al. reviewed the incidence of stroke in pregnancy and only reported 20 strokes in 130,000 women who delivered over a period of 10 years (88). Overall, for either type of stroke during or within 6 weeks after pregnancy, the adjusted relative risk is about 2.4 (95 % confidence interval, 1.6 to 3.6), and the attributable, or excess, risk is 8.1 strokes per 100,000 pregnancies (95% confidence interval, 6.4 to 9.7). The prevalence of hypertension, diabetes mellitus, and current smoking was found to be lower among pregnant women with stroke than among nonpregnant women with stroke in Baltimore–Washington Cooperative Young Stroke Study (89).

Pregnancy As a Risk Factor

Pregnancy is a relatively hypercoagulable state with markedly increased levels of fibrinogen, total body, and plasma levels of factors VII, X, and XII. The increased activity of factors of hemostasis is accompanied by an increase in activity and concentration of ATIII and acquired activated protein C resistance predisposing to thromboembolic events (90).

Many other physiologic changes occur in pregnancy that may impact the pathogenesis and management of stroke during pregnancy (91). Blood pressure decreases during the second and third trimesters due to decreased peripheral vascular resistance. Cardiac output, systemic blood pressure, and vascular resistance contribute to cerebral perfusion. Dramatic shifts in hemodynamics coupled with alterations in coagulation profile underscore the clinical significance of the physiologic adaptations in cerebral endothelial permeability and pressure. Middle cerebral artery perfusion pressure has been shown to increase steadily during gestation.

Presentation

The clinical features of arterial ischemic strokes during pregnancy are not unique, except for those of eclampsia-associated ischemic strokes, which comprise seizures and/or impairment of consciousness, in addition to focal deficits. CVT presents with a wide spectrum of symptoms and signs and can be confused with other diseases, in particular with eclampsia, encephalitis, intraparenchymal hemorrhage, and even with post-lumbar puncture headache. The differential diagnosis of hemorrhagic strokes includes eclampsia, pituitary necrosis, and CVT. It is noteworthy that hypertension and albuminuria, two main features of eclampsia, have been observed in about a third of intracranial hemorrhage caused by a ruptured vascular malformation during pregnancy (92).

Table 1 Causes of stroke in pregnancy

Generic causes of stroke during pregnancy	Causes of stroke unique to pregnancy
Premature atherosclerosis	Eclampsia
Hypertension	Caesarean delivery (88)
Cardiac disease	Choriocarcinoma
Hyperlipidemia	Postpartum cerebral angiopathy
Diabetes	Postpartum cardiomyopathy
Arterial dissection	Amniotic fluid embolus during labor
Takayasu's disease	<i>Associations of stroke in pregnancy</i>
Vasculitis	Migraine headache
Antiphospholipid antibody syndrome	Blood transfusion
Systemic lupus erythematosus	Anemia
Sickle cell disease	Age more than 35 years
Thrombotic thrombocytopenic purpura	Non-white race
Coagulopathies	Bromocriptine mesylate (used in postpartum for suppression of lactation)
Tobacco	Methylergonovine maleate (used in postpartum hemorrhage caused by uterine atony)
Cocaine or drug abuse	
Thrombophilic states	
Protein C and S deficiencies	
Antithrombin III deficiency	
Factor V Leiden mutation	
Hyperhomocysteinemia	
Mutations in the prothrombin gene	
Lupus anticoagulant	
Anticardiolipin antibody	

Etiology of Stroke

Causes of stroke in pregnant females are usually the same as causes in nonpregnant females. Though associations of migraine headaches and blood transfusion have been suggested, their exact etiologic role is unclear (87). Transfusion increased the risk of stroke more than 10-fold. Although the need for transfusion is increased in conditions that place a woman at an increased risk of stroke, such as severe pre-eclampsia, postpartum hemorrhage, and sickle cell anemia, transfusion itself may be a risk factor for stroke. Storage and preservation of red blood cells increases their aggregability, possibly increasing the risk of thrombosis (87). Age greater than 35 years and African-American race have also been found to be significant risk factors. Eclampsia is the main pregnancy-specific cause, which may be associated with focal neurologic deficits of sudden onset, consistent with a clinical diagnosis of stroke. The two other pregnancy-specific conditions (choriocarcinoma and amniotic fluid embolism) are rarely responsible for focal cerebral ischemia. Table 1 lists the causes of stroke in pregnancy grouped under generic causes, pregnancy specific causes, and associations of stroke in pregnancy that may not necessarily have an etiological role.

Pregnancy-Related Complications

Gestational diabetes and hypertension are both associated with increased risk of stroke (93).

Complications of pregnancy such as severe pre-eclampsia, eclampsia, infection, hyperemesis, and fluid and electrolyte imbalance are significant risk factors for pregnancy-related stroke (87).

Pre-eclampsia and Eclampsia

Pre-eclampsia is known to be an important risk factor for pregnancy-associated stroke. One-fourth of the

pregnancy-related infarcts are associated with eclampsia or pre-eclampsia. The hypercoagulable state of normal pregnancy is further potentiated in pre-eclampsia. There is increased expression of procoagulant proteins, such as tissue plasminogen activator, PAI1, von Willebrand factor, fibronectin, homocysteine, and thrombomodulin, and reduced levels of anticoagulant proteins, including antithrombin III, protein C, and protein S in women with pre-eclampsia (93). Beyond increasing risk of stroke during pregnancy, women with pre-eclampsia were 60% more likely to have a stroke in the months and years that followed their pregnancy.

Neurologic features of the pre-eclamptic–eclamptic syndrome include headaches, visual abnormalities owing to retinal or occipital lobe lesions, impairment of consciousness, seizures, or focal deficits of sudden onset (92). The clinical and neuroimaging findings are more consistent with edema, which is thought to result from a rapid increase in blood pressure with vasospasm of cerebral arterioles, subsequent loss of autoregulatory capacity, and disruption of the blood–brain barrier. Angiograms in patients with eclampsia have also shown segmental narrowing consistent with vasospasm of large and medium-sized cerebral arteries. Several causes of altered vascular reactivity, including increased sensitivity to normally circulating pressor agents, deficiency of vasodilating prostaglandins, and endothelial cell dysfunction, have been reported in eclampsia. MRI in pre-eclampsia or eclampsia may show nonspecific hyposensitivities in posterior regions, finding often labeled as posterior reversible encephalopathy syndrome.

Ischemic Stroke

During pregnancy, risk of cerebral infarction is the same as age-matched control subjects. Exacerbations of systemic lupus

erythematosus and Takayasu's disease may occur during pregnancy and may manifest as ischemic strokes. Pregnancy is classically associated with an increased risk of rheumatic disease recurrence.

Antibiotic prophylaxis has been advocated for all pregnant patients with a history of rheumatic fever, especially those with a history of rheumatic heart disease. The high risk of thromboembolism in gravid patients with prosthetic heart valves emphasizes the need for effective anticoagulation throughout the pregnancy, despite the potential fetal and maternal adverse effects of this treatment. Bioprosthesis do not seem to be associated with an increased risk of thromboembolism during pregnancy and may not require anticoagulant therapy.

Hemorrhagic Stroke

Eclampsia and ruptured vascular malformations are the most frequent causes of intraparenchymal hemorrhage (92). The risk of hemorrhagic stroke during pregnancy is more than the risk of ischemic stroke though it increases further 6 weeks postpartum. Common associations of intracranial hemorrhage in pregnancy are eclampsia, bleeding diathesis, cocaine, bacterial endocarditis, sickle cell disease, and metastatic choriocarcinoma. Aneurysmal subarachnoid hemorrhage may be life threatening and warrants urgent correction.

AVMs

The increased tendency of an aneurysm to bleed with advancing gestational age suggests that hemodynamic, hormonal, or other physiologic changes of pregnancy may play a role in aneurysmal rupture (92).

Risk of hemorrhage from an unruptured AVM is estimated to be around 3.5%. The optimal time to wait to conceive after surgical correction is controversial. For previously ruptured AVMs, risk of hemorrhage outweighs risk from surgical corrections. Surgical treatment might be considered before planning pregnancy. Women with repaired AVMs can undergo vaginal delivery under epidural, caesarean may be preferred for partially repaired or untreated AVMs. Stereotactic radiotherapy is not used in pregnant women. No data are available concerning embolization of AVM in pregnancy (92).

Neuroimaging Modalities

Computed tomography may harm the fetus or embryo both by exposure to ionizing radiation and by administration of iodine-based contrast material, if contrast is used. During head CT examination, only head is directly irradiated. Fetus is exposed only to radiation scattered throughout the body and shielding the abdomen does not significantly reduce the minimal fetal radiation dose. The teratogenic risk linked to radiation exposure is limited to the embryogenesis period, which runs from the second to fourth week of gestation. Iodinated contrast though not shown to have adverse effects except neonatal hypothyroidism is categorized as B class by FDA. Digital angiography procedures decrease the X-ray exposure and the amount of administered iodine if deemed necessary. Pregnancy does not modify the maternal tolerance to iodine. Good maternal hydration is needed to avoid fetal dehydration. After 6 months, there is a risk of fetal hypothyroidism, which can be diagnosed and treated at birth with an excellent prognosis (92).

Though longitudinal studies are lacking, MRI is generally considered safe during pregnancy. American College of Obstetricians and Gynecologists have reported no adverse fetal effects but still advise against the use of MRI in first trimester. Risk of gadolinium to fetus is not known; it is classified as category C by FDA. Magnetic resonance angiography might avoid the risk of radiation associated with computed tomography and angiography while evaluating blood vessel in stroke or AVM.

Pregnancy does not contraindicate radiologic procedures if they are deemed necessary. In case of acute stroke, CT head noncontrast may not detect acute strokes less than 6 to 8 hours in onset. MRI sequences including diffusion weight imaging (DWI) are currently the most accurate imaging test available for acute ischemia with sensitivity and specificity approaching 100%. Intravenous contrast is not required for DWI or magnetic resonance angiography.

Treatment Modalities

The potential benefits of antithrombotic drugs should be weighted against the potential risks to the mother and the fetus. Aspirin should be used for same indications as for stroke as in nonpregnant female. It has not been reported to cause any harmful effects in the second and third trimesters. Low-dose aspirin (60–150 mg/day) have been largely administered by obstetricians during the second and third trimesters of pregnancy in women at risk for pregnancy-induced hypertension without evidence of fetal or maternal adverse effects. The potential adverse effects of aspirin consumption late in pregnancy are maternal and fetal hemorrhage, premature closure of the ductus arteriosus, prolongation of labor, and delay in the onset of labor (92).

Warfarin is known to be teratogenic and causes congenital malformations in fetus by causing micro-hemorrhages in the fetal brain. Fetal warfarin syndrome is a well-reported entity. When therapeutic anticoagulation is warranted, heparin (unfractionated or low molecular weight) should be used. It does not cross the placenta and its short half-life makes dose adjustment easier in case of overdose, bleeding, or premature delivery. Heparin therapy may cause a persistent anticoagulant effect (for up to 28 h after the last injection of heparin) at the time of delivery, which increases the risk of bleeding and contraindicates epidural analgesia.

When anticoagulants are indicated during pregnancy, two schemes of anticoagulant treatment have been recommended: (i) heparin throughout pregnancy or (ii) heparin until week 13 followed by warfarin until the middle of the third trimester followed by heparin. Heparin should be discontinued immediately before delivery. Anticoagulation treatment is started again after delivery (92).

Partum–Postpartum Period

Kittner et al. in Baltimore–Washington Cooperative Young Stroke Study registry found that the risks of both cerebral infarction and intracerebral hemorrhage are increased in the 6 weeks after delivery but not during pregnancy itself (89). The extremely high relative risk of stroke during the postpartum period suggests a causal role for the large decrease in blood volume or the rapid changes in hormonal status that follow a live birth or stillbirth, perhaps by means of hemodynamic,

coagulative, or vessel-wall changes. A causal role for pre-eclampsia and eclampsia does not fully explain the much stronger associations with stroke found for the postpartum state than for pregnancy itself.

Postpartum Cerebral Angiopathy

Postpartum cerebral angiopathy is characterized by the rapid occurrence of severe headaches, nausea or vomiting, seizures, and less often focal neurologic signs with a delay varying from a few hours to 1 month after a normal pregnancy. This picture may suggest the diagnosis of a subarachnoid hemorrhage, but the CSF is normal or shows a moderate pleocytosis. Eclampsia may present with similar features, but in postpartum angiopathy patients do not necessarily have hypertension or proteinuria. Rapid spontaneous clinical recovery occurs in the vast majority of cases. Angiography shows transient focal vasospasm. In most reports cases, ergot alkaloids or other sympathomimetic drugs had been given in the preceding days or hours, hence inclusion of the disease in the category of Call-Fleming syndrome (92). Outcomes are variable though rapid spontaneous clinical recovery has been generally reported.

CVT

CVT presents with headaches, seizures, stroke-like symptoms, or mental status changes. Peak incidence is in immediate postpartum period though its occurrence during pregnancy is also known. CVT may lead to ischemic infarction or to intraparenchymal hemorrhage. MRI usually shows hemorrhagic infarcts and magnetic resonance venography may show thrombus in major sinuses or cerebral veins. Conditions that may present with similar symptoms like eclampsia, meningitis, or cerebral mass should be excluded.

Caesarian section and age greater than 25 are risk factors for CVT. Hypercoagulable state of pregnancy, preexisting coagulopathy like protein C or S deficiency, factor V Leiden mutation or antithrombin III antibodies, dehydration, or infection are usual causes. Heparin anticoagulation should be considered with similar indications as in nonpregnant female. Efficacy of venous thrombolysis or venous stenting is not established in pregnancy.

Traumatic damage to the endothelial lining of cerebral sinuses and veins during labor, hypercoagulable state, and stasis of intracerebral blood flow are the most likely explanations for the occurrence of most CVT in the puerperium. Puerperal infections and dehydration may contribute to the high frequency of CVT in developing countries.

Mode of Delivery and Outcomes

Risk of stroke in relation to the full range of outcomes of pregnancy (spontaneous or induced abortion, stillbirth, and live birth) has not been adequately studied. Caesarean delivery by itself is a risk factor for stroke accounting to the risk of thromboembolism from surgery (88).

Mode of delivery has not been adequately shown to affect outcomes in the history of gestational stroke though series have found higher incidence of caesarian deliveries in such patients (88). James et al. (87) reported several complications associated with pregnancy-related stroke—postpartum hemorrhage (OR 1.8), pre-eclampsia and gestational hyper-

tension (OR 4.4), fluid and electrolyte imbalance (OR 7.2), transfusion (OR 10.3), and the highest, pregnancy-related infection (OR 25.0). Case fatality rate for pregnancy-related stroke have been reported to be anywhere between 4.5% and 24% (87). Stroke during one pregnancy by itself is not a risk factor for stroke during subsequent gestation.

CONCLUSION

Stroke during pregnancy or shortly thereafter is etiologically heterogeneous and, as with stroke in any young patient, requires systematic evaluation (88). Prompt neuroimaging and neurologic consultation are recommended in any pregnant or postpartum female who presents with new neurologic symptoms suggestive of stroke.

ACKNOWLEDGEMENT

We want to acknowledge Ms Betty March for her work and assistance with this manuscript.

26 Sleep disorders and pregnancy

Pradeep Sahota and Sanjay Jain

INTRODUCTION

Pregnancy is associated with several hormonal, physiologic, physical, and behavioral changes that can cause alterations in sleep architecture, quality, and duration. As a result, it is not surprising that a majority of women report sleep disruption during pregnancy. In addition, pregnancy can affect preexisting sleep disorders such as insomnia, sleep-disordered breathing, and restless legs syndrome (RLS). The intimate relation between sleep and pregnancy has been well recognized and has, especially within the last few years, seen an increased interest in this field. This chapter aims to review changes occurring during pregnancy, which may have a bearing on sleep, and sleep disorders during pregnancy.

HORMONAL CHANGES DURING PREGNANCY THAT MAY AFFECT SLEEP

Pregnancy is characterized by hormonal changes that are aimed toward successful maturation of the fetus. These changes can affect normal sleep patterns directly and indirectly. There are increases in levels of circulating estrogen and progesterone throughout pregnancy. Estrogen production progressively increases in pregnancy, and levels during the last few weeks prior to delivery may be 1000-fold higher than that in ovulatory premenopausal women (1). Level of estrogen decreases abruptly after delivery of the fetus and placenta. Estrogen has been shown to reduce rapid eye movement (REM) sleep in animal studies. This may be due to its ability to increase brainstem norepinephrine (2). Progesterone levels gradually increase from 25 ng/mL at 6 weeks to 150 ng/mL at 37 weeks of pregnancy (3). Exogenously administered progesterone is associated with decreasing wakefulness, shortened latency to non-REM sleep, and increased duration of non-REM sleep (4). The effects of progesterone appear to be mediated by the action of its metabolites on brain GABA_A receptors (4,5).

Levels of other hormones that can influence sleep patterns such as prolactin and cortisol are also elevated during pregnancy. Overall, the effect of hormonal changes on sleep during pregnancy is unpredictable due to the wide variation in circulating levels of different hormones as well as the effect of other physical and physiologic changes that occur during pregnancy.

PHYSIOLOGIC CHANGES IN PREGNANCY THAT MAY HAVE A BEARING ON SLEEP

The expectant mother undergoes a variety of physiologic and physical changes that may lead to alteration of sleep during pregnancy. Majority of these changes occur as a result of the hormonal changes described above, but other factors play a role as well. Renal blood flow increases to a level of 50% to 85% above baseline throughout the first and second trimesters (6).

Dilatation of the renal pelvis and ureters occurs due to hormonal changes and mechanical effects of the enlarged uterus (7). These changes predispose to frequent micturition and therefore to several nocturnal awakenings to go to the bathroom.

Lower esophageal sphincter pressure begins to decrease in the first trimester of pregnancy, reaching a nadir in the 36th week. Gastrointestinal reflux symptoms are common, particularly in late pregnancy (8), and may be associated with frequent arousals from sleep.

Upper airway hyperemia, mucosal edema, hypersecretion, and increased friability may occur as a result of increased estrogen levels (3). Progesterone reduces the integrity of the vascular endothelium leading to fluid leakage from the intravascular to the extravascular space, causing tissue edema (9). Additionally, during pregnancy, there is an increase in the level of relaxin, an insulin-like growth factor hormone. It is both a muscle relaxant and a powerful vasodilator (10), properties that increase airway collapsibility and decrease airway caliber. Thus the increased levels of these hormones can potentially reduce the size of the upper airway significantly. Furthermore, progesterone increases phrenic nerve activity with consequent increase in diaphragmatic drive (11), and its property as a powerful respiratory stimulant has been recognized since the 1940s (12). An increase in metabolic CO₂ production and the increase in respiratory drive cause a significant increase in minute ventilation (13). This ventilatory augmentation, which is in excess of the increased CO₂ production, produces a respiratory alkalosis. The reduced arterial CO₂ of pregnancy may be a potential source of respiratory instability during sleep (14). Moreover, augmented respiratory drive may induce obstructive sleep-disordered breathing by increasing negative suction pressure on narrowed upper airway structures (15). In addition to changes in respiratory drive, pulmonary function in pregnancy is also affected by changes in the airways and thoracic cage. Chest wall and total respiratory compliance are reduced in late pregnancy (16). The expanding uterus produces a cephalad displacement of the diaphragm, causing a progressive 10% to 25% decrease in functional residual capacity (FRC) toward term (3,17). As a result of increased fetal demands and metabolic alterations in the mother, oxygen consumption increases by 20% to 33% by the third trimester (18). The combination of a reduced FRC and increased oxygen consumption results in a lowered oxygen reserve. Conditions that may cause further lowering of this reserve may potentially affect fetal oxygenation with adverse consequences.

SLEEP ARCHITECTURE CHANGES DURING PREGNANCY

Nonpregnant women of childbearing age have total sleep times on average of 7 to 9 hours per night, with 55% of the time

spent in light sleep, 20% in slow wave sleep (SWS), and 20% to 25% in REM sleep (19).

Numerous studies have examined changes in sleep architecture during pregnancy with variable findings (20–24). Most of these studies were however consistent in noting lighter and more disrupted sleep as pregnancy progresses. Wake after sleep onset increased from the second to third trimester, whereas REM sleep decreased from the first trimester to second (24,25). Brunner et al. also found, by spectral analysis, a progressive decrease in EEG power density in non-rapid eye movement sleep (25).

SLEEP DISORDERS AND PREGNANCY

The mother-to-be is predisposed to a number of sleep disorders due to the hormonal and consequently the physical and physiologic changes occurring during pregnancy. Insomnia, parasomnias, sleep-related movement disorders, sleep-related breathing disorders, and hypersomnolence have all been reported in pregnant patients.

INSOMNIA

The American Academy of Sleep Medicine, in its diagnostic and coding manual, defines insomnia as repeated difficulty with sleep initiation, duration, consolidation or quality that occurs despite adequate time, and opportunity for sleep and results in some form of daytime impairment. Insomnia is very commonly reported during pregnancy. In a survey of 192 pregnant women, 88% reported alteration in sleep as compared with their usual experience (21). The most frequent reasons for sleep disruption during pregnancy are urinary frequency (26), heartburn, and backache or ache in hips (21). In addition, there may be disruption of sleep due to nausea and vomiting during the first trimester and because of fetal movements during the third trimester of pregnancy.

Maternal factors such as maternal age (27), parity (28,29), altered circadian rhythm (30), and pregnancy-related disorders such as pre-eclampsia could also influence sleep during pregnancy. Parity may have a bearing on sleep quality and architecture. Compared with primiparas, multiparas had reduced sleep efficiency at all time points (19).

Nonpregnancy-related factors such as maternal smoking, inadequate sleep hygiene, and adjustment disorder may contribute to insomnia independent of the pregnant state.

Ohida and colleagues (31) reported that women exposed to passive smoking were likely to have sleep disturbances, such as subjective insufficient sleep, difficulty in initiating sleep, short sleep duration, and snoring loudly/breathing uncomfortably. Smoking pregnant women had an even greater prevalence of same sleep disturbances and also experienced excessive daytime sleepiness and early morning awakening (31).

SLEEP-DISORDERED BREATHING DURING PREGNANCY

Although snoring and apneas occur in pregnancy (32), there is lack of data regarding incidence and prevalence of sleep apnea in pregnant women. Most studies investigating sleep-disordered breathing were in the form of questionnaires with variable results (33–37). Despite conflicting results, there is agreement regarding higher prevalence of snoring in pregnant women as opposed to nonpregnant women.

Loube et al. (34), in their survey of 350 pregnant women and 110 age-matched nonpregnant women, found that snoring was more frequent (14%) in pregnant women as opposed to nonpregnant women (4%). They concluded that snoring was not associated with fetal compromise or adverse outcome. By contrast, the study by Franklin and Holmgren (35) suggests that snoring may be independently predictive of maternal hypertension and fetal growth retardation. Of the 502 pregnant women, 23% in their study reported snoring every night during the last week of pregnancy. Hypertension and pre-eclampsia were more common, and the incidence of infants born with Apgar score less than or equal to 7 was higher in women who habitually snored.

Obesity has been shown to have a causal association with sleep apnea (38,39). Pregnancy is associated with weight gain, which may exceed 20% or more by term (40). A recently published study suggests that the prevalence of pre-gravid obesity (defined as BMI > 29 kg/m²) in the United States has increased significantly from 13% immediately before pregnancy in 1993 to 22% immediately before pregnancy in 2002/2003 (41). Rapid gain in weight is known to be associated with a higher incidence of obstructive sleep apnea (OSA). It has not, however, been established by sleep studies whether excessive weight gain during pregnancy causes sleep apnea. In 1992, Feinsilver et al. (42) reviewed the physiologic adaptations in pregnancy and suggested an increased likelihood of sleep-disordered breathing in pregnant women. Upper airway changes, as described earlier, would predispose the patient to snoring and OSA. In addition, the respiratory alkalosis resulting from augmented minute ventilation and the enhanced sensitivity of the respiratory center to CO₂, as occurs in pregnancy, could predispose to central sleep apnea. On the other hand, there are physiologic adaptations, such as increased minute ventilation and pharyngeal muscle tone, due to elevated progesterone levels during pregnancy (43), which may be protective against sleep-disordered breathing. There is reduction in REM sleep (22) during pregnancy, which may protect against sleep apnea. Additionally, in late pregnancy, there is a greater tendency for women to sleep on their sides, thereby reducing the tendency to manifest severe sleep apnea.

The increased possibility of OSA occurring in pregnancy and its possible adverse effect on the fetoplacental unit has been hypothesized (44). There is evidence that pregnant women with preexisting obesity have a higher apnea-hypopnea index (45) and they may be at increased risk of OSA. In pregnant women who do have sleep apnea, it is felt that due to the lowered oxygen reserve in these patients, occurrence of OSA with oxygen desaturation can have undesirable consequences for the fetus. There are isolated reports of increase in incidence of babies with intrauterine growth retardation in pregnant women diagnosed with OSA (45,46). Other case reports suggest that treatment of the mother to be resulted in delivery of babies with normal birth weight (47). There are, however, no systematic studies of adverse outcomes of OSA during pregnancy.

Despite a lack of conclusive evidence of poor outcomes of pregnancy in women with OSA, pregnant women, especially those with preexisting obesity, and those giving a history of loud snoring, excessive daytime somnolence, or witnessed apneas should be considered to be at increased risk for sleep

apnea with possibility of adverse consequences for the fetus. There should, for this reason, be a low threshold for obtaining an overnight sleep study and initiation of treatment with nasal continuous positive airway pressure (CPAP) even if the patient has mild sleep apnea.

SLEEP-DISORDERED BREATHING AND PRE-ECLAMPSIA

Pre-eclampsia is a condition arising in the third trimester of pregnancy. It affects approximately 7% of all pregnancies and is characterized by abrupt hypertension, proteinuria, and edema of the hands, feet, and face. Risk factors for pre-eclampsia include family history, primiparity, advanced maternal age, multiple gestation, obesity, chronic hypertension, and renal disease (48). Sleep architecture is altered in women with pre-eclampsia, with a markedly increased time spent in SWS as compared with primigravidas with normal pregnancies (49). Women with pre-eclampsia were noted to have upper airway narrowing in both upright and supine postures as compared with nonpregnant and pregnant women (50). This predisposes women with pre-eclampsia to snoring and as many as 75% of women with pre-eclampsia were reported to snore by Iczl et al. Sleep studies in a subgroup of pregnant women with pre-eclampsia revealed higher prevalence of inspiratory flow limitation in these patients without associated oxygen desaturation (51). It is unclear whether this may have implications in the pathophysiology and treatment of this disorder. There is evidence that snoring is associated with increased blood pressure in women who suffer from pre-eclampsia, and it has been suggested that using a nasal mask to deliver CPAP may reduce obstruction and improve nocturnal blood pressure control.

RLS

RLS is a sensorimotor disorder characterized by a strong, nearly irresistible, urge to move the legs. This urge to move is often accompanied by other uncomfortable paresthesias felt deep inside the legs. The urge to move, or the unpleasant sensations, begin or worsen during periods of rest and are partially or totally relieved with movement. Symptoms typically occur in the evening or night.

Pregnancy is a known cause of secondary RLS. In a study by Nikkola, 4 out of 10 women were diagnosed with RLS after becoming pregnant (52). Sleep studies in these patients showed periodic limb movements in all 10 mothers-to-be, with an average frequency of 21.7 movements per hour. In another study, 23% women were noted to develop symptoms of RLS after becoming pregnant (Lee).

PARASOMNIAS

Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep. These events are manifestations of central nervous system activation transmitted into skeletal muscle and autonomic nervous system channels, often with experiential concomitants. Parasomnias, such as sleepwalking, and night terrors occurring during pregnancy and exacerbated by the condition have been reported. Hedman and colleagues, however, found that the frequency of most parasomnias decreases during pregnancy. They found a significant decrease

in sleepwalking, sleep talking, bruxism, and hypnagogic hallucinations from the prepregnant state. Prevalence of sleep paralysis was noted to decrease during the first trimester, but it increased during later pregnancy from 5.7% to 13.3% in the second trimester.

NARCOLEPSY

Narcolepsy is a condition characterized by excessive daytime sleepiness, with or without cataplexy. Other features such as hypnagogic hallucinations, sleep paralysis, and nocturnal sleep disruption may commonly occur in these patients. Narcolepsy is usually diagnosed in patients during adolescence or young adulthood. There is a paucity of data regarding effect of pregnancy on the course of narcolepsy. It is likely that symptoms of narcolepsy may be exacerbated by the sleep disturbances associated with pregnancy and also due to the fact that medicines typically used to treat narcolepsy have to be stopped, causing a withdrawal effect. Cataplexy, in severe cases, may be disabling, predisposing the pregnant patient to injury and jeopardizing the fetus.

MANAGEMENT OF SLEEP DISORDERS IN THE PREGNANT PATIENT

General management consists of advice regarding regular sleep schedules and practice of adequate sleep hygiene. Patients with insomnia should be counseled regarding stimulus control and relaxation techniques. Recognition of etiologic factors is important and every attempt should be made to optimally manage any underlying medical condition. For example, patients with gastrointestinal reflux symptoms may benefit from life style modification changes such as sleeping with the head end of bed elevated and by limiting portion sizes as well as avoiding oral intake at least 2 hours prior to bedtime.

Understandably, there are no clinical trials of pharmacologic treatment modalities for sleep disorders during pregnancy. Pharmacologic options therefore must be viewed with caution because of safety issues associated with use of medicines during pregnancy. Short-term zolpidem or diphenhydramine may be considered in patients with severe insomnia not responding to other measures.

Patients with narcolepsy should discontinue treatment with stimulants such as dextroamphetamine or methamphetamine. They may have to accept less stringent control of excessive daytime sleepiness and allow time for more frequent daytime naps. REM sleep suppressing medicines such as paroxetine or fluoxetine, which are pregnancy category B agents, may be used for control of cataplexy.

Similarly, medicines for RLS such as dopaminergic agents and benzodiazepines should ideally be discontinued. Patients may benefit from avoidance of caffeinated beverages and heavy exercise too close to scheduled bedtime. Administration of iron and folate supplements as is usually the practice during pregnancy may be helpful.

Patients with prior history of sleep apnea or those newly diagnosed with sleep apnea should be advised to use CPAP regularly. Despite theoretical concerns regarding diminished cardiac output and placental flow, there are no reports to suggest adverse effects from CPAP to the mother or the fetus. There may, however, be difficulty in tolerating CPAP due to factors such as intolerance to pressure, nasal congestion, and

stiffness, which may decrease adherence to CPAP regimen. This may be overcome by measures such as saline nasal rinses and use of topical nasal steroids, lowering of pressure to a more tolerable level, and sleeping with the head end of bed elevated.

CONCLUSION

Sleep disturbance is frequently reported during pregnancy (53). This is due to the several hormonal, physiological, physical, and behavioral changes that occur during the pregnant state. As a result of these changes, the pregnant woman may develop or have worsening of pathologic sleep conditions such as insomnia, sleep-disordered breathing, sleep-related movement disorders. Many of these conditions may be effectively treated, and lack of treatment may have adverse consequences for the mother and the fetus. Sleep evaluation should, therefore, be a part of routine prenatal checkup. Particular attention should be given to obese pregnant women and those who gain excessive weight during pregnancy, and to women who develop gestational hypertension or pre-eclampsia. There should be a low threshold for obtaining an overnight polysomnogram in these patients and treatment with CPAP should be considered even in patients who have mild sleep apnea. Treatment should also focus on adequate sleep hygiene techniques.

There is need for larger, multicenter studies with clinical and polysomnographic evaluation to improve our understanding of association between pregnancy and sleep disorders and to determine whether (i) sleep disorders influence the outcome of pregnancy and (ii) pregnancy influences the course of certain sleep disorders such as narcolepsy.

27 Pulmonary diseases in pregnancy

Leah Lande, Abraham Sanders, and Dana Zappetti

INTRODUCTION

Pregnancy induces significant changes in normal pulmonary physiology while also causing increased susceptibility to the effects of certain respiratory diseases. In the following chapter, the changes in pulmonary function and respiratory physiology that occur during normal pregnancy will be described, followed by a review of specific pulmonary disorders during pregnancy. Obstructive and restrictive lung diseases, pulmonary vascular disease, pulmonary infections, respiratory failure, and other topics will be reviewed in the context of pregnancy. In addition, the challenge of distinguishing between the normal physiologic dyspnea of pregnancy and an underlying pulmonary or cardiac disease will be discussed.

Respiratory disorders account for a small, but significant percentage of maternal morbidity and mortality (1,2). These are sometimes due to preexisting conditions that may be exacerbated by pregnancy such as pulmonary hypertension (PH), cystic fibrosis (CF), or restrictive lung disease or due to acute illnesses such as pulmonary embolism (PE), pneumonia, or adult respiratory distress syndrome. Particularly with respect to chronic progressive pulmonary diseases, physicians must be familiar with the potential maternal and fetal complications that can occur and be prepared to counsel women regarding these issues.

Changes in Lung Function During Pregnancy

Chest Wall and Diaphragm

Early in pregnancy, the overall diameter of the chest wall increases, possibly due to relaxation of the ligamentous attachments between the ribs and the sternum. More specifically, the subcostal angle increases by approximately 35°, the transverse diameter of the chest increases by approximately 2 cm, and the chest circumference expands by 5 to 7 cm. In later pregnancy, as the uterus enlarges, the level of the diaphragm rises approximately 4 cm, but this does not affect diaphragmatic excursion (3).

Pulmonary Function

Overall, respiratory muscle function is not altered by pregnancy. Maximum inspiratory and expiratory pressures remain unchanged. However, due to the changes in chest wall configuration as noted above, static lung volumes are altered. The total lung capacity is minimally reduced and the functional residual capacity (the amount of air remaining in the lungs at end expiration) is more significantly reduced due to elevation of the diaphragm in later stages of gestation. By contrast, due to the decrease in functional residual capacity, the inspiratory capacity (the maximum amount of air that can be inspired at end expiration in the resting state) is increased, and steady-state tidal volumes may be increased up to 30% to 40% (Table 1).

Airway function remains unaffected by pregnancy, with no change in forced expiratory volume in one second, forced vital capacity (FVC), or peak expiratory flow rates. Therefore, the use of a peak flowmeter in pregnant asthmatics that are experiencing respiratory symptoms can be invaluable in distinguishing between worsening of underlying airway disease and alternative causes for their symptoms, including the normal dyspnea of pregnancy. However, it is important that peak flows be performed in the upright position, as lying supine can result in small alterations in peak flow rates.

Gas Exchange

As gestation progresses, a state of chronic hyperventilation ensues. This is probably due to progressively increasing levels of progesterone, which is a known stimulant of respiratory drive, from approximately 25 ng/mL at 6 weeks to 150 ng/mL at term (4). By 8 weeks of gestation, there is already an increase in tidal volume as noted above. This increased tidal volume results in increased alveolar ventilation, with subsequent decreased arterial carbon dioxide (PaCO_2). PaCO_2 levels typically decrease from normal levels of 37 to 40 mmHg to 27 to 32 mmHg. This decrease in maternal PaCO_2 creates a favorable gradient for CO_2 transfer from the fetus across the placenta. The maternal pH is maintained within the normal range through increased renal excretion of bicarbonate with a subsequent mild metabolic acidosis, with typical serum bicarbonate levels of 18 to 21 mEq/L.

Maternal oxygenation (PaO_2) usually increases early in pregnancy (106–108 mmHg) as a result of decreased PaCO_2 , but as the uterus enlarges in the third trimester, the PaO_2 decreases slightly (101–104 mmHg), with a slight increase in alveolar to arterial oxygen gradient from 14 to 20 mmHg. This decrease in PaO_2 is even more pronounced in the supine position.

Oxygen consumption increases by approximately 20% during pregnancy to meet the increased metabolic demands of maternal organs, the fetus, and the placenta (5). These oxygen requirements are more pronounced during exercise and labor (6). Due to the decreased functional residual capacity, maternal oxygen reserve is lower, and pregnant women can develop a more rapid onset of hypoxia during periods of apnea or during attempted endotracheal intubation.

In the setting of slightly elevated maternal pH and elevated 2,3 DPG during pregnancy, the oxygen–hemoglobin dissociation curve is shifted to the right, resulting in a decreased affinity of hemoglobin for oxygen (Fig. 1). This not only favors an increased transfer of oxygen to the fetus, but also results in a decreased oxygen saturation of hemoglobin for any given level

Table 1 Pulmonary Function Changes During Pregnancy

Measurement	Definition	Change in pregnancy
Respiratory rate	Number of breaths per minute	None
Tidal volume	Amount of air inspired and expired with normal breathing	Increased 30–40%
Total lung capacity	Amount of air in lungs at maximal inspiration	Decreased 5%
Vital capacity	Amount of air that can be forcibly expired after maximal inspiration	none
Residual volume	Amount of air remaining in lungs after maximal expiration	Decreased 20–25%
Functional residual capacity	Amount of air remaining in lungs at resting expiratory level	Decreased 20%
Inspiratory capacity	Amount of air that can be inspired from resting expiratory level	Increased 5–10%
Inspiratory reserve volume	Amount of air that can be inspired at the end of normal inspiration	none
Expiratory reserve volume	Amount of air that can be expired from resting expiratory level	Decreased 15–20%

Figure 1 Oxygen dissociation curves for human maternal and fetal blood, indicating the physiologic range of PO_2 and O_2 for mother and fetus. Source: From Ref. 7.

of PaO_2 (8). This also causes the pregnant women to be more susceptible to hypoxemia. Although fetal partial pressure of oxygen is much lower (25–35 mmHg), the saturation is relatively higher than that in the adult due to displacement of the fetal oxygen–hemoglobin dissociation curve to the left. The fetus can be very sensitive to a small decrease in maternal PaO_2 due to the steep slope of the fetal oxygen dissociation curve in the 50% saturation range (9).

Dyspnea of Pregnancy

The increasing levels of progesterone throughout the course of gestation as well as the changes in lung function noted above are thought to be the main mechanisms responsible for the physiologic dyspnea of pregnancy. During the course of normal pregnancy, 60% to 70% of women experience a sensation of dyspnea (10). This sensation of breathlessness usually begins during the first trimester and gradually increases throughout the second and third trimesters. At 28 weeks of gestation, approximately 50% of women experience dyspnea walking up hills or climbing stairs, and 20% have dyspnea walking on flat ground (11). Distinguishing between the physiologic dyspnea of pregnancy and the presence of underlying cardiac or pulmonary disease can be a diagnostic challenge. The dyspnea of pregnancy is typically gradual in onset, is not associated with cough, wheezing, or chest pain, and is characterized by a clear lung exam and normal spirometry.

AIRWAY DISEASES

Asthma

Epidemiology

Asthma is the most common pulmonary disorder in pregnancy, affecting 8% of pregnant women (12). The National Asthma Education Program Working Group on Asthma in Pregnancy estimated that 10% of pregnant asthmatics have an acute exacerbation of asthma during labor, and 0.2% experience status asthmaticus during the course of their pregnancy (13,14). Approximately one-third of asthmatics have an improvement in asthma control during pregnancy, one-third have worsening during pregnancy, and one-third experience no change (13).

Maternal and Fetal Effects

Over the last 30 years, multiple studies have investigated the effect of asthma on maternal and fetal outcomes, with varying results. There have been reports of adverse outcomes, including low infant birth weight, congenital malformations, increased incidence of preterm labor, and increased incidence of maternal pre-eclampsia and hypertension, particularly in poorly controlled asthmatics (15). A recent case-control study of over 3000 women over 10 years showed only an increase in pre-eclampsia and maternal hypertension in poorly controlled asthmatic patients (16).

Symptoms and Triggers

Asthma is characterized by either partial or completely reversible airway obstruction, with airway inflammation, bronchospasm, and mucous hypersecretion. Typical symptoms of asthma include dyspnea, cough, wheezing, and chest tightness. These may be worse at night and, with exercise, may occur in the setting of an upper respiratory tract infection or after exposure to environmental triggers such as hot or cold air, dust or pollen, house dust mites, cockroach antigens, pets, or other inhaled irritants. Asthma symptoms can also be triggered by gastroesophageal reflux that is estimated to occur in up to 50% of pregnant women (17) or by postnasal drip that is precipitated by hyperemia and glandular hyperactivity in the upper respiratory mucosa during pregnancy.

Diagnosis and Monitoring

The diagnosis of asthma is made based on the clinical history as noted above with or without supporting physical exam findings of expiratory wheezing or rhonchi. The diagnosis is confirmed by spirometry demonstrating a reduced forced expiratory volume in one second (FEV1) with a reduced ratio

Table 2 Assessing Asthma Severity

	Intermittent	Mild persistent	Moderate persistent	Severe persistent
Symptoms	≤2 days/wk	>2 days/wk	Daily	Continuous
Nocturnal Awakenings	≤2 times/month	3–4 times/month	>1 time/wk	Nightly
Use of rescue inhaler	≤2 days/wk	>2 days/wk, but not >1 time/day	Daily	Several times/day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal	FEV1>80% predicted FEV1/FVC normal	FEV1>60% but <80% FEV1/FVC reduced 5%	FEV1<60% predicted FEV1/FVC reduced >5%
Recommended step for initiating treatment	Step 1	Step 2	Step 3	Step 4 or 5 and consider short course of systemic corticosteroids

of FEV1 to FVC, with further confirmation if airway reversibility is shown by an improvement by 12% and 200cc in either the FEV1 or the FVC after the administration of an inhaled bronchodilator. The sensitivity, however, of spirometry in the diagnosis of asthma is limited (18). Methacholine challenge testing, which can be used to diagnose asthma in patients with normal spirometry, is contraindicated in pregnant women due to a lack of safety data (19).

Once the diagnosis of asthma has been established, the cornerstone of asthma assessment is patient self-monitoring with a portable peak flowmeter. Patients should be instructed to measure their peak expiratory flow on a regular basis at different times of day to establish a baseline, and then to use the meter when experiencing new or changing respiratory symptoms, in order to facilitate early detection of an acute asthma exacerbation. The peak flowmeter is a particularly helpful objective assessment of pulmonary function in distinguishing between the normal dyspnea of pregnancy and worsening of asthma symptoms.

Physician assessment of asthma control involves tracking the frequency and severity of asthma symptoms, including the presence of nocturnal awakenings due to asthma and the use of short-acting inhaled beta-agonist rescue therapy. Most importantly, patients should be asked about their consistent use of controller medications and avoidance of environmental triggers. Pregnant asthmatics requiring regular controller medications should undergo monthly physician visits.

Treatment

The first step in the treatment of asthma is to identify and counsel patients on the avoidance of asthma triggers. In addition, assessment should be performed for the presence of other conditions that can exacerbate asthma such as allergic rhinitis, sinusitis, and gastroesophageal reflux disease and these conditions should be treated if present.

It is important to note that the risks of uncontrolled asthma far outweigh any risks from the medications used to control asthma (20).

Airway inflammation is treated with inhaled corticosteroids and bronchial hyper-responsiveness is treated with short- or long-acting bronchodilators. In addition, leukotriene receptor antagonists, theophylline, and cromolyn appear to be safe during pregnancy and may be considered in select patients (21). Most data on the safety of asthma medications in

pregnancy are observational, with the most extensively studied being albuterol and inhaled budesonide (21–23). Albuterol appears to be safe based on a review of six published studies including 1599 women and a prospective study including 1828 women, in whom no significant relationship was found between the use of inhaled beta-2 agonists and adverse pregnancy outcomes (21,24). The National Asthma Education and Prevention Program Working Group reviewed 10 studies, including 6113 patients who were treated with inhaled corticosteroids during pregnancy and found no increases in congenital malformations or adverse perinatal outcomes in these patients (24).

The pharmacologic treatment of asthma depends on the severity of the asthma symptoms and degree of physiologic impairment. Patients with mild, intermittent asthma (symptoms ≤2 days/wk and ≤2 nights/month with normal FEV1) do not require daily controller medications and can be managed with a short-acting inhaled bronchodilator as needed. Patients with persistent asthma (symptoms >two times/wk or >2 nights/month) require daily treatment with inhaled corticosteroids at increasing dosages depending on the severity and frequency of their asthma symptoms, with the addition of inhaled long-acting beta agonists in steps 4 to 6 (19,24,25) (Tables 2, 3, and 4).

Pregnant patients who had good asthma control prior to pregnancy should generally be instructed to continue on their prepregnancy regimen. In nonpregnant patients, it is recommended that if their asthma has been well controlled for 3 months, then they be considered for a step-down in their therapy. This may also be considered in pregnant patients requiring high-dose inhaled corticosteroids with long-acting inhaled beta agonists, with the goal of first eliminating the long-acting beta agonist if possible, as data are lacking regarding the safety of long-acting beta agonists during pregnancy. The safety of short-acting beta agonists and the accumulating clinical experience with these medications during pregnancy are reassuring. Therapy should be increased by one step (Table 3) in patients with poorly controlled asthma. Patients using their rescue inhalers more than twice a week should be considered for a step-up in therapy. If patients have very poor asthma control, therapy should be increased by two steps or a short course of systemic corticosteroids should be prescribed. A typical regimen would be oral prednisone 40 to 60 mg daily for 1 week, followed by a taper over 7 to 10 days.

Table 3 Steps of Asthma Therapy During Pregnancy

Step	Preferred controller medication	Alternative controller medication
1	None	-
2	Low-dose inhaled corticosteroid	LTRA, cromolyn, theophylline
3	Medium-dose inhaled corticosteroid	Low-dose inhaled corticosteroid plus LABA, LTRA, or theophylline
4	Medium-dose inhaled corticosteroid plus LABA	Medium-dose inhaled corticosteroid plus either LTRA or theophylline
5	High-dose inhaled corticosteroid plus LABA	-
6	High-dose inhaled corticosteroid plus LABA plus oral prednisone	-

Abbreviations: LTRA, leukotriene receptor antagonist; LABA, long-acting beta-2 agonist.

Table 4 Controller Medications for the Management of Asthma During Pregnancy

Inhaled corticosteroids	Usual dose	FDA pregnancy class
Budesonide	Low: 180–600 µg/day Medium: 600–1200 µg/day High: >1200 µg/day	B
Beclomethasone	Low: 80–240 µg/day Medium: 240–480 µg/day High: >480 µg/day	C
Fluticasone	Low: 100–300 µg/day Medium: 300–500 µg/day High: >500 µg/day	C
Long-acting beta agonists (add-on therapy to medium- or high-dose inhaled corticosteroids)		
Salmeterol	1 puff BID	C
Formoterol	1 puff BID	C
Leukotriene receptor antagonists		
Montelukast	10 mg daily	B
Zafirlukast	20 mg BID	B
Theophylline	400–600 mg/day (adjusted to level 8–12 µg/mL)	C
Cromolyn	2 puffs QID	B

Labor and Delivery Management

Acute exacerbations of asthma are rare during labor and delivery. Adequate analgesia with the use of epidural anesthesia may reduce the risk of bronchospasm and has the added benefit of reducing oxygen consumption and minute ventilation during labor. The ultimate goal of asthma management during labor and delivery is maintaining adequate oxygenation of the fetus by prevention of hypoxic episodes in the mother.

Cystic Fibrosis

Cystic Fibrosis occurs in about 1 in 1500 whites and 1 in 17,000 blacks (26). With improved therapy, median survival is now 33.4 years (26,27). The Cystic Fibrosis Foundation found that in 2004, 191 American women with CF were pregnant. Though many women with CF, particularly those with more mild disease, are able to undergo pregnancy without significant problems, pregnancy in CF patients has been associated with adverse fetal and maternal outcomes. Close management by a multidisciplinary team is required throughout the pregnancy. Overall, 25% of patients had preterm delivery, and the 2-year perinatal death rate was 14%. The mortality risk appears to be associated with more severe

disease, with the suggestion that an FEV1 < 60% of predicted, colonization with *Burkholderia cepacia*, poor nutrition, and diabetes mellitus are poor prognostic factors for both maternal and fetal outcomes (28–30). Women with CF with good pulmonary function prior to pregnancy do develop an increased frequency of pulmonary exacerbations and hospitalizations throughout the course of gestation, but there is no change in long-term survival compared with controls (30).

Bronchiectasis

There is little information known about the impact of bronchiectasis on pregnancy. Based on case reports in the literature, it appears that there is no change in pulmonary function during pregnancy and no significant effects on fetal outcomes if normal oxygenation is maintained (31,32). In cases in which maternal hypoxia was present, fetal growth retardation has been reported (31).

DISORDERS OF THE PULMONARY VASCULATURE

Pulmonary Hypertension

Pulmonary Hypertension is defined as an elevated mean pulmonary artery pressure of greater than 25 mmHg and a pulmonary capillary wedge pressure of greater than

15 mmHg, measured with a right heart catheter at rest (33). It can be primary, caused by a vasculopathy in the pulmonary arteries, or secondary, due to diseases affecting the lungs such as pulmonary emboli, interstitial lung diseases of many etiologies, emphysema, cardiac disease, or extra pulmonary diseases such as HIV, liver failure, or sleep apnea, with resultant hypoxemia (34).

It becomes relevant for obstetricians to learn about PH because women of childbearing age are more likely to suffer from primary pulmonary arterial hypertension (PAH) or congenital heart disease, and the hemodynamic demands of pregnancy can lead to increased cardiac output and hemodynamic or respiratory decompensation. With maternal mortality estimated between 30% and 50%, historically, the recommendation has been, for women with PAH, to avoid pregnancy with effective contraception and to terminate pregnancy should it occur (35). More recently, medications have become available that can lower pulmonary artery pressures, thereby improving exercise tolerance, quality of life, and survival. These medications, however, do not cure the condition (35,36). Use of these therapies, such as IV epoprostenol, inhaled nitric oxide, inhaled iloprost, oral calcium channel blockers, endothelin receptor antagonists (bosentan, ambrisentan), and sildenafil, have been tried and, in review, have resulted in lower but still high mortality, over 25% (37–40).

We would continue the recommendation to avoid pregnancy, but should the woman wish to proceed, consultation with expert cardiologists, pulmonologists, and anesthesiologists with experience with these new therapies and complications during delivery should be obtained. Termination of pregnancy should be considered if PH worsens, which is reported most often between 20 and 24 weeks, when most hemodynamic changes have occurred (37,40).

Pulmonary Embolism

Overview

Deep venous thrombosis and its manifestation, pulmonary embolism, (DVT/PE) are the leading cause of maternal death in the developed world. Estimated deaths in the United States and Europe are 1.1 to 1.5 per 100,000 deliveries, with 5 to 12 events of DVT/PE per 100,000 pregnancies, which is 7 to 10 times higher than age-matched nonpregnant women (41).

Two-thirds of DVT occur antepartum and are equally distributed among the trimesters. PEs occur more commonly post delivery, 43% to 60%, and the risk of DVT/PE is elevated for 6 weeks following delivery. Pregnancy is thus considered a hypercoagulable or thrombophilic state, increasing the risk of DVT/PE (42).

Pregnancy is associated with hypercoagulable changes in blood, venous stasis with decreased blood flow, compression of iliac veins by the uterus, the crossing of the right iliac artery over the left iliac vein, and immobilization. Trauma from the delivery or from interventions to aid in delivery can lead to vascular damage and therefore all variables of Virchow's triad: hypercoagulability, venous stasis, and vascular damage (41–43).

Other factors increasing the risk for DVT/PE include underlying thrombophilias (found in approximately 50% of episodes in pregnancy), previous DVT or family history of

DVT/PE, elevated BMI, immobilization, assisted reproduction, hemorrhage, infection, Caesarean delivery (especially emergent multiple pregnancies), age over 35, and pre-eclampsia (42).

Diagnosis

The diagnosis of DVT/PE in pregnancy is more complicated than that in the nonpregnant population, as the symptoms are nonspecific, overlap with those of normal pregnancy, and require the use of radiation-associated imaging, which patients and physicians wish to avoid due to negative effects on the fetus. Recommendations are extrapolated from studies in nonpregnant populations from which pregnant women were specifically excluded (41–45).

Most patients with DVT/PE will complain of shortness of breath, pleuritic chest pain, hemoptysis, syncope, or leg swelling occurring over minutes to hours. They may have tachypnea, tachycardia, hypotension, and shock. While these symptoms and signs are sensitive, they are not specific to confirm the diagnosis, and further objective testing, such as imaging, is required.

Consideration of the possibility of DVT/PE is the most important factor leading to a correct diagnosis and requires that one recognize the signs and symptoms while screening for risk factors in addition to pregnancy. Examination of the patient should focus on temperature, heart rate, respiratory rate, blood pressure, oxygen saturation, the presence of jugular venous distention, wheezing, rales, pleural rubs, heart murmurs or gallops, leg swelling, tenderness, and/or warmth. The differential diagnosis often includes pulmonary congestion, heart failure, atelectasis, asthma, pneumonia, and pneumothorax in addition to DVT/PE. A clinical probability for DVT/PE should be made. Clinical prediction rules and algorithms exist and have been evaluated in the nonpregnant population, but have not been similarly developed for the pregnant group. Therefore, if DVT/PE is suspected, further studies are required (41–43).

Electrocardiograms and arterial blood gases have not been demonstrated to be useful in excluding or making the diagnosis of PE, although they can aid in the evaluation of other conditions, such as myocardial infarction. d-Dimer testing remains problematic, as the levels increase in the blood through each trimester and often exceed the upper range of normal, which has been established in nonpregnant subjects (46). Furthermore, levels have not been developed to allow the treating physician to discriminate DVT/PE from normal pregnancy. By contrast, however, threshold levels have been developed in the nonpregnant patient. Therefore, the combination of a low suspicion for DVT/PE and a normal level of d-dimer in the blood effectively rules out the diagnosis. However, in those who have an intermediate or high clinical suspicion, a d-dimer study will neither diagnose nor exclude DVT and, therefore, it is not recommended.

Once the diagnosis is considered, and further testing is in progress, treatment should begin. The next test should be compression ultrasonography of the lower extremities. It is noninvasive and does not require radiation. If DVT is seen, PE can be diagnosed and treatment continues as it is the same for DVT and PE. Limitations to this study are its decreased accuracy in those without symptoms or signs of DVT or with isolated calf, iliac vein, or pelvic vein thromboses. If DVT is

not seen, further testing is indicated. Available studies include chest radiography, ventilation–perfusion scintigraphy (V/Q), computed tomography pulmonary angiography, pulmonary angiography, and CT or conventional venography (41,42,45).

While chest radiography can suggest an alternate diagnosis, such as fluid overload, pneumonia, or pneumothorax, it cannot definitively exclude or make a diagnosis of DVT/PE. V/Q scanning has been validated in the diagnosis of PE, in combination with pretest clinical probability determinations. A normal or near-normal scan and low clinical probability practically excludes the diagnosis in nonpregnant patients. A high clinical suspicion with a high probability scan confirms the diagnosis. All other combinations of clinical probability and scan interpretation do not confirm or exclude the diagnosis. The radiation dose from a complete V/Q scan is from 0.00028 to 0.00051 Gy; doses in humans of 0.01 Gy during gestation are estimated to be a threshold above which increased congenital abnormalities are seen. Fetal exposure to radiation of 0.01 Gy above normal background radiation may increase the probability of cancer before age 20 by 0.017 (41).

Results of V/Q scanning show that 70% are interpreted as normal and 25% are non-diagnostic. These results suggest that V/Q scanning may be a good first test to exclude PE, but many patients will require further testing (47).

CT scanning delivers 0.00003 to 0.00013 Gy to the fetus, similar to V/Q scanning; however, more radiation is received by the mother's breasts than the fetus. The incidence of breast cancer may be increased with chest CT. CT scans are reported either as positive or negative and are accurate in lobar vessels (97% accurate). In smaller segmental and subsegmental vessels, accuracy declines and both false-positive (reported clot where none exists) or false-negative results are noted. However, a negative scan can reliably exclude the diagnosis, and follow-up of those with negative scans show good outcomes without treatment. An advantage of CT is that other diagnoses may be made. The problem of isolated pelvic vein thrombosis can be associated with abdominal and back pain, and swelling of the leg may require CT scanning of the iliac veins and pelvis (41,48,49).

In studies of nonpregnant patients who undergo full diagnostic testing for DVT/PE, up to 25% of patients will have the diagnosis confirmed. In pregnant women, 10% to 15% will be found to have DVT/PE. Despite studying many patients who do not have DVT/PE, it is felt that with a mortality of 30% when untreated, compared with 8% when treated, evaluation leading to a diagnosis is required if a pregnant patient presents with signs or symptoms suggestive of possible DVT/PE (41).

If the V/Q scan and chest CT are non-diagnostic, conventional angiography can be done. This choice requires trained personnel both to perform and to interpret the study. It delivers more radiation than other studies, but offers the most certain diagnosis. However, with the widespread availability of CT scans, this test is less frequently done.

A suggested approach to the evaluation of DVT/PE is to consider the diagnosis in those who complain of acute dyspnea, pleuritic chest pain, hemoptysis, or syncope. A chest

radiograph, electrocardiogram, and ultrasound of the lower extremities should be obtained. Blood studies can include a blood count and d-dimer. If an alternative diagnosis is not made, or the ultrasound does not reveal DVT, then further imaging is needed. We recommend a CT angiogram, as this will be diagnostic in most cases. A CT angiogram requires informed consent from the patient and should include a discussion of radiation exposure to the patient and fetus, including a possible slightly elevated risk of cancer. If available, a discussion with radiology personnel and the application of breast shields can be attempted (41,50).

Therapy

The initial treatment of DVT/PE in both pregnant and nonpregnant patients is heparin. Low-molecular weight heparin (LMWH) (enoxaparin 1mg/kg up to 100mg twice daily, dalteparin using weight-based dosing of 5000–10,000 units twice daily, or tinzaparin 175 units/kg once daily at all weights) is preferred (41,44). Unfractionated heparin, given intravenously, was the standard historically, but studies have shown that the subcutaneous use of LMWH has therapeutic equivalence, better bioavailability and predictable dose response, a reduced risk of bleeding, weight-based dosing without the need for monitoring of coagulation, reduced risk of heparin-induced osteoporosis and fractures, and reduced risk of heparin-induced thrombocytopenia. Heparins neither cross the placenta nor are they excreted in breast milk. Allergic reactions are uncommon and include itching, urticaria, and erythematous plaques (44).

Full anticoagulation in the absence of other factors, such as an underlying thrombophilia or prior DVT/PE, must continue for at least 6 months, throughout the pregnancy, and at least 6 weeks postpartum.

In patients with massive PE, mortality with aggressive therapies exceeds 50%. These patients are hemodynamically unstable, with a large clot burden causing obstructive shock, right ventricular failure, hypoxemia, and hypotension. In the nonpregnant patient, the use of thrombolytics, such as tissue plasminogen activating factor, or streptokinase, are used. Thrombolysis, as well as surgical embolectomy, has been used in pregnant patients with successful outcomes (41,44,51).

For patients receiving heparin, some clinicians have recommended a reduction in dose to 75% of a full treatment dose after 30 days, extrapolating from studies in nonpregnant patients. This approach has not been confirmed with studies in pregnant patients but is not unreasonable (44).

If pregnant patients are receiving anticoagulation therapy and are approaching delivery, they can be switched from subcutaneous LMWH to IV unfractionated heparin 24 to 36 hours prior to elective induction of labor or caesarean section. If, however, spontaneous labor begins while the patient is receiving subcutaneous LMWH, epidural anesthesia cannot be administered.

A special situation involves women with a recent (less than 1 week previously) DVT/PE receiving full anticoagulation therapy near delivery. There is a higher rate of recurrence during this period. Options include insertion of an inferior vena cava filter and induction of labor with reinstatement of anticoagulation following delivery when hemostasis is

obtained, or switching from LMWH heparin subcutaneously to IV unfractionated heparin and cessation 4 to 6 hours prior to expected delivery (44).

Prevention

If a patient with known risk factors for DVT/PE, such as a history of prior idiopathic or pregnancy-associated DVT/PE or a known thrombophilia, becomes pregnant, their risk for recurrent DVT/PE during pregnancy will be increased. As a preventative strategy, low-dose subcutaneous LMWH should be given throughout the pregnancy and postpartum for 6 weeks. If women with known thrombophilia have not had DVT in the past, with the exception of antithrombin deficiency, they should receive low-dose prophylactic therapy throughout the pregnancy and for 6 weeks after delivery (34,44).

AMNIOTIC FLUID EMBOLISM SYNDROME

A rare but catastrophic situation is amniotic fluid embolism syndrome (also called anaphylactoid syndrome of pregnancy). It is rare, unpredictable, unpreventable, and has a high mortality rate between 20% and 90%. Survivors are often left with anoxic encephalopathy. After pulmonary thromboembolism, it is the next leading cause of unexpected maternal death. Women who undergo a difficult labor, who are older, who have a caesarean or instrumental delivery, and who have placenta previa or abruptio are at an increased risk (52).

The clinical presentation is the sudden onset of hypoxemia, hypotension, seizures, and coagulopathy during labor or within 30 minutes of delivery. The condition appears as a systemic process with hypoxemia due to ventilation perfusion mismatching followed by non-cardiac pulmonary edema, hypotension, decreased left ventricular function, and, within minutes, disseminated intravascular coagulation with bleeding. Occasional cases are reported following abortion, amniocentesis, or trauma. There are no specific tests that confirm the diagnosis. The differential diagnosis includes sepsis, acute PE, anaphylaxis, air embolism, anesthetic complications, transfusion reactions, eclampsia, heart failure, hemorrhage, or aspiration and all of these must be considered (52,53).

Treatment is supportive with supplemental oxygen, most likely with intubation and mechanical ventilation, trying to maintain a maternal PO₂ greater than 65 mmHg. Blood pressure should be maintained with norepinephrine or dopamine and fluids, while central access is obtained, and evaluation of fluid status is undertaken. Blood and blood products may be necessary, and delivery might be necessary as well, but bleeding must be controlled first (20,21).

The etiology of this syndrome is unknown, but it is felt to be inflammatory—a response to antigens in amniotic fluid in susceptible hosts (52–54).

RESTRICTIVE LUNG DISEASES

There are a number of chronic lung diseases affecting women of childbearing years that are characterized by reduced lung volumes and normal expiratory airflow. Their physiology is described as restrictive, as compared with the “obstructive” diseases such as asthma and CF. These diseases can cause increased respiratory distress in pregnant women, as the

normal physiology of pregnancy progresses with its increase in minute ventilation and oxygen consumption, changes in rib cage displacement, and intravascular volume, which add to baseline pulmonary dysfunction. We will discuss some of the more common disorders and their response to pregnancy (55,56).

Kyphoscoliosis

Kyphoscoliosis is a deformity of the spine with excessive curvature either posterior (kyphosis) or lateral (scoliosis). Women are more commonly affected than men, with a prevalence of 10.7% in women 25 to 74 years, documented in one study. Kyphoscoliosis, by causing a reduction in lung volumes, can lead to respiratory failure and death. The deformity of the chest wall compresses the lungs and leads to ventilation perfusion mismatching, hypoxemia, and, occasionally, hypercarbia. PH and heart failure can occur (57).

Despite these findings, and worsening respiratory function, reported outcomes of pregnancies appear to be good. Patients should have their pulmonary function tests measured, and oxygen saturation followed throughout pregnancy, at rest and with exercise, and should be supplemented when oxygen saturations drop below 95% (58).

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare lung disease more common in women. It can occur sporadically or can be associated with tuberous sclerosis. Pathologically, cysts and a multifocal nodular proliferation of immature smooth and perivascular epithelioid cells are found. Women may complain of shortness of breath, cough, or hemoptysis and can be found to have a pneumothorax or a chylous effusion in the chest or abdomen. The condition is associated with angiomyolipomas of the kidneys and meningiomas.

In the lungs, chest CT scanning shows multiple (more than 10) thin-walled air-filled cysts with preserved lung volumes and no other lung involvement. Pulmonary function tests may show expiratory airflow obstruction and/or restrictive abnormalities with hypoxemia and normal PCO₂. Prognosis is variable with median survival of 8 to 10 years following diagnosis and has been reported to be up to 20 years. No treatment is of proven benefit. Treatment is supportive with oxygen, bronchodilators, and occasionally lung transplantation.

It is believed that estrogens are related to the progression of the disease and should therefore be avoided. Pregnancy in these patients has been associated with an increased risk of pneumothorax and chylothorax. Those who are pregnant prior to the diagnosis of LAM appear to do well, while those whose diagnosis is made during pregnancy have an increased incidence of premature births and can have greater progression of the disease.

Therefore, women with LAM should be evaluated prior to pregnancy and advised of possible complications. Should they elect to become pregnant, or proceed with pregnancy, they should be evaluated for the progression of disease and pneumothoraces (59).

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder of unknown etiology that results in noncaseating granulomas in involved organs. It most commonly affects people under 40 years of age and, while affecting all races, is more common in blacks than whites. The lung is the most commonly involved organ (over 90%), and patients present with dyspnea, cough, fever, malaise, and weight loss. Other organs such as the heart, eyes, and skin are frequently involved. The diagnosis is made with a consistent clinical picture and a consistent biopsy. Many patients will spontaneously improve, while others will require treatment, usually glucocorticoids. Patients can progress to respiratory failure due to interstitial lung disease and fibrosis.

Sarcoidosis does not seem to affect fertility or increase the incidence of maternal or fetal complications. Corticosteroids may be administered before and during pregnancy. However, with the use of systemic steroids during pregnancy, there is a reported increase in the incidence of cleft palate in fetuses and women should be made aware of this possible side effect. Some women improve during pregnancy as endogenous steroid levels rise. If respiratory function deteriorates, supplemental oxygen might be needed (60).

INFECTIOUS DISEASES

Allergy and Upper Respiratory Tract Infections

Upper respiratory tract infections are common disorders for which patients, pregnant and nonpregnant, seek therapy. These disorders can be challenging in the pregnant patient because many of the relieving medications must be avoided and because noninfectious rhinitis is a common symptom during normal pregnancy.

Rhinitis of pregnancy occurs in 20% to 30% of women, and although it does not appear to affect outcome, it can certainly affect sleep, nutrition, and increase stress (61). Rhinitis of pregnancy is defined as nasal congestion and/or rhinorrhea lasting more than 6 weeks in the absence of signs of infection or a known allergen. Usually it is not necessary to treat pharmacologically and measures such as exercise (nasal vasoconstriction), saline spray or irrigation, and head of the bed elevation can be very effective (62). Intranasal glucocorticoid sprays do not seem to be beneficial, and when necessary, pseudoephedrine can be used after the first trimester and if there is no maternal hypertension (63).

Much like asthma, allergic rhinitis that is present prior to pregnancy may remain stable, worsen, or improve (64). Skin testing to identify an allergen is avoided during pregnancy given the possibility of a severe systemic allergic response during testing. Intranasal cromolyn sodium is safe and efficacious, and unlike in non-allergic rhinitis of pregnancy, intranasal glucocorticoids are effective and considered safe (65). Antihistamines are generally less effective and the intranasal formulations should be avoided. Second-generation antihistamines such as loratadine and cetirizine are the formulations of choice if more than topical therapy is needed. Decongestants have the added benefit of having vasoconstrictive properties, but because of this effect, they should be avoided in the first trimester. Nasal oxymetolazone, as in nonpregnant patients, should be used only for a short duration of 2 to 3 days to avoid rebound symptoms. If necessary,

pseudoephedrine can be used after the first trimester and if there is no maternal hypertension (65,66). Allergen immunotherapy is often successful in controlling symptoms of allergy—both rhinitis and asthma. While it is not recommended to start immunotherapy during pregnancy, for fear of systemic allergic reaction, patients who are tolerating a stable dose and who are benefiting from the therapy prior to pregnancy should continue their injections throughout pregnancy (67).

The practitioner must have a low threshold for suspecting bacterial sinusitis, as this entity is a common upper respiratory tract complication of pregnancy. Often the symptoms of fever and purulent discharge are absent. Radiologic evaluation with X-ray, computed tomography, or magnetic resonance imaging should be reserved for those not improving on antibiotics. Pathogens are identical to those in all bacterial sinusitis: *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae*. Treatment should be initiated with high-dose amoxicillin, amoxicillin–clavulanate, or one of the oral second- or third-generation cephalosporins. A penicillin allergic patient may receive trimethoprim–sulfamethoxazole or azithromycin but the fluoroquinolones, tetracycline, and doxycycline should all be avoided (68).

Just as in the nonpregnant host, it is estimated that 90% of acute bronchitis—productive cough due to airway inflammation with a clear X-ray—is viral in origin. Rhinovirus, influenza, parainfluenza, respiratory syncytial virus, and adenovirus are the usual implicated viral pathogens. Without a chest radiograph, it can be difficult to determine whether a lower respiratory tract infection is bronchitis or pneumonia. The presence of high fever, lack of upper respiratory tract viral symptoms, and leukocytosis might suggest pneumonia, and a chest X-ray and/or a course of antibiotics is probably warranted (69). Humidified steam can be more helpful than prescription or over-the-counter cough medication and should be encouraged.

Bacterial Pneumonia

Pneumonia in pregnant patients is rarely fatal and has the same incidence as in non-gravid individuals. However, there is both maternal and fetal morbidity associated with the condition such as hypoxemia and low birth weight (69). While a young, otherwise healthy pregnant woman may not have a classic presentation, fever, rigors, dyspnea, productive cough, and occasionally pleurisy are common presenting signs and symptoms of bacterial pneumonia. A chest radiograph is required and the risk of an undiagnosed pneumonia far outweighs the risk of fetal radiation if the usual shielding precautions are taken. Causative organisms are those common in community acquired pneumonia such as *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, Legionella, Mycoplasma, and Chlamydia. Treatment with azithromycin and, in severe cases, ceftriaxone, is recommended. As with sinusitis, doxycycline, clarithromycin, and the fluoroquinolones should be avoided. Aspiration is common during pregnancy, and when pneumonia develops around the time of delivery or after an aspiration event, anaerobic organisms should be considered and treated (70).

Influenza

There have been three major influenza pandemics in the past 100 years—1918, 1957, and the H1N1 pandemic of 2009. In all three pandemics, there was higher morbidity and mortality among pregnant women. Seasonal influenza also takes a toll on the gravid patient with smokers, asthmatics, and women with other comorbid medical conditions having a higher rate of serious complications and hospitalization. This is especially true in the third trimester. Why influenza infection affects this pregnant group of young patients more seriously than their nonpregnant peers is unclear – theories suggest some difference in the immune system, the propensity of pregnant patients to have pulmonary edema due to hypoalbuminemia, and decreased oncotic pressure or their higher baseline oxygen consumption. Pregnant patients with known or suspected seasonal influenza should be observed closely so that if respiratory symptoms appear, they can be hospitalized. Otherwise, the usual treatment of rest, fluids, and acetaminophen for fever and myalgias applies (71).

The 2009 pandemic H1N1 influenza virus caused serious disease requiring hospitalization in many pregnant patients. Especially in the third trimester, infected women experienced respiratory failure, miscarriage, and preterm births. This led to the gravid patient being a priority for vaccination that season. In fact, influenza vaccination is recommended for all pregnant patients as experience has shown no risk to the fetus and a favorable benefit (72). Oseltamivir should be given to all hospitalized gravid patients with the H1N1 strain even if the conventional 48 hours of symptoms has passed. As with most viral respiratory infections, the bacterial superinfection rate is high and concomitant antibiotics should be considered (73).

Tuberculosis

Over 11,000 active cases of tuberculosis were reported in the United States in 2009 (74). Pregnancy does not appear to change the pathogenesis or disease progression of tuberculosis (75). Skin testing is safe and the results are not altered by pregnancy. However, routine testing for latent tuberculosis is not recommended unless the woman has a specific risk of quick progression from latent to active disease such as HIV infection or a recent significant exposure. Skin testing during pregnancy indicates that the practitioner has an intention to treat during pregnancy. In that setting, a positive skin test warrants a chest X-ray and evaluation to rule out active disease and then prophylactic therapy with isoniazid. In everyone other than those with immunosuppression or a recent exposure, testing and/or latent tuberculosis therapy should be deferred until at least the third month postpartum, since the risk of isoniazid hepatotoxicity is increased during pregnancy and the early postpartum period (76–78).

Active tuberculosis occurring during pregnancy may be initially hard to diagnose, as fatigue and malaise might be misinterpreted and weight loss can be mild. The workup for tuberculosis is the same in a pregnant patient as for a nonpregnant patient, and a new diagnosis of active tuberculosis should always prompt an HIV test. Active disease should be treated, as the risk of untreated disease is certainly higher than that of antituberculosis drug therapy

(77). First-line therapy is isoniazid, rifampin, and ethambutol, but pyrazinamide should be avoided because of limited safety data in pregnancy. However, in those patients with HIV, drug resistance, or extensive disease, its use should be considered. Streptomycin is a known teratogen and causes congenital deafness, so it should be avoided. Kanamycin, amikacin, and capreomycin are to be avoided because all cause eighth nerve damage and can cause renal toxicity. Generally any patient with multidrug resistant disease or who fails first-line therapy should be seen by an expert in tuberculosis. All patients are monitored using directly observed therapy and for hepatotoxicity (78).

Pneumocystis Jiroveci Pneumonia due to the Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

With the implementation of highly active antiretroviral therapy, the last decade has seen a remarkable decrease in both the morbidity and the mortality associated with HIV and AIDS. However, the percentage of AIDS cases in women continues to grow annually. By 2007, 27% of adult AIDS patients were woman, and of these, 83% were women from communities of color (79). Heterosexual contact is the most common mode of acquisition in women and therefore issues surrounding the management of HIV/AIDS during pregnancy have become increasingly important.

In addition to an increased rate of viral and bacterial infections of the upper and lower airway, AIDS patients with a CD4 count <200 are susceptible to infection with *P. jiroveci*. Limited review of pregnant patients with *P. jiroveci* pneumonia during pregnancy suggests that mortality is higher in this group (50%) than in nonpregnant subjects and that risk is higher in the second and third trimesters of gestation (80). However, only a small number of cases have been reported in the literature and the women reported were almost all unaware of their HIV/AIDS status at the time of pneumonia diagnosis. Therefore, they were not receiving prophylaxis against this infection. Trimethoprim–sulfamethoxazole prophylaxis should be initiated using the same guidelines as for nonpregnant women (CD4 count less than 200). Generally, pentamidine should be used during the first trimester rather than trimethoprim–sulfamethoxazole. While the fetus is most susceptible to drug teratogenicity during the first 10 weeks of gestation, if the mother's health is poor, the benefit of therapy during this early gestational period likely outweighs the risk to the fetus (81–85). For active *P. jiroveci* infection at any time during pregnancy, trimethoprim–sulfamethoxazole remains the standard of care and steroid therapy should be considered in severe cases (80).

MISCELLANEOUS DISORDERS

Pulmonary Edema

Cardiogenic pulmonary edema is uncommon during pregnancy, but can occur late in pregnancy and early postpartum, usually due to heart disease, valvular problems such as mitral stenosis, or idiopathic cardiomyopathy. Patients complain of dyspnea and chest tightness, and may have bilateral infiltrates on chest radiograph. Therapy is similar to nonpregnant patients and includes diuresis and oxygen. However,

non-invasive positive pressure ventilation via mask is best not used due to the increased incidence of aspiration (86).

Non-cardiogenic pulmonary edema occurs in women receiving beta sympathomimetic agents for tocolysis. Usually, this condition occurs during administration of the drug, but can occur within 24 hours after discontinuation. Women complain of dyspnea and chest tightness, and rales may be present, as well as bilateral alveolar infiltrates on chest radiograph. Therapy is supportive with discontinuation of the beta agonist, oxygen, and diuresis. Resolution is expected within 24 hours (87).

Pleural Effusion

While there has been no specific study that identifies the disease processes causing pleural effusion in pregnancy, likely up to 25% of pregnant patients have small, asymptomatic pleural effusions visible on ultrasound. When pleural effusions are symptomatic, they cause dyspnea, cough, and possibly chest pain—if significant, there may be room air hypoxia due to shunting through underlying atelectatic lung. Symptomatic effusions in early pregnancy are either due to ovarian hyperstimulation syndrome or the same processes that cause effusions in nonpregnant patients: infection, cardiomyopathy, and PE. Neither pre-eclampsia nor the HELLP syndrome is associated with pleural effusion. Thoracentesis with drainage is indicated for diagnosis and/or the relief of symptoms due to a significant amount of pleural fluid. The small bilateral effusions described above that are asymptomatic generally are self-limiting and do not require intervention (88).

Sleep Disorders

Sleep-disordered breathing is prevalent in the general population and sleep disturbance is one of the most common complaints during pregnancy. However, there are limited data to elucidate the causes for sleep disturbance during pregnancy—difficulty lying in the supine position, nasal congestion, weight gain, and decreased time spent in rapid eye movement sleep have all been implicated (89,90). There is a suggestion that obese women who become pregnant have more sleep-disordered breathing, even in the first trimester, and this may be important if there is nighttime hypoxia that can affect the growth of the fetus. More work is needed in this area of sleep medicine (90).

Aspiration

Aspiration into the lung of stomach contents occurs most often during or immediately after labor. The combination of delayed gastric emptying, a relaxed lower esophageal sphincter, and increased intra-abdominal pressure with recumbency and sedation or analgesia increase the risk of vomiting and aspiration. Acutely, aspiration can lead to a chemical pneumonitis or bronchospasm, and aspiration of upper airway organisms such as anaerobes and streptococci can ultimately lead to a bacterial pneumonia. Chemical pneumonitis, while hard to distinguish from pneumonia, generally has an acute onset with dyspnea, cough, and low-grade fever. Radiographs reveal multifocal infiltrates with basilar predominance and treatment is supportive. Bronchospasm can be indistinguishable from

asthma with dyspnea and wheezing and is treated with bronchodilators (91,92).

Respiratory Failure and Mechanical Ventilation

Respiratory failure, defined as a PaO₂ of <60mmHg or pCO₂>50mmHg, is a rare complication of pregnancy. The patient in respiratory failure will be distressed, tachypneic, and with shallow breaths despite the use of accessory muscles. If supplemental oxygen by nasal cannula or face mask fails to keep the oxyhemoglobin saturation above 95% (required for adequate fetal oxygenation), intubation and mechanical ventilation should be considered (93). Oral intubation of the pregnant patient can be difficult, with the decreased functional residual capacity and increased oxygen consumption causing more rapid hypoxia and upper airway edema obscuring adequate visualization during direct laryngoscopy. Intubation should be performed by experts in airway management. While receiving treatment tailored to the cause of the respiratory failure, mechanical ventilation should be managed to maintain a pCO₂ in the 27 to 32 range, as this is the usual pCO₂ during pregnancy. Severe respiratory alkalosis (potentially causing decreased uterine blood flow), hypoxia, and acidosis should be avoided (93).

28 Psychiatric disorders in pregnancy

Robin Kopelman and Scott Stuart

Pregnancy and childbirth are naturally occurring life events accompanied by momentous neuroendocrine and psychosocial changes. These transitions are often accompanied by changes in mood and psychological functioning, and these changes in turn may have an impact on the developing fetus and/or infant.

One of the most unique aspects of perinatal medicine is its subject matter: it addresses the life and well-being of both the mother and her offspring. Likewise, perinatal psychiatry must address the suffering of the individual pregnant woman and her safety while being mindful of the significant potential effects of maternal mental illness on early child development (1,2).

Pregnancy and childbirth has historically been described—incorrectly—as a time of well-being, calm, and inner peace for women. Elevated gonadotropin levels, the sense of fulfillment, and the responsibility of caring for the young were believed to confer protection from mental disorders (3,4). Carefully designed studies, however, found no such decrease in the incidence of perinatal mental disorders (5,6). The current empirically based position is that events in women's reproductive cycles such as menstruation, pregnancy, childbirth, and menopause can be understood as biological (7) and psychological risk factors (8) for mood disorders.

Psychiatric disorders in the obstetric setting are frequent, with up to 40% of women having an identifiable mental disorder, most commonly depression (9,10). In the first several months postpartum, there is an increased risk for psychiatric admission or outpatient contact (4,11,12). It appears that the perinatal period places a subset of women at increased risk, and the overall prevalence and impact of the perinatal psychiatric disorders, as well as the unique treatment considerations for this population, make these disorders a topic of great significance for perinatal health-care providers. This chapter provides a current overview of the most common psychiatric disorders during pregnancy and the postpartum period.

MOOD DISORDERS IN PREGNANCY AND THE PUERPERIUM

An occasional low mood is a normal reaction to the disappointments, setbacks, and losses inherent in everyday life. It is usually transient and not associated with significant functional impairment. A depressed mood, however, may be a part of a serious, potentially disabling disorder such as major depressive disorder (MDD), bipolar disorder (depressive episodes alternate with periods of abnormally elevated or irritable mood), or dysthymic disorder (characterized by low-grade, more persistent depressive mood that has been present for at least 2 years). Epidemiologic data from around the world show that MDD is twice as common in women as in men (13).

Because low mood can be a normal experience, it is important for the clinician to be familiar with the diagnostic criteria for clinical depression. The *Diagnostic and Statistical Manual of Mental Disorders* (14) (DSM-IV) requires the presence of depressed mood or loss of interest and at least four of the following symptoms over the same 2-week period to diagnose major depression: weight loss or gain, insomnia or hypersomnia nearly every day, psychomotor agitation or retardation, fatigue or loss of energy, difficulties with concentration and memory, and guilt or suicidal thoughts.

Despite the serious consequences, detection rates for perinatal depression remain low, with only a small proportion of depressed women identified by health professionals (10,15). Depression in pregnant and recently delivered women may be underdiagnosed because of the common presence of symptoms that are also associated with normal perinatal changes, such as fatigue, insomnia, weight or appetite changes, and changes in libido (16,17).

Ultimately, less than one-third of depressed perinatal women receive treatment (10,15). Financial issues and concerns about safety of medications during pregnancy may play a significant role (18). Often, women discontinue medication on their own once they become aware that they are pregnant (19). Relapse rates for those women who discontinue antidepressants during pregnancy are high, with higher relapse rates in women with depression for more than 5 years, more than four episodes, and of younger age (20).

Rates of treatment can be improved by accurately identifying women with perinatal depression. A self-report questionnaire to screen for depression should be used with a standard interview in the obstetric setting to facilitate this (21). The Edinburgh Postnatal Depression Scale (22) is a commonly used screening measure, which is both sensitive and specific for perinatal depression. It focuses on psychologic symptoms, rather than the somatic symptoms associated with new parenthood, and has been validated for use in pregnancy (23). Additionally, it is brief (10 items) and is an easy-to-use score.

The treatment and therapeutic responses for depression during pregnancy and the postpartum period are similar to those outside of the perinatal period (24). The treatments of choice are psychotherapy and antidepressant medications (25–29).

DEPRESSION IN PREGNANCY

The incidence of major and minor depression during pregnancy is approximately 10% (30), which is similar to the nonpregnant female population (5). However, it may be as high as 27.6% among women in poor urban communities (31). Risk factors for perinatal depression are similar to those for depression at other times and consist primarily of a

personal or family history of depression and poor social support, particularly from the partner (8,32).

The risks of untreated depression during pregnancy are significant. Antenatal depression has been associated with an increased risk for pre-eclampsia (33), preterm delivery (34), and fetal growth retardation (35). Depressed pregnant women obtain less adequate prenatal care (36) and have more negative health behaviors (e.g., tobacco use) (37), both of which also negatively impact birth outcomes.

POSTPARTUM MOOD DISORDERS

The spectrum of postpartum mood disorders includes postpartum blues, postpartum depression (PPD), and postpartum psychosis.

Postpartum Blues

Postpartum blues is a transient experience characterized by insomnia, anxiety, mood lability, irritability, and tearfulness, occurring exclusively within the first 2 weeks after delivery. It occurs in up to 75% of postpartum women (38), making it so common that most practitioners believe that it should not be considered a disorder. It has a minor functional impact and usually resolves spontaneously. Management is limited to reassurance and support without medications. However, close follow-up is indicated; women experiencing severe blues symptoms are at higher risk to develop a postpartum depressive episode (39).

PPD

Prevalence estimates for PPD range from 6.8% to 13% (8,17,40–42) and up to 26% among adolescent mothers (43).

Risk factors for PPD include the following:

1. Personal or family history of depression (17,44).
2. Presence of depression during pregnancy (45).
3. Psychosocial factors such as marital conflict, being a single mother, lack of social/family support, the stress of caring for the infant (disrupted sleep and sleep deprivation), multiple births, complications during pregnancy (especially if necessitating prolonged bed rest), and other stressful life events during the year preceding the birth (30,44,46).

The onset of PPD occurs in up to 70% of patients within the first 3 months postpartum (41,47). The depressive episode may last from 3 months to 14 months (48), though women may have significant depression lasting much longer (49). The clinical picture of PPD is similar to that of major depression occurring in the nonpuerperal period (50,51).

Unrecognized or untreated depression may impair function and adversely affect the new mother's ability to care for her infant. Depression may also interfere with the new mother's ability to respond optimally to the infant and consequently may have adverse effects on early child development (1,2,52). Women with PPD are also less likely to engage in positive and healthy parenting practices (53).

Suicide and infanticide are the most serious complications of PPD. While approximately 15% of depressed individuals in the general population end their lives by suicide (54,55), having living children may offer some protection from suicide in the postpartum period (3). Women with perinatal

depression may nonetheless have thoughts of harming themselves or the infant (56) and the risk for suicide is a particular concern for these women (55). In the United Kingdom, suicide related to psychiatric disorder was found to be the leading cause of maternal death over the year following delivery (57).

Risk factors for suicide include a history of depression, prior suicide attempts, psychosis, and several psychosocial risk factors such as living alone, lack of family or social support, and feelings of guilt and hopelessness. Obstetricians should be aware of the risk and ask women about suicide and self-harm, as well as infanticide, with such questions as "Have you been feeling like life is not worthwhile?," "Have you had thoughts of harming yourself (or your baby), wanting to die or wanting to end your life?," "Have you thought about how you might harm yourself (or your baby) or end your life?," and "How likely is it that you might actually do something like that?" When suicidal or infanticidal ideation is present, emergency psychiatric consultation is warranted.

The pathogenesis of PPD remains undetermined. The belief that hormonal factors are the greatest contributors to PPD persists even though the empirical support that serum levels of gonadal hormones account for postpartum mood symptoms is equivocal at best (7). Likewise, there has not been clear evidence to support the hypothesis that a rapid decline of gonadal hormones and cortisol and/or the effect of their withdrawal on neurotransmitter activity trigger PPD (46,58,59).

There is, however, some recent research that suggests that there may be a subset of women who are susceptible to the abrupt hormonal withdrawal in the postpartum (60,61). Epidemiologic data demonstrating a high degree of overlap between the diagnosis of premenstrual dysphoric disorder and PPD have supported this theory (62,63). Several investigators have suggested that serotonin dysregulation in particular might play in PPD due to its role in depression at other times and its interaction with gonadal steroids (especially estradiol) (17,64–66). To date, treatment with selective serotonin reuptake inhibitors (SSRIs) have mixed results in preventing the onset of PPD (67). There are small amount of data suggesting prophylactic effects (58) and possible treatment benefit in PPD patients being treated with estradiol (68,69).

Postpartum Psychosis

The incidence of postpartum psychosis is 0.1% to 0.2% or 1 to 2 per 1000 births (70). In most cases, the onset occurs during the first 2 weeks postpartum. It is frequently heralded by one to two nights of insomnia and irritability (7). The most characteristic clinical presentation consists of confusion and delirium-like psychosis with disorganized behavior, mood lability, and hallucinations and delusions that are often focused on childbirth themes. While infanticide is quite rare, women with postpartum psychosis are more likely to experience thoughts of harming their infants than women with nonpsychotic PPD and are at risk for neglecting their infant (71,72).

Differential diagnoses for postpartum psychosis include bipolar disorder presenting as a manic episode, schizoaffective disorder, and major depression with psychotic features. The cognitive disturbance associated with postpartum psychosis

also makes thorough evaluation for delirium essential, with possible causes including cerebrovascular incidents (e.g., due to eclampsia), medications used in delivery, and metabolic or infectious etiologies (73). Research data suggest, however, that postpartum psychosis is most often a manifestation of bipolar disorder (74,75).

A personal or family history of postpartum psychosis as well as bipolar disorder (70,76) increases a woman's risk. The risk of recurrence in subsequent pregnancies is estimated to be 40% to 60% (77–79).

In addition to postpartum psychosis, psychotic illnesses in the puerperium also include schizophrenia. The lifetime prevalence of schizophrenia is about 1.5% spread equally across both genders, and women with schizophrenia get pregnant and give birth. Given that its peak age of onset is between 15 and 35 years of age, it is of particular clinical importance during women's reproductive years. However, the incidence of schizophrenia does not appear to be impacted by pregnancy and childbirth (70,80).

Schizophrenia and other psychotic disorders manifest a variable course ranging from acute episodes to a protracted disturbance of thought and behavior with gradual decline. Clinical course and prognosis are significantly improved by the availability of family and social support and psychiatric care. Patients may show negative symptoms (such as apathy or flat affect), disorganization, eccentric thinking and behavior, or acute psychotic manifestations, such as hallucinations or delusions. These symptoms may have a devastating impact on the mother and fetus or infant; women with schizophrenia have increased rates of a number of adverse pregnancy outcomes (81,82) and are at risk for suicide and other self-destructive behaviors, as well as infanticide (83).

As noted, any new-onset psychosis during pregnancy or the postpartum should be promptly evaluated for an identifiable medical (e.g., drug-induced psychosis, temporal lobe epilepsy, stroke, systemic lupus erythematosus, acute intermittent porphyria) or psychiatric (e.g., brief reactive psychosis, manic or depressive phase of bipolar disorder) cause. Treatment in the perinatal period includes control of the symptoms of disorganized thought and behavior through the administration of the lowest effective dose of antipsychotic medication (preferably from the high potency subgroup, such as haloperidol) and addressing psychosocial needs.

ANXIETY DISORDERS IN THE PERINATAL PERIOD

The course of anxiety disorders in the perinatal period, including obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), panic disorder, and generalized anxiety disorder, is variable. The relationship between the perinatal period and both obsessive compulsive disorder and PTSD makes additional discussion of these important.

Clinically, OCD presents with obsessions (intrusive thoughts or images) and/or compulsions (actions and rituals that the individual feels compelled to perform to reduce intense anxiety). Perinatal patients often report a fear of accidentally or intentionally harming the fetus or baby (84,85). The clinician should keep in mind that some patients may feel guilty because of their strange and frightening thoughts and may not report them spontaneously. It is helpful, therefore, for the clinician to inquire in a tactful and nonjudgmental way

whether the mother has any of these fears. These thoughts are not seen exclusively in OCD, as over 40% of women with PPD (86,87) and over 20% of new parents without a mental disorder (88) report these types of thoughts.

The prevalence of OCD during the perinatal period ranges from 0.2% to 3.9% and may be more common in the postpartum (89). Some women may be asymptomatic during one pregnancy, yet develop OCD in subsequent pregnancies (90). Pregnancy is believed to be a potential trigger for the onset of OCD (91) and the postpartum is considered to be a period for worsening of OCD (92). The onset of OCD may in fact be neurohormonally modulated. The possible role of estrogen, progesterone, oxytocin, and the serotonergic system has been investigated (93,94), but none of these hormones has been definitively linked to perinatal OCD.

PTSD develops subsequent to exposure to a traumatic event involving actual or threatened death or serious injury or a threat to the physical integrity of self or others. The response to the perceived threat is usually fear, helplessness, or horror. A typical triad of symptoms include reexperiencing of the event (e.g., nightmares, flashbacks), avoidance of stimuli associated with the event, and signs of hyperarousal such as insomnia or irritability (14). The prevalence of PTSD symptoms in perinatal women varies widely (0–7.7%) (95,96), with PTSD being most prevalent in a group of economically disadvantaged pregnant women.

In contrast to OCD, it is the events associated with the perinatal period rather than the hormonal changes associated with pregnancy and childbirth that are speculated to act as triggers for the development or exacerbation of PTSD symptoms. For example, deliveries that women appraise as traumatic, particularly those involving difficulties with pain control, powerlessness, or lack of control, are associated with PTSD (89). For women with a history of sexual abuse, procedures such as internal examination and delivery may trigger memories of the abuse (95,97).

Untreated anxiety disorders have been associated with negative outcomes such as preterm delivery (98). Anxiety in pregnancy, like perinatal depression, may have adverse effects on the emotional and behavioral well-being of children (99). More research is needed in this area as it is increasingly recognized that untreated anxiety and depression are likely to have a deleterious effect on fetal development.

Women with a history of anxiety disorders who plan to conceive should be informed of the variable course and the potential treatments. Treatment options for anxiety include psychotherapy and medication. Anxiety disorders are frequently associated with interpersonal difficulties such as fears of expressing anger, isolation, and excessive concern of being judged by others. Psychotherapy may be effective for both the anxiety and the interpersonal difficulties these patients have.

Medication may be necessary if symptoms interfere significantly with daily functions and/or psychotherapy is not accessible. As with other mental disorders, the use of medication should be assessed within a framework that balances the risks associated with nontreatment of the illness and the contextual and clinical factors that impact the woman's preferences, including her ability to access treatment, the risks to her personally from the illness, and the risks to the fetus or breast-feeding infant (100,101).

SSRI antidepressants, or the tricyclic antidepressants (TCAs), such as nortriptyline, may be helpful. Benzodiazepines have a role in the treatment of anxiety in the general population, but use of antidepressants is preferred in the perinatal period because they have better safety profiles in pregnancy and lactation (102).

TREATMENT: PSYCHOTHERAPY AND MEDICATIONS

Depression during pregnancy, PPD, and psychosis are potentially severe and disabling. Untreated, they may carry a significant risk to both the mother and to her offspring. The clinician needs to carefully weigh both the maternal benefits from the medications and the potential fetal risks (26,29,100,103). Medications during the first trimester, pregnancy, or the postpartum might be avoided if the depression is not severe and psychotherapy could be undertaken (26,27). This decision should be made in partnership with the patient. Again, careful assessment of the patient's experiences and clinical history, as well as the acceptability and accessibility of treatments is essential (18,100,101).

Psychotherapy can be an effective option for some women with perinatal depression. For women with milder symptoms who prefer psychosocial treatment, it should be considered first line. Psychologic treatments like interpersonal psychotherapy (IPT) are efficacious for antenatal depression (104). At present, there are not efficacy studies demonstrating the benefit of cognitive behavioral therapy (CBT) for antenatal depression. For postpartum women with milder symptoms, various psychosocial treatments delivered by nonmental health or mental health professionals have been shown to improve depressive symptoms (27). For more severe depression, benefit has only been shown in studies with well-defined treatments, such as IPT or CBT, delivered by highly trained professionals (27).

Psychotropic medication will be the first treatment choice for many women, particularly those with more severe illness or for whom other treatments are inaccessible. All psychotropic medications cross the placenta and their potential effects on the developing fetus must be considered (29). Three areas of potential impact of medications given during pregnancy are teratogenicity, if the medication is administered during the period of organogenesis; neonatal toxicity or withdrawal if the medication is given close to the time of birth; and later behavioral sequelae (103). There are few longitudinal studies examining behavioral changes in children exposed to antidepressants or depression during pregnancy (105), so subsequent discussion is focused on teratogenicity and withdrawal effects.

Antidepressants

TCAs have been available in the United States since 1963. Extensive cumulative experience has revealed no increased risk of major congenital malformations with their use in the first trimester (17,106). Use of TCAs in pregnancy has been associated with perinatal complications such as jitteriness and irritability in the newborn (103,107). Most investigators recommend the use of the secondary amine TCAs (e.g., nortriptyline) over the tertiary amines (amitriptyline).

While the SSRI antidepressants have been used for a shorter period of time, they have significant advantages over

the TCAs and are undoubtedly the most commonly prescribed (108). They have a more benign side effect profile, lacking cardiac toxicity or anticholinergic side effects, and have a much better safety profile compared with the tricyclics in cases of overdose (109).

The majority of studies have not found an increased rate of major malformations with the use of SSRIs in pregnancy (110–112). Some studies have demonstrated an increased, but small, risk of select anomalies (e.g., omphalocele, septal defects) with exposure to certain SSRIs (111–113). Concern has been raised about paroxetine, in particular, as two studies suggest that it confers an increased risk of cardiac defects with first-trimester exposure. The manufacturer subsequently changed product warning labels (114). Findings remain controversial (115), but at present, one should avoid initiating new treatment with paroxetine in women of childbearing age and consider fetal echocardiography in women exposed during early pregnancy. Third-trimester exposure to SSRIs has also been associated with a possible increased risk for persistent pulmonary hypertension of the newborn (116).

Peripartum effects of exposure include an association between SSRIs and premature delivery and low birth weight (34), though most studies have been unable to control for the possible impact of depression itself on pregnancy outcome. Furthermore, the slight decrease in birth weight and gestational age is not considered by most experts to be clinically significant. Both SSRIs and TCAs have been associated with symptoms secondary to discontinuation of medication exposure in the neonate (103,107,117). To minimize the risk of neonatal toxicity and withdrawal after delivery, the maternal dose of medication could be reduced during the 2 weeks prior to delivery (17).

Given the risk for recurrence of depression, psychiatric follow-up and maintenance treatment is considered the standard of care for perinatal disorders (118). Overall, a reasonable therapeutic goal for treating depression during pregnancy or PPD is to control symptoms and to recover function at a minimum effective dose of medication (17). When making a decision to reduce or temporarily discontinue medication, a discussion of the potential for relapse during pregnancy or postpartum is essential.

Other antidepressants are less commonly used, but may be encountered in perinatal women. The studies examining mirtazapine (119), bupropion (120,121), venlafaxine (122), trazodone, and nefazodone (123) do not suggest an increased risk of fetal anomalies. Monoamine oxidase inhibitors are generally not recommended for use in the perinatal period due to the lack of data and potential for hypertensive crisis (124).

In the immediate time period surrounding delivery, several additional issues should be considered. First, hepatic immaturity in the newborn may affect the metabolism of psychotropic medications, thus leading to potentially higher blood levels in the newborn (17). The infant's pediatrician should be informed of maternal medications to prevent possible adverse drug interactions with other medications that may be prescribed for the infant. Second, women who are not symptomatic in pregnancy or the postpartum, but who have a history of depression, especially PPD, may benefit from a preventive intervention with psychotherapy or antidepressant medication, though research data are limited at this time.

A woman might elect to initiate prophylactic treatment approximately 48 hours after delivery with an SSRI or start a preventive counseling intervention spanning pregnancy and postpartum (67,125).

All psychotropic medications are found in the breast milk at various concentrations. Infants' absorption rates vary and significant drug levels are rarely detected in infants' serum. These medications are not found in quantifiable amounts in breast milk and have not caused any adverse neonatal effect (126). In a pooled analysis, levels were particularly low for sertraline, paroxetine, and nortriptyline, making these medications preferred. Elevated infant levels occurred with fluoxetine and citalopram (127).

There are case reports of adverse events with breast-feeding exposure to all types of antidepressants. Most reports involve fluoxetine (105), probably due to its long half-life and resultant increased blood levels, making it generally not recommended for use in nursing mothers (126). Few long-term studies exist and clear evidence of developmental problems has not been described in infants exposed to antidepressant medications in breast milk (128). Prescription of an antidepressant for a breast-feeding woman is a case-specific, risk-benefit decision (101).

Mood Stabilizers

The mainstay of treatment and prevention of recurrence of bipolar disorder, including that during the perinatal period, is a mood stabilizer such as lithium carbonate, valproic acid, carbamazepine, or lamotrigine (129). Women who discontinue mood stabilizer treatment in the perinatal period have high rates of relapse (130). During an acute depressive or manic episode, an antidepressant or an antipsychotic medication may be necessary. Sleep hygiene in bipolar patients has been shown to be very important, and sleep deprivation itself may trigger relapse (131).

The association of cardiac malformations with lithium exposure in the first trimester is widely documented by the Lithium Baby Register. The risks of major congenital anomalies, cardiovascular abnormalities, and Ebstein's anomaly in fetuses who were exposed to lithium during the first trimester have been reported as 8% (15/183) and 3%, respectively (132,133). The relative risk seems to be smaller than initially reported and is estimated to be 1.5 to 3.5. Women who are on lithium maintenance and contemplate pregnancy should have preconception counseling.

Patients who have had a single episode of mood disorder could taper their lithium before conception and restart it if necessary after the first trimester. Lithium levels should be monitored closely during pregnancy. Current guidelines recommend taper 48 hours before delivery to avoid toxicity in the newborn (17) and restarting after delivery at prepregnancy dosing (134).

Patients with bipolar disorder who have had multiple episodes run a high risk of relapse without the medication. The maternal risk from recurrence may outweigh the fetal risk from exposure to lithium (17,135). Lithium is generally considered to be contraindicated during breast-feeding because its concentration in breast milk is about 40% of maternal serum (136-140). Both valproic acid and carbamazepine are considered compatible with breast-feeding

(17,140). Both should be avoided during pregnancy if possible because of their association with neural tube defects (17,141,142). An ultrasound examination of the fetal anatomy at 18 to 20 weeks is advisable. Lamotrigine may be another option for treatment during pregnancy and breast-feeding as it appears to have a more favorable safety profile than the other anticonvulsant mood stabilizers (143).

Antipsychotics

All antipsychotic medications (neuroleptics) cross the placenta and are secreted in breast milk. The atypical antipsychotics (clozapine, olanzapine, and risperidone) lack sufficient data with respect to potential teratogenic effects. Though they are increasingly used for psychosis and bipolar disorder due to improved medication tolerance and effectiveness in treating negative symptoms in schizophrenia, caution in use should be exercised.

Typical antipsychotic drugs have a larger amount of reproductive safety data available, especially haloperidol. The high-potency antipsychotics (e.g., haloperidol) are preferable to the low-potency drugs. Several of the typical antipsychotics (chlorpromazine, haloperidol) have been previously prescribed during pregnancy for hyperemesis with safety data in pregnancy obtained in these studies (144,145).

CONCLUSION

Psychiatric disorders are very common during pregnancy and the postpartum, and have a great deal of morbidity for both mother and infant. Many women are not recognized as having a psychiatric disorder, leading to a strong recommendation that screening instruments be used routinely in all obstetric settings. Both medications and psychotherapy are effective treatments, and all decisions regarding treatment must be made with a careful risk-benefit analysis that enlists the woman collaboratively in her care.

29 Renal diseases in pregnancy

Dana Negoï and Khaled Mohamed

INTRODUCTION

Caring for pregnant women with renal disease is usually a difficult task for both the obstetrician and the nephrologist. These pregnancies are viewed as high risk, due to concerns of increased maternal and perinatal morbidity and mortality. It is estimated that at least 4% of the women in the childbearing age carry a diagnosis of chronic kidney disease (CKD) (1) of different etiologies: diabetic nephropathy, lupus nephritis, polycystic kidney disease, reflux nephropathy, or different forms of glomerulonephritis. Although the frequency of conception decreases as the impairment in kidney function progresses, with levels as low as 0.5% per year in dialysis patients (2), it is not unheard of patients on either hemodialysis or peritoneal dialysis (PD) to get pregnant. When end-stage renal disease patients get a kidney transplant, the return of fertility is usually the rule and caring for these pregnancies is even more challenging due to the continued need for immunosuppression, with its associated fetal risks for congenital anomalies, and small-for-gestational-age babies (2).

This chapter is intended to provide information needed to take care of these patients, and will start by reviewing normal renal anatomy and physiology during pregnancy. The interplay between CKD, acute renal failure (ARF) or acute kidney injury, hypertension (HTN) and pregnancy will be further explored.

RENAL ANATOMY AND PHYSIOLOGY DURING PREGNANCY

There are marked changes in the renal hemodynamics and function during normal pregnancy, associated with significant anatomical changes such as increased renal size and dilatation of the collecting system. They occur in concert with multiple other physiologic alterations that take place during pregnancy, including significant expansion of the blood volume, increased cardiac output, and enhanced blood flow in several regions of the body (3) (Table 1).

Blood volume can increase almost 50% in a normal pregnancy, compared with the nonpregnant state. This represents roughly 1500 mL increase, of which about 500 mL is in red blood cell volume. Volume expansion starts in the first trimester, but is more marked in the second trimester and the rise is much less in late pregnancy. It is believed to be caused by the increased metabolic demands of the enlarged uterus with its increased vascularity, placenta and fetus, the need to protect the fetus against the harmful effects of decreased venous return when in supine and upright position, and the need to protect the mother against blood loss during delivery (3). Aldosterone levels are elevated, but it is not known whether this contributes to hypervolemia. It is accompanied by vasodilatation, especially in the pelvis. There are no clinical signs of volume overload in a normal

pregnancy (3). Expansion of the blood volume may be greater in multiple gestations or smaller in pre-eclampsia (4).

Other cardiovascular changes include increase in cardiac output and significant decrease in systemic vascular resistance with resultant decrease in blood pressure in normal pregnancy (4).

Dilatation of the Collecting System

Dilatation of the collecting system seems to be the result of a combined progesterone-induced ureteral smooth muscle relaxation and compression of the ureter by the enlarged uterus and iliac vessels. A pelvicaliceal diameter of up to 2 cm is usually allowed as “physiologic hydronephrosis” of pregnancy. Hydronephrosis is most commonly seen on the right, due to anatomical reasons (5,6). By ultrasound criteria, hydronephrosis is defined as at least 5 mm (5) dilatation of the calyceal diameter. This dilatation of the urinary collecting system starts developing during the second trimester, is seen only above the linea terminalis, and resolves in few weeks after delivery (6). Symptomatic hydronephrosis is not a frequent event, occurring in about 0.2% to 3% of pregnant women (7), but those who are symptomatic frequently have associated urinary tract infections (6).

The dilated collecting system can retain some of the urine meant to be saved for the twenty-four hour urine collections. As a result, creatinine clearance may be underestimated, unless the collection is done carefully and the patient is volume repleted before the test. If in the last few hours of the collection the patient is maintained in the left lateral recumbent position, the chances of obtaining a full collection are also increased.

Increase in Renal Volume

During pregnancy, the kidneys increase in volume, probably due to increase in blood flow and interstitial volume. A study of humans that excluded dilatation of the renal pelvicaliceal system demonstrated that renal volume can increase by 30% in normal pregnancy (8).

GFR

Renal hemodynamics undergo significant changes: renal plasma flow (RPF) increases by 50% to 80%, while GFR increases by 50% (9). Systemic and renal hemodynamics adaptations occur early in pregnancy, before complete placentation takes place, demonstrating that they are dependent mainly on maternal factors for their development (10). They are also present in pseudopregnancy, a condition where the fetoplacental unit is absent (11), and different studies have suggested roles for relaxin, an ovarian hormone, and also for nitric oxide synthase, prostaglandins, and endothelin (9).

The physiologic increase in GFR is the result of expansion in the renal plasma blood flow, associated with characteristic

renal vasodilatation resulting from both afferent and efferent arteriolar relaxation (11). The parallel reduction in preglomerular (afferent) and postglomerular (efferent) arteriolar resistance explains why single nephron GFR increases without an increase in the glomerular capillary pressure (11), which is an important phenomenon, and explains further why normal pregnancy is not followed by loss of kidney function. This last aspect was demonstrated in animal studies on rats (12), where it was shown that repetitive pregnancies were not associated with increased risk of deterioration of kidney function. Rats provide a good animal model to study this particular problem since they have a gestation of only 22 days. After six repetitive pregnancies,

the study rats had no renal changes compared with never-pregnant controls (12).

GFR increases to a maximum of about 50% by mid-pregnancy (13), remains elevated during the pregnancy, and returns to baseline values 3 months after delivery (1), while RPF starts to fall toward the end of pregnancy (13) (Fig. 1). The increase in GFR is not accompanied by an increase in the production of urea and creatinine: their serum concentration will decrease in pregnancy. Serum creatinine concentration falls by about 0.4 mg/dL, so the normal pregnancy range is 0.4 to 0.8 mg/dL (14).

Estimation of GFR using the modification of diet in renal disease (MDRD) formula has been recently evaluated in pregnant women. In a study that looked at three groups of pregnant women—healthy pregnant volunteers, women with pre-eclampsia, and pregnant women with previously known CKD—the MDRD formula significantly underestimated kidney function although performed better in pre-eclampsia and CKD group (15). Alper et al. found that the MDRD formula, along with the Cockcroft-Gault formula, was inaccurate in predicting GFR in pre-eclamptic patients (16).

Cystatin C is a low-molecular weight (MW) protein, which has been recently studied in the general population in an attempt to find a better endogenous marker that could be used for more accurate estimation of GFR (17). Studies have found that while serum creatinine levels decrease in pregnancy, cystatin C levels were higher for pregnant women as compared with healthy nonpregnant women (18) and also significantly higher in twin as compared with singleton pregnancies (18). Cystatin C levels increase during pregnancy in relationship to gestational age, being highest in the third trimester (19). Its actual role in pregnancy is very interesting, as cystatin C is a member of the cystatin superfamily of cysteine protease inhibitors. Proteinases and their inhibitors regulate the trophoblast invasion, and the serum concentration of cystatin C has been found in several studies to be increased not only in late pregnancy but also in pre-eclampsia (18–20). Based on the available data, it is unlikely that cystatin C will have any utility in monitoring kidney function in pregnancy but might prove useful in the early detection of patients who will develop pre-eclampsia (21).

Table 1 Physiologic and Anatomic Changes in Normal Pregnancy

Blood volume	Increased 50% (1500 cc)
Cardiac output	Mild increase
Net sodium retention	900 mmol
Systemic vascular resistance	Decreased
Systemic blood pressure	Decreased
Systolic	15 mmHg
Diastolic	10 mmHg
RPF	Increased 50–80%
GFR	Increased 50%
Glomerular capillary pressure	Unchanged
Serum osmolality	Decreased 10 mmOsm
Urine concentration and dilution	No change
Proteinuria	200–300 mg/day
Glucosuria	Present in the absence of diabetes
Serum creatinine, uric acid, BUN	Decreased
Serum cystatin C	Increased
Acid–base	Compensated respiratory alkalosis
Kidney volume	Increased 30%
Urinary collecting system	Dilated

Abbreviations: RPF, renal plasma flow; GFR, glomerular filtration rate; BUN, blood urea nitrogen.

Figure 1 Renal hemodynamics during normal pregnancy. *Source:* From Ref. 13. *Abbreviations:* GFR, glomerular filtration rate; RPF, renal plasma flow.

Renal Tubular Function in Pregnancy

Uric Acid

Uric acid after being freely filtered at the glomerular level is extensively reabsorbed, mainly in the proximal tubule, so that only 10% of the filtered load is excreted (13). Plasma concentration decreases early on in pregnancy by at least 25%, largely due to the significant rise in GFR, but also due to decrease in tubular reabsorption (13). In late pregnancy, the fractional excretion of uric acid decreases and the plasma levels trend toward nonpregnant levels (13).

Glucose

The presence of glucose in the urine may rather be a sign of tubular dysfunction than diabetes mellitus. Proximal and distal tubules have a decreased capacity to reabsorb filtered glucose due to an unknown mechanism. The increase in GFR causes an increase in filtered load of glucose on one hand. On the other hand, the increase in plasma volume may inhibit the tubular reabsorption of sodium and hence glucose (13).

Sodium

There is a gradual retention of sodium during pregnancy, reaching 900 mmol, due to a positive sodium balance and an increase in tubular reabsorption of sodium (22).

Water Metabolism

Although the kidneys' abilities to maximally dilute and concentrate urine are intact, the serum sodium concentration and serum osmolality concentration are about 5 mEq/L and 10 mOsm/kg, respectively, lower throughout most of gestation than in the nonpregnant state. This is mainly due to a decrease in osmotic threshold for thirst and arginine vasopressin (AVP) release (23). In addition, a transient increase in AVP clearance during mid-gestation may produce a diuresis, the so-called transient diabetes insipidus of pregnancy.

Proteins

Proteins present in the urine are a combination of plasma proteins that are normally filtered at the glomerular capillary level, and escape reabsorption in the proximal tubule, and proteins produced by the urogenital tract: 40% are represented by albumin, 15% to 20% are immunoglobulins, and 55% to 60% is Tamm–Horsfall glycoprotein, the latter being of tubular origin (24).

Albumin, MW 69,000 daltons (D), is a plasma protein usually filtered to a limited degree due to its MW and anionic charge. Below MW 60,000 D, there is a progressive increase in filtration at the glomerular level so that in healthy, nonpregnant subjects, low-MW proteins and only small amounts of albumin are normally filtered, then almost entirely reabsorbed and catabolized in the proximal tubule.

Normal urinary protein excretion averages 20 to 80 mg/day in normal nonpregnant women, with an accepted upper limit of normal of 150 mg/day. Albuminuria is considered to be a more sensitive marker for glomerular damage and CKDs than

total proteinuria (25), and the upper limit of normal for daily albuminuria is considered to be 30 mg (26).

In pregnancy, proteinuria is considered to be abnormal if exceeds 300 mg/day (27). Studies that have looked at proteinuria and albuminuria in normal pregnancy have found a maximum total daily urinary protein excretion of 260 mg/day (28), or even a little lower, at 200 mg/day (29), with an absolute amount of albumin, which does not seem to be higher than that in normal, nonpregnant state (30). Higby (28) found that total daily albumin excretion in normal pregnancy was 29 mg and Beetham (30) showed that there is a tendency for albuminuria to increase as the normal pregnancy progresses, being significantly higher in the third trimester compared with the first, but the absolute amount will remain less than 30 mg/day. The available evidence suggests that the diminished tubular reabsorption of low-MW proteins play a significant role for the increase in proteinuria during normal pregnancy (30,31).

The gold standard for total protein quantification is the 24-hour urine collection with its well-known limitations: can be inaccurate due to undercollection, is cumbersome for the patient, and the results are delayed pending collection. Screening for proteinuria using the dipstick (most sensitive to albumin) is fast and convenient in the clinic, where a random urine sample can be used. Unfortunately, the accuracy of the dipstick urinalysis in predicting significant proteinuria is poor (32), but the use of a protein to creatinine ratio in a spot urine seems to be a practical and reasonable choice (14).

Acid–Base Regulation

Plasma bicarbonate decreases during pregnancy, ranging from 18 to 22 mEq/L. It is believed that progesterone-induced hyperventilation occurs during pregnancy, leading to respiratory alkalosis with decrease in PCO₂ close to 27 mmHg and increase in pH to about 7.44. There is no apparent defect in renal handling of acid (33).

PREGNANCY IN WOMEN WITH CKD

The influence of pregnancy on the course of renal disease and the effect of renal disease on the outcome of pregnancy are important concerns in treating and advising patients with renal disease. The available published data on pregnancy in women with CKD have limitations due to small sample size, single-center and retrospective studies, using varied definitions of kidney disease, and adverse maternal and fetal outcomes (1,14,34). Given the low prevalence of CKD in women of childbearing age and difficulties related to randomization, it is easy to understand the complexity of conducting good quality trials in this population. In spite of these imperfections, factors that have consistently emerged, and are widely agreed upon, as important in influencing both maternal and fetal outcomes are advanced CKD, preexistent HTN, and proteinuria. Pregnant women who have normal or only mildly impaired kidney function, normal blood pressure, and little or no proteinuria before conception are expected to have an uneventful pregnancy, without maternal complications (worsening kidney function, HTN, and pre-eclampsia) and without fetal complications (prematurity,

small-for-gestational-age, fetal loss, etc.). On the other hand, those who have significantly impaired kidney function and/or HTN and proteinuria before conception are at increased risk for maternal and fetal complications. With respect to the type of the renal disease, the current consensus is that in primary nephropathies (IgA nephropathy, focal and segmental glomerulosclerosis, membranous glomerulonephritis, etc.), the above-mentioned factors dictate the maternal and fetal outcomes irrespective of the type of the disease; in systemic diseases with renal involvement such as diabetes mellitus (DM) and systemic lupus erythematosus (SLE), there are additional disease-specific features that will affect prognosis (1,14,34).

Effects of Pregnancy on Kidney Disease

In a study (35) involving CKD patients with serum creatinine levels lower than 1.4 mg/dL, it was shown that GFR, creatinine clearance, and effective RPF increase during gestation, similar to the response observed in women without underlying renal disease. It is then expected to see a decline in serum creatinine levels in these patients during pregnancy and a return to baseline values after delivery. Women with more advanced renal dysfunction will not always have the physiologic increase in GFR seen in women without or only with mild renal insufficiency, and their pregnancies are more frequently complicated with worsening kidney function (2,11,36). A potential mechanism for inducing permanent kidney damage during pregnancy could be an increase in intraglomerular pressure, but animal studies (11) have showed that even in the presence of preexistent renal damage, pregnancy does not lead to glomerular HTN.

Proteinuria usually increases during pregnancy, then declines after delivery (11). Among others, Katz et al. (35) analyzed 121 pregnancies in 89 women with previously known CKD. De novo or increased proteinuria was noted in almost 50% of the pregnancies, and 60% of those who were proteinuric during pregnancy had regression of proteinuria at follow-up.

When counseling patients regarding the effects of pregnancy on their kidney disease, prognosis is based, in general, on three categories of renal function, which have been described in the literature as mild, moderate, and severe (1).

Mild Decrease in Kidney Function (Serum Creatinine Lower Than 1.4 mg/dL) Before Conception

There is a general consensus that pregnancy usually does not modify the natural course of kidney disease in this setting. However, some patients with normal kidney function can have a temporary decline in renal function during pregnancy (35,37). Rarely, there can be an unexpected and irreversible loss of kidney function during pregnancy (38,39), which usually happens in more aggressive histologic forms of glomerular and/or tubulointerstitial disease (34). Jungers et al. (37) have shown that in women with reflux nephropathy, pregnancy had no negative impact on their kidney disease if they had normal kidney function at conception. Multiple other authors report similar positive results of pregnancies in women with serum creatinine less than 1.4 mg/dL (35,40,41).

The presence of HTN and proteinuria becomes major predictive factors for worsening kidney function in this clinical scenario.

Preexistent or untreated HTN has been found to be an independent risk factor for loss of renal function in few studies (41,42). The role of proteinuria was convincingly demonstrated by Hemmeler (43) in a retrospective analysis of 30 pregnancies in 19 patients with primary glomerular disease and normal kidney function and blood pressure at conception. This group was compared with a control group of 31 patients who did not become pregnant after the diagnosis of kidney disease. Patients were followed for 11 years, and at the end of follow-up, patients who became pregnant had higher serum creatinine levels than controls. Pregnancy and initial proteinuria were found to be independently related with the rate of loss of kidney function. Of the 30 pregnancies that were preceded and complicated with nephrotic-range proteinuria, 10 were followed by an accelerated rate of loss of kidney function compared with the other 20 pregnancies.

Jungers (41) also found that in patients with primary chronic glomerulonephritis and normal kidney function, proteinuria had a predictive role for the progression of kidney disease on pregnancy, although not as strong as HTN.

Moderate Decrease in Kidney Function (Serum Creatinine 1.4–1.8 mg/dL)

Moderate decrease in kidney function (serum creatinine 1.4–1.8 mg/dL) is associated with a higher risk of further decline during pregnancy. In a retrospective review (37), 19% of the patients with moderate decline in kidney function had irreversible further loss of maternal renal function. Proteinuria and HTN are more frequent in this population and additive risk factors for further decline in renal function (1,44).

Severe Decrease in Kidney Function (Serum Creatinine Greater Than 1.9 mg/dL)

Severe decrease in kidney function (serum creatinine greater than 1.9 mg/dL) has been shown to be a higher risk factor for renal function loss during pregnancy. The landmark study by Jones and Hayslett (44), published in 1996, showed that the risk of accelerated progression to end-stage renal disease was the highest when the serum creatinine concentration was above 2 mg/dL at the beginning of the pregnancy. With an initial serum creatinine of at least 1.4 mg/dL in 67 women and 82 pregnancies, they reported a pregnancy-related loss in renal function in 43% of the cases. The risk is even higher when uncontrolled HTN is present (34).

The only prospective study that analyzed the outcomes of pregnancies in patients with serum creatinine levels greater than 1.4 mg/dL (36) found an accelerated loss of kidney function only in the subgroup of patients with both estimated GFR <40 mL/min/1.73 m² and proteinuria >1 g/day before pregnancy.

Women with serum creatinine levels >3 mg/dL are usually infertile (45) due to amenorrhea or anovulatory menstrual cycles.

Based on the available information, women with CKD who contemplate to become pregnant should be advised about the possible risk of accelerated loss of kidney function if serum creatinine level is greater than 1.4 mg/dL before pregnancy. Proteinuria exceeding 1 g/day portends a higher risk for accelerated loss of kidney function and, in some cases, even a twofold higher incidence of end-stage renal

disease (1). HTN control should be a major goal of pregnancy. Even if they are normotensive before pregnancy, these patients are at higher risk of becoming hypertensive during pregnancy (1,35).

Pregnancy should probably be discouraged in patients with multiple risk factors: moderate to severe kidney disease, proteinuria, and HTN.

Effect of Kidney Disease on Fetal Outcomes

Mild Decrease in Kidney Function (Serum Creatinine Lower Than 1.4 mg/dL) Before Conception

Katz (35) observed in a retrospective study that there were more fetal complications in patients with serum creatinine lower than 1.4 mg/dL than in general population, but at acceptable levels. Ninety-four percent of the pregnancies resulted in live births. Abe (40) has also noted same positive results in women with GFR >70 mL/min and blood pressure less than 140/90 mmHg. In women with autosomal dominant polycystic kidney disease (42) and normal kidney function before conception (serum creatinine less than 1.2 mg/dL), preexistent HTN was the most important risk factor for the development of poor fetal outcomes, including prematurity and fetal loss.

Munkhaugen (46) found in a very recent study that women with estimated GFR 60 to 89 mL/min/1.73 m² were not at increased risk of pre-eclampsia, small-for-gestational-age, or preterm delivery unless they were also hypertensive.

Moderate and Severe Decrease in Kidney Function (Serum Creatinine >1.4 mg/dL)

Moderate and severe decrease in kidney function (serum creatinine >1.4 mg/dL) translates in higher risk for fetal loss, prematurity, and small birth weight. Jones and Hayslett (44) reported moderately reduced fetal loss (93% survival rate), but significantly increased preterm delivery (59% compared with the expected rate of 10% in general population) and growth retardation (37% of infants were below the 10th percentile for birth weight).

Abe (40) also found that in women with moderately decreased kidney function, the rate of live births was relatively high, except for cases where HTN was present before pregnancy and/or was not controlled during pregnancy.

Imbasciati (36) found that in women with GFR <40 mL/min/1.73 m² and proteinuria >1 g/day, pregnancy was associated with poor fetal outcomes: increased perinatal death and low birth weight.

Jungers (34) also found a high risk of fetal death when serum creatinine was 1.8 to 2.0 mg/dL. HTN and nephrotic-range proteinuria, when present early in pregnancy, were found to be additive risk factors for poor fetal prognosis.

In summary, when counseling women with CKD regarding fetal outcomes, the following recommendations could be made:

- Fetal survival rate seems to higher than 90%, but decreases when uncontrolled HTN and/or proteinuria are also present.
- Preterm delivery and growth retardation are more commonly found in women with at least moderate impairment in kidney function.

- HTN and proteinuria are additional risk for poor outcomes in this category, too.

MANAGEMENT

Over the years, the benefits of progress in obstetrics in neonatal care, including improved access to medical care, improved technology for fetal surveillance and antihypertensive medications available to treat high blood pressure in pregnant women, have translated in improved maternal and fetal outcomes in pregnancies that occur in women afflicted with CKD and HTN (37,42).

Pregnant women with CKD should be followed in collaboration with a nephrologist and with an obstetrician familiar with the effects of renal disease on pregnancy. Their prenatal visits should occur more frequently, ideally every 2 weeks until the third trimester and then weekly. Maternal renal function should be followed very closely, at least at monthly intervals, and asymptomatic bacteriuria should be promptly treated. Likewise, fetal surveillance with ultrasound and fetal heart monitoring should be done very closely. Maternal HTN requires special attention and needs to be treated efficiently. Preterm delivery needs to be offered when maternal renal function deteriorated rapidly, if fetal distress occurs, or pre-eclampsia is severe.

LUPUS NEPHRITIS

It remains questionable whether pregnancy exacerbates lupus. Earlier studies suggest that pregnant women with SLE clinically flare their disease three times more frequently during pregnancy and seven times more frequently postpartum compared with nonpregnant controls (47). More recently, it became apparent that the incidence of a lupus flares during pregnancy is more likely correlated with the disease activity before conception. Hayslett (48) showed that exacerbations or relapse occur in a wide range of patients during pregnancy or in the immediate period after delivery, namely in 25% to 60% of pregnancies. Relapses or exacerbations occur only in one-third of the patients if they had no signs of clinical activity 6 months before conception, as opposed to two-thirds of the patients when they had signs of clinical activity at onset of pregnancy. Activity of the disease also influenced fetal survival, which was 85% to 95% in patients with inactive disease and 50% to 80% in patients with active disease at conception. The presence of circulating anticardiolipin antibodies and lupus anticoagulant factors appears to worsen the perinatal outcomes. Fetal loss rate increases from 25% to about 60%, and the risk of maternal thromboembolism increases to about 50% (49,50).

The risk of prematurity and pre-eclampsia is increased even if patients have stable, but established renal disease and controlled HTN in the 6 months prior to conception (51). The risk of pre-eclampsia is high especially if the women have a history of antiphospholipid syndrome (52).

Flares cannot be prevented with routine increase in dose or prophylactic use of steroids, which are not recommended for this purpose either before pregnancy or after delivery (53). Therefore, women with lupus nephritis should be encouraged to postpone pregnancy for at least 6 months after the last flare.

The diagnosis of a lupus flare in pregnancy is not always straightforward, and the most challenging scenario is to make a distinction between pre-eclampsia and lupus flare, as they can both present with HTN, proteinuria, thrombocytopenia, and kidney injury (53). A renal biopsy is rarely needed, because a rising anti-dsDNA titer, and low complement levels are in favor of lupus flare, as opposed to hyperuricemia and abnormal liver function tests that favor pre-eclampsia. Flares are more common in women who had more than three flares before pregnancy, and the type of flare follows the previous known pattern of disease specific to the individual patient (51,53).

In pregnant women with active lupus nephritis, the maternal and perinatal outcomes are improved if a remission is achieved. Corticosteroids are the drugs of choice (51,53), given either as an increased oral form or intravenous methylprednisolone 500 mg daily for 3 days. Azathioprine can be used safely in pregnancy and during lactation (51,53). Hydroxychloroquine, often used to prevent flares, seems to be safe for use in pregnancy and should not be stopped in early pregnancy (51–53). Antiphospholipid-positive patients should be started on at least low-dose heparin to prevent thrombosis (52). The use of low-dose aspirin has been advocated for prevention of pre-eclampsia in patients at risk.

DIABETIC NEPHROPATHY

About 5% of pregnant women with type 1 DM can have diabetic nephropathy (54). Fortunately, most of them have preserved kidney function and the progression of their diabetic nephropathy does not seem to be affected by pregnancy in this situation. As is true with all patients with moderate to severe CKD, diabetic patients also will have higher risk of irreversible deterioration of kidney function during pregnancy, which has been estimated in some series to be as high as 40% (55); the risk of HTN and pre-eclampsia are also increased in diabetics. Proteinuria increases during pregnancy, an effect that could also be attributed to the cessation of ACE inhibition therapy due to potential teratogenic effects (54).

Women with diabetic nephropathy often have diabetic retinopathy, which should not go untreated during pregnancy. Diabetic retinopathy can progress during pregnancy and laser treatments are sometimes needed to prevent vision loss (54).

Perinatal outcomes are generally good with tight glycemic and blood pressure control.

Perinatal survival exceeds 95% (56,57), but there is a high risk of preterm delivery (50%) and small babies (15%) (56, 58–60). There is concern that prematurity can predispose the infants of diabetic mothers to long-term morbidity: severe psychomotor retardation and mild developmental retardation have been described in this setting (61).

ARF

The definition of ARF in pregnancy varies across studies. ARF has been defined as a creatinine level above 0.8 mg/dL, >25% decrement in GFR over the level documented before the beginning of pregnancy, or the need for dialysis (62–64). Since the 1960s, there has been a consistent decrease in the incidence of the ARF in pregnancy, which has been attributed to a steady decrease in the septic abortions in most developed countries

due to legalization of abortions and due to better access to care (63,64). The incidence of ARF in pregnancy has decreased from 20% to 40% in the 1960s to 2% to 10% in the 1980s (63).

Despite the decreased incidence, the development of ARF in pregnancy remains associated with significant morbidity and mortality.

ARF in pregnancy can be induced by any of the disorders leading to renal failure in the nonpregnant women: volume depletion, nephrotoxins, obstruction, interstitial nephritis, and so on. Pregnancy complications characteristic of each trimester can result in ARF. It is believed that the most common cause of ARF in pregnancy is pregnancy-related HTN (62,64,65).

Pre-eclampsia

Pre-eclampsia is a disorder specific of pregnancy, complicates around 5% of all pregnancies (66), and is characterized by new-onset HTN and proteinuria in excess of 300 mg/day, usually after 20 weeks of gestation. Blood vessels throughout the body are affected, and recently identified antiangiogenic substances of placental origin seem to be the cause of the diffuse endothelial dysfunction. The characteristic glomerular lesion, “endotheliosis,” appears histologically as endothelial swelling and occlusion of the capillary lumens, and although it is a variant of thrombotic microangiopathy, intraglomerular thrombosis is unusual (66). ARF is rare, and only 1.5% to 2% of the pre-eclamptic patients will have impairment of the kidney function (62). Patients with pre-eclampsia have an overall decrease in GFR and RPF, but not significant enough to cause ARF (62,63). They also have vasoconstriction and intravascular volume depletion, this way being at increased risk for the development of ARF when another obstetrical complication like hemorrhage or abruptio placentae is present. Superimposed volume depletion in these clinical scenarios will commonly lead to acute tubular necrosis and in the most severe cases to cortical necrosis (63). Treatment of pre-eclampsia-related ARF requires delivery of the fetus and placenta (63).

HELLP Syndrome

HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome occurs in 10% to 20% of the cases of severe pre-eclampsia (67). It has been reported that ARF can occur in 7% to 36% of the cases (67). Renal biopsy studies most commonly reported acute tubular necrosis or acute cortical necrosis in more severe cases (68) same as in less severe pre-eclampsia. Associated thrombotic microangiopathy has also been described, but with acute tubular necrosis as the dominant lesion (69).

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is not a common complication of pregnancy, but represents an obstetric emergency of the third trimester (70,71). The patients present with abdominal pain, nausea, vomiting, headache, malaise, anorexia, jaundice, and rarely with hepatic encephalopathy. The etiology could be related to a familial genetic defect in fatty acid metabolism (70). Up to 90% of the women with AFLP can develop ARF (70). Disseminated intravascular coagulopathy is usually present. Serum transaminases are generally not as

severely elevated as they are in hepatitis. Most patients with renal failure have evidence of decreased renal perfusion similar to hepatorenal syndrome or acute tubular necrosis. Treatment again involves delivery of the baby.

Thrombotic Microangiopathies

Thrombotic microangiopathies are thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS), pathologies that are very rarely seen in pregnancy, occurring in less than 1 in 100,000 pregnancies (71). HUS was initially described as occurring in the postpartum period, between 1 day and 3 months after delivery, but it has become clear that it can occur during pregnancy also (70). In patients with a severe form of familial deficiency of ADAMTS13, TTP can also present during pregnancy (72). ADAMTS13 is a metalloprotease, which normally binds the von Willebrand factors secreted by the endothelial cells. When ADAMTS13 is deficient, abnormally large multimers of von Willebrand factors accumulate and trigger platelet adhesion and aggregation inside the blood vessels with microthrombi formation (72). Familial forms of HUS have been also described, with both autosomal dominant and recessive form of inheritance and pregnancy as an eliciting event. A functionally abnormal factor H protein could be the cause of HUS in the autosomal dominant transmitted familial cases (72,73). Normally functional factor H protects endothelial cells from the damaging effects of the activated complement (72). The primary pathologic disorder in both TTP and HUS will be systemic or intrarenal microvascular aggregation of platelets, causing microangiopathic hemolytic anemia. These changes will be manifested by decrease in hemoglobin and platelets, presence of fragmented red blood cells on the peripheral blood smear (schistocytes), increase in lactic dehydrogenase (LDH), and decrease in haptoglobin. Liver enzymes may be normal or elevated, and coagulation studies are frequently normal (71). The classic clinical pentad of TTP consists of thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, fevers, and renal dysfunction. In HUS, renal failure is the predominant feature and sometimes it is difficult to make a clear distinction between the two entities (72). Renal involvement is associated with hematuria and proteinuria (71). Management involves plasma exchanges (plasmapheresis) until platelet counts and LDH levels normalize. Sometimes immunosuppressive therapy is required. Platelet transfusions should be discouraged, due to risk of microvascular thrombosis. Maternal morbidity and mortality are high in pregnancies complicated with TTP/HUS (71).

Obstructive Uropathy

Obstructive uropathy is uncommon in pregnancy. "Physiologic hydronephrosis" of pregnancy is an expected phenomenon, present in 80% to 90% of the normal pregnancies (5,6). Right-sided hydronephrosis occurs more commonly than left-sided one. The diagnosis of pathologic urinary tract obstruction during pregnancy can be difficult and can be recognized in some cases by the normalization of renal function in the lateral recumbent position, which relieves pressure on the ureters by the uterus, and its recurrence when supine (6). In some cases, however, either insertion of a ureteral catheter or delivery of the fetus is required.

Renal Cortical Necrosis

Renal cortical necrosis can be considered a severe form of ATN, often associated with disseminated coagulopathy and usually occurring in a setting of septic shock, septic abortion, or severe abruptio placentae. Bilateral renal cortical necrosis (BRCN) is estimated to occur in about 2% of the adult patients with ARF, but the incidence is the highest in obstetric patients, especially in the last part of pregnancy and postpartum (74). The risk of BRCN seems to be higher with prolonged anuria, usually longer than 2 weeks. Patients require dialysis and some will become dialysis dependent. Kidney biopsy provides the definitive diagnosis and prognostic information. Imaging techniques could be employed to show decreased cortical blood flow. CT angiogram or renal angiography shows decreased cortical nephrogram.

DIALYSIS AND TRANSPLANTATION

Multiple mechanisms that interfere with the hypothalamic–pituitary–ovarian axis cause marked decrease in fertility in young women with advanced CKD and those requiring dialysis (75). Recent publications report fertility rates ranging between 1% and 7%, which is much improved compared with older literature (76–78). These improved trends could be due to improved CKD management translated in increased dialysis population, better dialysis techniques, and improved care of the high-risk pregnancies.

Pregnancy in dialysis patients remains a very challenging clinical situation, where even the diagnosis of pregnancy itself may be a difficult task. Serum markers like β -HCG may be falsely elevated in dialysis patients due to poor renal excretion, and ultrasound evaluation is needed to confirm and date the pregnancy (79). Spontaneous abortion remains common, occurring in 21% of pregnancies reaching second trimester (80). Overall, it has been reported that only 50% of the pregnancies result in surviving infants (77). Premature delivery is very common, occurring in 80% of pregnant dialysis women (77). Other common fetal complications include polyhydramnios and low birth weight (77,81,82). Maternal risks include acid–base abnormalities, HTN, volume overload, and pre-eclampsia. Due to these increased complication rates, most centers do recommend contraception in women of childbearing age on dialysis. When pregnancy does occur, it should be managed by a multidisciplinary team comprising nephrologists, obstetricians, dialysis staff, and neonatologists.

Although in most reported cases pregnant patients have been on hemodialysis, successful pregnancies have also been reported in PD (77,82–84). Whether one dialysis modality is superior to other in pregnant patients is unclear due to lack of randomized controlled studies. Feasibility of intensifying hemodialysis, limitations of PD volumes due to the gravid uterus, and prevalent practices among nephrologists may play a role in the choice of a particular renal replacement therapy over another.

The precise details of the dialysis management in pregnant patients are beyond the scope of this textbook, but some of the principles suggested by experts in this field are enumerated in Table 2.

Prolonged or intensive dialysis during pregnancy results in longer gestational periods, higher fetal birth weights, and

Table 2 Recommendations for Dialysis Management in a Pregnant Patient

Treatment factor	Recommendation
Frequency of treatments	Intensifying HD four to six times/wk after first trimester (goal >20 hr/wk) Increasing no. of PD dwells (8–12 L/day)
Predialysis BUN	<45–50 mg/dL
Dialysate	Bicarbonate—25 mEq/L Potassium 3–4 mEq/L (adjust based on HD frequency and serum values)
Anemia	Hgb target 10–11 g/dL May need increase in Erythropoietin dose Iron saturation >30%, use IV iron to maintain levels Folate 1 mg/day
Blood pressure/hemodynamics	No clear guidelines. Diastolic BPs below 80–90 Avoid maternal volume depletion and hypotension during dialysis Avoid ACEI, ARBs Ultrafiltration goals to be adjusted as pregnancy progresses accommodating placental and fetal growth (approx. 1 lb/wk) Fetal monitoring during HD once fetus viable

Abbreviations: HD, hemodialysis; BUN, blood urea nitrogen; PD, peritoneal dialysis; Hgb, hemoglobin; BP, blood pressure; ACEI, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers. Source: From Ref. 76,77,81–84.

greater fetal survivability (76,77,80). Home hemodialysis and nocturnal hemodialysis are emerging modes of intensive HD that have shown to offer multiple clinical advantages in terms of HTN, volume status, and mineral metabolism. A retrospective study from Canada prescribing nocturnal HD (>36 hr dialysis) for women in childbearing age group showed not only improved fertility rates (15%) but also more successful live births and fewer maternal–fetal complications (85).

With successful kidney transplantation, fertility seems to be restored to near normal within a few months. The U.S. National Transplant Pregnancy Registry (NTPR) reported a total of 1208 pregnancies in 781 kidney transplant recipients (86). Live births occurred in approx. 75% of the patients based on NTPR and the U.K. registry data (87,88).

Despite improved outcomes following transplantation, a different set of complexities entail kidney transplant recipients who become pregnant. Impact of pregnancy on the kidney allograft, premature delivery, pre-eclampsia, and the long-term effects of immunosuppressive medications on the offspring remains some challenges in this group. Counseling about pregnancy should start in the pre-transplant period, continued following transplantation, and reliable contraception is recommended until patient is ready to embark on a planned pregnancy (89–91). The optimal timing of pregnancy after transplantation is considered to be 1 to 2 years. Analyses of the NTPR data have suggested greater percentage of nonviable outcomes in female transplant recipients who became pregnant less than 6 months after transplantation (86). Several individual factors should be considered when offering advice for the timing of pregnancy including adequacy of allograft function (serum creatinine <1.5 mg/dL), recent episodes of acute rejection, and risk of opportunistic infections (86).

These pregnancies should also be considered high risk and preferably managed by both transplant physicians and specialists in high-risk pregnancies. Major goals during pregnancy are to optimize maternal health, including allograft function, maintain a normal metabolic environment (normoglycemia), minimize complications associated with preterm births, detect and manage hypertensive complications

especially pre-eclampsia, and ensure adequate fetal growth. Pre-eclampsia occurs in approximately one-third of pregnant women with kidney transplant, and diagnosing it can be challenging as many transplant patients can have preexisting proteinuria and an increasing trend in blood pressures after 20 weeks of gestation (92).

Urinary tract infections are the most common complication in pregnancies following kidney transplantation probably due to an immunosuppressed state and the increased likelihood of reflux. Most investigators recommend screening in all pregnant women and treating any positive cultures (93).

Rejection of the kidney allograft is unusual and the risk is considered to be no higher than in the nonpregnant transplant patients if pregnancy is properly planned (90). Anemia can frequently complicate pregnancy post-transplantation even in the absence of kidney function deterioration (90). Compared with normal pregnancies, transplant recipients have lower erythropoietin levels (94).

The anatomic location of the allograft in the iliac fossa does not interfere with vaginal delivery and most transplant patients can deliver vaginally unless there are some obstetric indications (90). One of the challenges in pregnancies post-transplantation is the choice and dosing of immunosuppressive medications. Transplant recipients should be maintained on immunosuppressive medications during pregnancy with some modifications to avoid allograft rejection and consequently fetal loss (90). Cell counts, renal parameters, liver function tests, and drug levels should be frequently monitored to avoid significant toxicity.

Most immunosuppressive medications are considered risky by the Food and Drug Administration; however, the U.S. registry data do not show any consistent pattern of congenital anomalies associated with the use of calcineurin inhibitors (cyclosporine and tacrolimus), azathioprine, or steroids (89). These are still considered as mainstay therapy for pregnant transplant patients by most centers given their relatively safer profile. Cyclosporine can be associated with low birth weight and also may exacerbate HTN during pregnancy (90). Tacrolimus has been associated with an increased incidence of DM and hyperkalemia in the newborns (95). Azathioprine has been shown to be teratogenic

in higher doses in animals; however, these effects were not reproduced in humans (96). Case reports have described fetal adrenal insufficiency and thymic hypoplasia when corticosteroids are used in higher doses but these rarely occurred in doses of 15 mg/day or less (97–99).

Mycophenolate mofetil and sirolimus are contraindicated and should be stopped 6 to 12 weeks prior to conception due to risks of teratogenicity (86,100).

Most transplant immunosuppressive medications are excreted in the breast milk although in small amounts and no adverse effects have been reported (86). Although recommendations are evolving in this area, most transplant centers currently advise against breast-feeding (101).

In the absence of any guidelines for the management of pregnant dialysis patients and increased fetal complications, it may be prudent to advise effective contraception and delaying pregnancy until after transplantation. Improved outcomes have been reported in the transplant literature; however, the use of immunosuppressive medications adds another dimension and makes pregnancies more difficult to deal with in the post-transplant period.

30 Acute abdomen in pregnancy

Nicole Fearing and William L. Holcomb

One of the most anxiety-provoking patients to deal with is the pregnant patient with acute abdominal pain. It is widely quoted that 1/500–635 pregnancies will be complicated by an acute abdomen requiring surgery. With two patients to think about, mother and child, and the complications that can go along with a delayed or missed diagnosis, it is no wonder it leads to anxiety for all involved. To deal with the complexities that go along with diagnosing an acute abdomen in a pregnant patient, one needs to understand not only the differential diagnosis but also the physiologic changes of pregnancy that will affect the evaluation and diagnosis.

PHYSIOLOGIC CHANGES OF PREGNANCY

Physical findings in the pregnant patient with an acute abdomen are different from that of the nonpregnant one. Much of the decreased prominence of abdominal signs is due to the expanding uterus. In the patient who is not pregnant, the average weight of the uterus is 70g. Over 40 weeks of pregnancy, it can expand to 1110g and can have an intrauterine volume of 5liters (1–3). As this enlargement occurs, the intestine and omentum are pushed into the upper abdomen. The omentum is less able to be the watchman of the abdomen and wall off areas of peritonitis due to encroachment of the uterus. The ovaries will come to lie posterior to the uterus (1). This makes assessment of ovarian pathology more difficult especially by transabdominal ultrasound. With the enlargement of the uterus also comes stretching of the abdominal wall. As the abdominal wall stretches, it shows fewer signs of direct peritoneal irritation. Classic signs, such as rebound and guarding, are less prominent.

Previously a paper by Baer et al. in 1932 reported that with the enlargement of the uterus, the appendix moves upward and laterally from its usual position at McBurney's point so that by late pregnancy it is actually closer to the gallbladder. He showed this by performing barium enemas to show the position of the appendix and cecum (4). In 2003, a paper by Hodjati and Kazerooni in the International Journal of Gynecology and Obstetrics reevaluated the anatomical location of the appendix with pregnancy. In their prospective study, three groups of women were compared. The first was 165 women in their 37th to 40th week of pregnancy who were undergoing elective c-sections. The second group was 26 women between 19 and 39 weeks of pregnancy with acute appendicitis. The final group was 100 nonpregnant females with acute appendicitis. Each was evaluated for appendix location and normal was noted to be within 2cm of McBurney's point. In their study, 15% of the first group had an abnormal position, 23% of the second group, and 17% of the third. The study showed no significant difference between the normal control and those who were pregnant (5).

Other physiologic changes may be attributed to hormonal changes associated with pregnancy such as the elevation in estrogen and progesterone levels. Several studies have shown that as levels of these hormones increase throughout pregnancy, orocecal motility slows. A study by Wald et al. showed that the gastrointestinal motility slowed by one-third during the third trimester of pregnancy compared with postpartum rates (6,7). It has also been shown that levels of the hormone motilin decrease. This affects the migrating motor complex also leading to slowed orocecal motility (8). The slowed transit can compound problems with constipation or other underlying abdominal pathology making diagnosis again more difficult. Progesterone has also been linked to decreased lower esophageal sphincter pressure and affects the urologic system. Dilation and slowing of peristalsis of the ureters have been associated with increase in progesterone. This may lead to urinary tract infection from urinary stasis (9,10).

There are normal changes that take place in pregnancy, which change the results of laboratory tests. This can make looking for bleeding or infection more difficult. Laboratory test results expected in pregnancy are shown in Table 1. For a few tests, the lab results can still have significant diagnostic value especially in the case of pyelonephritis, hepatitis, or pancreatitis.

IMAGING AND THE PREGNANT PATIENT

With the fetal effects of radiation to consider, it is important to understand what imaging modalities are available and safe. While there may be anxiety in using some radiologic modalities, it is important to remember that the greatest danger to both fetus and mother may be delay in diagnosis.

Ultrasound

Ultrasound may be used as both a diagnostic and a therapeutic modality. It is the imaging modality of choice due to its ease of use, low cost, and safety. It may be used to evaluate mother and fetus at the same time providing evaluation of amniotic fluid and size of the fetus while possibly diagnosing relevant pathology in the mother.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a safe modality to use providing diagnostic information on the mother with little risk to the fetus at any stage of pregnancy. MRI is beneficial compared with computed tomography (CT) in that it is capable of giving large field-of-view images in any plane with excellent soft-tissue contrast (11). There is no exposure of the mother or the fetus to any ionizing radiation. Often no contrast is needed to establish a diagnosis. Gadolinium, a contrast agent used in MRIs, does cross the placenta and its

Table 1 Changes in Laboratory Test Results Expected in Pregnancy

Test	Result
Hemoglobin	Decreased
Hematocrit	Decreased
White blood cell count	Increased
Differential white blood cell count	Increased neutrophils
Platelet count	Unchanged
Electrolytes (serum)	Decreased CO ₂
Glucose (fasting)	Decreased
Creatinine (serum)	Decreased
Amylase	Slightly increased
Aspartate aminotransferase	Unchanged
Alanine aminotransferase	Unchanged
Alkaline phosphatase	Increased
g-Glutamyl transpeptidase	Unchanged
Urinalysis	Unchanged
Arterial blood gas	Decreased pCO ₂ ; slightly increased pH

effects on the fetus are not well understood. However, there is general consensus that it should not be used in the pregnant patient unless there is high likelihood that benefits of its use outweigh the risk to the fetus. In the acute abdominal setting, MRI is beneficial for evaluation of the biliary tree for stones with sensitivity greater than 90% (11). It may be used to diagnose acute appendicitis, bowel obstruction, and areas of abscess formation, inflammation, and hemorrhage.

CT

CT use is often feared due to the risk of ionizing radiation to the fetus. Guidelines for surgical problems during pregnancy from the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) state that expeditious and accurate diagnosis should take precedence over concerns for ionizing radiation. Radiation dosage should be limited to 5 to 10 rads in the first 25 weeks of pregnancy (12). Modern CT scanners deliver doses of radiation below this as a single test. A CT of the abdomen–pelvis delivers about 2 to 4 rads (13–16). However, cumulative radiation exposure must be considered: other tests that have been done may affect the decision to use CT. Consider also that IV contrast should not be used and try to minimize cuts of the CT.

Nuclear Medicine

Fetal exposure with nuclear medicine studies is quoted to be less than 0.5 rads. This again is below the limit of 5 to 10 rads quoted. In light of this, the radionuclotides may be administered including technetium-99 (13,17).

Once workup is completed, decision for treatment will depend on the specific diagnosis. However, there are some tenants for surgery that hold true for all patients. Indications for emergency laparotomy are no different in the pregnant patient than that in a nonpregnant patient. If possible, elective procedures should wait until after the pregnancy is completed unless that is a compelling reason that it benefits the patient or the pregnancy. Elective procedures include cholecystectomy for uncomplicated gallstone disease and inguinal hernia repair for asymptomatic hernia. The second trimester of pregnancy is the best time for performance of any elective or semi-elective

procedure. The decision to perform a c-section delivery should be made outside of the decision for an exploratory laparotomy. Successful vaginal deliveries can be performed postoperatively.

Perioperative Considerations

Perioperative consideration should be given to fetal heart monitoring. It is difficult to keep fetal heart monitors on sterily during an abdominal surgery and monitoring may create a significant distraction. There are no definitive studies demonstrating that intraoperative fetal monitoring makes a difference in fetal outcome. The value of intraoperative fetal monitoring must be determined on a case by case basis. Pre- and postoperative fetal and contraction monitoring are recommended at a viable gestational age.

Preterm labor is also a concern with this population. The use of tocolytics is somewhat controversial and no consensus exists. The SAGES guidelines recommend no prophylactic use of tocolytics (13). Their use is also not recommended in the presence of maternal infection (9). Tocolytic benefits must be weighed against risks and obstetric consultation is warranted.

Laparoscopy and Pregnancy

At one time, it was felt that laparoscopy could only be used safely in the first and second trimesters of pregnancy. However, there are several published reports of use of laparoscopy in the third trimester without detriment to the patient or fetus. The SAGES guidelines now state that laparoscopy may be performed in any trimester and indications are the same in the pregnant and nonpregnant patients (13).

ACUTE APPENDICITIS

Appendicitis is the most common indication for nonobstetric surgery and occurs in 1/766 to 1/3000 pregnancies (18,19). There is no increased risk of appendicitis associated with pregnancy, but there is credible concern that the severity is increased in the pregnant patient. This may be due to the difficulty and delay of diagnosis during pregnancy. There are many common symptoms of pregnancy that may mimic appendicitis, such as nausea, vomiting, and round ligament pain. The leukocytosis of pregnancy may also obscure evaluation. It has also been previously reported that the anatomic location of the appendix changes with the growing uterus. More recent studies as noted previously in this chapter have refuted this idea and overall the appendix remains in its normal position. The diagnosis of appendicitis preoperatively in the pregnant patient has been reported in only one-half to three-fourth of the cases taken to the operating room (OR) (18,20,21). Finally due to the difficulty in diagnosis and the subjective reluctance of some to take a pregnant patient to the OR, the incidence of perforation is about 25% to 40% (18,21,22). This is even more concerning in light of the risk of fetal demise, which is 7% to 10% in the nonperforated appendicitis case and up to 24% if the appendix is perforated (18,22–24).

Signs

Direct abdominal tenderness is the most constant physical finding among pregnant patients with appendicitis. Only rarely is this finding absent (25,26). In the first trimester, tenderness is usually well localized in the right lower quadrant. With advancing gestation, there is still some thought that

tenderness may be found in the right periumbilical area or right upper quadrant; however, in the study by Hodjati et al., this was not necessarily true. About 55% to 75% of patients have demonstrable rebound tenderness (21,25–28). One-half to two-thirds of patients have abdominal muscle rigidity (21,25–29). Rovsing's sign is present approximately equally in pregnant as in nonpregnant patients with appendicitis. Psoas irritation is less frequently observed in pregnancy (30). Rectal examination is often overlooked in the pregnant patient with appendicitis, but one group has found that tenderness is usually present, especially in the first trimester (25). Fever and tachycardia are variably present and are not sensitive signs for appendicitis in pregnancy.

Diagnostic Aids

The physiologic leukocytosis (as high as 15,000/mm³) during pregnancy and the wide range of normal values limit the usefulness of the leukocyte count for the diagnosis of appendicitis (21). Severe disease may be present when the leukocyte count is normal (20). Greater than 80% polymorphonuclear leukocytes are often present when appendicitis complicates pregnancy (21,25). Again, however, the test is not sufficiently sensitive to rule out disease and it discriminates poorly between those patients with and those without appendicitis. Ten to twenty percent of pregnant patients with appendicitis have an abnormal urinalysis, usually showing pyuria alone (25,27). Bacteriuria indicates a urinary tract infection. Asymptomatic bacteriuria is common enough in pregnancy that it may well occur coincidentally with appendicitis (31). Ultrasound may be the initial radiologic evaluation tool for diagnosis of appendicitis. However, it may be variable in its results due to operator performance, the gravid uterus, or a retrocecal appendix. MRI and CT are gaining popularity as evaluation tools. A recent systematic review from 2009 showed good sensitivity and specificity of both when ultrasound was normal or inconclusive (18).

Treatment for appendicitis is either open or laparoscopic appendectomy. Choice should be made depending on the skill and comfort level of the surgeon and clinical picture. No longer is laparoscopy limited to the first and second trimesters of the pregnancy. Reports now show the safety of laparoscopy in the third trimester as well (32). Advantages reported for laparoscopy over the open approach include better intra-abdominal visualization, less uterine manipulation, less postoperative pain, early return of GI function, and earlier ambulation postoperatively (32,33).

Technique for laparoscopic entrance into the abdomen is variable. Veress needle, and open Hassan-type techniques are both reported and are safe in those experienced in the techniques (32). Veress needle insertion usually is done in the midclavicular line about 2 cm below the costal margin. Once performed, the port may be placed blindly or better yet with an optical trocar. Open surgery should be performed over the point of maximum tenderness or at McBurney's point.

CHOLELITHIASIS

Although laparoscopic cholecystectomy is reported to be the most common laparoscopic procedure in pregnancy, pregnancy itself does not increase the risk of acute cholecystitis. It is reported to occur in about 1 in 1600 to 10,000

pregnancies (34–36). During pregnancy, the formation of gallstone and gallbladder sludge is common, but most women remain asymptomatic.

Signs and Symptoms

As in the nonpregnant patient, the most reliable symptom is right upper quadrant pain. Previous studies have shown that about 28% present with pain (9,37).

About half of the patients have vomiting and a minority are febrile (38). Patients will often give a history of previous similar episodes. Right upper quadrant direct tenderness is usually present, but in the absence of complications, rebound tenderness is rare. The pain may radiate to the back. In the occasional patient, there is a palpable gallbladder.

Cholecystitis may be confused with appendicitis, particularly in the third trimester. Landers and colleagues (38) reported a woman at 30 weeks of gestation who underwent laparotomy to rule out appendicitis. The appendix was normal, but she developed *Salmonella* sepsis postoperatively. The gallbladder was found to be the source of the organism when she subsequently returned to the OR for cholecystectomy.

Diagnostic Aids

Gallstones are present in more than 95% of patients with cholecystitis. Ultrasonography has been found to be extremely accurate in the diagnosis of cholelithiasis. With cholecystitis, it may show not only gallstones but also gallbladder wall thickening and pericholecystic fluid. Ultrasound can also show common bile duct dilation. Since this modality does not require ionizing radiation, it is preferred in pregnancy. If additional diagnostic information is needed for clinical management, the radiation dose of a radionuclide scan of the gallbladder is not prohibitive.

Blood tests are of limited diagnostic value for the patient suspected to have cholecystitis. Leukocytosis may be present, but it is neither a sensitive nor a specific marker. Serum alkaline phosphatase is normally elevated in pregnancy. A high value should not be taken as evidence of cholestasis. Other hepatic enzymes, such as aspartate transferase and alanine transferase, may be helpful in distinguishing cholecystitis from hepatitis. Transient elevation of the serum amylase level may be seen in up to one-third of patients (39,40). A markedly elevated serum amylase level suggests pancreatitis, which may complicate the course of gallbladder disease. Occasionally, a patient may be jaundiced with an elevated bilirubin level. If the patient has had persistent vomiting, evaluation of electrolyte status is essential.

Treatment

Treatment of symptomatic cholelithiasis, otherwise known as biliary colic, can be controversial. Many people recommend nonoperative treatment for biliary colic. However, as shown in their review of the disease, Steinbrook et al. reported recurrence of symptomatic gallstones in 92% of women managed nonoperatively in their first trimester, 64% in their second, and 44% in their third (13,41). A 57% symptom recurrence during pregnancy and a 23% complication rate of acute cholecystitis and gallstone pancreatitis are reported (13,42).

Many favor initial treatment for the pregnant patient with uncomplicated acute cholecystitis to be supportive. Intravenous fluids should be given to prevent dehydration and the patient is made nothing-by-mouth. Nasogastric suction is appropriate if there has been significant vomiting. Analgesia may be given as needed. Meperidine is preferred to morphine, as the latter may produce spasm of the sphincter of Oddi. All narcotics may affect the sphincter of Oddi, but it appears to be more so with morphine. *Since* early cholecystitis is a sterile process, antibiotics are often unnecessary. If symptoms are persistent, or if systemic or local signs are prominent, broad-spectrum antibiotic coverage is warranted (43). Patients who fail to respond to conservative measures, or who have recurrent bouts of illness, are candidates for surgery. Selected patients may be considered for a percutaneous drainage procedure, that is, cholecystostomy tube, in order to defer definitive therapy (44).

The patient who responds promptly to supportive therapy may be observed, with the hope of avoiding an operation during pregnancy, or may be scheduled for an elective cholecystectomy. A prospective comparison of these treatment strategies is unavailable. Many authors favor the former approach, but the latter has proponents (45,46). Medical therapy is associated with a high risk of relapse, often requiring hospitalization prior to delivery (46). If there is choice about the timing of cholecystectomy, the second trimester seems to be the interval when fetal complications are minimized.

Though once considered contraindicated, there is a growing body of literature supporting the safety of laparoscopic cholecystectomy during pregnancy (47,48). SAGES guidelines list laparoscopic cholecystectomy as the procedure of choice in the pregnant patient with gallbladder disease regardless of trimester (13). The procedure is usually performed in the second trimester, but many cases have been reported in the first and third trimesters. Guidelines published by SAGES note that intraoperative cholangiography exposes both the mother and the fetus minimally and may be used selectively intraoperatively during cholecystectomy (13). Pelvic shielding is recommended. Endoscopic retrograde cholangiopancreatography with papillotomy and stone extraction may also be performed during pregnancy (49–51). This may be done pre-, post-, or intraoperatively (13). Candidates for this procedure would be those with known or suspected calculous obstruction of the biliary duct. Fetal irradiation can be minimized by uterine shielding and limitation of fluoroscopy time.

Course

Acute cholecystitis may be complicated by empyema, perforation, pancreatitis, or failure to respond to medical management. As stated previously, management is supportive unless the patient has pancreatitis, cholangitis, or common bile duct obstruction (9). Among patients managed conservatively during pregnancy, 62% to 84% may be carried through to delivery without operation (38,39,40). In the series reported by Landers and coworkers (38), medical therapy was deemed to have failed if symptoms persisted beyond the 4th day in the hospital, or if there were more than three recurrences in the same trimester. Pleading against excessive conservatism, Dixon and colleagues (45) cited two cases in which patients required total parenteral nutrition for 27 and 30 days,

respectively. One of these patients developed pancreatitis. Of 26 patients in their series, 15 had recurrent episodes of biliary colic during pregnancy (45). Data from published series are often incomplete, but perinatal outcome appears to be favorable if disease is uncomplicated or if surgical treatment is effected in the second trimester (31,39,40,45,52).

PANCREATITIS

Occurrence

Pancreatitis is an unusual, but potentially devastating, complication of pregnancy that may present with acute abdominal pain. In more recent series, case:delivery ratios range from 1:1289 to 1:3333 (53–56). Pregnancy may predispose women to the development of pancreatitis, but this notion is poorly substantiated and controversial (53,54,57,58). Recognized risk factors for pancreatitis include cholelithiasis, alcohol use, hyperlipidemia, hyperparathyroidism, abdominal trauma, viral infections, and certain drugs (particularly diuretics). The presence of gallstones is the most common etiology among pregnant patients; they are found in up to 90% of cases (55–57,59).

Symptoms and Signs

The presentation of pancreatitis is similar in the pregnant and nonpregnant patients. Among cases reviewed by Wilkinson (55), 75% presented with acute abdominal pain. Typically, the pain is of sudden onset and located in the epigastrium. Nausea and vomiting are usually present and may be severe. Very ill patients may present in shock. Generally, the patient is in acute distress. There may be a low-grade fever and a few patients are jaundiced. Epigastric tenderness is the most reliable physical finding. Peritoneal signs are absent or minimal. Bowel sounds are diminished. With severe hemorrhagic pancreatitis, blood may infiltrate the flanks (Grey Turner's sign) or the umbilicus (Cullen's sign).

Laboratory Aids

Serum amylase and lipase should be evaluated in pregnant patients with concern for pancreatitis as would be done for those who were not pregnant. Karsenti et al. in 2001 performed a prospective case-controlled study of serum amylase and lipase controls in normal pregnancy. Their study showed that serum amylase levels are the same in both pregnant and nonpregnant patients. Lipase is different in pregnant patient during the first trimester only and is lower at that time than in nonpregnant patients. They found that during the final two trimesters, there are no significant differences. Their final conclusion was that both amylase and lipase levels should be evaluated in the pregnant patient. They also concluded that serum lipase levels correlated better with acute pancreatitis than did amylase levels (35,60). Elevations of serum amylase also may be seen with intestinal perforation, infarction, or obstruction, and a variety of other conditions.

Other laboratory findings may be hypoglycemia (sometimes severe), hyperglycemia, hyperbilirubinemia, hypocalcemia, hemoconcentration, and electrolyte derangements. Imaging procedures are of limited usefulness for the patient with suspected pancreatitis in pregnancy. Upper abdominal ultrasonography may yield information about concomitant gallbladder disease, but the pancreas is often not well seen. CT or

MRI may be of benefit in severely ill patients with a doubtful diagnosis.

Treatment

The initial treatment of pancreatitis in pregnancy is supportive and does not differ from treatment for the nonpregnant patient. Corrections of hypovolemia, as well as the electrolyte, glucose, and calcium disturbances, are necessary. Oral intake is withheld. If the patient has moderate or severe disease, continuous nasogastric suctioning is often instituted. Total parenteral nutrition may be used if the course of disease is prolonged (61). If gallbladder disease is causative, cholecystectomy or endoscopic papillotomy may be considered once the patient's condition is stable (49).

Course

The mean duration of acute symptoms is about 6 days, but recovery may be prolonged and complicated (55). Estimates of maternal mortality vary widely from 0% to 37%, probably reflecting bias in case selection and improvements in diagnosis and therapy (53,55–57,59). In one compilation of reported cases, the perinatal mortality associated with maternal pancreatitis was estimated to be 38% (55). More recent series indicate a better outlook with perinatal mortality of 11% or less (53,57,59). In a recent review of 43 pregnant patients at one institution from 1983 to 1993, there were no maternal deaths, two stillbirths, and one neonatal death due to prematurity (56). As expected, the risk of perinatal death increased with severity of maternal disease.

INTESTINAL OBSTRUCTION

Occurrence

An increasing frequency of intestinal obstruction during pregnancy has been attributed to a higher rate of intra-abdominal operations, with subsequent adhesions, among women of reproductive age. Rates of occurrence are from 1/1500 to 1/16,000 (35,62). Despite the fact that 50% of pregnant women experience nausea and 33% have problems with emesis, cases rarely occur during the first 4 months of pregnancy (35,63). They are fairly evenly distributed thereafter and into the puerperium. A previous laparotomy, most often appendectomy or an adnexal operation, seems to be the most important risk factor. About one-half of simple intestinal obstruction during pregnancy is due to postoperative adhesions. Volvulus is the next most common condition (9). It, too, may be caused by adhesions. Intussusception is less common. Incarcerated inguinal or femoral hernias, or obstruction resulting from carcinoma, are exceedingly rare among pregnant patients (64).

A special note should be made about pregnant patients who have had gastric bypass surgery. A known risk of this surgery is internal herniation, which can lead to acute bowel obstruction. This may be due to a defect in the mesentery at the jejunal-jejunostomy or a Peterson's defect behind the Roux limb in a Roux En Y gastric bypass. This complication can put a patient and the fetus at serious risk of morbidity and mortality. Any patient who has had bariatric surgery should undergo immediate evaluation when showing signs of obstruction, and surgery should not be delayed if suspicion is high for internal herniation.

Symptoms and Signs

Abdominal pain, vomiting, and constipation are symptoms expected with intestinal obstruction. Almost 90% of affected pregnant patients will have abdominal pain (66). The pain may be constant or periodic. In the third trimester, it may be confused with the pain of labor or placental abruption. Pain may sometimes radiate to the flank, imitating that of pyelonephritis (65). The severity of the pain may not reflect the severity of the disease (67). Patients are often anxious and apprehensive (68). Emesis is a highly variable symptom among patients with intestinal obstruction during pregnancy. With more proximal obstruction, vomiting appears earlier in the course of disease and is more frequent. There may be considerable delay in resumption of emesis after the first episode. Severe obstruction may be present without any vomiting (66). Whereas constipation is a common symptom in pregnancy, complete cessation of stool and flatus is not. Such a report should strengthen suspicion for the diagnosis. With proximal obstruction, bowel movements may continue for a time following the onset of disease. Obstruction may lead to significant dehydration associated with low urine output, mild-to-moderate tachycardia, and hypotension.

Early in the course of disease, physical findings may be subtle. The classic picture of direct abdominal tenderness, distension, and high-pitched tinkling bowel sounds is the exception rather than the rule. Abdominal tenderness may be entirely absent (67). Pressure on the uterus may cause pain when transmitted to distended bowel, misleading the clinician to suspect a uterine process. Abdominal distension is difficult to assess in late pregnancy when the risk for bowel obstruction is the greatest. At presentation, bowel sounds are often described as normal (66). In some cases, particularly with cecal volvulus, a tender cystic mass may be palpable (69,70). Rebound tenderness, fever, tachycardia, and shock are late findings (67).

Diagnostic Aids

Leukocytosis may occur, but is of little help in the diagnosis of intestinal obstruction. Electrolyte abnormalities and hemoconcentration may be present if there has been prolonged emesis or if fluid has accumulated within distended bowel. There may be an elevation of serum amylase levels. Radiographic studies are often essential for diagnosis and should not be avoided out of concern for fetal effects. An upright plain film of the abdomen is the best initial study. Other studies, with or without contrast media, may also be appropriate and should not be delayed if findings on plain films are not typical and suspicion is present. Sequential films may be necessary for proper evaluation of initially normal or equivocal radiologic findings (67).

Treatment and Course

Treatment of intestinal obstruction in pregnancy is the same as that for the nonpregnant patient. Clinical management includes prompt correction of fluid and electrolyte deficits, decompression of bowel, relief of obstruction, and resection of nonviable tissue. Prompt fluid resuscitation is especially important in pregnancy, since uterine blood flow depends upon a normal maternal blood volume. If patients are in shock or significantly impaired, a foley catheter may be required to

monitor urine output. As fetus mortality is high with bowel obstruction, early surgery is warranted. Adequate operative exposure and thorough inspection of the full length of the bowel should not be compromised. Usually, a midline abdominal laparotomy incision is optimal. In some cases, it may be necessary to empty the uterus to accomplish satisfactory surgical therapy. However, this can most often be avoided (71). As a rule, the treatment of intestinal obstruction is surgical. Selected cases of early sigmoid volvulus have been successfully treated with colonoscopy, long-tube and rectal-tube decompression alone (72). In the case of bowel obstruction, it may not be optimal to attempt a laparoscopic exploration in a pregnant patient. There will be limited exposure due not only to the enlarged uterus but also to the dilated bowel. The bowel may also be friable and easily torn with manipulation causing enterotomies.

The obstetrician should be aware of the entity called colonic pseudo-obstruction, or Ogilvie's syndrome, which tends to occur following cesarean section (73). The clinical presentation is that of large bowel obstruction, but no mechanical stricture or volvulus is present. Radiographs will show marked gaseous distension of the cecum that usually extends to involve the ascending colon and transverse colon. The distal colon and rectum are gasless. Typically, there is little, if any, fluid in the distended bowel and contrast studies reveal no site of mechanical obstruction. If massive distension goes unrelieved, cecal perforation, a life-threatening complication, may occur. Treatment consists of bowel decompression by either colonoscopy or operative cecostomy (74). Neostigmine is an alternative treatment. This agent must be used in a monitored setting with atropine available as it may cause significant bradycardia.

Intestinal obstruction is a serious complication of pregnancy associated with maternal mortality in 10% to 20% and perinatal mortality in 20% to 30% of cases (68,71,75). There are several recent reviews of the topic (76–78). Perdue et al. noted in their review of 66 cases of obstruction that time from the patients' admission to surgery was about 48 hours. Twenty-three percent of patients in that review were found to have dead bowel requiring resection; maternal mortality was 6% and fetal mortality was 26% (78). Intrauterine fetal death and preterm delivery are the most common perinatal complications. Diagnostic vigilance and timely therapy afford the best prospects for a favorable outcome.

URETERAL CALCULI

A case:delivery ratio of approximately 1:1600 has been estimated for symptomatic urolithiasis in pregnancy (79,80). Stone passage seems to occur as often during pregnancy as outside of pregnancy. The causes for urolithiasis are varied. Among 78 women of reproductive age who were evaluated for urolithiasis, 42% had idiopathic hypercalciuria, 13% had hyperuricuria, 10% had primary hyperparathyroidism, 13% had infection stone, 3% had cystinuria, and 19% had idiopathic lithiasis (81).

Pain, usually in the flank but sometimes in the abdomen, is almost always the presenting complaint. Nausea, vomiting, dysuria, urgency, fever, or gross hematuria may be associated. About one patient in four will give a past history of urolithiasis (79,80). Costovertebral angle tenderness is almost always

present. In one series, abdominal tenderness was elicited in 6 of 20 patients (79). Concomitant urinary tract infection may obscure the diagnosis of ureteral calculi.

Microscopic hematuria is found in about 75% of cases. The absence of hematuria at presentation does not rule out a stone. The patient suspected of urolithiasis should be instructed to strain her urine in search of a stone until the diagnosis is clarified. Ultrasonographic imaging of the urinary tract may be helpful in the evaluation of the patient with suspected urinary calculi; the stone, or evidence of ureteral obstruction, may be apparent. Transvaginal ultrasound examination may reveal a distal ureteral calculus (82).

The urinary collecting system, particularly the right side, is often physiologically dilated in the latter half of pregnancy (83). This effect should not be confused with ureteral obstruction. Duplex Doppler waveforms of the intrarenal arteries may help distinguish obstructed from non-obstructed collecting systems, obstruction being associated with a high resistivity index (84). Intrarenal resistivity in pregnancy appears to be no different from that outside of pregnancy, even in the presence of physiologic pelvic dilatation (85). Radiographic evaluation, if needed, may be accomplished with minimal radiation exposure by obtaining a plain abdominal film and a film 20 to 30 minutes after injection of contrast dye. Additional delayed films may be necessary in some cases. If urolithiasis is confirmed, a metabolic evaluation is warranted.

In planning treatment, relevant factors include the size and location of the stone, the degree of obstruction, the severity of symptoms, and the presence of infection. Most calculi will pass spontaneously with hydration. If necessary, minimally invasive treatment options, such as ureteral stent placement, ureteroscopic retrieval, or percutaneous nephrostomy, may be considered (86). These procedures have been safely performed throughout pregnancy (87–89). Open ureterolithotomy is rarely required. Extracorporeal shock-wave lithotripsy has not been approved for use during pregnancy. Unless severe infection complicates the course of urolithiasis, a good perinatal outcome is expected.

ADNEXAL TORSION

Among women requiring laparotomy for adnexal torsion, about 20% are pregnant (90,91). About one-half of the cases of adnexal torsion are associated with an ovarian neoplasm, most often a dermoid cyst. In the reproductive-age group, approximately 2% of cases are associated with ovarian malignancy (90). Gonadotropin-induced ovarian hyperstimulation is a risk factor for torsion and about 16% of affected pregnancies are complicated by adnexal torsion (92). Symptomatic torsion occurs usually in the first, sometimes in the second, but rarely in the third trimester. The right side is involved more frequently than the left (90).

Pain is almost always the presenting symptom, but the nature of the pain is highly variable. The onset may be sudden or gradual. The character may be sharp and intermittent, or dull and constant. In about two-thirds of cases, the pain is unilateral in the lower abdomen. It may be generalized or, uncommonly, it may radiate to the back or flank. Nausea and/or vomiting are present in about half of the patients. Various urinary symptoms are less often reported (91,92). Abdominal

tenderness is the most constant physical finding. Peritoneal signs are variably present. There may be adnexal tenderness or a mass. Leukocytosis may be present, but a normal white blood cell count does not rule out the diagnosis. Ultrasonographic imaging may aid in the identification and characterization of an adnexal mass. Color Doppler sonography may show absent arterial flow in the central ovarian parenchyma. Absent central ovarian venous flow may be a more sensitive finding in cases of adnexal torsion (93). Comparison with the uninvolved contralateral ovary may aid in sonographic diagnosis. Given the nonspecific clinical presentation, it is not surprising that the preoperative diagnosis is often erroneous (90,91).

Torsion of the ovary and/or the Fallopian tube leads to venous congestion, edema, and, ultimately, arterial compromise. The course may be complicated by ovarian rupture or hemorrhage. Some patients report previous episodes of transient pain, indicating that spontaneous reversal of torsion may, at times, occur.

Surgery may be done laparoscopically and is recommended by SAGES guidelines for both diagnosis and treatment of the torsed ovary unless clinical severity warrants a laparotomy (13). The conventional surgical therapy of adnexal torsion is extirpation of the involved tissues, particularly if they appear ischemic or necrotic. If it is necessary to remove the corpus luteum prior to 10 weeks of gestation, there is justification for progesterone supplementation in an effort to maintain the pregnancy. If tissue distal to the site of torsion appears viable, unwinding of the adnexa is an alternative therapy. One group has advocated unwinding, regardless of the appearance of the adnexa, in cases of ovarian hyperstimulation syndrome (94). If the ovary is conserved, the surgeon must be assured that it does not contain a neoplasm. There is little information available to quantify the fetal risk following adnexal torsion. Generally, the pregnancy outcome is good (92).

HERNIAS

Hernias of the abdominal wall or groin are not uncommon in the general population today. Repair of a hernia is one of the most common surgical procedures in the country. Hernias during pregnancy, however, are uncommon, and much less is written about them in the literature. Whenever a pregnant patient has a hernia that is symptomatic, prompt consultation with a general surgeon is prudent.

GROIN HERNIAS

The two most common types of groin hernia are inguinal and, less commonly, femoral. The incidence in women is about 8% to 9% of all groin hernias (95–98). In a retrospective analysis of 21,318 pregnant patients by Ochslein-Kolble et al., it was found that there was an incidence of inguinal hernia during pregnancy of 1/2000. Seventy-five percent of those women were multiparas (99).

Diagnosis

Diagnosis of a groin hernia may be more difficult in a female than a male patient. The standard exam is for palpation of a bulge in the inguinal region on Valsalva that is either reducible or irreducible. If a bulge is difficult to feel, consideration for an ultrasound should be made. Ultrasound of the groin for hernia evaluation may be more difficult in the

obese or pregnant patient. Occasionally, MRI or CT may be used if clinically warranted to evaluate the groin region. The differential diagnosis for a groin mass includes round ligament varicosity, enlarged lymph node, lipoma, abscess, vascular aneurysm, and of course direct, indirect, or femoral hernias (95,97,99,100).

Treatment

Treatment for an inguinal hernia in a pregnant female varies little from that in a nonpregnant female. If the patient has an acute problem such as incarceration or strangulation of that hernia, emergent treatment should be done. An open inguinal herniorrhaphy may be performed, and if the bowel is found to be nonviable, conversion to an open procedure may be warranted. Mesh may be used for a repair if there is no infection or nonviable bowel. If there is concern for infection, a tissue repair should be performed. In the event that it is not an urgent situation, watchful waiting would be prudent with the repair of the hernia after the pregnancy is complete (97). Buch et al. in their review of 12 patients with inguinal or umbilical hernias during pregnancy showed that repair could be done postpartum with no significant increase in recurrence. Surgery on these patients was done on average at 22 weeks postpartum (97). Reports of inguinal hernia repair at time of C-section have been written. A study by Ochslein-Kolble showed that in eight women who developed an inguinal or umbilical hernia during pregnancy, a tissue repair as a combined procedure with cesarean section was not only feasible but also safe with no recurrences at 56 months (99).

VENTRAL HERNIA

Ventral hernias encompass umbilical, epigastric, and incisional. Incidence of umbilical hernias in pregnancy has been reported to be between 2% and 5%. The incidence of incisional hernias in pregnancy is unknown (95,101,102). Herniation of abdominal contents, uterine fibroids, or the gravid uterus through the hernia defect can be a concern in the pregnant female with a ventral hernia (95,101). If the gravid uterus is incarcerated in the hernia defect, consideration for immediate surgery must be taken due to risk not only of intrauterine growth retardation but also of strangulation of the uterus. In this case, cesarean section is performed with tissue repair of the hernia if possible.

DIAPHRAGMATIC HERNIA

A rare type of hernia that can complicate pregnancy is the diaphragmatic hernia. This type of hernia may be congenital, such as a posterolateral Bochdalek hernia or an anteriomedial hernia of Morgagni, or the more common acquired hiatal hernias.

Signs and Symptoms

Patients with these types of hernias may not know that they have a hernia of the diaphragm until symptoms appear during pregnancy (103,104).

Symptoms may include upper abdominal or chest pain, nausea, and vomiting all of which may worsen as the pregnancy progresses (103,105,106). Patients may also present acutely obstructed with a toxic appearance due to dehydration and herniation of abdominal contents into the chest. These patients may be tachycardic and or have dyspnea (103).

Diagnosis

Diagnosis may be made by an upright anteroposterior and lateral chest X-ray. This may show abdominal contents in the chest with air fluid levels noted in the chest.

Treatment

Management will depend on the acuity of the situation. Due to the increased intra-abdominal pressure exerted by the growing uterus, there is concern that if not repaired during the pregnancy, there may be high morbidity and possibly mortality for the mother and child during the pregnancy or labor. Kurzel et al. in 1988 were emphatic about surgery for this condition stating that in their review of 18 reported cases of this type of hernia, there were 8 maternal and 6 fetal deaths. They felt that repair should be performed prior to labor regardless of whether the hernia was symptomatic or not. Their recommendations for treatment that if there were signs of obstruction, immediate repair should be undertaken regardless of fetal stage of development. If the patient was in the first or second trimester, repair should be done to prevent intra-abdominal contents from pushing into the chest cavity and possibly becoming strangulated. Furthermore, if the patient was asymptomatic in her third trimester, the baby should be followed for fetal maturity. When deemed mature, then elective c-section should be performed with hernia repair done at that time (105).

CONCLUSION

There are many sources of acute abdominal pain in the pregnant patient. Prompt evaluation and coordination between the obstetrician and the general surgeon may make the difference between an excellent outcome and a catastrophe.
